Joining of the viral genome and the host's chromosomal DNA is the hallmark of a retroviral infection. Integrase, the enzyme that catalyzes this step of HIV life cycle, is a promising therapeutic target. On binding to specific sequences in viral DNA, HIV-1 integrase catalyzes two consecutive steps during integration: 3′-processing, endonucleolytic cleavage of the 3′-ends of the viral cDNA and strand transfer, ligation of the viral 3′-OH cDNA ends to the 5v-DNA phosphate of an acceptor DNA (host chromosome).[169] Several compounds have been developed to block integration at different steps, and some are being assessed in phase II and phase III human clinical trials. The most advanced compounds belong to the class known as strand-transfer inhibitors (STIs), namely diketo aryl (DKA) and DKA-like inhibitors. Raltegravir (MK-0518) is a first-in-its-class oral integrase inhibitor (INI). It is the first INI approved for use in the United States (October 2007) in combination with other anti-HIV agents in HIV-infected adults. In a phase III clinical trial, 16 weeks or longer of treatment in addition to an optimized treatment regimen resulted in a significant decrease in HIV RNA PCR and improvement in CD4 counts. Even more striking, 61 percent of patients taking MK-0518 alone experienced reduced viral load versus 5 percent of patients taking placebo alone. $CD4^+$ counts increased two to three times more in patients taking MK-0518 than in those receiving placebo. MK-0518 is available in tablet form (400 mg) and may be a promising option for adolescents and children in the future. The treatment-related adverse effects most commonly reported are diarrhea, nausea, fatigue, headache, and itching. Another potent STI, GS-9137, is being investigated in phase II trials in treatment-naïve and treatment-experienced adult patients with HIV infection.[131]

SUPPORTIVE TREATMENT

Preventive measures applicable to immunodeficient individuals should be applied to the HIV-infected child. Examples include measles, influenza, and varicella prophylaxis after exposure. Additionally, routine childhood health care preventive measures, including adequate nutritional support, age and developmentally appropriate stimulation, dental and skin hygiene, and immunizations, should be offered to children with HIV infection or AIDS. Table 204–15 outlines suggested immunizations for HIV-infected children. The live viral measles-mumps-rubella vaccines are now recommended for all HIV-infected children, regardless of symptoms. Varicella vaccine is recommended for HIV-infected children without significant immune compromise. A second dose of varicella vaccine should be administered to children at age 4 to 6 years of age, following the first dose given at 12 to 15 months. Immunization of healthy household infants with the varicella vaccine also is recommended. Influenza vaccine should be administered yearly starting at age 6 months. Patients with HIV infection are at increased risk for acquiring meningococcal disease. Meningococcal conjugate vaccine (MCV4) is preferred in patients aged 11 to 55 years and now is approved for use in 2- to 10-year-old children.[38]

The newer quadrivalent human papillomavirus (HPV) vaccine, Gardasil, is a vaccine consisting of non-infectious HPV-like particles. It is now recommended in a three-dose schedule for girls aged 11 to 12 years, although it may be administered in girls as young as 9 years.[36]

IMMUNE-BASED THERAPIES

The cardinal immune manifestation of HIV infection is the development of progressive $CD4^+$ lymphopenia with resultant

clinical disease associated with severe immunodeficiency. Therefore, replacement of the $CD4^+$ T-lymphocyte pool is a logical approach for immune-based therapies. Immune modulators have been assessed as single therapeutic agents or in combination regimens in adult clinical trials. Using IL-2 infusions for 5-day cycles every 8 weeks, in addition to ART medications, Kovacs and associates[126] documented sustained elevations in $CD4^+$ T-cell counts without increase in plasma HIV RNA levels in adult patients with HIV infection and $CD4^+$ T-cell counts of 200 cells/mm^3 or higher. The same investigators also demonstrated that intermittent IL-2 therapy preferentially increased proliferation of $CD4^+$ naïve and memory T-cell populations in HIV-infected patients.[125] Katlama and associates[114] reported sustained increases in $CD4^+$ T-cell counts in HAART-treated patients with persistent $CD4^+$ T-cell counts less than 200 cells/mm^3 using subcutaneous IL-2 for 5 days every 6 weeks at doses of 4.5 million IU twice daily.

IFN-α has been documented to produce in vitro antiretroviral activity. IFN-α is presumed to inhibit HIV replication by diminishing the assembly and release of mature virus particles from infected cell surfaces.[168] A significant antiretroviral effect of IFN-α in resting $CD4^+$ T cells also has been documented.[46] INF-α initially was studied as a therapeutic agent for Kaposi sarcoma with good response rates, but significant side effects limit its use in HIV infection. The utility of immune-based therapies in pediatric or adolescent HIV infection may include their use in treatment of concomitant chronic HBV infection or ZDV-resistant, HIV-associated immune thrombocytopenia.[143]

VACCINES

Goals for the development of an HIV vaccine include prevention of persistent HIV infection, prevention of severe clinical disease (AIDS), and therapeutic immunization to control HIV infection. The first candidate preventive vaccines tested in human trials in late 1980s were based on the HIV-1 envelope (Env) glycoproteins gp120 or gp160, an approach aiming to induce neutralizing antibodies. The major limitations of this approach were lack of neutralizing antibody activity against a diversity of primary patient isolates of HIV-1 because of genetic variability and structural complexity of the HIV-1 envelope glycoproteins and absence of envelope-specific cytotoxic T-lymphocyte (CTL) responses.[91,116,144] Because of the growing recognition of the limitations of these traditional vaccine strategies, much effort currently is being focused on the development and assessment of two novel strategies for vaccination: live vector-based approaches and plasmid DNA immunogens.

The live vectors studied most extensively are poxviruses. A study performed in HIV-uninfected, low-risk human volunteers showed that recombinant canarypox vaccine carrying Env, Gag, Pol, and Nef epitopes elicited low titer HIV-1–specific antibody responses in as many as 70 percent of vaccine recipients. Moreover, HIV-1–specific CTL responses were observed to a broad range of epitopes up to 10 months following the last canarypox immunization.[72] A phase I human clinical trial with modified vaccinia virus Ankara (MVA) is ongoing. Studies suggest that replication-incompetent adenovirus vectors (Adenovirus serotype 5; Ad5) are very effective in eliciting HIV-1-specific CTL responses in small laboratory animals and monkeys.[189] The major limitation of this approach is that most humans have preexisting immunity to the Ad5 vector from natural exposure. To overcome this problem, strategies exploring vaccine vectors from rare human Ad serotypes are being developed.[10] A consecutive immunization strategy, known as "prime-boost," involving priming with DNA and boosting with a live recombinant vector, is being explored. A study that was performed in rhesus macaques showed that a DNA priming with a single recombinant MVA booster containing multiple immunodeficiency virus proteins elicited highly effective memory immune response on mucosal challenge with a chimera of simian and HIVs (SHIV-89.6P).[4] However, this approach did not prevent the macaques from acquiring SHIV infection. A study of an adenovirus vector-141V T-cell epitope vaccine in 3000 HIV at-risk subjects was halted in 2007 because the vaccine recipients developed as many HIV infections as did the placebo group, bringing into question the feasibility of this approach.[52]

Numerous HIV vaccine trials have been performed in HIV-exposed and HIV-infected children. The vaccines were safe, but the immunogenicity was poor compared with the results in adult studies.[128,179]

PROGNOSIS

Since the mid-1990s, mortality and morbidity rates for children and adolescents with HIV infection have declined dramatically in developed nations. Effective efforts directed toward early diagnosis have allowed for earlier administration of primary viral therapy to prevent HIV transmission and prompt treatment and prevention of opportunistic infections. In the United States and developed nations, opportunistic disease and death still affect the youngest infants, and public health strategies to slow these continued outcomes are ongoing. Pediatric research in developed nations should continue to address therapeutic interventions that allow for care of now chronically infected children and adolescents who are surviving and striving to contribute to their world. In addition, careful follow-up of HIV-exposed and neonatal antiviral-exposed individuals should be a priority effort in developed nations in which mother-to-child prevention regimens are established.

For developing nations, resources and research to stem the continued tide of HIV infection are of paramount importance. Efforts must be made to reduce global perinatal transmission rates further and to define HIV detection methods that allow earliest intervention in affected children. Effective vaccine development clearly would have a significant and worldwide impact on adults and children exposed to HIV.

Research and prevention initiatives must now be coupled with socioeconomic and political efforts to find the will to sustain a global impact on HIV transmission and treatment. Duplication of the achieved successes in preventing perinatal transmission in industrialized countries is needed desperately in sub-Saharan Africa, East Asia, and Central America, where competing medical needs limit available local funding for prevention of HIV transmission and for HIV treatment. When viewed from this perspective, placing the highest priority on global confrontation of this epidemic that threatens the future of our children is imperative.

SUBSECTION 13

Prion-Related Diseases

CHAPTER 205

Transmissible Spongiform Encephalopathies (Creutzfeldt-Jakob Disease, Gerstmann-Sträussler-Scheinker Disease, Kuru, Fatal Familial Insomnia, New Variant Creutzfeldt-Jakob Disease, Sporadic Fatal Insomnia)

William J. Britt

The group of neurodegenerative diseases classified as transmissible spongiform encephalopathies (TSE) represents a subset within a group of diseases that also have been termed infectious amyloidoses or cerebral proteopathies.[185,231] These diseases are characterized by progressive cortical dysfunction linked to the accumulation of insoluble, proteinaceous aggregates in the central nervous system (CNS) (Table 205–1). The protein aggregates characteristic of these diseases are composed of polymeric fibrils of a host-encoded protein deposited in several different regions of the CNS and within other organ systems, particularly in lymphoid organs. Amyloid may be present in TSE, and its role in the pathogenesis of these diseases is uncertain. However, the symptoms associated with the spongiform encephalopathies are thought to arise from cellular and end-organ dysfunction associated with the abnormal deposition of an isoform of a normal cellular protein, PrP^c, encoded by the *PRNP* gene.[36,71,185] The physiologic function of PrP^c remains incompletely defined, and no null alleles of the *PRNP* gene have been identified, raising the possibility that some of the symptoms associated with these diseases are caused by a loss of normal PrP^c function.[168] The TSE share several clinical features with other cerebral amyloidoses, and the insoluble protein aggregates exhibit biophysical properties similar to plaques found in Alzheimer disease. In contrast to these diseases, the TSE can by definition be transmitted by parenteral inoculation or by other less efficient routes, such as ingestion of contaminated tissue from the nervous system.

TABLE 205–1 Naturally Occurring Transmissible Spongiform Encephalopathies

Host	Disease
Human	Kuru
	Creutzfeldt-Jakob disease
	Sporadic
	Familial
	Infectious
	Variant Creutzfeldt-Jakob disease
	Gerstmann-Sträussler-Scheinker syndrome
	Fatal familial insomnia, sporadic fatal insomnia
Sheep, goats	Scrapie
Mink	Transmissible mink encephalopathy
Deer, elk	Chronic wasting disease
Cattle	Bovine spongiform encephalopathy, bovine amyloidotic spongiform encephalopathy
Cats	Feline spongiform encephalopathy

TSE were diseases recognized only in domestic livestock in northern Europe until late in the 20th century. Scrapie, a disease of sheep, was described first in the mid-1700s.[36] Farmers realized early on that the agent responsible for scrapie is communicable and instituted control measures that included isolation and destruction of affected animals and herds.[36] Recent evidence has suggested that the scrapie agent can persist in contaminated soil for at least 16 years, a finding that explains the reported recurrences of this disease in flocks that had been culled decades earlier.[96] Although farmers were aware of the communicability of scrapie between herds of sheep and had documented its spread among sheep, its transmissibility was not formally demonstrated until 1936.[80] Shortly thereafter, scrapie developed in a flock of sheep that were inoculated with a vaccine for louping ill prepared from CNS tissue derived from sheep that had been exposed to scrapie.[36] Together, these reports provided definitive evidence of the transmissible nature of scrapie. The term *slow virus disease* was

initially coined by veterinarians to describe the natural history of this curious group of diseases in domestic animals that included a prolonged incubation period measured in years and a relentlessly progressive clinical deterioration once symptoms appeared.[206] This term was used to describe this group of diseases until the 1980s, when investigators began to consider that although the agent responsible for the spongiform changes in scrapie-infected mice is transmissible, it cannot be classified as a conventional virus. A decade earlier, the observational and laboratory studies of kuru, a progressive cerebellar ataxia and dementia that occurred predominantly in adolescent and young adults of the Fore tribe in Papua New Guinea, provided an important piece of the puzzle of the etiology of this group of diseases.[3,100] The natural history of kuru was described initially by Vincent Zigas and Carleton Gajdusek and was noted to be associated with the ritual cannibalism practiced by this tribe. In 1959, an astute veterinary neuropathologist, William Hadlow, observed a striking similarity of the spongiform changes in the brains of patients with kuru to the brains of sheep with scrapie and suggested that these two diseases could be caused by similar mechanisms, possibly a transmissible agent.[109] Considering the possibility that kuru is caused by a transmissible agent, Gajdusek and coworkers[92-94] eventually demonstrated that the clinical and histopathologic findings of kuru can be transmitted to chimpanzees and other nonhuman primates by inoculation of brain tissue from patients with kuru. Interestingly, Gajdusek and coworkers initially thought that the experiment was a failure because the animals did not become symptomatic until nearly 2 years (18 to 21 months) after intracranial inoculation was performed, and later reports from this same laboratory indicated that nearly 20 years elapsed between the inoculation and the development of disease in some chimpanzees.[14,36] Subsequent studies by other investigators have demonstrated that brain homogenates from patients with Creutzfeldt-Jakob disease (CJD), Gerstmann-Sträussler-Scheinker (GSS) disease, fatal familial insomnia (FFI), and most recently variant CJD (vCJD) can transmit spongiform changes to nonhuman primates.[25,183] More recently, a variant of FFI, sporadic fatal insomnia, has been identified and added to this group of transmissible neurodegenerative diseases.[165,177] The hypothesis that transmissible neurodegenerative diseases are caused by a protein was suggested first by Griffith[108] in 1967 and later more extensively developed by Prusiner[183] and coworkers. The claim that the etiologic agent of scrapie is an isoform of a normal host protein, PrP^c (alternatively referred to as prion protein), that can transmit disease in the absence of nucleic acid was met initially with great skepticism and even today continues to evoke debate.[63,64,160,183] During the ensuing decade, the hypothesis that a protein can promote the formation of a polymeric fibrillary, insoluble plaque without the requirement of nucleic acid encoding a protein of an infectious agent has been supported by studies from several laboratories. This hypothesis represented a paradigm shift in biology, and Stanley Prusiner was awarded a Nobel Prize in 1997 for his groundbreaking studies of prion diseases. Interestingly, approximately 20 years earlier, Gajdusek also was awarded a Nobel Prize for his description of the transmissible nature of kuru and similar diseases of the CNS.

The most recent chapter in the TSE saga is the appearance of mad cow disease (bovine spongiform encephalopathy [BSE]) in Great Britain in the mid-1980s, and by the late 1990s, nearly 200,000 diseased animals had been destroyed.[48] Mad cow disease has been discovered in cattle in several countries within Europe and most recently in the United States. Of greatest concern has been the transmission of BSE to more than 100 individuals in Great Britain and at least three cases in France.[48] BSE has been reported in the United States, and a significant increase in the incidence of TSE of elk and deer (chronic wasting disease) has been reported in wild game farms in the western United States as well as in wild deer herds in the midwestern United States.[166,232] Because of the concern that large numbers of human cases could eventually develop secondary to contamination of food products and pharmaceutical reagents with BSE or through contact with contaminated tissue from deer or elk, substantial interest has developed in the study of TSE.

EPIDEMIOLOGY

The natural history of human TSE usually is described in the context of the epidemiology of CJD. Three different modes of acquisition of disease have been described: (1) sporadic, (2) inherited mutations in the cellular gene encoding PrP^c (genetic), and (3) acquired or infectious following exogenous exposure to prion-contaminated material, such as after neurologic procedures (infectious) (see Table 205–1). Little is known about genetic or environmental factors that contribute to the development of sporadic forms of these diseases, although numerous epidemiologic studies have claimed associations ranging from ingestion of mutton to exposure to blood products after surgery.[4,40,78,164] Studies in cases of CJD have revealed numerous genetic mutations in the cellular gene encoding the normal cellular prion protein, PrP^c, associated with the development of disease, and they have been defined as genetic causes of CJD and other TSE (see following section). Polymorphism in the methionine at position 129 in the coding sequence of PrP^c is the genetic polymorphism most commonly recognized as being associated with sporadic CJD.[176] Homozygosity at methionine 129 of PrP^c is seen in approximately 64 to 81 percent of patients with sporadic CJD yet is present in only approximately 39 percent of the general population and is thought to predispose an individual to both iatrogenic and sporadic CJD.[2,176,240] Interestingly, valine homozygosity at this position was associated more frequently with cases of CJD with onset in those younger than 40 years.[2] Furthermore, a retrospective analysis of a small number of patients with kuru revealed that all were homozygous for methionine at position 129 and all had more rapidly progressive disease with a shorter incubation period than did other patients with kuru from this cohort.[150] Fore women surviving exposure to contaminated material during the ritual cannibalistic feasts were shown to be more likely to be heterozygous at methionine 129 (76%) than were similarly aged Fore women who had not been exposed to the cannibalistic feasts.[168] This result suggested that heterozygosity at methionine 129 provided a survival advantage. The codon at position 129 also appears to modulate the clinical course of inherited TSE such as FFI, and patients homozygous for methionine at position 129 have a more rapid clinical course than do patients heterozygous at this codon.[171] Polymorphisms in the PrP^c, including those that occur at position 129, have not been associated with the development of vCJD after exposure to BSE-contaminated material; in fact, all human cases in Great Britain have been homozygous for methionine at position 129.[130] Heterozygosity at methionine 129 is thought to confer resistance by inhibiting PrP^c protein:protein interactions.[176] Interestingly, sequence analysis of the *PRNP* gene from populations throughout the world suggested that the observed increased frequency of heterozygosity at position 129 could be explained by widespread cannibalism among primitive humans and selection of methionine 129 heterozygotes secondary to increased disease penetrance associated with exposure of susceptible methionine 129 homozygotes to prion-contaminated tissue.[168] This conclusion has been challenged by other investigators.[209]

Sporadic CJD is the most common TSE in humans and accounts for approximately 85 percent of all cases of CJD.[40] It occurs worldwide at a rate of approximately $1/10^6$ population.[40] CJD is a disease of late middle age, with a mean age at onset of 55 to 65 years. Cases of CJD range from 20 to 84 years, with the youngest cases being described in patients 16 to 18 years old.[39,88,170]

Little evidence exists for case-to-case transmission of CJD, with the obvious exception of cases resulting from iatrogenic transmission of CJD.[61] Vertical transmission of CJD has not been reported in studies of human CJD. Anecdotal reports of occurrence of CJD in the spouses of individuals with CJD raise the possibility of horizontal transmission.[42] Alternatively, disease in spouses could result from shared environmental exposures. Sporadic cases of non-CJD TSE previously thought to be caused solely by genetic mutations have been reported, thus extending the spectrum of TSE in humans.[151,165] With the exception of cases that can be linked to an inherited genetic mutation, no epidemics of CJD have been reported, an observation that led British epidemiologists to suspect that a link exists between what was initially thought to be an increased frequency of CJD in young adults and the outbreak of BSE in the British Isles.[6,13,79,103,226,238]

Genetic mutations in the cellular prion gene, *PRNP*, can result in a variety of inherited TSE and are likely to account for the reported outbreaks of TSE in isolated populations. Because of the relatively late onset of disease even in patients with well-characterized mutations in *PRNP*, the possibility that TSE are inherited diseases of the CNS was not considered until more recent studies of the host cell origin of prions and the discovery that a cellular gene encoded the pathogenic protein associated with TSE. Estimates from various studies suggest that between 5 and 15 percent of cases of CJD may arise from mutations in the cellular *PRNP* gene.[40] Genetic linkage studies have demonstrated that TSE are inherited as an autosomal dominant trait, an observation consistent with several studies in families with FFI and GSS.[21,126,169] In addition, defined mutations in the *PRNP* gene have been shown to account for the increased rate of TSE in either geographically or ethnically isolated populations, such as Libyan-born Jews, an ethnic group with an incidence of TSE nearly 40 times greater than that observed in other populations.[61,82,102,127,128,134,211] A large number (>20) of mutations in *PRNP* have been described and appeared to be scattered throughout the gene. Reported mutations include both point mutations in the coding sequence changes, resulting in amino acid substitutions, and octapeptide insertions.[55,61,101,128,180,188] Because mutations in *PRNP* by definition are not present in cases of sporadic CJD, mutations of this cellular gene are not thought to play a direct role in the development of CJD in these individuals. Thus, the mode of acquisition of the TSE agent in these individuals has not been defined. In sporadic cases of CJD, the proposal has been made that spontaneous generation of the TSE agent could be occurring extremely infrequently and result in CJD. However, when scrapie was eliminated in sheep in New Zealand and Australia by culling diseased herds, spontaneous development of scrapie has not been described in these herds, suggesting that spontaneous development of the agent of TSE leading to scrapie in sheep is almost nonexistent.[64] In most cases, disease secondary to a genetic mutation in *PRNP* develops in patients of middle age, suggesting that although these diseases exhibit an autosomal dominance inheritance, the genetic background of the host contributes significantly to the observed phenotypes.

Although farmers and neuropathologists were well aware that scrapie is readily transmissible, the possibility that human TSE also are transmissible was not demonstrated until Gajdusek and coworkers defined the natural history of kuru in the Fore tribe in Papua New Guinea.[3] Kuru was seen most commonly in adolescent and young adults of both sexes but only in older women. The disease was common, with an incidence of 1 percent in this tribe, and was a significant cause of death in this population.[3] Gajdusek carried out a detailed observational study of the Fore people, including their ritualistic cannibalism of the dead. This ritual included homogenization of the brains of dead relatives in bamboo cylinders with use of crude hand tools. The brain was reportedly ingested as well as smeared over the body by relatives and other members of the tribe. During most of their childhood, Fore children remained with their mothers and other women of the village, including the time spent preparing the brains of dead relatives for ritual cannibalism. It is during this time that the exposure to the agent responsible for kuru was thought to occur, either by ingestion of the contaminated brain material or through skin abrasions that were present secondary to the nearly universal scabies infestation. Gajdusek and coworkers hypothesized that kuru is caused by an infectious agent and injected homogenates prepared from the brain of a deceased kuru patient into nonhuman primates; following an incubation period of more than 2 years, a disease similar to kuru was observed in the experimental primates.[14] After the transmissibility of kuru was demonstrated in experimental animals, several other TSE were shown to be transmissible in nonhuman primates and other experimental animals.[14,44,74,217,219] Subsequent studies demonstrated that kuru could be transmitted to nonhuman primates by oral ingestion of contaminated tissue.[98] Although the origin of the TSE agent responsible for kuru in the Fore tribe is unknown, the most plausible explanation is that a spontaneous mutation in the cellular PrP^c gene resulted in a case of TSE in the Fore tribe that then was introduced and propagated in the population by cannibalism. After ritual cannibalism was halted by the government of these districts in Papua New Guinea, new cases of the disease disappeared, and the last case of kuru in an individual younger than 30 years was reported in 1985.[3] Cases of kuru have developed some 40 to 50 years after exposure to infectious material, illustrating the prolonged incubation period of these diseases.[76,142]

Before the 1980s, cases of TSE occurring in children and adolescents, with the exception of kuru, were either extremely rare or not recognized. In the late 1980s, cases of TSE resembling CJD were reported in young adults who as young children had received injections of human growth hormone prepared from cadaveric pituitary glands.[35,44,46] The thought was that the practice of pooling pituitary glands from a large number of cadavers increased the risk of contamination of the preparation with prions from subclinical cases of TSE. More than 100 cases of TSE occurring after patients were injected with contaminated growth hormone preparations have been reported.[61] Whether new cases of TSE will develop in adults given cadaveric growth hormone before the mid-1980s remains uncertain, but with a mean incubation period of 12 years in documented cases, it is unlikely that significant numbers of new cases will be reported.[37,46] Other sources of TSE include dura grafts, corneal transplants, contaminated stereotaxic neurosurgical equipment, and, more recently, blood transfusions.[7,37,41,83,107,110,123,174,180] An alarming case of TSE occurred in a chimpanzee after the use of a stereotaxic electrode that 2 years previously had been used in a procedure involving a patient with CJD. Because this electrode had been decontaminated numerous times with conventional sterilization methods before its use in this experimental animal, this case illustrated the potential for the occurrence of iatrogenic transmission of TSE to humans undergoing neurosurgical procedures.[99] Two confirmed and two probable cases of vCJD occurring after receipt of blood transfusions have been described in Great Britain.[115] Studies of experimental models of TSE, primarily scrapie in mice, have shown that the scrapie agent initially amplifies in titer in spleen and regional lymph nodes and enters the CNS by a blood-borne route or by infection of the peripheral nervous system.[1,136,138,140,148,159] In addition, studies in mice have demonstrated that brain tissue from animals injected with hamster scrapie can harbor the infectious agent for a prolonged time without evidence of disease.[118,191] Even during a period of inactive persistence and replication, the scrapie prion could be detected, suggesting that transmission of prion disease by contaminated blood products or surgical instruments may occur even if screening assays for the detection of prions are mandated.[189] To further cloud the issue, other investigators have postulated that less

virulent strains of prions can attenuate the virulence of other strains of prions, which then can be transmitted readily during asymptomatic periods.[163,228] After transmission to a secondary host has occurred, the phenotype of the more virulent strain could be expressed. These findings are particularly worrisome because of the possibility that food products from cattle with subclinical BSE could continue to be consumed. Similarly, the possibility exists that the low incidence of vCJD in Great Britain, in spite of what most authorities consider was a much larger exposure to BSE before eradication of BSE-containing herds, could be explained by persistence of infectious agents in genetically resistant individuals or possibly be secondary to persistence in non-CNS organ systems.[28,118] Previously, these studies raised the possibility that TSE could be acquired by transfusion of blood and blood products obtained from infected hosts.[149]

Considerable controversy existed about the importance of transmissibility of TSE by blood and blood products. Investigators argued that the risk is exceedingly small on the basis of experimental studies in rodents and epidemiologic studies involving patients receiving quantities of blood products, such as hemophiliacs.[1,32,34,85,223,225,239] However, BSE has been transmitted to sheep by blood transfusions, and buffy coat preparations have been shown to transmit TSE to experimental primates.[24,125] The U.S. Food and Drug Administration has recommended a very conservative policy for blood and blood products because of these theoretical concerns, and more recently, this policy has been reinforced by the reports of blood transfusion–acquired vCJD.[114,152,244] In addition to the exclusion of donors with symptoms consistent with TSE, individuals who have lived or visited Great Britain and other countries with BSE for a cumulative period of 3 months during the interval of 1980 to 1996 are also excluded as donors (*http://www.redcross.org/services/biomed/0,1082,0_557_,00.html)*. With the possible exception of kuru, little evidence was available previously to suggest that TSE such as CJD could be acquired by ingestion of contaminated tissue.[40] This claim was challenged in the early 1990s by the reports of several young adults with CJD in Great Britain.[79,238] Inspection of the rates of CJD in England revealed that the incidence of CJD was approximately 15-fold higher than earlier, based on surveillance studies from previous decades.[31] In the years preceding the startling increase in rate of CJD, the cattle industry in Great Britain was being devastated by the spreading epidemic of BSE, a disease ultimately shown to be a TSE.[112,208,236] A similar disease had been noted in domestic cats as well as in animals housed in zoos, where they had been fed British beef and beef byproducts.[25,75,208] The first case of human disease thought to be associated with BSE was termed vCJD and was described in 1995, about 10 years after the first cases of BSE were reported in cows, although more careful analysis suggested that the first cases of BSE probably occurred in the 1970s.[208,238] During the ensuing years, investigators have closed the circle of evidence, showing that vCJD represents the transmission of BSE to humans, presumably by ingestion of contaminated beef or byproducts from BSE-infected cattle.[72,120,207,210] These byproducts include many common household and medical products, such as gelatin in food products and in pharmaceutical capsules, bouillon cubes used for food preparation, and a wide variety of foodstuffs containing beef.

Although the origin of BSE is far from settled, most investigators concur that changes in the rendering of beef and sheep carcasses to remove fat for the preparation of meat and bone meal for use as a protein supplement in animal feeds led to the epidemic. Before the late 1970s, beef carcasses were heated and extracted with hydrocarbons such as chloroform to delipidate the homogenate.[33,81,218,236,238] Omitting the hydrocarbon-extraction step apparently decreased inactivation of bovine prions, thus allowing introduction of this agent into the food products of British cattle. The epidemic began slowly in cattle, with the first case documented in 1986; by the mid-1990s, more than 3500 new cases of BSE were being reported each year. As a result of the BSE epidemic, 200,000 diseased cattle died as a result of BSE and nearly 4.5 million cattle were slaughtered preemptively, at a cost of approximately 4 billion English pounds, to curtail the epidemic.[5,48,208,243] BSE has been documented in U.S. herds, resulting in a ban of exportation of beef to several economically important markets.[195] As noted before, transmission to humans was suggested first in 1995 after the findings of CJD in three young adults were reported; and by 1996, additional cases of CJD in young adults were thought to be secondary to transmission from exposure to beef from BSE-infected cows.[72] Of the initial 20 human cases, only one individual was older than 40 years, and the mean age of human cases was 28 years.[6,184,226,228,245] Additional evidence from in vitro studies of the protein agents responsible for BSE and vCJD and from animal inoculation indicated that vCJD represented a human infection with the agent responsible for BSE.[31,75,119,147] Because the BSE epidemic was recognized first in 1985, researchers argued that the incubation period is approximately 10 years. On the basis of studies in kuru and experimental animal models of TSE, this estimate was determined to be dependent on exposure, genetic susceptibility, and as yet other unrecognized risk factors.[60,153] For this and other reasons, mathematical projections of the extent of the human epidemic have been based on theoretical estimates of exposure rates, possible dose-dependent incubation periods, and as yet undefined host genes that may alter susceptibility to TSE. Even though most of these variables cannot be quantified, arguments have been put forth that the epidemic in humans has peaked and the 120 or so cases of vCJD that have resulted from contaminated beef will be the extent of human disease associated with BSE.[97,228] In contrast, other models of the current data suggest that as many as 100,000 people may be affected. Perhaps the most compelling argument against such a large number of human cases has been the slowly evolving epidemic of vCJD in humans, with the number of new cases declining, although several investigators have contested this hypothesis.[69,97,228,237]

PATHOLOGY AND PATHOGENESIS

Although the histopathologic features of TSE have been described well, the pathogenesis of these diseases remains unknown and the nature of the etiologic agent continues to evoke controversy. The initial claim that TSE resulted from a transmissible protein was met with considerable skepticism both because a paradigm of biology was challenged and because key elements of the supporting scientific data were incomplete. The vast majority of experimental studies have been performed with the agent responsible for scrapie in sheep, which had been adapted for growth in mice and other small animals. Early studies that argued that the scrapie agent did not contain a nucleic acid were based on studies with ultraviolet radiation inactivation of the agent. An important note is that these studies did not exclude the possibility that the scrapie agent contained nucleic acid but instead argued that if it contained nucleic acids, the coding sequence was so limited that it could not encode any replicative functions.[16,17,183] In fact, later calculations based on inactivation by gamma rays suggest that the scrapie agent could contain between 2 and 4 kilobase pairs of DNA.[197] Other experiments demonstrated that the infectivity of the scrapie agent could be eliminated or significantly reduced by treatment with agents that denatured proteins, such as guanidine hydrochloride, sodium hypochlorite (bleach), and proteases.[183] Together, these data led several groups of investigators to postulate that the agent is an infectious protein.[23,108,187] Prusiner and coworkers[187] isolated an infectious fraction from a scrapie-infected hamster brain homogenate and obtained partial amino acid sequence. This fundamental finding led to the identification of

the prion (PrP^c) and eventually the finding that a cellular gene, *PRNP*, present on chromosome 20, encoded the transmissible agent responsible for the development of scrapie in mice and hamsters.[12,65] Not all investigators have been convinced that the scrapie agent is an infectious protein, and recently published data have been cited as evidence that it is a small virus.[160,162] Once the protein encoded by the *PRNP* gene had been identified and definitively linked to scrapie and other TSE, many investigators thought that the pathogenesis of these diseases would be elucidated quickly. However, the pathogenesis of these diseases remains uncertain, perhaps because of the inability to assign a function to the normal protein product, PrP^c. The conformation of the normal cellular form of PrP^c is primarily alpha-helical and is susceptible to protease digestion. Various functions have been proposed for the normal nonpathogenic isoform of the cellular PrP^c, yet transgenic mice lacking the gene encoding PrP^c have a normal life span and exhibit only minor variations in normal sleep patterns.[53,54,77,186] Most interestingly, these mice are completely resistant to prion disease regardless of the source of exposure, a finding that is consistent with the hypothesis that PrP^c is necessary for the disease process associated with scrapie and other TSE.[1,53] In contrast to the normal cellular form of PrP^c that is composed of four alpha-helical domains, the pathogenic form of PrP^{sc} (scrapie prion protein; also termed PrP^{res}) exists in an extended beta sheet, is insoluble, and is partially resistant to protease digestion (PrP protease resistant or PrP^{res}). The partial resistance of PrP^{res} to proteinase K digestion is a characteristic that allows pathogenic prions to be detected in tissue specimens and has been widely used to identify products of the conversion reaction of PrP^c to PrP^{res}.[167,201] The conversion of PrP^c to PrP^{res} represents a central paradigm of the prion hypothesis and is thought to occur either as the result of a process similar to the nucleation of crystal formation by seeding the normal cellular pool of PrP^c with PrP^{res} or, alternatively, as the result of a template-directed misfolding of a normal cellular protein. Thus, PrP^{res} can be viewed as a transmissible, infectious agent that catalyzes the conversion of the normal cellular protein to a form associated with protein deposition in the CNS, cell death, and eventually clinical disease in the host.

The normal cellular protein, PrP^c, is a small membrane glycoprotein that is covalently linked to cellular membranes, including the plasma membrane, by a glycosylphosphoinositol (GPI) linkage.[212-214] This cell surface form can be released by treating cellular membranes with phospholipases.[214] In addition, a secreted form of the protein also is expressed. Genetic mutations in the cellular PrP^c gene appear to predispose the protein to assume other topologies, including a transmembrane form.[111,222] Membrane-associated forms are postulated to play an important role in the neurodegeneration associated with the accumulation of the misfolded forms of PrP^c, and secreted forms can accelerate disease in a genetically susceptible animal.[111] Chesebro and coworkers[66] demonstrated that transgenic mice encoding a GPI-anchorless form of PrP^c could generate an abnormal protease-resistant PrP^{res} (see later) that could be transmitted to other animals and induce formation of amyloid plaques but failed to cause clinical spongiform encephalopathy (scrapie equivalent in mice) in experimental animals. Interestingly, when the anchorless form was co-expressed with the wild-type form of PrP^c, accelerated disease was seen.[66] Thus, it appears that a cell surface–linked PrP^c is required for induction of disease yet that amyloid-like deposits can be formed from the secreted form of PrP^c and disease can be induced when both secreted and wild-type PrP^c are expressed.[66] Consistent with this observation has been the description of a transmissible PrP^c amyloid disease without spongiform encephalopathy after inoculation of tissue containing amyloid deposits from a patient with GSS without CNS spongiform degeneration.[182] Together, these studies argue that PrP^c misfolding, protease resistance, and amyloid formation are sufficient to confer transmissibility to the PrP^{res} but that these characteristics in themselves may not be directly responsible for transmissible disease. The challenge to existing paradigms of molecular biology and genetics, including the self-replication of a protein, were quickly noted by investigators in this field. Importantly, several investigators previously demonstrated that distinctive strains of the scrapie agent exist and that these strains induce definable and reproducible phenotypes of disease in experimental animals.[18,27,49,50,137] These well-accepted and reproducible studies strongly argued for the presence of a genetic program in the scrapie agent that was most consistent with a nucleic acid–containing agent. More recently, several studies have suggested that the phenotypic behavior of scrapie strains may be entirely dependent on the pathogenic conformation that the PrP^c assumes when it is exposed to pathogenic forms of PrP^c, which in turn is dependent on its post-translational modifications.[19,58,59,216,228,229,233] Thus, researchers argued that the phenotypes of scrapie strains are entirely dependent on the protein structure of PrP^c and independent of any nucleic acid–encoded genetic trait. A second characteristic of etiologic agents of TSE that was difficult to ascribe to an infectious protein is the species barrier for transmission of prions between species. This phenotypic characteristic was noted when the scrapie agent from sheep was first adapted to mice and subsequently to other species, including hamsters. Other examples of a species barrier include BSE, in which 1000 lethal doses (as defined in cattle) must be given to a mouse to induce disease.[234] Interestingly, the species barrier not only contributes to the absolute resistance of species to infection with prions derived from other species but also can lengthen the mean incubation period in a population. The species barrier often is invoked to explain the rarity of TSE, even in populations repeatedly exposed to TSE in other species (e.g., humans exposed to scrapie-infected sheep), and possibly the relatively low number of human cases of vCJD that develop after exposure to beef contaminated with BSE.[72] A more worrisome aspect of the phenomenon of species barrier is that subclinical infections could result from exposure to BSE and subsequent transmission, leading to secondary cases with clinical symptoms.[118,228] A unifying explanation for the restriction of the transmission of prion disease between species that has been proposed argues that a species restriction is related to the efficiency with which exogenous prions interact with endogenous host-derived PrP^c to form PrP^{res}.[1,58,59,71,124,144,192,216,227] Although considerable gaps in the understanding of the infectious agent responsible for TSE persist and at times have contributed to the controversy that surrounds the infectious protein hypothesis, more recent in vitro studies have shifted the view of the field toward the infectious protein hypothesis. These studies include the findings that protease-resistant prions (PrP^{res}) that appear identical biochemically to PrP^{res} derived from infected brain can be produced in cell-free systems in vitro.[1,58,143] However, until recently, these preparations could not transmit disease to uninfected animals unless they were supplemented with brain tissue derived from diseased animals, presumably because their titer was too low.[116] A more recent study using a system to amplify prion production through sequential folding, sonication, and feeding of new substrate produced titers of in vitro–derived prions that could transmit TSE to susceptible animals and accelerate the development of symptoms in infected animals.[57] The results from this in vitro system have provided compelling evidence for a mechanism of recruitment of cellular proteins by a misfolded protein and subsequent protein deposition as an etiology of diseases classified as TSE.

Although several mechanisms can be envisioned to explain how a misfolded host protein can lead to the recruitment and misfolding of additional copies of the protein, how the deposition of PrP^{res} can lead to disease remains unclear. The loss of normal protein function and the development of disease in humans have several well-studied examples, such as cystic fibrosis.[106,241] These diseases are associated with loss of function of an essential cellular

protein. In contrast, the accumulation of cellular proteins, such as amyloid secondary to overproduction of a normal protein, can lead to disease and usually is associated with deposition and loss of organ function. In the case of TSE, the proposed mechanism for the generation of pathogenic prions appears fundamentally different in that the conformational change from a predominance of alpha-helical structure of PrP^{c} to molecules containing extensive amounts of an extended beta sheet, PrP^{res}, results in the accumulation of insoluble, protease-resistant proteins that can recruit additional normal cellular proteins into this conformation. In vitro cell-free systems and studies from kindred with inherited TSE such as GSS and FFI have shown that exposure to the misfolded prion protein such as PrP^{res} can result in this conversion.[1,58,59,62,91,196] In genetic TSE such as GSS and FFI, the genetic mutation is inherited as an autosomal dominant trait, and interestingly, the PrP^{res} pathogenic form of the prion protein has been shown to be derived from the mutant allele individual heterozygous for this allele.[1,58,62] The energetics required for the conversion in conformation of PrP^{c} to PrP^{res} are thought to be unfavorable and could require a mutant template or perhaps a chaperone protein (protein X).[58,135,143,220] Because the conversion reaction is essentially irreversible, this change in protein conformation results in the accumulation of the insoluble and protease-resistant PrP^{res} protein. Arguments have been put forth that certain conformations of PrP^{c} favor the conversion to pathogenic forms of PrP^{res}, thus providing additional constraints on the expression of disease that could explain the non-PrP^{c} genetic contributions to disease susceptibility and also provide a final common pathway for genetic and infectious forms of the disease.[1,222] Interestingly, several studies have argued that different protease fragments that are generated after PrP^{res} treatment with protease K may be associated with different patterns of disease in the CNS and thus provide additional diversity in disease phenotype attributed to this single, small protein.[178,179,228] Once the pathogenic PrP^{res} accumulates, additional newly synthesized molecules are converted into PrP^{res}, and clinical symptoms develop, depending on the site of cell loss in the CNS. Accumulation of the PrP^{res} isoform probably involves a combination of new synthesis of PrP^{res} and the decreased clearance of the misfolded aggregate. The failure in the clearance of the misfolded pathogenic isoform may ultimately be the major pathway leading to accumulation of PrP^{res} and disease.[1,200] Finally, studies have linked copper binding to the product of the PrP^{c} and oxidation of the prion protein.[1,29,193,204,242] Alternatively, a copper-containing prion complex localized to the synaptic junction could protect normal synapses from oxidants or perhaps play a direct role in copper metabolism or transport.[132,204] Loss of normal prion function by misfolding could then lead to neuronal loss. The importance of these newly described characteristics of PrP^{c} remains incompletely defined at this time.

Although inoculation of a susceptible host with prion-contaminated cadaveric growth hormone or the use of contaminated instruments during neurosurgical procedures clearly can transmit CJD, the route of infection leading to vCJD is only assumed to be through oral ingestion of contaminated beef, based on studies in nonhuman primates.[25,228] As noted earlier, studies have demonstrated that other TSE, including kuru, can be transmitted by oral ingestion of infectious material, but only ingestion of large inoculums and often requiring extended incubation periods.[98] In studies in mice, researchers have shown that 10 g of BSE-infected cow brain can infect and kill most mice.[11] Even though extrapolating from these data a comparable dose required for human infection will be difficult, these findings demonstrate that the BSE agent can be transmitted by oral ingestion.

The pathway leading from ingestion of PrP^{res} tissue to deposition in the CNS has been shown to require local replication in lymphoid tissue, which is thought to be followed by blood-borne dissemination to the nervous system.[1,113,138,140] High titers of infectious prions can be found in the liver and the spleen as well as in lymphoid tissue such as the tonsil and other lymphoid tissue of the oropharynx and gut, suggesting that the titer of the infecting PrP^{res} is amplified in these tissues before spread to the CNS. In vCJD, PrP^{res} can be found in the tonsils at levels as high as 10 percent of the infected brain.[116,230] However, these findings were reported to be restricted to vCJD, reflecting a characteristic of the PrP^{res} of vCJD or possibly secondary to the route of inoculation. Studies in mice have demonstrated that performing splenectomy before inoculating with the scrapie agent can prolong the disease course, and subsequent studies have demonstrated the importance of replication in cells derived from bone marrow in neuroinvasion.[68,133,145] Other studies have demonstrated that expression of PrP^{res} in the peripheral nervous system is sufficient to transmit disease, suggesting that direct hematogenous dissemination to the brain is not necessary for transmission of TSE.[190] Prions are thought to replicate in these tissues before spreading to the CNS, and a study documented the presence of PrP^{res} in the appendix of an individual that was removed 8 months before the onset of TSE.[121] Investigators once thought the B lymphocytes represented a likely candidate for the cell transmitting the PrP^{res} to the CNS; however, studies have provided data inconsistent with this mechanism of transmission.[9,30,73,140,172,173,205] Studies have provided evidence for the role of follicular dendritic cells in lymphoid tissue as sites of prion replication and may direct the prion to the CNS.[133,145] Other investigators have suggested that host cell molecules as yet unidentified may provide the necessary interactions with the prion molecule, which permits their trafficking with migratory myeloid cells and, ultimately, entry into the CNS. Candidate molecules included components of the complement system based on the study of PrP^{res} in transgenic mice lacking specific components of the complement system, perhaps secondary to the expression of Fcγ and complement receptors CD21/CD35 by follicular dendritic cells.[20,141,155]

The pathologic findings of TSE include the hallmark of a triad of histologic findings: (1) neuronal loss, (2) proliferation of reactive astrocytes, and (3) status spongiosis.[15] *Status spongiosis* is a descriptive term of degeneration of neurons and collapse of the cortical cytoarchitecture leading to vacuolation of the neuropil.[15] Amyloid plaques also are observed in some patients, and in some cases PrP^{res} is present in these plaques.[15,52,139] Whether the distribution of spongiform lesions is related to the pathogenesis of these disorders or merely reflects the duration of disease before the onset of clinical symptoms is unknown; however, some TSE, such as FFI, exhibit a preponderance of histopathologic changes in specific locations, such as the thalamus.[15,52,158,177,221] Recent descriptions of the neuropathologic process of vCJD have suggested that distinctive histopathologic changes may be present in the cases thus far studied[228] and include a distinctive plaque containing a central amyloid core and fibrillary periphery with extensive spongiform changes in the immediate periphery of the plaque.[89,130] The surrounding spongiform changes are proximal to the plaque, and the remaining neuropil is relatively intact.[52,130] These findings are unique to vCJD cases and are not seen in sporadic CJD cases from outside Great Britain.[51,131] Histopathologic lesions in the cerebral and cerebellar cortices, basal ganglia, thalamus, and brain stem also have been described.[131] Involvement of the cerebellum appears to be more common in vCJD than in reported cases of sporadic CJD, but this finding may be related to the differences in the age at onset of disease in these two populations, as recent findings from young patients with sporadic CJD have suggested that these patients present with a syndrome more closely resembling vCJD than sporadic CJD in older patients.[22] Last, electron microscopic studies of plaques from vCJD brain tissue have suggested subtle but recognizable differences between plaques obtained from patients with vCJD and CJD.[89]

CLINICAL MANIFESTATIONS

Only the clinical manifestations of sporadic CJD and vCJD are discussed; other TSE, such as GSS and FFI, are diseases that are unlikely to be encountered in pediatrics (Table 205–2). The interested reader is referred to discussions of these diseases in adults.[38,86,95,154,158] Clinical signs and symptoms during the early stages of CJD are subtle and often complex and include both motor and sensory dysfunction. Abnormalities in gait and vision and complaints of headache, dizziness, and paresthesias often are noted.[38,47,175,198] Intellectual dysfunction, including loss of memory, speech abnormalities, anxiety, and depression, also are often presenting complaints of patients with early stages of CJD.[22,38,47] Neurologic abnormalities may include corticospinal tract dysfunction as manifested by hyperreflexia, spasticity, and extensor plantar reflexes. Visual disturbances include visual field abnormalities and, in some cases, cortical blindness. Seizures are not a frequent clinical symptom of patients with CJD. Other less frequent findings include evidence of autonomic system dysfunction and, rarely, lower motor neuron disease.[175,202] Although death secondary to complications associated with the vegetative state usually occurs within 1 year of onset of symptoms, a small percentage of patients may exhibit a prolonged disease course.[47]

The clinical symptoms of vCJD are distinct from those of sporadic CJD, and because this disease has been reported in an adolescent, it could potentially be encountered by pediatricians. The age range for reported cases of vCJD is 16 to 48 years, a distribution clearly outside that of sporadic CJD. Symptoms associated with this TSE have included psychiatric and sensory disturbances, such as dysesthesias and paresthesias with electromyographic evidence of denervation. Psychiatric symptoms included anxiety, depression, anorexia, social withdrawal, and other nonspecific complaints. As the disease progressed, more familiar findings of TSE, including pyramidal tract dysfunction, rigidity, cerebellar dysfunction, and myoclonus, developed. Visual disturbances also were noted late in the disease. The duration of illness has exceeded 1 year in most patients with vCJD and follows complications associated with the vegetative state. As noted before, the clinical presentation of sporadic CJD in young individuals more closely resembles that of vCJD than of sporadic CJD in older individuals.[22]

DIAGNOSIS

The diagnoses of CJD and vCJD require a high index of suspicion and, in the case of vCJD, a history compatible with exposure to contaminated beef or beef byproducts or, possibly, a previous neurosurgical procedure. Routine laboratory findings are nonspecific and not helpful. No consistent reports demonstrate systemic or CNS inflammation; thus, routine laboratory analysis of cerebrospinal fluid often is nondiagnostic. Assays for specific cerebrospinal fluid proteins, such as the 14-3-3 protein, tau, or neuron-specific enolase, may provide helpful laboratory evidence of CJD or vCJD. [104,105,129,146,203,246] Definitive premortem diagnosis requires biopsy tissue, and histopathologic diagnosis can be facilitated by use of PrP^{res}-specific antibodies in both immunocytochemistry and Western blot assays.[8,52,228,230] The use of monoclonal antibodies specific for PrP^{res} has permitted a more thorough understanding of the distribution of prions in CNS and non-CNS tissue in patients with TSE. Hill and coworkers have reported that tonsillar biopsy followed by detection of PrP^{res} by both Western blot and immunocytochemistry is useful for establishing the diagnosis of vCJD disease.[90,117] This approach has been particularly valuable for defining the incidence of vCJD infection in populations such as has been carried out in studies in Great Britain.[90,122]

Imaging of patients with suspected prion disease has been extremely helpful in establishing the diagnosis of these rare diseases. Although computed tomography may reveal a variety of structural abnormalities, none is sufficiently specific to be considered diagnostic. In contrast, several investigators have claimed that magnetic resonance imaging findings of increased T2 signals from the striatum and thalamus are specific for prion diseases,

TABLE 205–2 Human Transmissible Spongiform Encephalopathies

Disease	Acquisition	Clinical Features
Kuru	Ingestion of or percutaneous inoculation with contaminated central nervous system tissue during ritual cannibalism in Fore tribe in New Guinea Last case reported in 1985	Bimodal age distribution with disease in adolescence and in older adults Adolescents presented with ataxia, dementia with prominent cerebellar involvement Rapidly progressive disease
Creutzfeldt-Jakob disease (CJD)	Sporadic cases account for 85% of reported cases of CJD; approximately 15% are secondary to defined mutation in PrP^c, and an unknown number are secondary to infection Well-documented cases after neurosurgical procedures and injection of cadaveric growth hormone	Classic presentation of dementia, sensory abnormalities followed by loss of motor functions Rapid progression of symptoms with death usually occurring <1 year of onset Disease of late middle age except in cases acquired after iatrogenic transmission
Variant Creutzfeldt-Jakob disease (vCJD)	Acquired through exposure to beef or beef byproducts contaminated with bovine spongiform encephalopathy Route of acquisition unknown but presumed to be oral	Presentation similar to CJD but disease progresses more slowly, with death occurring >12 months after symptoms develop Mean age of cases approximately 28 years, with documented cases in adolescents
Gerstmann-Sträussler-Scheinker syndrome (GSS)	Autosomal dominant inheritance with documented point mutations in PrP^c gene	Disease of middle age, with mean age at onset of 45 years Motor abnormalities and progressive dementia
Familial fatal insomnia (FFI)	Autosomal dominant inheritance with point mutations in PrP^c gene (missense mutation codon 178)	Disease of middle age Presentation includes insomnia, dysautonomia, and motor dysfunction
Sporadic fatal insomnia	No genetic mutations identified, but homozygosity at methionine 129 characteristic	Presentation similar to FFI and neuropathologic changes similar

especially vCJD.[10,87] Other investigators have suggested that abnormal signals originating from the pulvinar in the thalamus are distinctive for vCJD and should be considered highly predictive.[10,70,157] Similarly, electroencephalographic tracings from patients with CJD and vCJD are characteristic but not diagnostic. The classic findings are synchronous bilateral biphasic or triphasic periodic sharp waves on a background of generalized slowing.[26,67,215] The lack of a characteristic electroencephalographic tracing and magnetic resonance imaging findings should cast doubt on the diagnosis of CJD or vCJD, especially several months after onset of clinical symptoms.

PREVENTION AND TREATMENT

Because effective treatments of TSE remain as yet undefined, prevention of disease remains the goal of current medical practice. Infection that occurs after exposure during neurosurgical procedures (including dural grafts and stereotaxic electrodes), exposure to contaminated CNS tissue in the form of growth hormone or gonadotropic hormone preparations, and corneal grafts are well-known modes of transmission of TSE that are preventable in most cases. Because transmissions by blood and blood products have been reported, the American Red Cross has placed restrictions on donors to exclude those who may have been exposed to agents associated with TSE (see previous sections). Cases of TSE that follow exposure to human feces, urine, or mucosal secretions have not been reported; therefore, current universal precautions employed in health care settings should suffice to prevent nosocomial transmission during routine care of the patient with TSE. The inactivation of tissue and fluid suspected of being contaminated with prions is problematic. Early studies indicated that subjecting prion-containing brain tissue to temperatures in excess of 360° C resulted in only approximately a 90 percent reduction in infectivity.[45] In addition, CJD has been transmitted from paraffin-embedded tissue sections.[43] Several different approaches for decontamination of prion-contaminated tissue and instruments have been proposed.[161,194,199] Suffice it to say that the concentration of prions in lymphoid and nervous tissue should be emphasized to anyone in contact with patients with TSE, and material that may be contaminated with prions should be handled in a rigorous manner to ensure safe disposal. To date, no cases of transmission after routine dental procedures have been reported.

There currently are no known treatments of TSE. In vitro models of PrP^{c} folding have suggested that a variety of agents may limit production of pathogenic forms of PrP^{res} in neuroblastoma cells in vitro. Comprehensive reviews of treatment modalities have been published, and the interested reader is referred to these publications.[56,224] Derivatives of Congo red, polyene antibiotics related to amphotericin B, branched polyamines, and phenothiazines all have been reported to exhibit some activity and to delay onset of disease in experimental animals.[224] To date, no evidence that any of these proposed therapies would be effective in human TSE has been reported. Interestingly, at least two recent reports have suggested that anti-prion antibodies may offer a therapeutic approach to TSE. These reports suggested that anti-prion antibodies directed at cell surface PrP^{c} prevented infection of susceptible cells and also eliminated infection in a chronically infected cell line.[84,181,235] These findings argued that impaired clearance of misfolded PrP^{c} contributed to disease in animals infected with PrP^{res} and that passive antibody therapy could potentially cure similar infections in vivo. Treatment of mice with soluble lymphotoxin-β blocked follicular dendritic cell maturation and inhibited the development of scrapie in inoculated, susceptible mice, suggesting that interventions with agents that can block neuroinvasion may be efficacious.[156,173]

SECTION XVIII

CHLAMYDIA

CHAPTER 206

CHLAMYDIA INFECTIONS

Margaret R. Hammerschlag

Chlamydiae are obligate intracellular pathogens that have established a unique niche within the host cell. They cause a variety of diseases in animal species at virtually all phylogenic levels. Until fairly recently, the order has contained one genus with four recognized species: *Chlamydia trachomatis*, *Chlamydia psittaci*, *Chlamydia pneumoniae*, and *Chlamydia pecorum*.[29,35,39,49] *C. trachomatis* and *C. pneumoniae* are the most significant human pathogens, and *C. psittaci* is an important zoonosis. *C. pecorum* primarily infects cattle and other ruminants; there is no description of disease in humans. Recent taxonomic analysis involving the 16S and 23S rRNA genes have found that the order Chlamydiales contains at least four distinct groups at the family level and that within the family Chlamydiaceae are two distinct lineages.[35] This analysis has suggested splitting of the genus *Chlamydia* into two genera, *Chlamydia* and *Chlamydophila*. Two new species, *Chlamydia muridarum* (formerly the agent of mouse pneumonitis) and *Chlamydia suis* (an important pathogen of swine), would join *C. trachomatis*. *Chlamydophila* would contain *C. pecorum*, *C. pneumoniae*, and *C. psittaci* and three new species split off from *C. psittaci*: *Chlamydophila abortus* (causes abortion in cattle and sheep; rarely has caused abortion in humans), *Chlamydophila caviae* (formerly *C. psittaci* guinea pig conjunctivitis strain), and *Chlamydophila felis* (causes epidemic keratoconjunctivitis in cats). Controversy about this reclassification is continuing, but for the purposes of this chapter, I refer to these organisms as *Chlamydia*.

Recently, several chlamydia-like organisms that are endosymbionts of free-living amebae have been identified.[51,84] These organisms, which include *Parachlamydia acanthamoebae*, *Simkania negavensis*, and *Neochlamydia hartmannellae*, have been termed environmental chlamydiae. Analyses of nearly full length 16S rRNA gene sequences of these isolates showed that they clustered with other members of the order Chlamydiales but in a lineage separate from those of the genera *Chlamydia* and *Chlamydophila* (16S rRNA sequence similarities <88%). This bacteria-protozoa interaction might have been a driving force for the development of effective mechanisms by bacteria to survive phagocytosis by unicellular eukaryotes, which in turn may have been a first step in the evolution of intracellular bacterial pathogens of higher organisms.

Chlamydiae are characterized by a unique developmental cycle with morphologically distinct infectious and reproductive forms: the elementary body and the reticulate body. They have a gram-negative envelope without detectable peptidoglycan, although recent genomic analysis has revealed that both *C. trachomatis* and *C. pneumoniae* encode proteins forming a nearly complete pathway for the synthesis of peptidoglycan, including penicillin-binding proteins.[77,123] This finding is the basis for the so-called chlamydial peptidoglycan paradox, given that it has been known for decades that chlamydial development is sensitive to β-lactam antibiotics. Chlamydiae also share a group-specific lipopolysaccharide (LPS) antigen and use host adenosine triphosphate (ATP) for the synthesis of chlamydial protein.[108] Although chlamydiae are auxotrophic for three of four nucleoside triphosphates, they do encode functional glucose-catabolizing enzymes that can be used for the generation of ATP. As with peptidoglycan synthesis, for some reason these genes are turned off.[123] All chlamydiae also encode an abundant protein, the major outer membrane protein (MOMP or OmpA), that is surface exposed in *C. trachomatis* and *C. psittaci* but apparently not in *C. pneumoniae*.[123] MOMP is the major determinant of the serologic classification of *C. trachomatis* and *C. psittaci* isolates.

After infection develops, the infectious elementary bodies, which are 200 to 400 μm in diameter, attach to the host cell by a process of electrostatic binding and are taken into the cell by endocytosis that does not depend on the microtubule system. Within the host cell, the elementary body remains within a membrane-lined phagosome. The phagosome does not fuse with the host cell lysosome. The inclusion membrane is devoid of host cell markers, but lipid markers traffic to the inclusion, which suggests functional interaction with the Golgi apparatus. The elementary bodies then differentiate into reticulate bodies that undergo binary fission. After approximately 36 hours, reticulate bodies differentiate into elementary bodies. At approximately 48 hours, release may occur by cytolysis or by a process of exocytosis or extrusion of the whole inclusion, with the host cell left intact. Chlamydiae also may enter a persistent state after treatment with certain cytokines such as interferon-γ, treatment with antibiotics, or restriction of certain nutrients. In the persistent state, metabolic activity is reduced. The ability to cause prolonged, often subclinical infection is one of the major characteristics of chlamydiae.

INFECTION CAUSED BY *CHLAMYDIA TRACHOMATIS*

EPIDEMIOLOGY

C. trachomatis infection is the most prevalent sexually transmitted infection and infectious disease in the United States today.[22,23] The Centers for Disease Control and Prevention (CDC) estimates that the number of new *C. trachomatis* infections exceeds 4 million annually.[23] The prevalence of chlamydial infection is associated less with socioeconomic status, urban or rural residence, and race or ethnicity than is the case with gonorrhea and syphilis. The prevalence of *C. trachomatis* infection consistently is higher than 5 percent among sexually active adolescent and young adult women attending outpatient clinics, regardless of the region of the country, the location of the clinic (urban or rural), and the race or ethnicity of the population.[40] In sexually active adolescents, the prevalence commonly exceeds 10 percent and may exceed 20 percent.[45] Decreasing age at first intercourse and increasing age at marriage have contributed importantly to the

higher prevalence of infection with *C. trachomatis*. Infection with *C. trachomatis* tends to be asymptomatic and of long duration. If a pregnant woman has active infection during delivery, the infant may acquire the infection and, as a consequence, either conjunctivitis or pneumonia.[100] Rarely, children also may acquire chlamydial infection as a result of sexual abuse.

INFECTIONS IN OLDER CHILDREN

C. trachomatis has not been associated with any specific clinical syndrome in older infants and children. Most attention given to *C. trachomatis* infection in these children has concentrated on its relationship to sexual abuse. Isolation of *C. trachomatis* from a rectal or genital site in children without previous sexual activity may be a marker of sexual abuse; moreover, evidence for other modes of spread, such as through fomites, is lacking for this organism. Perinatal maternal-to-infant transmission resulting in vaginal or rectal infection has been documented, with prolonged infection lasting for periods up to 3 years. This duration can be an important confounding variable in evaluation of possible sexual abuse in a young child.

Vaginal infection with *C. trachomatis* was reported uncommonly in prepubertal children before 1980. The possibility of sexual contact frequently was not even discussed. In 1981, Rettig and Nelson[120] reported concurrent or subsequent chlamydial infection in 9 of 33 (27%) episodes of gonorrhea in a group of prepubertal children. However, *C. trachomatis* was not found in any of 31 children with urethritis or vaginitis that was not gonococcal. No information was given about possible sexual activity.

Most studies have identified rectogenital chlamydial infection in 2 to 3 percent of sexually abused children when these children underwent routine culture for the organism.[23] Most of those with chlamydial infection were asymptomatic. In two early studies that had control groups, similar percentages of control patients also were infected.[56,71] A larger study subsequently conducted by Ingram and colleagues[72] found a stronger association between vaginal chlamydial infection and a history of sexual abuse but not with pharyngeal infection, which was found in a similar number of controls. Rectal infection was detected in only 1 of 124 abused children. A recent CDC-sponsored multicenter study of sexually transmitted infections in children, birth to 13 years of age, being evaluated for suspected sexual abuse found infection with *C. trachomatis* in 15 of 536 (2.8%), all of whom were asymptomatic. Two (0.37%) of these children were positive in the rectum; the others were positive in the vagina. Sixty percent of the children who were positive for *C. trachomatis* gave a clear, credible detailed description of molestation.

In the setting of repeated abuse by a family member during the course of a long time, the development of infection would be difficult to demonstrate. The 2006 guidelines for the treatment of sexually transmitted diseases from the CDC do not recommend that samples for culture of *C. trachomatis* be obtained routinely from the pharynx and urethra in children who are suspected victims of sexual abuse.[23] The major reasons were the low yield from the urethra, the tendency for longer persistence of perinatally acquired pharyngeal infection, and the potential confusion with *C. pneumoniae*.[7]

Although asymptomatic, perinatally acquired nasopharyngeal infection with *C. trachomatis* may persist for at least 2 years; respiratory tract infection in older children and adults appears to be a distinctly uncommon occurrence, the reasons for which are not clear. *C. trachomatis* has been isolated from the pharynx of some adults and apparently is related to certain sexual practices. These infections have been asymptomatic. Two earlier studies based entirely on serology suggested that *C. trachomatis* might be a cause of pharyngitis and community-acquired pneumonia in adults.[81,82] Subsequent studies using culture methods did not confirm these findings.[44,67] The original studies probably detected cross-reacting antibody to *C. pneumoniae*.

C. trachomatis can cause pneumonia in older children or adults in two specific situations. One is in immunosuppressed persons. Several well-documented cases of *C. trachomatis* pneumonia in persons with leukemia, bone marrow transplant recipients, and those with acquired immunodeficiency syndrome (AIDS) have been reported.[73,83,98,102] In all these cases, *C. trachomatis* was isolated from biopsy specimens of lung tissue or bronchoalveolar lavage fluid. Several patients also had a serologic response that was diagnostic of acute *C. trachomatis* infection. Unfortunately, the clinical findings were nonspecific. These adults had none of the features that are distinctive of infantile chlamydial pneumonia.

Several cases of pulmonary infection after exposure to *C. trachomatis* serovars L1 and L2 in the laboratory also have been reported.[8] These infections probably were acquired by inhalation of aerosolized organisms. Clinically, these patients had high fever, night sweats, and cough and were found to have mediastinal lymphadenopathy, pneumonitis, or splenomegaly alone or in any combination. In two cases, the diagnosis of lymphoma was seriously considered. These findings are not unexpected, given the severity of lymphogranuloma venereum genital infection. Accidental exposure to the aerosolized trachoma biovar of *C. trachomatis* has not been associated with the development of significant illness.

DIAGNOSIS OF *CHLAMYDIA TRACHOMATIS* INFECTIONS

Culture remains the "gold standard" of diagnosis for detection of *C. trachomatis* from the vagina or rectum in prepubertal children. *Chlamydia* culture has been defined further by the CDC as isolation of the organism in tissue culture and confirmation by microscopic identification of the characteristic inclusions by fluorescent antibody staining.[22,23] Since the 1980s, numerous nonculture tests, including enzyme immunoassay (EIA), direct fluorescent antibody tests, and nucleic acid amplification tests (NAATs), have been approved for establishing the diagnosis of *C. trachomatis* genital infections in adults and adolescents. The only EIA and direct fluorescent antibody tests still available in the United States are Pathfinder *Chlamydia* direct fluorescent assay and EIA microplate (Bio-Rad Laboratories). Although these tests are approved by the Food and Drug Administration (FDA) for vaginal and urethral specimens from adolescents and adults, they are not approved for these sites in children. The DNA probe PACE 2 (Gen-Probe, San Diego, CA), which is still used in many laboratories, does not have approval for any site in children, including the conjunctiva.

A major advance in the diagnosis of *C. trachomatis* infection during the past decade has been the introduction of NAATs. These tests have high sensitivity, perhaps even detecting 10 to 20 percent more cases than is possible with culture, while retaining high specificity.[23] Currently, three commercially available NAATs are FDA approved: polymerase chain reaction (Amplicor; Roche Molecular Diagnostics, Nutley, NJ), transcription-mediated amplification (Gen-Probe), and strand displacement amplification (ProbeTec; Becton Dickson, Sparks, MD). Polymerase chain reaction and strand displacement amplification are DNA amplification tests; both use primers that target gene sequences on the cryptogenic *C. trachomatis* plasmid, which has approximately 10 copies per cell. Transcription-mediated amplification is an RNA amplification assay. A fourth DNA NAAT, ligase chain reaction (LCx; Abbott Diagnostics, Abbott Park, IL), was withdrawn from the market by the manufacturer in 2002. NAATs that are currently commercially available have FDA approval for cervical swabs from women, urethral swabs from men, and urine from men and women. The transcription-mediated amplification also has approval for vaginal swabs from

adults and adolescent women. Several studies have demonstrated that self-collected swabs also are suitable specimens.

Nonculture tests should never be used for rectal or vaginal sites in children or for any forensic purposes in adolescents or adults[22,23]; only culture should be used. Isolation of the organism in tissue culture should be confirmed by microscopic identification of the inclusions by staining with a fluorescein-conjugated, *C. trachomatis* species–specific monoclonal antibody. EIAs are not acceptable for confirmation of culture results, and their use has led to false-positive reports.[54,117] Isolates of *C. trachomatis* also should be preserved for further testing if necessary. The use of nonculture tests for detection of *C. trachomatis* in vaginal and rectal specimens has been associated with a large number of false-positive results.[53,117] Fecal material can give false-positive reactions with any EIA; none is approved for this site in adults. Common bowel organisms, including *Escherichia coli*, *Proteus* spp., vaginal organisms such as group B streptococcus, and *Gardnerella vaginalis*, and even some respiratory tract flora, such as group A streptococcus, also can yield positive reactions with EIAs.[117] Because all of the available EIAs use genus-specific antibodies, if they are performed on respiratory tract specimens, these tests will detect *C. pneumoniae* as well.[8] NAATs also are not approved for the detection of *C. trachomatis* in rectogenital specimens from prepubertal children and rectal specimens in adults. The major problem with rectal specimens is the presence of inhibitors of DNA polymerase, which can lead to false-negative results. Data on the use of NAATs for vaginal specimens or urine from children are very limited and insufficient to allow unqualified recommendation of their use.[32,45,78,93] Several studies used ligase chain reaction, which no longer is available.[32,45,78] The CDC-sponsored multicenter study of sexually transmitted diseases in children, birth to 13 years of age, being evaluated for suspected sexual abuse also compared NAATs (ProbeTec and TMA) and use of urine to culture for establishing the diagnosis of *C. trachomatis* infection.[10] The NAATs appeared to be more sensitive than culture for vaginal specimens with retention of specificity. Of the 15 children who had positive results for *C. trachomatis*, 7 were positive by culture, 10 were positive by NAAT of vaginal swab, and 13 were positive by NAAT of urine. All positive NAAT results were confirmed as *C. trachomatis* by *ompA* genotyping. Two of the seven culture-positive children were positive in the rectum but not in the vagina. Thus, although use of urine for NAAT testing correlated with positive vaginal culture or NAAT results, it obviously will miss rectal infection. Because the prevalence of *C. trachomatis* infection in children being evaluated for suspected sexual abuse has remained less than 3 percent, a potential problem exists with the positive predictive value of a single NAAT result. The 2006 CDC sexually transmitted diseases treatment guidelines recommend that NAATs be used as an alternative to culture *only* if confirmation is available.[23] Confirmation tests should consist of a second FDA-approved NAAT that targets a gene sequence different from the one used in the initial test.

TREATMENT

Chlamydial infections in older children may be treated with oral erythromycin (50 mg/kg/day four times a day orally to a maximum of 2 g/day for 7 to 14 days). Children older than 8 years may be treated with tetracycline (25 to 50 mg/kg/day four times a day orally for 7 days). Azithromycin, 1 g orally as a single dose, also may be used in children who weigh at least 45 kg, are 8 years of age or older, or both.[57]

INFECTION CAUSED BY *CHLAMYDIA PSITTACI*

Human infection with *C. psittaci* was described first probably by Juergensen in 1874 or Ritter in 1876. Ritter described seven cases of an unusual pneumonia that appeared to be caused by parrots and finches that were caged in the study of his brother's home in Switzerland. After these reports, several outbreaks of a similar disease in Europe established the association with exposure to birds. The term *psittacosis* was coined by Morange in 1892 from the Greek word for parrots, *psittakos*.

THE ORGANISM

C. psittaci is a diverse species that affects psittacine and nonpsittacine birds.[1] The known host range includes 259 avian species.[63] Birds that have been reported to have *C. psittaci* infection contain six major domestic species: chickens, turkeys, Pekin ducks, Muscovy ducks, geese, and pigeons. Infections in these species have been associated with significant outbreaks in humans.[20,21] In the past, chlamydial infection in psittacine birds was termed psittacosis, whereas disease in wild and domestic fowl was called ornithosis. However, as *C. psittaci* strains isolated from psittacine or nonpsittacine species have been shown to produce identical disease in birds of either grouping, this distinction is artificial. The more universally applicable term *chlamydiosis* can be usefully employed to describe chlamydial infections of all animal species.

EPIDEMIOLOGY

Chlamydial infections in birds are important because they represent a biologic hazard to human health as well as economic loss to the poultry industry.[20,21] *C. psittaci* has been recovered from symptomatic and from apparently healthy birds. Infection principally involves the gastrointestinal tract, and the chlamydiae are shed in feces or through infectious respiratory tract discharges.[135] Clinically inapparent, latent infections may be the predominant state. Overt clinical disease may be activated by stress factors, including overcrowding, poor nutrition, other bacterial and viral infections, and transportation.[21,128]

Apparently healthy birds shedding chlamydiae can infect other birds or humans through contact. Infectious chlamydiae in respiratory secretions or feces may remain viable for several months. Transmission of disease is mainly through aerosols of fecal or feather dust, but oral infection is an alternative route. Transmission through eggs has been shown in chickens, ducks, seagulls, and psittacine birds.[135] However, most infected eggs do not hatch. In the nest, parent birds may infect their young, which may carry the infectious agent for many years. Young birds are more susceptible to infection than are older birds, and some species seem to be more susceptible than others are. Often, disease carriers may be identified by the transmission of disease to other susceptible birds or by the sudden death of young nestlings with apparently healthy parents.[135]

From 1988 through 2003, 935 human cases of psittacosis were reported to the CDC.[128] According to the most recent report from the CDC, 85 percent of cases of psittacosis in the United States were associated with exposure to birds; 70 percent of these reported cases were the result of exposure to caged pet birds.[21] Individuals at highest risk of acquiring psittacosis included bird owners or fanciers and pet shop employees. Since 1984, several major outbreaks of psittacosis have occurred in the United States in turkey-processing plants, where approximately 300 persons were infected.[20,63] Workers exposed to turkey viscera were at the highest risk of acquiring infection.[20] In 1995, the CDC investigated an outbreak of avian chlamydiosis in a shipment of more than 700 pet birds from a Florida bird distributor to the Atlanta area.[105] Affected birds included parrots, parakeets, finches, lovebirds, cockatiels, conures, and canaries. Clinical psittacosis or

serologic evidence of *C. psittaci* infection was found in 30.7 percent of households with birds from the infected flock. An average of 21 days (range, 1 to 47 days) elapsed between purchase of the bird and the onset of symptoms. Most of the infected individuals had mild or asymptomatic illnesses. Among persons in exposed households, illness occurred more frequently if the recently purchased bird had become sick or had died. Kissing or nuzzling, handling, and feeding the bird all were significantly associated with the development of clinical psittacosis, but in contrast to earlier studies, cleaning the bird's cage was not. The risk for acquiring clinical psittacosis varied significantly by type of bird to which the individual was exposed. The attack rate was highest for individuals exposed to parrots.

Inhalation of infectious aerosols derived from the feces, fecal dust, or secretions of *C. psittaci*–infected animals is thought to be the primary route of infection. The source birds can be infected asymptomatically or can show signs of infection such as anorexia, ruffled feathers, depression, and watery green droppings. Psittacosis frequently is a systemic infection in birds, and the turkey strains can induce severe pericarditis.[135]

Psittacosis is an uncommon occurrence in children. In a series of 135 cases from Australia observed during a 15-year period, the youngest patient was 17 years of age.[141] Children may be less likely to be exposed to birds. Bird keeping is more commonly a hobby of adults, and the parents are the ones who usually clean the cage of the family's pet bird. An outbreak of psittacosis involving two adolescents was reported from a small village in Scotland. The source of the infection appeared to be the local pet shop, which had taken delivery of four lovebirds, two of which died shortly after arrival.[106] Another report described a family outbreak during which three members of a family of nine persons contracted severe pneumonia.[15] A newly purchased cockatiel appeared to be the primary source, but person-to-person transmission was likely between 19-year-old twin brothers who shared a bedroom, one of whom had no direct contact with the bird. A retrospective review of the records of the Public Health Laboratory at Leeds, England, for cases with a fourfold rise in *Chlamydia* complement-fixation (CF) titer identified 219 patients during a 24-year period from 1965 to 1989.[27] The ages ranged from 9 months to 87 years; only five (2.2%) of the patients were younger than 10 years, but on review, only 34 of the total cases were thought to be psittacosis. All involved antecedent avian exposure, but the ages were not specified.

CLINICAL MANIFESTATIONS

Infection with *C. psittaci* in humans may range from clinically inapparent to severe infection involving multiple organ systems as well as pneumonia.[141] Symptomatic *C. psittaci* infection in humans may present as two forms: a severe atypical pneumonia or pneumonitis and a systemic toxic or septic form without respiratory involvement. In both cases, fever, chills, muscle aches and pains, and severe headache are typical. Other manifestations may be diarrhea, nausea, and vomiting. The mean incubation period is 15 days after exposure (range, 5 to 21 days). The onset usually is abrupt, with complaints of fever, cough, and headache. The fever is high and frequently associated with rigors and sweats. The headache can be so severe that meningitis can be considered a possibility; 33 percent of patients in the Australian series underwent lumbar puncture.[141] The cough usually is nonproductive, and rales may be heard on auscultation. Chest radiographs generally are abnormal, with variable infiltrates. Pleural effusions also may be present. In contrast, most of the individuals in the Atlanta outbreak had very mild disease characterized by fever, headache, and cough.[105]

LABORATORY FINDINGS

The white blood cell count usually is not elevated, but mild leukocytosis may be present. Almost 50 percent of patients in the Australian series had abnormal liver function test results, including elevated levels of aspartate aminotransferase, alkaline phosphatase, and bilirubin.[141]

DIAGNOSIS

Because of the varying clinical findings, establishing the diagnosis of psittacosis can be difficult. A history of exposure to birds is important, although as many as 20 percent of patients with psittacosis may not have a history of such contact.[128] In the Australian series, 85 percent of patients had a history of recent bird contact, 71 percent of whom described a strong history of contact with birds.[141] Only five patients had been exposed to poultry. Pneumonia caused by *C. pneumoniae* also can have similar clinical findings.[114,115] Data from both Sweden and Denmark have suggested that many cases of *psittacosis* caused by *C. pneumoniae* with no history of exposure to birds probably have occurred, and the diagnosis has been established serologically with CF.[38,104] An outbreak of suspected psittacosis in a boys' boarding school in England was reported in 1984.[114] The outbreak involved 20 children, 13 to 18 years of age, and four adults. The illness was mild and characterized by pharyngitis and influenza-like symptoms, including headache, fever, and cough. The diagnosis was established on the basis of serology (CF titers). No avian source was identified. Because the cases occurred during a 3-month period, person-to-person spread was suggested. Subsequent analysis of the sera suggested that the outbreak was caused by *C. pneumoniae*.[115] Person-to-person spread rarely occurs in psittacosis; secondary cases tend to be severe, however.

Other infections that can produce the syndrome of pneumonia with high fever, unusually severe headache, and myalgia include *Mycoplasma pneumoniae* infection, tularemia, tuberculosis, fungal infection, legionnaires' disease, and various bacterial infections. The diagnosis of psittacosis in the human population is based primarily on clinical findings, epidemiology, and serology.

The diagnosis of human infection with *C. psittaci* has not changed substantially for many years. The mainstay of diagnosis remains serology with the CF test. According to the 2000 recommendations from the CDC,[21] a confirmed case of psittacosis requires a compatible clinical illness, usually with a good history of avian exposure. Laboratory confirmation can be made by one of the three following methods: (1) culture of *C. psittaci* from respiratory secretions, (2) fourfold or higher increase in CF or microimmunofluorescence (MIF) titer in sera collected at least 2 weeks apart, and (3) an MIF IgM titer of 16 or higher. A probable case should be epidemiologically linked to a confirmed case or have a single CF or MIF antibody titer of 32 or higher in at least one serum sample obtained after the onset of symptoms. As with use of MIF for the diagnosis of *C. pneumoniae* infection, cross-reactions with other *Chlamydia* spp. and bacteria can occur.[107] Cross-reaction with *Legionella longbeachae* also has been described in a patient with fulminant pneumonia caused by *C. psittaci*.[129]

Although *C. psittaci* will grow in the same culture systems used for the isolation of *C. trachomatis* and *C. pneumoniae*, very few laboratories culture for *C. psittaci*, mainly because of the potential biohazard.

CF is a genus-specific test; thus, infection caused by *C. pneumoniae* can give titers of 32 or higher. Early treatment with tetracycline also may suppress the antibody response. Even though many laboratories can isolate *C. psittaci*, it is not a service provided routinely by most clinical microbiology laboratories. The

CDC reported using a modification of the MIF test for the serodiagnosis of human psittacosis.[137] In the 78 patients examined, psittacosis was diagnosed on the basis of compatible clinical symptoms after exposure to sick birds. Conventional CF was positive in 36 (46%) of the patients. The MIF test detected diagnostic antibody responses in all the CF-positive patients and in another 12 patients whose sera were negative or anticomplementary according to CF. Seven other patients were thought to have *C. pneumoniae* infection because of their MIF antibody response.

Several reports also have examined the use of nonculture methods, including direct fluorescent antibody, EIA, and polymerase chain reaction (PCR), for the direct identification of *C. psittaci* in clinical specimens. Several in-house PCR assays for detection of *C. psittaci* have been reported in the literature.[97,111] Most reported studies have assessed only the ability of these assays to amplify laboratory isolates; they have not been evaluated extensively for detection of *C. psittaci* in clinical specimens from humans with suspected psittacosis. Only a small number of human cases of psittacosis documented by PCR have been reported in the literature.[97,111] In 1997, the CDC reported one of the most extensive evaluations of the use of PCR in the investigation of a psittacosis outbreak.[97] Most of the specimens tested were from birds. The target sequence of the assay was the 16S rRNA gene. The first amplification was genus specific, and the second was multiplexed and could differentiate among *C. psittaci*, *C. pneumoniae*, and *C. trachomatis* on the basis of the molecular weight of the amplicon. With the use of this assay, *C. psittaci* was detected in 13 (17.3%) of 75 sick or dead birds involved in three avian psittacosis outbreaks; 5 of the 13 PCR-positive birds were also culture positive. None of the throat swab specimens from four humans involved in this outbreak were positive by PCR or culture, but one individual had a *C. psittaci*–specific MIF IgG titer of 512. The CDC [21] provides a list of laboratories that test human specimens in its current recommendations for the control of *C. psittaci* infection in humans and pet birds (Table 206–1).

TREATMENT

The recommended treatment of psittacosis in adults and children older than 8 years is 500 mg of tetracycline orally every 6 hours for 7 to 10 days. Erythromycin (50 mg/kg/day, up to 2 g/day, for 7 to 10 days) also can be used. The experience in the Australian series[141] and anecdotal reports suggest that tetracycline may be more effective than erythromycin. The initial infection does not appear to be followed by long-term immunity. Re-infection and clinical disease can develop within 2 months of treatment; two well-documented cases of re-infection are reported in the literature. A pet shop employee had two episodes of psittacosis 11 months apart. Each episode met the CDC's confirmed case definition.[19]

INFECTION CAUSED BY *CHLAMYDIA PNEUMONIAE*

THE ORGANISM

The first isolates of *C. pneumoniae* were obtained serendipitously during trachoma studies in the 1960s.[48] After the recovery of a similar isolate from the respiratory tract of a college student with pneumonia in Seattle, Grayston and colleagues[50] applied the designation TWAR after their first two isolates, TW-183 and AR-39. On the basis of inclusion morphology and staining characteristics in cell culture, *C. pneumoniae* initially was considered a *C. psittaci* strain. Subsequent analysis, however, has demonstrated that this organism is distinct from both *C. psittaci* and *C. trachomatis*.[49] Sequencing has revealed that *C. pneumoniae* differs significantly from *C. trachomatis* in several areas. *C. pneumoniae* encodes 21 polymorphic membrane proteins versus 9 in *C. trachomatis*. Polymorphic membrane proteins may be surface exposed in *C. pneumoniae*.[77] Ultrastructural studies have demonstrated an elementary body morphology distinct from that of *C. trachomatis* and *C. psittaci* (Fig. 206–1).[24] However, some isolates of *C. pneumoniae*, including IOL-207, have been found to have round elementary bodies.[18,116] Thus, it may not be a consistent species characteristic. Restriction endonuclease pattern analysis, nucleic acid hybridization studies, and amplified fragment length polymorphism analysis suggest a high degree of genetic relatedness (>95%) among the *C. pneumoniae* isolates examined thus far and less than 10 percent homology with either *C. trachomatis* or *C. psittaci*.[17,26,35,49,96] At this point, we do not have a strain typing system for *C. pneumoniae*. A plasmid has been detected in a single isolate obtained from a horse but not from any human isolate of *C. pneumoniae*.

EPIDEMIOLOGY

C. pneumoniae appears to be a common human respiratory pathogen. The organism also has been isolated from nonhuman mammalian species, including a horse, koalas, bandicoots, and reptiles and amphibians, although the role that these infections may play in human disease is unknown.[13,75,85,119] The mode of transmission remains uncertain but probably involves infected respiratory tract secretions. Acquisition of infection by droplet aerosol was described during a laboratory accident.[68] *C. pneumoniae* can remain viable on Formica countertops for 30 hours and can survive small-particle aerosolization.[36,131] Spread of *C. pneumoniae* within families and enclosed populations such as military recruits has been described.[55,80,139]

Several serologic surveys have documented rising chlamydial antibody prevalence rates in school-age children that reach 30 to 45 percent in adolescents.[16] This increasing prevalence of chlamydial antibody during childhood probably is attributable to *C. pneumoniae*. The proportion of community-acquired pneumonia associated with *C. pneumoniae* infection has ranged from 0 to 19

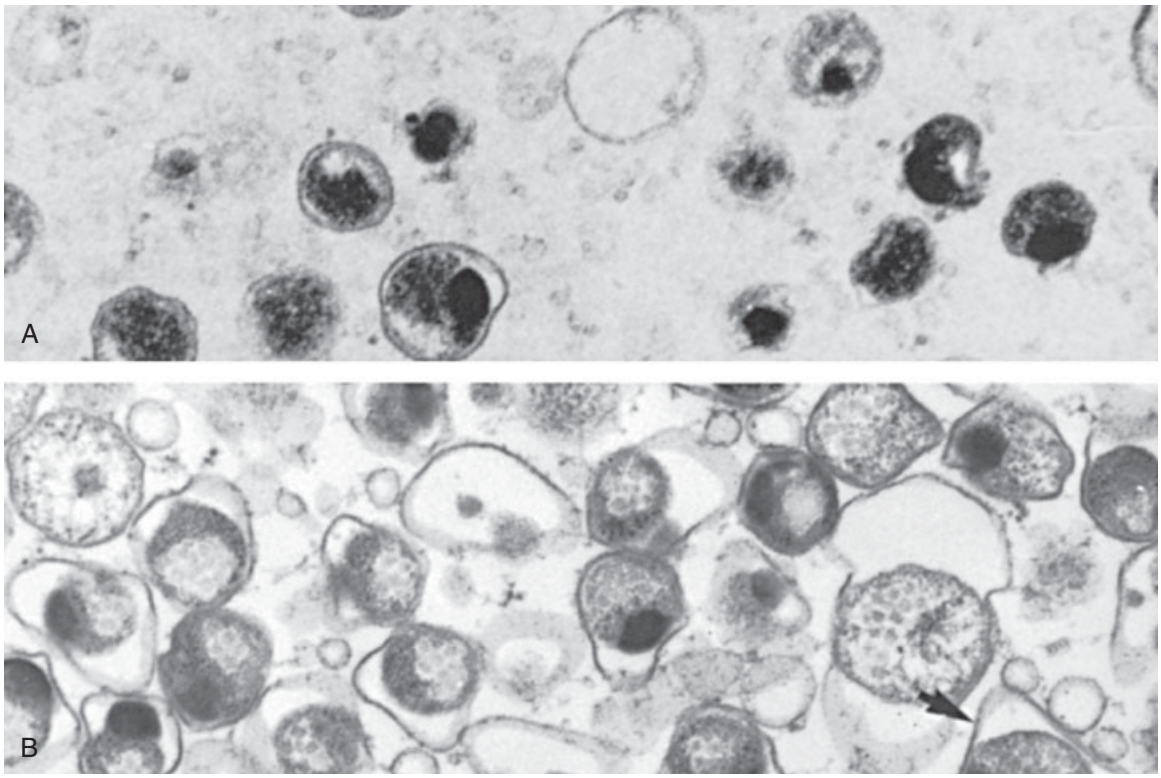

Figure 206–1 Electron micrograph of *Chlamydia trachomatis* (**A**) and *Chlamydia pneumoniae* (**B**) inclusions demonstrating the morphology of the elementary body. The elementary bodies of *C. pneumoniae* have a pear shape because of a loose periplasmic membrane *(arrow)*, unlike the typically round elementary bodies of *C. trachomatis* and *C. psittaci*.

percent, varying with the geographic location, the age group examined, and the diagnostic methods used.*

Studies of the role of *C. pneumoniae* in lower respiratory tract infections in pediatric populations have found evidence of infection in 0.3 to more than 44 percent (Table 206–2). Most of these studies have relied entirely on serology for diagnosis. Early studies that relied on serology suggested that infection in children younger than 5 years was rare[48,140]; however, in a study of Filipino children younger than 5 years with lower respiratory tract infection, nearly 10 percent had either acute or chronic antibody to *C. pneumoniae*.[124] In Brooklyn, the proportion of lower respiratory tract infections associated with *C. pneumoniae*, as determined by culture, increased from 9 percent in children younger than 5 years to 19 percent in children and adolescents 5 to 16 years of age.[25]

Studies that have used culture have found a poor correlation with serology, especially in children.[12,33,61] Although 7 to 13 percent of children 6 months to 16 years of age enrolled in two multicenter pneumonia treatment studies were culture positive and 7 to 18 percent met the serologic criteria for acute infection with the MIF test, they were not the same patients.[12,61] Only 1 to 3 percent of the culture-positive children met the serologic criteria, and approximately 70 percent were seronegative.

In studies to date, acute infection with *C. pneumoniae* does not appear to vary by season. Studies have found much lower preva-

lence of infection than reported in the 1990s, suggesting that cycling during the course of time may occur.[84,86]

Prolonged culture positivity lasting several weeks to several years after acute infection has been reported.[25,29,33,55] Asymptomatic nasopharyngeal carriage also occurs in 2 to 5 percent of adults and children.[11,33,46,69,84] The role that asymptomatic carriage plays in the epidemiology of *C. pneumoniae* is not known, but possibly these persons serve as a reservoir for spread of infection.

CLINICAL MANIFESTATIONS

The spectrum of disease associated with *C. pneumoniae* is expanding. Most infections probably are mild or asymptomatic. Longitudinal serologic data obtained during an epidemic among military recruits in Finland suggest that only approximately 10 percent of infections result in clinically apparent pneumonia.[80] Initial reports emphasized mild atypical pneumonia clinically resembling that associated with *M. pneumoniae*.[47,48,125] In several subsequent studies, however, pneumonia associated with *C. pneumoniae* was clinically indistinguishable from other pneumonias.[12,61] Co-infection with other pathogens, especially *M. pneumoniae* and *Streptococcus pneumoniae*, can be a frequent occurrence.[12,61] In one multicenter pneumonia treatment study, 20 percent of the children with positive *C. pneumoniae* cultures were co-infected with *M. pneumoniae;* they could not be distinguished from children who were infected with either organism alone.[12] *C. pneumoniae* has been associated with severe illness and even death, although the role of preexisting chronic conditions as contributing factors in many of these patients is difficult to assess. In some cases, however, *C. pneumoniae* clearly appears to be implicated as a serious pathogen, even in the absence of underlying disease. *C. pneumoniae* was isolated from the respiratory tract and the pleural fluid of a previously healthy adolescent boy with severe pneumonia complicated by respiratory tract failure and pleural effusions (Fig. 206–2).[5]

The role of host factors remains to be determined. Although *C. pneumoniae* has been detected in bronchoalveolar lavage fluid from 10 percent of a group of patients with AIDS and pneumonia, its clinical role in these patients is uncertain because most of these patients were co-infected with other well-recognized pathogens, such as *Pneumocystis carinii* and *Mycobacterium tuberculosis*.[4] Gaydos and colleagues[42] identified *C. pneumoniae* infection by PCR in 11 percent of a group of immunocompromised adults with human immunodeficiency virus (HIV) infection, malignant neoplasms, and other immune disorders, including systemic lupus erythematosus, sarcoidosis, and common variable immunodeficiency. *C. pneumoniae* appeared to be responsible for 14 to 19 percent of episodes of acute chest syndrome in children with sickle-cell disease.[30,101] *C. pneumoniae* infection in these patients appeared to be associated with more severe hypoxia than was infection with *M. pneumoniae*.

C. pneumoniae may act as an inflammatory trigger for asthma. Several cases of culture-documented *C. pneumoniae* infection in patients with significant bronchospasm have been reported.[53,55] Asthmatic bronchitis was diagnosed in one patient, and she was receiving systemic and topical steroids.[65] This patient did not improve until her chlamydial infection was treated. Hahn and associates[53] reported an association between serologic evidence of acute *C. pneumoniae* infection and wheezing in adults seen for lower respiratory tract illness. However, they were able to isolate the organism from only 1 of 365 patients. As part of a study in children, *C. pneumoniae* was isolated from 13 of 118 children (11%) 5 to 15 years of age who were evaluated initially for either new or acute exacerbations of asthma.[33] Treatment of the infec-

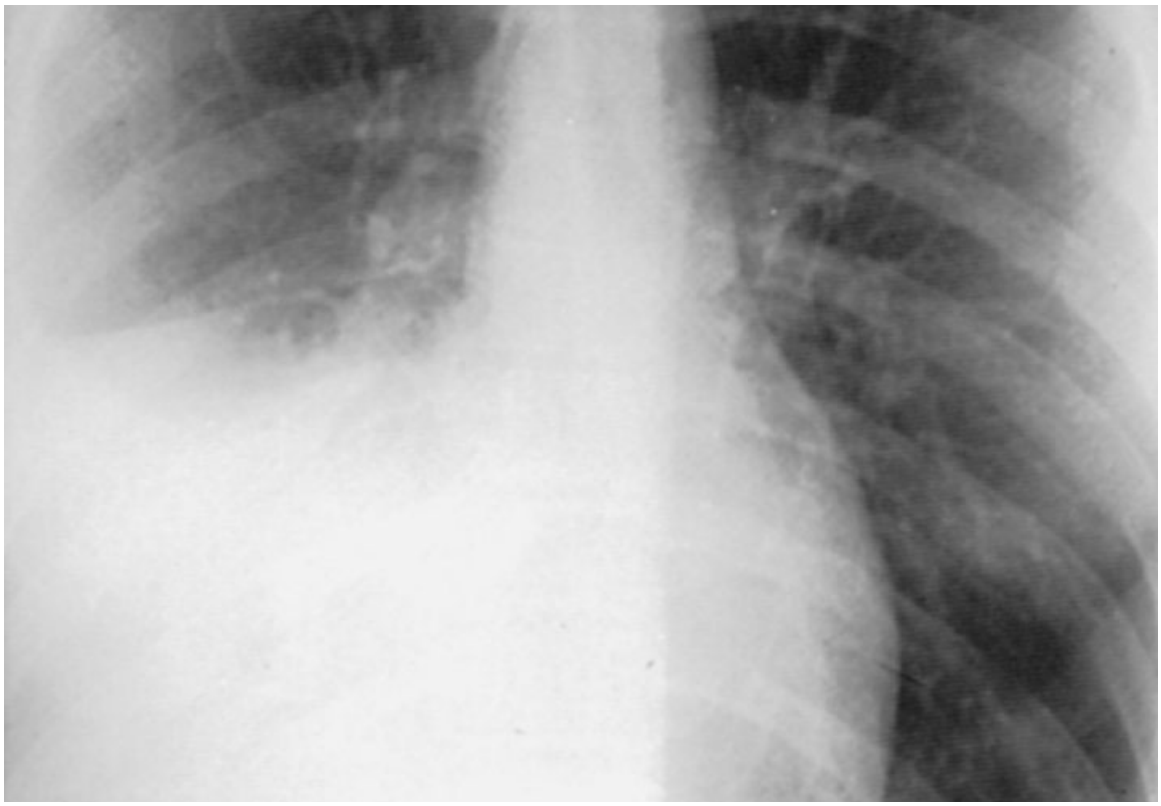

Figure 206–2 Chest radiograph of a 19-year-old man with *Chlamydia pneumoniae* pneumonia demonstrating pleural effusion in the right lung. *C. pneumoniae* was isolated from the pleural fluid.

tion appeared to result in both clinical improvement and improvement in pulmonary function test scores. Only five of the children with confirmed infection had detectable IgG antibody to *C. pneumoniae*. One child who did not comply with his antibiotic therapy was culture positive on five occasions during a 3-month period. Anti–*C. pneumoniae* antibody as determined by MIF was never detected. Specific anti–*C. pneumoniae* IgE was, however, detected in 85.7 percent of the culture-positive asthmatics compared with 9 percent of the children with *C. pneumoniae* pneumonia who were not wheezing.[34] This finding suggests that the bronchial reactivity seen with *C. pneumoniae* infection may be IgE mediated. The potential prolonged, persistent *C. pneumoniae* infection may produce chronic inflammation and trigger bronchospasm in susceptible persons. *C. pneumoniae* has been demonstrated to induce in vitro ciliostasis in ciliated bronchial epithelial cells.[127] Animal studies also suggest that steroids can reactivate *C. pneumoniae* lung infection in mice.[92] In addition, immune-mediated phenomena, including erythema nodosum and iritis, have been described as complicating *C. pneumoniae* infection.[130,138]

The role of *C. pneumoniae* in upper respiratory infections is not as well defined. *C. pneumoniae* has been isolated from the middle ear fluid of children and adults with otitis media.[11,110] Block and colleagues[11] recovered *C. pneumoniae* from the middle ear fluid of eight children, 3 months to 14 years of age, with acute otitis media. *C. pneumoniae* was the sole pathogen isolated in two patients. Co-pathogens in the remaining six patients included β-lactamase–positive *Haemophilus influenzae* and *Moraxella catarrhalis*, along with penicillin-resistant and penicillin-sensitive *S. pneumoniae*. Five of the children who were positive for *C. pneumoniae* responded favorably despite not being treated with antibiotics active against the organism, either a course of an oral β-lactam or single-dose intramuscular ceftriaxone. Symptoms suggestive of sinus involvement are not uncommon in patients with upper respiratory tract infection associated with *C. pneumoniae*, but only one case of isolation of the organism, from a 47-year-old man with sinusitis, has been reported.[67] Cultrara and colleagues[28] examined nasopharyngeal swabs, ethmoid and maxillary sinus biopsy samples, and adenoids from 20 children, 3 to 16 years of age, with chronic sinusitis. *C. pneumoniae* was not isolated from any sinus tissue but was isolated from the nasopharyngeal swab and adenoid tissue of a 6-year-old child. The results of this study suggest that *C. pneumoniae* does not play a significant role in chronic sinusitis in children. Data also are limited on the potential role of *C. pneumoniae* in pharyngitis. Although one study found serologic evidence of *C. pneumoniae* in 8.5 percent of adult patients with pharyngitis,[66] Hyman and associates[69] reported that 19 percent of asymptomatic adults who were culture or PCR negative (or negative by both modalities) fulfilled the serologic criteria for acute *C. pneumoniae* infection.

DIAGNOSIS

A specific laboratory diagnosis of *C. pneumoniae* infection can be made by isolation of the organism from nasopharyngeal or throat swabs, sputum, or pleural fluid, if present. The nasopharynx appears to be the optimal site for isolation of the organism.[12] The relative yield from throat swabs and sputum is not known. Isolation of *C. pneumoniae* requires culture in tissue; the organism cannot be propagated in cell-free media. Initial studies suggested that *C. pneumoniae* was more difficult to isolate in tissue culture than was *C. trachomatis*.[48] Originally, the same methods were used: HeLa or McCoy cells pretreated with dextran diethylaminoethyl. Multiple passages were needed, the inclusions were small and difficult to see, and, in general, the yield was poor. *C. pneumoniae* grows more readily in other cell lines derived from respiratory tract tissue, specifically, HEp-2 and HL cells.[121] Omission of pretreatment with dextran diethylaminoethyl results in much larger inclusions, and specimens need only one passage. Culture with an initial inoculation and one passage should take 4 to 7 days.

Nasopharyngeal cultures can be obtained with Dacron-tipped, wire-shafted swabs. Each lot of swabs should be treated in a mock infection system to ensure that no inhibitory effects occur on either the viability of cells or recovery of chlamydiae. Specimens for culture should be placed in appropriate transport media, usually a sucrose phosphate buffer with antibiotics and fetal calf serum, and stored immediately at 4° C for no longer than 24 hours. Viability decreases if specimens are held at room temperature. If the specimen cannot be processed within 24 hours, it should be frozen at –70° C until culture can be performed. After 72 hours of incubation, culture confirmation can be performed by staining with either a *C. pneumoniae* species–specific or a *Chlamydia* genus–specific (anti-LPS) fluorescein-conjugated monoclonal antibody.[103] Inclusions of *C. pneumoniae* do not contain glycogen and thus do not stain with iodine. Unfortunately, no commercially produced *C. pneumoniae*–specific culture-confirmation reagents are available. If a genus-specific antibody is used, *C. pneumoniae* should be confirmed by differential staining with a specific *C. trachomatis* antibody; if that result is negative, the isolate is either *C. pneumoniae* or *C. psittaci*. If the patient has not had avian exposure, psittacosis would be highly unlikely.

Because isolation of *C. pneumoniae* initially was considered to be difficult and limited, emphasis was placed on serologic diagnosis. However, performance of the MIF test also is limited to a small number of research laboratories. The MIF test was modified from the test used for *C. trachomatis* by use of elementary bodies from TW-183 or other *C. pneumoniae* strains as the antigen. With the MIF test, one can detect IgG, IgM, and IgA antibodies. Grayston and colleagues[48] proposed a set of criteria for the serologic diagnosis of *C. pneumoniae* infection with the MIF test that have been used by many laboratories and clinicians. For acute infection, the patient should have a fourfold rise in IgG titer, a single IgM titer of 16 or higher, or a single IgG titer of 512 or higher. Past or preexisting infection is defined as an IgG titer of 16 or higher but lower than 512. These researchers further proposed that the pattern of antibody response in primary infection differed from that in re-infection. In initial infection, the IgM response appears approximately 3 weeks after the onset of illness and the IgG response at 6 to 8 weeks. In re-infection, the IgM response may be absent and the IgG response occurs earlier, within 1 to 2 weeks.[48] A fourfold titer rise or a titer of 64 or higher with CF also is considered to be diagnostic. Initially, Grayston and colleagues[50] found that fewer than one third of hospitalized patients with suspected *C. pneumoniae* infection had detectable CF antibody. However, in a report of a small outbreak of *C. pneumoniae* infection in University of Washington students, all seven patients with pneumonia had CF titers of 64 or higher.[48] The CF test is genus specific.

Because of the relatively long period until the development of a serologic response in primary infection, the antibody response may be missed if convalescent sera are obtained too soon (i.e., earlier than 3 weeks after the onset of illness). The use of paired sera also affords only a retrospective diagnosis, which is of little help in terms of deciding how to treat a patient. The criteria for use of a single serum sample have not been correlated with the results of culture and are based primarily on data from adults. The antibody response in acute infection may take longer than 3 months to develop. Acute, culture-documented infection also can occur without seroconversion, especially in children.[12,25,33,43,61] Only 28 percent of the culture-positive children enrolled in a multicenter pneumonia treatment study had detectable anti–*C. pneumoniae* antibody by MIF, and only 1 percent met the serologic criteria for acute infection.[12] Most of them had no detectable antibody by the MIF test, even after 3 months of follow-up.[12] However, the results of immunoblotting revealed

that these children have antibody to numerous *C. pneumoniae* proteins but that less than 30 percent react with MOMP, which is the antigen presented in the MIF test.[87] Although MOMP has been demonstrated to be immunodominant in *C. trachomatis* infection, it does not appear to be immunodominant for *C. pneumoniae*.[9,70,87]

Background rates of seropositivity also can be high in some populations. Hyman and associates,[69] as part of a study of asymptomatic *C. pneumoniae* infection in subjectively healthy adults in Brooklyn, found 81 percent to have IgG or IgM titers of 16 or higher. Seventeen percent had evidence of "acute infection" (IgG titer > 512, IgM titer > 16, or both). However, none of these persons was culture or PCR positive. Similar results were reported by Kern and associates[79] in healthy firefighters and policemen in Rhode Island. The specificity of the MIF IgM assay can be affected by the presence of rheumatoid factor. A study from the Netherlands found an increased probability of false-positive results caused by rheumatoid factor with increasing age.[136] Sera should be routinely absorbed before MIF IgM testing is performed. Hyman and colleagues[69] absorbed all the IgM-positive sera, and the titers did not change. Some IgG antibody may result from a heterotypic response to other chlamydial species because cross-reactions with MOMP occur among the three species, as do cross-reactions caused by the genus LPS antigen. Moss and colleagues[107] reported that antibodies to *C. pneumoniae* and *C. psittaci* were found in as many as half of all chlamydial IgG–positive persons attending a clinic for sexually transmitted diseases. This point is reinforced by the observation that studies from the early 1980s suggesting *C. trachomatis* as a cause of community-acquired pneumonia and pharyngitis in adults and children were probably detecting antibody to *C. pneumoniae* rather than *C. trachomatis*.[81,82] Other organisms that have been reported as possibly causing cross-reactions on MIF are *Bartonella*[94] and *Bordetella pertussis*.[74] The latter could be significant because adults with pertussis frequently have a chronic cough or severe bronchitis, which is a clinical feature often ascribed to *C. pneumoniae*. Other studies have found significant homology between human and *C. pneumoniae* heat shock protein 60 (HSP-60) and *E. coli* GroEL.[109] Picornavirus proteins also have been reported to share antigenic determinants with HSP-60/65, including the HSP-60 of humans and *C. pneumoniae*, which conceivably could lead also to cross-reactions in the MIF assay.[60]

Moreover, the MIF test is not standardized, and reading of the slides has a large subjective component and requires an experienced microscopist. A study by Peeling and coworkers[112] attempted to address the problem of interlaboratory variation in performance of the MIF test by sending a panel of 22 acute and convalescent sera to 14 different laboratories. Nine of the laboratories used an in-house MIF. The antigens in most of the assays were either AR-39 or TW-183. Three laboratories used one of two commercially available kits, which included either AR-39 or Kajaani 6 as the antigen. The remaining two laboratories used the Washington Research Foundation kit, which uses TW-183. The overall agreement in assay results (to get within one twofold dilution of the gold standard, as read at the University of Washington) was 80 percent. The range was 50 to 100 percent, depending on the isotype. Agreement in serodiagnostic criteria was 69 percent for negative, 68 percent for "chronic," and 87 percent for a fourfold increase in IgG. This observation has been confirmed in subsequent evaluations of the performance of the MIF assay.[86]

Although EIA serology test kits offer the promise of standardized performance and objective end-points, none has been evaluated adequately in comparison to culture or PCR.[31] Most have been compared with only MIF. None has FDA clearance or approval for use in the United States. One commercial assay, the Medac recombinant enzyme linked immunosorbent assay, uses a recombinant LPS antigen; others are based on LPS-extracted elementary bodies or synthetic peptides.[31,88,113] These kits can measure IgG, IgM, and IgA antibodies, but cutoffs vary from kit to kit, and the criteria for a positive result (acute infection, past infection) can be complex.[32,103,134] A study from the United States compared recombinant LPS EIA with culture and found that the sensitivity ranged from 13 percent for IgM antibody in children to 78 percent for either IgA or IgG antibody in adults with respiratory infection.[88] Specificity in comparison to culture ranged from 21 to 91 percent. Persson and Haidl[113] reported cross-reaction with recombinant EIA and parvovirus, primarily for IgM, but it also was seen to a lesser extent with IgG and IgA. This cross-reaction was not seen with MIF.

The CDC has proposed some modifications of the serologic criteria for establishing the diagnosis of *C. pneumoniae* infection.[31] Although the MIF test was considered to be the only serologic test currently acceptable, the criteria were made significantly more stringent. Acute infection as determined by MIF was defined as a fourfold rise in IgG or an IgM titer of 16 or higher, and the use of a single elevated IgG titer was discouraged. An IgG titer of 16 or higher was considered to indicate past exposure, but neither elevated IgA titer nor any other serologic marker was thought to be a validated indicator of persistent or chronic infection. The CDC did not recommend the use of any EIA for detection of antibody to *C. pneumoniae*.

The number of *C. pneumoniae* organisms present in the respiratory tract of persons with pneumonia or other respiratory tract diseases is smaller than the number found in genital *C. trachomatis* infection. PCR appears to be the most promising technology in the development of a rapid, nonculture method for detection of *C. pneumoniae*. More than 25 in-house PCR assays for detection of *C. pneumoniae* in clinical specimens have been reported in the literature.[14,86] None of these assays is standardized or extensively validated in comparison to culture for detection of *C. pneumoniae* in respiratory specimens. None is commercially available or has FDA approval. Major variations in these methods include collection and processing of specimens, primer design, nucleic acid extraction, detection and identification of amplification products, and ways to prevent possible false-positive and inhibitory reactions. The primers used most frequently have been those based on the *omp1* gene, the 16S rRNA gene, the 16S and 16S-23S spacer rRNA genes, and a *C. pneumoniae*–specific cloned *Pst*I fragment.[14,86] Some assays have used single amplification; some have been nested. Methods for detecting the amplification product include agarose gel electrophoresis, Southern blot, EIA, and polyacrylamide gel electrophoresis.[14,86] Studies suggest significant interlaboratory variation in performance of PCR for *C. pneumoniae*.[3,91] Use of nested PCRs has been associated with a high risk of contamination due to amplicon carryover.[3] Real-time PCR may be the method of choice; several assays have been reported in the literature, but none has been validated compared with culture.[2,3]

The CDC did not recommend any specific assay because of a lack of comparative data[31] and suggested that more studies need to be conducted with proper controls and larger numbers of clinical specimens from patients. The CDC also suggested that any new PCR assay be compared with a sensitive culture system.

TREATMENT

Chlamydia spp. are susceptible to the tetracyclines, macrolides, and quinolones.[126] *C. pneumoniae*, like *C. psittaci*, is resistant to sulfonamides.[126] To date, few published data have described the response of *C. pneumoniae* to antimicrobial therapy. Most of the treatment studies of pneumonia caused by *C. pneumoniae* published thus far have relied entirely on diagnosis by serology; consequently, microbiologic efficacy could not be assessed. Anecdotal reports have suggested that prolonged courses, up to

3 weeks, of either tetracyclines or erythromycin may be needed to eradicate *C. pneumoniae* from the nasopharynx of adults with influenza-like illness and pharyngitis.[55] The results of two pediatric multicenter pneumonia treatment studies found that 10-day courses of erythromycin and clarithromycin and 5 days of azithromycin suspension were equally efficacious; they eradicated the organism in 79 to 86 percent of children.[12,61,122] Quinolones, including levofloxacin and moxifloxacin, also have been demonstrated to have 70 to 80 percent efficacy in eradicating *C. pneumoniae* from adults with community-acquired pneumonia.[58,59] Most patients improved clinically despite persistence of the organism. Persistence does not appear to be secondary to the development of antibiotic resistance.[58,59,122,126]

On the basis of these limited data, the following regimens for respiratory tract infection caused by *C. pneumoniae* can be suggested: in adults, doxycycline, 100 mg twice a day for 14 to 21 days; tetracycline, 250 mg four times a day for 14 to 21 days; azithromycin, 1.5 g during a period of 5 days; levofloxacin, 500 mg/day orally or intravenously for 7 to 14 days; and moxifloxacin, 400 mg/day orally for 10 days. For children, suggested regimens include erythromycin suspension, 50 mg/kg/day for 10 to 14 days; clarithromycin suspension, 15 mg/kg/day for 10 days; and azithromycin suspension, 10 mg/kg on day 1 followed by 5 mg/kg/day once daily on days 2 to 5. Some patients may require re-treatment.

INFECTIONS DUE TO OTHER CHLAMYDIALES SPECIES

The most studied member of this group of organisms is *Simkania negevensis*, which was first identified as a contaminant in tissue culture in Israel.[84] The *S. negevensis* 16S and 23S ribosomal DNA both have 80 to 87 percent sequence identity with members of the Chlamydiales. The organism has been associated with a variety of respiratory illnesses, including bronchiolitis in infants from Canada and Israel, community-acquired pneumonia and chronic obstructive pulmonary disease in adults from Israel, and respiratory tract infection in children and adults from Cornwall, England. *S. negevensis* has a life cycle similar to that of Chlamydiales, with a biphasic intracellular morphology with electron-dense nonreplicating elementary bodies and replicating reticulate bodies of comparable sizes. Distinct differences exist in that the growth cycle is longer, 12 to15 days compared with 48 to 72 hours for Chlamydiaceae. Unlike *Chlamydia*, *S. negevensis* is totally resistant to penicillin. *S. negevensis* has been found to be present in drinking water and reclaimed waste water in the Negev, Israel. The organism has also been shown to be able to replicate in amebae and to survive for long periods in amebal cysts, which would allow it to survive in water. On the basis of this, it has been proposed that *S. negevensis* may be transmitted to humans by drinking water.

Parachlamydia acanthamoebae, previously called Hall's coccus, is an endosymbiont of *Acanthamoeba*.[51,52] The organism was described initially as bacteria-like structures in trophozoites of *Acanthamoeba* isolated from patients with fever and pneumonia associated with use of humidifiers.[51] The bacteria-like structures subsequently were identified as *P. acanthamoebae*. The organism has been isolated from nasal mucosa of healthy human volunteers and a bronchoalveolar lavage specimen from a patient with a diagnosis of viral pneumonia. However, *P. acanthamoebae* appears to be a rare cause of pneumonia in humans. Greub and colleagues[52] were able to identify *P. acanthamoebae* DNA by PCR in only 1 of 1200 bronchoalveolar lavage specimens from patients with pneumonia of unknown etiology. This patient was a 31-year-old HIV-positive man who presented with cough, fever, and bilateral infiltrates on chest radiography. No other pathogens, including *C. pneumoniae*, *Legionella pneumophila*, *Pneumocystis carinii*, or mycobacteria, were detected. A subsequent study from the same group using serology suggested that *P. acanthamoebae* might be responsible for approximately 8 percent of pneumonias in a series of patients with head trauma and suspected aspiration pneumonia. The in vitro susceptibilities of *P. acanthamoebae* appear to be similar to those of *Chlamydia* except that they are constitutively resistant to quinolones.[95]

Rickettsial Diseases

CHAPTER 207

Rickettsial and Ehrlichial Diseases

Morven S. Edwards ❂ Ralph D. Feigin

The Rickettsiaceae family was named to honor H. T. Ricketts. Dr. Ricketts discovered and described the cycle of the rickettsial agent causing Rocky Mountain spotted fever (RMSF) early in the 20th century. He died in 1910 from typhus fever while in Mexico investigating that disease.

Rickettsial diseases were grouped historically because they possessed a number of common characteristics: the agents are similar in size and shape visible by light microscopy as coccobacillary forms; they multiply intracellularly in susceptible hosts; the characteristic pathologic lesion is a widespread vasculitis of small blood vessels, except for Q fever, in which pneumonitis can be of equal importance; all are acute illnesses characterized by fever, headache, and rash, with the exception of Q fever, which has no rash, and ehrlichiosis, which often has no rash; the infecting agents are susceptible, early in the course of infection, to several broad-spectrum antibiotics; and all occur under natural conditions in either insects (lice and fleas) or arachnids (ticks and mites), and these vectors are, with the exception of Q fever, the primary means by which these diseases are transmitted to humans.

Within the past 2 decades, sequencing of genes has refined the classification and phylogeny of Rickettsiaceae.[29] On the basis of genetic and antigenic information, rickettsiae traditionally are divided into groups as shown in Table 207–1: the spotted fever group, the typhus group, and the scrub typhus group. The agent of scrub typhus, *Orientia tsutsugamushi*, is in the genus *Orientia* within the Rickettsiales group. The *Ehrlichia* group has four genera; two of these, *Ehrlichia chaffeensis* and *Anaplasma phagocytophilum*, are the agents of human monocytic and human granulocytic anaplasmosis, respectively. This chapter considers the rickettsial and ehrlichial diseases of importance in childhood that are listed in Table 207–1 as well as Q fever, although the agent of Q fever, *Coxiella burnetii*, now is classified in the gamma group of Proteobacteria.

In each of the rickettsial and ehrlichial infections except louse-borne typhus, humans are an incidental or accidental blind-end host and do not contribute to the survival of the vector. These diseases vary enormously in severity, from benign, self-limited illnesses without mortality to fulminating infections. A high index of suspicion leading to prompt establishment of diagnosis and institution of appropriate therapy is an important factor in enhancing the survival of children with rickettsial diseases.

THE SPOTTED FEVERS

The spotted fever group is composed primarily of rickettsial infections that are transmitted by ticks, but rickettsialpox, caused by *Rickettsia akari*, is a mite-borne infection and is included in this group. By comparison with other rickettsiae that grow exclusively in cytoplasm, the spotted fever group of rickettsiae also can multiply in the nuclei of susceptible animal cells.

RMSF is the most severe and important disease in the spotted fever group; it occurs throughout the temperate zone of North America. An illness apparently identical to RMSF occurs in South America, where it is called São Paulo disease. Other less severe forms of tick-borne spotted fevers occur in Europe, Asia, Africa, and Australia; they are distinguished from each other by geographic location as well as by differences in the spotted fever rickettsiae that cause them.[34]

ROCKY MOUNTAIN SPOTTED FEVER

HISTORICAL ASPECTS. RMSF, caused by *Rickettsia rickettsii*, was recognized first in Idaho and Montana at the turn of the 20th century. For decades, it was considered limited to the Rocky Mountain region. Beginning in the 1930s, RMSF was identified in the eastern United States and subsequently in all geographic areas of the country. For a decade after the introduction of broad-spectrum antibiotics around 1950, the incidence declined in both the east and the west. In recent years, infection rates have fluctuated (Fig. 207–1). From 1997 through 2002, 3649 cases were reported. More than half of the reported cases were from only five states: North Carolina, South Carolina, Tennessee, Oklahoma, and Arkansas.[6,7] The absolute number reported in 2004, 1514 cases, was the highest in United States history.[12]

The incidence of RMSF in the Rocky Mountain region had begun an inexplicable steady decline even before the antibiotic era; by 1988, fewer than 20 cases were reported in the Rocky Mountain and Pacific coastal areas. This trend has continued, and the major endemic regions currently are the south Atlantic, southeastern, and south central states (Fig. 207–2).

ETIOLOGY, MORPHOLOGY, GROWTH, AND METABOLISM. *R. rickettsii*, the etiologic agent of RMSF, is a small coccobacillus measuring 0.3 to 0.5 μm in diameter and 0.3 to 4 μm in length. Organisms usually occur singly but can appear in strands or as diploids with slightly pointed ends and a transparent band between the two bacilli. Electron microscopy reveals a two-layered cell wall and a cytoplasmic membrane. The chemical composition of rickettsiae is similar to that of gram-negative bacteria. Rickettsiae must penetrate into living cells to grow and multiply. They are grown most readily in the yolk sacs of embryonated eggs; but under special conditions, they also grow well in certain tissue culture cells. Once inside, rickettsial cells multiply by transverse binary fission.

Rickettsiae take on a characteristic red color when stained with Gimenez stain. *R. rickettsii* possess a soluble antigenic moiety that is shared with their antigenic variants in the spotted fever group and rickettsialpox. Living *R. rickettsii* organisms contain a toxin; when these organisms are injected intravenously, mice die within 6 to 12 hours, long before significant multiplication has occurred.

This chapter retains contributions by Edward S. Murray, now deceased.

TABLE 207–1 Characteristics of Some Important Rickettsiae and Ehrlichiae Causing Infections in Children

Disease	Agent	Distribution	Transmission	Mammalian Host
Spotted fever group				
Rocky Mountain spotted fever	*R. rickettsii*	Western Hemisphere	Tick bite	Wild rodents, dogs
Mediterranean spotted fever	*R. conorii**	Mediterranean, Caspian, and Black Sea coastal regions; Africa, Southeast Asia	Tick bite	Wild rodents, dogs
Rickettsialpox	*R. akari*	Worldwide	Mite bite	Mice
Typhus group				
Epidemic typhus	*R. prowazekii*	Worldwide	Infected louse feces rubbed into broken skin or as aerosol to membranes	Humans, flying squirrels
Murine typhus	*R. typhi*	Scattered pockets, worldwide	Flea bite	Rodents
Scrub typhus group	*Orientia tsutsugamushi*	Japan, Southeast Asia, west and southwest Pacific	Mite bite	Wild rodents
Ehrlichiosis group				
Human monocytic ehrlichiosis	*Ehrlichia chaffeensis*†	Worldwide	Tick bite	Deer, dogs, humans
Human granulocytic anaplasmosis	*Anaplasma phagocytophilum*	United States, Europe	Tick bite	Deer, humans, other mammals

**In addition*, Rickettsia australis *(Queensland tick typhus)*, Rickettsia sibirica *(Siberian tick typhus)*, Rickettsia slovaca, *and* Rickettsia japonica *(Japanese spotted fever)*, *among others, are antigenically and geographically distinct entities.*
†E. ewingii *also causes granulocytotropic ehrlichiosis in humans.*

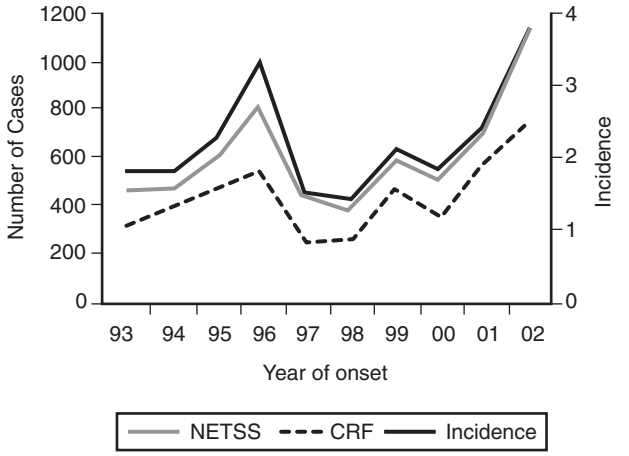

Figure 207–1 Number and incidence of Rocky Mountain spotted fever per million population in the United States, 1993-2002, as determined by the cases reported to the Centers for Disease Control and Prevention by the states through the National Electronic Telecommunications System for Surveillance (NETSS) and case report form (CRF). *(Data from Chapman, A. S., Murphy, S. M., Demma, L. J., et al.: Rocky Mountain spotted fever in the United States, 1997-2002. Vector Borne Zoonotic Dis 6:170-178, 2006.)*

EPIDEMIOLOGY AND TRANSMISSION. Because RMSF rickettsiae are primarily parasites of ticks, the epidemiology of human disease is associated intimately with the biology of the ticks that transmit it. Disease can be acquired in the laboratory, and workers must comply with protective measures. RMSF has been transmitted by blood transfusion[41] and by aerosol.[19,25]

The Rocky Mountain wood tick *(Dermacentor andersoni)* in the west and the American dog tick *(Dermacentor variabilis)* in the east and central United States are natural carriers and vectors of the disease. The brown dog tick *(Rhipicephalus sanguineus)* is implicated as a vector of *R. rickettsii* in eastern Arizona.[9] RMSF rickettsiae do not kill their arthropod hosts but are passed transovarially to subsequent generations of ticks. Congenitally acquired rickettsiae in tick eggs can persist through larval and nymphal stages to the adult stage during the course of a 2-year cycle; infected adult ticks can survive for as long as 4 years without feeding. Mammals act as the blood meal source for ticks during their various metamorphoses. A study in Maryland and Virginia in the late 1960s showed that 15 different mammals, including field mice, and 18 types of birds could be intermediate hosts. Many small wild animals as well as dogs possess antibodies to RMSF, indicating that they participate in the tick-mammal-tick cycle.[35]

Dogs are thought to be an important link in the RMSF cycle in nature. Rickettsial strains were isolated for the first time from the blood of sick or dying dogs in the 1970s; the rickettsial strains isolated were closely antigenically related to or identical to human disease–causing *R. rickettsii*. In addition, rising titers of RMSF antibodies were demonstrated in clinically ill dogs. Dogs appear to be susceptible to virulent *R. rickettsii*, but dogs can have RMSF antibodies without having any history of previous illness.

Moreover, all but a few of the rickettsiae found in ticks appear to be antigenically distinct from the rickettsiae isolated from both sick dogs and humans. The data presently available do not clarify the role of dogs in the RMSF cycle. Dogs may be accidental hosts of RMSF rickettsiae, much as humans are; they may mechanically transport ticks from infected tick islands to the proximity of humans, or they may play an important role in maintaining or increasing the reservoir of virulent *R. rickettsii* in nature.

A large serosurvey of children living in the southeast and south central regions of the United States found that as many as 12 percent had immunofluorescence antibody titers consistent with prior infection caused by *R. rickettsii* or antigenic spotted fever group rickettsiae, suggesting that subclinical infection occurs commonly.[23] Additional prominent epidemiologic features of RMSF are its seasonal character—most cases occur during the period of greatest tick activity, from April to September; its prevalence—it is the most common rickettsial disease in the United States and a growing infectious disease problem, with nearly two thirds of cases occurring in children younger than 15 years and the peak incidence occurring among children 5 to 9 years of age[35]; and its focal nature—relatively small areas in a state can account for a high percentage of that state's recorded cases; for example, 89 percent or more of all cases of RMSF occurring in New York State are reported from Long Island, Clermont County in Ohio reports approximately 10 percent of all Ohio cases of RMSF, and Cape Cod and the offshore islands generally account for almost all the cases reported in Massachusetts.

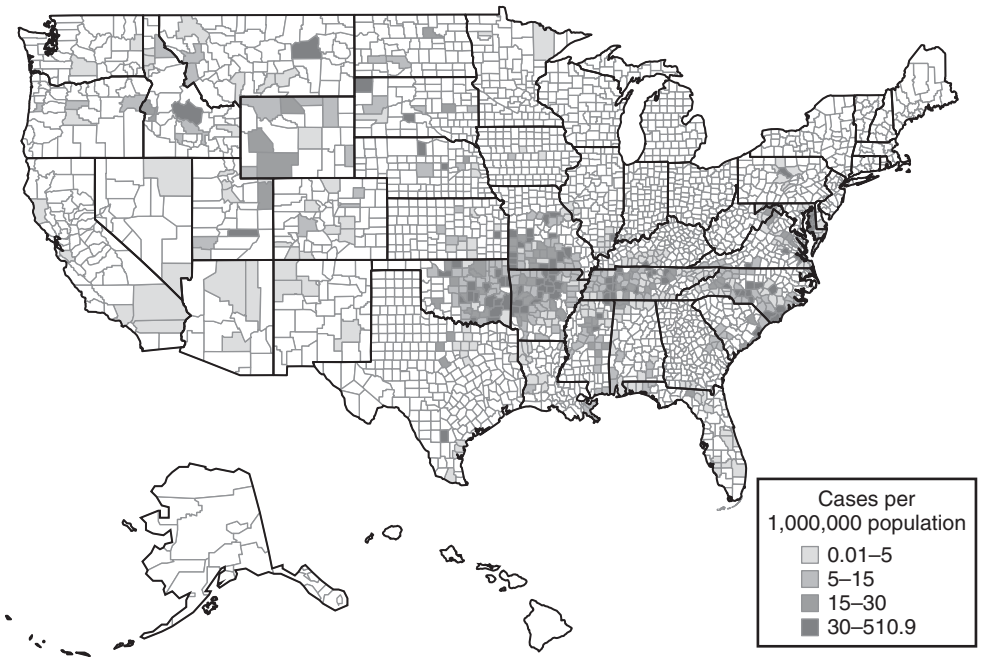

Figure 207–2 Annual incidence of Rocky Mountain spotted fever per million population by county in the United States, 1997-2002, based on reports from the National Electronic Telecommunications System for Surveillance and case report forms submitted to the Centers for Disease Control and Prevention. *(Data from Chapman, A. S., Murphy, S. M., Demma, L. J., et al.: Rocky Mountain spotted fever in the United States, 1997-2002. Vector Borne Zoonotic Dis 6:170-178, 2006.)*

PATHOGENESIS. The primary pathologic lesion of RMSF is found in the vascular system after the individual has been bitten by an infected tick. Rickettsiae multiply in endothelial cells lining small blood vessels and disseminate by the bloodstream. They can be demonstrated in both the cytoplasm and the nucleus of cells.[35] Focal areas of endothelial proliferation and perivascular mononuclear cell infiltration lead to thrombosis and leakage of red blood cells into the surrounding tissues. Potential mechanisms of cellular injury that are postulated include injury to cell membranes caused by the penetration of multiple rickettsiae, followed by a crescendo of rickettsial release; depletion of adenosine triphosphate by intracellular rickettsiae, which causes failure of the sodium pump and an influx of water; competition by *R. rickettsii* for crucial metabolic substrates; and damage to the cell by toxic products of rickettsial metabolism.[40,43]

Vascular lesions probably account for the more prominent clinical manifestations, such as rash, headache, and mental confusion, as well as terminal heart failure and shock. Vascular lesions can be found everywhere but are appreciated most readily in the skin, gonads, and adrenal glands. Parenchymatous inflammation accompanies vasculitis in the heart and central nervous system. Interstitial myocarditis, patchy in distribution, can be demonstrated regularly in fatal cases. The location of rickettsiae by immunofluorescence coincides with the patchy distribution of the myocarditis. Pathologic examination reveals interstitial edema and inflammation with relative preservation of myocardial fibers.[39] In neural parenchyma, both mononuclear infiltration and focal proliferative glial nodules usually are topographically related to inflamed blood vessels.[13] In the kidney, inflammation involves both vessels and the interstitium in most patients. Acute tubular necrosis occurs. In the lung, rickettsial involvement of the pulmonary microcirculation results in interstitial pneumonia, evidenced by alveolar septal congestion and interstitial edema, alveolar edema and hemorrhage with a fibrinous and mononuclear exudate, and interlobular septal edema. Organisms are demonstrable in the pulmonary microcirculation by immunofluorescence, indicating that the pathologic changes most likely are caused by direct infection and are not toxin mediated. Hepatic lesions include portal triaditis consisting of polymorphonuclear leukocytes and large mononuclear cells, portal vasculitis, sinusoidal leukocytosis, erythrophagocytosis by Kupffer cells, and increased hepatic weight; rickettsial organisms are demonstrable in portal blood vessels and sinusoidal lining cells.[18,27]

Negative nitrogen balance can be extreme. Early in infection, it can be related to excretion of nitrogen in urine; but after several days, it is related to insufficient intake of protein. The serum albumin concentration can be depressed as a result of protein loss, hepatic dysfunction related to the disease process itself, and leakage of protein through the damaged endothelium of the blood vessel walls.

Profound hyponatremia occurs, commonly related to a shift in water from the intracellular to the extracellular space, the loss of sodium through excretion in urine, and an exchange of sodium for potassium at the cellular level.[21] Intracellular sodium increases slightly. Destruction of some cells results in increased serum concentrations of potassium and massive losses of potassium in urine. Intracellular overhydration of the medulla oblongata has been proposed to contribute to a fatal outcome in some patients. Plasma concentrations of aldosterone and antidiuretic hormone are increased in some but not all patients.[20,30]

CLINICAL MANIFESTATIONS. A history of tick bite is elicited in only 50 to 60 percent of children with RMSF.[26] Fever, headache, rash, toxicity, mental confusion, and myalgia are the major clinical features of RMSF.[35] The onset of the disease in humans, which usually occurs approximately 7 days (range, 2 to 14 days) after being bitten by an infected tick, can be gradual or abrupt. The temperature rises rapidly to 40° C or 40.6° C (104° F or 105° F). Although the pattern of fever can remain persistently high, a considerable number of patients show dramatic temperature oscillations during a period of a few hours.

The rash of RMSF is an almost pathognomonic feature of the disease; it appears by the second or third day of illness in most patients but occasionally is delayed until the sixth day or later. As many as 15 percent of patients never develop a rash. The initial lesions are small erythematous macules that blanch on pressure; they rapidly become maculopapular and petechial and later, in untreated patients, can become confluently hemorrhagic. Rarely, they progress to massive skin necrosis.[16]

Usually, the rash first appears peripherally on the wrists and ankles and, within a few hours, spreads up the extremities to the trunk. An especially striking feature of the rash of RMSF is its regular occurrence on the palms and soles. Eschars, which are characteristic of other rickettsial diseases, rarely are reported with RMSF.[36] On occasion, RMSF can be "spotless" or "almost spotless."[31] The absence of a rash should not delay the institution of appropriate therapy if the historical and clinical features suggest a diagnosis of RMSF.[15,28]

The headache in adults and older children is characteristic. It is intense, persistent night and day, and intractable to all efforts at alleviation. However, young children may not complain of headaches. Toxicity is a salient feature of the disease. Signs of meningoencephalitis are common findings; the patient is restless, irritable, and apprehensive, and this stage can progress rapidly to mental confusion and delirium. Children can become comatose. Meningismus is not always accompanied by abnormalities in cerebrospinal fluid; cerebrospinal fluid is generally clear, with minor elevations in the lymphocyte count (<10/mm^3). A case of eosinophilic meningitis caused by RMSF has been reported.[8] Grand mal or focal seizures can occur. Cortical blindness and central deafness (transient or persistent) have been reported.[4] Other neurologic manifestations can include ataxia, spastic paralysis, and sixth nerve palsy. These signs and symptoms usually are short-lived, but they can persist beyond the acute illness.[14,35] RMSF exerts a mild but consistent effect on intellectual functioning that can result in learning disability and a corresponding difficulty with school performance in children who previously had RMSF.[44]

Cardiac involvement occurs frequently in RMSF. Close observation and evaluation with electrocardiography, echocardiography, and chest radiography are indicated. Congestive heart failure and arrhythmias are common events.[22]

Pulmonary involvement occurs in 10 to 40 percent of reported cases and is manifested as rales, abnormal chest radiograph, or abnormal arterial blood gas measurements. The chest radiograph can show focal infiltrates or pulmonary edema and cardiomegaly.[10,24]

Myalgia or muscle tenderness is a common feature. Characteristically, the patient complains bitterly when the calf or thigh muscles are squeezed.

Ocular manifestations occur most commonly in the retina and include venous engorgement, retinal edema, papilledema, cotton-wool spots, retinal hemorrhage, and retinal artery occlusion. One patient has had severe anterior segment uveitis and an iris nodule, presumed to be due to a widespread RMSF vasculitic process.[11]

Other signs include edema of the extremities or face, a stiff neck, and conjunctival suffusion. Enlargement of the spleen or liver occurs relatively infrequently, yet gastrointestinal symptoms and signs are common manifestations during the early course of RMSF. In one series of 131 patients, 56 percent reported nausea or vomiting, 34 percent had abdominal pain, and 20 percent had diarrhea at the initial visit for medical care. Jaundice also has occurred with RMSF.[38]

As noted with other rickettsial diseases but not adequately explained, patients with glucose-6-phosphate dehydrogenase deficiency appear to account for a disproportionate number of those who die of RMSF.[37]

DIAGNOSIS. Specific treatment must be initiated promptly, and it is imperative that physicians establish a provisional diagnosis based on presenting clinical features and epidemiologic considerations.

Presenting laboratory features are not distinctive but can assist in establishing the diagnosis. For the first 4 or 5 days of illness, the white blood cell count is normal or low. As the disease progresses, leukocyte counts can rise to between 11,000 and 30,000 cells/mm^3. Thrombocytopenia of varying severity occurs in most cases. The adherence of platelets to the surface of *Rickettsia*-infected endothelial cells contributes to the reduction in the number of circulating platelets.[32] Thrombocytopenia and hyponatremia are presenting laboratory findings in more than half of children with RMSF.[5]

Rickettsia rickettsii can be identified by immunohistochemical staining or polymerase chain reaction (PCR) of tissue specimens.[2,42] Assays for PCR-based detection of *R. rickettsia* in blood or tissue specimens are available at the Centers for Disease Control and Prevention (CDC) reference laboratories.[3]

The diagnosis is confirmed by demonstration of a fourfold or greater change in titer between acute and convalescent serum specimens obtained 2 to 3 weeks apart by one of a number of rickettsial group–specific serologic tests.[3] These include enzyme immunoassay (EIA), indirect immunofluorescence antibody (IFA), latex-agglutination, indirect hemagglutination, microagglutination, and complement-fixation tests. The most widely available of these confirmatory tests is the IFA assay. An interval of 7 to 10 days after the onset of illness is required before an antibody response is detectable. On occasion, it is necessary to arrive at a probable diagnosis from a single high-titer convalescent serum specimen. A probable diagnosis is constituted by a single serum titer of 1:64 or greater by IFA; 1:128 or greater by indirect hemagglutination, latex agglutination, or microagglutination; or 1:16 by complement fixation in convalescent serum. The Weil-Felix serologic test is insensitive and nonspecific and should not be used.

DIFFERENTIAL DIAGNOSIS. Measles and meningococcemia are the infections for which RMSF is most frequently mistaken. A petechial rash that involves the palms and soles and spreads centripetally is unlike true or modified measles. A centripetally spreading rash can be seen in the atypical measles syndrome. Thus, a careful history of previous measles immunization, particularly with killed vaccine, should be obtained. Meningococcemia can be a more difficult problem; early in both diseases, a normal or low leukocyte count, signs of meningeal irritation, and cerebrospinal fluid pleocytosis can be present. An inability to definitively differentiate RMSF from meningococcemia should not delay initiation of empiric antimicrobial therapy because both infections are potentially fulminating and fatal. Treatment should be initiated promptly with a tetracycline and with an expanded-spectrum cephalosporin until the diagnosis is confirmed.

The differential diagnosis also includes typhoid fever, leptospirosis, rubella, scarlet fever, disseminated gonococcal disease, infectious mononucleosis, secondary syphilis, rheumatic fever, enteroviral infection, immune thrombocytopenic purpura, thrombotic thrombocytopenic purpura, immune complex vasculitis, hypersensitivity reactions to drugs, murine typhus, rickettsialpox, recrudescent typhus, ehrlichiosis, and sylvatic *Rickettsia prowazekii* infection, which is enzootic in flying squirrels.[35]

General Considerations for the Treatment of Rickettsial Diseases

The rickettsial diseases, especially RMSF, louse-borne typhus, and scrub typhus, are potentially fatal infections for which specific therapy is available. Adequate antibiotic treatment is highly effective, so patients who are treated during the first week of illness almost invariably improve promptly. If the disease is allowed to proceed into the second week untreated, even optimal therapy becomes progressively less effective.

Because rickettsial diseases can be fulminant, prompt initiation of optimal specific therapy is important. Initiation of treatment before the fifth day of illness optimizes the likelihood of having a good outcome.

Doxycycline is the drug of choice for treatment. Although tetracyclines generally should not be used in children younger than 8 years, the rationale for their use in this setting is severalfold: (1) staining of teeth by tetracycline is dose related and unlikely to occur in association with one or two short courses of therapy; (2) doxycycline is less likely to stain developing teeth than are other tetracyclines, possibly because it binds less to calcium; (3) doxycycline is also the treatment of choice for ehrlichiosis.[1] Chloramphenicol may not be effective against ehrlichiosis. A fluoroquinolone is an alternative drug.[33]

For children weighing less than 45 kg, the dosage of doxycycline is 2.2 mg/kg orally or intravenously twice daily. Children weighing 45 kg or more should receive 100 mg orally or intravenously twice daily.[6]

The thrombocytopenia and blood coagulation deficiencies can herald disseminated intravascular coagulation. Prompt initiation of adequate antimicrobial therapy is the first essential step. Severe thrombocytopenia can require platelet transfusion.

Because of the widespread endothelial damage that occurs in severe rickettsial infection, a severely ill patient can be more ill than is apparent. Providing supportive care to the patient is important. Careful sequential evaluation of serum and urine electrolytes, renal function, and body weight is essential for planning and guiding fluid therapy. Hyponatremia is managed by providing maintenance fluids or by instituting modest fluid restriction.

TREATMENT OF ROCKY MOUNTAIN SPOTTED FEVER. Although doxycycline is effective against RMSF, pediatric caregivers must consider RMSF in the differential diagnosis to ensure an accurate diagnosis and institution of proper therapy. Treatment should continue for 3 days after the child is afebrile. The usual duration of therapy is 7 to 10 days.

PROGNOSIS. The fatality rate from RMSF in the preantibiotic era was approximately 25 percent. Recovery is optimized when appropriate antimicrobials are provided within the first 5 days of illness. Nonetheless, the overall mortality rate from RMSF in the United States remains 5 to 7 percent; death occurs primarily in patients in whom establishment of the diagnosis is delayed beyond the first week of illness. Death occurs, usually between the 9th and 12th day of illness, in association with vascular collapse, thrombocytopenia, and renal or heart failure, alone or in combination. Central nervous system involvement and disseminated intravascular clotting commonly occur.

Bronchopneumonia can develop in seriously ill patients, and overzealous administration of parenteral fluid can precipitate cardiac failure. Neurologic deficits such as speech or swallowing dysfunction, global encephalopathy, ataxia or gait disturbance, and cortical blindness are sequelae of infection in approximately 15 percent of children.[5] Digital necrosis occurs rarely. Solid immunity follows recovery from RMSF, even if therapy is initiated as early as a day or two after the onset of symptoms.

PREVENTION. Control of ticks in their habitat would be a costly undertaking and is not practical.[17] In contrast, personal measures for reducing tick contact within infested areas are inexpensive and highly effective. Wearing pants tucked into boots, limiting access to exposed skin around the neck and wrists, and frequently inspecting for ticks reaching these areas are important means of reducing contact. Early de-ticking is particularly valuable because infected ticks must be attached and feeding for 4 to 6 hours or more before they can transmit the disease. The application of repellents such as dimethyl phthalate to clothes and exposed parts of the body affords additional protection. Immunization has the potential to prevent RMSF, but no licensed *R. rickettsii* vaccine is available in the United States.

MEDITERRANEAN SPOTTED FEVER

HISTORICAL ASPECTS. Mediterranean spotted fever was described by Connor in 1910 and is a tick-borne infection caused by *Rickettsia conorii.* The name *Mediterranean spotted fever* was adopted in 1932. Other names given to this illness include boutonneuse fever, Kenya tick bite fever, African tick typhus, India tick typhus, Israeli spotted fever, and Marseilles fever. A resurgence of this disease has been reported, especially in Spain, Italy, and Israel.[51]

EPIDEMIOLOGY. Mediterranean spotted fever is an acute disease caused by *R. conorii*. In the Mediterranean region, the vector is the brown dog tick, *Rhipicephalus sanguineus.* The tick is the reservoir as well as the vector for *R. conorii*, so direct contact with dogs is not the sole risk factor for infection, but habitual contact with dogs is a feature in some children who acquire the infection.

Mediterranean spotted fever occurs in all age groups of both sexes. The epidemiologic pattern is determined by the biology of the tick; consequently, a consistent seasonal peak occurs from June to October. The prevalence of the disease is unknown. The incidence seems to be rising, however, perhaps because of an increase in recognition of the infection and an increase in the number of dogs in urban areas. The incidence in certain occupational subgroups can be reduced through better standards of hygiene.[51]

CLINICAL MANIFESTATIONS. The infecting bite is unnoticed in most cases. Conjunctival inoculation occurs occasionally. The incubation period ranges from 6 to 10 days. The primary lesion, tache noire (black spot), described and named by Pieri in the 1920s, develops at the site of the tick bite, is not painful, and rarely is pruritic.[57] It occurs most often on the head in children and on the legs in adults. The lesion develops central necrosis, an eschar develops, and regional lymph nodes enlarge. The initial lesion heals slowly and resolves after 10 to 20 days without scarring, although residual pigmentation can persist indefinitely.

Tache noire is pathognomonic but is evident in only 30 to 90 percent of patients. Multiple lesions occur occasionally. Formation of the lesion requires a substance secreted by the tick and another of rickettsial origin; it is not reproduced by a separate bite of an uninfected tick or by experimental inoculation of *R. conorii.* An inflammatory infiltrate, predominantly mononuclear, accumulates at the tache noire site, suggesting the importance of T cell–mediated immunity in local host defense.

The onset of disease usually is abrupt, with malaise and fever that reaches temperatures of 39° C to 40° C (102.2° F to 104° F) within the first 2 or 3 days. The fever continues for 6 to 12 days, but antibiotics can shorten the febrile period. Severe and unremitting headache is a typical feature of the disease in adults.[46] Headache is a feature of infection in less than one third of pediatric patients; its lower frequency contributes to the milder presentation in this age group.[48] Arthralgia and myalgia, especially of the leg muscles, is a prominent feature in adults; in children, it is rarely of sufficient severity to restrict mobility.

A maculopapular exanthem that develops on the third to the fifth febrile day is almost universally present. Lesions are present initially on the extremities, spreading within a day or so to the trunk, neck, face, buttocks, palms, and soles. The initial lesions are macular, pink, and irregularly defined but become maculopapular within hours. They generally measure 1 to 4 mm in diameter. The rash persists for 10 to 20 days after the remission of clinical symptoms. It can become purpuric or intensely pruritic. Atypical cutaneous manifestations such as petechial, purpuric, or papulovesicular rashes occur occasionally.[48,51]

The cutaneous manifestations are caused by involvement of the vascular structures of the dermis. Rickettsemia during the

incubation period probably seeds the endothelial cells of the capillaries, arterioles, and venules. The vasculitis produced is much like that seen in RMSF. It gradually disappears during convalescence, and as the maculopapules fade, a brown discoloration of the skin may be noticed.

Cardiovascular and respiratory changes are transient and nonspecific. Bradycardia is the most consistent finding, but other dysrhythmias can occur. In more seriously ill patients, pericarditis, heart failure, and myocarditis have developed.

Phlebitis of the lower limbs is the main vascular complication. Venous thrombosis is a recognized complication, and pregnant patients are particularly prone to venous thrombosis. Pneumonitis, pleuritis, pleuropericarditis, and adult respiratory distress syndrome have been described in association with Mediterranean spotted fever.

In addition to the headache that is characteristic of rickettsial illnesses, varying degrees of impaired consciousness can occur. Rarely, stupor, delirium, convulsions, and transient hypoacusis may be noted. Neurologic sequelae have been observed after rickettsial encephalitis.

Renal function is not altered in most cases, although nephritis with acute renal failure has occurred occasionally. The liver is palpable in a third of patients, and the spleen can be enlarged in 20 percent of children. Tests of hepatic function reveal an increase in serum transaminase levels in one fourth to one half of pediatric cases. Alkaline phosphatase levels are elevated in one third of patients. Needle biopsy of the liver reveals foci of hepatocellular necrosis and a predominantly mononuclear reaction to the necrosis at sites of infection by *R. conorii*. The lesion differs from a true granuloma in that it is not an aggregate of epithelioid macrophages.[58]

A variety of other systemic symptoms can occur. Photophobia and bilateral conjunctivitis have been reported. Severe unilateral conjunctivitis suggests that transmission of the disease occurs by the conjunctival route. Uveitis, choroiditis, retinal artery occlusion, and neuroretinitis are uncommon ocular disturbances.[45,50]

Hematologic abnormalities include isolated cases of autoimmune anemia and mixed cryoglobulinemia associated with Mediterranean spotted fever. Some studies report a high incidence of hypoproteinemia. Immune complex–mediated vasculitis associated with Mediterranean spotted fever has been described.[49]

On occasion, Mediterranean spotted fever can have a malignant, rapidly fatal course, even in previously healthy children. The illness is consistent with a widespread vasculitis characterized by irreversible shock, encephalopathy, disseminated intravascular coagulopathy, and renal failure.[60]

DIAGNOSIS. Rickettsial organisms can be detected by immunofluorescence if biopsy is performed early in the course of disease or by restriction fragment length polymorphism analysis of a PCR product from the tache noire.[55,59] *R. conorii* cannot be isolated from blood cultures by routine laboratory procedures. The clinical findings, geographic location, and epidemiologic considerations help establish the diagnosis.

The diagnosis can be established by one of multiple serologic tests that include complement-fixation, latex-agglutination, microagglutination, Western blot, and indirect IFA assays.[51,53,56] An IFA assay for *R. conorii* is commercially available. Identification of specific IgM by immunofluorescence can identify acute infection, although some patients with proven Mediterranean spotted fever treated early with antibiotics have normal IgM levels.

DIFFERENTIAL DIAGNOSIS. Before the rash appears, differentiation of Mediterranean spotted fever from other acute infections is difficult. Even after appearance of the rash, the disease can be confused with measles, meningococcemia, and secondary syphilis. Other rickettsial diseases should be considered, especially in the absence of a tache noire. Cross-reactions among rickettsiae occur with indirect immunofluorescence.

TREATMENT AND PREVENTION. Mediterranean spotted fever generally has a benign course, and fatalities rarely occur. Doxycycline is the drug of choice. Alternative regimens are clarithromycin or azithromycin administered orally at a dosage of 15 mg/kg/day in two doses for 7 days and 10 mg/kg once daily for 3 days.[47,48] Use of chloramphenicol or ciprofloxacin also is effective therapy. The optimal duration of specific therapy has not been definitively established, and regimens ranging from single doses to treatment for up to 15 days have been reported.[52]

The major effective methods of control involve avoidance of tick bites. Natural immunity occurs after infection, and antibodies persist for as long as 4 years after acute illness. Effective vaccines are not available.[54]

RICKETTSIALPOX

HISTORICAL ASPECTS. First described in New York City in 1946 by Sussman as Kew Gardens spotted fever, rickettsialpox is a benign spotted fever group rickettsial disease caused by *Rickettsia akari*.[65,67,73] Reporting of rickettsialpox declined in the latter decades of the 20th century; fewer than 50 cases were reported by the New York City Department of Health between 1980 and 1999. At least 34 cases were confirmed in 2001 and 2002, possibly as the result of increased awareness and detection of the disease after the bioterrorism anthrax attacks of 2001.[71]

THE ORGANISM. The etiologic agent, *R. akari*, is an obligate intracellular gram-negative coccobacillus that is morphologically identical to *R. rickettsii*. The principal vector is the house mouse mite, *Liponyssoides sanguineus*. Rodents, particularly the house mouse, *Mus musculus*, serve as a reservoir for *R. akari*.

EPIDEMIOLOGY AND TRANSMISSION. Most rickettsialpox in the United States has been reported from New York City, but cases also have occurred in many other cities in the United States and worldwide in Russia, Korea, and South Africa. Whereas house mice are the natural hosts of the mite transmitting rickettsialpox in the United States, rats have been shown to host the mite in Russia, and wild rodents are suspected of carrying the disease in South Africa. The reservoir for rickettsialpox may extend to additional, as yet unidentified, wild or domestic animals.

The disease has a natural cycle between the mite vector and the house mouse.[66] The mite passes the disease transovarially, so it is both a reservoir and vector. Humans acquire infection when depletion of mouse hosts caused by reduced availability of food, poison, disease, or trapping forces infected mites to seek an alternative host, namely, people. The disease affects persons of all ages. Males and females are equally susceptible.[62,63]

PATHOLOGY. Biopsy specimens from eschars are characterized by variable degrees of epidermal and dermal necrosis. Ulcerated lesions typically have neutrophils and thrombosed vessels in the ulcer base. The primary pattern of inflammation is a deep perivascular mononuclear cell infiltrate. Immunohistochemical staining reveals spotted fever group rickettsiae predominantly within the macrophages or mononuclear cells of the perivascular infiltrates associated with eschars or papules.[69]

CLINICAL MANIFESTATIONS. The incubation period of rickettsialpox is 9 to 14 days after the usually painless mite bite

occurs.[62,68] The primary lesion is a papule that develops at the site of the mite bite. This lesion progresses through a papulonodular stage to a tense 0.5- to 2-cm vesicle that ruptures to form an eschar with surrounding induration, which is the hallmark of the disease.[72] Two eschars can be seen. Regional lymph nodes related to the primary eschar are almost invariably enlarged.

Constitutional symptoms develop approximately a week after the mite bite. Fever and malaise are commonly present. The fever is irregular, with temperature fluctuating between 37.8° C and 39.5° C (100° F and 103° F), and rarely lasts longer than 6 or 7 days. It usually is accompanied by the frontal headache characteristic of rickettsial diseases. Rhinorrhea, cough, sore throat, nausea, vomiting, and abdominal pain are occasional findings.[64]

The rash is the most remarkable aspect of the disease. It usually develops within several days of the onset of fever as scattered nonpruritic macules, which rapidly become firm maculopapules; within a day or two, vesicles develop on the summits of the papules. The lesions usually appear on the face, trunk, and extremities, with sparing of the palms and soles.[61] The number of lesions ranges from 5 or 6 to more than 100.

DIAGNOSIS. The diagnosis can be made by immunohistochemical staining of skin biopsy specimens, by PCR of amplified gene products from eschars or culture of *R. akari* from eschars, and by serologic assays. These tests, used singly or in combination to establish the diagnosis, are available through the CDC. A fourfold increase in serum antibodies to *R. akari* between acute and convalescent sera or a single titer of more than a 1:64 dilution is considered diagnostic. Cross-reaction is seen between antibodies to *R. akari* and *R. rickettsii*, but titers are greater when reacted with *R. akari* than with *R. rickettsii* antigen.[71]

DIFFERENTIAL DIAGNOSIS. Anthrax is a differential consideration. Rickettsialpox lacks the striking brawny, nonpitting edema surrounding the eschar that is characteristic of anthrax. Anthrax is not associated with the characteristic papulovesicular rash of rickettsialpox. The haphazard distribution of the characteristic papulovesicles is similar in appearance to chickenpox rash in an adult. Infectious mononucleosis, gonococcemia, and infection with echovirus or coxsackieviruses also should be considered.[70] Patients often give a history of having worked in basements, around incinerators, or in similar areas that might be infested by house mice and their mites.

TREATMENT. Rickettsialpox is a self-limited nonfatal disease that resolves within 7 to 10 days in untreated patients. Treatment shortens the duration of symptoms, usually to 24 to 48 hours.[62] Doxycycline is the drug of choice. A treatment course of 3 to 5 days is sufficient.

OTHER SPOTTED FEVER GROUP RICKETTSIOSES

A number of antigenically distinct *Rickettsia* spp. cause disease in humans. Among these, *Rickettsia japonica* is the etiologic agent of Japanese spotted fever, *Rickettsia sibirica* of Siberian tick typhus, and *Rickettsia australis* of Queensland tick typhus. Dogs are the principal mammalian reservoir; ticks also act as reservoirs by virtue of transovarial transmission. Other newly recognized tick-borne diseases, such as *Rickettsia slovaca* infection, for which the wild boar is the main host, have been described in Europe.[74] *Rickettsia felis* has the unusual niche of a flea host.[75] The diseases caused by these and other rickettsial species have similar clinical, pathologic, and epidemiologic patterns. They produce a mild disease, similar to that of Mediterranean spotted fever.

Treatment is similar to that of RMSF.

TYPHUS GROUP

Two diseases in the typhus group, epidemic typhus and endemic typhus, are considered. Clinically and pathologically, these illnesses are similar; epidemiologically, they are different and hence are described under separate headings.

EPIDEMIC TYPHUS

HISTORICAL ASPECTS. Epidemic typhus, or louse-borne typhus, is transmitted by the human body louse. Epidemic typhus is a classic human plague and has had a major role in the history of nations for centuries. It has undoubtedly been more decisive than some military campaigns, as Zinsser[92] has convincingly described in his book *Rats, Lice and History.*

Epidemic typhus occurs only in the presence of the lice, which multiply to astronomical numbers during periods of war, famine, and poverty. Epidemics occurred in the 19th century in Europe, Asia, Africa, and the United States; the last recorded American epidemic occurred in Philadelphia in 1893. After World War I, more than 30 million people in eastern Europe had epidemic typhus, and an estimated 3 million died. During World War II, typhus affected millions of people in prison camps, the eastern European combat zone, and North Africa. In the 1970s, tens of thousands of cases occurred in uncontrolled epidemics in Burundi and Rwanda in Central Africa. In the 1980s, Ethiopia and Nigeria reported the greatest number of cases worldwide since World War II.[86] A small outbreak occurred in Russia in 1997.[87]

Since 1976, at least 30 cases of disease caused by *Rickettsia prowazekii* have been documented in the United States. They have occurred sporadically. The presumed source of infection is the flying squirrel *(Glaucomys volans)*.[80,85,88]

THE ORGANISM. The etiologic agent is *Rickettsia prowazekii.* Its morphologic features, growth, metabolism, toxin production, and staining characteristics are similar to those of rickettsiae of the spotted fever group. Antigenically, the organisms of louse- and flea-borne typhus form a separate group, although they show some minor antigenic cross-reactivity with the spotted fever group.

EPIDEMIOLOGY AND TRANSMISSION. Humans are the primary reservoir for *R. prowazekii*. Persons who recover from typhus are a reservoir of *R. prowazekii* in interepidemic periods. Relapses in chronically infected persons, known as Brill-Zinsser disease, can occur many years after the primary attack.[83] The presence of sporadic *R. prowazekii* infection, however, suggests that perpetuation of epidemic typhus is possible because it may persist in an animal reservoir.

Transmission of typhus is initiated when a louse becomes infected during a blood meal from a person with *R. prowazekii* infection. After 5 to 10 days of incubation, great numbers of rickettsiae are shed in louse feces. Transmission from an infected louse to a new host can occur by several mechanisms. Because a louse defecates as it feeds, infected feces can be rubbed into a louse bite wound. In addition, dried louse feces can gain access to the mucous membranes of the eye or respiratory tract. The epidemic spread of typhus reflects louse temperature preferences. Lice prefer blood meals from humans with a normal temperature and tend to leave febrile patients (as well as the dead). Crowding renders transfer to new hosts easy.

PATHOLOGY. The pathologic process is similar to that described for the spotted fever group of diseases.

CLINICAL MANIFESTATIONS. The onset of illness usually is abrupt, occurring 1 to 2 weeks after the individual has been

bitten by an infected louse. Because of partial immunity from the primary typhus attack, recrudescent infection almost always is a milder, shorter, and less debilitating illness. The major clinical signs and symptoms of primary disease are fever, headache, and a rash. Body temperature generally rises rapidly to 40° C (104° F) or higher. In untreated patients, it remains at this level with minor fluctuations until death or recovery occurs. The rash usually appears on the trunk by the fourth to seventh day; it spreads peripherally to the extremities and typically spares the face, palms, and soles. Initially, the rash consists of macules that fade on pressure; they soon become fixed as maculopapules and later become petechial or hemorrhagic. A severe, intractable headache is a characteristic manifestation. Typhus fever manifesting as encephalitis, meningitis, or meningoencephalitis can occur. Severe, untreated cases can progress to prostration, stupor, or delirium with terminal myocardial and renal failure. Complications occur uncommonly but can include gangrene, parotitis, otitis media, acute pericarditis, myocarditis, pericardial effusion, pleurisy, pleural effusion, and pneumonia.[79,90,91]

DIAGNOSIS. The diagnosis is established by immunohistochemical staining or PCR of amplified gene products in tissues, by isolation of the organism, or serologically by demonstration of a fourfold rise in antibody titer between acute and convalescent serum specimens obtained 2 to 3 weeks apart. These tests are available through the CDC. The IFA test is the preferred serologic assay, but EIA, dot immunoassay, and latex-agglutination testing are available.[78]

DIFFERENTIAL DIAGNOSIS. The rash of louse-borne typhus begins centrally on the trunk and spreads peripherally to the extremities, whereas the reverse is true for RMSF. Moreover, a rash on the palms and soles, a common event in RMSF, rarely is observed in typhus. Typhus usually occurs in epidemics under conditions of crowding and high louse populations.

TREATMENT. Doxycycline is the treatment of choice. Therapy is given until the child is afebrile for at least 3 days and clinical improvement is evident; the usual duration is 7 to 10 days. Fluoroquinolones or chloramphenicol are alternative agents. Doxycycline is the preferred treatment for relapse of epidemic typhus. Louse-infested people should be treated with gel or cream pediculicides containing pyrethrins, piperonyl butoxide, crotamiton, or lindane to halt the spread of disease.[78]

PROGNOSIS. Case-fatality rates in untreated cases correlate with age. A fatal outcome is uncommon in children; the fatality rate is 10 percent in young adults and as high as 60 to 70 percent in those older than 50 years.

PREVENTION. The insecticides lindane and malathion are effective in reducing louse infestation during typhus epidemics. Dusting insecticides onto the clothes of louse-infested populations is effective for delousing and curtailing louse-borne typhus epidemics. Washing clothing in hot water kills lice and their eggs.

ENDEMIC TYPHUS

HISTORICAL ASPECTS. Endemic or murine typhus is a zoonotic disease passed among rats by the rat flea and only occasionally and accidentally transmitted to humans by the bite of an infected rat flea. The disease occurs worldwide, primarily along coastal areas and around granaries where rats abound. During the first half of the 20th century, endemic typhus was prevalent along the Atlantic seaboard and Gulf Coast areas, where 2000 to 5000 cases were reported annually. Only 60 to 80 cases are currently reported annually, and most of these are from southern California, southern Texas, the southeastern Gulf Coast, and Hawaii.[76,82]

THE ORGANISM. The causative organism, *Rickettsia typhi* (formerly *Rickettsia mooseri*), is similar to *R. prowazekii* in metabolism, growth, toxin production, and staining characteristics, although it is slightly smaller and more uniform in size. The rat flea, *Xenopsylla cheopis*, is the usual vector that transmits *R. typhi* to humans.

EPIDEMIOLOGY AND TRANSMISSION. The rat flea acquires infection when feeding on an acutely ill rat. The rickettsiae multiply in the flea without causing ill effects, but infected flea feces teem with rickettsiae for the rest of the flea's life. Rat fleas prefer to feed on rats but will feed on people if rats are not available. If the flea bites a person, infected feces can be rubbed into the bite wound or transferred in a dried aerosol to the conjunctivae or respiratory tract.

Humans are not related to the maintenance of *R. typhi* in nature. However, serologic and molecular analysis suggests that the cat flea, *Ctenocephalides felis*, which has a propensity to feed on humans, also can serve as a vector.[81] In California, sporadic cases have been related to transmission of *R. typhi* by fleas from opossums to humans.[76] The overall seroprevalence of 0.6 percent in children and the finding of antibody-positive children residing in Kentucky, Oklahoma, and Missouri suggest that typhus may be widely prevalent in the United States.[84]

PATHOLOGY. The pathologic process is analogous to that described for the spotted fever group of organisms.

CLINICAL MANIFESTATIONS. The incubation period is 5 to 10 days after a flea bite occurs. Only half of affected children report an antecedent bite. The most common clinical features are fever, found in all patients, and rash and headache, each observed in three fourths or more of affected children. The classic triad of fever, headache, and rash occurs in only half of affected children.[89] The symptoms and signs are similar to those of louse-borne typhus; the principal differences are that endemic typhus is milder and of shorter duration. The temperature does not rise much above 39° C (102° F). The headache is less severe, and the maculopapular rash is less extensive and of shorter duration. Children who receive appropriate antibiotics undergo defervescence in 1 to 3 days; without appropriate treatment, defervescence occurs after 2 to 3 weeks.[82] Complications seldom occur, and the mortality rate is 1 percent or less.

DIAGNOSIS. A fourfold change in titer between acute and convalescent sera by indirect IFA, latex agglutination, complement fixation, or EIA is diagnostic. Differentiation among antibodies produced in response to epidemic typhus is difficult but may be accomplished by use of an IgM-specific EIA, if needed. Immunohistochemical staining or PCR of amplified gene product of tissues and culture, available through the CDC, also can be used for confirmation.

DIFFERENTIAL DIAGNOSIS. Because endemic typhus is a mild illness and the rash can be evanescent, the disease can be confused with any disease that causes a fever of unknown origin in a patient who does not generally appear to be acutely ill.

TREATMENT. The treatment of choice is doxycycline. Treatment should be continued for at least 3 days after defervescence and evidence of clinical improvement is evident, usually for 5 to 10 days.[77]

PREVENTION. Limiting of rat populations is the principal mode of prevention. Insecticides applied to rat runs can reduce the flea population. Rat populations can be reduced by poisoning, trapping, and eliminating rat harborages and by rat-proofing buildings.

SCRUB TYPHUS

HISTORICAL ASPECTS. Scrub typhus is a febrile illness caused by *Orientia tsutsugamushi*. The infection is transmitted to humans by the bite of trombiculid mites. Scrub typhus was a prominent cause of acute febrile illness among military personnel deployed in endemic regions during World War II and in the Korean and Vietnam conflicts.

THE ORGANISM. The causative organism, *Orientia* (formerly *Rickettsia*) *tsutsugamushi*, is distinguished by remarkable antigenic heterogeneity. Marked strain differences in scrub typhus rickettsiae also appear to contribute to striking differences in severity of disease in the same or different localities. The antigenic heterogeneity thus far has thwarted efforts to develop an effective vaccine.

EPIDEMIOLOGY AND TRANSMISSION. Scrub typhus is confined geographically to a roughly triangular area extending from northern Japan and eastern Russia in the north, to northern Australia in the south, to Pakistan and Afghanistan in the west, thus including Korea, China, Thailand, and other South Asian countries as the region of endemicity.[102] Scrub typhus cases reported from other geographic locales reflect international travel to the endemic area.

Trombiculid mites serve as vectors for infection and transmit the rickettsiae to their own progeny through infected ova. Only one of the four stages of trombiculid mite maturation, the six-legged larval form, feeds on field rodents that are the reservoir hosts. Other stages of the mite are spent in the soil, where they feed on organic matter. Infection occurs most commonly in the rainy months from June to November.

PATHOLOGY. The basic pathologic process of scrub typhus is a perivasculitis of the small blood vessels analogous to the other rickettsial diseases. In addition, an eschar or necrotic inflammatory lesion develops at the site of the mite bite, with subsequent development of regional lymphadenopathy similar to that caused by rickettsialpox. General lymphadenopathy occurs commonly in scrub typhus.

CLINICAL MANIFESTATIONS. In at least two thirds of cases, the initial mite bite lesion develops into a necrotic eschar. The preferential site for eschar distribution in adults is truncal[99]; in children, eschars are seen commonly in moist intertriginous areas such as the genitalia and perineum.[102] The incubation period is approximately 1 to 2 weeks, and characteristic features of the disease develop at approximately the same time that the eschar is noted. After regression of the eschar, a scar often remains and has been shown to persist for up to 25 years.[97]

In a contemporary prospective report of scrub typhus in 30 children presenting with febrile illness of at least 5 days' duration in Thailand, common physical signs included lymphadenopathy (93%), hepatomegaly (73%), eschar (68%), conjunctival hyperemia (33%), maculopapular rash (30%), interstitial pneumonia (30%), and splenomegaly (23%).[102] The rash of typhus fever commonly occurs between the fifth and eighth day of illness; in children, it is not easily recognized without careful observation. The lymphadenopathy is generalized and is especially prominent in the axilla, neck, and inguinal areas. Myocarditis and disseminated intravascular coagulation also have been reported.[100] Central nervous system involvement, observed in one of 30 children in the prospective report, ranges from aseptic meningitis to frank meningoencephalitis.[102] The severity of the clinical manifestations varies widely.

DIAGNOSIS. The mainstay of scrub typhus diagnosis is serologic testing. The "gold standard" is the IFA assay; however, there is little consensus in IFA methodology and positivity cutoff limits. Blacksell and colleagues[93] reviewed the evidence base for various methodologies and the criteria for positive IFA results and concluded that the diagnosis should be based on a fourfold or greater increase in the IFA titer in paired serum specimens and on a single sample only when there is an adequate local evidence base.

Other tests, such as enzyme-linked immunosorbent assay, dot immunoassay, indirect immunoperoxidase, and Weil-Felix assays, are also used.[96,101] The last can be the only serologic test available in less developed countries, but it is poorly sensitive; OX-K agglutinins develop in only a little more than 50 percent of scrub typhus patients. Moreover, OX-K agglutinins also are produced by relapsing fever.

Identification of the rickettsial strain in infected patients by use of strain-specific monoclonal antibodies in an inhibition enzyme-linked immunosorbent assay or PCR with strain-specific primers offers potential for establishing the diagnosis in the acute stage of the illness.[94,95] An eschar PCR assay, evaluated prospectively, demonstrated high sensitivity and specificity compared with IFA.[98]

DIFFERENTIAL DIAGNOSIS. Scrub typhus can be suspected when a patient gives a history of recent exposure in a geographic area where scrub typhus occurs. If, in addition, a local eschar, evanescent rash, and general and regional lymphadenopathy along with fever, headache, and conjunctival suffusion are present, the physician should be alerted to suspect scrub typhus; however, it cannot be differentiated with certainty from dengue, leptospirosis, malaria, or typhoid fever.

TREATMENT. Doxycycline is the treatment of choice. Children have responded well to treatment for 4 to 7 days.[102] Doxycycline is rickettsiostatic, and patients with scrub typhus who are treated in the first week of illness can require sporadic short courses of antibiotic therapy for prevention of relapse.[103] Chloramphenicol also is effective. Strains with reduced susceptibility to antibiotics have been observed in northern Thailand. Rifampin may offer an alternative for treatment of infection acquired in that locale.[104]

PROGNOSIS. The prognosis varies widely because of significant differences in the severity of disease caused by different strains in different populations and in various geographic areas. Mortality rates in the pre-antibiotic era ranged from 1 to 60 percent. With the use of antimicrobials, fatalities rarely occur. When treatment is begun early in the course of scrub typhus, relapses as well as definite second attacks of the disease can occur. The heterogeneity of scrub typhus strains probably accounts for re-infections.

PREVENTION. Vector control involves impregnating clothing and smearing exposed skin surfaces with dimethyl or dibutyl phthalate. Short-term vector control of camping grounds can be accomplished by cutting, burning, or bulldozing vegetation, along with heavy spraying with insecticides such as lindane. Chemoprophylaxis is feasible for persons with high-risk exposure for short periods. Doxycycline given once a week provides effective chemoprophylaxis against naturally transmitted scrub typhus if the prophylaxis is started before exposure to infection and con-

tinued for 6 weeks after exposure.[103] No satisfactory vaccine has been produced.

Q FEVER

HISTORICAL ASPECTS. Edward Derrick named the illness he described in 1937 Q (for query) fever.[109] The Q fever rickettsia was discovered in the late 1930s independently by Burnet and Freeman in Australia and by Cox in the United States; the organism was named *Coxiella burnetii.* Q fever is an acute rickettsial infection worldwide in distribution that is characterized in humans by fever, headache, and an associated pneumonitis in more than 50 percent of cases.[124]

THE ORGANISM. *C. burnetii* is distinctive among rickettsiae in being highly resistant to heat, desiccation, and chemicals. It is a pleomorphic coccobacillus that exhibits antigenic phase variation. Phase I variants are associated with mammalian infection; phase II variants, of reduced virulence, follow propagation and are associated with truncation of the lipopolysaccharide of *C. burnetii*. Acute Q fever is characterized by antibodies against phase II antigens; chronic Q fever is characterized by the presence of anti–phase I antibodies.

EPIDEMIOLOGY AND TRANSMISSION. Q fever is unique among the human rickettsial infections in that it is primarily a disease of animals transmitted to humans by contact with infected animals rather than by an arthropod bite. Q fever is primarily a zoonosis infecting cattle, sheep, goats, and rodents worldwide as well as marsupials in Australia and cats in Canada.[123,131]

In domestic livestock, the infection usually is inapparent and remains latent until some stress or physiologic alteration, such as parturition, leads to multiplication of the organism in birth tissues and excretion of rickettsiae in milk, urine, and feces.[115] At the time of parturition, the placental tissues and fluids of sheep, cattle, and goats contaminate the ground; dried dust particles containing the markedly resistant organisms can be blown about and remain potential sources of infection for many months. Epidemics of Q fever can occur in abattoirs, in textile plants where bales of wool are processed, in tanneries, and in shearing camps as well as in rural areas in children who are exposed at the annual spring lambing time.[112] Outbreaks have been reported in research laboratories.[111,117]

Infection, in most cases, occurs by inhalation. Ticks are a negligible factor in passing the disease to humans but appear important in transmission of the disease to small wild rodents and some domestic animals. Chronic Q fever in pregnancy can involve the placenta. The use of a suppressive regimen that controls the mother's placentitis may contribute to the delivery of a healthy baby.[106] At least two confirmed cases of *C. burnetii* infection in a human fetus have been reported; however, no teratogenic effects have been described. Human milk can serve as a source of infection in breast-fed babies.[125]

The prevalence of Q fever probably is underestimated. More than 40 percent of persons who have frequent contact with farm animals such as goats, cattle, and sheep are seropositive for Q fever antibodies. The disease has been diagnosed in an increasing number of children younger than 3 years and should be considered during an evaluation for fever of unknown origin.[125]

PATHOLOGY. Mortality from Q fever is rare, but the pathologic process has been well defined with the use of both autopsy and biopsy specimens. *C. burnetii* can be seen in lung macrophages at autopsy and in lung biopsy specimens.[122] Liver biopsy specimens demonstrate granulomatous changes with a dense fibrin ring surrounding a lipid vacuole. Rickettsial organisms are not found in these lesions, which are consistent with but not pathognomonic for Q fever.[114] Similar granulomata have been noted in bone marrow.[130] Valvular vegetations are seen when endocarditis complicates Q fever. Organisms have been detected intracellularly from affected valves.

CLINICAL MANIFESTATIONS. The incubation period is 9 to 20 days. A self-limited febrile illness and pneumonia are the most common manifestations of Q fever in children.[116] The most common presentation in adults is an influenza-like illness with varying degrees of pneumonia and hepatitis.[120] The disease usually begins abruptly, and presenting findings can include chills, high fever, malaise, myalgia, chest pain, and headache; rash is not present.[126] Despite a paucity of physical findings, chest radiographs reveal multiple round segmental opacities in more than 50 percent of patients. Pleural effusion, lobar consolidation, and linear atelectasis occur less commonly.[118] Hepatitis is a common clinical feature of Q fever, especially in younger patients.[124] Other findings can include pericarditis, rhabdomyelitis, petechial rash, and hemolytic anemia.[108,113,129] Other reported complications include myocarditis, pericarditis, meningoencephalitis,[110] glomerulonephritis,[128] and inappropriate secretion of antidiuretic hormone.[107] The disease usually is mild and lasts only 1 or 2 weeks. The overall mortality rate is approximately 1 percent.

Adults in whom chronic Q fever and endocarditis develop can have a mortality rate as high as 30 to 60 percent.[127] Chronic disease is rare in childhood. Children with Q fever endocarditis usually have underlying congenital heart disease.[116] Q fever osteomyelitis can involve one or several bones and should be suspected in children with a history of exposure to farm animals or when granulomatous lesions are present on bone biopsy specimens.[119]

DIAGNOSIS. Confirmation of the diagnosis requires one of the following: a fourfold change in antibody titer between acute and convalescent specimens taken 2 to 3 weeks apart to *C. burnetii* antigen by IFA, EIA, or complement-fixation assays; anti–phase II antibody is present in early primary disease, whereas anti–phase I antibody is present in higher titer than anti–phase II antibody in patients with chronic disease[121]; positive PCR result; positive immunostaining of *C. burnetii* in tissues; or isolation of *C. burnetii* from a clinical specimen.[105]

Attempts to isolate the organism should be undertaken only in reference laboratories.

DIFFERENTIAL DIAGNOSIS. Q fever should be considered in children with fever of unknown origin when the history suggests possible exposure to *C. burnetii*. The often severe and puzzling cases of myocarditis, pericarditis, or endocarditis can develop months after the original infection, so Q fever should be included in the differential diagnosis of these processes. In such patients, serologic tests using Q fever antigens can reveal extremely high Q fever antibodies.

TREATMENT. Doxycycline is the drug of choice; treatment reduces the duration of symptoms by several days. The acute disease usually is self-limited. Fluoroquinolones and chloramphenicol are alternatives. Patients with endocarditis should receive prolonged treatment with doxycycline and hydroxychloroquine. Children with Q fever endocarditis have required valve replacement to achieve cure of infection.

PROGNOSIS. The overall mortality rate from uncomplicated Q fever is approximately 1 percent. Most patients recover completely with or without treatment. In the rare instances of complications such as myocarditis, pericarditis, and especially

endocarditis, permanent disability and even fatal outcome can occur.[127]

PREVENTION. Whole-cell and acellular vaccines have been developed for use in animals and high-risk individuals. A whole-cell vaccine is licensed in Australia. Q fever vaccine for children is not licensed in the United States. Adherence to proper hygiene when handling parturient animals can reduce the risk of contracting Q fever in the farm setting. Preventive measures should be in place in animal research facilities.

EHRLICHIOSIS

HISTORICAL ASPECTS. Human ehrlichioses are named after Paul Ehrlich. In the United States, these illnesses are caused by at least three pathogens: *Ehrlichia chaffeensis* is the agent of human monocytic ehrlichiosis (HME),[133] *Anaplasma phagocytophilum* (formerly *Ehrlichia phagocytophila*) is the agent of human granulocytic anaplasmosis (HGA, formerly human granulocytic ehrlichiosis), and *Ehrlichia ewingii* is the agent of *E. ewingii* ehrlichiosis.[140] Each pathogen is tick borne and produces a febrile illness characterized by headache, anorexia, and myalgia. Before the initial description of human illness by Maeda and associates in 1987,[157] the ehrlichioses were considered primarily veterinary diseases. *Ehrlichia canis*, closely related to *E. chaffeensis*, was studied extensively since its recognition in the 1930s as causing an acute febrile illness in dogs. During the 1960s in Vietnam, the illness became known as tropical canine pancytopenia; a large number of trained military working dogs died with symptoms of anorexia, weight loss, and pancytopenia followed by fatal epistaxis.[171] *E. chaffeensis*, a name derived from Fort Chaffee, Arkansas, where the isolate originated, was identified in 1991 as the agent causing HME. In 1994, *A. phagocytophilum* was identified as the causative agent of HGA.[141]

THE ORGANISMS. *Ehrlichia* and *Anaplasma* (formerly *Ehrlichia*) are small gram-negative obligately intracellular bacteria. *E. chaffeensis* and *E. ewingii* multiply preferentially in granulocytes, and *A. phagocytophilum* multiplies in macrophages.

EPIDEMIOLOGY AND TRANSMISSION. Since the initial report of human illness was published, hundreds of cases of HME in adults and many in children have been reported.* Cases of ehrlichiosis have been diagnosed from every state except North Dakota and South Dakota.[161] Reported cases of HME are concentrated in the southeastern and south central areas of the country. Illness occurs in the months when ticks are prevalent, from March to October,[149] and approximately 80 percent of the children in whom the infection is diagnosed have a history of having a tick bite within the 3 weeks before the onset of symptoms. The seroprevalence of *E. chaffeensis* titers of 1:160 or higher was 3 percent among children residing in the southeast and south central regions of the United States, indicating that childhood ehrlichial infections often can be asymptomatic or unrecognized.[159]

The lone star tick, *Amblyomma americanum*, is the principal vector of HME and *E. ewingii* ehrlichiosis, although alternative tick vectors, such as *Dermacentor variabilis*, the American dog tick, and *Ixodes pacificus*, the Western black-legged tick, occasionally can transmit infection in some geographic regions. The reservoir for HME has not been fully clarified, but deer and livestock are the preferred hosts of *A. americanum*. Proximity to a wildlife reserve served as a risk factor for acquiring HME in one reported cluster of cases.[169]

The initial reports of HGA were from the upper Midwestern states of Wisconsin and Minnesota. Most infections have been reported from the northeastern and north central regions, but cases also are reported from the Pacific western states, especially California. Many hundreds of human cases have been identified. A tick bite frequently precedes the illness, and the black-legged or deer tick, *Ixodes scapularis*, is the principal vector in the northeastern and north central states. The Western black-legged tick, *I. pacificus*, is the primary vector in the Pacific western states. Because the predominant host of the deer tick, the white-tailed deer, has a wide geographic distribution, HGA can be more prevalent than is currently documented.[152,163,166]

Perinatal transmission of ehrlichiosis has been documented. The mother apparently was infected with the agent of HGE toward the end of her pregnancy and gave birth to a normal infant. Symptoms in both the mother and infant resolved after treatment with doxycycline.[155]

PATHOGENESIS AND PATHOLOGY. The pathogenesis of ehrlichiosis is incompletely elucidated. Although it is capable of establishing infection in numerous organs and tissues, the primary target cell for HGE is the granulocyte, and for HMA, it is the macrophage. Granulomata of the bone marrow occur frequently in HME, suggesting that involvement of the reticuloendothelial system may be important in pathogenesis.[144]

Organisms enter the cytoplasm of host cells and proliferate in phagosomes into elementary bodies. These individual organisms multiply by binary fission into immature inclusions called initial bodies. Mature groups of elementary bodies form morulae, which are released by rupture of the cell to re-initiate the infecting process.[157]

CLINICAL MANIFESTATIONS. The estimated incubation period for HME is 12 to 14 days. Like RMSF, HME is an acute febrile illness manifested as fever, headache, anorexia with or without vomiting, and myalgia.[150,164,170] The features of HME are shown in Table 207–2. Rash, which can be macular, maculopapular, or petechial, seldom develops in adult infections. In pediatric infections, rash appears to be a common symptom, with a distribution often including both the trunk and extremities.

Meningitis as a manifestation of HME has been reported in children. Symptoms can range from irritability and meningismus to obtundation with response only to painful stimuli.[139,142,151] Initial examination of cerebrospinal fluid reveals pleocytosis

TABLE 207–2 Clinical and Laboratory Features of Adult and Pediatric Monocytic Ehrlichiosis

Feature*	Percentage of Cases	
	Adult (*N* = 46)	Pediatric (*N* = 20)
Fever	96	100
Anorexia	76	78
Headache	80	100
Myalgia	74	67
Rash	20	65
Leukopenia†	61	72
Thrombocytopenia‡	52	78
Elevated aspartate aminotransferase§	76	83

**Some features not specified for all patients.*
†Fewer than 4000 white blood cells/mm³.
‡Fewer than 150,000 platelets/mm³.
§More than 55 U/L.

*See references 136-138, 143, 146, 151, 153, 154, 156, 158, 160.

ranging from approximately 50 to 1400 white blood cells, usually with a predominance of mononuclear cells; a range of 5 to 40 red blood cells; mildly elevated protein; and a normal to slightly low glucose value. Complete recovery is the rule.

One half to two thirds of adults and children have mild leukopenia and thrombocytopenia. One child had a documented decline in the white blood cell count from 13,000 to 1600 during an interval of several hours.[147] Usually, thrombocytopenia is not associated with clinical bleeding, but disseminated intravascular coagulopathy has been reported.[157] Elevations of aspartate aminotransferase, usually modest, peak at approximately 1 week into the illness, with values ranging from twice normal to several thousand. Uncommon manifestations of illness include protracted fever, renal dysfunction occasionally of sufficient severity to require dialysis, hyponatremia, hypoalbuminemia, and toxic shock syndrome.[148,168] Persistent infection during the course of a 2-month interval and infection complicating human immunodeficiency virus disease have been documented.[145,162]

The clinical features of HGA are similar to those of HME, with fever, malaise, myalgia, and headache occurring consistently. Rash occurs in less than 10 percent of cases. Morulae can be demonstrated in the cytoplasm of neutrophils but not mononuclear cells. Leukopenia, generally mild, is a feature of the illness in approximately half of the patients, and thrombocytopenia develops in most. As with HME, serum aspartate aminotransferase activity is elevated in most cases.

DIAGNOSIS. The diagnosis of HME or HGA is confirmed by one of the following: (1) isolation of *Ehrlichia* or *Anaplasma* from blood or cerebrospinal fluid, (2) a fourfold or greater change in antibody titer by indirect IFA in serum samples collected 2 to 3 weeks apart, (3) PCR amplification of ehrlichial DNA from a clinical sample,[134,135] or (4) detection of intraleukocytic morulae and a single IFA titer of 64 or greater.[132] A probable case is defined as a single IFA titer of 64 or greater or the presence of morulae within infected leukocytes.[161]

DIFFERENTIAL DIAGNOSIS. Human ehrlichiosis must be distinguished from other tick-borne diseases, especially RMSF. The illnesses are similar in that both have manifestations of diffuse vasculitis. Ehrlichiosis is less likely to be accompanied by rash and more often is associated with leukopenia or pancytopenia. The similarity of ehrlichiosis and RMSF is emphasized by two retrospective serosurveys in which approximately 10 percent of specimens from patients lacking the serologic criteria for a diagnosis of RMSF fulfilled diagnostic criteria for ehrlichiosis.[154,167] Other tick-borne illnesses, such as Lyme disease, babesiosis, Colorado tick fever, relapsing fever, and tularemia, should be included in the differential diagnosis.

Simultaneous HME and *Borrelia burgdorferi* infection has been described.[136] Whether it represents dual infection or is an instance of antigenic cross-reactivity is unknown. Kawasaki disease can have features mimicking ehrlichiosis; paired sera from a group of children with Kawasaki disease, however, failed to react with a panel of *Ehrlichia* antigens.[165]

TREATMENT. The drug of choice for treatment of human ehrlichiosis is doxycycline. The recommended dosage is 4 mg/kg/day in two divided doses (maximum, 200 mg/day). Treatment should continue for at least 3 days after defervescence for a course of 5 to 10 days.[132] Mild clinical illness can resolve without antimicrobial treatment, although fever can be protracted.[149,150,164] However, human ehrlichiosis can have a fatal outcome, so doxycycline treatment should be initiated when the diagnosis is suspected, without regard for the age of the child. Severe cases can require a longer course of treatment.

MYCOPLASMA

CHAPTER 208

MYCOPLASMA AND UREAPLASMA INFECTIONS

James D. Cherry

Mycoplasmas and ureaplasmas, the smallest free-living microorganisms, are ubiquitous in nature. More than 100 species have been recovered from many animals, including human beings.[548,669,687,688] Of this group, 17 have been identified as human pathogens or as part of the "normal" human flora, with *Mycoplasma pneumoniae*, *Mycoplasma hominis*, and *Ureaplasma urealyticum* found to cause disease frequently in children. A protean array of illnesses in children is caused by infection with these organisms.

The generic name *Mycoplasma* is derived from Greek and Latin. *Myco* refers to the mycelial, or filamentous, characteristic, and *plasma* indicates the plasticity and pleomorphism of the organism.[646] *Urea* in *Ureaplasma* indicates the presence of urease in this genus.[228] (For neonatal infections, see Chapter 75).

HISTORY

In 1898 Nocard and Roux[509] recovered the first *Mycoplasma* organism from cattle with contagious pleuropneumonia. Shortly after the original discovery, many other mycoplasmas were recovered from several different animals.[265] These other mycoplasmas, which frequently were not associated with disease, originally were called *pleuropneumonia-like organisms;* this designation was abbreviated to PPLO. The term PPLO enjoyed general use until the early 1960s.

The first isolation of a mycoplasma from a human was reported in 1937 by Dienes and Edsall.[152] This organism, now recognized as *M. hominis*, was recovered from an abscessed Bartholin gland. In 1944 Eaton and colleagues[167] reported the recovery of an organism, originally called the *Eaton agent*, from persons ill with primary atypical pneumonia. For many years, the Eaton agent was considered to be a virus, even though it was inhibited by streptomycin and chlortetracycline.[165,166] In 1961 Marmion and Goodburn[431] noted that the Eaton agent was morphologically similar to PPLOs. In 1962 the organism now known as *M. pneumoniae* was cultivated on a cell-free agar medium and was shown in human volunteer studies to be the etiologic agent of primary atypical pneumonia.[87,89,265]

In 1954 Shepard[590] reported the recovery of PPLOs with a distinctive small-colony characteristic from men with and without nongonococcal urethritis. These T strains (T for tiny), as they were called, now are classified as *Ureaplasma.* More recently, another mycoplasma, *Mycoplasma genitalium*, has been associated with genital tract infections, and three mycoplasma species have been noted to co-infect patients with human immunodeficiency virus (HIV) infection.[470,651]

CLASSIFICATION

Mycoplasma and *Ureaplasma* are the two genera of the family Mycoplasmataceae, in the order Mycoplasmatales, which belongs to the class Mollicutes.[228,548,687,688] Both *Mycoplasma* and *Ureaplasma* require cholesterol for growth, have a genome with a molecular weight of approximately 4.5×10^8, and have nicotinamide adenine dinucleotide (NADH) oxidase localized in the cytoplasm. These species lack a cell wall, as do all organisms within the class Mollicutes.[297] Members of the genus *Mycoplasma* do not hydrolyze urea, whereas the two species within the genus *Ureaplasma* do.

The "normal" human mollicate flora includes 14 *Mycoplasma*, 2 *Ureaplasma*, and 1 *Acholeplasma* spp.[82,170,228,392,661,669] These organisms are listed by site of most common isolation and frequency of occurrence in Table 208–1. *Mycoplasma salivarium* and *Mycoplasma orale* are commonly part of the normal respiratory flora and have not been associated with illness in nonimmunocompromised persons. *M. hominis*, *U. urealyticum*, and *Ureaplasma parvum* also are recovered commonly from humans, and frequently they are related causally to illness.

Mycoplasma buccale, *Mycoplasma faucium*, *Mycoplasma amphoriforne*, *Mycoplasma primatum*, *Acholeplasma laidlawii*, and *Mycoplasma lipophilum* rarely are isolated and are not thought to cause disease in non-immunocompromised humans. *M. genitalium* and *Mycoplasma fermentans* have biologic and morphologic features that suggest they may be pathogenic in people, but their role in human genital disease is debated.[647,668,687] Persistent infections in blood, bones, joints, and kidneys with *M. fermentans*, *U. urealyticum*, *Mycoplasma penetrans*, *Mycoplasma pirum*, and *M. hominis* have occurred in patients with immunodeficiencies.[25,468,668] *M. pneumoniae* is a common cause of respiratory and other human illness.

MYCOPLASMA PNEUMONIAE

PROPERTIES

Morphology

Because mycoplasmas lack a cell wall, they all tend to be pleomorphic. Kammer and colleagues[325] studied the morphologic characteristics of *M. pneumoniae* organisms grown in broth medium by scanning electron microscopy and grouped their observations by days of incubation. From 0.3 to 2 days, the predominant morphologic feature consisted of 0.51 ± 0.011-μm symmetric round forms in tightly packed clusters. During the interval from day 2 to day 6, branched and straight filaments and bulbs were the predominant forms. The bulbous elements had a diameter of 0.25 ± 0.006 μm, and the filamentous forms were 0.19 ± 0.005 μm in diameter. The filaments were intertwined, and occasional round forms were observed. From day 6 to day 10, the organisms had a rounded shape but were asymmetric. Their diameter was 0.72 ± 0.027 μm, and they occurred in groups of three or four cells. Biberfeld and Biberfeld[38] noted that *M. pneumoniae* filamentous forms varied in length from 1 to 5 μm.

TABLE 208–1 Mollicutes Flora of Humans Listed by Site of Most Common Isolation and Prevalence

Organism	Prevalence
Respiratory Tract	
Mycoplasma salivarium	Very common
Mycoplasma orale	Very common
Mycoplasma buccale	Rare
Mycoplasma faucium	Rare
Mycoplasma lipophilum	Rare
Mycoplasma pneumoniae	Common
Mycoplasma amphoriferme	Rare
Acholeplasma laidlawii	Rare
Genitourinary Tract	
Mycoplasma hominis	Very common
Mycoplasma genitalium	Rare
Mycoplasma fermentans	Rare
Mycoplasma primatum	Rare
Mycoplasma spermatophilum	Rare
Mycoplasma penetrans	Rare
Ureaplasma urealyticum	Very common
Ureaplasma parvum	Very common
Blood	
Mycoplasma pirum	Rare

Data from references 392, 429, 617, 661, 668, 672, 687, 688.

The ultrastructure of *M. pneumoniae*, as well as that of all members of the family Mycoplasmataceae, is relatively simple and consists of a cell membrane and cytoplasm.[228,667] In 7-day *M. pneumoniae* cultures, Domermuth and associates[153] noted the following characteristics: elementary bodies 105 to 120 nm in diameter, mature cells with a maximal diameter of 690 to 750 nm and an average diameter of 440 to 590 nm, asymmetry of the limiting membrane, electron-dense lines outside the limiting membrane, and dense bodies as cytoplasmic inclusions.

Wilson and Collier[707] studied the ultrastructure of *M. pneumoniae* in hamster tracheal organ culture and noted filamentous organisms with trilaminar membranes; the cells were polymorphic, but each had a specialized terminal structure at the site of attachment to the organ culture. This terminal structure had a dense central core containing a denser central filament. Between the organism and the organ culture cell, fusion was not detected, but a loose network of fibrils was noted between the two surfaces. The bodies of the mycoplasmas contained densely staining fibrillar material and cytoplasmic granules, both of which contained nucleic acid.

Motility and Multiplication

Bredt[59] studied *M. pneumoniae* motility and multiplication on a glass surface in liquid medium by phase-contrast microscopy. The organisms were observed to multiply by binary fission; first, short filamentous structures were formed, which then separated into two cells. A growth cycle between two separations lasted approximately 3 hours. After division, the new cells moved by means of a gliding motion. The gliding speed has been noted to be approximately 0.2 to 0.5 μm/sec, but maximal speeds of 1.5 to 2.0 μm/sec have been observed.[541]

Composition

Mycoplasmas are composed of approximately 40 to 60 percent protein, 10 to 20 percent lipid, and a variable amount of carbohydrate. The *M. pneumoniae* genome is circular, double-stranded DNA with a contour length of 4.8×10^8 d.[474] The guanosine plus cytosine content of the DNA is 38.6 to 40.8 percent.[54,499,548,649]

Growth Characteristics and Physical Properties[84,265,548,646,667]

M. pneumoniae grows in *Mycoplasma* broth medium and on agar enriched with yeast extract and animal serum. *M. pneumoniae* ferments carbohydrates and requires sterol for growth. It grows under both anaerobic and aerobic conditions, but growth is more consistent when it is incubated in nitrogen and 5 percent carbon dioxide. When compared with other mycoplasmas isolated from humans, *M. pneumoniae* grows relatively slowly, with visible formation of colonies rarely occurring in less than 1 week and possibly taking 3 weeks or more. Repeated agar passage results in more rapid growth, and laboratory strains thus treated produce colonies in 3 days.

M. pneumoniae colonies on agar generally appear different from the classic *Mycoplasma* "fried egg" look noted with other types recovered from humans. The *M. pneumoniae* colony is spherical and dense, with a rough ("mulberry") surface.

M. pneumoniae has the following enzyme systems: $NADH_2$ oxidase, nicotinamide adenine dinucleotide phosphate ($NADPH_2$) oxidase, lactate dehydrogenase, probably succinic dehydrogenase, and diaphorases.[265] In liquid medium the following can be noted: acid color change in medium with added glucose and phenol red as a result of glucose metabolism, reduction of methylene blue in medium as a result of dehydrogenase activity, and reduction of 2-3-5 tetrazolium chloride to red formazan by dehydrogenase activity.[646]

On agar, *M. pneumoniae* hemolyzes erythrocytes in an agar overlay by liberation of peroxide. Erythrocytes and other cells adsorb to *M. pneumoniae* colonies, and organisms in suspension cause hemagglutination.

Mycoplasmas including *M. pneumoniae* are heat sensitive. They have a half-life of less than 2 minutes at 50° C and lose viability within 1 week at room temperature.[667] They can be stored for several years at –20° C, but –70° C is optimal for long-term storage.

Mycoplasmas are resistant to osmotic environmental changes but are sensitive to detergents. They are inhibited by gold salts and antibiotics not directed against cell wall synthesis.

Antigenic Composition

The following immunologic reactions have been noted in association with *M. pneumoniae*–host serum interactions: specific complement fixation; precipitation in gel; growth inhibition; indirect hemagglutination; metabolic inhibition; antigen-antibody union identified by immunofluorescence, enzyme-linked immunosorbent assay (ELISA), and radioimmunoassay; adherence inhibition assay; and nonspecific complement fixation (positive serologic test result for syphilis) and agglutination (cold and *Streptococcus* MG agglutinins).[73,291,306,392,538,646] *M. pneumoniae* organisms have both membrane and cytoplasmic antigens.[192,334] Two membrane antigens can be identified by immunodiffusion,[531] with the major membrane antigen being found in the lipid fraction of the organism.[334] The antigens are glycolipids and are of major importance in complement fixation, metabolic inhibition, and mycoplasmacidal reactions.[77] The cytoplasmic (soluble) antigen, which also contains lipid, can be identified by complement fixation when the antigen is prepared by phenol extraction.

Humans have an IgG immune response to six principal protein antigens.[91,140,141,226,358,364,547,685] These six polypeptides have the following molecular masses: 170, 130, 90, 45, 35, and 30 kd. The 170-kd antigen is the P1 protein. This protein is localized at the surface of the terminal organelle (terminal structure), is the major adhesin responsible for attachment, and is the cause of the gliding motility of the organism. Antibodies to P1

protein inhibit hemadsorption and adherence to respiratory epithelium.[287,289,290,305,323,359,630] Another important adhesin is the 30-kd protein (P30 adhesin). In addition to the P1 and P30 proteins, at least six accessory proteins are involved in the adherence of *M. pneumoniae* to host cells.[548] These accessory proteins are HMW1, HMW2, HMW3, and A, B, and C.

M. pneumoniae strains can be divided into two types on the basis of the sequence variation in the P1 gene.[157,158,163] Five subtypes of the type 1 strain and three subtypes of the type 2 strain have been noted by restriction fragment length polymorphism (RFLP). Kannan and Baseman have recently shown that *M. pneumoniae* liberates a 68-kDa protein that possesses ADP-ribosyltransferase (ART) activity.[327] This toxin is immunogenic and is synthesized in vivo, suggesting that it might be responsible for airway cellular damage.

Membrane determinants of *M. pneumoniae* cross-react with the erythrocyte glycoprotein containing the I antigen and the related sugar chain (F1)[271,309]; with pneumococcal serotypes 23 and 32[8]; with the glycolipids of spinach, parsnips, carrots, and selected strains of *Staphylococcus aureus* and group A streptococci; and with perhaps the filamentous hemagglutinin of *Bordetella pertussis*.[250,303,335,681]

Animal Susceptibility

M. pneumoniae grows and causes pneumonia in hamsters and cotton rats and causes inapparent infection of the bronchial epithelium of chicken embryos.[538]

EPIDEMIOLOGY

Epidemic Pattern

In large urban areas *M. pneumoniae* is endemic; infection and disease occur throughout the year. Foy and associates[208,214] noted cultural or serologic evidence of *M. pneumoniae* infection in a Seattle prepaid medical care group during all seasons throughout an 11-year period. Similar endemicity has been reported in other studies.[465,471,508] In addition to the background endemic pattern, *M. pneumoniae* enjoys a cyclic epidemic pattern that is specific for a particular urban community. Epidemics have occurred at 3- to 7-year intervals.[177,214,321,394,508] Epidemics, which develop slowly, usually start in the fall and persist in the community for 12 to 30 months.

As part of an influenza surveillance program, Layani-Milon and associates[373] studied acute respiratory infections in outpatients for six winters in the Rhône-Alpes region of France by using a polymerase chain reaction (PCR) plus a hybridization–based detection system. Each year from 1992 to 1997, at least one peak of *M. pneumoniae* infection was noted in the late fall. Overall, they studied 3897 children and adults with acute respiratory illnesses, and 7.3 percent were found to be infected with *M. pneumoniae*. The yearly rate of *M. pneumoniae* cases fell from 10.1 percent in 1992 to 1993 to 2.0 percent in 1995 to 1996; in the subsequent year (1996 to 1997), it rose to 4.2 percent.

Incidence of Infection and Disease

In the past, most pediatricians and other physicians considered *M. pneumoniae* illness to be uncommon in the general population. The initial epidemiologic studies were concerned mainly with the occurrence of pneumonia in closed populations such as the military and boarding schools.[88,465,568,626,628,679] During the past 43 years, however, many large studies in civilian populations, coupled with more sensitive serologic techniques, have indicated that both infection and disease with *M. pneumoniae* occur commonly.*

Hornsleth[283] examined 367 serum samples collected from children hospitalized in Copenhagen from September 1963 to May 1965 for complement-fixing antibodies. He noted that 42 percent of infants 6 to 11 months of age had demonstrable antibody; from 1 to 9 years of age, more than two thirds of the children had antibody. Suhs and Feldman[634] found a similar high prevalence of hemagglutination-inhibiting antibody in the sera of residents of Point Barrow, Alaska, but only 5 percent of the serum samples from a children's home in Syracuse had measurable antibody.

Brunner and associates[69] detected serum antibody by the sensitive radioimmunoprecipitation test in 28 percent of 7- to 12-month-old infants, 55 percent of 13- to 24-month-old children, 67 percent of 25- to 60-month-old children, and 97 percent of persons older than 17 years. The high antibody prevalence noted in this study, as well as the findings in Copenhagen and Alaska, suggests an infection incidence rate of approximately 20 to 30 percent per year in a susceptible population of young children. The prevalent antibody noted at an early age in these studies possibly is not caused specifically by *M. pneumoniae* infection but instead could be the result of exposure to the many cross-reacting antigens in nature.[8,234,335] However, studies by Fernald and colleagues,[194] in which infants and children in a daycare center were monitored systematically, indicated a yearly infection rate of approximately 12 percent.

Monto and colleagues,[471] in a large study involving 3243 persons, investigated the incidence of infection in six yearly cohort groups of children and adults. Infection was determined by significant rises in titer of complement-fixing antibody on three serum specimens collected during a 1-year period from each subject. The overall yearly infection rate was found to be 5.3 percent. The highest rate (8.8%) occurred in the 5- to 9-year-old group. Infants younger than 1 year had a rate of 2.8 percent.

Brunner and associates[69] noted that geometric mean antibody titers tended to increase with increasing age, which suggested that the older children were being re-infected. Fernald and colleagues[194] reported that 5 of 22 children infected with *M. pneumoniae* in their investigation experienced re-infections during the 5-year observation period. In the study of Monto and associates,[471] 24.4 percent of the 172 infections detected in subjects of all ages were re-infections. During a 12-year serologic surveillance period, Foy and coworkers[214] noted great variation in the incidence of *M. pneumoniae* infection; in the period from October 1965 to May 1966, only 0.2 percent of 398 children had fourfold rises in complement-fixation antibody titer, whereas during the May 1973 to May 1974 period, 35 percent of 246 subjects 10 to 20 years old had serologic evidence of infection.

The incidence of disease caused by *M. pneumoniae* depends on the endemic or epidemic prevalence of the organism in the community and is age related. The incidence of *M. pneumoniae* by age for two epidemics and the surrounding endemic periods in Seattle was studied by Foy and associates.[214] The highest epidemic attack rate was 14 per 1000 children 5 to 9 years of age, and the highest endemic attack rate (4 per 1000) occurred in the same age group. Ten- to 14-year-old children had the second highest attack rate during both epidemic and endemic periods. The attack rate in children younger than 5 years was about twice that observed in young adults.

The ratio of symptomatic to asymptomatic infection has varied in different studies. In family studies, both Balassanian and

*See references 20, 22, 42, 69, 80, 132, 151, 155, 161, 170, 174, 194, 209-212, 214, 217, 219, 239, 240, 242, 248, 283, 311, 318, 321, 394, 402, 408, 454, 471, 472, 503, 508, 519, 589, 634, 666.

Robbins[22] and Foy and associates[212] noted that only 15 percent of infections were asymptomatic, whereas Saliba and associates[568] noted that 55 percent of the residents of a boys' home had asymptomatic infection. Chanock and colleagues[88] observed that only 1 of 30 infections in Marine recruits was manifested as clinically apparent pneumonia.

Incubation Period

The reported incubation period has varied from a mean of approximately 1 week in volunteer studies and point-source epidemics to 3 weeks in community outbreaks.* In a volunteer study, Rifkind and colleagues[553] administered tissue culture–grown *M. pneumoniae* in a concentration of 320 to 1280 EID_{50} (mean egg-infective dose) into the nose and posterior pharyngeal area of 27 men with no demonstrable antibody. In this study, pneumonia occurred 9 to 12 days after inoculation, following 1 to 3 days of upper respiratory illness. In six volunteers, only upper respiratory illness was noted, and the incubation period varied from 4 to 9 days. In a similar study in which volunteers received 10^6 to 10^7 broth-grown organisms, the incubation period was 8 to 10 days.[607]

In an interesting common-source outbreak caused by an intense 8-hour exposure at a party, the peak incubation period was 13 days, and most of the cases occurred between days 11 and 14.[180] In another probable point-source outbreak, which may have resulted from a room aerosol, the incubation period varied from 4 to 9 days.[570] In studies of case-to-case intervals in families, Foy and associates[212] reported a median incubation time of 23 days, with most of the cases occurring between days 16 and 25. In similar studies, Copps and colleagues[132] noted an average interval of 21 days, and Biberfeld and Sterner[42] found a modal value of 20 days. A point-source outbreak in a family unit was described in which all seven family members became ill 10 to 16 days after the onset of symptoms in the index case.[336]

The longer incubation period in the family situation than in the volunteer studies and the point-source outbreaks may be the result of larger inocula in the last instances. In contrast to other respiratory illnesses such as measles and influenza, the spread of disease caused by *M. pneumoniae* in both closed populations such as military training units and boarding schools and open communities is usually slow. For example, the introduction of influenza or measles into a family most often results in infection of all susceptible persons from the primary case. In contrast, the spread of *M. pneumoniae* through a family of six people probably would require three or four passages. Foy and associates[212] noted secondary attack rates in families of 64 percent for children and 17 percent for adults. Biberfeld and Sterner[42] reported secondary infection rates of 41 and 84 percent, respectively, for adults and children in families. In contrast to family groups, the spread of *M. pneumoniae* in schools and other situations of brief exposure is low.[209,218] In one Seattle elementary school, the infection rate was 18 percent. Foy and Alexander[208] believe that neighborhood spread among playmates is more important than school exposure in community transmission of *M. pneumoniae*.

Transmission in families occurs during the acute phase of illness, and transmission by persons with asymptomatic infection has not been documented.[209]

Geography

The endemic and epidemic presence of *M. pneumoniae* has been demonstrated in the urban areas of developed countries with temperate climates throughout the world.† Serologic investigations in more remote areas including both arctic and tropical zones also indicate the presence of *M. pneumoniae* infection. Suhs and Feldman[634] found measurable antibody in the serum of 68 percent of 169 persons in Point Barrow, and Golubjatnikov and associates,[242] in a study of children in a remote Mexican highland community, detected seropositivity in 16 percent of 637 children. Serologic evidence of infection also has been noted in Cairo, Singapore, Hong Kong, the West Indies, and southern Africa.[85,321] Incidence studies have not been performed in rural areas, but patterns of infection probably would be characterized by epidemic periods of a year or so and then complete absence of *M. pneumoniae* circulation for several years.

Sex

Although the results of studies have varied, the difference in the incidence of *M. pneumoniae* disease by sex is small. During the 11 years of study in Seattle, Foy and associates[214] noted that the rate of *M. pneumoniae* pneumonia was higher in women than in men in the 30- to 39-year age group (1.8 versus 1.2 per 1000); in infants, boys were afflicted more often than girls, but otherwise the rates for children by sex were virtually identical. Jensen and associates[318] found that pneumonia, otitis media, and nasopharyngitis in various combinations occurred more commonly in boys than in girls. Monto and colleagues[471] noted that boys younger than 5 years of age had more infections, but that the reverse was true for children 5 to 14 years of age. In other studies involving all age groups, males have shown a slightly greater frequency of illness than females.[430,508] In the Seattle family studies, symptoms were more severe in boys than in girls.

PATHOGENESIS AND PATHOLOGY

Sequence of Events in Infection

M. pneumoniae infection is acquired via the respiratory route from the respiratory secretions of an ill person infected with this agent. Spread can be accomplished by small-particle aerosols or large droplets of secretions coming in contact with the epithelial surface of the nasopharynx and perhaps the surfaces of the lower respiratory tract (trachea, bronchi, and bronchioles) as well. In volunteer studies, Couch[135] observed that the 50 percent human infectious dose by small-particle aerosol was 1 colony-forming unit (nasal instillation required a dose that was 100 times greater).

Because epidemiologic data indicate the need for close and perhaps prolonged personal contact for transmission of infection, transmission by small-particle aerosol probably occurs rarely under natural conditions. After acquisition of the infectious agent, multiplication occurs extracellularly on mucous membrane surfaces. The incubation period, which varies from 4 days to more than 3 weeks, probably depends strongly on the size of the original inoculum. The extent of the respiratory infection increases during the incubation period, and shedding of organisms in respiratory secretions can be observed 2 to 8 days before clinical illness.[135] Initial symptoms of infection include headache, malaise, fever, sore throat, and cough; evidence of lower respiratory tract disease is present within the succeeding 3 days.[151,553] The method of extension of infection within the respiratory tract is unknown. The extent of disease possibly depends totally on the initial distribution of the infectious agent at the time of acquisition rather than on spread of infection from a primary upper respiratory site.

After the onset of clinical symptoms, the concentration of *M. pneumoniae* in respiratory secretions peaks, remains high for approximately 1 week, and then persists for 4 to 6 weeks or longer.[135,151] The associated symptoms and signs in disease caused

*See references 42, 132, 180, 209, 212, 216, 553, 570, 608, 669.
†See references 42, 151, 187, 209, 214, 311, 394, 417, 430, 490, 508, 622.

by *M. pneumoniae* (meningitis, arthritis, hemolytic anemia, rash, pericarditis) suggest the possibility of frequent dissemination of the organism from the respiratory tract. Some reviews on the subject tend to discount the possibility of generalized *M. pneumoniae* infection and attribute the associated systemic clinical findings to immunologic events related to respiratory infection.[135,151] However, little published evidence indicates that the organism has been sought carefully in the blood and other sites of dissemination. In many instances *M. pneumoniae* has been recovered from or identified by PCR in the blood, pericardial fluid, middle ear fluid, vesicular skin lesions, pleural fluid, kidneys, brain, and cerebrospinal fluid (CSF).* In addition, the observation of low CSF glucose in *M. pneumoniae* meningoencephalitis suggests direct involvement by the organism.[346]

Pathology

Pathologic findings in *M. pneumoniae* disease of children have not been reported, and only minimal data from adults are available. However, a reasonable understanding of the pathologic process of *M. pneumoniae* disease can be constructed from studies in the hamster, various tracheal organ cultures, and human biopsy and postmortem material.[156,322,419,456,523,656,714] The primary damage in *M. pneumoniae* infection is to the epithelial lining of the mucosal surfaces of the respiratory tract. This damage has been observed on the surface of bronchi, bronchioles, and alveoli, and clinical symptoms in children suggest that similar pathologic changes occur in the trachea and upper respiratory tract as well. Specifically conspicuous is destruction of the ciliated epithelium of the bronchi and bronchioles. Because of mucosal desquamation and ulceration, the lumina contain considerable debris; added to this debris is an inflammatory exudate consisting of fibrin, mononuclear cells, and neutrophils. The alveolar spaces contain similar exudate and edema fluid.

The walls of the bronchi and bronchioles are thickened by edema and contain an infiltrate of macrophages, lymphocytes, and plasma cells. The alveolar walls are also thickened and contain lymphocytes, mononuclear cells, and erythrocytes. Dilation of the septal capillaries occurs. Edema and cellular infiltration extend into the interstitial spaces. Gross examination of the lungs reveals areas of hemorrhage and congestion. The pleura may contain patches of fibrinous exudate, and pleural fluid may be present. The pneumonic areas may be discrete or widespread.

A biopsy specimen of a vesiculopustular skin lesion revealed an epidermis with mild acanthosis and marked edema that primarily was intracellular.[656] The papillary and upper reticular dermis contained neutrophils and round cells, and hemorrhagic foci were present within the upper corium and epidermis. The blister fluid contained plasma protein and neutrophils. Findings in other organs include mesenteric lymphadenitis, focal hepatic necrosis, follicular splenitis, acute myocarditis, and hemorrhagic encephalitis.

Immunologic Events

SPECIFIC ANTIBODY. A specific serum antibody response usually occurs after infection with *M. pneumoniae*, and it can be measured by many different serologic techniques: immunofluorescence, complement fixation, indirect hemagglutination, precipitation, growth inhibition, mycoplasmacidal antibody test, ELISA, radioimmunoassay, adherence inhibition assay, and radioimmunoprecipitation test.†

Complement-fixing antibodies occur early in *M. pneumoniae* disease, reach a peak titer in approximately 1 month, and then decline slowly over a variable period. Fluorescent-staining antibodies and antibody determined by ELISA have temporal patterns similar to those of complement-fixing antibodies. Growth-inhibiting antibodies appear later (2 to 3 weeks after the onset of illness), peak later, and persist longer than complement-fixing antibodies do. The initial serum immune response includes specific IgM, IgG, and IgA antibodies. After clinical illness and convalescence, specific antibody is located mainly in the IgG serum fraction. Occasionally, significant levels of IgM antibody persist for several months or years after infection.[37,70,173,319] Antibody titer responses in infected children are generally of a lesser magnitude than those in adults.[161] Asymptomatic infections in children may not be associated with a measurable serum antibody response. *M. pneumoniae*–specific IgE antibodies have been detected in the sera of patients with asthma, atopic dermatitis, or both conditions.[662]

After infection, specific antibody is also present in nasal secretions and sputum.[36,66] In volunteer studies, Brunner and colleagues[66] noted that 42 and 73 percent of subjects had respective IgA nasal and sputum responses. Biberfeld and Sterner[43] found specific antibody in 44 of 55 sputum specimens from patients with *M. pneumoniae* infection of the lower respiratory tract. They noted IgA antibody in all specimens tested, IgG antibody in 24 of 31 specimens, and IgM antibody in 13 of 27 specimens.

SPECIFIC CELL-MEDIATED IMMUNITY. Fernald and coworkers[190,191] have shown that lymphocytes from adults previously infected with *M. pneumoniae* undergo blast transformation when cultured in vitro in the presence of *M. pneumoniae* organisms. In age-related studies, researchers noted that only one of nine children younger than 4 years with documented previous infection had evidence of specific cell-mediated immunity as measured by lymphocyte stimulation.[194] In contrast, 7 of 12 children older than 4 years and 87 percent of an adult group demonstrated specific lymphocyte stimulation. This study suggests that specific cell-mediated immunity increases as a function of age and depends on repeated infection. Koh and colleagues[347] noted high levels of interleukin-4 (IL-4) and a high IL-4/interferon-γ ratio in the bronchoalveolar lavage fluid of children with *M. pneumoniae* pneumonia, thus suggesting a predominant T_H2-like cytokine response.

Martin and colleagues[433] found that leukocytes from volunteers with *M. pneumoniae* infection demonstrated chemotaxis in the presence of the organism, whereas leukocytes collected before infection did not. Patients infected with *M. pneumoniae* also respond with interferon-α in their blood and nasopharyngeal secretions early in infection and with interferon-γ during convalescence.[491,492]

NONSPECIFIC RESPONSES. Antibodies to several diverse antigens develop during human infection with *M. pneumoniae*. The best known of these antibodies are cold agglutinins, and they are useful in the diagnosis of *M. pneumoniae* pneumonia.[134,186,266,311,610] Cold agglutinins are directed against the I antigen of erythrocytes.[309,395,610] Most pneumonias in which serum cold agglutinins are noted are caused by *M. pneumoniae*. Cold agglutinins are detected in the serum of approximately 75 percent of patients with *M. pneumoniae* pneumonia; they are less common in *M. pneumoniae* infection without pneumonia.[84]

Patients with *M. pneumoniae* also frequently develop antibodies to the MG strain of nonhemolytic streptococci[393] and occasionally to *M. genitalium*,[397] *M. hominis*,[573] *Mycoplasma hyorhinis*, *Mycoplasma orale*, *Mycoplasma pulmonis*, *M. salivarium*, and *Mycoplasma mycoides* variety *mycoides*, the etiologic agent of contagious pleuropneumonia of cattle.[385] Cross-reacting antibodies to filamentous hemagglutinin and pertactin of *Bordetella pertussis* also

*See references 1, 26, 30, 46, 146, 205, 295, 328, 349, 372, 410, 411, 415, 486, 489, 496, 497, 548, 613, 614, 638, 663.

†See references 67-69, 73, 160, 193, 266, 291, 306, 392, 403, 538, 579, 653.

occur.[681] Other heterologous antibodies found in the serum of patients with *M. pneumoniae* infection include those to smooth muscle, the mitotic spindle apparatus, brain, lung, liver, and Wasserman (WR) cardiolipin antigen.[36,44,396] In addition to these findings, Biberfeld and Norberg[40] detected immune complexes by the platelet aggregation technique in the sera of 16 of 39 patients with acute respiratory illness caused by *M. pneumoniae*. Mizutani and Mizutani[462] demonstrated the presence of circulating immune complexes in most patients with pneumonia caused by *M. pneumoniae*. The same investigators also detected rheumatoid factor in the sera of patients with *M. pneumoniae disease*.[463]

Possible Mechanisms of Disease Production

Numerous studies have been performed in an attempt to understand the pathogenesis of respiratory disease caused by mycoplasmas.[69,102-104,117-119,125,127-130] Of particular interest in human *M. pneumoniae* infection is the apparent high prevalence of infection in infants, children, adolescents, and young adults but the frequently mild nature of disease in infants and young children in comparison with older patients. Some studies suggest that the more severe disease in older patients is associated with reinfection and is mediated somewhat by immunologic responses.

Organ culture and animal studies indicate that damage at the site of primary infection—the respiratory epithelium—is the result of close organism-cell attachment.[102,128,130,288,399,400,484,536,675] This attachment of organism to cell uses neuraminic acid receptors on the cell.[612] In an organ culture system with *M. mycoides* variety *capri*, ciliary damage was decreased when the cellular receptor sites were treated with receptor-destroying enzyme.[102] Lipman and associates[399,400] noted that one attenuated *M. pneumoniae* strain had lost its ability to cytadsorb. The close association of organism and cell allows the transport of specific damaging material to the cell. Although the precise nature of this substance is not known, the data available suggest that it might be hydrogen peroxide. It is liberated by *M. pneumoniae* in vitro; in organ culture studies, hydrogen peroxide has been shown to be the damaging factor in another *Mycoplasma* infection.[102,400,401] In cell culture, *M. pneumoniae* inhibits host-cell catalase activity.[10] This inhibition of catalase activity enhances the toxicity of the hydrogen peroxide generated by the microorganism. *M. pneumoniae* also enters host cells and persists intracellularly for at least 7 days.[24]

Damage to ciliated respiratory epithelial cells also could be caused by the recently identified ADP-ribosylating cytotoxin.[327] Another possible important component of *M. pneumoniae* pathogenicity is the induction of proinflammatory and other cytokines during infection.[710]

Fernald and associates[194] noted that specific cell-mediated immunity to *M. pneumoniae* as measured by lymphocyte transformation becomes more prevalent with increasing age, as does specific antibody. Their studies suggest that more than one exposure to antigen may be necessary to elicit both humoral and cellular responses. Fernald and Glezen,[195] in an inactivated *M. pneumoniae* vaccine trial in children, noted that lymphocyte sensitivity developed in many recipients, but not a humoral antibody response. In a trial of an inactivated vaccine in adults, Smith and associates[607] found that on challenge infection, an exaggerated illness occurred in vaccinees who failed to form humoral antibodies after immunization. These findings have led to the consideration that persistent specific cell-mediated responsiveness might contribute to the pulmonary process in *M. pneumoniae* infection. However, the incubation period of illness in adults and children is similar, which argues against the sensitization theory.[114]

Foy and associates[215] noted that complement-fixing antibodies remained elevated for 2 to 9 years after infection with pneumonia but fell quickly after the second year in persons with mild illness. Protection against re-infection was better in those who previously had pneumonia than in those with mild symptoms.

CLINICAL MANIFESTATIONS

Pneumonia

Pneumonia is the most important clinical manifestation of *M. pneumoniae* infection, and this agent is responsible for 10 to 20 percent of all cases of pneumonia.* The highest incidence of pneumonia caused by *M. pneumoniae* in Seattle occurred in children 5 to 14 years of age.[214] In a study in Chiba Prefecture, Japan, researchers noted that the peak age of lower respiratory tract illness caused by *M. pneumoniae* was 4 years.[488] In a prospective study of community-acquired pneumonia in Finland, 11 percent of the children with *M. pneumoniae* infection were younger than 5 years of age, 32 percent were between 5 and 9 years of age, and 57 percent were 10 to 14 years of age.[267] Although researchers frequently state that *M. pneumoniae* pneumonia rarely occurs in children younger than 5 years of age, in actuality, the incidence in this group was found to be about twice that noted in young adults in Seattle.[214] Pneumonia caused by *M. pneumoniae* occurs less commonly in children younger than 2 years of age and rarely in infants younger than 6 months of age. The apparent frequency of *M. pneumoniae* pneumonia is influenced by the relative occurrence of pneumonia caused by other pathogens. During the child's first 5 years of life, *M. pneumoniae* is only one of many agents (e.g., respiratory syncytial virus, adenoviruses, parainfluenza viruses, influenza viruses, *Streptococcus pneumoniae*, *Haemophilus influenzae*) that cause pneumonia. During later childhood and adolescence, pneumonia as a consequence of infection with these other agents is a rare event; therefore *M. pneumoniae* is the leading cause of pneumonia in these persons.

Because isolation rates of *M. pneumoniae* during both endemic and epidemic periods do not vary greatly by season, as do those of common respiratory viruses, the proportion of patients with *M. pneumoniae* pneumonia increases during the summer months.

SYMPTOMS AND SIGNS. Since 1961, a large number of studies have reported the frequency of signs and symptoms in *M. pneumoniae* infection.† Unfortunately, many studies have included only special populations such as the military and, with few exceptions, community investigations have failed to indicate differences by age. In only three investigations have data regarding children been itemized separately.[64,211,629] Table 208–2 presents the relative frequency of symptoms and signs as compiled from eight studies in which both children and adults were included. The hallmark of pneumonia caused by *M. pneumoniae* is fever and cough. The onset of illness usually cannot be demarcated clearly, but malaise, fever, and headache are early complaints. Cough has an onset 3 to 5 days after the beginning of illness and is initially nonproductive. Foy and colleagues[218] and Biberfeld and coworkers[41] noted that 77 and 100 percent, respectively, of the patients that they studied had maximal temperatures greater than 38.9° C (102° F). Copps and associates[132] found that 58 percent of the group that they evaluated had temperatures higher than 39.4° C (103° F) and that 4 percent had temperatures higher than 40.6° C (105° F).

The reporting of headache in association with *M. pneumoniae* pneumonia has varied considerably. Nakao and associates[490]

noted this complaint in only 8 percent of subjects, whereas Biberfeld and associates[41] and Foy and colleagues[218] reported it in two thirds of those studied. Chills and the production of sputum are present in about 50 percent of ill patients. Again, great differences among investigations are noted, and they probably are related to the relative ages of the patients.

Coryza is unusual in *M. pneumoniae* pneumonia; therefore its occurrence should suggest another etiologic agent for illness in a specific patient. In a study involving children exclusively, Stevens and colleagues[629] noted that coryza occurred more commonly in young children; as might be expected, they found productive cough more frequently in their older patients. Hoarseness, earache, sore throat, gastrointestinal complaints, and chest pain occur in approximately 25 percent of patients.

On physical examination, about 75 percent of patients have auscultatory evidence of pneumonia, and approximately half have pharyngitis. Remarkable lymphadenopathy, particularly with cervical involvement, is noted in approximately 25 percent of patients. Twenty-one percent of the patients studied by Foy and associates[218] had otitis media. In other studies, this manifestation was noted in about 5 to 10 percent of cases. Conjunctivitis was reported in almost half the patients reported by Fransen and associates.[224] In contrast, except for Jansson and colleagues,[312] who noted conjunctivitis in 3 percent of their study group, this finding was not mentioned in the other reports. Similarly, rash was reported in 6, 11, and 17 percent, respectively, in the studies in Minnesota, Wisconsin, and Seattle,[132,219,424] but it was not mentioned in the other studies.

The most common finding on chest auscultation is dry rales, but musical rales with expiration are noted occasionally. Rales usually persist for 2 weeks, and hearing them a month or more after the onset of disease is not unusual. Occasionally, patients have no auscultatory evidence of pulmonary disease throughout their illness, in spite of the presence of abnormalities on chest radiographs. During illness, cough becomes increasingly prominent; initially it is nonproductive, but later, it may produce a frothy white sputum in older children and adolescents. The sputum also may appear purulent and contain blood. Cough persists for 3 to 4 weeks and longer after nonrespiratory symptoms such as fever and headache have subsided.

In a study of 44 children with lower respiratory illness caused by *M. pneumoniae*, Stevens and associates[629] noted the following frequencies of symptoms and signs: cough, 97 percent; malaise, 82 percent; vomiting, 40 percent; abdominal pain, 35 percent; headache, 32 percent; rash, 20 percent; fever higher than 38° C (>100.4° F), 78 percent; rales, 78 percent; pharyngitis, 32 percent; rhonchi, 30 percent; bronchial breathing, 27 percent; and otitis media, 27 percent. Foy and coworkers[211] found that chills and productive cough were more common in adults than children and that temperatures tended to be higher in children.

In a large study involving 108 children with *M. pneumoniae infection*, wheezing occurred with the acute illness in 40 percent.[565] When the children in this study were evaluated 3 years after their acute illness, they were found to have three indicators of lung function that had mean values significantly lower than those in control children.

Few reports specifically describe pneumonia caused by *M. pneumoniae* in young children.[21,95,122,212,254,488,603,629] However, a review of the case descriptions available indicates that illness, when it occurs, can be severe and relatively prolonged when compared with common viral and bacterial infections. Singer and DeVoe[603] reported a 3-year-old severely ill child who had a temperature of 39.4° C, a pulse of 150, and a respiratory rate of 40. Diffuse pulmonary involvement of the right upper lobe and lingular segments of the left lower lobe was observed by radiography, although rales and altered breath sounds could not be heard. The patient's condition worsened over a 6-day period. At this time, specific therapy with erythromycin was instituted, and slow recovery followed. The child had a normal white blood cell count, transiently elevated serum aspartate aminotransferase and alanine aminotransferase values, and microscopic hematuria. Grix and Giammona[254] observed two 5-year-old children with extensive pneumonia, pleural effusions, and febrile periods of 10 and 16 days. Stevens and associates[629] reported a 5-year-old boy with pulmonary consolidation and aseptic meningitis, and Clyde and Denny[122] described an asymptomatic 3-year-old boy with a "feathery infiltrate" in the right upper lung field. In a family study, Foy and colleagues[212] investigated four children younger than 6 years. In a 4-year-old child, the pneumonia persisted for more than 1 month, and in this child's brother, the illness lasted approximately 2 weeks. I have seen a 4½-year-old girl with scattered infiltrates throughout both lung fields and febrile illness of 14 days' duration.[95]

Severe and extensive pulmonary disease occurs occasionally in *M. pneumoniae* infection.* Massive lobar pneumonia is noted on occasion, and pleural effusions are fairly common findings.† A number of cases of necrotizing pneumonitis with massive pleural effusions have been described.[109,691] All these children had protracted periods of fever and respiratory distress. The adult respiratory distress syndrome has been observed, and illness has suggested pulmonary embolism with infarction.[202,542,601,678] Chronic interstitial pulmonary fibrosis and fulminant fatal diffuse interstitial fibrosis have been noted in two adults with *M. pneumoniae* pneumonia, and localized bronchiectasis developed in a 20-year-old man at the site of previous acute lung infection.[108,244,323,639] Children who had a delay in onset or inadequate duration of macrolide treatment were found by Marc and associates[426] to have reduced lung diffusion capacity after

*See references 97, 100, 108, 109, 112, 131, 199, 202, 209, 254, 257, 331, 391, 404, 421, 426, 452, 479, 489, 510, 514, 523, 542, 554, 596, 599, 601, 603, 616, 621, 691.

†See references 20, 100, 107, 109, 123, 149, 199, 202, 254, 407, 410, 480, 487, 489, 510, 603, 621, 691.

contracting *M. pneumoniae* pneumonia. A 5-year-old girl had severe necrotizing pneumonitis, and an adult had bronchiolitis obliterans organizing pneumonia.[404,514] *M. pneumoniae* pneumonia is generally more severe in patients with preexisting cardiorespiratory problems, immunodeficiencies, and sickle-cell disease.[31,112,223,231,314,452,528,596,616]

Four patients—one child, one adolescent, and two adults—have been found to have lung abscesses in association with *M. pneumoniae* infection.[108,391,599] The illness in the adolescents and adults was characterized by productive cough and chest pain for 2 to 4 weeks. In one patient, clinical recovery and clearance of the pulmonary lesion were dramatic with tetracycline therapy; two other patients received suboptimal therapy but eventually recovered. The child with a lung abscess was a 6-year-old girl who had a 7-day history of cough and a 4-day history of fever.[108] In addition to the abscess, she had pleural effusion, thrombocytopenia, and disseminated intravascular coagulation. One 18-year-old man with extensive consolidation of the right lower lung field had residual pleural scarring 8 months after the acute illness.[480]

A newborn who contracted congenital pneumonia, probably via vertical transmission of *M. pneumoniae*, has been described.[677]

Clyde[121] reported factors that correlated with *M. pneumoniae* pneumonia in a study of 1139 subjects with community-acquired pneumonia. Positive factors were sore throat, headache, fever of 38.9° C or higher, exanthem, family size of four or more, and ear infection. In the same study, pneumonia did not correlate with coryza, leukocytosis (15×10^9/L or more and 10×10^9/L or more), preexisting disease, recurrent pneumonia, hospitalization for treatment, or cigarette smoking.

Although recovery from *M. pneumoniae* pneumonia is usually complete, two studies suggest that persistent abnormalities in lung function can occur after illness.[469,565]

RADIOGRAPHY. Because the classic clinical entity, primary atypical pneumonia, has numerous causes but often is used as a synonym for *M. pneumoniae* pneumonia, much confusion has ensued about the spectrum of the radiographic appearance of the specific mycoplasmal infection. The radiographic pattern of primary atypical pneumonia is varied, but bilateral, diffuse, reticular infiltrates are common components.[409,580,606] Subsequent study has indicated that the diffuse interstitial pattern is an uncommon finding in *M. pneumoniae* infection and more often is the result of infection with other agents such as viruses, fungi, and *Chlamydia*.[63,233,498,540,674]

Brolin and Wernstedt[63] carefully evaluated the radiographic findings in 56 patients with significant *M. pneumoniae* pneumonia; 21 of the patients were younger than 20 years. They noted the following distribution of different patterns: typical lobar pneumonia, 8 patients; predominantly alveolar but not total consolidation, 13; interstitial (either reticular or nodularetic), 20; a combination of lobar pneumonia and other alveolar involvement without total consolidation, 2; a combination of lobar involvement and interstitial, 10; and a combination of alveolar involvement without total consolidation and interstitial, 3. Alveolar patterns were more common in females; interstitial involvement was found more frequently in males. Twenty-two percent of patients had enlargement of the hilar or paratracheal lymph nodes, and 14 percent had pleural effusion.

The persistence of radiographic changes is variable. Brolin and Wernstedt[63] noted that 13 percent of their patients who underwent follow-up studies had abnormal findings more than 4 weeks after the initial study. They observed that persistence tended to be longer in patients with alveolar disease than in those with interstitial patterns. The degree of clinical symptoms and pulmonary physical findings frequently correlates poorly with the apparent degree of involvement noted on radiographs. In many patients with significant symptoms, only minimal interstitial changes are observed. In other instances, patients with lobar pneumonia often have few clinical findings indicating pulmonary disease.

Lee and colleagues[376] reported the chest CT features in 11 children and 5 adults with *M. pneumoniae* pneumonia. The children had the following findings: lobar or segmental consolidation 100%, pleural effusion 82%, lymphadenopathy 82%, and volume decrease of the involved lobe 73%. None of the children had diffuse nodules of ground-glass attenuation, septical thickening, or bronchial wall thickening. In contrast with the children, the adults had diffuse nodules of ground-glass attenuation 80%, septical thickening 40%, lymphadenopathy 40%, bronchial wall thickening 40%, and volume decrease of the involved lobe 20%. None of the adults had lobar or segmental consolidation and pleural effusion.

Kim and associates[339] performed high-resolution computed tomography on 38 children who had been hospitalized with *M. pneumoniae* pneumonia 1 to 2.2 years previously. Abnormalities in two or more lobes, which corresponded to the initial chest radiographic infiltrates, were found in 37 percent of the children. Young age (<8 years) at the time of hospitalization and high *M. pneumoniae* antibody titer were found to be risk factors for the subsequent abnormalities.

NONSPECIFIC LABORATORY DATA. The total leukocyte count in patients with pneumonia caused by *M. pneumoniae* is most often normal, but variation is considerable.* In a group of more than 250 children younger than 15 years, Foy and associates[211] noted that 30 percent and 6 percent had total leukocyte counts greater than 10,000 and 15,000 cells/mm^3, respectively. In a group of 45 children, Stevens and colleagues[629] observed leukocytosis in 33 percent of patients and leukopenia in one patient. Sixty-seven percent of the children had neutrophilia, and one patient had neutropenia. An increased percentage of band form neutrophils in *M. pneumoniae* pneumonia is an unusual finding.

The erythrocyte sedimentation rate is elevated in all cases,[39,132,311] and this elevation is usually marked. Biberfeld and colleagues[39] noted that 16 of 37 patients had erythrocyte sedimentation rates of 50 mm/hr. Serologic tests for syphilis are found to be falsely positive on occasion, and serum cold agglutinins and antibodies to *Streptococcus* MG antigen are common findings.[37,84,88,151] Results of the direct Coombs test are frequently positive, and elevated levels of serum IgM are noted.[37,186] Urinalysis results are generally normal.

Respiratory Disease Other than Pneumonia

COMMON COLD AND UNSPECIFIED UPPER RESPIRATORY ILLNESS. By strict definition (significant nasal symptoms, no pharyngitis, and minimal fever), *M. pneumoniae* rarely causes the common cold. However, mild upper respiratory illness is noted frequently as the only manifestation of *M. pneumoniae* infection in children, adolescents, and young adults.† The frequency of unspecified upper respiratory tract illness as a manifestation of *M. pneumoniae* infection, when compared with other manifestations resulting from infection with this agent, varies considerably among studies. Feizi[185] studied patients from a country practice in England and noted that 50 percent of the patients had upper respiratory tract symptoms. Illness in these persons was often prolonged, however, and lasted as long as 7 to 10 weeks. In a review in Scotland, only 3 percent of 596 *M.*

*See references 39, 132, 177, 211, 218, 225, 311, 465, 629, 674.
†See references 85, 133, 151, 161, 183, 185, 187, 194, 212, 218, 282, 373, 408, 465, 490, 502, 568.

pneumoniae infections were classified as upper respiratory tract illness. In studies of common respiratory illnesses in children in which viruses and other agents were sought, *M. pneumoniae* was noted in 2 to 5 percent of patients with upper respiratory tract illness.[85,151,408]

PHARYNGITIS AND NASOPHARYNGITIS. As noted in Table 208–2, pharyngitis is observed in approximately half of all patients with *M. pneumoniae* pneumonia. However, pharyngitis as the major manifestation of *M. pneumoniae* infection occurs less commonly. Parrott[525] found that 12 percent of children admitted to the hospital with severe "bronchitis-pharyngitis" had *M. pneumoniae* infection. Jensen and associates[318] noted the frequent occurrence of pharyngitis and otitis media in children infected with *M. pneumoniae*. In a study of 715 children and adolescents with pharyngitis, Glezen and colleagues[238] reported that 36.8 percent had group A streptococcal infection and 3.1 percent were infected with *M. pneumoniae*. When the *M. pneumoniae* infections were grouped by age, the peak (11.4%) occurred in the 12- to 14-year-old group, and none were observed in children younger than 6 years. Five patients with *M. pneumoniae* infection had concomitant group A streptococcal infection, but the illnesses in these cases could not be distinguished clinically from those caused by either agent alone. Cervical lymphadenopathy occurred in approximately 50 percent of those infected, and the pharyngeal lesion was exudative in 43 percent. In a study of 127 children with acute pharyngitis, 25 (20%) were found to have serologic evidence of *M. pneumoniae* infection.[174] Seven (28%) of these children had pharyngeal exudates and 10 (40%) had cervical lymphadenopathy.

In a study involving 131 adult patients with pharyngitis, 10.6 percent were found to have serologic evidence of *M. pneumoniae* infection.[351]

OTITIS MEDIA AND BULLOUS HEMORRHAGIC MYRINGITIS. Although the incidence has varied in different studies, otitis media is noted in approximately 5 percent of children and adolescents with *M. pneumoniae* pneumonia. The role of *M. pneumoniae* as an etiologic agent in common acute otitis media in children is unclear. Halsted and associates[258] noted that 12 percent of children with otitis media had serologic evidence of *M. pneumoniae* infection, but they were unable to recover the agent from middle ear fluid. In a study in which children were selected because of *M. pneumoniae* infection in a family member, 47 of 49 children with otitis media had *M. pneumoniae* infection.[318] Räty and Kleemola[545] used PCR to detect *M. pneumoniae* in 16 of 380 (4%) middle ear fluid samples from 138 children with acute otitis media.

In a volunteer study, myringitis developed in 13 of 52 subjects.[553] Findings were usually bilateral and associated with throbbing pain. The appearance of the tympanic membrane varied from mild injection to severe inflammation with edema. Hemorrhagic areas on the drum were noted in five subjects, and serous-appearing blebs containing blood were observed in two. Bullous myringitis also has been noted only occasionally with natural *M. pneumoniae* infection.[64,122,212,218,424,613] In one study of 148 children and adults with *M. pneumoniae* pneumonia, 27 (18%) were found to have bullous myringitis.[424] Using PCR Kotikoski and associates[355] studied middle ear fluid from 30 children and blister fluid from 12 children with acute meningitis and found no evidence of *M. pneumoniae* DNA.

SINUSITIS. Although clinically recognized sinusitis has been reported rarely in patients with *M. pneumoniae* infection, Griffin and Klein[253] found radiographic evidence of sinusitis in approximately two thirds of a group of Navy recruits with *M. pneumoniae* pneumonia. In general, the patients with sinusitis had more prolonged illness than did recruits without sinusitis. Savolainen and colleagues[575] noted that 11 of 310 patients with acute maxillary sinusitis had fourfold or greater rises in complement-fixing antibody to *M. pneumoniae*. In chronic suppurative maxillary sinusitis, cultures for *M. pneumoniae* have been performed but no organisms were isolated.[35,619]

ACUTE BRONCHITIS. Acute bronchitis characterized by fever, cough, and rhonchi, with or without associated pharyngitis, is a frequent manifestation of *M. pneumoniae* infection.* Of 40 patients with *M. pneumoniae* infection, Feizi[185] reported that 6 had bronchitis, 3 had upper respiratory tract illness plus bronchitis, and 1 had sinusitis plus bronchitis. In contrast to these findings, Hornsleth[283] noted that only 1 of 25 patients with *M. pneumoniae* infection had acute bronchitis. In the differential diagnosis of acute bronchitis, *M. pneumoniae* infection accounts for 10 to 20 percent of cases.[86,90,151,178,531]

CROUP. *M. pneumoniae* infection has been associated only occasionally with croup. Parrott[525] found no instances of *M. pneumoniae* infection in a large number of children with croup, and Chanock and Parrott[90] did not list this agent as an etiologic consideration in croup. In contrast, extensive studies in both Seattle and Chapel Hill have revealed that approximately 2 percent of croup cases are associated with *M. pneumoniae* infection.[151,210,240,407] Because no descriptions of clinical illness are available, a reasonable assumption is that croup caused by *M. pneumoniae* infection is generally mild and without distinguishing characteristics.

BRONCHIOLITIS AND INFECTIOUS ASTHMA. Approximately 5 percent of cases of bronchiolitis are caused by infection with *M. pneumoniae*, but the percentage varies among studies.[85,86,90,151,161,210,240,407,525] In two large studies, no instances of *M. pneumoniae*–associated bronchiolitis were reported.[282,283] *M. pneumoniae* also is a relatively common cause of asthmatic bronchitis and recurrent wheezing in asthmatic children.[34,281,292,519,589] Horn and associates[281] noted that *M. pneumoniae* was isolated from 6.6 percent of children with wheezy bronchitis, and Berkovich and associates[34] found *M. pneumoniae* infection in 7 of 33 episodes of wheezing in asthmatic children. Biscardi and coworkers[45] studied children 2 to 15 years of age hospitalized for severe asthma. Of 119 children with previously diagnosed asthma, 24 (20%) had *M. pneumoniae* infections during the exacerbation that caused their hospital admission. In 51 children with first asthma episodes, *M. pneumoniae* infection was demonstrated in 26 (50%). Children with a first attack of asthma associated with *M. pneumonia* infection were significantly more likely to have asthma recurrences than children whose primary episodes were not related to *M. pneumniae* infection. Lehtinen and colleagues[381] studied 220 children with wheezing associated with viral infection and found that 5% were co-infected with *M. pneumoniae*. Wheezing also occurs during *M. pneumoniae* pneumonia.[21,565] Freymuth and colleagues[228] identified *M. pneumoniae* in nasal aspirate samples by PCR in 3 of 132 children (2%) with acute exacerbations of asthma.

OTHER. Exacerbations of chronic obstructive pulmonary disease have been associated with *M. pneumoniae* infection.[105,368,449,609,701] By culture, Cherry and associates[105] did not obtain any *M. pneumoniae* isolates from the bronchial specimens of adults with chronic bronchitis. However, more recently, Kraft and colleagues,[357] using PCR, detected *M. pneumoniae* in the bronchoalveolar lavage or bronchial biopsy specimens of 9 of 18 adults with chronic asthma. Smith and associates[609] were unable to show that patients with chronic obstructive pulmonary disease had increased susceptibility to infection in comparison with

*See references 85, 86, 90, 178, 185, 282, 283, 490, 502, 525, 568.

normal subjects. Illness suggestive of pertussis has been described in three children.[369,629] Teig and associates[655] studied nasal brush specimens and induced sputum from 38 children with stable chronic lung disease and from 42 healthy controls for the presence of *M. pneumoniae* DNA by PCR. Specimens from 4 (10.5%) of the children with chronic lung disease had *M. pneumoniae* DNA, whereas none of the specimens from control patients were positive. In two provocative studies Esposito and coworkers[175,176] found that *M. pneumoniae* infections may play a role in recurrent respiratory infections in children. In their studies they found that children with tonsillopharyngitis or other respiratory infections due to *M. pneumonia* who were treated with azithromycin (10 mg/kg/d for 3 days weekly, for 3 weeks) were significantly less likely to have recurrent repiratory tract infections than children with similar *M. pneumoniae* infections who did not receive azithromycin treatment.

Exanthem and Enanthem

Exanthem as a manifestation of *M. pneumoniae* infection is a common occurrence, but its incidence has varied considerably among different studies.* In large studies involving children in which *M. pneumoniae* infection was evaluated in a specific geographic area, the incidence of exanthem has varied from 3 to 33 percent.† Foy and associates[218] noted rash in 17 percent of 319 patients with *M. pneumoniae* pneumonia during a 5-year surveillance period. In a study involving only children, Stevens and colleagues[629] noted exanthem in 9 percent of their patients. Copps and coworkers,[132] in a community outbreak in La Crosse, Wisconsin, found that 11 percent of their patients with pneumonia also had rash.

The cutaneous manifestations in *M. pneumoniae* infection are protean. Most common is an erythematous maculopapular rash that is most prominent on the trunk and back; the lesions may be discrete (rubelliform) or confluent (morbilliform). Though not the most common cutaneous manifestations of *M. pneumoniae* infection, erythema multiforme and Stevens-Johnson syndrome are the most often reported and the most serious.‡

In Table 208–3 the clinical findings in 29 well-documented cases of *M. pneumoniae* infection with exanthem are presented; in Table 208–4 the specific mucocutaneous findings in 20 of the 29 patients are itemized. Of the total group, all but 8 were males, 24 of the 29 were younger than 20 years, and 12 of the 20 were younger than 11 years. The duration of exanthem was longer than 7 days in all but 2 patients; all patients were febrile, and in 17 cases, the rash occurred during fever.

Fourteen patients had generalized ulcerative stomatitis, and seven had tonsillitis or pharyngitis. Severe conjunctivitis was observed in eight patients, and this manifestation was seen only in those with vesicular or bullous cutaneous lesions. All eight patients with severe conjunctivitis also had generalized ulcerative stomatitis. Surprisingly, vesicular or bullous exanthems with oral and eye lesions (Stevens-Johnson syndrome) rarely occur in females.[20,437,629]

As noted in Table 208–3, 25 of the 29 patients had pneumonia. The occurrence of rash as the major manifestation of *M. pneumoniae* infection is probably rare. In a study of 112 patients who had suspected infectious exanthems without pneumonia, Cherry and associates[99] could find none with *M. pneumoniae* infection. Foy and colleagues[212] noted a 2-year-old child with only rash, Stutman[633] reported a 15-year-old boy with Stevens-Johnson syndrome but not pneumonia from whom the organism was recovered from a vesicular lesion, and Ruhrmann and Holthusen[562] observed frequent cases of mild erythema multiforme without pneumonia.

In an analysis of 42 cases of erythema multiforme seen during a 20-year period, Villiger and associates[680] noted a presumptive or definite diagnosis of *M. pneumoniae* infection in 14 children. Nine of the children were boys (64%), and eight of the illnesses had mucous membrane involvement.

Many patients with *M. pneumoniae* infection and exanthem have a history of antibiotic administration before development of the rash; this observation suggests the possibility that the rash is drug induced rather than a result of the infectious process. As noted in Table 208–3, 17 patients had received antibiotics before the rash appeared, and the exanthem was present before the administration of antibiotic therapy in 10. Although these data incriminate the infection as a cause of exanthem, the large number

20	417	11	F	Papular; most marked on hands and feet	0	0

Modified from Cherry, J. D., Hurwitz, E. S., and Welliver, R. C.: Mycoplasma pneumoniae *infections and exanthems. J. Pediatr.* 87*:369-373, 1975.*

of cases in association with the administration of antibiotic raises the possibility that the antibiotic intensifies the dermosensitive potential of the infectious agent in a manner similar to that noted between Epstein-Barr virus and ampicillin in infectious mononucleosis. *M. pneumoniae* has been recovered from the blister fluid of two patients with erythema multiforme.[415]

Other unusual cutaneous manifestations include erythema nodosum, pityriasis rosea, varicella-like, urticaria, and Cockade purpura.[100,243,248,371,489,562,583,656]

Cardiac Manifestations

Cardiac involvement during *M. pneumoniae* infection generally is considered to be unusual.* However, studies of Pönkä[534] and Sands and associates[572] and survey data of Noah[508] and Assaad and Borecka[18] indicate that *M. pneumoniae* myocarditis and pericarditis are important causes of both morbidity and mortality. In a study of fatal viral and mycoplasmal infections, Assaad and Borecka[18] noted six cardiovascular deaths related to *M. pneumoniae* infection during a 9-year period. Noah[508] found that 1 percent of 700 patients with *M. pneumoniae* infection had cardiac manifestations as the main clinical feature. Pönkä[534] published findings of a 7-year study involving 560 patients with serologic evidence of *M. pneumoniae* infection. In this group, 69 patients with cardiac manifestations were detected; of these 69 patients, 25 had carditis for which no causal agent other than *M. pneumoniae* could be incriminated. Pönkä[534] also reviewed the world literature and found a total of 33 other cases of carditis.

Of 25 carefully studied patients, 17 had respiratory symptoms before the diagnosis of carditis and 10 had radiologically confirmed pneumonia. All but four patients had fever. Of the 25 patients, 2 were younger than 10 years and 2 were in the 10- to 19-year age group. Of the 33 cases in the literature, 7 were 20 years or younger. Of this survey group, 25 of the 33 had respiratory illness and in 19 it was recorded as pneumonia.

Of the 25 patients in Finland reviewed by Pönkä, 6 had pericarditis and the remainder had perimyocarditis. Antibiotic therapy in 11 patients did not appear to shorten the duration of illness or diminish the number of cardiac sequelae. At a 16-month follow-up, 11 patients had persistent cardiac damage. Another interesting aspect of this study was the finding of rises in *M. pneumoniae* complement-fixing antibody titer in five adults with myocardial infarcts.

Chergui and associates[94] described a 45-year-old man with bilateral interstitial infiltrates and second-degree heart block. He was treated with erythromycin, and the heart block, fever, and respiratory distress cleared on hospital day 5.

Hematologic Manifestations

Severe hemolytic anemia has been reported on several occasions in patients with *M. pneumoniae* infection.* Most cases of *M. pneumoniae* hemolytic anemia have been associated with marked pulmonary involvement. Stevens-Johnson syndrome is a common associated finding, and myocarditis has been noted on two occasions.[131,184,185,337,629] In general, severity of illness correlates with high titers of cold agglutinins.

The hemolysis may be severe and acute, often with a 50 percent reduction in hemoglobin concentration. In contrast to uncomplicated pulmonary disease, the leukocyte count in patients with hemolytic anemia frequently is elevated markedly with a predominance of neutrophils. Results of the direct Coombs test are usually positive. Clinical experience suggests that administration of steroids in conjunction with proper antibiotic therapy may be beneficial in this illness. Boccardi and associates[53] observed a 7-year-old boy with hemolytic anemia and transitory paroxysmal cold hemoglobinuria.

Feizi[186] has demonstrated that clinically inapparent compensated hemolysis frequently is associated with *M. pneumoniae* pulmonary infection. Fiala and associates[198] noted that bone marrow suppression also contributed to the anemia in a patient whom they studied. Ruhrmann and Holthusen[562] reported a hemorrhagic variant of erythema multiforme (Cockade purpura) similar to Henoch-Schönlein disease in *M. pneumoniae* infection; they

*See references 98, 131, 145, 184, 186, 198, 284, 337, 419, 557, 585, 602, 629, 643.

*See references 93, 94, 106, 181, 184, 230, 248, 333, 337, 369, 390, 486, 507, 638.

also noted severe thrombocytopenia not associated with hemolytic anemia. Gill and Marrie[236] reported a 27-year-old man who had hemophagocytosis with an *M. pneumoniae* infection. Two children with hemophagocytic lymphohistiocytosis in association with *M. pneumoniae* infections have been reported.[301] Also noted has been a 4-year-old girl with neutropenia, thrombocytopenia, and acute hepatitis.[92] Severe *M. pneumoniae* infection with pneumonia, thrombocytopenia, and disseminated intravascular coagulation has been described.[108,111]

Gastrointestinal Findings

NONSPECIFIC FINDINGS. Approximately 25 percent of patients with *M. pneumoniae* pneumonia have nausea, vomiting, diarrhea, or some combination thereof (see Table 208–2). Aside from these complaints, gastrointestinal problems in association with *M. pneumoniae* infection are rare events. Stevens and associates[629] found that 15 percent of a group of 44 children with infection had notable abdominal pain. Referred abdominal pain with pneumonia also has been observed.[185]

LIVER INVOLVEMENT. Liver involvement in *M. pneumoniae* infection is a surprisingly rare event. Levine and Lerner[389] reported that mild increases in transaminases occur and that acute and chronic active hepatitis has been noted with respiratory symptoms and proven *M. pneumoniae* infection, but they provided no further information. MacLean[417] reported a 13-year-old girl who initially had a sore throat and then 9 days later had clinical and laboratory evidence of hepatitis. Murray and associates[483] presented a case report of an adult with typical *M. pneumoniae* pneumonia in whom liver function and enzyme studies indicated hepatitis. Helms and colleagues[269] noted that 6 of 17 patients with *M. pneumoniae* pneumonia had elevated aspartate aminotransferase values. Enzyme changes have been observed in other case evaluations,[391,424,603] and hepatic necrosis has occurred.[419]

Simonian and Janner[602] reported a 12-year-old boy who had pleural effusion, hepatitis, and hemolytic anemia. Narita and associates[497] noted two children with lymphadenopathy and liver dysfunction. These two patients are of interest because both had mycoplasmemia and neither had pneumonia.

SPLENIC INFARCT. Two children (a 13-year-old girl and a 10-year-old boy) with pneumonia due to *M. pneumoniae* had splenic infarcts and transient antiphospholipid antibodies.[708]

PANCREATITIS. In 1974 Märdh and Ursing[429] reported six patients with respiratory illnesses, serologic evidence of *M. pneumoniae* infection, and pancreatitis. In four patients, pancreatic symptoms began 1 to 2 weeks after the onset of respiratory illness; in the other two patients, the pancreatitis was subclinical. Diabetes developed in two patients, one of whom died. At postmortem examination, pneumonitis and pancreatitis were confirmed. In a study of pancreatitis, Leinikki and Pantzar[383] noted that sera from 18 of 56 patients had rises in complement-fixing antibody titer to *M. pneumoniae*. Because none of the patients in this study had respiratory illness suggestive of *M. pneumoniae*, the investigators suggested that perhaps the antibody responses were not specific for *M. pneumoniae* infection but were caused by a cross-reacting infection or were the result of autoantigens from pancreatic damage. Leinikki and associates[384] have conducted further studies; their belief is that the antibody response is nonspecific, but their data neither confirm nor refute this assumption. In another study, Freeman and McMahon[227] also noted serologic evidence of *M. pneumoniae* infection in 33 percent of patients with pancreatitis. Oderda and Kraut[513] reported a 22-month-old girl with pancreatitis and a rise in complement-fixing antibody titer to *M. pneumoniae*. This child had no respiratory symptoms.

Arthritis

Mycoplasmas other than *M. pneumoniae* are a common cause of arthritis in animals other than human beings.[126,310] In many instances the animal diseases suggest human rheumatoid arthritis. Consequently, researchers have searched extensively for mycoplasmas in humans with rheumatoid arthritis, but to date, no associations have been established. However, *M. pneumoniae* infection clearly is associated occasionally with joint manifestations.* In a review of 1259 patients with *M. pneumoniae* infection, Pönkä[533] noted transient arthritis in 0.9 percent. Two patients were found to have Reiter syndrome. Hernandez and colleagues[273] reported seven instances of arthritis in 38 persons with *M. pneumoniae* respiratory disease. In one patient, the illness lasted 18 months and was associated with the development of rheumatoid factor.

Twenty-one instances of illness suggestive of rheumatic fever have been described.[32,115,320,367,473,486,493,584,699] In all 21 patients, large joints were involved; 18 patients had joint swelling or effusion, whereas 3 had only pain. Most patients had a history of preceding respiratory illness with sore throat, and 10 of the 21 had radiographic evidence of pneumonia. The sedimentation rate was elevated in all patients in whom the test was performed. One child had an erythema marginatum–like rash, as well as polyarthritis and fever.[473] Poggio and colleagues[530] reported a child with reactive arthritis 3 weeks after the onset of diarrhea and a respiratory tract infection. Leukocytoclastic vasculitis plus polyarthritis associated with *M. pneumoniae* infection has been described in a young adult.[527]

Muscular Disease

Berger and Wadowksy[33] reported a 15-year-old girl with right lower lobe pneumonia, hepatitis, and rhabdomyolysis associated with *M. pneumoniae* infection. Minami and associates[458] have reported a 4-year-old boy with pneumonia and a rhabdomyolysis associated with a marked titer rise to *M. pneumoniae* using a passive agglutination assay. Polymyositis has been noted in association with *M. pneumoniae* infection on six occasions.[526]

Neurologic Disease

Several large community and military studies of *M. pneumoniae* pneumonia and other respiratory illnesses are notable in that neurologic disease is not described.[88,132,177,218,311,465,479] However, other studies, particularly those performed more recently, indicate a surprising spectrum of neurologic illness associated with *M. pneumoniae* infection.† The failure to find neurologic disease in the initial large studies mentioned was probably due not to its absence but to the orientation of the investigators; neurologic disease was not studied under the respiratory investigation protocols. In three large studies of *M. pneumoniae* illness involving 1856 cases, 2.6 to 4.8 percent had neurologic illness.[502,508,535] Assaad and Borecka[18] noted five fatal *M. pneumoniae* infections in which central nervous system (CNS) findings were the major clinical manifestations.

In 1973 Lerer and Kalavsky[388] reported 5 cases of neurologic disease associated with *M. pneumoniae* infection and analyzed 45 cases from the literature. They noted the following frequencies

*See references 32, 144, 231, 234, 273, 320, 367, 369, 429, 484, 493, 533, 564, 699.

†See references 1, 3-5, 11, 13, 14, 16, 18, 19, 22, 26, 29, 30, 39, 42, 46, 65, 76, 110, 120, 124, 147, 156, 162, 179, 185, 196, 203, 225, 241, 275, 276, 284, 302, 328, 332, 338, 341, 346, 350, 352-354, 361, 370, 382, 386, 398, 414, 436, 457, 476, 481, 494, 502, 506, 508, 512, 514, 516, 522, 535, 561, 567, 578, 594, 604, 614, 623, 625, 629, 642, 644, 657, 663, 665, 675, 684, 695, 702.

of specific clinical involvement: generalized encephalitis, 30 percent; spinal nerve roots, 30 percent; meningitis, 20 percent; cranial nerves, 20 percent; focal encephalitis, 16 percent; cerebellum, 14 percent; psychosis, 8 percent; and spinal cord, 2 percent. Combined involvement was noted in 36 percent of cases; in 79 percent, a history of antecedent respiratory illness was elicited. Fifty-three percent of the patients were 20 years or younger, and 15 percent were younger than 10 years. Eighty percent of the children and adolescents were males. The onset of neurologic disease occurred 3 to 23 days after the onset of respiratory illness, with a mean value of 10 days. Five deaths were noted, and 22 percent of the survivors had residual neurologic deficits.

In a review of 61 patients with *M. pneumoniae*–associated neurologic disease during a 24-year period in Helsinki, Finland, Koskiniemi[354] noted that 45 of the patients were children and that all these children had encephalitis. Of the total group, 5 patients (8%) died and 14 (23%) had severe sequelae.

In a study of acute childhood encephalitis in Toronto, Canada, 9 of 50 children (18%) with adequate microbiologic study had evidence of *M. pneumoniae* infection.[350] Interestingly, four of the nine children also had evidence of concomitant viral infection. In a further study of encephalitis at the same center during a 5-year-period, researchers noted that 50 of 159 children (31%) with encephalitis had evidence of *M. pneumoniae* infection[46]; in this analysis, 30 of the 50 cases (60%) had microbiologic evidence of other concomitant infections. Respiratory prodromal symptoms preceded the encephalitis in approximately 67 percent of the patients in whom the diagnosis was based on culture, PCR, or both. Two children had acute demyelinating encephalomyelitis. Long-term neurologic sequelae occurred in 48 to 64 percent of cases. During the past decade 1988 patients were referred to the California Encephalitis Project.[110] *M. pneumoniae* was the most common agent implicated; there were 111 patients with evidence of *M. pneumoniae* infection and 84 (76%) of these patients were children.

In other studies, aseptic meningitis is reported more frequently; other less common findings include poliomyelitis-like syndrome, bilateral sensorineural deafness, Reye syndrome, cerebral infarction, optic disk swelling, brain stem syndrome, transverse myelitis, psychosis, cerebellar syndrome, radiculopathy, brachial plexus neuropathy, demyelinating polyneuropathy with syndrome of inappropriate secretion of antidiuretic hormone (SIADH), acute disseminated encephalomyelitis (ADEM), bilateral striatal necrosis, Tourette syndrome, intracranial hypertension, Bell palsy, and Guillain-Barré syndrome.* Arthur and Margolis[16] noted the appearance of *Mycoplasma*-like structures in granulomatous angiitis of the CNS at postmortem examination of a 35-year-old man.

Mixed Infections

In many studies of *M. pneumoniae* infection, cultural or serologic evidence of concomitant or sequential infection with other infectious agents has been noted.† In a large study of patients hospitalized with acute respiratory illness, Fransen and associates[224] found that 64 percent of patients with rises in complement-fixing antibody titer to *M. pneumoniae* also had antibody titer rises to viral, chlamydial, or bacterial agents. In this group, the most common concomitant infections were with parainfluenza viruses. The occurrence of mixed infection did not appear to have a pronounced effect on clinical manifestations; the only significant difference between patients with mixed infection and those with single *M. pneumoniae* infection was the more common finding of a high erythrocyte sedimentation rate in the former group. In several other large studies of disease caused by *M. pneumoniae*, concomitant infections were common, but no evidence of synergistic or antagonistic roles of one agent for another was noted.[187,238,466,622,623] Renner and associates[550] found a lower than expected frequency of seropositivity to *M. pneumoniae* in 91 serum pairs with seroconversion to influenza A virus.

The high rate of possible mixed infections in the large encephalitis study in Toronto is of particular interest.[46] In addition to common respiratory viruses and enteroviruses, they noted herpes group viruses, *Bartonella henselae*, and *Mycobacterium tuberculosis*. In studies of *Bordetella pertussis* infection, evidence of mixed infection with *M. pneumoniae* or perhaps serologic cross-reactivity has been found repeatedly.[303,681]

The observation by Grady and Gilfillan[245] that 81 percent of patients with legionnaires' disease also had serologic evidence of *M. pneumoniae* infection is interesting. In the same study, 29 percent of all patients seropositive for *M. pneumoniae* also were seropositive for the legionnaires' disease antigen. Comparable studies performed by the Centers for Disease Control and Prevention failed to find a similar rate of high co-positivity in sera obtained in other legionnaires' disease epidemics. Another study found no serologic relationship between *M. pneumoniae* and *Legionella pneumophila*.[549] Severe bacterial disease after *M. pneumoniae* infection has been reported occasionally. Stadel and colleagues[620] noted *H. influenzae* pneumonia and bacteremia after a mild *M. pneumoniae* illness; Biberfeld and colleagues[41] reported staphylococcal septicemia in two cases of *M. pneumoniae* pneumonia, and Rykner and associates[564] recovered pneumococci from the pleural exudate of a patient with *M. pneumoniae* pneumonia.

Kleemola and Kayhty[343] found fourfold or greater increases in *M. pneumoniae* complement-fixing antibody titer in 40.7 percent of 54 patients with bacterial meningitis. However, they thought that this antibody response was not caused by specific *M. pneumoniae* infection but by cross-reactive glycolipids resulting from the bacterial infection.[343,344]

Lind and associates[398] reported that 4 of 19 patients with neurologic disease and *M. pneumoniae* infection had serologic evidence of concomitant viral infection.

Other Disease Associations

Foy and colleagues[212] noted that both ear involvement and pneumonia as manifestations of *M. pneumoniae* infection occurred more commonly in children with previous tonsillectomy. Putman and associates[539] found that in all but 3 of 31 patients with sarcoidosis, the serum complement-fixing antibody titer to *M. pneumoniae* was 1:32 or higher, whereas in a similar-sized control group without sarcoidosis, only 2 persons had titers of 1:32 and none had higher titers. Other interesting observations include multiple birth defects in a newborn exposed to *M. pneumoniae* in utero,[58] a tubo-ovarian abscess in a young woman from whom *M. pneumoniae* was isolated in pure culture,[660] fever of unknown origin in a 32-year-old man,[362] glomerulonephritis in a few patients with pneumonia,[532] inappropriate secretion of antidiuretic hormone in a 6-year-old boy,[401] acute IgA nephropathy,[636] and optic disk swelling and iritis.[569]

Recurrent Disease

The results of several investigations suggest that recurrent *M. pneumoniae* infection is a frequent finding.[66,196,626] Repeat infections can be associated with severe disease such as pneumonia. In the Seattle studies, second attacks of pneumonia have been documented, and similar findings have been observed in England.[208,220,222,282]

*See references 1, 11, 13, 14, 19, 29, 124, 156, 162, 241, 264, 275, 302, 338, 341, 346, 353, 370, 386, 398, 436, 476, 481, 506, 511, 522, 524, 561, 567, 578, 594, 623, 629, 642, 657, 665, 675, 684, 695, 702.

†See references 6, 22, 46, 169, 187, 188, 225, 238, 245, 251, 303, 350, 387, 395, 425, 432, 465, 466, 494, 550, 620, 622, 623, 681, 698.

DIAGNOSIS

Differential Diagnosis

Because the clinical manifestations of *M. pneumoniae* infection are protean and because infections occur commonly in children and adolescents, this agent should be considered in the differential diagnosis of most infectious illnesses. Most important is its consideration in patients with pulmonary disease, in whom illnesses caused by viruses (particularly adenoviruses, parainfluenza viruses, influenza viruses); *Chlamydia psittaci; Chlamydia pneumoniae; Coxiella burnetii;* bacteria (particularly *S. pneumoniae*, *B. pertussis*, *H. influenzae*, *M. tuberculosis);* and fungi (particularly *Histoplasma capsulatum* and *Coccidioides immitis)* are the main differential possibilities. Because the clinical manifestations, including the radiographic appearance of the lungs, are frequently similar in the various differential possibilities, the following other factors are important: status of the host (normal or immunologically compromised), the environment (human, animal, or inanimate source), the age of the patient, the incubation period, and the season.

In otherwise healthy children, *M. pneumoniae* is a common cause of pneumonia in those older than 3 years and is the leading cause of pneumonia in older children and adolescents. The lack of coryza is sometimes useful in differentiating *M. pneumoniae* pneumonia from that caused by common viral agents, and elevation of the white blood cell count along with an increase in band form neutrophils is evidence against a mycoplasmal etiologic agent, except in patients with concomitant hemolytic anemia. The occurrence of exanthem and, in particular, Stevens-Johnson syndrome should lead the physician to suspect *M. pneumoniae;* similarly, the occurrence of hemolytic anemia, joint manifestations, or neurologic signs and symptoms with pneumonia should lead the physician to strongly suspect *M. pneumoniae* as the etiologic agent. Because the pulmonary manifestations of *M. pneumoniae* infection are not always clinically apparent, a physician investigating an unusual acute or subacute case (aseptic meningitis or other neurologic illness; exanthem; enanthem; hepatitis; pancreatitis; pericarditis, myocarditis, or both; and arthritis) would be wise to consider the possibility of *M. pneumoniae* as the etiologic agent and to obtain appropriate chest radiographs, as well as definitive cultures and serologic studies.

Specific Diagnosis

SERUM COLD AGGLUTININS. Despite the considerable confusion in the literature and by physicians in general regarding the diagnostic value of the serum cold agglutination test for *M. pneumoniae* infection, my opinion is that when it is used appropriately, the test is a simple and useful procedure. One cause for confusion was a report in 1966 in which only 1 of 28 children with positive cold agglutination titers actually had serologic evidence of *M. pneumoniae* infection by complement fixation.[635] However, this report can be criticized because the study population consisted of 444 children younger than 4 years and only 170 of this group had pneumonia. Because cold agglutinins are noted occasionally in the sera of patients of all ages with a variety of illnesses, for useful results, their study should have been restricted to patients likely to have *M. pneumoniae* lower respiratory tract disease.[100,200,234,394] In various studies of pneumonia, serum cold agglutinins at a titer of 1:32 or higher were found in 50 to 90 percent of patients with *M. pneumoniae* infection.[42,84,88,225,234,311,479,629,679] In general, the cold agglutinin response correlates directly with the severity of pulmonary involvement; patients with extensive lobar involvement nearly always have positive titers[3] (1:32), whereas those with only minimal findings on radiographic study frequently have equivocal or negative titers. Positive cold agglutination titers have been observed in 18 percent of adenoviral pneumonias in a study involving a military population.[234] In general, the higher the cold agglutinin titer, the more likely that a particular illness is caused by *M. pneumoniae*.

A rapid screening test for cold agglutinins is available and useful.[231,252] This test is performed by adding 4 drops of blood to a tube containing sodium citrate or another anticoagulant. The tube is placed in ice water (0° C to 4° C) in a freezer for approximately 30 seconds and then examined immediately for coarse agglutination by tilting the tube on its side. When the tube is warmed, the agglutination should resolve, and it can be reproduced again by repeating the ice water cooling procedure. A modified version of this rapid test was used in 126 children in an emergency department who had asthma exacerbations.[83] The test had a sensitivity of 78.3 percent and a specificity of 41.3 percent when compared with an IgM ELISA.

SPECIFIC ANTIBODY DETERMINATIONS. Several specific antibody tests (growth inhibition, immunofluorescence, indirect hemagglutination, precipitation, mycoplasmacidal antibody, complement fixation, ELISA, adherence inhibition assay, radioimmunoassay, and radioimmunoprecipitation) can be used to measure serum antibodies to *M. pneumoniae*. In the past only the complement-fixation test was available routinely. A fourfold rise in complement-fixation antibody titer indicates acute *M. pneumoniae* infection. Because complement-fixation antibody in *M. pneumoniae* infection is of relatively short duration, the observation of a fourfold fall in titer also can be useful on occasion in assigning etiologic significance in a particular illness. High single titers (≥1:256) usually indicate recent infection but rarely can be used to relate the cause of an illness specifically to *M. pneumoniae.* Because *M. pneumoniae* infection is associated with a relatively long incubation period, the development of antibodies is occurring at the time of acute disease. As a consequence, fourfold changes in titer can occur in a short interval (5 days), and collection of paired sera 5 to 7 days apart usually reveals a significant rise in complement-fixation antibody titer.

In recent years most diagnostic laboratories have replaced the complement-fixation test with commercial immunofluorescence or ELISA for demonstration of antibodies to *M. pneumoniae* antigens.* These tests, in addition to demonstrating rises in antibody values in paired sera, can identify specific IgM and IgA antibodies in single serum samples. In general, when used by experienced laboratory personnel, both immunofluorescence and ELISA have sensitivities and specificities similar to those of the complement-fixation test for determining significant increases in antibody values in paired serum specimens. In addition, demonstration of specific IgM or IgA antibody in a single serum sample suggests a recent infection. Today the most common method used for diagnosing *M. pneumoniae* infection in clinical practice in the United States is the single serum IgM assay. However, it should be pointed out that most available tests have low specificity so that overdiagnosis is common.[28,138,164,505,640] Furthermore, the specific IgM and IgA responses after infection may last for several months; therefore demonstration of these antibodies in a single serum sample may be misleading with regard to the diagnosis of specific illness. Hence in most instances, paired sera (5 to 14 days apart) should be examined to confirm a clinical diagnosis. Also useful is the determination of cold agglutinin titers at the time of IgM ELISA. If an ELISA IgM test is positive and a cold agglutinin test is negative, the physician should be skeptical of the former value.

CULTURE. With proper media, experienced personnel have little difficulty isolating *M. pneumoniae* from throat swabs of

*See references 7, 28, 78, 138, 164, 168, 182, 201, 304, 348, 378, 477, 505, 543, 600, 611, 640, 658, 659, 676, 694.

infected patients.[9,671] However, because *M. pneumoniae* is relatively slow growing, in most instances requiring more than 1 week of incubation, culture is of less use for diagnosis of routine cases than serologic study is. Cultures should be performed in all unusual situations; specifically, joint fluid, CSF, pericardial fluid, and biopsy material should be cultured. The modified SP-4 medium, which is more sensitive than conventional mycoplasma culture media, coupled with the agar plate immunofluorescence identification procedure, may assist the cultural diagnosis of *M. pneumoniae*.[671]

DETECTION BY POLYMERASE CHAIN REACTION. A large number of studies have indicated the usefulness of PCR for demonstration of specific *M. pneumoniae* DNA in sputum, throat, nasopharyngeal, blood, CSF, urine, and tissue specimens.* Numerous different primers have been used to identify gene sequences of the P1 cytoadhesin protein, the adenosine triphosphatase asperon, or 16S ribosomal RNA gene sequences. Using culture plus serologic criteria as the comparative standard, several studies have shown excellent sensitivity and specificity.

TREATMENT

Antimicrobial Therapy

M. pneumoniae is sensitive in vitro to erythromycin, tetracyclines, chloramphenicol, clarithromycin, azithromycin, several aminoglycosides, and quinolones.[27,151,299,300,313,427,504,605] It is resistant to all penicillins and for practical purposes to the cephalosporins. In spite of this demonstrated in vitro sensitivity of the organism, plus several studies that have shown clinical therapeutic effectiveness,† a common misconception of many physicians is that antibiotic therapy is of little value in the treatment of illness caused by *M. pneumoniae*. This idea had its origin before the present era, when many patients with viral pneumonia were given a diagnosis of primary atypical pneumonia and treated unsuccessfully with antibiotics.

In 1961 Kingston and associates[340] demonstrated the therapeutic effectiveness of demethylchlortetracycline for pneumonia caused by *M. pneumoniae*. Since then, several other antibiotics have been studied carefully and also have been found to be effective against *M. pneumoniae* pneumonia.[84,151,218,234,311,562,586,605,608] The drugs of choice for pneumonia caused by *M. pneumoniae* are either erythromycins or tetracyclines. Because of the adverse effects of tetracyclines on teeth, a macrolide is the drug of choice in children. In *M. pneumoniae* pneumonia, the dose of erythromycin for children is 40 to 50 mg/kg every 24 hours administered every 6 hours for a minimum of 10 days. For adolescents and adults, the dose of erythromycin or tetracycline is 2 g every 24 hours administered every 6 hours. In general, the effectiveness of antibiotic therapy correlates directly with the severity of pneumonia and the elapsed time of illness before the initiation of therapy.

Azithromycin and clarithromycin both are approved for the treatment of community-acquired pneumonia in children.[51,262] Their advantage is less frequent dosing, shorter duration of therapy, and less gastrointestinal disturbance in older patients. The azithromycin dosing schedule is 10 mg/kg/day (maximal dose, 1 g/day) on day 1, followed by 5 mg/kg daily (maximal dose, 500 mg/day) for 4 days. The clarithromycin dose is 15 mg/kg/day administered every 12 hours for 10 days (maximal dose, 1 g/day). Macrolide-resistant strains of *M. pneumoniae* from clinical isolates have been noted in Japan.[434] The importance of this finding is presently not known.

In all other clinical manifestations of *M. pneumoniae* infection except pneumonia (e.g., nonpulmonary respiratory infection, neurologic disease, Stevens-Johnson syndrome), antibiotic therapy has not been evaluated adequately. In general, otitis media, pharyngitis, croup, and bronchiolitis appear to be mild, self-limited illnesses that require no therapy. In more serious illness such as Stevens-Johnson syndrome and neurologic disease, individual case studies have indicated little evidence of therapeutic benefit with either erythromycin or tetracycline therapy. However, my opinion is that when diagnosed, most *M. pneumoniae* infections should be treated because there is little to lose and in vitro data suggest the possibility of efficacy. Jensen and colleagues[318] noted that prophylactic administration of oxytetracycline to family contacts prevented disease but not infection. Azithromycin prophylaxis has been used successfully in two hospital outbreaks of *M. pneumoniae* pneumonia.[294,342]

Corticosteroid Therapy

Steroids have been used in the management of severe pulmonary disease, Stevens-Johnson syndrome, encephalitis, and hemolytic anemia. Although definitive data are lacking, several case studies suggest associated clinical benefit; steroids seem to be particularly useful in treating severe hemolytic anemia. A 6-year-old girl with brain stem and striatal encephalitis complicating *M. pneumoniae* pneumonia experienced neurologic improvement within 48 hours of administration of intravenous immunoglobulin.[567]

Recently Lee and associates[377] reported on the use of prednisolone in the treatment of 15 children with *M. pneumoniae* pneumonia in whom the clinical course worsened while receiving appropriate macrolide therapy. Corticosteroid treatment in these children was related to clinical and radiologic improvement. Cimolai[113] noted dramatic improvement in a 7-year-old girl treated with methylprednisolone, and in 1964 Copps[131] noted dramatic improvement in an adolescent with persistent fever, severe pneumonia, and hemolytic anemia when treated with a corticosteroid and erythromycin.

General Management

Children and adolescents with *M. pneumoniae* pneumonia should be discouraged from engaging in excessive physical activity during the acute illness and for a 2-week period during convalescence because clearance, as observed by radiography, is slow and lags behind apparent clinical well-being. Older children and adolescents should be advised of their contagiousness to others; this risk period exists as long as cough persists, even with successful antibiotic therapy.

PREVENTION

Because of the marked and prolonged morbidity associated with *M. pneumoniae* infection, which has been particularly troublesome in the military, much effort was directed toward the development of vaccines. In 1965 Jensen and associates[317] reported encouraging initial trials with an inactivated vaccine. In this study, significant rises in *M. pneumoniae* growth-inhibiting antibody titer developed in 25 of 30 volunteers. Later challenge studies with the same vaccine indicated that 9 of 10 volunteers with serum antibody were protected, but illness more severe than that in the unvaccinated control group occurred in vaccinees who did not have an antibody response after initial immunization.[607] This altered reactivity on challenge suggested a sensitization process perhaps similar to that observed with other inactivated

*See references 1, 46, 75, 148, 159, 237, 280, 296, 316, 420, 447, 455, 461, 475, 485, 495, 529, 544, 552, 581, 587, 614, 641, 706, 709.
†See references 51, 84, 151, 212, 218, 234, 311, 340, 562, 582, 586, 605, 608.

antigen vaccines and indicated the need for caution in further trials.[137,196] Other trials of inactivated vaccines in both adults and children have had varying degrees of success.[451,467,700]

A trial with a live attenuated vaccine (a temperature-sensitive mutant) gave encouraging results.[249] However, because further study of natural *M. pneumoniae* disease indicated that re-infection occurs commonly and because sensitization may play a role in pathogenesis, proceeding slowly in conducting further vaccine trials in children seems prudent.[194]

The degree of contagion of *M. pneumoniae* is relatively low, so isolation methods should be effective in preventing spread of disease. The studies of Jensen and associates[318] and the hospital azithromycin trials[294,342] indicate that in certain circumstances (in particular, high-risk subjects such as patients with sickle-cell disease and high-risk populations), prophylactic administration of antibiotics may be justified.

UREAPLASMA

PROPERTIES

Ureaplasmas (formerly *T-strain mycoplasmas*) are distinguished from all other members of the order Mycoplasmatales by their production of urease and their ability to hydrolyze urea.[592,593,650] The genus *Ureaplasma* contains two species, *U. parvum* and *U. urealyticum*.[687] These two species were previously described as two biovars of *U. urealyticum*. Biovar 1 is now *U. parvum* and biovar 2 is *U. urealyticum*. The morphologic characteristics of *Ureaplasma* sp. in young liquid medium culture are similar to those of other mycoplasmas. Round-ovoid elements approximately 330 nm in diameter with a range of 100 to 850 nm are found; rod-shaped and filamentous structures also occur, and the latter have a length of 2 μm and a width of 50 to 300 nm.[47,593,704] In clinical material, short, bacillary forms with monopointed ends are common findings. Organisms are surrounded by a single trilaminar membrane approximately 10 nm thick with pilus-like structures radiating from the surface. Multiplication occurs by a simple budding process and perhaps by binary fission.

On unbuffered standard *Mycoplasma* agar with a pH of 6.0, *Ureaplasma* sp. colonies are small (20 to 30 μm) and circular, with irregular borders, and grow downward into the agar.[593] On buffered agar, *Ureaplasma* sp. colonies are bigger and often have the "fried egg" appearance of typical large colony-forming mycoplasmas.[421]

Isolation of *Ureaplasma* sp. from clinical material is assisted by the demonstration of urease activity.[197,591,652] In liquid medium containing urea and phenol red, growth of *Ureaplasma* sp. results in the production of ammonia, with a resultant increase in pH and a change in color. Subculture from broth to agar medium that contains urea and manganese sulfate yields dark brown ureaplasmal colonies.

EPIDEMIOLOGY

The main reservoirs of human strains of *Ureaplasma* sp. are the genital tracts of adult men and women.[15,217,441-443,652,669,675,687] Infants become colonized during passage through the birth canal of an infected woman.[221,345,379,637,687] With ruptured membranes, the infant can be infected in utero.[345] *Ureaplasma* sp. have been recovered from the following sites in newborn infants: throat, nose, genitourinary tract of girls, urine of boys, external auditory canal, umbilicus, and perineum. Not all infants of infected women become colonized, and neonatal colonization tends to not persist. In one study in which *Ureaplasma* sp. were recovered from 38 percent of girls and 6 percent of boys at birth, follow-up during a 2-year period revealed a decreasing prevalence of colonization; at 2 years, none of the children had positive cultures.[217]

During prepubertal childhood, *Ureaplasma* sp. are recovered only rarely from urine or genital specimens.[213,379] After puberty, colonization is a common occurrence and is primarily the result of sexual contact.[439,441,443] Colonization in adults is related directly to sexual activity. In population studies, *Ureaplasma* sp. rarely are isolated from persons with no sexual experience, but they occur in approximately 50 percent of men and 75 percent of women for whom sexual intercourse with three or more partners is reported.

CLINICAL MANIFESTATIONS (see Chapter 75 for Neonatal Infections)

Because *Ureaplasma* can be recovered with considerable frequency from the throat, eyes, and genitourinary tract of babies and from the genitourinary tract of postpubertal males and females who are well, establishing cause-and-effect relationships in disease frequently has been difficult. Studies suggest the following disease associations with *Ureaplasma* in human genitourinary and reproductive disease: good to strong association with nongonococcal urethritis, prostatitis, and urethral syndrome; moderate association with epididymitis, involuntary infertility, repeated spontaneous abortion and stillbirth, chorioamnionitis, and low birth weight; weak association with urinary calculi, pyelonephritis, Reiter disease, and pelvic inflammatory disease; and no association with Bartholin gland abscess, vaginitis, cervicitis, postabortal fever, and postpartum fever.* Most illnesses related to or possibly related to *Ureaplasma* infection are not pediatric problems; only those of direct or indirect importance in pediatric and adolescent medicine are considered here.

Nongonococcal Urethritis

Nongonococcal urethritis occurs more commonly than gonococcal urethritis in men in most developed countries.[263,308,438,686] Approximately 40 percent of cases of nongonococcal urethritis are caused by *Chlamydia trachomatis*, and 20 to 30 percent are the result of *Ureaplasma* infection.[55,56,136,277,442,576] Clinical differentiation of disease caused by *C. trachomatis* and *Ureaplasma* has not been studied, but nongonococcal and gonococcal urethritis have been evaluated comparatively.[260,308,380,683]

The incubation period in nongonococcal urethritis is relatively long, with most cases occurring 10 to 20 days after exposure, whereas with gonorrhea, the period is shorter, usually less than 1 week.[260] The onset of symptoms in nongonococcal urethritis is generally more gradual than that associated with gonorrhea. Virtually all men with gonorrhea have a urethral discharge, and most have both discharge and dysuria. In contrast, Jacobs and Kraus[308] found that only 38 percent of men with nongonococcal urethritis had both dysuria and discharge. In the same study, 15 percent of patients with nongonococcal urethritis had only dysuria, whereas only 2 percent of those with gonococcal urethritis had a similar complaint. On examination, Handsfield[260] found the discharge in nongonococcal urethritis to be purulent in 36 percent of his cases, nonpurulent in 9 percent, and of an intermediate character in the remaining 55 percent. In contrast, 73 percent of patients with gonorrhea had a purulent discharge, 27 percent had an intermediate discharge, and none had a nonpurulent discharge. Because of the more gradual onset and the usually less severe symptoms, patients with nongonococcal urethritis are less prompt in seeking medical care than those with gonorrhea are. Jacobs and Kraus[308] found that 76 percent of patients with discharge and gonococcal infection came to the clinic within 4 days of onset, whereas only 43 percent of similar

*See references 71, 81, 82, 172, 363, 366, 446, 624, 632, 652, 654, 664.

nongonococcal urethritis patients visited the clinic within 4 days of disease onset. Without treatment, nongonococcal urethritis symptoms subside gradually in some patients during a 1- to 3-month period.[517]

After penicillin, ampicillin, or spectinomycin treatment of men with urethral gonorrhea, urethritis recurs (postgonococcal urethritis) in many patients.[279] Studies of postgonococcal urethritis indicate an etiologic role for *C. trachomatis; U. urealyticum* is probably responsible for some cases.[518]

A 7½-year-old sexually inactive boy with recurrent urethritis associated with *U. urealyticum* infection has been described.[588]

Chorioamnionitis

In a study of 249 puerperal women and their babies, Shurin and colleagues[597] noted on histologic examination of the placentas that *Ureaplasma* sp. were recovered from 37.5 percent of babies whose placentas showed chorioamnionitis and from only 19 percent of those with normal placentas. In this study, no adverse effects could be attributed to either the placental lesions or colonization of the babies. Caspi and associates[79] reported a 32-year-old woman with amnionitis in whom *Ureaplasma* was recovered from her blood. After delivery, the same organism was recovered from the blood of one of the twin infants.

Other Infections

Ureaplasma was determined to be the cause of postoperative mediastinitis in an adult after undergoing coronary artery bypass surgery.[232,258]

DIAGNOSIS AND TREATMENT

Demonstration of infection by *Ureaplasma* sp. can be established easily by presently available culture techniques. However, assigning causation of disease is more difficult because of its ubiquitous presence in normal persons. In clinical practice the most important differential consideration is between gonococcal infection and nongonococcal urethritis. Although the symptoms of the two illnesses are frequently different, sufficient overlap exists to render arriving at a specific diagnosis without laboratory aid hazardous. Microscopic examination of a urethral specimen is essential. In most instances the observation of gram-negative cell-associated diplococci on Gram stain is sufficient for a diagnosis of *Neisseria gonorrhoeae* infection. When smears reveal polymorphonuclear neutrophils without organisms suggestive of gonococci, a specific bacterial culture should be performed. Because infection with multiple agents occurs commonly and postgonococcal urethritis is a frequent problem, one is advised to investigate initial illnesses completely in adolescents with cultures for bacteria, *Chlamydia*, and *Ureaplasma. Ureaplasma* also can be detected by PCR.[48,556,627,712]

Patients with nongonococcal urethritis should be treated with tetracycline (40 mg/kg/24 hr every 6 hours; persons weighing more than 50 kg should receive 500 mg every 6 hours) for 10 days.[260,278] *Chlamydia* and *Ureaplasma* are also sensitive to erythromycin, so this antibiotic is a useful alternative for patients in whom tetracycline is contraindicated. With adolescent patients, it is prudent to seek out and treat the sex partners whenever possible.

MYCOPLASMA HOMINIS

PROPERTIES

Three basic morphologic forms of *M. hominis* have been observed by phase-contrast microscopy: coccoidal cells 30 to 80 nm in diameter, diploforms and filamentous forms with a thickness of 30 to 40 nm, and forms with variable lengths reaching 40 μm or more.[52,60,62,153] Bredt[61] studied newly isolated strains and noted that coccoid forms and ring- or disk-shaped cells were predominant; with some strains, filamentous forms of variable length also were noted. Multiplication occurs by binary fission, by fragmentation of filaments and rings, and by budding.[52,555]

Anderson and Barile[12] studied the ultrastructure of *M. hominis* and noted considerable variability in internal components. In some cells, ribosome-like granules in the cytoplasm and a more central area of netlike strands were present, suggestive of a nucleus. Other cells had only irregular densities within the cytoplasm. In some instances, dense cytoplasmic bodies were observed; in other cells, vacuoles were seen.

On *Mycoplasma* agar, *M. hominis* colonies are approximately 200 to 300 μm in diameter and have the typical mycoplasmal "fried egg" appearance.[652] *M. hominis* grows on ordinary blood agar and produces pinpoint nonhemolytic colonies. *M. hominis* metabolizes arginine to ammonia, so arginine-supplemented liquid medium with a pH indicator (phenol red) can be used for primary isolation. *M. hominis* can be identified specifically and differentiated from other human mycoplasmas that metabolize arginine by growth inhibition by specific antibody.

M. hominis has two cytoadhesins that are membrane proteins; they allow attachment to cells of the urogenital tract.[272] Attachment is to sulfated glycolipids of the host cells.[515]

EPIDEMIOLOGY

Like those of *Ureaplasma* sp., the main reservoirs of *M. hominis* are the genital tracts of adult men and women.[221,439,441,443-445,652,687] Infants become colonized during passage through the birth canal, but such colonization tends to not persist. In a recent study of 208 women at delivery, *M. hominis* was recovered from cervicovaginal specimens in 11 percent and the gastric secretions of 1 percent of newborns.[246] In prepubertal children, *M. hominis* only rarely is recovered from urine or genital specimens. Postpubertal genital tract colonization results primarily from sexual contact.

M. hominis can be recovered from the oral cavity of 1 to 5 percent of normal adults.[617]

CLINICAL MANIFESTATIONS (for Neonatal Infections see Chapter 75)

Studies suggest the following disease associations with *M. hominis* in human genitourinary and reproductive diseases: good to strong association with pyelonephritis, pelvic inflammatory disease, postabortal fever, and postpartum fever; moderate association with prostatitis, vaginitis, and cervicitis; weak association with Bartholin gland abscess; and no association with nongonococcal urethritis, epididymitis, urinary calculi, Reiter disease, urethral syndrome, involuntary infertility, repeated spontaneous abortion and stillbirth, and chorioamnionitis.* With the exception of pelvic inflammatory disease and complications of pregnancy, which occur in adolescents, the other disease associations reported do not involve pediatric patients.

M. hominis has been recovered on two occasions from the CSF of a 2½-year-old girl with a ventriculoperitoneal shunt.[690] Because she had no complications from the infection and only minimal CSF inflammation, no treatment was initiated. Three months later, the organism could not be isolated from CSF and the child was doing well.

*See references 50, 71, 81, 171, 172, 235, 256, 365, 520, 521, 560, 595, 624, 652, 654, 672.

In volunteer studies in adults, researchers found that *M. hominis* could produce exudative pharyngitis.[478] Moffet and associates[464] isolated *M. hominis* from the throat of 1 of 174 infants and children with pharyngitis but made no similar isolation from a control group of children without pharyngitis. Neu and Ellner[500] recovered *M. hominis* from the throat of 1 child in a group of 56 with exudative pharyngitis. Other *M. hominis* infections include septicemia in a 10-month-old burned infant,[143] chronic multifocal osteomyelitis in an 8-year-old,[293] septicemia after heart surgery in a 5-year-old girl,[142] and exudative vaginitis in a 10-year-old girl.[689] In one study 10 patients with sickle cell disease were found to have acute chest syndrome in association with *M. hominis* recovery from sputum or bronchoscopy specimens.[501] A 4-year-old girl was found to have *M. hominis* endocarditis following biventricular repair of her congenital heart defect.[154] Surgical wound infections have been due to *M. hominis* infections.[360,558]

In adult patients the following clinical manifestations have been caused by *M. hominis:* mediastinitis,[435] endocarditis,[189,285] pneumonia in a previously healthy man,[566] wound infections as surgical sites,[460] brain abscess,[286,364,713] and bacteremia in a patient with multiple injuries.[255]

DIAGNOSIS AND TREATMENT

Illness caused by *M. hominis* infection rarely occurs in children. This organism should be considered an etiologic possibility in wound infections and a variety of illnesses in which routine cultures are negative. The possibility of *M. hominis* as an etiologic agent also should be considered in adolescent girls with pelvic inflammatory disease. *M. hominis* is readily isolated on routine mycoplasma media and infection can also be determined by PCR.

M. hominis is usually sensitive to tetracycline, and this antibiotic is the drug of choice unless it is otherwise contraindicated.[57,74,631,645,646,703] During the past decade, resistance of *M. hominis* to tetracyclines has increased.[139,440] The organism also is usually sensitive to clindamycin, rifampicin, quinolones, and chloramphenicol. In contrast to *U. urealyticum* and *M. pneumoniae*, *M. hominis* is markedly resistant to erythromycin.

MYCOPLASMA FERMENTANS, MYCOPLASMA GENITALIUM, MYCOPLASMA PENETRANS, MYCOPLASMA PIRUM, AND AIDS-ASSOCIATED MYCOPLASMAL INFECTIONS

MYCOPLASMA FERMENTANS

M. fermentans originally was isolated from the genital tract of men and women 50 years ago, but it has not been established as a cause of genitourinary disease.[563,648,669] This organism has been isolated from the blood of leukemia patients, from the joint fluid of patients with arthritis, and from the blood and urine of patients with acquired immunodeficiency syndrome (AIDS).[24,49,428,470,482,696,705] *M. fermentans* has been identified by PCR in the peripheral blood mononuclear cells and lymph nodes of HIV-infected patients.[264,329,358,574] The organism also has been recovered from the blood of homosexual men without HIV infection.[329,358,418] *M. fermentans* has been identified in synovial fluid samples from 15 patients with inflammatory arthritic diseases including rheumatoid arthritis.[615]

MYCOPLASMA GENITALIUM

M. genitalium first was identified and reported in 1981.[651,654,669,672] It was cultured from the urethral swabs of two men with nongonococcal urethritis. The organism also has been recovered from the respiratory tract of patients with pneumonia who were participating in an *M. pneumoniae* vaccine trial.[23] *M. genitalium* has biologic features that indicate its pathogenic potential and it has caused infection and disease in experimentally infected chimpanzees.[651,669,673] With the use of PCR, Jensen and associates[315] presented evidence suggesting a causative role in some cases of nongonococcal urethritis. *M. genitalium* is an emerging sexually transmitted infection[423] and a cause of mucopurulent cervicitis in women[422] and nongonococcal urethritis (NGU) in males.[450] The organism also has been recovered in mixed culture with *M. pneumoniae* from the synovial fluid of a patient with pneumonia and subsequent polyarthritis.[670]

MYCOPLASMA PENETRANS

M. penetrans is a relatively newly recognized species isolated from the urogenital tract of patients with AIDS.[405,406] In a seroprevalence study, Wang and associates[692] found that 35.4 percent of HIV-infected patients had antibody versus only 0.4 percent of HIV-seronegative subjects. They subsequently noted a high prevalence of antibody to *M. penetrans* in the sera of homosexual men but not in the sera of other HIV transmission groups.[693] In a more recent study, Grau and colleagues[247] found that 18.2 percent of HIV-infected patients had antibody to *M. penetrans*, whereas only 1.3 percent of HIV-seronegative persons had antibody. *M. penetrans* antibody seroprevalence increased with progression of HIV-associated disease, and it was associated predominantly with homosexual practices in the HIV-infected patients. No pediatric data relating to *M. penetrans* seroprevalence are available.

MYCOPLASMA PIRUM

M. pirum originally was recovered from eukaryotic cell cultures, and its origin was traced to a human tumor cell line.[7,150,375] It has been recovered more recently from primary lymphocyte cells in patients with AIDS.[49]

AIDS-ASSOCIATED MYCOPLASMAL INFECTIONS

The frequent identification of *M. fermentans*, *M. pirum*, and *M. penetrans* infections in HIV-infected patients has led to the consideration that they may function as cofactors in the progression of HIV infection.[49,356,470] Although these mycoplasmas have the capacity to invade cells and to be potent immunomodulators, their pathogenic role, if any, in association with HIV has not been determined yet.

MYCOPLASMA AND *UREAPLASMA* INFECTIONS IN IMMUNOCOMPROMISED PATIENTS

Patients with hypogammaglobulinemia are susceptible to severe persistent infection with *Ureaplasma* sp., *M. hominis*, *M. amphoriforne*, *M. pneumoniae*, and *M. orale*.[17,207,224,468,537,559] Clinical manifestations include osteomyelitis, arthritis, cellulitis, and chronic respiratory illness. Patients need to be treated for prolonged periods with high-dose intravenous immunoglobulin and antibiotics to which the specific agents are susceptible. Severe and persistent infections also have occurred in liver, kidney, and bone marrow transplant recipients, as well as other immunocompromised patients.[116,307,326,416,459,528,618,682]

Yechouron and associates[711] reported a 64-year-old man with Hodgkin lymphoma who died of septicemia caused by

Mycoplasma arginini, an animal pathogen.[711] Three children with cancer had pneumonia in which bronchoalveolar lavage fluid specimens yielded *U. urealyticum*.[72] Two of the patients died, and the survivor's improvement coincided with erythromycin treatment. A 9-year-old boy had an abdominal infection with *M. hominis* after liver transplantation,[412] and a 15-year-old girl had septic arthritis due to *M. hominis* 2 months after renal transplantation.[453]

SECTION XXI

FUNGAL DISEASES

CHAPTER 209

CLASSIFICATION OF FUNGI

David A. Bruckner ❂ Heidi M. Kokkinos

Fungi are prominent causes of serious infections in immunocompromised and hospitalized individuals. Organisms once thought to be contaminants can play important roles in pathogenesis in humans. The laboratorian must learn the basic structures of fungi and principles of classification to recognize and to identify medically important fungi.

The medically important fungi are contained in a biologic kingdom called Fungi.[9] These organisms are divided into two groups on the basis of their basic growth pattern: yeasts and molds. Yeasts are unicellular fungi that reproduce by budding or by fission. Molds are multicellular fungi that grow by means of filamentous threads called hyphae. Developed reproductive propagules can be found on the hyphae and are used to propagate or to disseminate the organism.[2,3]

Fungi may reproduce sexually or asexually. The sexual form of growth is called the teleomorph, and the asexual form is called the anamorph. The teleomorph and the anamorph forms of the same fungus have different names. *Pseudallescheria boydii*, for example, is the teleomorph of two anamorphs, *Scedosporium apiospermum* and *Graphium eumorphum*. Although the sexual means of reproduction forms the basis of the taxonomy of fungi, it is the anamorph that is isolated predominantly from specimens of patients. For this reason, the anamorph name usually is used in reports from a clinical microbiology laboratory.

The kingdom Fungi is composed of four phyla.[6] The phylum name is defined by the type of sexual spore produced. Sexual spores are specialized structures that house the products of meiosis after sexual reproduction. The phylum names and the type of sexual spore formed by its members are as follows:

1. Zygomycota (zygospores)
2. Ascomycota (ascospores)
3. Basidiomycota (basidiospores)
4. Chytridiomycota (motile oospores)

The phylum Chytridiomycota does not contain any human pathogens. Another group, which is not taxonomically referred to as a phylum, contains fungi that do not produce sexual spores or for which no association has been made between the anamorph and teleomorph forms. This group is referred to as *anamorphic fungi*[8] or *fungi imperfecti*. The teleomorph phase has not been detected or described for many human pathogens; therefore, a genus name may be found under a well-described phylum as well as under the anamorphic fungi.

The taxonomic scheme depicted is based on various sources.[1,4,6,9,11] The original draft of the scheme was published in 2003.[6]

The basic taxonomic units are the species, and they are grouped into a hierarchical system that includes genera, families, orders, classes, and phyla. The categories may by subdivided (e.g., subphylum, subclass, suborder) to indicate degrees of relationship. Populations within a given species that have some characteristics in common may be set apart as tribes or varieties or some other subset designation. Delineation of the zoopathogen *Ajellomyces capsulatus*, the teleomorph of *Histoplasma capsulatum*, is as follows:

Kingdom: Fungi
- Phylum: Ascomycota
  - Class: Ascomycetes
    - Order: Onygenales
      - Family: Onygenaceae
        - Genus: *Ajellomyces*
          - Species: *Ajellomyces capsulatus* (anamorph: *Histoplasma capsulatum*)
            - Variety: The varietal state applies to the anamorph.[9]
              - *H. capsulatum* var. *capsulatum*
              - *H. capsulatum* var. *duboisii*
              - *H. capsulatum* var. *farciminosum*

This chapter includes taxa known to contain medically important fungi. Classes, orders, and families not known to contain pathogens are omitted. More detailed considerations can be obtained by consulting the references.[1-11]

Kingdom: Fungi
- Phylum: Zygomycota. The teleomorph (sexual form) consists of zygospores. The anamorph (asexual form) consists of sporangiospores within a sporangium.
  - Class: Zygomycetes
    - Order: Mucorales
      - Family: Mucoraceae
        - Genus: *Apophysomyces*
          - *Absidia*
          - *Mucor*
          - *Rhizomucor*
          - *Rhizopus*
      - Family: Cunninghamella
        - Genus: *Cunninghamella*
      - Family: Mortierellaceae
        - Genus: *Mortierella*
      - Family: Saksenaeaceae
        - Genus: *Saksenaea*
      - Family: Syncephalastraceae
        - Genus: *Syncephalastrum*
      - Family: Thamnidiaceae
        - Genus: *Cokeromyces*
    - Order: Entomophthorales—agents of entomophthoromycoses
      - Family: Basidiobolaceae
        - Genus: *Basidiobolus*
      - Family: Ancylistaceae
        - Genus: *Conidiobolus*

Phylum: Ascomycota. The teleomorph (sexual phase) consists of ascospores borne in an ascus. The anamorph (asexual phase) may be unicellular yeasts or multicellular molds. Molecular phylogeny studies have been used to define this group, even when a known teleomorph for a given anamorph has not been described.

- Class: Hemiascomycetes (Endomycetes)—yeasts (unicellular fungi)
  - Order: Saccharomycetales—ascomata absent. Asci are formed singly or in chains. Yeast cells divide by budding or fission.
    - Family: Saccharomycetaceae
      - Genus: *Candida*
        - *Saccharomyces*
- Class: Ascomycetes—molds. For more complete descriptions, see references 4 and 11.
  - Order: Onygenales—ascomata are cleistothecia
    - Family: Arthrodermataceae—agents of tinea (ringworm)
      - Genus: *Arthroderma*
        - *Microsporum* (anamorph)
        - *Trichophyton* (anamorph)
        - *Epidermophyton* (closely related, but no teleomorph has been described)
    - Family: Onygenaceae—agents of endemic pulmonary mycoses
      - Genus: *Ajellomyces* (teleomorph)
        - *Histoplasma* (anamorph)
        - *Blastomyces* (anamorph)
        - *Emmonsia* (anamorph)
        - *Coccidioides* (anamorph; no teleomorph has been described)
        - *Paracoccidioides* (anamorph; no teleomorph has been described)
  - Order: Eurotiales—ascomata are cleistothecia
    - Family: Trichomaceae—contains the greatest number of human pathogens
      - Genus: *Aspergillus* (anamorph)
        - *Penicillium* (anamorph)
        - *Paecilomyces* (anamorph; no teleomorph has been described)
  - Order: Ophiostomales—ascomata are perithecia with long necks
    - Family: Ophiostomaceae
      - Genus: *Ophiostoma* (teleomorph)
        - *Sporothrix* (anamorph)
  - Order: Hypocreales—ascomata are mostly perithecia
    - Family: Hypocreaceae—contains agents of mycoses
      - Genus: *Acremonium* (anamorph)
        - *Fusarium* (anamorph)
        - *Trichoderma* (anamorph)
        - *Verticillium* (anamorph)
  - Order: Microascales—ascomata are cleistothecia or perithecia
    - Family: Microascaceae
      - Genus: *Pseudallescheria*
        - *Scedosporium* (anamorph)
        - *Microascus*
        - *Scopulariopsis* (anamorph)
  - Order: Sordariales—ascomata are cleistothecia or perithecia; rarely pathogens
  - Order: Dothideales—ascomata are cleistothecia
    - Family: Didymosphaeriaceae
      - Genus: *Neostudina* (teleomorph)
    - Family: Herpotrichiellaceae—agents of phaeohyphomycoses and chromoblastomycoses
      - Genus: *Cladophialophora* (anamorph)
        - *Exophiala* (anamorph)
        - *Fonsecaea* (anamorph)
        - *Phialophora* (anamorph)
        - *Rhinocladiella* (anamorph)
    - Family: Mycosphaerellaceae
      - Genus: *Cladosporium* (anamorph)
    - Family: Piedraiaceae
      - Genus: *Piedraia* (teleomorph)
  - Order: Pleosporales
    - Family: Pleosporaceae
      - Genus: *Cochliobolus* (teleomorph)
        - *Bipolaris* (anamorph)
        - *Curvularia* (anamorph)
        - *Drechsleria* (anamorph)
- Class: Archiascomycetes[4]—found as trophozoites, cysts, and intracystic bodies; originally considered members of the kingdom Protozoa[7]
  - Order: Pneumocystidales
    - Family: Pneumocystidaceae
      - Genus: *Pneumocystis*[10]

Phylum: Basidiomycota. The teleomorph is a basidium bearing basidiospores. The anamorphs are yeasts or molds. Arthroconidia are reproductive propagules of some molds.

- Class: Hymenomycetes
  - Order: Tremellales
    - Family: Filobasidiaceae
      - Genus: *Filobasidiella* (teleomorph)
        - *Cryptococcus* (anamorph)
  - Order: Trichosporonales
    - Family: Trichosporonaceae
      - Genus: *Trichosporon* (anamorph)
- Class: Ustilaginomycetes
  - Order: Malasseziales
    - Family: Malasseziaceae
      - Genus: *Malassezia* (anamorph)
- Class: Urediniomycetes
  - Order: Sporidiales
    - Family: Sporidiobolaceae
      - Genus: *Rhodotorula* (anamorph)
        - *Sporobolomyces* (anamorph)

ANAMORPHIC OR FUNGI IMPERFECTI

These fungi have no known teleomorph phase and have been placed in a separate category for the convenience of discussion. At one time, these fungi were placed in the phylum Deuteromycota; however, this designation no longer is used in medical mycology. The anamorphic fungi are divided into subgroups but are not given names associated with orders or families.

SUBGROUP: BLASTOMYCETES. These organisms are unicellular fungi that reproduce by budding or fission. Although these yeasts have no described teleomorphic phase, they are related to the ascomycetes and basidiomycetes.

Genus: *Candida*
Cryptococcus
Rhodotorula
Trichosporon

SUBGROUP: HYPHOMYCETES. These molds produce asexual conidia. Moniliaceous forms have hyaline hyphae and conidia. Like the Blastomycetes, these forms have ascomycete or basidiomycete affinities. Moniliaceous hyphomycetes are the following:

Genus: *Acremonium*
Aspergillus
Blastomyces

Coccidioides
Epidermophyton
Fusarium
Microsporum
Penicillium
Trichophyton

Dematiaceous forms have dark conidia and hyphae and are agents of chromoblastomycosis and phaeohyphomycosis.

Genus: *Bipolaris*
Cladophialophora
Cladosporium
Curvularia
Phialophora
Rhinocladiella
Sporothrix

SUBGROUP: COELOMYCETES. These are molds that produce reproductive elements within pycnidia or on acervuli. They are agents of mycetoma and wound infections.

Genus: *Phoma* (pycnidium forming)
Colletotrichum (acervulus forming)

SUBGROUP: AGONOMYCETES (*MYCELIA STERILIA*). Molds with no reproductive propagules belong to this group.

Genus: *Rhizoctonia*

ORGANISMS OF UNCERTAIN POSITION

The taxonomic position of *Rhinosporidium seeberi* has always been uncertain.[5] Rhinosporidiosis presents as tumor-like masses in the nasal mucosa or on conjunctiva of humans.[9] Studies involving 18S rRNA genes from infected tissue have shown a phylogenetic relationship to a novel group of protists infecting fish and amphibians. The fungus is "the first known human pathogen from the DRIPs clade, a novel clade of aquatic protistan parasites (Ichthyosporea)."[5]

Prototheco sis is a rare cutaneous disease caused by *Prototheca* spp. The taxonomic position of these microorganisms is not established, but they are thought to be achloric algae. Although not considered to be fungi, they often are included in medical mycology texts.[9]

CHAPTER 210

ASPERGILLUS AND ASPERGILLOSIS

William J. Steinbach ❂ Ana Burgos

The incidence of *Aspergillus* infection is increasing and carries a dismal mortality.[5,85,116] Invasive aspergillosis is the most common cause of mortality due to invasive mycoses, generally attributable to the success with prophylactic antifungal regimens and easier diagnostic examinations for *Candida* infection. Invasive aspergillosis is gaining prominence probably as a result of the use of more intensive immunosuppressive therapies for graft-versus-host disease (GVHD) and rheumatologic diseases, increased use of mismatched or unrelated donor transplants, use of newer preparative regimens to avoid rejection or relapse, and increased early post-transplantation survival due to better control of bacterial and cytomegalovirus infections.[85,153] Unfortunately, at present, there are not optimal methods for either establishing early and accurate diagnosis or consistently providing effective treatment. Currently, the field is in a state of rapid advancement, both of newer molecular tools and of novel antifungal strategies.

THE ORGANISM

Although the genus *Aspergillus* contains approximately 185 species, most human disease is caused primarily by *Aspergillus fumigatus*, *Aspergillus flavus*, *Aspergillus niger*, *Aspergillus terreus*, and *Aspergillus nidulans*. *A. fumigatus* causes approximately 90 percent of cases of invasive aspergillosis.[24] A review of *Aspergillus* cultures found that amphotericin B–resistant *A. terreus* was seen in only 3 percent of isolates in cases of invasive aspergillosis but exclusively in cases of invasive aspergillosis (i.e., no cases of colonization).[106] *A. fumigatus* is responsible for most pulmonary disease, whereas most isolated sinus disease is caused by *A. niger* and *A. flavus*.[106]

Aspergillus is a ubiquitous organism, but its ecologic niche is the soil, where it functions as a saprophytic fungus growing on organic debris and recycling carbon and nitrogen.[163] Currently, no sexual stage has been identified for *A. fumigatus*, thereby eliminating the possibility for performing classic genetic studies, but genomic evidence suggests that it is capable of sexual reproduction.[103] Asexual reproduction is abundant and characterized by the production of green pigmented echinulate asexual conidia (spores). The conidia are produced in chains basipetally from the phialides borne on clavate vesicles. This reproductive structure is where the genus name *Aspergillus* is derived, from the aspergillum used to sprinkle holy water in the Catholic Mass. The morphologic features of the conidia and conidiophores are largely used to distinguish the individual *Aspergillus* species.

Aspergillus aerosolize conidia, which immunocompetent people asymptomatically breathe every day, and most people inhale an estimated several hundred *A. fumigatus* conidia a day.[44] Infection in immunocompromised patients usually is acquired through inhalation of airborne conidia. Two lines of host defense exist against *Aspergillus*, macrophages and neutrophils, and both mechanisms of host defense appear to be required for resistance to invasive disease. The first defense is formed by alveolar macrophages, and in vitro murine studies have suggested that resident pulmonary macrophages are responsible for eliminating inhaled *Aspergillus* conidia from the lung.[122,123] If conidia escape, they develop into invasive *Aspergillus* hyphae and become susceptible to neutrophil killing by the release of toxic reactive oxygen species.[125] The host can develop disease through neutropenia, high challenge doses of conidia overcoming macrophages, or corticosteroid suppression of macrophage conidiacidal activity.[34]

A. fumigatus, in particular, is highly successful at causing invasive disease in immunocompromised patients because of several characteristics, such as thermotolerance, small and abundant pigmented conidia, fast growth rates, production of toxic secondary metabolites, and numerous enzymes involved in breaking down complex polysaccharides. The ability to grow at 37° C is crucial for the development of human disease. Some *Aspergillus* spp. can grow at this high temperature, reportedly *A. fumigatus* can survive at temperatures up to 75° C, and this thermotolerance is likely to be a major factor in its ability to cause human morbidity.[7] In addition, at 37° C in a nutrient-rich environment, *A. fumigatus* can grow at an extremely fast rate.

Conidia are 2.5 to 3 μm in diameter, and this small size allows them to remain buoyant in the air for prolonged periods and to be inhaled deep into the lung alveoli. When inhaled by an immunocompetent person, conidia rarely have deleterious effects because they are cleared by phagocytic cells of the innate immune system. However, severe allergic disease can occur with repeated exposure to large doses of conidia. Pigments found on the conidial surface are thought to play important roles in mediating the effects of damaging reactive oxygen species produced by phagocytic cells.[108] Mutants of *A. fumigatus* that lack these conidial pigments are more susceptible to killing by alveolar macrophages than are their pigmented counterparts.[71] Whole genome sequencing of several *Aspergillus* spp. has revealed that these fungi contain large numbers of enzymes involved in degrading complex polysaccharides.[39] Although these enzymes allow *Aspergillus* spp. to be enormously successful as saprophytes, these enzymes also are thought to contribute to their ability to cause invasive mycoses.

Species of *Aspergillus* also are well known for their production of secondary metabolites. Perhaps the most well known *Aspergillus* metabolite is the carcinogen aflatoxin produced by some strains of *A. flavus*. Although aflatoxin is extremely carcinogenic, its role in the development of human mycoses has not been thoroughly examined to date. Various suspected putative *Aspergillus* virulence factors have been reviewed extensively,[74] and earlier gene disruption studies examined proteases, toxins, hemolysins, melanin pigmentation, and other gene products with little success. The true virulence of *A. fumigatus* is likely to be a multifactorial combination of these described attributes.

CLINICAL PRESENTATION

Aspergillus spp. are unique among pathogens; they are responsible for a gamut of infections extending across the clinical spectrum to include primary allergic reactions, saprophytic involvement, and invasive disease.[86] The type of *Aspergillus* infection generally depends on the immunologic background of the infected host; immunodeficient patients develop invasive disease, and immunoreactive patients develop an allergic disease. Most frequently encountered among the myriad clinical presentations are presentations involving the lungs, such as allergic bronchopulmonary aspergillosis and acute or chronic invasive pulmonary aspergillosis (IPA). Other common infections caused by *Aspergillus* spp. include invasive chronic sinusitis, cutaneous aspergillosis, aspergilloma, and cerebral aspergillosis.[24,86] The clinical manifestations of these infections are subtle and nonspecific and commonly occur late in the course of disease. As a result, a high index of suspicion needs to be maintained to implement treatment in the early stages of disease. Unfortunately, the patients most vulnerable to *Aspergillus* infections are the least likely to display significant symptoms, adding to the difficulty of establishing the diagnosis.[24]

PULMONARY ASPERGILLOSIS

Aspergillus spp. are ubiquitous in the environment, and one major portal of entry is the respiratory tract. Most people inhale the conidia daily, which usually is not a problem for the immunocompetent host as the functioning immune system will quickly clear the conidia. In some immunocompetent patients, this inhalation could result in nonpathogenic saprophytic colonization, whereas this conidial acquisition in the immunocompromised patient likely will result in establishment of invasive disease.[144] IPA is the most frequently documented form of aspergillosis and contributes considerably to morbidity and mortality among high-risk patients.[27] In a systematic review of the literature regarding the case-fatality rate of aspergillosis (1995-1999), 70 percent of infections were found to be invasive pulmonary disease.[77] As with other forms of *Aspergillus* infections, the burden of IPA is sustained by immunocompromised patients, including hematopoietic and solid organ transplant recipients, cancer patients, patients with various congenital immune deficiencies such as chronic granulomatous disease (CGD), and patients treated for autoimmune diseases.[117]

The clinical manifestation of IPA is heterogeneous; typically, it may include fever unresponsive to broad-spectrum antibiotics, dry cough, shortness of breath, pleuritic chest pain, hemoptysis, and pulmonary infiltrates on radiography.[2] Whereas neutropenic patients usually present with fever, approximately 20 percent of patients, specifically those receiving high-dose corticosteroid therapy,[54] will have no fever or cough the first several days of infection.[86] In general, disease often is bilateral diffuse pulmonary infection, and dyspnea is a more common presentation in these patients. Progression of infection is characterized by invasion of small vessels leading to hemoptysis as a primary symptom of IPA in some neutropenic patients. Two patterns of hemorrhage may be identified: (1) hemorrhagic infarction due to vascular invasion; and (2) during recovery from neutropenia, formation of mycotic aneurysms, which can rupture and result in fatal hemoptysis.[94]

Although patients undergoing treatment of cancer constitute the majority of individuals at risk for acquisition of *Aspergillus* infections, another largely pediatric population deserving a separate discussion is those with underlying CGD because IPA is the leading cause of mortality in these patients. In fact, patients with CGD have an estimated 33 percent lifetime risk of acquiring invasive aspergillosis, and IPA may be the first manifestation of CGD. Unlike the acute, rapidly progressive illness described for other immunocompromised patients, the clinical course in patients with CGD is characterized by an insidious onset of fatigue, fever, increased sedimentation rate, and pneumonia.[127] Presentation in a patient with CGD often does not have typical clinical symptoms (including a completely asymptomatic patient) and may consist of only an elevated erythrocyte sedimentation rate in the setting of no fever. In the early course of the disease, an acute neutrophilic response occurs in which the neutrophils surround hyphae. However, in patients with CGD, the hyphae

remain intact as a result of impaired neutrophil-mediated killing of hyphae. In this setting, pulmonary aspergillosis is a chronic progressive infection that may spread locally to involve pleura, vertebrae, and the chest wall. In contrast to patients with neutropenia, patients with CGD do not have hyphal angioinvasion as a feature of their disease. The halo sign (angioinvasion with surrounding tissue ischemia), cavitated lesions, and pulmonary infarcts are not typical findings in CGD. In a long-term follow-up study of 39 patients with CGD, the lungs were the site of infection in 23 percent of the 478 cases observed overall, and 67 percent of the patients had at least one episode of pneumonia.[76] Furthermore, among the 151 cases in which an infectious agent was identified, 12 (8%) of these isolates were *Aspergillus* spp.

INVASIVE *ASPERGILLUS* SINUSITIS

Fungal sinusitis can be manifested as allergic, saprophytic, or invasive disease. Invasive *Aspergillus* sinusitis probably is underdiagnosed because of its variable clinical presentation and the difficulty in establishing the diagnosis[24,54,86] due to a decreased inflammatory response in affected patients. Patients can present with nasal congestion, discharge, headache, facial pain or swelling, and abnormal findings of the nasal cavity, such as pallor of the nasal septum or turbinate mucosa. Epistaxis, orbital swelling, and high fever also can be present.[97] However, definitive diagnosis can be established best by endoscopic evaluation and selective biopsy. Common findings on endoscopy include pallor of the mucosa, discoloration or granulation of the mucosa due to ischemia that develops as a result of angioinvasion, and, as the disease progresses, a blackened necrotic focus (Figs. 210–1 and 210–2). Extension into bony structures can occur at the site of necrosis, leading to spread of the disease into adjacent structures, such as the orbit and the brain, which carries a high mortality rate.

Although imaging is not diagnostic, it can aid in establishing the diagnosis because it can be used as a road map for endoscopy by showing which sinuses are involved (Fig. 210–3). In a review of 25 patients with rhinosinusitis, 44 percent showed evidence of invasion beyond the sinus cavities on computed tomography (CT).[42] In the same study, however, 12 percent of patients had a normal CT scan, again highlighting that a high index of clinical suspicion must guide establishment of the diagnosis to ensure the best outcome.

CEREBRAL ASPERGILLOSIS

Aspergillus infections most commonly involve the lungs, but disease can disseminate through the bloodstream and involve distant organs. One of the most frequent sites of dissemination

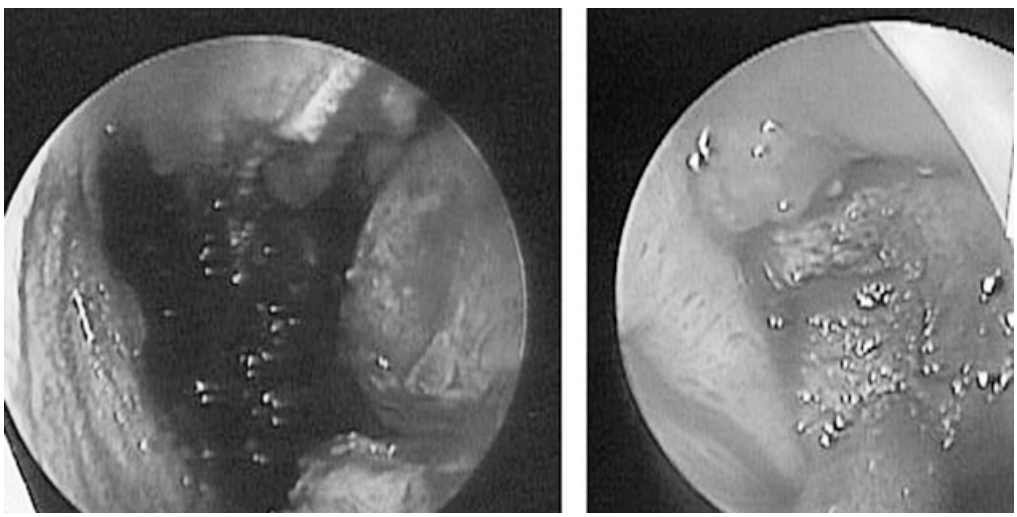

Figure 210–1 A 12-year-old with acute myelogenous leukemia and unrelated cord blood transplantation who developed *A. fumigatus* sinusitis. Endoscopy shows classic pale mucosa. (See companion Expert Consult web site for color version.)

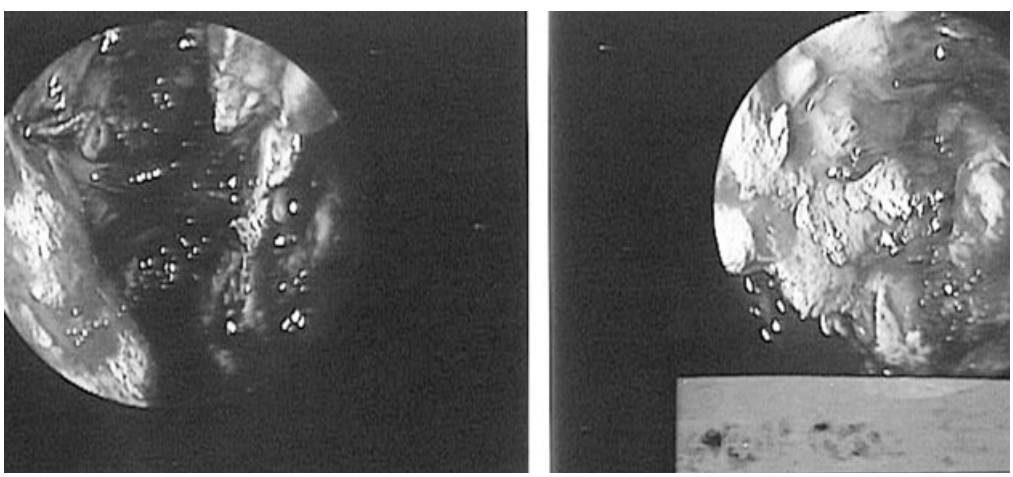

Figure 210–2 In the same patient as in Figure 210–1, endoscopy shows necrotic mucosa at the basilar skull area. (See companion Expert Consult web site for color version.)

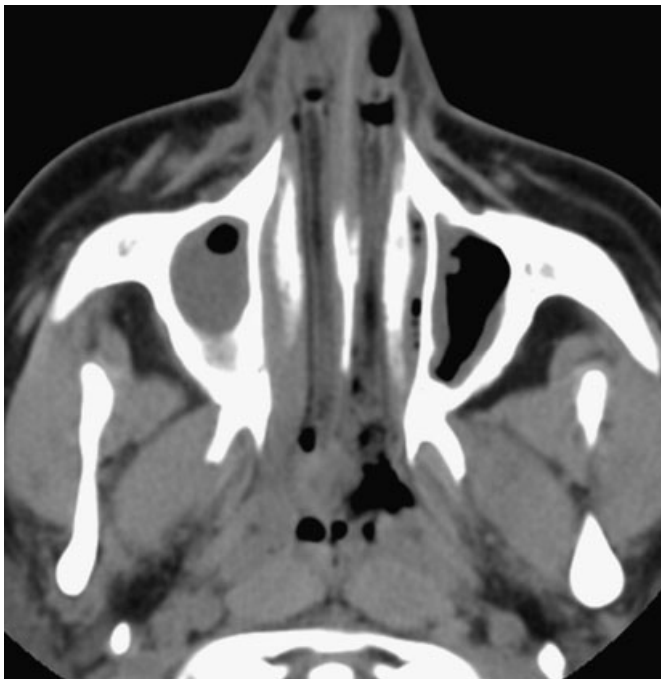

Figure 210–3 In the same patient as in Figure 210–1, CT shows complete opacification of the right maxillary sinus.

is the central nervous system (CNS).[47] Cerebral aspergillosis also may be a result of direct extension through the sinuses. Studies have shown that CNS aspergillosis may be found in an estimated 40 to 50 percent of patients with invasive aspergillosis and acute leukemia or allogeneic stem cell transplantation.[57,121] As with other *Aspergillus* infections, *A. fumigatus* is the species most frequently encountered in cerebral aspergillosis, but other implicated species are *A. flavus*, *A. niger*, and *A. nidulans*.[58] Clinical presentation often does not include more classic symptoms for an intracranial process, such as headache, nausea, or vomiting. Instead, patients present with alterations in mental status, convulsions, hemiplegia or hemiparesis, ophthalmoplegia, and loss of consciousness. Severely immunocompromised patients may not display these symptoms, and disease progresses more rapidly.

Aspergillus hyphae are angioinvasive and thrombose arteries to create hemorrhagic infarcts; as a result, CNS aspergillosis can present as solitary or multiple abscesses and, less commonly, as mycotic aneurysms and carotid artery invasion. Cerebral aspergillosis also can appear as meningitis or granuloma.[58] Cerebral aspergillosis presents as multiple areas of low density and no enhancement even with the administration of contrast material on CT, and lesions usually are located within the basal ganglia and gray-white matter junction. On magnetic resonance imaging (MRI), these same abnormalities appear as foci of intermediate T2 signal surrounded by a rim of higher signal.[101,143] Aspergillosis of the CNS carries a case-fatality rate of nearly 90 percent,[77] so prompt diagnosis and treatment are key to survival. Unfortunately, definitive diagnosis requires biopsy, and typically these patients are too coagulopathic to undergo such a procedure.

CUTANEOUS ASPERGILLOSIS

Neonates, burn victims, hematopoietic stem cell transplant (HSCT) recipients, solid organ transplant recipients, and other immunocompromised patients are the ones most frequently found to develop cutaneous aspergillosis. Although it is not the most commonly encountered *Aspergillus* infection, cutaneous infection has a reported incidence between 4 and 11 percent.[22,161] Cutaneous aspergillosis can be primary, a result of direct skin injury or traumatic inoculation, or secondary, a result of hematogenous spread or extension from infected underlying structures.[147] Primary cutaneous aspergillosis has been associated with intravenous access devices, adhesive dressings, and sites of burns or surgery. Premature infants are at particular risk because their skin is immature and most vulnerable. HSCT recipients generally develop disease as a result of hematogenous seeding from a primary source, usually the lungs. Lesions often begin as erythematous, indurated papules that progress to ulcerative, painful, and necrotic lesions.[134] Treatment involves débridement and excision of necrotic tissue, which provides diagnostic material, and systemic intravenous antifungals as well as topical preparations. The role of topical antifungal treatment alone is unclear, and it is probably inadequate if it is used alone, as often the cutaneous aspergillosis is a harbinger of underlying undiagnosed systemic disease.

CHRONIC ASPERGILLOSIS

Chronic aspergillosis is encountered less frequently than is acute disease, and the patient population affected typically is distinct as well. A degree of immune suppression does exist in these patients, and exposure to corticosteroids is a common finding. Underlying conditions include corticosteroid use for chronic lung disease, diabetes mellitus, and alcoholism.[24] Three separate categories are used to describe chronic aspergillosis.[30] The first is chronic cavitary pulmonary aspergillosis, in which multiple cavities form and expand and may be occupied by fungus balls. The second is chronic fibrosing pulmonary aspergillosis, which, as the name connotes, is characterized by progression of the cavities into extensive pulmonary fibrosis. The final category has been defined as chronic necrotizing pulmonary aspergillosis, also known as either subacute invasive or semi-invasive pulmonary aspergillosis.[30] The third category is an indolent pulmonary infection of patients with mild or moderate defect in immune function such as in the setting of prolonged corticosteroid use, unlike the other categories, and may be seen after resolution of neutropenia.[86] Chronic necrotizing pulmonary aspergillosis is a slowly progressive disease, and clinical signs observed include cough, fever, fatigue, and weight loss. Diagnosis requires biopsy, and treatment is with long-term antifungal therapy.[63]

ASPERGILLOMA

Aspergillomas consist of a mass of tangled hyphae, cellular debris, fibrin, and few inflammatory cells. They develop as a complication of existing cavitary lesions and are typically found in the upper lobes where there is poor drainage.[86,144] The cavitary lesions may be a result of tuberculosis infection, sarcoidosis, bullous emphysema, and other diseases associated with cavitary lung lesions. *A. fumigatus* typically causes pulmonary aspergilloma, and patients may remain asymptomatic, although many present with recurrent hemoptysis. Perhaps the earliest radiographic sign is pleural thickening of a preexisting lung cavity. Later, as the fungus ball develops, CT or plain radiography will show a solid and round mass within the cavity separated from the thickened wall by an air crescent sign.[46] Aspergillomas can be classified as simple or complex on the basis of radiologic criteria; simple indicates those lacking constitutional symptoms, paracystic lung opacities, cyst expansion, or progressive pleural thickening.[64] Treatment of active disease is aimed at control and prevention of complicating symptoms such as hemoptysis, and surgical resection is the definitive treatment. However, given the high morbidity and mortality rate in complex aspergilloma, surgi-

cal intervention is reserved for high-risk patients. Other treatment modalities, such as endobronchial and intracavitary instillation of antifungals, have been attempted with some success given that systemic therapy is ineffective at diffusing into the cavity containing the fungus ball.[64,86]

ALLERGIC BRONCHOPULMONARY ASPERGILLOSIS

Allergic bronchopulmonary aspergillosis occurs in asthmatic and cystic fibrosis patients and is a pulmonary disease caused by type I and type III hypersensitivity reactions to *A. fumigatus* allergens. Exposure to and inhalation of *Aspergillus* spores result in saprophytic colonization of the bronchial airways, which then triggers an IgE-mediated allergic inflammatory response. Over time, bronchial obstruction takes place, and patients can present with productive cough, wheezing, and chest pain; fever and malaise also are presenting symptoms.[135] Diagnosis is based on eight criteria: (1) history of bronchial obstruction (asthma), (2) peripheral blood eosinophilia, (3) elevated serum IgE levels, (4) specific IgE and IgG to *Aspergillus* antigen in serum, (5) immediate (type I) skin reactivity to *Aspergillus* antigen, (6) precipitating antibodies to *Aspergillus*, (7) transient pulmonary infiltrates, and (8) central bronchiectasis. Allergic bronchopulmonary aspergillosis is characterized radiologically by bronchial wall thickening, pulmonary infiltrates, and central bronchiectasis, a result of the type III hypersensitivity reaction.[86,144] Therapy consists of administration of corticosteroids to effectively control inflammatory responses and the antifungal itraconazole. Itraconazole has been established as the first-line agent for allergic bronchopulmonary aspergillosis in several studies.[16,19,136]

EPIDEMIOLOGY

It is critical to understand both the individual patient with invasive aspergillosis and the epidemiology of the pathogen to predict the likelihood of disease development as well as to prognosticate the outcome. Host factors are paramount, and the clinician needs to take into consideration the underlying and concomitant diseases as well as the degree and type of immunosuppression. Aspergillosis is the most common mold infection, and a review of more than 5500 patients who underwent HSCT during a 15-year period found that more than 7 percent had mold infections, including 342 patients with proven or probable *Aspergillus*, 31 patients with *Fusarium*, 29 with Zygomycetes, and 10 with *Scedosporium* infections.[85] Invasive aspergillosis is the leading cause of infectious death in HSCT recipients, and one study showed that 36 percent of all confirmed nosocomial pneumonia in these patients was caused by *Aspergillus* infection, with a crude mortality rate of 95 percent.[102] The incidence of *Aspergillus* infection in HSCT recipients has ranged from 3 to 7 percent,[90,164] but the true incidence is likely to be dependent on the follow-up duration of individual studies. A review of more than 5500 HSCT patients from 1990 to 1998 found that the yearly incidence of invasive aspergillosis increased in both allogeneic transplants (5% to 12%) and autologous transplants (1% to 5%), whereas the incidence of non–*A. fumigatus* spp. as the cause of invasive pulmonary disease dramatically increased after 1995 (18% to 34%).[85] In another study of 13 HSCT recipients with invasive aspergillosis, the risk for development of the disease was 12.8 times higher among recipients of allogeneic than of autologous HSCT.[99] A retrospective review of 409 patients showed 13.1 percent had invasive aspergillosis, which was 17.2 percent of all isolated pathogens in allogeneic transplant recipients and 3.8 percent in autologous transplant recipients.[68]

A well-characterized bimodal distribution of aspergillosis in HSCT recipients correlates with pre-engraftment neutropenia (median of 16 days after transplantation) and the peak of GVHD (median of 96 days after transplantation).[152] This correlation probably relates to the two major mechanisms of protection against invasive aspergillosis, alveolar macrophages and granulocytes. Most patients (86%) with autologous transplants were diagnosed with invasive aspergillosis while they were neutropenic, whereas patients with allogeneic transplants were at greatest risk after engraftment or during impairment of cell-mediated immunity caused by cytomegalovirus infection or GVHD.[152] In large reviews of patients undergoing allogeneic HSCT, invasive aspergillosis was diagnosed at a mean of 88 to 115 days after transplantation,[87,99,116,121] with mortality rates exceeding 80 percent. In some studies,[87,99] most cases were diagnosed after day +30; in another study,[56] no cases of invasive aspergillosis were diagnosed during the neutropenic period after transplantation. Pediatric patients undergoing transplantation generally are less vulnerable to all infections than are their adult counterparts,[37] and a review of 585 infections in 276 children who underwent HSCT found 38 (6%) mold infections in the first year after transplantation, including 28 *Aspergillus* infections.[6]

The risk of invasive aspergillosis is calculated to increase from 1 percent per day after the first 3 weeks of neutropenia to 4 to 5 percent per day after 5 weeks,[126] with a 70 percent incidence after neutropenia exceeds 34 days.[41] Prolonged or marked macrophage dysfunctions that result from underlying disease and its treatment also can predispose patients to invasive aspergillosis. Therefore, risk for development of infection is higher with advanced underlying disease, transplantation performed during relapse of malignant disease or chemotherapeutic rescue therapy, GVHD, or concurrent infection such as with cytomegalovirus.[126] In a survey of 24 medical centers of 148 invasive aspergillosis patients, 30 percent also had a bacterial infection, 20 percent also had a viral infection, and 19 percent also had another fungal infection.[106]

Corticosteroids also are well-known major risk factors for the development of invasive aspergillosis and can suppress the ability of monocytes-macrophages to kill conidia through inhibition of nonoxidative processes and impairment of lysosomal activity. Corticosteroids also inhibit polymorphonuclear neutrophils in their chemotaxis, oxidative bursts, and activity against hyphae.[35] In general, corticosteroids suppress macrophages, whereas cytotoxic chemotherapy decreases neutrophil number and function. Corticosteroids also greatly accelerate the growth of *A. fumigatus*, in one study increasing the doubling time to 48 minutes.[98]

In several HSCT recipient risk-factor studies, only moderate-severe GVHD and steroid prophylaxis for GVHD[6,87,116,166] or total-body irradiation[166] were significant variables in the multivariate analyses. In one study, several parameters were found to influence survival in the period from HSCT to diagnosis of fungal infection, all related to cumulative dose of prednisolone. In the multivariate analysis, a relative risk of 8.78 of death from invasive aspergillosis was noted in patients with acute active GVHD (grade 2 or more) or extensive chronic GVHD combined with a cumulative total prednisolone dose of more than 7 mg/kg in the 1 week before diagnosis.[116]

Only a few pediatric studies have been performed to examine risk factors for development of invasive aspergillosis. One study found that the highest incidence of invasive aspergillosis was seen in children who had undergone allogeneic bone marrow transplantation (4.5%) and those with acute myelogenous leukemia (4%). Specifically, the incidence of invasive aspergillosis in patients with acute myelogenous leukemia was significantly greater than the incidence in patients with acute lymphoblastic leukemia (RR, 5.6; 95% CI, 4.6-7.0).[167]

Little specific information is available on the fundamental epidemiology of pediatric invasive aspergillosis, and most epidemiologic investigations do not offer pediatric analyses.[20,38,68,166] One study of 327 patients with invasive aspergillosis from 1985 to 1999 did stratify patients into three age groups.[85] A total of 13

percent of patients were younger than 19 years, 34 percent were between 19 and 40 years, and 53 percent were older than 40 years. The number of transplants performed in that youngest age group was not reported, so a true incidence of pediatric disease cannot be calculated. The true incidence of invasive aspergillosis in children, therefore, remains unknown despite numerous epidemiologic studies of the disease.

Even large-scale studies of infections in pediatric HSCT recipients do not answer the fundamental questions. In a study of 148 pediatric HSCT recipients from 1986 to 1996 with 8 proven patients with invasive aspergillosis, 48 patients had suspected invasive fungal infection, but the results were not stratified between *Candida* and *Aspergillus* infection, and no specific invasive aspergillosis analyses were performed.[55] A larger report reviewed 510 pediatric HSCTs in 485 patients from 1990 to 1998.[6] There were 26 cases of invasive aspergillosis (4.79% of infections) in 584 culture-proven infections during the first year after transplantation. This pediatric report was the first to employ tools beyond descriptive statistics to analyze pediatric invasive aspergillosis. A multivariable analysis showed that invasive aspergillosis was more likely to be associated with severe GVHD (RR, 7.5%; 95% CI, 3.0-18.4). Additional analyses revealed that there were 10 cases of invasive aspergillosis in the first 30 days, 13 cases from 31 to 100 days after transplantation, and 3 cases from days 101 to 365 after transplantation.

Autopsy data from Japan for patients with invasive aspergillosis from years 1989, 1993, and 1997 analyzed the patients on the basis of age into single-decade blocks.[70] Of a total of 412 autopsies of patients with invasive aspergillosis, 14 invasive aspergillosis cases were in children aged 0 to 9 years and 24 were in those aged 10 to 19 years. By comparison, 92 cases were in patients aged 50 to 59 years, and 102 cases were in patients aged 60 to 69 years. The study did not report the total number of children in each range who underwent autopsy, so again, calculation of an incidence of pediatric invasive aspergillosis is impossible.

In an excellent review of invasive aspergillosis case-fatality rates pooled from 1941 patients from clinical trials, cohort or case-control studies, and case series of 10 or more patients with definite or probable invasive aspergillosis from 1995 to 1999, some stratification of case-fatality rate by decade of life was noted.[77] The mean age of all patients was 44.2 years (range, 3 to 91 years), and the youngest cohort (≤20 years) had a case-fatality rate of 68.2 percent (15/22). The next highest case-fatality rate was 59.3 percent in the age group 21 to 30 years. The investigators concluded that little variation exists in mortality by age, but the one pediatric case-fatality rate was considerably higher than that of the other age cohorts, suggesting the epidemiologic possibility that pediatric and adult invasive aspergillosis differ in outcome.

DIAGNOSIS

The diagnosis of invasive aspergillosis often is not straightforward. Because of the myriad clinical presentations, diagnosis of invasive aspergillosis is categorized as "proven," "probable," or "possible" disease on the basis of meeting certain clinical, microbiologic, and radiologic criteria designed by the European Organization for the Research and Treatment of Cancer and the Mycoses Study Group.[4] These criteria have served as a standard in clinical trials to group patients with similar disease characteristics, but these criteria are not perfect, and the designers have specifically cautioned against their implementation in routine clinical practice. Nonetheless, these distinctions have served the community well to establish a common framework for discussion about disease in the complicated high-risk patient. In general, proven and probable invasive aspergillosis can be considered as one entity because numerous clinical trials have shown their general equivalency in patient outcomes. However, possible disease is a vague entity and should be excluded from clinical trial design, and the clinical diagnosis should be strongly reconsidered.

CULTURES

A proven diagnosis of aspergillosis requires isolation from an otherwise sterile culture and histologic demonstration (Fig. 210–4).[4] However, this "gold standard" of tissue biopsy often is considered too invasive and complicated by bleeding or secondary infection in HSCT recipients. In a prospective study of 3857 clinical specimens from 230 patients, there were 86 positive mold cultures, including 95 percent as *Aspergillus* spp.[166] However, the important distinction for a positive *Aspergillus* culture must be made between disease and colonization. A 1-year retrospective study found that only 12 percent of patients with *Aspergillus*-positive cultures met criteria for invasive aspergillosis. Among high-risk patients, a positive culture was associated with invasive aspergillosis in 50 to 65 percent of cases; among intermediate risk, in 8 to 28 percent; and with low risk, rarely.[106]

In one study, the predictive value of respiratory tract cultures from patients with IPA was 40 to 100 percent.[145] Even in patients with established disease, the sputum specimens commonly are negative,[54,118] which is probably because IPA is predominantly infiltrative and does not have aerial growth in the bronchial tree.[54] Colonization with *Aspergillus* spp. has been a marker for reduced short-term survival, as 12 percent of colonized patients died within 3 months. IPA was diagnosed in 12 percent of patients with a positive culture, but this figure is likely to be an underestimate as culture specimens were not always obtained because diagnosis often was made by radiographic imaging.[106] In one study of heart transplant recipients, during a 10-year study period, *Aspergillus* spp. were recovered from 30 episodes from 27 heart transplant recipients (incidence: 10.5%). The overall positive predictive value was 60 to 70 percent, but it increased to 88 to 100 percent when it was recovered from a respiratory specimen other than sputum and decreased to 50 to 67 percent when it was

recovered from sputum. The sensitivities of fungal and conventional media for the recovery of *Aspergillus* spp. were 95 to 100 percent and 33 to 38 percent, respectively.[95]

Prior nasal colonization before receipt of a transplant has been associated as a predictor of subsequent IPA in some studies,[1] but the results have not been duplicated in others.[59] A prior episode of invasive aspergillosis does not eliminate the chance of having a successful HSCT, as one study reported recurrences in 9 patients with invasive aspergillosis before transplantation, and all patients showed no signs of delayed engraftment compared with transplant recipients without a history of invasive aspergillosis.[129]

Aspergillosis rarely is diagnosed by blood culture.[43] In a study of 1477 separate positive cultures, more than a dozen were positive, but most were associated with pseudofungemia or terminal events noted at autopsy.[106] In general, the *Aspergillus* hyphal mass that develops in the lumen during angioinvasion remains in place until the force of blood flow causes hyphal breakage, which then allows the mass to circulate. The likelihood of a blood culture capturing these irregularly and infrequently discharged units is small. This difficulty in detection of *A. fumigatus* in blood culture stands in contrast to other angioinvasive filamentous fungi (e.g., *Fusarium* spp., *Paecilomyces lilacinus*, *Scedosporium prolificans*, and *Acremonium* spp.) that have the ability to discharge a steady series of unicellular spores into the bloodstream, which are more likely to be captured in a blood sample. This ability to sporulate in tissue and blood has been termed adventitious sporulation.[124] As *A. terreus* also displays adventitious sporulation, histopathologic and potassium hydroxide examination of these spores also can allow rapid, presumptive identification of *A. terreus*. Therefore, a positive blood culture with *A. terreus* or another mold that demonstrates adventitious sporulation should not be ignored, and a positive blood culture with other *Aspergillus* spp. should be further evaluated.

RADIOLOGY

IPA characteristically is manifested on radiographs as multiple, ill-defined, 1- to 3-cm peripheral nodules that gradually coalesce into larger masses or areas of subsegmental and segmental consolidation. Lobar or diffuse pulmonary consolidation is a common finding.[18] Chest radiographs can be abnormal, but in one series they were normal in approximately 30 percent of patients in the week preceding death.[115]

IPA has two classic radiologic signs. The halo sign occurs in neutropenic patients with a hemorrhagic nodule caused by angioinvasion. An early CT finding of the halo sign is a rim of ground-glass opacity surrounding the nodule. In one study, the halo sign was seen in all patients with biopsy-proven IPA, but it is so nonspecific it was seen also in patients with zygomycosis, organizing pneumonia, or pulmonary hemorrhage.[165] These early lesions subsequently change into a cavitary lesion or lesion with an air crescent sign 2 to 3 weeks later when neutropenia recovers.[18,69] In one study, this sign was seen in 48 percent of patients 3 to 10 days after recovery of neutropenia.[121] Cavitation of the nodules or masses occurs in approximately 40 percent of patients and is characterized by an intracavitary mass composed of sloughed lung and a surrounding rim of air. A retrospective review of the CT findings for 47 autopsy-proven cases of IPA showed that nodular lesions and cavitation occurred significantly more often compared with controls.[48]

Just as the clinical presentation is nonspecific and heterogeneous, so are the findings in radiologic studies (Figs. 210–5 and 210–6). Although in most patients disease is seen as round infiltrates, peripheral wedge-shaped lesions, and the typical halo sign early in the course of IPA during the neutropenic period, hyphal angioinvasion is not a feature of disease in patients with CGD, and therefore the halo sign, cavitated lesions, and pulmonary infarcts are not typically found (Fig. 210–7). Instead, areas of tissue destruction secondary to the reactive acute and granulomatous inflammatory process are seen.[93]

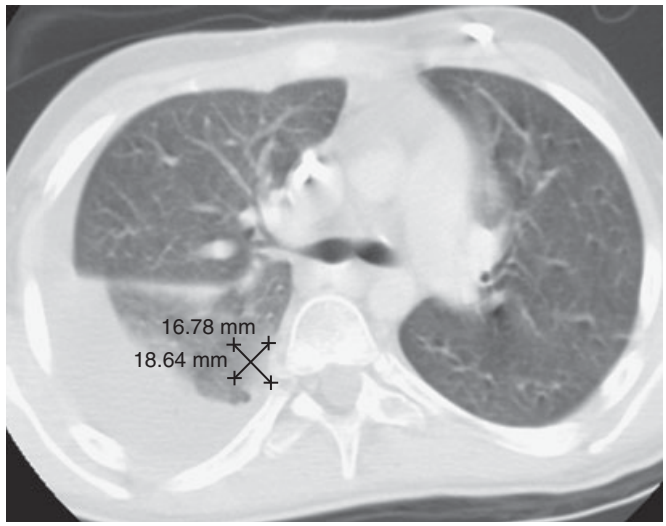

Figure 210–5 In a 15-year-old with Shwachman-Diamond syndrome and acute myelogenous leukemia, CT shows right lower lobe pulmonary nodules and pleural effusion.

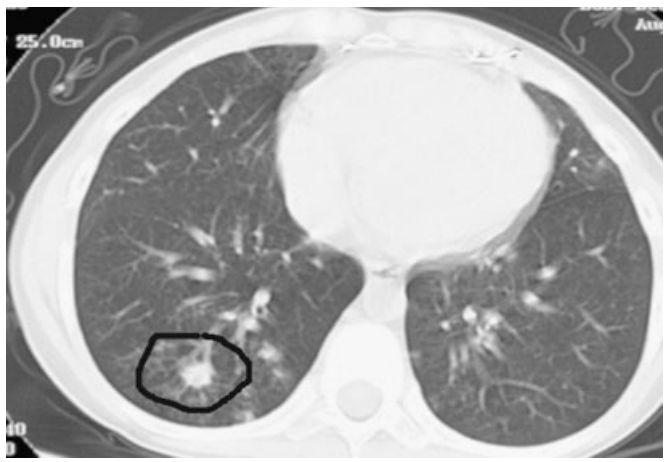

Figure 210–6 In an 11-year-old with cystic fibrosis after bilateral lung transplantation, CT shows bibasilar nodular opacities. Encircled is a 1-cm opacity associated with some peripheral speculation.

A long-term CT follow-up in 40 non–human immunodeficiency virus immunocompromised patients with IPA showed that formation of cavitation most strongly predicted the time until radiologic remission and beneficial outcome occurred. In that study, the natural history of early IPA lesions was evaluated, and 90 percent of patients were found to experience an increase in lesion size and number followed by a plateau in size and a decrease in number. Cavitation of the lesions developed in 55 percent of patients, and complete radiologic remission within a median 80 days was observed in 42.5 percent of patients. The number of days until remission without cavitation (50 days) was less than that for those with cavitation (95 days), so formation of no cavitation was strongly predictive of radiologic remission.[11] In one study, the appearance of the air crescent sign had no relationship to duration of neutropenia, and it showed a tendency to appear in large lesions, such as consolidation or mass, rather than in small lesions, such as nodules.[66]

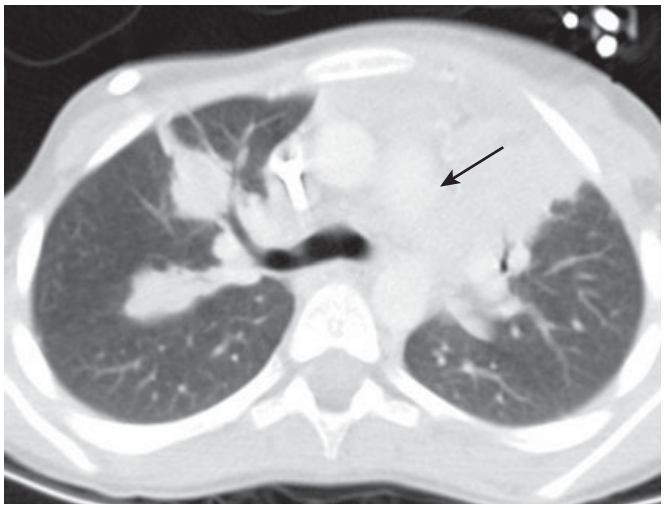

Figure 210–7 In a 9-year-old with chronic granulomatous disease, CT shows a soft tissue mass within the anterior mediastinum with heterogeneous enhancement. The mass caused convex deformity of the left anterior chest wall.

CT still remains a cornerstone to diagnosis. In a study of 37 cases of IPA, the mean time to diagnosis in bone marrow transplant recipients was reduced from 7 days to 1.9 days by chest CT.[14] One study comparing the usefulness of CT of the chest, latex agglutination test, and determination of plasma (1,3)-β-D-glucan levels for early diagnosis of IPA in 215 patients concluded that CT is the most beneficial. CT scan signs preceded a positive latex agglutination test result by 7.1 days and a positive (1,3)-β-D-glucan assay by 11.5 days.[61]

Radiologic differences for invasive aspergillosis may exist between adult and pediatric patients. In adult series of pulmonary aspergillosis, approximately 50 percent of cases show cavitation and 40 percent air crescent formation.[40] In one 10-year review of pediatric patients (mean age, 5 years), central cavitation of small nodules was found in only 25 percent of children, and no evidence of air crescent formation within any area of consolidation was found.[143] Another pediatric report had a 22 percent (6/27) rate of cavitation on chest radiography,[3] and yet another had a 43 percent (6/14) rate of cavitation on CT.[141] In these last two pediatric series, the mean ages were higher than those in the other report of lower rates of cavitation with no air crescent formation, suggesting that a spectrum of radiologic disease presentation exists that is related directly to age, with cavitation and air crescent formation more likely to develop in the older child and adult than in the younger child.

A review of 27 pediatric patients showed that radiographic changes developed after HSCT, but before diagnosis of pulmonary fungal infection, and included unilateral infiltrates (52%) slightly more often than bilateral infiltrates. At the onset, the infiltrates were interstitial (41%), alveolar (41%), and mixed (18%). Hilar or mediastinal lymphadenopathy and pleural effusion or thickening were rare findings. By the time the diagnosis of pulmonary fungal infection was established, the infiltrates were largely bilateral (66%) and alveolar or nodular (74%), including 22 percent of patients having cavitary lesions.[3]

Thoracic MRI findings are not as characteristic as are chest CT findings, and the typical MRI sign is the target sign, a nodular lesion with a lower signal in the center compared with a higher, contrast-enhancing signal intensity in the rim on T1-weighted images. This sign is highly suggestive of late-stage disease.[8] MRI is the modality of choice for diagnosis of cerebral aspergillosis, being preferred to CT for sensitivity (Fig. 210–8). Findings often show multiple lesions located in the basal ganglia that include an intermediate signal intensity, lack of contrast enhancement, and absence of mass effect.[91] CT of the head often reveals one or multiple hypodense, well-demarcated lesions. Hemorrhage and mass effect are unusual findings, but for patients with adequate peripheral white blood cell counts, a ring enhancement and surrounding edema are more frequent findings.[24] T2-weighted MRI shows very decreased signal intensity compared with that of bacterial sinusitis, which shows increased signal intensity.[24]

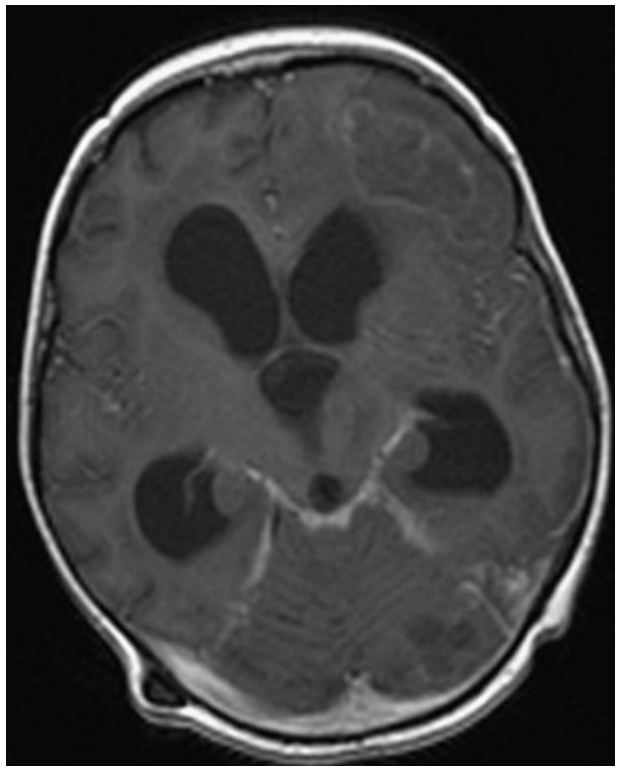

Figure 210–8 A 3-year-old with medulloblastoma and chemotherapy and radiation therapy who presented with new-onset acute mental status change. T1-weighted axial MRI shows multiple lesions in the subcortical area.

BRONCHOALVEOLAR LAVAGE

Bronchoalveolar lavage (BAL) often is useful in diagnosis of invasive aspergillosis, but a negative BAL result does not conclusively rule out disease. In one study, the BAL fluid was analyzed in 23 consecutive patients with histologically proven invasive aspergillosis, and only 7 patients (30%) had BAL specimens diagnostic for invasive aspergillosis. In the group in which BAL was diagnostic, 71 percent had multiple changes on thoracic CT compared with 25 percent of patients with negative BAL results. The diagnostic yield of BAL was not associated with clinical symptoms or duration of neutropenia. A thorough review of the diagnostic yield of BAL specimens in patients with histologically proven invasive aspergillosis yielded sensitivities of approximately 40 percent (range, 0-67%),[114] but in one study, BAL had a sensitivity of only 50 percent even in patients with focal invasive aspergillosis.[88] The sensitivity of respiratory tract culture specimens in general has ranged from 15 to 69 percent,[106] and in one study it increased to 50 to 70 percent in high-risk invasive aspergillosis groups. However, the sensitivity of BAL samples may be increased by use of a galactomannan enzyme immunoassay and by quantitative polymerase chain reaction (PCR), thus increasing

the yield of bronchoscopy and possibly precluding the need of further invasive procedures. In a large retrospective study at a major cancer center, these assays were applied to BAL fluid samples, and researchers demonstrated that each assay yielded a sensitivity higher than that commonly reported for BAL fluid culture. Concurrent use of both assays yielded the highest sensitivity (82%), detecting *Aspergillus* spp. in two thirds of the culture-negative samples from patients with IPA.[96]

SEROLOGIC TESTING

Serologic testing for antibodies to *Aspergillus* antigens is helpful to establish the diagnosis of aspergilloma or allergic bronchopulmonary aspergillosis in immunocompetent individuals, but serology unfortunately plays little role in the immunocompromised patient because growth of *Aspergillus* does not correlate with an increase in anti-*Aspergillus* antibody titers.[74] For example, serologic examination of 18 patients with invasive aspergillosis showed that anti-*Aspergillus* antibody detection was negative in all cases, probably because of profound immunosuppression.[121]

However, despite the historical lack of success with antibody testing, a movement is under way to use antibody testing in patients before immunosuppression in an attempt to discern who is most likely to develop invasive aspergillosis subsequently. A study to evaluate antibody responses by use of an enzyme-linked immunosorbent assay (ELISA) format in different types of aspergillosis patients showed that three recombinant antigens may have an important diagnostic potential.[120] The recombinant antigens with possible diagnostic utility are 18-kd ribonuclease, 360-kd catalase, and 88-kd dipeptidyl-peptidase V. In aspergilloma patients, all three of the antigens were equally useful for establishing the diagnosis, but only catalase was found to be useful in both immunocompetent and immunocompromised patients.

GALACTOMANNAN ANTIGEN TESTING

Galactomannan (GM) is a major cell wall component of *Aspergillus*, and the highest concentrations of GM are always released in the terminal phases of the disease.[74] An ELISA technique was introduced using a rat anti-GM monoclonal antibody, EBA-2, which recognizes the 1→5-β-D-galactofuranoside side chains of the GM molecule.[80] A sandwich ELISA technique was introduced in 1995,[137] and by use of the same antibody as both a capture and detector antibody in the sandwich ELISA (Platelia *Aspergillus*, Bio-Rad, France), one can lower the threshold for detection to 1 ng/mL. This technique is employed in the currently commercially available GM assay for diagnosis of invasive aspergillosis.

Positive assay results are suggestive of invasive disease, but false-positives are especially high during the neutropenic period after HSCT. A 3-year prospective trial showed that the sensitivity of serial monitoring was 90 percent, specificity was 98 percent, and negative predictive value was 98 percent. All 30 patients with proven invasive aspergillosis tested positive, with no false-negatives. GM detection preceded the development of infiltrates on chest radiography in 68 percent of patients. The false-positive rate was 14 percent, and therefore the improved sensitivity over that of latex agglutination is counterbalanced by the loss of specificity and greater number of false-positives.[81] Other studies have reported the incidence of false-positives at 5 to 8 percent and suggested they were due to cytotoxic agents, increased resorption of GM, or cross-reacting factors from the intestines.[149] In a meta-analysis conducted to characterize the clinical utility of GM assays, 27 studies from 1996 to February 28, 2005, were identified, and overall, the GM assay had a sensitivity of 71 percent and a specificity of 89 percent for proven cases of invasive aspergillosis as defined by the specific clinical criteria.[107] Of note, considerable heterogeneity was noted among the studies, and in subgroup analysis, the performance of the test differed by patient population as well as by which reference diagnostic standard was used. In patients with hematologic malignant disease or who had undergone hematopoietic transplantation, the assay was most useful, but the sensitivity and specificity in solid organ transplant recipients were 22 percent and 84 percent, respectively.

Serial testing performed at least twice a week has been recommended.[26] In one study, an increase in value during the first week of observation was predictive of treatment failure in allogeneic HSCT recipients.[10] In the largest prospective study of hematology and HSCT recipients with confirmed or probable invasive aspergillosis, GM was detected in 65 percent of patients an average of 8.4 days before CT scans or cultures were positive, and GM was detected in 40 percent of patients before the onset of clinical symptoms by a mean of 6.9 days. The sensitivity of GM detection in bone marrow transplant recipients was 89 percent, with a specificity of 98 percent. The test was performed easily, with results being available in 4 hours, and two successive samples with elevated GM values were required for positivity.[138] One study found the sandwich ELISA with a sensitivity of 60 percent and a specificity of 82 percent.[82] Another prospective study involved 186 consecutive patients at risk for invasive aspergillosis monitored twice weekly and yielded a sensitivity of 93 percent and specificity of 95 percent; in most cases, antigenemia was detected a median of 6 days before clinical symptoms were manifested.[80] Unfortunately, the GM assay has decreased sensitivity in the setting of a patient receiving anti-*Aspergillus* antifungals, although the specificity for detection does not change.[83] Therefore, assay results must be interpreted in the proper context.

Establishing the diagnosis of pediatric invasive aspergillosis with new antigen tests, such as the GM assay that is approved for use in adult patients and recently in pediatric patients, is difficult; studies have shown repeated differences in pediatric and adult values. In one prospective study from 1995 to 1998 of 450 adult allogeneic HSCT recipients (3883 samples) and 347 children with hematologic malignant neoplasms (2376 samples), the false-positive rate was 2.5 percent (10/406) in adult patients and 10.1 percent (34/338) in children. Although the sensitivity and specificity of the test with use of an optical density of greater than 1.5 in at least two sequential samples were 88.6 percent and 97.5 percent, respectively, the sensitivity in adult patients increased to 100 percent and the specificity dropped to 89.9 percent in children.[139] In another study of 797 episodes, including 48 pediatric patients, the false-positive rate in the group with fever of unknown origin was 0.9 percent in adults and 44.0 percent ($p < .0001$) in children. In addition, the specificity of the test was lower in children at 47.6 percent compared with 98.2 percent ($p < .0001$) in adult patients.[53] Numerous theories have sought to explain the increased false-positivity in children, ranging from *Bifidobacterium bifidum* spp. in the gut microflora that mimics the epitope recognized by the EBA-2 in the ELISA kit[89] to GM-positive infant formula used in pediatric patients,[160] but the complete answer remains elusive.

Questions remain about the GM false-positive results already mentioned as well as about false-negative results in some specific pediatric patients, such as those with CGD. One report describes a non-neutropenic 4-year-old child with CGD and invasive aspergillosis diagnosed by lung biopsy who had persistent false-negative serum GM test results.[150] Another study that evaluated patients with CGD ($n = 10$) and Job syndrome ($n = 6$) and invasive aspergillosis found that GM antigenemia was detected in 4 of 15 cases of CGD and Job syndrome versus 24 of 30 cases of all other immunocompromised conditions ($p = .0004$).[157] The GM assay will play an important role in noninvasive diagnosis of invasive

aspergillosis in the future, but complete elucidation of how to manage and to analyze this assay in children is lacking.

(1,3)-β-D-GLUCAN

(1,3)-β-D-Glucan is an integral cell wall component and, in contrast to GM, is not normally released from the fungal cell.[74] Factor G, a coagulation factor of the horseshoe crab, is a highly sensitive natural detector of (1,3)-β-D-glucan.[100] The "G test" detects (1,3)-β-D-glucan by a modified limulus endotoxin assay and detects *Aspergillus*, *Candida*, and even *Cryptococcus*, but it does not identify the genus of the fungi detected.[100] The G test is used widely in Japan, but these tests yield positive results only at advanced stages of infection in most patients.[62] A 1-year prospective study of patients with hematologic malignant disease and controls found the sensitivities of real-time PCR to be 79 percent, of the GM assay to be 58 percent, and of the G test to be 67 percent, with specificities of 92 percent, 97 percent, and 84 percent, respectively.[60] Currently, the (1,3)-β-D-glucan assay is available in the United States as the Fungitell assay (Associates of Cape Cod, Falmouth, MA).

In a study comparing (1,3)-β-D-glucan and GM, the sensitivity, specificity, and positive and negative predictive values for GM and β-glucan tests were identical. False-positive reactions occurred at a rate of 10.3 percent in both tests, but the patients showing false-positive results were different in each test. Both tests anticipated the clinical diagnosis and CT abnormalities, but (1,3)-β-D-glucan test results tended to become positive earlier than GM test results. A combination of the two tests improved the specificity (to 100%) and positive predictive value (to 100%) of each individual test without affecting the sensitivity and negative predictive values.[105] Another study compared GM, PCR, and (1,3)-β-D-glucan testing of patients with hematologic disorders, and the receiver operating characteristic (ROC) analysis showed that an area under the ROC curve was greatest for the GM assay, using two consecutive positive results. This result suggests that the GM assay was the most sensitive at predicting the diagnosis of invasive aspergillosis in high-risk patients with hematologic disorders.[65]

POLYMERASE CHAIN REACTION

Although GM assays created a noninvasive test with improved sensitivity and specificity, recent efforts have focused on defining an optimal primer sequence for a PCR detection method. At present, this diagnostic method is not commercially available, and reports can be difficult to interpret because of the lack of experimental standardization between centers. Because of the ubiquitous nature of the mold, the value of this test will probably be its high negative predictive value. Issues remaining unresolved in the use of PCR are the best source of material (e.g., whole blood, serum, plasma, BAL specimens), the amplification protocol (e.g., real-time, sample volume, extraction methods), and the primer selection (e.g., "panfungal," 18S rRNA, 28S rRNA, mitochondrial DNA).[67] Use of PCR in BAL specimens compared with blood samples seems less promising because of the higher number of false-positives. Real-time PCR assays seem to decrease the risk of getting false-positive results and have better reliability than conventional PCR.[21]

Reported sensitivities in numerous retrospective reports of PCR are 55 to 100 percent, with negative predictive values generally around 100 percent.[113] The high negative predictive value is consistent with PCR as a sensitive marker for any colonizing or infecting aspergilli, and a patient with a suspected invasive aspergillosis who has a negative PCR result most likely does not have the organism.[112] In a 2-year prospective study of 121 patients with hematologic malignant neoplasms analyzed twice weekly with screening of whole blood samples, the negative predictive value of two or three consecutive positive PCR results was 98 percent, with a sensitivity of 75 percent and a specificity of 96 percent. When PCR was detected only once, it was never associated with disease and resolved without antifungal treatment, thus indicating only a transient *Aspergillus* DNAemia.[72]

In another prospective PCR study in 84 allogeneic HSCT recipients, all patients with proven or probable invasive aspergillosis were PCR positive, and PCR was found to be the earliest indicator for patients with new-onset invasive aspergillosis, preceding the first clinical signs by a median of 2 days and preceding the diagnosis based on typical radiographic findings by a median of 9 days. For patients without a history of invasive aspergillosis who tested positive with PCR twice, sensitivity was 100 percent, and the negative predictive value was 100 percent.[50] In another study of patients with invasive aspergillosis, diagnosis by a positive PCR preceded radiologic signs by a median of 4 days. In addition, the disappearance of fungal DNA correlated with successful therapy, and the patients who died of invasive aspergillosis remained PCR positive.[36] In one study, PCR positivity preceded radiologic diagnosis in 11 of 18 patients, and an ELISA did not precede a positive PCR on any patient. PCR was more sensitive than was ELISA, although ELISA had no false-positives.[162]

PCR has been used to detect *Aspergillus* in BAL specimens, but that does not allow distinction between colonization and invasive disease. A prospective evaluation of 197 BAL samples in febrile, neutropenic patients with lung infiltrates showed that all immunocompromised patients with a negative PCR had no evidence of fungal disease, and only a few patients without immunocompromise showed positive results without evidence of disease. Further dividing into a high-risk group (patients with acute leukemia undergoing chemotherapy), the negative predictive value was 100 percent.[12] A two-step PCR was shown to detect down to as little as 10 fg of *Aspergillus* DNA (approximately 5 CFU/mL) and was tested in 100 consecutive patients with BAL and 278 consecutive patient blood samples. BAL PCR was positive in 17 immunocompromised patients, with a specificity of 93 percent and negative predictive value of 100 percent. Comparatively, in the blood samples, sensitivity was only 20 percent, but negative predictive value was 100 percent.[13]

TREATMENT

Overall success in treatment of invasive aspergillosis is dependent on numerous factors, not simply the choice of specific antifungal therapy. As with all infectious pathogens, the clinician should understand the epidemiology in the local setting, as different *Aspergillus* spp. will respond uniquely to different therapies. Any antifungal prophylaxis used before establishment of the diagnosis of invasive aspergillosis could have an effect on the ultimate use of agents designed for targeted therapy, including drug interactions and development of antifungal resistance. The cornerstone of antifungal therapy for invasive aspergillosis is prompt and aggressive institution of antifungal therapy, largely based on clinical suspicion of infection. Diagnostic work-up needs to be aggressive, but it should never delay initiation of therapy.

Since its initial approval for use in 1958, amphotericin B deoxycholate was the first-line therapy for invasive aspergillosis and the gold standard against which other therapies were measured. However, with overall survival rates of approximately 34 percent among patients treated with amphotericin B, in addition to limited tolerance as a result of acute and chronic toxicities, a better antifungal clearly was needed. Itraconazole became available in 1990 for the treatment of *Aspergillus* infection, but it was not without flaws, the most prominent of which were decreased fungicidal activity compared with amphotericin B, unpredictable

bioavailability in high-risk patients, and significant drug interactions.[132] The next step taken in the search of a better antifungal was the development of three different lipid formulations of amphotericin B, the advantages of which included an increase in the daily dose, high tissue concentrations with better delivery to reticuloendothelial organs, decrease in infusion-related side effects, and decrease in renal toxicity.[33] These three lipid formulations, amphotericin B lipid complex, amphotericin B colloidal dispersion, and liposomal amphotericin B, currently are indicated for patients with systemic mycoses, primarily invasive aspergillosis, who cannot tolerate or are refractory to conventional amphotericin B.[132] To date, no large randomized study has been performed to determine if any of the lipid formulations has improved efficacy over conventional amphotericin B, but data show that liposomal amphotericin B has less infusion-related toxicity.[45] A study to determine if lipid formulations are better than conventional amphotericin B, although informative, may not ever take place because of the introduction of voriconazole and a whole new class of antifungals, the echinocandins.

Voriconazole is a second-generation triazole and synthetic derivative of fluconazole that was approved for use in the United States in May 2002 for primary therapy for invasive aspergillosis. Among the instrumental trials leading to this approval is the multicenter noncomparative, open study of 116 patients treated with voriconazole as primary therapy (60 patients) or salvage therapy (56), which showed a response rate of 59 percent in the primary treatment of invasive aspergillosis and 38 percent rate for salvage treatment. The response rate for patients with IPA was 60 percent.[29] The other critical trial is that by Herbrecht and coworkers,[52] a large prospective comparative study that showed that voriconazole had a better response rate in the primary treatment of invasive aspergillosis compared with amphotericin B, 52.8 percent compared with 31.6 percent. Survival rates also increased, from 57.9 percent for amphotericin B to 70.8 percent for voriconazole. This improved response rate has translated well to the pediatric population, as shown by a review of 42 children treated for invasive aspergillosis with voriconazole.[155] An analysis of the compassionate open-label use of voriconazole in children for refractory invasive aspergillosis demonstrated a 43 percent complete or partial response. Voriconazole also was shown in these studies to be better tolerated and to have less toxicity in both adults and children. The main side effects of voriconazole are reversible visual disturbances in as many as 40 percent of patients, elevated transaminases, and occasional skin reactions most likely due to photosensitization.[119] It is available in both intravenous and oral formulations.

Another new triazole is the recently approved posaconazole, a derivative of itraconazole. No randomized studies have examined posaconazole for primary therapy for invasive aspergillosis, but numerous in vitro and in vivo data suggest that this triazole will be as effective as voriconazole as a potential first-line agent against invasive aspergillosis.

The echinocandins are an entirely new class of antifungals that interfere with cell wall biosynthesis. This is a distinct mechanism of action compared with the second-generation triazoles that work by inhibiting cytochrome P450 enzymes responsible for conversion of lanosterol to sterol and thus compromising the fungal cell membrane.[159] Three compounds, caspofungin, micafungin, and anidulafungin, currently are approved in the United States. Caspofungin, the first in the echinocandin class, has shown potent efficacy against *Aspergillus*.[78] The first clinical trial, conducted by Maertens and colleagues,[79] was an open-label, noncomparative study in 90 immunocompromised patients with definite or probable aspergillosis. Caspofungin produced a complete or partial response in 45 percent of patients, including 50 percent of 64 patients with probable invasive aspergillosis and 23 percent of 13 patients with disseminated aspergillosis. This result was validated by two subsequent clinical trials in which caspofungin resulted in complete resolution or stabilization of disease in 74 percent of patients (n = 31) in one trial and had an overall response rate of 56 percent (n = 32) in the other.[15,146]

Micafungin is an echinocandin lipopeptide compound that is fungistatic in vitro, like others in its class, with median minimum inhibitory concentration (MIC) values for *Aspergillus* spp. substantially lower than those of other non-echinocandins.[142] A noncomparative, open-label, multicenter study in adult and pediatric patients to examine the safety and efficacy of micafungin in the treatment of invasive aspergillosis that had failed to respond to prior therapy or for which other therapy could not be tolerated was conducted during 1998 to 2002. Of the 225 patients who met diagnostic criteria, a favorable response rate was reported in 35.6 percent (80/225), and of those treated with only micafungin, a favorable response was seen in 6 of 12 (50%) of the primary and 9 of 22 (40.9%) of the salvage therapy group.[28] Anidulafungin is another echinocandin that has been approved in the United States for treatment of candidemia and esophageal candidiasis, and an in vitro study looking at its efficacy against *Aspergillus* spp. isolates showed it to be the most active antifungal agent of those tested, with an MIC_{90} of less than 0.03 mg/L.[128] Currently, no prospective, comparative trials of any echinocandins as primary therapy for invasive aspergillosis have been performed; instead, most clinicians use the fungistatic echinocandins in a role for salvage therapy.

Beyond controlled clinical trials, very little investigation has been conducted into the treatment practice patterns or outcomes of pediatric patients with invasive aspergillosis. The largest study of treatment practices and outcomes in overall invasive aspergillosis reviewed 595 patients treated by 89 physicians. The patients analyzed were 0 to 86 years old, and the mean age was 42.3 years.[104] In a European review of diagnosis and therapeutic outcome, 123 patients were analyzed, with a mean age of 46 years (range, 9-83 years).[27] An older report of 2121 published cases[31] and a report on therapeutic outcome in 1223 cases of invasive aspergillosis[25] also did not specifically exclude children, but no specific data were supplied on the pediatric patients with invasive aspergillosis.

No dedicated, prospective, large-scale investigation into treatment of pediatric invasive aspergillosis has been conducted. One large data set analyzed adult and pediatric invasive aspergillosis outcomes separately. The adult data were an analysis from the open-label, multicenter clinical study of emergency use of amphotericin B lipid complex at 5 mg/kg/day from 1990 to 1995 in the treatment of patients with proven or probable invasive fungal infections who failed to respond to previous systemic antifungal therapy (including amphotericin B at a cumulative dosage of at least 500 mg), developed severe nephrotoxicity (serum creatinine concentration ≥2.5 mg/dL in adults or ≥1.5 mg/dL in children), had pretreatment renal insufficiency, or developed severe acute toxicity.[154] Patients were excluded if a systemic antifungal or investigational drug was administered concurrently with the amphotericin B lipid complex. This study evaluated 551 patients with 556 courses of amphotericin B lipid complex therapy, of which 291 patients fulfilled criteria for evaluation of efficacy. The mean age of all enrolled patients was 37.2 years (range, 21 days to 93 years). There were 130 cases of invasive aspergillosis, with a complete or partial response rate of 42 percent, stable response in 12 percent, and failure in 45 percent of patients. The complete or partial response rate of probable invasive aspergillosis (n = 74) was 38 percent; of disseminated invasive aspergillosis (n = 27), 30 percent; of sinusitis (n = 14), 64 percent; and of single-organ extrapulmonary invasive aspergillosis (n = 15), 67 percent. The analysis of 556 treatment episodes did not stratify pediatric responses, but a subsequent analysis was performed of 54 of the 111 pediatric patients (<18 years) from that study.[158] The mean patient age was 9.3 years (range, 21 days to 16 years). There were 25 cases of invasive aspergillosis with a

complete or partial response rate of 56 percent, stable response in 8 percent, and failure in 36 percent of patients. The complete or partial response rate of probable invasive aspergillosis ($n = 10$) was 50 percent; of disseminated invasive aspergillosis ($n = 7$), 29 percent; of sinusitis ($n = 5$), 100 percent; and of single-organ extrapulmonary invasive aspergillosis ($n = 3$), 67 percent.

In a retrospective French study of 46 pediatric patients treated with amphotericin B lipid complex for invasive fungal infections from 1994 to 1997,[51] the mean age of 23 patients with invasive aspergillosis was 9.7 years (3 months to 18 years). Eighteen of 23 (78%) patients showed cure (52%) or improvement (26%); therapy failed in 22 percent. Three patients who initially improved later relapsed, dropping the cure or improvement rate to 15 of 23 (65%).

An analysis of the compassionate open-label use of voriconazole in children for refractory invasive aspergillosis with clinical or radiologic progression of disease after 7 days or more of systemic antifungal therapy in children younger than 16 years included 42 patients with proven or probable invasive aspergillosis.[155] The mean age of all 58 children with invasive fungal infections, including invasive aspergillosis, and 16 patients with other systemic fungal disease was 8.2 years (range, 9 months to 15 years). Analysis of the 42 patients with invasive aspergillosis revealed a complete or partial response rate of 43 percent and a stable response in 7 percent of patients; 10 percent of patients were intolerant of therapy, and therapy failed in 40 percent. The complete or partial response rate of probable invasive aspergillosis ($n = 12$) was 33 percent; of CNS invasive aspergillosis ($n = 6$), 50 percent; of disseminated invasive aspergillosis ($n = 7$), 86 percent; of sinusitis ($n = 7$), 29 percent; and of single-organ (bone, liver, or skin) invasive aspergillosis ($n = 10$), 30 percent.

Although several reviews of combination therapy in systemic mycoses have been published,[75,109] only a few retrospective clinical reviews of combination invasive aspergillosis therapy exist.[31,111] There has been only a single published combination antifungal clinical trial for invasive aspergillosis,[148] and it was never completed. That study enrolled 18 patients with documented pulmonary aspergillosis; only 1 of 9 patients receiving amphotericin B monotherapy survived, and 2 of 9 treated with amphotericin B plus 5-flucytosine survived. The study was terminated because of poor outcomes in both arms, but outcomes might have been poor because a lower dose of amphotericin B (0.5 mg/kg/day) was used and a definite diagnosis was required. Therefore, in view of the low number of patients and the poor outcomes in both arms, no firm conclusion could be drawn about the possible superiority of that combination therapy.

Although no controlled clinical trial supports the use of combination therapy for invasive aspergillosis and its efficacy has not been conclusively established,[110] clinicians are desperately seeking new strategies for improved outcome. However, the experimental and clinical data do not reveal proven benefits with combinations, nor do they fully define the preferred combination for further exploration in a large clinical trial. The range of data from synergy to antagonism actually parallels the wide range of unproven treatment practices used by clinicians today searching for the best care for their patients.

Denning and Stevens[31] previously reviewed a total of 2121 cases reported in 497 articles concerning clinical aspects of invasive aspergillosis from 1966 to 1990, analyzing 446 treatment courses in 379 patients from 210 articles. That 1990 review[31] revealed 89 clinical cases of combination therapy reported in 54 articles: amphotericin B plus rifampin (26 cases) and amphotericin B plus 5-flucytosine (63 cases). The largest analysis of combination therapy for invasive aspergillosis reviewed 6281 total cases of invasive aspergillosis management and added an additional 12 years and 386 clinical cases of combination antifungal therapy reported in 236 articles[133] to that original 1990 study. After closer inspection and exclusion of 11 cases in 7 articles from the 1990 review and 215 cases in 154 articles from 1990 to 2001 that did not meet inclusion criteria, that large combination analysis analyzed a total of 249 clinical combination cases reported in 128 articles.

In that analysis, three combination regimens represented the majority of reported clinical experience; many (49%) involved amphotericin B plus 5-flucytosine, whereas amphotericin B plus itraconazole (17%) and amphotericin B plus rifampin (11%) were used less frequently. However, after inclusion of the lipid formulations of amphotericin B (i.e., amphotericin B lipid complex, amphotericin B colloidal dispersion, and liposomal amphotericin B), the frequency of those three combinations increased from 77 to 89 percent of the total number of combinations analyzed. Finally, inclusion of those nine patients who were treated with one combination regimen and then switched to another increased the contribution of these three regimens to 91 percent of combination strategies ever reported. Although these data helped lay the foundation of combination therapy in the past, the combinations used historically are not necessarily the combinations employed by today's clinician.

The 249 clinical cases represented a total of 23 different antifungal combinations, including 16 unique double antifungal and 7 triple antifungal regimens. A total of 64 percent of patients showed improvement, with the mortality rate from invasive aspergillosis at 34 percent. This response rate is higher than the general reporting of approximately 34 percent survival in patients treated with customary monotherapy.[77] There were also 27 reports of in vitro combination antifungal therapy against *Aspergillus* spp. published from 1974 to 2001, analyzing 34 different combinations. Analysis revealed in vitro synergy (38%), additivity (25%), indifference (27%), and antagonism (10%). An additional 18 reports of in vivo combination antifungal therapy in animals published from 1975 to 2001 analyzed 15 different combinations and their outcomes. The most frequently tested combination was amphotericin B plus 5-flucytosine, followed by amphotericin B plus itraconazole. The in vivo results were positive less frequently, with synergy (14%), additivity (20%), indifference (52%), and antagonism (14%). As a whole, the previous experimental data and clinical experience offer hope that newer strategies will improve outcomes.

Regardless of the continuous stream of data, the in vitro and in vivo interactions must continue to be questioned because of so many confounding patient variables, leaving clinical experience still the most accurate tool. Numerous factors that contribute to clinical efficacy include the complex interaction of the fungal virulence, the intrinsic or acquired fungal resistance, and the host immune condition and its interaction with the therapeutic agents. However, clinical relevance might best be related to patient factors (e.g., recovery of neutropenia, cessation of glucocorticoid therapy) and not intrinsically related to the susceptibility of the fungus itself.

One study to help address this issue of combination therapy of voriconazole plus caspofungin was a retrospective review of 47 patients with proven or probable invasive aspergillosis from 1997 to 2001 who experienced failure of primary therapy with amphotericin B formulations.[84] Patients initially received therapy with amphotericin B (1 mg/kg/day) or a lipid formulation (amphotericin B lipid complex or liposomal amphotericin B, both at 5 mg/kg/day). Salvage therapy was begun with voriconazole ($n = 31$) versus voriconazole plus caspofungin ($n = 16$) after 7 days or more of amphotericin B therapy. The change to the combination antifungal therapy was made in the institution's protocol in February 2001 in the middle of the retrospective window analyzed. In early 2001, the protocol was altered so caspofungin (70-mg load, then 50 mg daily) was used in combination with voriconazole therapy, thus creating the combination therapy arm of this retrospective analysis. Importantly, most patients received salvage therapy

because of clinical failure, not antifungal intolerance, yet no patients received their voriconazole or voriconazole plus caspofungin as primary therapy for invasive aspergillosis.

The overall survival rate 3 months after the day of diagnosis of invasive aspergillosis was higher among those who received combination therapy ($p = .048$). Similarly, 3-month survival after the start of salvage therapy was greatest among patients who received combination therapy (HR, 0.43; 95% CI, 0.17-1.1; $p = .050$). Finally, the probability of death also was lower in those patients receiving combination therapy ($p = .024$). In the bivariable analysis (controlling for antifungal therapy and receipt of HSCT), the combination showed an improved 3-month overall survival rate (HR, 0.27; 95% CI, 0.09-0.78; $p = .008$).

Others have suggested that the preclinical data with combination therapy seem promising yet inconsistent.[151] The point was made that usually historical control studies tend to underestimate results in the control group and show larger treatment effects than randomized studies do. Second, the advent of newer diagnostic tools for invasive aspergillosis (galactomannan assay, high-resolution computed tomography) cannot be adequately included in a retrospective analysis, and finally is the issue of consistency in shifting to salvage therapy. Marr and colleagues responded to other comments[17] and in analyzing the patients at 1 year found no difference in overall survival rates ($p = .26$). Importantly, at that 1-year mark, only seven patients in the voriconazole arm and one patient in the combination arm were alive. Subsequent analyses of these eight patients did reveal a decreased probability of dying of invasive aspergillosis ($p = .024$) and a larger probability of dying of other causes ($p = .042$), but again, only eight total patients were analyzed.

The current clinical use of combination therapy for invasive aspergillosis is rampant, even in the absence of a definitive clinical trial advocating its benefit. There are many editorials on combination therapy design questions, calls to arms to begin a combination antifungal clinical trial, standardization attempts for animal models, and opinions on the value of in vitro checkerboard testing. The data continue to mount with no clear indication. Perhaps we will never achieve the same improvement in mortality rates seen from amphotericin B to voriconazole clinically but will only be able to obtain a slight increase in benefit with combination strategies. Perhaps the decrease in fungal burden is all we can hope to achieve, and this will translate into clinical benefit. However, survival does remain the experimental standard, as survival incorporates host response as well as antifungal activity itself.

Antifungal resistance is not considered for invasive aspergillosis in the same fashion as one would depict resistance of bacteria to antibacterial agents or even of *Candida* spp. to antifungals. In those two examples, resistance often is inherent (e.g., *Candida krusei* and fluconazole) or develops after prolonged exposure pressure (e.g., antibacterials). Although it has not been proved in any large-scale format, the prevailing thought is that *Aspergillus* spp. do not develop resistance in this format but that certain species are intrinsically resistant to certain classes of antifungals.

For years, *A. terreus* was a recalcitrant *Aspergillus* spp. because of its now well-described in vitro resistance to amphotericin B,[140] which has been confirmed in animal models.[156] A review of in vitro analyses, multiple animals, and previously reported clinical cases showed nearly uniform failure with amphotericin B against *A. terreus*.[131] A multicenter retrospective analysis of more than 80 cases from 1997 to 2002 demonstrated that mortality was decreased in those patients who received voriconazole instead of amphotericin B therapy.[130] Other studies have shown that patients with *A. terreus* disease are more likely to be neutropenic,[49] are more likely to have disseminated disease, and have a decreased response to all classes of antifungals compared with patients infected with *A. fumigatus*.[73]

Antifungal resistance among *A. fumigatus* isolates is not a common finding. Itraconazole resistance was described first in 1997,[32] and one study estimated that 2.1 percent of more than 900 *A. fumigatus* isolates were resistant to itraconazole.[92] A large study examining 200 sequential isolates of *A. fumigatus* from 26 immunocompromised patients found similar antifungal susceptibility both before and after treatment with both amphotericin B and itraconazole, suggesting that emergence of resistance while receiving antifungal therapy is likely to be a rare event.[23]

Other interventional therapies used in the treatment of invasive aspergillosis include growth factors such as granulocyte colony-stimulating factor and granulocyte-macrophage colony-stimulating factor, granulocyte transfusions, interferon-γ, and surgery. Granulocyte colony-stimulating factor increases the number of circulating polymorphonuclear neutrophils and enhances phagocytic activity and oxidative burst metabolism. Interferon-γ promotes tumor necrosis factor–α production and enhances polymorphonuclear neutrophil and mononuclear cell–induced damage. It has been proved to help prevent invasive aspergillosis in patients with CGD and is used as prophylactic therapy in these patients.[132] Surgical intervention is indicated in patients with acute hemoptysis, for relapse prophylaxis before HSCT or the next cycle of chemotherapy, and for lesions impinging on great vessels or major airways.[9]

CHAPTER 211

Blastomycosis

Stephanie H. Stovall ✪ Gordon E. Schutze

Blastomyces dermatitidis is a dimorphic fungus that is responsible for a systemic disease characterized by granulomatous and suppurative lesions. Illness occurs when fungal spores are inhaled into the lungs and undergo transition into an invasive yeast phase. Once in the yeast phase, these organisms may not be cleared by bronchopulmonary phagocytes and may proliferate before immunity develops. The infection may be halted and resolved by the host at this point, or progression of the infection leading to localized pulmonary involvement or extrapulmonary disease may occur. Such dissemination results in the involvement of other parts of the body, most notably the skin and bones. Although the highest prevalence of disease with this organism is observed in North America, blastomycosis has been documented to occur worldwide.

Gilchrist and Stokes[27,28] were the first to describe blastomycosis in the late 1890s. During the next decade, the heightened awareness of the disease by the medical community produced reports from various regions of the United States, with most cases occurring in the Chicago area.[60] Because of this finding, blastomycosis became known as Chicago disease or Gilchrist disease. A widely accepted concept during these early studies was that two forms of the disease (cutaneous and systemic) existed and that each represented a different portal of entry by the organism. Many years later, Schwarz and Baum[66] established that blastomycosis is a primary pulmonary process and that the cutaneous manifestations are secondary to dissemination from the lung. More recently, blastomycosis became known as North American blastomycosis because of an erroneous perception that the disease is limited to North America; but because this disease now is recognized as having a worldwide distribution, it is known at present as blastomycosis.

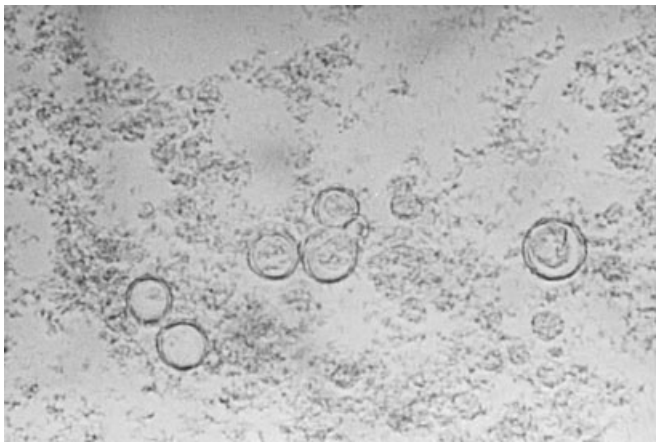

Figure 211–1 Wet preparation demonstrating the spherical shape of *Blastomyces dermatitidis*.

THE ORGANISM

B. dermatitidis is the causative agent of blastomycosis. The organism has two forms: sexual (the teleomorphic or perfect state) and asexual (the anamorphic or imperfect state). The sexual form of the fungus is named *Ajellomyces dermatitidis*, whereas the asexual form is actually *B. dermatitidis*. The asexual stage exhibits dimorphism, during which the fungus grows as a yeast form at body temperature and as a mycelial form at room temperature. At 37° C, the yeast form appears as a large round organism (6 to 15 μm in diameter) with a thick wall that can produce a single bud (Fig. 211–1). Characteristically, this bud is connected to the parent yeast by a wide base of attachment and usually will equal the size of the parent before detachment. At 25° C to 30° C on laboratory medium, *B. dermatitidis* grows as a white to gray-brown mold (mycelia) with a delicate, silky appearance. On microscopic examination, the mold is characterized by filamentous colonies composed of thin, uniform septate hyphae (1 to 2 μm in width) that produce conidiophores that branch at right angles to the main hyphal segment. The solitary conidia (spores), which are located at the end of the conidiophores, are small (2 to 10 μm in diameter) and may be oval or pyriform (pear shaped). These conidia are similar to the microconidia of *Histoplasma capsulatum*, but the conidia of *B. dermatitidis* do not form tuberculate macroconidia as do those of *Histoplasma*. The appearance of *B. dermatitidis* mycelia is not pathognomonic for the organism, and definitive identification depends on conversion of the organism to the yeast form by culture at 37° C.

ECOLOGY AND EPIDEMIOLOGY

Only a paucity of data concerning the ecology and epidemiology of this disease exists. Without data on the ecology of the organism, knowledge about the epidemiology of disease caused by this organism is derived from studies of sporadic cases. Although significant data on the epidemiology of the disease have been gathered with such studies, gaps in our knowledge will become clarified when the ecology of the agent is defined better. Because *B. dermatitidis* cannot be recovered easily from nature and an adequate skin test antigen is not available for conducting population surveys, the present knowledge of this disease is based on case reports of sporadic infections and outbreaks of human and canine disease. The use of new molecular techniques such as polymerase chain reaction may provide fresh insight into the epidemiology of this organism in the coming years.[46]

The natural reservoir of *B. dermatitidis* is not defined as precisely as are the reservoirs for other systemic mycoses (e.g., bird droppings, *H. capsulatum*), but this organism is assumed to have its reservoir in a habitat similar to that of the other dimorphic fungi. *B. dermatitidis* appears to be a soil saprophyte and presumably exists in the mycelial form in nature. The organism probably thrives in a location that is high in organic material, is abundant in moisture, has an acid pH, and even may be enriched with animal excreta.[39] The yeast and mycelial phases of the organism seem to disappear rapidly when they are placed in the soil, whereas conidia can survive for several weeks.[47] Desiccation of such an area with subsequent disturbance of the site results in an infectious aerosol of mycelial fragments and conidia.[59] Conidia also may be released from mycelia on the soil or from decaying material when it is wetted or disturbed.[35,37]

Speculation on the natural source of this organism began shortly after it was recognized. Several investigators have noted an association between water and *B. dermatitidis*. Denton and Di Salvo[19] were able to recover the organism in 10 of 356 samples along 1 mile of road by the Savannah River. Furcolow and associates[26] published an extensive review of cases of canine and human blastomycosis that occurred during a prolonged period (1885 to 1968); a high incidence of disease was demonstrated south of the Ohio River and east of the Mississippi River. Recently, Baumgardner and colleagues[4] reported a disproportionate number of human and canine cases near the waterways of the western Eagle River in Wisconsin. In addition, at least five human outbreaks of blastomycosis have occurred along river banks.[14,38,39,72] The exact role of the water, however, currently is not understood.

Blastomycosis has been reported to occur worldwide, but many of these reported cases have not withstood scrutiny. Unequivocal cases of blastomycosis from South America have not been described in the past 4 decades. Isolated cases have been reported from England, Switzerland, and Poland, and sporadic infections have been found in the Middle East and India. Most cases, however, are reported from the eastern portion of North America (east of the 100th meridian), with a smaller number scattered throughout Africa.[2]

All age groups are susceptible to blastomycosis. The age distribution varies with each series of cases published because of differences in the populations examined. Most patients, however, are between the ages of 20 and 70 years; only 3 to 13 percent of reported cases occur in patients younger than 20 years.[26,44,48,50] Two patients who were 3 weeks of age or younger have been described.[45,74] Exceptions to this age spectrum occur in outbreaks, in which cases in children can predominate. Although some studies in adults have demonstrated a preponderance of men infected with *B. dermatitidis*, previous studies in children and adolescents have not shown such a trend.[41,58,69,77] Case rates for blastomycosis have been described to be highest for African American and Aboriginal patients, but the general speculation is that the racial difference in case rates reflects the population in the community of the endemic region. The age, sex, and race distributions of children with blastomycosis, therefore, appear to be a matter of exposure and not susceptibility of the individual.

Domestic dogs and cats also are susceptible to *B. dermatitidis*.[9,29] Dogs, in particular, seem to be as susceptible to *B. dermatitidis* as humans are. Because of this finding, canine blastomycosis has become a surrogate marker for human blastomycosis. The incidence and prevalence of canine blastomycosis have been studied extensively to supplement our knowledge about the geographic distribution of the disease. Menges and associates[49] were among the first to conclude that humans and dogs acquire their infections from the same source and that no evidence has been found of passive transmission of illness from dog to human or vice versa.

PATHOGENESIS AND PATHOLOGY

Five methods of transmission of *B. dermatitidis* have been described: inhalation, accidental inoculation, dog bites, conjugal transmission, and intrauterine transmission. By far the most common portal of entry into the body is through the lungs. Not until the work of Schwarz and Baum[66] in the early 1950s did researchers recognize that *B. dermatitidis* is inhaled from the environment and results in a subclinical or mild respiratory illness. In most situations, disease at other body sites is a result of hematogenous spread from the lungs, even if it is not recognized clinically. Primary cutaneous blastomycosis has occurred secondary to accidental needle inoculation, often in a veterinarian or pathologist, or by dog bites.[30,40] Person-to-person spread of blastomycosis does not occur, except in certain situations. One well-recognized case of conjugal transmission and two of intrauterine transmission to neonates have been reported.[16,45,74]

Blastomycosis begins with inhalation of the conidia of *B. dermatitidis* into the lungs, followed by development of an inflammatory response with neutrophils and macrophages. Most conidia are killed easily by these phagocytes, but those that succeed in changing into the yeast form are more resistant to phagocytosis. The large size of the yeast form and resistance to the oxidative mechanisms of killing used by phagocytes render the yeast form more difficult to kill. During the next 4 to 8 weeks, unphagocytosed yeast forms proliferate, and patients may be asymptomatic or complain of an influenza-like illness with fever, arthralgia, myalgia, productive cough, and pleuritic chest pain.[64] The infection may be halted by the host at this stage, or progression of the infection may lead to localized pulmonary and extrapulmonary disease.

Subclinical cases of blastomycosis probably develop more commonly than do symptomatic ones.[73] The high number of asymptomatic infections supports the theory that healthy individuals are fairly resistant to infection. The exact mechanisms of both natural and acquired resistance to infection are not understood. Natural resistance is thought to be mediated by neutrophils, monocytes, and alveolar macrophages. Human neutrophils phagocytose the conidia of *B. dermatitidis* rapidly and effectively; within 2 hours, 90 percent of the conidia are located intracellularly,[22] whereas the yeast forms are moderately resistant to killing by neutrophils. Human alveolar macrophages exhibit phase transition–associated fungicidal and fungistatic activities by irreversibly blocking conidial phase transition to the yeast form or reversibly inhibiting phase transition by causing the accumulation of unusual intermediate forms.[70]

Only recently have we been able to characterize features of acquired resistance in blastomycosis. No relationship between the presence of specific antibody against *B. dermatitidis* and the development of resistance to disease has been found. Specific cellular immunity, however, appears to occur in all patients infected with this organism. BAD1 (*Blastomyces* adhesin 1) serves as an adhesin and a virulence factor by inducing suppression of tumor necrosis factor (TNF)–α.[25] Antigen-specific T cells are stimulated to produce lymphokines (e.g., interferon-γ) that activate macrophages, thereby resulting in enhanced fungicidal activity.[6] This enhanced fungicidal activity is due, at least in part, to up-regulation of TNF-α production by macrophages. In vivo data of experimental infection show that neutralization of TNF-α exacerbates pulmonary infection.[24] Kethineni and colleagues[34] note that young murine macrophages co-cultured with *B. dermatitidis* produced half the amount of TNF-α as did mature macrophages. Treatment with interferon-γ increased fungicidal activity of bronchoalveolar macrophages and polymorphonuclear leukocytes. In addition, a pilot experiment in blastomyces-infected young mice revealed increased survival in those treated with interferon-γ.

CLINICAL MANIFESTATIONS

PULMONARY DISEASE

Symptomatic illness develops in approximately 50 percent of infected children, with most of these illnesses appearing initially as an acute or chronic pulmonary process. Patients with acute pulmonary blastomycosis have symptoms similar to those of an acute bacterial process. Cough (which may be productive), fever, malaise, and chest pain are the most common complaints of patients.[58] In many instances, patients may respond initially to routine antimicrobial therapy, only to have their constitutional symptoms return at a later date. Unlike disease in adults, which may take years to progress to a chronic pulmonary process, diseases in children rarely progress longer than 6 months without a return of symptoms.[77]

A mass effect, fibronodular patterns, and consolidation are frequent findings on chest radiography in adults with blastomycosis.[10,18,57] Little information exists on the chest radiographic patterns commonly encountered in children, but extensive consolidation of the involved lobes appears to be the most common finding.[41,58,65] Consolidation has been described to involve all lobes of the lung and may be multilobar or bilateral. Multiple small cavitary lesions, pleural effusions, hilar adenopathy, and nodular infiltrates also have been described. Mass lesions, which occur commonly in adults, frequently are not demonstrated in children, probably because mass lesions are associated more commonly with chronic disease, whereas lobar consolidation is more consistent with acute disease. The consolidation demonstrated on chest radiography may mimic that of an acute bacterial process (Fig. 211–2), whereas the chronic chest abnormalities associated with blastomycosis (e.g., mass lesions, cavitary lesions) may be confused with tuberculosis or neoplasms. Mass lesions, consolidation, air bronchograms, nodular infiltrates, and satellite lesions

commonly are found in adults with pulmonary blastomycosis who have undergone computed tomography of the chest.[75] Computed tomographic findings in children have been limited to consolidation, pulmonary abscess, and paratracheal adenopathy[65] (Fig. 211–3). Patients with severe radiographic disease may have slow pulmonary recovery and suffer from long-term sequelae, but most patients with pulmonary blastomycosis have normal pulmonary function testing at follow-up.[1]

DISSEMINATED DISEASE

Even though the numbers are small, disseminated disease appears to be present in 50 to 80 percent of children in whom blastomycosis is diagnosed.[65,69,77] The most common site of disseminated disease in children is the bones (Fig. 211–4). Although the long bones (e.g., the tibia, humerus), ribs, and vertebrae (Fig. 211–5) are involved most frequently, almost any bone is vulnerable.[61] Skin disease has been described in children, but the classic verrucous lesions seen in adults are uncommon findings in children (Fig. 211–6). Pustular or ulcerative lesions may be demonstrated, but they usually occur in children as a result of underlying bone involvement (Figs. 211–7 and 211–8). Skin lesions involving sun-exposed areas of the body (e.g., the nose, ears) also may be seen (Fig. 211–9). Other areas of involvement that have been described include the liver, spleen, heart, lymph nodes, psoas muscle, kidney, middle ear, and central nervous system (Fig. 211–10).[32,33,77]

DISEASE IN IMMUNOCOMPROMISED PATIENTS

Information concerning infection with *B. dermatitidis* in immunocompromised children is limited[79]; however, data exist on blastomycosis in immunocompromised adults and in adults with diabetes mellitus.[42,56,67,71,76] Unlike other fungi (e.g., *H. capsulatum*, *Cryptococcus neoformans*), this agent has caused infection in only a small number of patients with acquired immunodeficiency syndrome (AIDS), probably because many of these patients have less exposure to regions endemic for the organism. Pulmonary involvement is the most common manifestation of disease in immunocompromised patients, and adult respiratory distress syndrome is encountered more frequently than in immunologically normal hosts. Torres and colleagues[71] described a 13-year experience of endemic mycoses at a cancer hospital. Only two patients were found to have blastomycosis. Both patients were lymphopenic. Neither patient developed disseminated disease or died of fungal disease. Increased mortality rates (30-54%) have been described, with a large proportion of patients who die of other causes having evidence of persistent blastomycosis at the time of death. Many issues regarding therapy for this group of patients are not understood, but lifetime suppressive therapy appears to be indicated.

Figure 211–6 Verrucous lesion of blastomycosis on the face of a child.

Figure 211–7 Purulent wound drainage overlying a region of osteomyelitis with blastomycosis.

DISEASE DURING PREGNANCY

Prenatal diagnosis of blastomycosis in pregnant women has been well documented.[42] Of the 19 women described in these reports, evidence of disseminated disease was noted in 10; 6 had pulmonary disease alone, 1 had isolated skin disease, 1 had adult respiratory distress syndrome requiring ventilatory support and early cesarean section, and 1 was not described. These 19 pregnancies culminated in the birth of 20 infants (one set of twins). None of the infants was found to be infected at birth. The placentas of the seven women were examined for evidence of *B. dermatitidis*. Only the mother with adult respiratory distress syndrome had organisms in the placenta. Organisms were located on the maternal as well as on the fetal side of the placenta. Two neonates developed disease during the first month of life.

NEONATAL DISEASE

Two neonates had an acute onset of respiratory distress within 3 weeks of birth.[45,74] Both infants died of their illness, and abnormalities on autopsy were limited to the lungs. One mother was noted to have lesions consistent with blastomycosis on her face and thigh,[74] whereas the second mother had a lesion on her right lower extremity.[45] Only one mother allowed an extensive physical examination to be performed, and her genital examination was unremarkable. The second mother denied having genital lesions; she refused therapy for blastomycosis and 2.5 years later died of a disseminated illness caused by *B. dermatitidis*. Autopsy findings revealed that her uterus and both ovaries had multiple abscesses, with the left ovary being almost entirely unrecognizable as a result of chronic infection.[78] The pathophysiologic process of neonatal disease is not understood entirely. Because the pathologic changes caused by *B. dermatitidis* were limited to the lungs in these neonates, this illness certainly could have been caused by aspiration of vaginal secretions that were colonized with this organism at birth. Autopsy findings in the second mother, however, certainly raise the question of transplacental passage of the organism.

DIAGNOSIS

Because no clinical syndrome is characteristic of blastomycosis, an unequivocal diagnosis requires isolation of the organism from a clinical specimen. A presumptive diagnosis can be made when the characteristic yeast is visualized in respiratory secretions, purulent material, or histopathologic sections. For patients with pulmonary disease, respiratory secretions can be obtained through sputum production, bronchoscopy with bronchoalveolar lavage, or open lung biopsy. Sputum samples usually are more helpful in older patients; such specimens are difficult to obtain in young children. Likewise, obtaining adequate specimens with the use of bronchoscopy and bronchoalveolar lavage in young children has been shown to be problematic. The need to perform open lung biopsy in patients with pulmonary blastomycosis after they receive negative results from flexible bronchoscopy and bron-

Figure 211–8 Ulcerative lesion overlying a region of osteomyelitis secondary to blastomycosis.

Figure 211–9 Crusted skin lesion on the nose caused by *Blastomyces dermatitidis*.

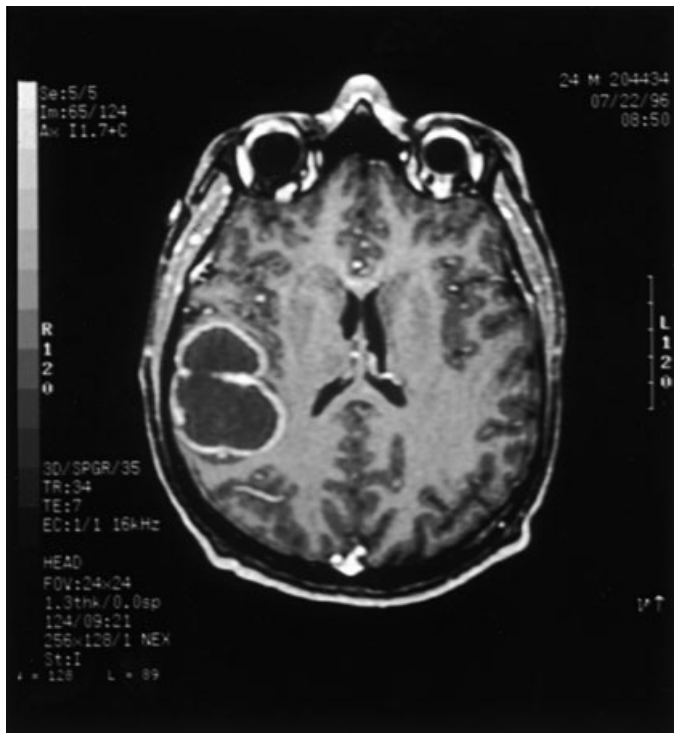

Figure 211–10 Computed tomographic scan of the brain demonstrating a multiloculated abscess in the right temporal lobe as a result of infection with *Blastomyces dermatitidis*.

choalveolar lavage demonstrates the technical limitations of this procedure in the pediatric population.[65] Bronchial brushings and bronchoscopically directed biopsy would improve recovery of the organism, but these procedures are technically difficult to perform in younger patients at this time. Because of the difficulty of establishing the diagnosis of pulmonary blastomycosis in young patients, it is recommended that children and adolescents who are thought to have blastomycosis undergo lung biopsy if sputum and bronchoscopic examination are nondiagnostic.[65]

Respiratory or purulent wound secretions can be examined by light microscopy of wet preparations with or without the use of potassium hydroxide to visualize the characteristic yeast forms. Other staining techniques, such as the calcofluor white stain, can be useful for analyzing specimens when the number of organisms in the specimen is limited. Gomori methenamine silver or periodic acid–Schiff stain may be useful for examining histopathologic specimens[44] (Fig. 211–11). The presence of pyogranulomata in a pathologic specimen should alert one to the diagnosis of blastomycosis, but organisms may be difficult to locate with the use of hematoxylin and eosin stains; in such instances, Gomori methenamine silver or periodic acid–Schiff stain may be helpful. Specimens collected for culture should be placed on a culture medium that will ensure recovery of all clinically significant fungi. The use of a more enriched agar, such as Sabouraud agar with brain-heart infusion, is essential for the recovery of such organisms as *B. dermatitidis*. Specimens potentially contaminated with bacteria or other fungal agents should be placed on an additional agar containing antimicrobial agents (e.g., chloramphenicol, cycloheximide) to inhibit the growth of these contaminants.

In some situations, however, isolation attempts are unsuccessful, and alternative laboratory tests may be used. Most currently available serologic tests are performed by complement fixation, immunodiffusion, or enzyme immunoassay with a yeast-phase antigen (A antigen). These assays have been most useful as epidemiologic tools, not for the clinical diagnosis of disease, because of poor sensitivity and specificity resulting from cross-reactivity with the antigens of other fungi (e.g., *H. capsulatum*). The most sensitive of these tests is the commercially available enzyme immunoassay.[7] However, a 120-kd protein that reacts with antibodies to *Blastomyces* has been identified.[36] This surface protein, designated WI-1, has been demonstrated to be a key antigenic target of humoral and cellular responses during infection. In a study comparing WI-1 and A antigen, WI-1 was found to be more reactive and specific for the binding of serum antibodies to *Blastomyces*.[31] Preliminary testing with WI-1 used as a target in a radioimmunoassay demonstrated that 93 percent of 27 patients with blastomycosis had positive serologic results within 60 days of diagnosis and that only 5 percent of 84 patients from whom the fungus was not identified had positive results.[68] Even though advances have been made, the role of serology remains limited in establishing a diagnosis. If serology is used, the most accurate method of testing is enzyme immunoassay. Antigen testing in body fluids also is a potentially helpful alternative; however, although the sensitivity is good, it is lacking in specificity. Of patients with known blastomycosis, 93 percent had positive urinary antigen assays. Unfortunately, cross-reactivity was noted in 96 percent of patients with histoplasmosis, 7 of 10 with penicilliosis marneffei, and all patients with paracoccidioidomycoses.[23]

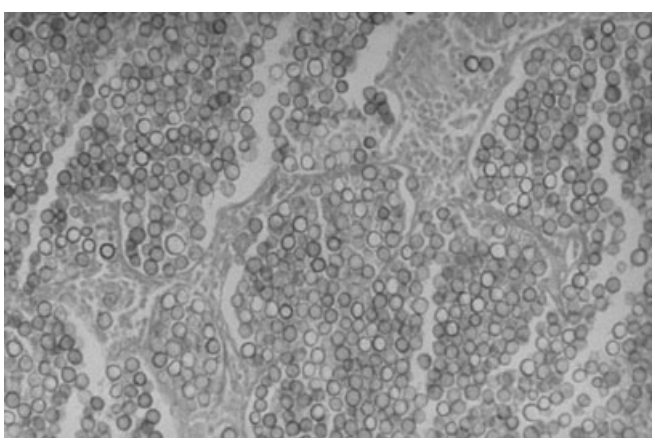

Figure 211–11 Overwhelming infection with *Blastomyces dermatitidis* demonstrated in lung tissue with a silver stain.

TREATMENT

Before antifungal medications were available, the mortality rate associated with blastomycosis usually exceeded 60 percent. After the introduction of effective medications for the treatment of blastomycosis, all patients received therapy when the diagnosis was established. This concept has been challenged because of the toxicity of amphotericin B and the recognition that self-limited cases of pulmonary blastomycosis exist.[63] Since the advent of safe and effective oral medications for the treatment of blastomycosis in adults, this controversy has lessened.[12] However, for children with blastomycosis, of whom as many as 80 percent have disseminated disease, the decision to withhold therapy for pneumonia secondary to blastomycosis can be dangerous. If a diagnosis of blastomycosis is established by culture after the patient has made a spontaneous recovery without therapy, the use of antifungal therapy might be questioned. If therapy is withheld, patients must be monitored carefully for months or even years for evidence of reactivation or dissemination of disease. Accidental introduction of blastomycosis into the skin through needle puncture or bite wounds usually can be treated locally by vigorous cleaning with tincture of iodine, an iodophor, or chlorhexidine.

The use of ketoconazole (400 to 800 mg/day for 6 months) for blastomycosis in adults has achieved cure rates of up to 89 percent.[8] However, little is known about the use of ketoconazole for blastomycosis in children. The recommended dose of ketoconazole in children, as established for the treatment of *Candida* infection, is 5 to 10 mg/kg/day given as a once-daily dose,[17] which would approximate the 400 to 800 mg suggested for blastomycosis in a 70-kg individual. When such a dose was used in five children with blastomycosis, two had relapses (one associated with noncompliance) and two had progression of their disease. The one patient who was cured also underwent a lobectomy, which would have eliminated the area with a large number of organisms.[65] Until more data become available, ketoconazole appears not to be effective for the treatment of blastomycosis in pediatric patients.

Fluconazole has been demonstrated to be effective against blastomycosis in 65 percent of adults at a dose of 200 to 400 mg daily.[55] A treatment failure rate of 30 percent was observed in the high-dose (400 mg/day) group, which included the youngest patient in the study. The investigators concluded that fluconazole is moderately effective against blastomycosis in adults and that its efficacy is similar to that of ketoconazole. No data on the treatment of blastomycosis with fluconazole are available for patients younger than 18 years. Hence, fluconazole does not have a role in the treatment of blastomycosis in pediatric patients.

The recommended therapy of choice for acute non–life-threatening blastomycosis in adults is itraconazole (400 mg/day) for 6 months.[12,21,62] Few data exist on the use of itraconazole in pediatric patients with blastomycosis, but doses of 5 to 10 mg/kg daily have been used safely and effectively in infants and children in other situations.[5,20,51,53] One study used itraconazole (5 to 7 mg/

kg/day; maximum, 200 mg/day) to treat four pediatric patients with blastomycosis.[65] Two patients were treated successfully with itraconazole after an initial treatment failure with a previous antifungal regimen. A third patient's initial trial with itraconazole for his pulmonary blastomycosis failed despite directly observed therapy. This patient had undetectable itraconazole levels in his serum, presumably caused by drug-drug interactions between primidone and itraconazole. The fourth patient completed a 6-month course of itraconazole for her pulmonary blastomycosis without relapse. Although data are limited because of the extremely small numbers of patients studied, itraconazole appears to be superior to ketoconazole or fluconazole for the treatment of blastomycosis in children. A dosage of 10 mg/kg (maximum of 400 mg/day) for itraconazole for 6 to 12 months is currently recommended.[12] In addition, serum levels of itraconazole should be determined after the patient has received it for at least 2 weeks to ensure adequate drug levels.[12]

Data are limited on the efficacy of newer antifungal agents in the treatment of blastomycosis. Both in vitro data and animal studies have shown efficacy of voriconazole and posaconazole.[31] Use of these newer agents in humans is limited to case reports.[3,54]

The agent with the greatest proven success for the treatment of blastomycosis in pediatric patients remains amphotericin B deoxycholate.[58,65,69,77] A total course of 25 to 30 mg/kg approaches a 100 percent cure rate. Therefore, for patients with life-threatening or central nervous system disease, neonates, and pregnant or immunocompromised patients, amphotericin B deoxycholate is recommended. Lipid formulstions of amphotericin B at a dose of 3 to 5 mg/kg/day may also be used.[12]

Specific treatment recommendations are outlined in Table 211–1. In cases of mild to moderate pulmonary disease or mild to moderate non–central nervous system disseminated disease, a combination of amphotericin B and itraconazole may be used. Treatment can be initiated with amphotericin B and changed to itraconazole to complete 6 months of therapy once the patient has been stabilized. In most instances, this change occurs after approximately 10 to 14 doses of amphotericin B deoxycholate at 1 mg/kg per dose. Caution should be used in patients with osteomyelitis because many experts suggest that these patients should receive a total of 1 year of itraconazole therapy.[12]

TABLE 211–1 Treatment Recommendations for Blastomycosis in Children

Type of Disease	Drug of Choice	Alternative
Pulmonary		
Life-threatening	Amphotericin B	May change to itraconazole when patient improves
Mild-moderate	Itraconazole	
Central nervous system	Amphotericin B	
Non–central nervous system		
Life-threatening	Amphotericin B	May change to itraconazole when patient improves
Mild-moderate	Itraconazole	
Immunocompromised host	Amphotericin B	Suppressive therapy should be continued with itraconazole
Neonate	Amphotericin B	

Because of the unpredictable nature of drug interactions, any patient receiving itraconazole with other medications that may interact with itraconazole should be monitored closely and have documentation of adequate serum levels. Close follow-up of these patients for identification of those with progression or relapse of their disease is mandatory. If patients do not have a clinical response within 2 to 4 weeks, if adequate serum levels cannot be obtained, or if clinical deterioration is documented, amphotericin B should be substituted for itraconazole for the treatment of blastomycosis.

Surgery, other than for establishment of the diagnosis, has a limited role in therapy for blastomycosis. Surgery is indicated for drainage of large abscesses or for removal of devitalized tissue in the occasional patient with osteomyelitis who is responding poorly to therapy. Surgery never should be considered curative and always should be performed in association with appropriate antifungal therapy. The duration of therapy should not be shortened simply because the patient has undergone surgical resection of the involved area.

Isolation of patients with pulmonary disease caused by blastomycosis is not required because the person-to-person spread of this disease has never been attributed to respiratory secretions. Furthermore, no special precautions are required for patients with open wounds caused by blastomycosis.

CHAPTER 212

Candidiasis

Katherine M. Knapp ❂ Patricia M. Flynn

Candidiasis refers to infection with any of the yeast species of the genus *Candida* and encompasses a broad range of clinical manifestations. Most candidiasis is caused by *Candida albicans*, although other non-*albicans* species have been reported with increasing frequency in recent years. Hippocrates noted oral candidiasis (thrush) in infants, and for centuries afterward, candidiasis was regarded merely as a superficial and nonthreatening infection. A benign course is typical for *Candida* infections in otherwise healthy individuals, but for those whose immune systems are compromised, *Candida* spp. are opportunistic pathogens that may lead to disseminated disease and even death. Medical advances that have improved survival rates for many conditions that once were frequently fatal, such as prematurity and cancer, also have affected host defenses and microbial ecology, leading to an increased population at risk for acquisition of invasive candidiasis.

THE ORGANISM

Members of the genus *Candida* characteristically are round to oval vegetative cells possessing the ability to produce pseudohyphae (chains of elongated yeast forms) under certain conditions and the inability to develop ascospores (spores within a parent cell). The genus name *Candida* is derived from the Latin word *candidus* ("white") and reflects the creamy white appearance of *Candida albicans*, the species name of which is derived from the Latin for "to become white."

Candida spp. yeast forms are easily distinguished from *Cryptococcus* organisms by their lack of a capsule. Rapid laboratory identification of *C. albicans* may be made by provoking formation of germ tubes (septated cylindrical extensions) by the blastospore on incubation in human serum. *Candida* spp. may be distinguished from one another and from other yeasts by their use of carbohydrate substrates, which differs sufficiently among the *Candida* spp. to allow a biochemical profile for identification. These profiles have been established on the basis of the species' use of selected carbohydrates as carbon sources in the presence of oxygen (assimilation) and in the absence of oxygen (fermentation).

More than 150 species of *Candida* have been described, but only a small number of them are considered to be of medical importance. However, as infections caused by non-*albicans* species are recognized increasingly, more of these species may be reported in immunocompromised patients in the future. *C. albicans* remains the species most frequently causing disease in humans. However, azole-resistant *C. albicans* organisms are identified increasingly, and this finding, along with the observed increase in non-*albicans* infections, has implications for appropriate treatment of antifungal-resistant yeast infections. Non-*albicans* species that have been reported to cause disease in humans include *Candida glabrata*, *Candida guilliermondii*, *Candida kefyr* (formerly *Candida pseudotropicalis*), *Candida krusei*, *Candida lusitaniae*, *Candida parapsilosis*, and *Candida tropicalis*.

HOST SUSCEPTIBILITY

The relationship of *Candida* spp. to their human hosts is dependent on the number of organisms, the virulence of the species, and the host resistance. *Candida* spp. are frequent colonizers of human skin and mucous membranes but do not typically cause disease in immunocompetent individuals. Compared with other organisms that do cause disease in the immunocompetent host, *Candida* spp. have relatively low virulence factors. Therefore, for *Candida* spp. to establish infection, the number of organisms must be high, the host resistance must be impaired, or some combination of the two factors must exist.

Usually the number of organisms to which an individual has been exposed is not known. In one experiment with a known quantity of organisms, a healthy adult volunteer ingested a suspension containing more than 10^{12} organisms of *C. albicans*, and within 3 hours, he was febrile and *C. albicans* was cultured from both blood and urine samples.[49] Because the number of organisms will be unknown in most cases and because virulence is essentially constant, the predominant determinant for disease is the degree of host defense impairment.

Studies of responses of the immunocompetent host to *Candida* spp. suggest that eventually all components of the immune system are affected. The ability of *Candida* spp. to adhere to and invade host tissue is a major determinant of the virulence of these organisms. Although the microbial flora of the skin and mucosal surfaces serve as an important defense in the host's resistance to colonization and infection with *Candida* spp., the organisms are able to adhere to and invade host tissues. The host's antibody response to *Candida* spp. includes generation of secretory and humoral anti-*Candida* IgA[67] and specific anti-*Candida* IgE,[61] a transient IgM response with the infection, and circulating IgG found in most immunocompetent adults.[124] The IgG antibodies effectively opsonize *C. albicans*. *Candida* activates the alternative complement pathway.[108] Polymorphonuclear leukocytes,[19] monocytes, and eosinophils[52,53] ingest and kill *Candida*. A polysaccharide component of *C. albicans* can induce the formation of suppressor lymphocytes.[89]

Individuals with impaired host response to *Candida* spp. include neonates, pregnant women, and those who have congenital or acquired immunodeficiencies, immunosuppression due to medication (chemotherapy, corticosteroids) or radiation therapy, malignant neoplasms, endocrinopathies, debilitation caused by trauma or surgery, or alterations in mucosal barriers or normal flora due to catheterization or medications (particularly antimicrobials).

EPIDEMIOLOGY

Candida spp. are ubiquitous, are found in the environment in soil and water, and are frequent colonizers of human skin and mucosal membranes. *Candida* spp. also have been isolated from various species of domesticated animals. The incidence of invasive disease has been increasing coincident with advances in medical technology allowing improved survival of at-risk individuals, such as premature newborns, patients with cancer, and trauma victims.

In normal circumstances, transmission of *Candida* spp. requires contact of a colonized site with a mucous membrane or skin surface. Newborns may develop oral and cutaneous *Candida* infections after delivery through colonized vaginal mucosa.[48,69] Interestingly, however, a study suggests that vaginal mucosa may not be the main route of transmission of *Candida* spp. to the neonate.[15] Caramalac and colleagues[15] cultured vaginal mucosa of

100 women at the time of delivery and cultured the oral mucosa of their newborns. The incidence of *Candida* colonization was similar in the women who delivered vaginally (47.2%) and in those who delivered by cesarean section (46.4%), but oral mucosal colonization was more common in the neonates who were delivered vaginally (25%) compared with those who were delivered by cesarean section (3.6%). However, although infants who were delivered vaginally were more likely to be colonized with *Candida* spp., in only two cases (6%) were genotypic-phenotypic concordances between the maternal and neonatal isolates identified.

Although *C. albicans* has been shown to be cultured readily from air in the rooms of patients with cutaneous candidiasis, the significance of airborne transmission of *Candida* has not been determined.[66] Although nosocomial transmission has been reported frequently in neonatal and other closed hospital units, the source of transmission is not always clear. A recent Cochrane Database review found no evidence either to support or to refute use of measures such as cohorting or patient isolation rooms for neonates colonized with *Candida* spp.[68] The authors of that review stated that no standard policy of isolation measures exists and emphasized the importance of research into appropriate isolation measures. Studies using restriction enzyme fragment analyses have demonstrated that *Candida* colonization may be acquired from the environment or from staff members in closed hospital units.[12,102]

Several reports have indicated an increasing trend of non-*albicans Candida* infections in both adults and children.[47,58,109,132] *C. parapsilosis* is the most common non-*albicans* species isolated in pediatric patients, and it is isolated more commonly in children than in adults, for whom *C. glabrata* is the non-*albicans* species most frequently identified.[1,47,55,88,131,132] *C. parapsilosis* has been identified also as an emerging pathogen among adult oncology patients.[100] In some neonatal units, *C. parapsilosis* has surpassed *C. albicans* as the most common *Candida* species isolated. The increased rates of non-*albicans* species are possibly related to increased use of fluconazole.

The increased use of azole antifungals has been associated also with an increase in azole-resistant *Candida* spp. Increases in fluconazole-resistant species of *Candida*, especially *C. krusei* and *C. glabrata*, were recognized soon after fluconazole was introduced as a prophylactic agent in bone marrow transplant recipients.[126] Trifilio and colleagues[110] reported 10 breakthrough fungal infections in patients receiving voriconazole prophylaxis: 5 were caused by *C. glabrata* (which has variable susceptibility to azoles) and 1 was caused by *C. krusei* (which is inherently resistant to fluconazole). *Candida rugosa* is another species, not recognized until 1985, that has been reported increasingly and is resistant to azole antifungals.[87]

PATHOGENESIS AND PATHOLOGY

C. albicans, in addition to being the most common of the *Candida* spp., is the most pathogenic. *Candida* virulence factors include the ability of the organism to express adhesins, to transition from yeast to hyphal form, and to produce secretory aspartyl proteinases (SAPs) and phospholipases that facilitate invasion of tissue.[75,114] The initial step in colonization is adherence of the *Candida* blastospore (yeast form) to the mucosal or dermal epithelial cells. Once the yeast transforms to the hyphal stage, infection may become established. The exact mechanism by which *C. albicans* invades mucosal tissues is not well understood. Data support a proposed mechanism by which *C. albicans* invades mucosal tissues by proteolytic degradation of E-cadherin, the major protein in the epithelial adherens junctions.[114] Another proposed mechanism suggests that SAPs facilitate adhesion to and degradation of mucins (mucus O-linked glycoproteins) in the oral cavity and gastrointestinal tract.[18]

The SAP and phospholipase B (PLB) genes have been shown to be differentially expressed in humans.[75] Naglik and colleagues[75] analyzed gene expression in 137 cases of human oral or vaginal *Candida* colonization or disease. They found that *SAP2* and *SAP5* were the genes most commonly expressed during both colonization and disease states. Expression of other genes was correlated with disease and not carriage. *SAP1*, *SAP3*, and *SAP8* were expressed in both oral and vaginal disease but were preferentially expressed in vaginal infections. *PLB1* was correlated with oral but not vaginal disease.

Invasion of the mucous membrane leads to the formation of an adherent pseudomembrane, which is composed of epithelial cells, leukocytes, keratin, and food debris.[21] Mucosal lesions may progress to sharply demarcated ulcers with a base of granulation tissue covered by a fibrinous exudate and granulocytes intermixed with the organisms. Disseminated *Candida* infection is spread hematogenously from portals of entry, primarily from mucous membrane lesions. All organ systems may be involved in disseminated disease, but the kidneys, lungs, liver, brain, and spleen are affected most frequently. Microabscesses are formed in the body's pyogenic response to systemic disease. Granulomatous reactions occur infrequently.

Candida catheter-related infections also are associated with formation of biofilm.[20,77] *Candida* organisms within this sessile environment can be much more highly resistant to antifungal agents, rendering treatment difficult without removal of the catheter.

CLINICAL TYPES

Candida spp. may cause disease at any body site, although some areas are affected more commonly than are others, and the site and extent of disease indicate the relative immunocompetence of the host. For example, candidiasis involving the mouth and diaper area is a common occurrence in infants, most of whom are healthy children. On the other hand, chronic mucocutaneous candidiasis or disseminated disease suggests an underlying immune defect in the host.

The following sections describe manifestations of candidiasis classified by site of infection.

OROPHARYNGEAL CANDIDIASIS

Thrush (Acute Pseudomembranous Candidiasis)

Thrush is the most common type of candidiasis in infants and children and is caused almost exclusively by *C. albicans*. The lesions of thrush usually appear as white patches resembling milk curds affecting the dorsal and lateral aspects of the tongue, pharynx, gingivae, and buccal mucosa. These lesions coalesce in the formation of an adherent pseudomembrane composed of desquamated epithelial cells, leukocytes, keratin, necrotic tissue, and food deposits.[21] Removal of the pseudomembrane leaves an erythematous denuded lesion. Although pseudohyphal forms are abundant in thrush, the organisms rarely penetrate deeper than the stratum corneum, and in mild cases, the lesions are not painful. The subepithelial tissues may be involved, leading to edema and microabscess formation.

Acute Atrophic Candidiasis (Glossitis)

Glossitis is characterized by a smooth and erythematous tongue surface from erosion of the papillae of the tongue dorsum. Glossitis results from alteration of the bacterial flora of the oral mucosa due to use of broad-spectrum antibiotics. Typically, the white pseudomembranous lesions seen in thrush are absent or

minimal. Glossodynia (painful tongue) is a common complaint. The symptoms and lesions typically resolve with discontinuation of broad-spectrum antibiotics.

Angular Cheilosis (Perlèche)

Perlèche results from habitual licking at the corners of the mouth, which creates an environment in which *Candida* can establish infection. The infection is manifested as painful fissuring and erythema at the corners of the mouth. The lesions may evolve into shiny erythematous lesions associated with desquamation of the epithelium and surrounding hyperkeratosis.

Leukoplakia and chronic atrophic candidiasis are additional oropharyngeal manifestations of *Candida* infection that rarely are reported in the pediatric population.

ESOPHAGEAL CANDIDIASIS

Dysphagia is the characteristic finding in esophageal candidiasis, although in many cases affected individuals will be asymptomatic. Pain may occur with swallowing or may be a persistent finding. Patients may complain of retrosternal, paravertebral, intrascapular, or subscapular pain. Patients may also experience nausea and vomiting. Given that the distal third of the esophagus is the site most frequently affected, it is perhaps not surprising that many patients will not have thrush. Endoscopy reveals white patches similar in appearance to thrush on erythematous and friable esophageal mucosal tissue. An esophagram may reveal mucosal ulcerations in a cobblestone pattern. In advanced disease, larger lesions and strictures may develop, as may fistulas or esophageal perforation.

GASTROINTESTINAL CANDIDIASIS

The true incidence of gastrointestinal candidiasis is not known. Adequately documented cases have been associated with an underlying abnormality. Lesions localized to the stomach have been found predominantly in patients with peptic ulcer disease or malignant neoplasms or who have undergone gastric resection.

Although diarrhea and abdominal pain have been reported in patients with *Candida* spp. recovered from their stool, the relevance of the *Candida* to the symptoms is not always clear. In one review of the literature, the authors concluded that the available data show a strong correlation between antifungal treatment in patients with *Candida* spp. in their stools and resolution of diarrhea in those patients.[54]

Gastrointestinal *Candida* lesions are common manifestations in immunocompromised pediatric patients. In a review of 109 children with cancer and deep organ candidiasis studied ante mortem and at autopsy, *Candida* lesions were found in the esophagus in 49 patients, in the stomach in 40 patients, in the small intestine in 37 patients, and in the colon in 48 patients.[39] *Candida* spp. have been implicated also in typhlitis in immunocompromised patients. *Candida* infections of the gallbladder and biliary system also have been reported.

PERITONEAL CANDIDIASIS

Peritonitis caused by *Candida* spp. may occur as a complication of peritoneal dialysis, intestinal surgery, or bowel perforation. Abdominal distention, fever, and vomiting may occur, but in many cases, the typical signs of peritonitis may be absent.[41] Dissemination to other organs seldom occurs in cases of peritoneal candidiasis.[6,43,106] Clinical features of fungal peritonitis cannot be differentiated from bacterial peritonitis, and diagnosis must be made by microbiologic examination and culture of peritoneal fluid.[23] The outcome of fungal peritonitis in pediatric dialysis patients usually is more favorable than that in adults.[121]

A recent retrospective review of fungal peritonitis in pediatric patients receiving peritoneal dialysis described risk factors and evaluated treatment outcomes.[93] The authors reviewed 321 episodes of peritonitis in 159 patients, nine of whom were diagnosed with fungal peritonitis (2.9%). *Candida* spp. accounted for 78 percent of the fungal infections, and *C. albicans* specifically for 44 percent of the fungal infections. As with previous studies, preceding antibiotic use was found to be a risk factor for development of fungal peritonitis; 78 percent of the patients had received antibiotics in the previous month, 86 percent of them for bacterial peritonitis. Prior infection with gram-negative bacteria in particular is a risk factor for development of fungal peritonitis.

CANDIDIASIS OF THE URINARY TRACT

The presence of *Candida* in voided urine specimens is not always indicative of infection of the urinary tract. *Candida* spp. frequently are recovered in the urine of immunocompromised patients, in those with indwelling urinary catheters, and in those receiving antibiotics. Furthermore, data indicate that counts of 100,000 or more colonies of *Candida* spp. per milliliter of urine are no more indicative of urinary tract infection than are lower counts.[81] The symptoms of urinary tract candidiasis are similar to those that occur with analogous bacterial infections.[28] Lesions similar to those seen with thrush or esophageal candidiasis may be seen by cystoscopy on the bladder mucosa in patients with cystitis. *Candida* spp. also may cause renal microabscesses, papillary necrosis, and obstructive renal lesions. Many cases of urinary tract candidiasis are associated with underlying structural defects. In 26 cases with candidiasis and candiduria at the Mayo Clinic, 23 (88%) had urinary tract abnormalities.[2]

VAGINAL CANDIDIASIS

Vaginitis caused by *C. albicans* occurs commonly and is not indicative of a serious underlying disease. Vaginal candidiasis is characterized by pruritus and a white or watery discharge. The vaginal mucosa is erythematous with white lesions like those seen in thrush and other forms of mucosal candidiasis. Candidiasis also may affect the skin of the perineum, causing papular or ulcerative lesions.

RESPIRATORY TRACT CANDIDIASIS

Candida spp. are known to colonize respiratory tract mucosa, and their presence in cultures taken from respiratory specimens is not necessarily indicative of infection. Candidiasis may affect any site within the respiratory tract.

Respiratory involvement may be associated with oropharyngeal candidiasis. A syndrome of extensive oral candidiasis and hoarseness has been described in patients infected with human immunodeficiency virus (HIV) and in patients receiving immunosuppressive chemotherapy. Laryngoscopy has demonstrated discrete plaques of *Candida* on the vocal cords in such patients.[51,98]

Candidiasis limited to the bronchi occurs rarely and typically is associated with pulmonary parenchymal and systemic disease. Manifestations of pulmonary candidiasis include localized or diffuse pneumonia, nodular lesions, abscesses, and empyema.[34,81,127] Pulmonary candidiasis typically presents with nonspecific findings of fever and tachypnea. Definitive diagnosis requires an

invasive procedure such as lung biopsy to demonstrate the organism in tissue.

In addition to causing disease by infiltrating deeper tissues, *Candida* spp. within the respiratory tract may lead to an allergic response. Pulmonary allergy is not well defined, but both polysaccharide and protein extracts of *C. albicans* have been shown to provoke asthmatic attacks in atopic patients.[44]

MUSCULOSKELETAL CANDIDIASIS

Most cases of *Candida* arthritis have been reported in association with systemic candidiasis. The knee is the site most often reported to be affected. Joints may be infected by direct inoculation or by hematogenous spread and may be associated with a contiguous osteomyelitis. Nonsystemic candidal infection occurring after prosthetic arthroplasty has been reported.[17]

Candida osteomyelitis has been reported in several sites, including the spine, upper and lower extremities, ribs and costochondral junctions, mandible, and sternum.[22,81] Many of the reported cases of *Candida* osteomyelitis have occurred in infants younger than 14 weeks. In such cases, the lesion typically affects the lower extremity, which is shown to be osteolytic with cortical bone erosion.[123]

CARDIAC CANDIDIASIS

Candida spp. may infect any part of the heart. The clinical manifestations of *Candida* endocarditis are similar to those of subacute bacterial endocarditis. However, in contrast to bacterial endocarditis, blood cultures frequently are sterile in *Candida* endocarditis. Most cases of fungal endocarditis are caused by *Candida* spp. In one review of 319 cases of fungal endocarditis, *Candida* accounted for 67 percent of cases.[65] *Candida* spp. are not a common cause of endocarditis but are associated more frequently with endocarditis occurring in patients with systemic candidiasis and indwelling central venous catheters. In a review of 109 children with systemic candidiasis, 28 were found to have cardiac lesions.[39] The presence of an indwelling central venous catheter was associated with incidence of cardiac involvement in these children; only 3.7 percent of those without evidence of carditis had a central venous catheter compared with 18 percent of those with carditis. The aortic and mitral valves are the valves most frequently affected. Valvular involvement may be difficult to visualize by two-dimensional echocardiography. In addition to invasion of the endocardium, *Candida* spp. may cause embolization with occlusion of major arteries, necrosis, and microabscesses. *Candida* infection of the myocardium may be manifested as nonspecific electrocardiographic changes, such as supraventricular arrhythmias, QRS changes, and marked T-wave changes.[32]

CENTRAL NERVOUS SYSTEM CANDIDIASIS

The central nervous system (CNS) frequently is involved in disseminated candidiasis, although involvement of the CNS in the absence of disseminated disease rarely occurs. Autopsy studies have shown the incidence of CNS candidiasis to be less than 1 percent.[85,115] In one review of 29,659 autopsies, CNS candidiasis was noted in only seven cases (0.023%); however, all but two of those cases involved disseminated disease.[115] Involvement of the CNS has been described in approximately 25 to 50 percent of cases of systemic candidiasis.[39,56]

Candida spp. may cause meningitis, ependymitis, vasculitis and thrombosis, mycotic aneurysm, demyelination, transverse myelitis, and parenchymal lesions including macroabscesses and microabscesses, noncaseating granulomas, and nodules.[56]

Patients with CNS candidiasis may not demonstrate any signs indicative of neurologic involvement, or they may show nonspecific signs and symptoms of meningitis or encephalitis. *Candida* meningitis may be manifested as respiratory decompensation in premature neonates. Approximately half of all infants with *Candida* meningitis will not have positive blood cultures.[8] Many patients with *Candida* meningitis will not have evidence of cerebrospinal fluid pleocytosis or hypoglycorrhachia. Examination of cerebrospinal fluid and computed tomography or magnetic resonance imaging should be performed in cases of suspected *Candida* CNS disease and in cases of cardiac candidiasis, as CNS and cardiac candidiasis frequently co-occur in patients with disseminated disease.

In a report of pediatric oncology patients, duration of profound neutropenia with fever, antibiotic therapy, and administration of total parenteral nutrition were found to be significant factors associated with a diagnosis of *Candida* meningitis.[63] In that review, 11 of 12 cases were caused by *C. tropicalis*, and all cases were fatal.

OPHTHALMIC CANDIDIASIS

Careful routine ophthalmic examination should be performed in all patients with disseminated candidiasis. Retinitis is seen frequently in low-birth-weight neonates with disseminated candidiasis.[4] Chorioretinal involvement typically is manifested as white fluffy lesions that may extend to the vitreous. Patients may complain of eye pain, blurred vision, scotomata, and photophobia. Because retinal lesions may not be seen in severely neutropenic patients, careful ophthalmic examination in these patients after resolution of the neutropenia is vital.[36]

Candida endophthalmitis also has been described in as many as 20 percent of patients receiving total parenteral nutrition; hence, maintaining a high index of suspicion in this population and considering routine ophthalmologic evaluation are prudent.[35,70]

CUTANEOUS CANDIDIASIS

Some cutaneous manifestations of *Candida* infection are seen commonly in otherwise healthy children. *Candida* is a frequent cause of diaper dermatitis in healthy children. Infants with *Candida* diaper dermatitis will demonstrate obvious discomfort when urine comes in contact with the affected skin. Nail infection (paronychia) caused by *Candida* spp. is a frequent complication of thumb sucking, or it may develop after other trauma to the nail or surrounding tissue; it is characterized by intense erythema of the affected area.

Cutaneous *Candida* infections are seen frequently in immunocompromised patients, such as those with HIV infection or lymphoproliferative disease and those receiving immunosuppressive medications. Very-low-birth-weight infants may present with diffuse erythema and crusting of dependent and intertriginous areas, and many of these infants are found to have disseminated candidiasis.

CANDIDEMIA

Candidemia is associated with significant morbidity and with mortality rates of approximately 20 to 25 percent in children in general, 37 percent in pediatric patients in intensive care units, and approximately 45 to 55 percent in neonates and infants.[57,84,97,101,107,111,130] Neutropenia, endotracheal intubation, location in the intensive care unit, and presence of an arterial catheter have been identified as risk factors for death in pediatric patients with candidemia.[84,130]

Neonates with candidemia frequently have multiple positive blood cultures even after beginning antifungal therapy, and 10 percent may have candidemia for 14 days or more.[8]

DISSEMINATED CANDIDIASIS

Disseminated candidiasis may be designated acute (abrupt onset, with fever, fungemia, and evidence of organ involvement) or chronic (i.e., hepatosplenic candidiasis, usually seen in leukemic patients following recovery of neutrophil counts after chemotherapy).

In most cases of disseminated candidiasis, the infection is concentrated in two or three areas. The lungs, kidneys, liver, spleen, and brain are affected most frequently. *Candida* organisms are disseminated to these organs hematogenously from lesions of the gastrointestinal tract, oral mucosa, or skin. Although transient candidemia may occur without discernible foci of infection, most severely immunocompromised patients with candidemia will have disseminated disease.[128] Clinical manifestations of disseminated candidiasis depend on the sites and extent of involvement. Underlying conditions that predispose patients to development of disseminated candidiasis include cancer, HIV infection or acquired immunodeficiency syndrome (AIDS), history of solid organ or hematopoietic stem cell transplantation, premature birth, and presence of indwelling central venous catheters.

The retinal lesions seen in *Candida* endophthalmitis and a maculopapular rash are two clinical manifestations that are strongly indicative of disseminated candidiasis. The skin lesions have been described in patients with hematologic malignant neoplasms and typically are discrete, firm, erythematous papules measuring 0.5 to 1.0 cm in diameter. The rash frequently is characterized by a nodular center surrounded by a halo of erythema and may be generalized. Biopsy specimens of the rash will show both yeast and pseudohyphal forms. Biopsy may be vital for establishing a definitive diagnosis to exclude other infectious causes in the susceptible immunocompromised host.

Clinical manifestations of 109 pediatric oncology patients with disseminated candidiasis evaluated for 2 months before death were compared with findings at autopsy.[39] In approximately 90 percent of the cases, patients had developed fever or neutropenia, had received antibiotics or immunosuppressive agents, or were known to be in relapse of malignant disease in the 2 months before death. The major organs involved, in order of frequency, were the lungs, spleen, kidneys, liver, heart, and brain. More than one organ was involved in 88 percent of the patients, and in many cases, the organ involvement was not suspected before autopsy. For example, lesions were not detected by radiographs performed in the last 10 days of life for half of the patients with *Candida* involvement of the lungs, and laboratory evaluations of renal and hepatic function were normal in half of the patients with *Candida* involvement of the kidneys and liver detected at autopsy. Although 93 percent of the children were colonized with *Candida* spp., in only 17 percent of the patients was *Candida* cultured from antemortem blood specimens. Other studies have demonstrated an increased incidence of systemic candidiasis in pediatric patients colonized with *Candida* spp. at multiple sites.[60,62]

Zaoutis and colleagues[132] retrospectively reviewed cases of candidemia at a tertiary care children's hospital and identified risk factors for disseminated disease. In that series, only 24 percent of the children had an underlying oncologic diagnosis. Of 153 patients with candidemia, 17 percent had evidence of disseminated disease, and a third of those had involvement of more than one organ. The organs most commonly involved were the lungs (58%), liver (23%), kidney (16%), and brain (12%). In that series, candidemia persisting for more than 3 days with a central venous catheter in place, and immunosuppression were independent risk factors for development of disseminated disease in affected pediatric patients.

DIAGNOSIS

The diagnosis of candidiasis requires the association of clinical observations with laboratory tests identifying the organism. In some cases, a biopsy may be indicated to establish the diagnosis of candidiasis in diseased tissue.

Direct microscopic examination of specimens may help establish a diagnosis quickly. Specimens swabbed or scraped from surface lesions mounted in 20 percent potassium hydroxide or calcofluor will reveal the 3- to 7-mm-diameter ovoid budding yeast cells or pseudohyphae. *Candida* organisms stain well with Gram stain or with periodic acid–Schiff, Gomori methenamine silver nitrate, and toluidine blue stains. Organisms can be identified only tentatively as *Candida* spp. by direct microscopic examination, and in some preparations, differentiation of *Candida* spp. from other yeasts or even molds such as *Aspergillus* spp. may be difficult.

Both yeast and pseudohyphal forms may be seen in biopsy specimens. The early tissue reaction to infection is acute suppurative inflammation that may progress to granulomatous inflammation. Microabscesses frequently are seen in biopsy specimens.

Candida spp. may be cultured on Sabouraud dextrose media, which typically is prepared with an antibiotic to prevent overgrowth of bacteria contaminating the specimen. Cycloheximide, which is sometimes included in media to prevent saprophytic fungal overgrowth, also may inhibit some strains of *Candida* spp. and should not be used. Blood culture bottles should be vented for optimal growth. On solid media, *Candida* spp. appear as moist white or cream-colored colonies with well-demarcated borders. In contrast to most other *Candida* spp., *C. albicans* produces germ tubes when suspended in serum for a period of 1 to 4 hours, a characteristic that is used by laboratories for rapid presumptive diagnosis of *C. albicans* colonization or infection. *Candida* spp. are definitively identified by biochemical fermentation and assimilation tests.

Antibody testing is not useful in establishing the diagnosis of invasive candidiasis. *Candida* colonization may lead to positive antibody test results, even in the absence of invasive disease. Furthermore, immunocompromised patients may not mount sufficient antibody response even in the presence of invasive candidiasis. Antigen testing for SAPs has shown promise in vitro and in animal experiments.[24,72,74] Many new molecular diagnostic tests hold promise but are not readily available or standardized.

To date, an assay for β-1,3-glucan is the only non–culture-based diagnostic approved by the Food and Drug Administration (FDA) for diagnosis of invasive candidiasis.[77,82] β-1,3-glucan is a polysaccharide component of the *Candida* cell wall that is not found in humans, and therefore its presence in a sample of human tissue is indicative of fungal infection. Recent data suggest that the β-1,3-glucan test could be used also in establishing the diagnosis of *Candida* biofilms on implanted devices.[77] Although removal of a catheter is recommended in candidemia, doing so is not always a viable option, and use of a test to identify biofilm catheter-associated infection would allow clinicians to identify those patients for whom removal of the device is most critical.

Polymerase chain reaction testing for *Candida* spp. was reported first in 1990 and shows great promise for establishing rapidly and accurately a diagnosis of invasive candidiasis.[14,24] Currently, molecular diagnostic tests lack standardized and commercially available DNA extraction procedures, and many methods of polymerase chain reaction format and design need to be standardized.[24]

The definitive diagnosis of disseminated candidiasis is difficult to establish, but the diagnosis may be made if *Candida* is recov-

ered from otherwise sterile body fluids (blood, spinal fluid, bone marrow) in an immunocompromised patient with compatible clinical features in whom other causes of infection have been excluded.[40] Computed tomographic scans are useful in recognizing lesions of the liver, spleen, kidneys, or brain that are sufficiently characteristic for a presumptive diagnosis of systemic candidiasis.[5,30]

TREATMENT AND PREVENTION

In recent years, several new drugs have become available for the treatment of candidiasis. The appropriate drug or combination of drugs depends on the location and extent of infection. The following recommendations are based on the comprehensive and authoritative guidelines for the treatment of candidiasis developed by an expert panel of the Infectious Diseases Society of America.[83]

ANTIFUNGAL AGENTS

Until recently, treatment options for invasive candidiasis were limited. Amphotericin B deoxycholate was developed in the 1950s and had been the mainstay of therapy for decades until the recent development of several new agents and classes of antifungals. There are three main classes of antifungal drugs: the polyenes (amphotericin B deoxycholate and its lipid formulations), azoles, and echinocandins.

Polyenes

Use of amphotericin B deoxycholate, or "conventional" amphotericin B, has largely been supplanted by its less toxic lipid formulations. Amphotericin B is associated with infusion-related effects of high fevers and chills and with dose-limiting nephrotoxicity. In the 1980s, scientists used liposome technology to develop new formulations of amphotericin B that were better tolerated, allowing administration of larger doses.[78]

There are currently three lipid formulations of amphotericin B: amphotericin B lipid complex, amphotericin B cholesteryl sulfate complex (amphotericin B colloidal dispersion), and liposomal amphotericin B. Use of the cholesteryl sulfate complex form has not been widespread in the United States, and in one study, infusion-related events were more common with this formulation compared with conventional amphotericin B.[13] Wingard and colleagues[125] evaluated the safety of liposomal amphotericin B compared with amphotericin B lipid complex as empiric therapy in patients with fever and neutropenia and found that liposomal amphotericin B was better tolerated, with significantly less fever, chills, nephrotoxicity, and treatment-related discontinuation of antifungal therapy. Infusion-related events may occur with any of the formulations, and intolerance of one product does not necessarily indicate that a patient will have an adverse reaction to a different formulation.[33,45]

Higher doses of amphotericin B are possible with the better-tolerated lipid formulations. Although the usual recommended dosing of liposomal amphotericin B is 3 to 5 mg/kg daily, Walsh and colleagues[119] found that dosages as high as 15 mg/kg daily were effective and well tolerated.

Liposomal amphotericin B (AmBisome) is FDA approved for use in pediatric patients older than 1 month as empiric therapy in febrile neutropenia and for systemic candidiasis when risk of toxicity precludes the use of conventional amphotericin B. Amphotericin B lipid complex (Abelcet) is FDA approved for systemic candidiasis in pediatric patients who are intolerant of or refractory to conventional amphotericin B therapy (recommended dose, 5 mg/kg daily).

Amphotericin B products are active against most species of *Candida*, but resistance may be likely in isolates of *C. guilliermondii* and *C. lusitaniae*.

Azoles

Azole antifungals act by disrupting synthesis of ergosterol in the fungal cell membrane, by inhibiting the cytochrome P450 enzyme 14α-demethylase. The azoles include fluconazole, itraconazole, voriconazole, posaconazole, and ravuconazole, all of which are active against *Candida* spp.

Fluconazole, available in both oral and intravenous formulations, has been widely used and is well tolerated, and its increased use has been associated with an increased incidence of fluconazole-resistant organisms. Many fluconazole-resistant organisms are susceptible to the newer azoles. Fluconazole (Diflucan) has an FDA-approved indication for pediatric patients older than 6 months for treatment of systemic disease and candidiasis of the mouth and esophagus.

Itraconazole is poorly absorbed orally. Absorption is improved with the liquid formulation, but it is not well tolerated. An intravenous formulation of itraconazole also is available. Given the availability of more palatable options, itraconazole has a limited role in the treatment of *Candida* infections.

The second-generation triazoles have broader antifungal coverage than does fluconazole and may have activity against fluconazole-resistant organisms. Voriconazole (Vfend) is FDA approved for pediatric patients aged 12 years or older for treatment of esophageal candidiasis. The recommended dosing for this indication is 200 mg every 12 hours for patients weighing 40 kg or more or 100 mg every 12 hours for patients weighing less than 40 kg. Posaconazole (Noxafil) is available only as a liquid oral formulation, which must be taken with high-fat meals to optimize absorption. It is FDA approved for prophylaxis in pediatric patients aged 13 years and older who are severely immunocompromised.[16,112] The recommended dose for this indication is 200 mg (5 mL) three times a day with a full meal or liquid nutritional supplement.

Echinocandins

The echinocandins are the first new class of antifungal agents developed in decades. Echinocandins act on the fungal cell wall. Because the human host has no cellular equivalent of the fungal cell wall, the echinocandins are very well tolerated. All echinocandins are available as parenteral formulations administered once daily, and all have the same general spectrum of coverage. Anidulafungin differs from the other echinocandins in that it slowly degrades in plasma rather than being metabolized, and it may also have activity against *Candida* spp. (i.e., *C. parapsilosis*) that are resistant to other echinocandins.[113] Caspofungin has an FDA-approved pediatric indication. Available data from clinical trials and clinical experience suggest that the echinocandins are safe and effective in pediatric patients.[7,31,103,116] Pharmacokinetic studies of caspofungin in children indicate that the initial proposed pediatric dosing of 1 mg/kg daily is suboptimal and that 50 mg/m^2 daily dosing is comparable to adult dosing of 50 mg daily.[116] A study of the pharmacokinetics of micafungin in pediatric patients aged 2 to 17 years with febrile neutropenia showed linear pharmacokinetics and increased clearance as a function of decreased age.[103] Clearance was approximately 1.35 times greater in those aged 2 to 8 years compared with those aged 9 to 17 years. Dosing in that study was initiated at 0.5 mg/kg/day and increased up to 4.0 mg/kg/day. Micafungin does have a pediatric indication

in Japan, where the usual dose recommended for candidiasis is 1 mg/kg/day, which may be increased as indicated up to 6 mg/kg/day. A study of safety and pharmacokinetics of anidulafungin in pediatric patients with neutropenia demonstrated that doses of 0.75 mg/kg/day or 1.5 mg/kg/day are comparable to adult dosing of 50 mg daily or 100 mg daily, respectively.[7]

The echinocandins have been shown to be highly effective alternatives to previously available standard treatment options for invasive candidiasis. In studies of treatment of invasive candidiasis, caspofungin has been shown to be at least as effective as amphotericin B,[71] and micafungin compared favorably to liposomal amphotericin B,[50] and anidulafungin to fluconazole,[94] in noninferiority trials.

OROPHARYNGEAL CANDIDIASIS

Oropharyngeal candidiasis typically may be treated topically. Children who are able to hold the suspension in the mouth as long as possible before swallowing may receive nystatin 400,000 to 600,000 units (4 to 6 mL) four times a day. In infants 200,000 units (2 mL) nystatin should be applied to the affected areas four times daily. Clotrimazole also is effective and is given five or six times daily as a 10-mg troche that is held in the mouth until it dissolves completely. Use of gentian violet as a 0.5 or 1.0 percent solution swabbed onto the buccal mucosa twice daily has largely been supplanted by use of nystatin suspension. Gentian violet is moderately effective but causes irritation and ulceration of the mucosa with prolonged use, and the purple staining can be messy and unattractive.

For infants with thrush, it is important to address sites that may be colonized with *Candida* to effectively treat the infection. Nystatin cream may be applied four to six times daily to areas that have sustained contact with the infected infant's mouth (e.g., the mother's nipple area for breast-fed infants and the appropriate digits of the hands for those infants who habitually suck their thumbs or fingers). For bottle-fed infants, if the bottle nipple is to be reused, it should be boiled after each use. Pacifiers or other objects with sustained contact with the infant's mouth also should be boiled after each use. The avoidance of unnecessary antibacterials also is an important aspect in the prevention of thrush.

More severe or refractory cases of oropharyngeal candidiasis, particularly in immunocompromised children, may require treatment with an oral or intravenous medication. A 14-day course of fluconazole suspension given once daily, as a 6 mg/kg dose on day 1 and then at 3 mg/kg, has proved to be superior to nystatin for the treatment of oropharyngeal candidiasis in immunocompromised children.[29] Itraconazole and ketoconazole[38] also may be used but are less effective than is fluconazole.[83] Neutropenic patients, in particular, with severe cases of oral candidiasis may benefit from short courses of an intravenous antifungal agent.

ESOPHAGEAL CANDIDIASIS

Esophageal candidiasis is treated usually with a 2- to 3-week course of fluconazole. Treatment should continue for 1 to 2 weeks after resolution of symptoms. Dosing for *Candida* esophagitis is the same as for oropharyngeal candidiasis: a loading dose of 6 mg/kg, followed by 3 mg/kg daily for the remainder of the treatment course. Voriconazole also is FDA approved for children at least 12 years of age for esophageal candidiasis. Refractory cases may be treated with intravenous agents. Esophageal candidiasis may lead to complications of stricture, secondary infection, and perforation.

PERITONEAL CANDIDIASIS

For pediatric patients receiving peritoneal dialysis who develop *Candida* peritonitis, fluconazole has been recommended as first-line therapy because of its excellent bioavailability and peritoneal absorption and its broad activity against most *Candida* spp.[93,122] However, the most recent adult guidelines recommend amphotericin B (or fluconazole or voriconazole or caspofungin) combined with flucytosine as first-line therapy.[90,93] Flucytosine has a questionable role now that fluconazole has been shown to be safe and effective and to achieve good systemic levels when it is given both orally and intraperitoneally. The catheter should be removed, but no consensus exists about timing of removal. Early but not immediate catheter removal, to provide peritoneal lavage with fluconazole to help prevent peritoneal adhesions and to maintain peritoneal membrane viability, is a rational approach supported by available data.[93,121]

CANDIDIASIS OF THE URINARY TRACT

Candiduria can be cleared with a 2-week course of oral fluconazole, but recurrence is common.[105] Other treatment options for *Candida* cystitis in the absence of renal or systemic involvement include oral flucytosine and bladder irrigation with amphotericin B.[26,27] Serial urine cultures should be obtained to document clearance of candiduria. Intravenous therapy for 4 to 6 weeks is indicated for patients with renal candidiasis and those in whom disseminated infection is suspected.

VAGINAL CANDIDIASIS

Vaginal candidiasis may be effectively treated topically with azoles (e.g., clotrimazole or miconazole) or with nystatin suppositories. A single 150 mg dose of oral fluconazole is a simple and effective treatment option for adults.[73,86]

CENTRAL NERVOUS SYSTEM CANDIDIASIS

CNS candidiasis should be treated with intravenous antifungals, typically as part of combination therapy. The combination of amphotericin B (0.5 to 1 mg/kg/day) or one of its lipid formulations plus flucytosine (150 mg/kg/day in four equally divided doses) may be synergistic for *Candida* meningitis. Amphotericin B penetrates into the cerebrospinal fluid poorly, whereas flucytosine penetrates readily. Duration of treatment depends on clinical response and should be continued for a minimum of 4 weeks.

Candida meningitis is a frequent complication of candidemia in neonates and is associated with high morbidity and mortality rates. Accordingly, *Candida* meningitis in a neonate should be treated aggressively. Few data are published about the use of fluconazole in meningitis, and, although it has been reported to treat meningitis successfully,[42] an amphotericin B product, alone or in combination with flucytosine, is recommended for treatment of neonatal *Candida* meningitis.

CANDIDEMIA

Any of the main classes of antifungal agents may be used for treatment of candidemia or systemic disease. Fluconazole is an acceptable option for susceptible organisms, but clinicians must be aware of the increasing incidence of azole-resistant organisms. Clinicians also should be aware that some species of *Candida* may be inherently resistant to polyenes (e.g., *C. lusitaniae*) and echi-

nocandins (e.g., *C. parapsilosis*) as well. Combination therapy with an amphotericin B product plus fluconazole is also recommended as an alternative option for treatment of candidemia.[83,95] A study of this combination of antifungals in non-neutropenic subjects showed a trend toward improved successful treatment and more rapid clearance of *Candida* spp. from the bloodstream.[95]

Removal of vascular catheters is recommended in all cases of candidemia.[83] However, removal of a catheter is not always feasible given the cost and complications that may be associated with replacing it. Nucci and Anaissie[79] conducted a review of the literature to evaluate the impact of removing a catheter on outcomes. They identified 203 studies of candidemia, only 14 of which evaluated outcome of removal or retention of a catheter. Of those 14 studies, only four met the selection criteria of including multivariate analysis with odds ratios and 95 percent confidence intervals and included confounding variables. Those four studies, none of which was a prospective randomized trial, had conflicting results, and the authors concluded that available data do not support the consensus recommendation for universal catheter removal. However, the authors agreed with the consensus recommendations but proposed expanding them to include those situations in which removal of a catheter is not feasible.

In neonates with candidemia, delay (more than 1 day after beginning antifungal treatment) in removing or replacing catheters is associated with increased mortality rates and neurodevelopmental impairment.[8] Although no large randomized trials of catheter management in neonatal candidiasis have been performed, available data support prompt removal or replacement of vascular catheters in neonates with candidemia.[8,11]

Candidemia in neonates also is associated with significant morbidity. Benjamin and colleagues[9] have provided suggestions for end-organ evaluation in neonates with candidemia. These suggestions include routine evaluation of cerebrospinal fluid (including culture), head ultrasonography, ophthalmologic examination, and echocardiography in all neonates with candidemia.

DISSEMINATED CANDIDIASIS

Intravenous therapy is indicated initially for patients with disseminated candidiasis as well as for those with CNS, cardiac, or respiratory involvement. For patients who respond to initial intravenous therapy, are clinically stable, and are infected with an azole-susceptible strain, a switch to oral fluconazole therapy at 6 mg/kg/day is acceptable for continuation therapy. Duration of treatment depends on clinical response and should be continued for a minimum of 4 weeks. Broad-spectrum antibiotics and immunosuppressive drugs should be avoided if at all possible.

EMPIRIC THERAPY

For patients with febrile neutropenia who do not respond to broad-spectrum antibiotics within a week of therapy, the likelihood of systemic fungal infection is sufficient (approximately 30%) to warrant initiation of empiric antifungal treatment.[37,91] Amphotericin B has been the empiric antifungal therapy of choice for fever with neutropenia, but some concern exists that some *Candida* spp. isolated from severely immunocompromised patients may be resistant to usual concentrations of amphotericin B achieved in vivo.[92] In one study, all episodes of candidemia caused by isolates with minimal inhibitory concentrations greater than 0.8 μg/mL of amphotericin B and half of those with minimal inhibitory concentrations of 0.8 μg/mL or less were fatal.[92] However, another study using the National Committee for Clinical Laboratory Standards method failed to demonstrate that the results of in vitro susceptibility testing for amphotericin B and fluconazole predicted outcome of therapy in patients with candidemia.[96]

Although amphotericin B has been the standard empiric therapy in fever with neutropenia, newer antifungal agents have been shown to be safe and effective when they are used for this purpose.[117,118,120] A multicenter, randomized, double-blind study comparing conventional amphotericin B with liposomal amphotericin B found that the liposomal formulation was as effective as conventional amphotericin B in empiric therapy and was associated with fewer breakthrough fungal infections and less treatment-related toxicity.[120] In that study, only three breakthrough *Candida* infections occurred in the group treated with liposomal amphotericin B (two caused by *C. parapsilosis* and one by *C. krusei*), compared with 12 in the group treated with conventional amphotericin B ($p = .03$). Walsh and colleagues[118] compared voriconazole with liposomal amphotericin B in a multicenter randomized study and determined that voriconazole is an acceptable alternative to amphotericin B formulations for empiric therapy in fever with neutropenia. The frequency of breakthrough fungal infections was significantly less in the voriconazole-treated group ($p = .02$); two invasive *Candida* infections occurred in the voriconazole-treated group compared with six in the group treated with liposomal amphotericin B.[118] In another randomized, double-blind, multicenter trial, Walsh and colleagues[120] found caspofungin to be as effective as is liposomal amphotericin B for empiric therapy. In that study, breakthrough fungal infections and therapy-related adverse events were similar in incidence in the two groups (16 cases of invasive candidiasis in the caspofungin-treated group compared with 15 in the group treated with liposomal amphotericin B), but fever, chills, nausea, and nephrotoxicity were less common manifestations in the caspofungin group.[120]

A clinical predictive model for neonatal candidemia has been developed that may assist clinicians in deciding when to begin empiric antifungal therapy in at-risk neonates. Benjamin and associates[10] suggest considering initiation of antifungal therapy when blood cultures are obtained in neonates who are less than 25 weeks' estimated gestational age, have thrombocytopenia, or are 25 to 27 weeks' estimated gestational age and have received a third-generation cephalosporin or carbapenem in the previous 7 days. The authors caution that before widespread use of antifungals is initiated, these recommendations need to be evaluated prospectively, as was the predictive model for febrile neutropenia.

PROPHYLAXIS

Prophylactic administration of antifungal agents has been shown to reduce the incidence of *Candida* infections in those at risk for acquiring fungal infection. However, associations between use of azole antifungal prophylaxis and increases in incidence of azole-resistant *Candida* spp. have been reported.[80,99,104,126]

Fluconazole prophylaxis began to be used routinely in some neonatal intensive care units after the publication of a single-center, randomized trial supporting its efficacy in preventing candidiasis in extremely low-birth-weight neonates (those with birth weight of less than 1000 g).[46,59] One propensity analysis suggested that for every eight extremely low-birth-weight infants for whom candidiasis could be prevented, one life could be saved.[129] Routine fluconazole prophylaxis had not been recommended because of the lack of data about safety and resistance and because it had not been evaluated in large prospective studies.[3,25,59,64,76] However, a recent multicenter, prospective, randomized, double-blind, placebo-controlled trial demonstrated that fluconazole prophylaxis reduces incidence of *Candida* colonization and invasive disease in very-low-birth-weight infants (those with birth weight below 1500 g).[59]

CHAPTER 213

Coccidioidomycosis

Ziad M. Shehab

Coccidioidomycosis is an infection caused by a dimorphic fungus of the genus *Coccidioides*. The primary pulmonary infection produced by this organism usually is self-limited, but disseminated and fatal disease may occur. In the United States, coccidioidomycosis is an endemic disease of the southwestern states and results in 150,000 infections per year.[68] In other parts of the United States, it also is seen in individuals who have traveled or lived in the endemic areas of the Southwest or Mexico.[26,33,50] The disease is endemic in other areas of the Western Hemisphere, most notably in northern Mexico and in certain countries in South and Central America.[111] With population growth in the endemic areas of the Southwest and increased population mobility, clinicians in nonendemic parts of the country likely will encounter this disease, particularly in its more severe or disseminated forms.

Coccidioidal granuloma, a form of disseminated coccidioidomycosis, was described first by Posadas in 1892 in Argentina.[48] The disease initially was thought to be a form of skin tumor. Rixford and Gilchrist associated it with what they thought was a protozoon resembling coccidia and named it *Coccidioides*. They divided it into two species, *Coccidioides immitis* and *Coccidioides pyogenes*. Ophuls and Moffitt, in 1900, were the first to attribute coccidioidal granuloma to the fungus *C. immitis*. Although earlier investigators had noted fungal growth on cultures from pathologic specimens, they dismissed these organisms as contaminants. Between 1900 and 1936, numerous reports of coccidioidal granuloma appeared in the medical literature, but the association between coccidioidal granuloma and acute pulmonary infection remained unrecognized. In 1936, Gifford and associates[72] and Dickson[53] were responsible for the concept that *C. immitis* could cause either a primary or a secondary type of illness. The primary form previously had been known in California as *San Joaquin fever* or *valley fever*.

In the period that followed, the epidemiology of the disease[134,138] and ecology of the organism[57,102] were studied carefully by many investigators, led by the efforts of Charles Smith. Many different forms of therapy were tried for the disseminated disease during this era, but none proved satisfactory.[60] In 1957, with the use of amphotericin B, effective antifungal therapy became available, and the prognosis associated with the disseminated form of the disease improved.

As with many pathogenic fungi, the life cycle of *C. immitis* demonstrates two distinct phases: a saprophytic, or vegetative, phase and a parasitic phase. In nature and on most laboratory media, the organism grows as a mycelium with branching, septate hyphae. After 5 to 7 days, the aerial mycelia show development of rectangular spores (arthrospores, arthroconidia) separated by empty nonviable cells (Fig. 213–1). At this stage, the hyphae

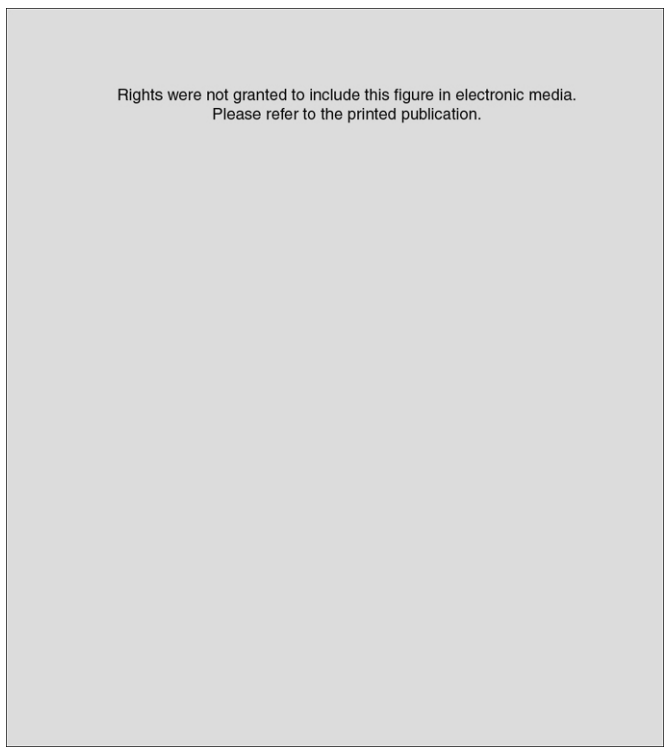

Figure 213–1 Mycelial form of *Coccidioides immitis*. Arthroconidia are separated by vacuolated cells. *(From Davis, B. D., Delbecco, R., Eisen, H. W., et al.: Microbiology: Including Immunology and Molecular Genetics, 3rd ed. Hagerstown, Harper & Row, 1980.)*

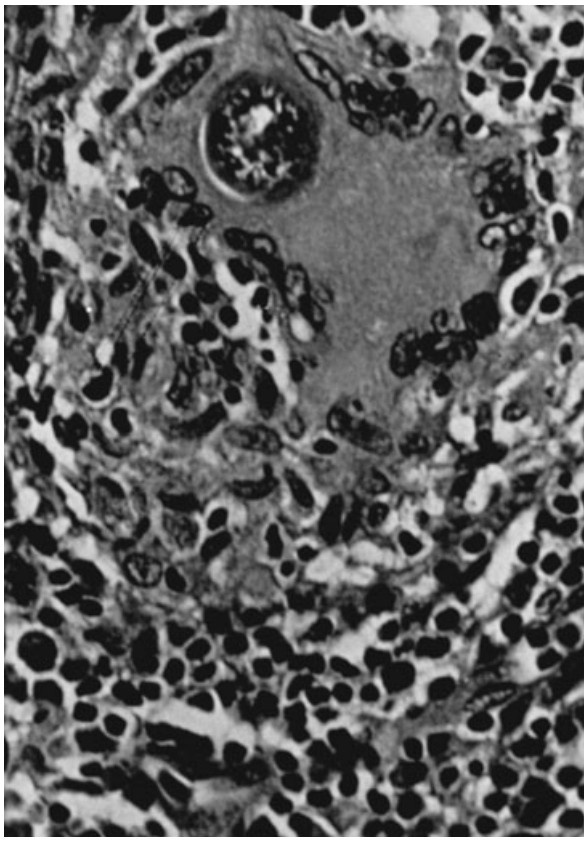

Figure 213–2 Coccidioidal granuloma showing a multinucleated giant cell containing a spherule filled with endospores. The adjacent field contains lymphocytes and plasma cells.

become fragile, and the arthroconidia, measuring 2 to 8 μm in diameter, easily become airborne. Because of their size, they can reach the alveolar spaces of the lung when they are inhaled.

On gaining access to the tissues of the mammalian host, the arthroconidia begin the parasitic phase of the life cycle. They enlarge and develop into spherules during the course of approximately 48 hours by undergoing internal segmentation containing endospores that are 2 to 5 μm in size. The spherules (Fig. 213–2) are round, double-walled structures measuring 20 to 100 μm in diameter. The endospores are released into the surrounding tissues by rupture of the spherule wall. They, in turn, may grow into mature spherules by maturation of the endospores in vivo to spherules, repeating the tissue phase of the life cycle of the organism. Alternatively, when the spherule ruptures, releasing the endospores into the environment, hyphal formation can occur and the cycle, thereby, is repeated in nature.[156]

C. immitis grows on laboratory media relatively easily, producing colonies that become visible in 3 to 4 days. They represent the mycelial phase of the fungus and appear as flat, smooth, and gray colonies, from which spicules may project in some, whereas others have the look of a velvety membrane. The colonies appear as tufts in the second week and then develop cobweb-like aerial hyphae. Pigmentation may be seen after 2 weeks and is observed best as a brownish undersurface. Variability in colony morphology can be significant. Of the two species of *Coccidioides* that are recognized, *C. immitis* is prevalent in California; *C. posadasii* accounts for isolates from Texas, Mexico, and South America. Both species can be found in Arizona.[62] No clinical differences have been identified between the two species. Identification is accomplished by inoculation of the mycelia into laboratory animals and demonstration of the conversion of the fungus to the spherule phase. However, reliable techniques showing in vitro conversion to the spherule stage, demonstration of specific exoantigens, or identification of the organism by genetic probes have been developed and obviate the need for animal inoculation.[129]

EPIDEMIOLOGY

Coccidioidomycosis is endemic in the Western Hemisphere between 40 degrees of latitude north and south. In the United States, these areas lie in the southwestern states, especially in Arizona, California, western Texas, and southern New Mexico. The areas in which coccidioidomycosis is prevalent generally correspond to the lower Sonoran life zone.[111] This life zone is characterized by an arid to semiarid climate, with hot summers and relatively short winters with limited rainfall and few freezes. Most of the fungal growth occurs during the rainy season in alkaline soil and at low altitude, conditions that favor the growth of the creosote bush that often coexists with *C. immitis*.[57] The fungus is found in the soil to a depth of 20 cm, especially in the walls of rodent burrows, and is isolated infrequently from surface soil during hot, dry weather[57] or in soils rich with other organisms.[102] Environmental conditions in endemic regions apparently inhibit growth of competitive organisms.[57] A variety of animals, including rodents, cattle, sheep, and dogs, have been shown to develop naturally acquired infection. Arthroconidia become airborne during wind storms or during disruption of soil by construction work and farming.[32,63] Prolonged droughts followed by heavy rains also have resulted in an increase in the number of cases, such as occurred in California in 1992 and 1993.[31] Archeologic excavations and digging by children in soil containing the organism have been reported to result in local outbreaks.[34,124,158] In addition, transmission has been reported to occur by contaminated fomites, such as dusty clothing and farm products.[1,127] Because of the ease by which arthroconidia become airborne, the organism is dangerous to laboratory personnel. Epidemics have resulted from inadvertent opening of a single culture plate.[90]

Primary coccidioidal infection occurs most frequently in summer and fall, following the rainy seasons. Arthroconidia are more likely to become dispersed because of the dry weather after promotion of greater hyphal growth by the wet environment.[57,66,94,111,134,135] Variations in seasonal infection rates also are explained partially by the occurrence of dust storms[111,135] and earthquake activity.[32] Significant increases in the number of cases are being seen in the Southwest, with high incidence periods in the winter being associated with environmental and climactic changes.[66,114]

Susceptibility to primary coccidioidal infection is unaffected by age, sex, or racial background.[60] Estimates of infection rates in endemic areas, which are based on the risk for development of infection in children, have been declining. For example, infection rates measured by skin test reactivity to skin test antigens have declined from approximately 10 percent in 1937-1939 to 2 percent in 1959 and to less than 1 percent thereafter in kindergarten and first-grade students who had lived all of their 5 to 7 years in Kern County, California.[97] Similarly, the annual risk has been estimated to be 2 and 4 percent in college students in Tucson, Arizona.[94] Incidence rates are higher in older male children, in rural areas, during wind storms, and for those with occupational exposure.[123,125,134] In contrast with susceptibility to primary infection, the frequency of dissemination varies considerably, being higher in infants,[37,38,87,132] Filipinos, Hispanics, and blacks.[63,72,83] Filipinos have 170 times and blacks 10 times the incidence of dissemination in comparison with non-Hispanic whites. However, some of this increased risk may reflect environmental exposure to high inocula of *C. immitis*.[6] Immunosuppressed hosts also are at increased risk for development of disseminated infection. In particular, patients with active coccidi-

oidomycosis and human immunodeficiency virus (HIV) infection are at greatly increased risk for development of severe pulmonary disease and disseminated infection.[3,160]

The tissue phase of the organism is the spherule, which is not infectious. Although mycelial growth can be found in cavities when they are carefully searched, no evidence exists of person-to-person spread of *C. immitis*,[78,156] except in special situations in which the fungus is allowed to revert to its airborne form, such as growth from wound drainage on a plaster cast.[56] Patients with coccidioidomycosis do not require isolation, even when draining wounds are present. In such circumstances, dressings should be changed frequently to prevent growth of the fungus and the formation of arthroconidia.

Once limited to the lower Sonoran life zone, the disease is seen throughout the country because of the ease and frequency of travel, increased populations in endemic areas, and reactivation of infection in immunocompromised hosts, including transplant recipients, patients with acquired immunodeficiency syndrome (AIDS), and recipients of tumor necrosis factor–α inhibitors. In these patients, delays in establishing the diagnosis can be fatal, and rapid recognition of the diagnosis and prompt institution of appropriate therapy mandate that a timely and accurate diagnosis be established.

PATHOGENESIS AND PATHOLOGY

Acquisition of *Coccidioides* spp. infection usually is through the respiratory tract. Researchers surmise that most human infections may result from exposure to only a single spore.[65] Rarely, direct cutaneous inoculation may occur by puncture of the skin with a contaminated object.[52,82,107] Growth of the organism stimulates an intense inflammatory response, and, in most patients, the infection remains localized to the lung and hilar nodes. In a minority of patients, clinically significant extrapulmonary dissemination occurs by way of lymphatics or the bloodstream.

The initial inflammatory response of acute pulmonary coccidioidomycosis predominantly is a polymorphonuclear leukocyte reaction, possibly related to a chemotactic effect of endospores or complement activation from other *C. immitis* antigens. Tissue necrosis, spherules, and a few mononuclear cells are present at this stage of the disease, but epithelial giant cells are infrequent findings. This bronchopneumonic process can occur in any lobe of the lung. The inflammatory response, however, is ineffective because neutrophils do not show any killing of coccidioidal forms at any stage of growth of the organism. Although this response may slow the progress of the infection temporarily, it ultimately cannot arrest the disease process.[65] Killing has been demonstrated with natural killer cells and mononuclear leukocytes. Numerous studies have demonstrated the importance of T cells in controlling the infection, as evidenced by delayed cutaneous hypersensitivity, peripheral lymphocyte transformation, and production of interferon-γ.[65] Dermal hypersensitivity correlates well with other measures of peripheral blood lymphocyte responsiveness, such as lymphocyte transformation and cytokine production.[4] As the disease progresses, cell-mediated immune defenses become defective, possibly as a result of antigen overload, suppressor cells, immune complexes, or fungal immunosuppressive substances, resulting in an ineffective response by type 2 helper cells.[42,141]

Disseminated coccidioidomycosis resembles progressive tuberculosis of childhood by its spread, which usually occurs within weeks or months after the initial infection develops. However, endogenous reactivation of treated primary disease may occur, particularly among individuals receiving immunosuppressive therapy[21] or among those with HIV infection.[3,66] Extrapulmonary spread may occur anywhere in the body, but lesions are found most frequently in bone, soft tissue, lymph nodes, and meninges. Bone lesions resemble chronic osteomyelitis (Fig. 213–3). Infection of the brain substance is a rare event, but meningitis occurs commonly and frequently localizes in the basilar area.[22,83]

Figure 213–3 Osteomyelitis in a 14-year-old boy with disseminated coccidioidomycosis. An osteolytic lesion involves the distal radius.

The pathologic findings of fatal coccidioidomycosis have been reviewed extensively.[84] The tissue reaction in disseminated disease predominantly is granulomatous but can be accompanied by elements of acute inflammation. Typically, the granulomatous lesions contain abundant giant cells and histiocytes. Caseous necrosis is a common occurrence, and spherules usually can be identified lying freely and within macrophages (see Fig. 213–2). Fibrous tissue may surround areas of inflammation, but calcification is an infrequent occurrence. Autopsy studies in patients with coccidioidomycosis and AIDS show poor granulomatous responses and larger numbers of organisms in lung tissue than those seen in non-AIDS patients.[75]

Most cases of disseminated coccidioidal infection in the first months of life have been associated with heavy exposure to dust; these infants apparently acquire their infection by the respiratory route.[39,87] Nearly all the described infants in this age group have had severe disease,[37,38,87,144] but primary infection sometimes may go unrecognized.[38] Although women who develop coccidioidomycosis late in pregnancy may be at increased risk for development of disseminated disease,[151] with a few exceptions,[35,99] their infants are born free of infection.[39,40,133,149] In several patients with apparent perinatal transmission, the mothers had coccidioidal endometritis, and infected amniotic fluid was the most likely source of their infants' infections.[17,99,130,140]

Dissemination of coccidioidomycosis occurs more frequently in immunosuppressed patients who have resided in an endemic area,[66,103] but immunologic abnormalities have not been detected in other groups, such as Filipinos, who also are at high risk for development of disseminated disease. Once dissemination occurs, the patient's cell-mediated immunity frequently is

impaired,[29,42,43,139] especially if extensive infection is present.[14,137] Dissemination can occur in patients who have a selective lack of response to coccidioidal antigens, as evidenced by negative skin test results to coccidioidin or spherulin, and who do not have evidence of generalized anergy. In vitro measurements of lymphocyte transformation to phytohemagglutinin or to specific cell wall antigens of *C. immitis* also are depressed.[14,42] In contrast, patients with disseminated disease with positive skin test results usually have normal in vitro lymphocyte responses that are similar to those found in healthy persons who have recovered from primary infection.[43,109,162] Furthermore, patients who have recovered from severe disseminated disease may show return of specific and nonspecific cell-mediated immunity.[14,29,60,139] Infected children demonstrate immunologic findings similar to those described in adults, but they have not been studied as well.

CLINICAL MANIFESTATIONS

PRIMARY INFECTION

The clinical features of acute coccidioidomycosis in children are thought to be similar to the manifestations observed in adults (Fig. 213–4).[136] Studies in Air Force personnel indicate that infection is subclinical or indistinguishable from a mild upper respiratory tract infection in 60 percent of nonimmunocompromised hosts.[136,139] Twenty-five percent experience an influenza-like illness lasting 1 to 2 days, whereas the remainder have more severe lower respiratory illnesses including lobar pneumonia, pleural effusions, and, occasionally, pericarditis.[60,65,116] With intensive exposure such as occurs during military field exercises, the attack rate may be high and a large proportion of infections may be symptomatic.[44] The disease may mimic bacterial pneumonia and sepsis.[10,101] When serologic studies are used routinely in the evaluation of community-acquired pneumonia in endemic areas, almost 30 percent of such pneumonias in adults are the result of coccidioidal infection.[148] The most common form of symptomatic infection is a subacute, self-limited pulmonary illness. Some patients, however, will experience more complicated pulmonary infections or even extrapulmonary disease; these patients are those who are most likely to be seen by physicians outside the endemic areas and may require extensive work-ups, and delays in establishing the diagnosis may occur if coccidioidomycosis is not considered.[26,50] Severe disease is more likely to develop in individuals with diabetes or those with a recent history of cigarette smoking.[126]

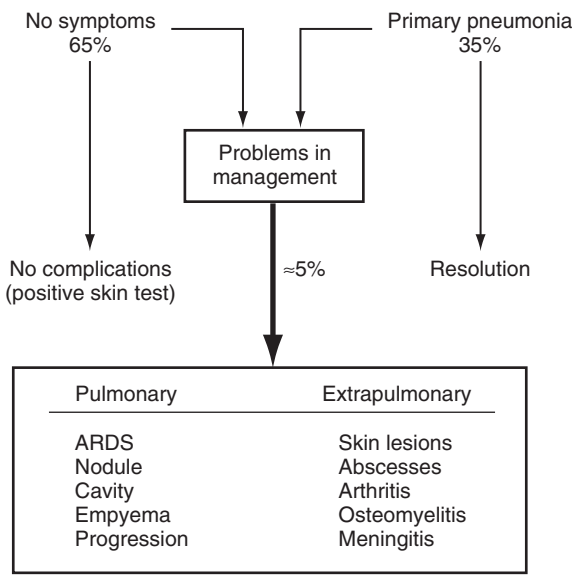

Figure 213–4 Clinical spectrum of coccidioidomycosis. ARDS, adult respiratory distress syndrome. *(From Galgiani, J. N.: Coccidioidomycosis. Reprinted by permission of the Western Journal of Medicine* 159*:153-171, 1993.)*

The usual incubation period is 10 to 16 days, but it may range from less than a week to almost a month.[60] In young adults, fatigue (77%), cough (64%), chest pain (53%), and dyspnea (17%) are the most common symptoms. Fever was present in 46 percent, with arthralgias, myalgias, and headaches being reported in 22 percent each.[143] In infants, stridor rarely may be present as a result of primary infection of subglottic tissue.[71,79] Chest pain sometimes is severe and usually is pleuritic.[143] It may be followed by vague chest pain that persists for several months.[55,60,65]

Transient rashes probably occur more frequently in children than in adults and are observed in slightly more than half of symptomatic children.[82,123] Two types of rashes are seen, based on time of presentation and immune status. Those that present early in the illness are erythematous and maculopapular.[60,82,154,158] They vary in severity, ranging from diffuse eruptions resembling measles or scarlet fever to more common and less extensive processes localized to the lower trunk and thighs.[60,82] In a few patients, urticarial lesions may be present.[154] Erythema nodosum and erythema multiforme–like lesions appear somewhat later in the course of illness, usually after the third day to as late as 3 weeks.[52,60,164] Erythema nodosum correlates with the development of cell-mediated immunity and is associated with a low incidence of dissemination.[13,55,60,134] This symptom complex may occur in other diseases, including tuberculosis, histoplasmosis, and group A beta-hemolytic streptococcal infections and inflammatory bowel processes. However, its presence in a child residing in some endemic areas, such as the San Joaquin Valley, nearly always signifies acute coccidioidal infection. For unknown reasons, erythema nodosum occurs less frequently in infected children inhabiting other endemic areas, such as Tucson.[123] The condition is self-limited, usually resolving within a few days to several weeks. Erythema nodosum occurs two to four times more frequently in adult women than in adult men, but this difference is not apparent in childhood infection.[134] The rash is an infrequent manifestation in blacks, Hispanics, and Filipinos. Erythema multiforme is seen more commonly in children.

Acute arthritis or arthralgia is an additional hypersensitivity manifestation, and occasionally one or both accompany primary coccidioidal infection. Because these findings usually are transient and do not signify dissemination, the presumption is that spherules are not present in the involved joints at this stage of the disease.[55]

The radiographic appearance of primary coccidioidomycosis is not specific.[15,36,77,123] Bronchopneumonic infiltrates are the most frequent finding and often are associated with hilar lymphadenopathy. Segmental or lobar consolidation and nodular or patchy pulmonary infiltrates also can occur. Small pleural effusions or pleuropericardial reactions also occur frequently (Fig. 213–5) and usually are sterile.[100] These radiographic findings resolve in 90 to 95 percent of symptomatic cases, albeit slowly in some, and usually do not necessitate specific therapy.

In a minority of patients, cavitation, nodule formation, bronchiectasis, or calcification may develop at the site of the pulmonic infiltrate.[19,27] The cavities usually are thin walled and asymptomatic and rarely require surgical therapy. Many resolve spontaneously[95] but result, nonetheless, in the need for prolonged care and convalescence. Rarely, the cavities lead to the development of an empyema or a bronchopleural fistula, which is more likely to occur in immunosuppressed patients or in diabetics.[88] Nodules and thin-walled cavities develop in 5 percent of patients with coccidioidal pneumonia.[141] These lesions are well circumscribed,

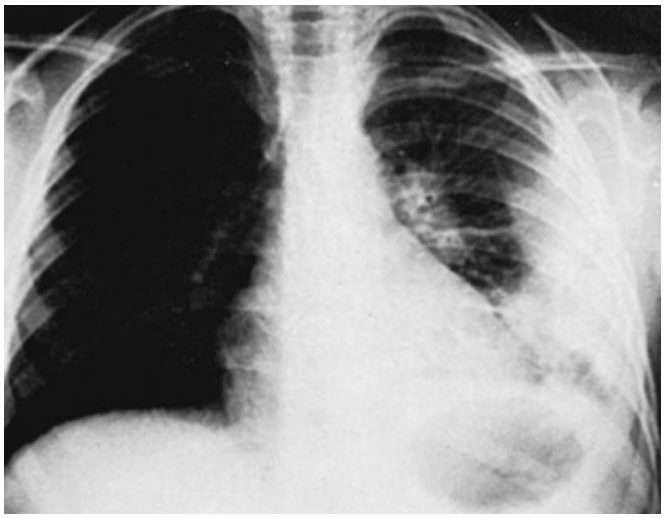

Figure 213–5 Chest radiograph of a patient with acute pulmonary coccidioidomycosis showing pulmonary infiltrates, extensive pleural fluid, and enlargement of the left hilum.

Figure 213–6 Swelling and chronic draining sinus over the proximal phalanx of the index finger. The infant has disseminated coccidioidomycosis with involvement of the underlying bone.

typically single, and less than 6 cm in diameter. In most patients, these lesions are asymptomatic. In adults, these nodules may be confused with carcinoma of the lung, thus requiring excision or diagnostic fine-needle aspiration.[54] A miliary pattern, indicating hematogenous or lymphatic spread, sometimes can be appreciated in immunocompromised hosts and, rarely, in immunocompetent hosts as well.[12] On occasion, endotracheal or endobronchial lesions can be demonstrated by endoscopy.[117]

In neonates, the constellation of radiographic findings of focal consolidation with diffuse nodular densities associated with nonspecific symptoms and minimal clinical evidence of respiratory tract infection has been described but is not specific for coccidioidomycosis at this age.[17,36] Chorioretinitis as a manifestation of systemic disease also has been reported.[73]

In contrast with primary pulmonary infection, primary cutaneous coccidioidomycosis is an uncommon occurrence.[52,107] Most cases have been reported in laboratory workers,[90] but this form of infection also is recognized in children.[107] The lesion of primary cutaneous disease resembles a chancre and is associated with regional lymphadenitis. In adults, usually only mild constitutional symptoms are present, and the process spontaneously resolves within 2 to 3 months. However, in children, progressive and prolonged infection may occur commonly; antifungal therapy may be necessary.[107,157]

The manifestations of primary coccidioidal disease thus are varied, and no constellation of symptoms and signs is specific enough to establish a diagnosis, rendering the use of specific laboratory tests a requirement.

DISSEMINATED COCCIDIOIDOMYCOSIS

Except in very young children, dissemination appears to occur less frequently in pediatric patients than in adults (0.5%), although this view has been questioned.[92,132] Spread of infection usually becomes apparent within a few weeks to a few months after the initial infection occurs and is heralded by persistent fever, toxicity, and insidious development of lesions outside the chest. An occasional patient develops disseminated disease after having an asymptomatic primary infection.[47,59,92] Disseminated disease rarely can be manifested with peritonitis, pericarditis, empyema, laryngeal lesions, or neck or gluteal abscesses.[23,46]

Skin Disease

The most common cutaneous manifestation of disseminated coccidioidomycosis is verrucous granuloma that characteristically is located at the nasolabial fold.[60,82] These lesions may heal or may continue to progress. The lesions mimic those caused by other fungi, tuberculosis, actinomycetes, and syphilis. The subcutaneous tissues also may be involved and result in large "cold" abscesses and the development of sinus tracks leading to chronic ulcers.[55]

Bone and Joint Disease

Involvement of bone results in chronic osteomyelitis,[20,49,89] which may drain into soft tissue (Fig. 213–6) and form fistulas to the overlying skin.[47] The bones most frequently infected are the vertebrae, tibia, metatarsals, skull, and metacarpals. The lesions are present in a single bone in 60 percent of the cases; two bones are involved in 20 percent, three in another 10 percent, and four or more bones in the remainder. On radiographic examination, the lesions typically are lytic (see Fig. 213–3). Vertebral osteomyelitis is characterized by involvement of all parts of the vertebra with relative sparing of the disk.[55] Spread of infection locally leading to meningitis is a serious concern with vertebral osteomyelitis.

Meningitis

Meningitis may be the sole site of extrapulmonary disease, particularly in whites, but it also occurs as part of widespread dissemination.[22,81,91,131] It may present acutely with the primary infection or appear up to 6 months later. The most common symptom is headache. Altered mental status, sluggishness, ataxia, and vomiting are other common symptoms. The child often lacks signs of meningeal irritation and sometimes presents with signs of focal neurologic deficits. The pathologic process is that of granulomatous and suppurative basilar meningitis, with frequent presence of parenchymal involvement with granulomata and abscesses of the spinal cord and brain.[58,106] Vasculitic complications with infarction and stroke-like findings may be abrupt in onset.[58,155] Examination of the cerebrospinal fluid (CSF) usually reveals moderate pleocytosis (few to more than 10,000) with mononuclear cell predominance, low CSF glucose concentration, and elevated protein level.[30,81,131] These findings are typical for

CSF sampled from the lumbosacral space. However, considerable variation occurs in the cell count, chemistry, and antibody content of fluid obtained from the ventricles, cisterna magna, or lumbosacral space[74,81,131]; the lumbosacral space exhibits the more severe changes, that is, lower glucose concentration, higher protein level, higher cell count, and higher CSF coccidioidal complement-fixation titer. Eosinophilic pleocytosis in the CSF is suggestive of coccidioidal meningitis and should prompt performance of an appropriate diagnostic work-up; it is of no prognostic value.[121] The CSF culture often is negative for the fungus, whereas CSF antibody often is detectable in 75 percent of specimens.[30] The diagnosis is confirmed by a positive CSF culture, serology, or both. The diagnosis is supported by a positive serum serologic result or culture of *Coccidioides* spp. from a nonpulmonary site. Before amphotericin B became available, coccidioidal meningitis was uniformly fatal, and the average length of survival in children was 5.5 months. Death with coccidioidal meningitis now is a relatively rare event. However, adults with neuroimaging abnormalities, especially hydrocephalus with or without cerebral infarction, have a high mortality rate.[11]

Genital Coccidioidomycosis

Like tuberculosis, coccidioidomycosis can involve the pelvic organs. Early studies had indicated an alarming risk of dissemination and death in women who acquired coccidioidomycosis, especially during the third trimester of pregnancy.[45] In a population-based study, Wack and colleagues[151] showed that coccidioidomycosis occurs infrequently during pregnancy but remains associated with serious complications when the disease develops in the third trimester or soon after delivery. Women with erythema nodosum are much less likely to experience disseminated disease than are pregnant women without erythema nodosum.[13] Wide variations are reported in the rates of dissemination and fatality among pregnant women, although all studies agree that the rate of dissemination in pregnant women is higher than that in the general population.[25,44] Coccidioiduria may be a silent manifestation of disseminated disease.[115]

Coccidioidomycosis in the Immunocompromised Host

Conditions that result in immune suppression, particularly T-lymphocyte dysfunction, such as those present in patients with lymphoma or bone marrow or solid organ transplantation, predispose the individual to more fulminant forms of coccidioidomycosis.[21,124] Infections may be the result of primary infection or of reactivation. Solid organ transplantation recipients are at the highest risk in the first year after undergoing transplantation, especially during their primary infection. Dissemination also can occur late as a result of reactivation of an old infection. Control of coccidioidal infection depends primarily on cell-mediated immunity. The risk is increased by a prior history of coccidioidomycosis or a positive serologic reaction just before transplantation.[21] Dissemination occurs in as many as 75 percent of such patients, and multiple sites of infection are common findings. An increased risk of acquiring symptomatic disease and disseminated coccidioidomycosis was described in patients receiving therapy with tumor necrosis factor–α antagonists.[16] Patients infected with HIV are at a greatly increased risk for development of severe forms of pulmonary coccidioidomycosis[3] and extrapulmonary diseases, including meningitis.[160] In HIV-infected patients, active coccidioidomycosis may represent recrudescence of old infection or may be the result of primary infection.[3] A CD4 count of less than 250/μL is associated significantly with the development of active disease. In HIV-infected patients who are relatively immunocompetent, the disease often is manifested as a community-acquired pneumonia similar to that of HIV-uninfected individuals. In HIV-infected patients, the clinical manifestations vary, ranging from minimal systemic symptoms without a pulmonary focus to severe cough and dyspnea associated with diffuse pulmonary disease and a radiographic pattern showing a discretely nodular appearance resembling *Pneumocystis* in those with CD4 counts of less than 250/μL. The severity of presentation is correlated inversely with CD4 counts. Even with appropriate antifungal therapy, the prognosis of HIV-infected patients with depressed CD4 counts who develop diffuse pulmonary coccidioidomycosis is poor, with a mortality rate of 70 percent.[61,67] HIV-infected patients also may present with evidence of extrapulmonary dissemination, typically meningitis or lymph node or cutaneous involvement. An important note is that many HIV-infected patients who have positive serologic results without evidence of active disease go on to develop active coccidioidomycosis during the course of time[9] and may be candidates for therapy.

DIAGNOSIS

In endemic areas where an awareness of the disease exists, the diagnosis of coccidioidomycosis usually is established readily by obtaining appropriate laboratory studies. However, even in these areas, coccidioidal pneumonia may be more prevalent than previously thought and may be underdiagnosed.[148] In nonendemic areas, the diagnosis is not considered unless a travel history is obtained. Cases have occurred even after brief exposure in an endemic area. Primary pulmonary coccidioidomycosis resembles other lower respiratory illnesses, including those caused by viruses, bacteria, mycoplasma, *Mycobacterium tuberculosis*, and other fungi (e.g., *Histoplasma*).

The hematologic findings in primary coccidioidal infection consist of elevation of the erythrocyte sedimentation rate, leukocytosis, and, frequently, eosinophilia.[60] Marked eosinophilia may be a clue that dissemination has occurred.[80] Specific diagnosis usually is based on the results of serologic reactions, cultures, and sputum examination.

CULTURE AND IDENTIFICATION OF THE FUNGUS

The organism is detected readily by direct examination and culture from purulent material. The yield from other sources, such as pleural fluid, blood, and gastric aspirates, is somewhat lower. Only approximately a third of CSF samples are culture positive, and direct examination of the CSF almost always yields negative results.[82,143] Detection of the fungus from the blood is an uncommon occurrence and is associated with severe forms of disseminated disease.[5]

In severe pulmonary or disseminated disease, microscopic examination of bronchopulmonary lavage specimens, exudates, or biopsy specimens is diagnostic if typical spherules containing endospores are seen. Hematoxylin and eosin–stained sections can be used to demonstrate spherules, but they are used mainly to show the inflammatory process. The periodic acid–Schiff stain is useful for demonstrating the spherule contents (Fig. 213–7), whereas methenamine silver stains highlight the wall of the spherule. Potassium hydroxide stains are useful but lack sensitivity and specificity; calcofluor white fluorescent stains are more sensitive but require experienced technologists.[129] Cytologic examination of sputa is more sensitive than are potassium hydroxide stains.[152] The spherules do not pick up the Gram stain.

In HIV-infected patients who present with pulmonary infiltrates, coccidioidal spherules may be identified in bronchopulmonary lavage specimens by the same methenamine silver stain used to identify *Pneumocystis*. Indeed, in areas endemic for coccidioidomycosis, the possibility of concomitant pulmonary infections with both *Coccidioides* and *Pneumocystis* or other pathogens should be kept in mind in this patient group.[104] Cytologic exami-

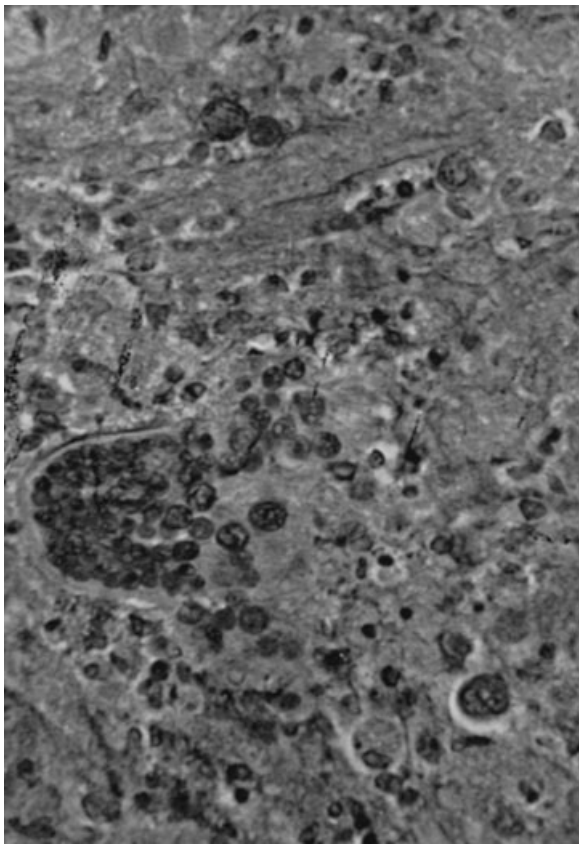

Figure 213–7 A spherule that recently has ruptured and is in the process of releasing endospores.

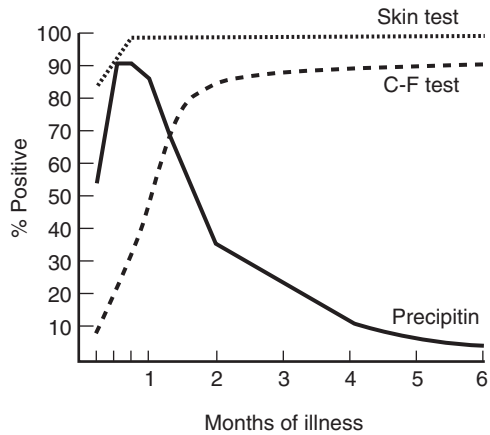

Figure 213–8 Immunologic reactions in symptomatic primary coccidioidomycosis, relating time of appearance and duration to the frequency of positive reactions. *(Based on Smith, C. E., Beard, R. R., Rosenberger, H. G., et al.: Effect of season and dust control on coccidioidomycosis. J. A. M. A.* 132*:833-838, 1946.)*

nation of bronchial wash or bronchoalveolar fluid is diagnostic in only approximately a third of persons with or without HIV infection and is less sensitive than culture.[54]

With the rare exception of persons with primary cutaneous infection, the finding of spherules in tissues outside the thoracic cavity is evidence that the patient has disseminated disease. For this reason, biopsy may be useful for establishing a diagnosis, particularly in patients with borderline or low complement-fixation antibody titers. Cultures of *Coccidioides* spp. from body fluids, sputum, or exudates can be performed on most laboratory media. If coccidioidomycosis is suspected, the use of mycologic media containing cycloheximide can be helpful. The handling of the cultures is hazardous and requires special biosafety precautions.[90] *Coccidioides* spp. are designated Select Agents by the Centers for Disease Control and Prevention, requiring handling in secure and contained environments. *Coccidioides* spp. grow on routine bacterial, fungal, and *Legionella* media. Once a nonpigmented mold is grown, confirmation is achieved best by use of genus-specific genetic probes that allow rapid confirmation, usually within hours.[110] The probe does not differentiate between *C. immitis* and *C. posadasii*, and it is not clinically relevant to differentiate the two species. Real-time polymerase chain reaction assays are being developed for rapid detection of *Coccidioides* spp. in clinical specimens but are not commercially available.[18]

SKIN TEST

Intradermal skin tests using lysates of either the mycelial phase (coccidioidin) or the spherule phase (spherulin) have been used to elicit delayed hypersensitivity. They are used as an epidemiologic tool and are no longer commercially available.

SEROLOGIC STUDIES

Figure 213–8 illustrates the serologic and skin test responses of symptomatic patients with primary coccidioidomycosis. The initial antibody response to coccidioidal infection predominantly is in the IgM fraction and is responsible for the positive precipitin test result that accompanies primary infection. These responses can be measured by tube precipitins, latex agglutination, enzyme immunoassay, or immunodiffusion methods.[113] Fifty percent of patients yield positive results in the first week, and 90 percent show precipitins within 2 to 3 weeks. Thereafter, antibody reversion occurs, and by 5 months, only 10 percent of patients with uncomplicated infection yield positive results.[138] Serum precipitins may persist in some patients with disseminated infection or may reappear with reactivation of infection. Precipitating IgM antibody detected by the tube precipitin assay or by immunodiffusion usually indicates acute infection.[138] In contrast with that seen with complement fixation, the magnitude of the precipitating antibody titer does not correlate with an increased risk of dissemination.[137] On occasion, IgM antibody has been detected in cord blood of newborns whose mothers had detectable antibody. These infants did not have any evidence of infection on follow-up.[113] Latex agglutination is sensitive, rapid, and easy to perform but frequently yields false-positive reactions,[113] and positive results should be confirmed by a second method. It also gives false-positive results in spinal fluids and in diluted sera and should not be used for these specimens.[112]

Serum IgG antibodies that fix complement usually appear later and last 6 to 8 months.[113] They are seen more commonly in more symptomatic infections and are detected in 50 to 90 percent by 3 months after the onset of symptoms. At least 90 percent of persons show a positive IgM or IgG response after having symptomatic primary infections. The main methods of detection of these antibodies are immunodiffusion, immunoassays, and complement fixation.[105,113,153,161] These assays correlate well, and immunodiffusion, particularly, is useful for detecting antibody in patients whose sera are anticomplementary.[113]

Immunodiffusion yields few false-positive results and can detect early asymptomatic infection in persons infected with HIV.[9] This method seems to be slightly more sensitive than is complement fixation in detecting early infections.[93]

More recently, enzyme immunoassay has become available. This assay compares well with more traditional assays (complement fixation, immunodiffusion, latex agglutination) and does not suffer from the subjectivity required to interpret the other

assays.[64,105] The IgG enzyme immunoassay has a sensitivity of 92 percent, whereas the IgM assay has a sensitivity of 77 percent. When both assays are combined, the sensitivity is excellent,[93,105] but the test suffers from false-positive results in patients with blastomycosis or suspected noncoccidioidal pulmonary illness.[93]

Antibodies measured by complement fixation are slower to develop and primarily are in the IgG fraction.[113] Usually, they are not detected in serum samples obtained during the first week of infection, and their rise may occur as late as 3 months after onset of symptoms.[86,138]

The magnitude of the complement-fixation antibody response correlates closely with the severity of infection and the likelihood of dissemination.[138] Although the antibody titer cannot be used as the sole indicator of dissemination, titers of 1:32 or greater in most laboratories are highly suggestive of extrapulmonary spread of infection[85,138]; 61 percent of these patients have a titer of at least 1:16, whereas 95 to 100 percent of those without dissemination have a titer lower than 1:16. The titer of complement-fixation antibody parallels disease activity and is useful in following the progress of patients with disseminated disease. A few patients, especially those with extensive pulmonary involvement and pleural effusion, develop high titers without other clinical evidence of dissemination.[100] Conversely, some patients with dissemination, particularly those with single lesions in skin, bone, or meninges, have lower titers.

Some patients with immunodeficiency disease, in particular HIV infection, may have extensive disease with low or undetectable antibody levels.[3,113] Bone marrow transplant recipients may yield no serologic or skin test response before or shortly after bone marrow transplantation, and aggressive attempts may be required to culture the fungus for diagnosis.[124] Some patients with HIV infection may have persistently positive serologic test results in the absence of any clinical disease. These patients are at high risk for development of active coccidioidomycosis and should be treated early.[9]

The complement-fixation antibody is detectable in the CSF of 70 percent of patients at the time of diagnosis of coccidioidal meningitis and eventually becomes detectable in almost all. The antibody measured is not a reflection of serum levels but rather is thought to indicate specific immunoglobulin biosynthesis by cells residing within or contiguous to the central nervous system. On occasion, patients with vertebral osteomyelitis or epidural abscesses yield low complement-fixation titers in the CSF without other evidence of meningeal involvement.

TREATMENT

PRIMARY INFECTION

In more than 90 percent of children, primary coccidioidomycosis is a self-limited illness, and antifungal therapy is not needed. In some children with severe primary disease, therapy with antifungals may be justified either to abbreviate the period of morbidity or to lessen the chance of dissemination in those with an elevated complement-fixation titer.

Which patients with primary uncomplicated pulmonary infections should receive therapy remains controversial. In general, evidence of severe infection or of concurrent risk factors such as immunosuppression should lead to the initiation of therapy. Severe infections usually are heralded in adults by weight loss of more than 10 percent, intense night sweats for a duration of longer than 3 weeks, infiltrates involving more than half of one lung or portions of both lungs, prominent or persistent hilar adenopathy, complement-fixation titer to *C. immitis* of greater than 1:16, failure to develop normal skin test hypersensitivity to coccidioidal antigens, inability to work, or symptoms that persist for longer than 2 months.[68] Diagnosis of primary coccidioidomycosis during the third trimester of pregnancy or immediately post partum should raise consideration of treatment. Amphotericin B is recommended for pregnant women because of the teratogenic potential of fluconazole and possibly of the other azoles.[2] Because of their high risk of dissemination, persons of African or Filipino ancestry should be considered for antifungal therapy, which typically consists of oral azoles for 3 to 6 months. When reticulonodular or miliary disease is seen, therapy usually is initiated with amphotericin B or high-dose fluconazole. Amphotericin B seems to yield a faster response and is replaced by an azole after a few weeks. The total course of therapy should last for at least 1 year and should be followed by oral azole therapy for secondary prophylaxis.[68]

Asymptomatic pulmonary cavities generally do not require therapy. Consideration should be given to excision of some cavities that persist for longer than 2 years, are progressively enlarging, or are adjacent to the pleural cavity. In patients with cavities that result in local discomfort, superinfection, or hemoptysis, therapy with oral azoles may alleviate the symptoms. Resection of localized cavities is an alternative to recurrent courses of antifungal therapy.[68] Pyopneumothorax results from rupture of a cavity into the pleural space. Its treatment is surgical with or without a course of antifungal therapy. Chronic fibrocavitary disease usually is treated with oral azoles for at least a year. In patients with inadequate responses, increasing the dose of azole, switching to a different azole, and administering amphotericin B are options. Surgical resection may be helpful in localized disease or when significant hemoptysis has occurred.[68]

DISSEMINATED DISEASE

Nonmeningeal Dissemination

Patients with disseminated disease who have clinically apparent lesions outside the thoracic cavity almost always should receive antifungal therapy, usually with an azole (fluconazole or itraconazole). In fulminant infections, amphotericin B is the agent of choice and usually yields faster responses.

Treatment is indicated for patients with extrapulmonary dissemination. The classic therapy consists of amphotericin B deoxycholate administered initially at a dose of 1 to 1.5 mg/kg/day and then tapered to 1 to 1.5 mg/kg/day three times a week. The usual total dose in adults is 1 to 2.5 g. In children, the maximal dose has not been defined because children better tolerate the toxicities of amphotericin B. Local instillation or irrigation of abscesses and cavities with amphotericin B or other antifungal agents may be beneficial but has not been studied systematically.[20,89] Amphotericin lipid-complexed preparations offer the possibility of administering higher doses with less toxicity and have largely replaced intravenous amphotericin B deoxycholate.

The total dose of amphotericin B depends on the patient's age and severity of disease. Most patients respond to between 15 and 45 mg/kg, with total dose and duration of therapy determined by the patient's response. The azoles have been tested extensively in this form of the disease. The main agents used for this purpose are itraconazole and fluconazole. In a randomized, double-blind study of progressive nonmeningeal coccidioidomycosis, a trend toward better efficacy with itraconazole, especially in the subgroup of patients with skeletal infections, was demonstrated.[70] This approach must be weighed in children against the need for more frequent drug administration and diet limitations related to the absorption of itraconazole. Ketoconazole has the advantage of being significantly less costly than are the other two azoles; it is associated, however, with more gastrointestinal discomfort and may impair testosterone secretion and adrenal steroid synthesis without causing an adrenal crisis.[24,119] Itraconazole and ketocon-

azole have important drug interactions, most notably with cyclosporine and diphenylhydantoin.[76] Anecdotal reports suggest that voriconazole and posaconazole can be effective therapies in patients refractory to fluconazole therapy.[7,41,120] A single case report demonstrates beneficial results with the concurrent use of interferon-γ.[96] In general, the azoles are used for a few months after resolution of symptoms or for at least a year of therapy. Caution should be exercised with the use of fluconazole in pregnancy, as cases of multiple congenital malformations somewhat reminiscent of the Antley-Bixler syndrome have been described.[2] The role of echinocandins is unclear at present.

Surgical therapy seldom is required in patients with primary disease, but therapeutic thoracentesis may be indicated rarely when pneumonitis is complicated by large pleural effusions. Surgery also is necessary when pericardial involvement is complicated by tamponade. Patients with persistent coccidioidal cavities (>1 year) may require lobectomy, especially if the lesions are symptomatic.[68] Coccidioidal lymphadenopathy occasionally requires excision. In general, bone and joint disease requires a combined surgical and medical approach. Coccidioidal arthritis typically responds poorly to systemic therapy, and synovectomy may aid in the control of symptoms.[20,118,159] Osteomyelitis optimally is dealt with by curettage and drainage of the involved bone, with the addition of amphotericin B therapy, itraconazole, or fluconazole.[20,28,49,70] Within endemic areas, screening of HIV-infected patients serologically by immunodiffusion or complement fixation may be useful to identify active cases early. Consideration should be given to offering antifungal prophylaxis to such persons. Treatment is recommended for all HIV-infected individuals with active coccidioidomycosis and CD4 counts of less than 250/μL. Once the infection is controlled, discontinuation of the therapy is reasonable if the CD4 count has risen to more than 250/μL, except in cases of meningitis, in which the therapy should be lifelong. Azoles have been used for prophylaxis in patients with solid organ transplants, both primary and secondary. The duration of treatment usually is 6 to 12 months or more, and the optimal duration is unknown. Because of their inhibition of the cytochrome P450 system, levels of cyclosporine and tacrolimus should be monitored.[21] Whether such prophylaxis is effective remains unclear, and the potential for drug resistance should be weighed. In a retrospective cohort study, clinical response, the lowest complement-fixation titer, the end-of-therapy complement-fixation titer, and a fourfold drop in complement-fixation titer were not predictive of relapse in nonmeningeal forms of disseminated coccidioidomycosis, whereas a peak complement-fixation titer of greater than 1:256 and a persistently negative coccidioidin skin test result were independently associated with increased risk.[108]

Meningeal Disease

Amphotericin therapy of coccidioidal meningitis has been associated with a marked improvement in survival rates. However, this treatment needs to include prolonged intrathecal therapy through lumbar, ventricular, or cisternal administration. This therapy is associated with significant side effects that include headache, nausea, vomiting, chills and fever, arachnoiditis, and, occasionally, paralysis, seizures, and coma.[81,142] The symptoms of arachnoiditis may be indistinguishable from those of microbiologic relapses.[81] Ketoconazole has been used with some success in meningitis, but it also is associated with a high relapse rate[51]; in high doses (1200 mg daily in adults, 15 to 23 mg/kg/day in children), therapy has been successful,[81,131] but such doses tend to be tolerated poorly in adults.[65]

Studies using 400 mg of fluconazole or itraconazole in the treatment of meningitis without concurrent use of amphotericin B show good results, with response rates of approximately 80 percent.[69,145-147] Many patients who do not show improvement with this regimen demonstrate clinical improvement when the dose is increased up to 1000 mg of fluconazole or 600 mg of itraconazole. Fluconazole currently is the preferred drug.[68] On the basis of limited data, the pediatric dose of fluconazole is approximately 12 mg/kg/day.[128] Patients generally respond clinically within 1 to 2 months, although abnormalities of the CSF may persist in some patients for a prolonged period. When therapy has been stopped, increases in CSF cell count or complement-fixation antibody titer may be the only indications of reactivation of meningeal disease and signify a need to intensify therapy.[55] Some investigators use intra-CSF administration of amphotericin in conjunction with azole therapy in the hope of achieving a faster response.[142]

Significant attention should be paid to CSF flow dynamics because almost all children with coccidioidal meningitis develop obstructive hydrocephalus, which requires ventriculoperitoneal shunting and rarely a second shunt to drain a "trapped" fourth ventricle.[81,131] Hence, the advantage of a drug such as fluconazole, which can be given systemically, obviates the problems of impaired CSF flow faced when intrathecal or intraventricular therapy is used.

Studies have indicated that the relapse rate after discontinuation of azole therapy is high. Of 14 persons treated for coccidioidal meningitis with azoles (ketoconazole, itraconazole, or fluconazole) for periods ranging from 8 to 101 months, 11 (78%) had a relapse of disseminated coccidioidomycosis within 0.5 to 30 months after therapy was stopped. There were no clinical or laboratory predictors of patients at risk for having a relapse. The data thus indicate that moderately prolonged azole therapy for coccidioidal meningitis suppresses but does not eradicate the infection, suggesting the need for prolonged if not lifelong therapy.[41,51,120] Voriconazole rarely has been used as a rescue agent after failure of fluconazole. The data on its use in meningitis remain scanty. Posaconazole has limited CSF penetration, and its role in central nervous system infections, if any, remains to be defined.

PROGNOSIS

Primary pulmonary coccidioidal infection usually is self-limited, with complete recovery occurring in 1 to 3 weeks. In a small proportion of cases, localized complications of the primary infection, such as pleural effusion or pericarditis, prolong the clinical course. Dissemination is a rare event in whites and is less likely to occur in patients with positive skin test results. Until the late 1950s, no effective therapy was available for the more severe forms of coccidioidomycosis, and the mortality rate of patients with disseminated disease was approximately 50 percent.[60] The mortality rate of patients with multiple sites of dissemination and those with coccidioidal meningitis approached 100 percent.[150] Presently, therapy with amphotericin B or azoles may cure some of these patients and in many others prolongs useful life. Certain forms of disseminated infection, such as joint involvement, particularly are resistant to systemic therapy and may persist for many years without other signs of dissemination. For patients with HIV infection, therapy for disseminated coccidioidomycosis usually is not curative, and lifelong suppressive therapy with intermittent doses of amphotericin B or oral azoles may be required to prevent relapses in those with CD4 counts of less than 250/μL.

PREVENTION

T_H1 responses have been associated with protection against human coccidioidomycosis. Persons recovering from infection with *Coccidioides* are immune to exogenous reinfection. The for-

malin-killed spherule vaccine, which had been immunogenic in mice and monkeys, proved not to be effective in humans. The 27K vaccine seems the most promising at present, but it is heterogeneous and its protective component has not been identified. Efforts are ongoing for the identification of a suitable protein or mixture of proteins for use in a vaccine.[42] Other efforts at prevention have been aimed at control of dust and eradication of the organisms from the soil.[135]

CHAPTER 214

Paracoccidioidomycosis

Gil Benard ✪ Maria José Soares Mendes-Giannini

Paracoccidioidomycosis, formerly known as South American blastomycosis, usually is a progressive chronic disease that preferentially affects the lungs, skin, mucous membranes, adrenals, and reticuloendothelial system. Benign, self-limited infections also have been documented occasionally. Two types of clinical presentations are described: the acute-subacute (juvenile) and the chronic (adult) forms of the disease. Children generally present with the acute form, which affects predominantly the reticuloendothelial system organs. The mycosis is limited geographically to various Latin American countries.[18,24,29,80,103,105,109,142,187]

The disease was described originally by Lutz[103] in Brazil in 1908 and initially observed in children in 1911 by Montenegro.[107]

THE ORGANISM

Paracoccidioides brasiliensis, the etiologic agent of this disease, is a dimorphic fungus. The recognition of *P. brasiliensis* as an anamorph in the phylum Ascomycota, order Onygenales, family Onygenaceae has been accomplished by means of molecular tools.[20] The fungus has four or five DNA chromosomes showing molecular sizes ranging from 2 to 10 Mb.[70,134] *P. brasiliensis* genome size was estimated to be approximately 30 Mb.[43] A study of *P. brasiliensis* gene density suggests that this fungus contains between 7500 and 9000 genes, which is in agreement with the estimated gene number for ascomycete fungi genomes. Different groups have addressed the overall scenario of gene expression in *P. brasiliensis* yeast versus mycelium, or undergoing phase transition in vitro, making use of different molecular methods.[71,86,113,148] The existence of three different phylogenetic species (S1, PS2, and PS3) of *P. brasiliensis* has been demonstrated.[122]

It grows as a mold at room temperature (14° C to 24° C) and as yeast at 37° C. In the mycelial phase, growth is slow, requiring approximately 3 to 4 weeks; the colony is white to tan and compact, with short aerial mycelia. On microscopic examination, hyphae are fine (0.8 to 2.5 μm in diameter), septate, interlaced, and hyaline. Chlamydoconidia (20 to 50 μm in diameter), round to subspherical, terminal and intercalary, as well as arthroconidia may be observed.[103] Some isolates can produce aleurioconidia, uninucleate pear-shaped pedunculated or terminal structures, after long periods of incubation and under nutritional deprivation (media with reduced carbohydrate content).[29,173] The small size of these conidia (<5 μm) renders them compatible with alveolar deposition; furthermore, such conidia have been shown to be infectious when they are inhaled.[124]

The mycelial phase is not distinctive, and subcultures at 37° C are required for complete identification. At this temperature, *P. brasiliensis* produces soft, wrinkled, cream-colored colonies that develop in approximately 6 to 10 days. On microscopic examination, the most characteristic feature is the presence of multiple budding yeast cells; the parental cell produces various peripheral buds and acquires the appearance of a pilot's wheel. *P. brasiliensis* may possess alternative control mechanisms during cell growth to manage multiple budding and its multinucleate nature.[1] Single buds and short chains also are produced, but they are not diagnostic. Cells are variable in size (2 to 40 μm) and have a thick cell wall and internal vacuoles. This phase of growth is identical to the one observed in tissue and pathologic materials.[29,80,103,133,142,163] The organism does not readily take most bacterial or hematologic stains. *P. brasiliensis* is aerobic and, in its mycelial phase, grows well in the regular mycologic media to which antibiotics and cycloheximide have been added to reduce growth of bacteria and saprophytic fungi.[29,103] The isolation should be attempted by the use of modified Sabouraud agar, yeast extract agar plus antibiotics and cycloheximide, yeast extract–phosphate agar, brain-heart infusion agar plus blood and antibiotics, or tryptic soy agar plus fungus water extract and horse serum, incubated at room temperature.[102]

TRANSMISSION

Paracoccidioidomycosis is not a contagious disease.[29,80,103,142,172,216] A single case of placental involvement that did not result in fetal infection has been reported.[23] Epidemic outbreaks have not been reported, and only a few cases in family members have been documented,[103-106,142,216] which could be attributed to the long periods of mycosis latency between the moment of infection and the appearance of overt clinical manifestations.[109,171] Consequently, the memory of the activity contributing to the infection of the patient or of the accompanying individuals usually has been forgotten,[27] which prompted Borelli[27] to coin the name "reservarea" for those places in the endemic areas where the fungus has its habitat and humans acquire the infection. This concept differs from that of an endemic area, which implicates the place where the disease is diagnosed.

P. brasiliensis infection in animals as proved by culture or histologic examination has been shown consistently in armadillos, mammals that probably acquire the infection when they disturb the terrestrial habitat of the fungus,[33,140,173,196] and more recently in a dog.[176] Unfortunately, the microniche of *P. brasiliensis* has not been identified properly; soil has been incriminated, but the number of isolates from this source is small.[165] The inhibitory effect of pesticides on *P. brasiliensis* may suggest that they can interfere with attempts to isolate *P. brasiliensis* from soil.[151] Recently, the role played by deforestation in increasing both exposure and incidence rates has been documented in Brazil in Amerindians and in children.[48,75,176] Species-specific inner primers derived from rDNA regions (internal transcribed spacer [ITS], 5.8S gene) have been described, and the nested polymerase chain reaction (PCR) sensitivity was higher for the detection of *P. brasiliensis* in soil than in culture and animal inoculation. The fungus was detected in soil artificially seeded (positive soil control) and from environmental samples collected in an armadillo burrow.[204] This approach probably would improve the fungal microniche studies. The ecologic factors that prevail in the reserve area also have been characterized, with the following being significantly associated with the disease: altitude from 1000 to 1499 meters above sea level, rainfall from 2000 to 2999 mm, and presence of humid forests and of coffee and tobacco crops.[35] Environmental correlates (soil texture and precipitation) indicate that moisture availability plays an important role in paracoccidioidomycosis distribution.[197] The fertile regions of endemic areas have the highest incidence rates of paracoccidioidomycosis.[35,207]

Paracoccidioidomycosis was thought, and still is by some, to be acquired by trauma. However, clinical and experimental data indicate that infection is acquired most commonly by inhalation.[29,84,106,133,143]

EPIDEMIOLOGY

AGE

More than 70 percent of the patients are 30 years of age or older. Until recently, the number of childhood cases was shown to be only 2.1 percent in the first decade of life.[8,12,45,103,107,216] In 1976, Castro and del Negro[45] published one of the largest series of children with paracoccidioidomycosis diagnosed in a 30-year period. They found that among 1899 patients with this disease seen at the Hospital das Clinicas in São Paulo, Brazil, only 70 (3.6%) of the patients were 14 years of age or younger. However, in 1999 and in the same state, Blotta and colleagues[24] found that 5.6 percent of the paracoccidioidomycosis patients diagnosed between 1988 and 1996 were younger than 14 years, thus showing an increase over the l976 figure. In 1998, Rios-Gonçalves and associates[176] analyzed the records of 36 children who had been diagnosed in the state of Rio de Janeiro during a period of 25 years. In a similar period, Fonseca's group[75] described 13 children, 12.7 percent of all cases, who had been diagnosed in the Amazonian states of Pará and Tocantins, forest areas that have been colonized since the 1970s and where paracoccidioidomycosis formerly had been regarded as rare. In certain places, the infection rates measured by a positive skin test reaction also were high. In 1976, Pedrosa[156] conducted a skin testing survey among rural children (6 to 11 years of age) in a particular county of Rio de Janeiro where paracoccidioidomycosis had been diagnosed previously in a 3-year-old boy. He found that 34 percent of the children tested positive for paracoccidioidin, a figure indicative of early exposure to *P. brasiliensis*.

In 1996, Londero and colleagues[107] compiled the records of 106 children with the mycosis, including those formerly analyzed by Castro and del Negro.[45] This series, some compilations,[15,147,158] several individual reports, and a thesis[8] have revealed that the disease occurs more frequently in individuals 12 to 15 years of age than in younger children (Table 214–1). More than 250 reports of paracoccidioidomycosis in children aged 3 to 14 years, including those analyzed by Londero and colleagues,[107] have been found in a literature search.[174] The prevalence of infection with *P. brasiliensis* was evaluated in a cross-sectional study of 298 asymptomatic schoolchildren in the Brazilian Amazon region. The reactivity of children to two different *P. brasiliensis* antigen preparations, paracoccidioidin and a purified 43-kd glycoprotein (gp43), was 4.6 percent. However, in the group of individuals receiving paracoccidioidin who had a positive histoplasmin skin test result, the prevalence of exposure to *P. brasiliensis* was 44 percent, suggesting that the use of the paracoccidioidin prepara-

TABLE 214–1 Age and Gender Distribution in 354 Children with Paracoccidioidomycosis

	Age		
Gender*	3-9 yr	10-14 yr	Total by Gender (%)
Male	95	125	220
Female	63	71	134
Total by age	158 (41.8%)	196 (58.2%)	354 (100%)

**Male-to-female ratio = 1.6:1.*
Data from references 24, 34, 47, 49, 75, 131, 147, 156, 158, 177, 178.

tion may result in cross-reactions with other environmental fungi.[95]

The relative paucity of children with this mycosis in comparison with the figures reported in adults[18,24,45,103,105,106,117,191,211] may be explained, in part, by the effective control exerted by most hosts on the progression of the primary infection, by the long incubation period characteristic of the mycosis, and by the establishment of latent foci that may become apparent clinically many years after initial exposure.[11,29,46,79,84,106,109,171] Benard and associates[14] consider that the association with different age groups is related to the epidemiology of paracoccidioidomycosis because in the endemic areas, as previously shown, children become exposed to the fungus at an early age. In healthy children, appropriate defenses usually curtail development of the mycosis, but in infants of low socioeconomic conditions, the transition from infection to overt disease may be accelerated and aggravated by the mycosis itself, by malnutrition, or by other associated conditions.[14,15,24,45,75,176] In addition, unknown susceptibility factors, the intensity of exposure to the infectious source, the virulence of certain *P. brasiliensis* isolates, and other factors may well contribute to the development of the disease in children.[11,12,15,49,75,107,216]

GENDER

Adult men are afflicted with much greater frequency than are women (male-to-female ratio, 14:1).[18,24,29,75,103,106,142,216] In children, however, the disease affects boys and girls in approximately equal proportions.[18,24,45,42,107,147,176,216] In the review published by Londero and associates,[107] which included children up to 14 years of age, a slight predominance of male patients was noted in the older group (see Table 214–1). These findings suggest that the sex hormones, the hormone-dependent immunologic factors, or both play a role in determining the outcome of the host-parasite interaction.[4,5,11,29,168] Researchers have shown that in vitro estrogens inhibit *P. brasiliensis* mycelium to yeast transition, thereby hindering the progression of the infection.[4,29,168] Analysis of the mortality profile from paracoccidioidomycosis according to gender and age showed similar death totals for both genders in the groups younger than 20 years. The majority of deaths among male patients (97.14%) occurred in individuals older than 15 years, with only 2.37 percent among individuals younger than 15 years. Among female patients, most deaths from paracoccidioidomycosis (89.21%) also occurred in those older than 15 years, but 9.75 percent did occur in those younger than 15 years; that rate is nearly five times the percentage observed in males. These findings corroborate the literature, according to which the infection and disease occur equally between the genders during childhood, with a slight predominance of males with the disease, compared with an absolute predominance of males among adults with the chronic form of the mycosis.[52]

OCCUPATION AND RACE

Almost half of the reported cases in adults occur in individuals whose occupations require extensive exposure to the soil.* Adult residents of areas in which paracoccidioidomycosis is endemic generally develop disease that is less severe than that seen in immigrants or in people who migrate to highly endemic settings. These people often develop disseminated infection, much like the juvenile cases do.† The influence of genetic traits on the mycosis has not been elucidated,[61] but in patients with the unifocal chronic form of the disease, a mild clinical presentation in which lesions are restricted or localized, the HLA allele most commonly seen was DRB1*11, suggesting that the participation of HLA antigens may influence the outcome of the host-parasite interaction in paracoccidioidomycosis.[181]

GEOGRAPHIC DISTRIBUTION

Paracoccidioidomycosis is restricted to Latin America, from Mexico to Argentina; some countries within this area (Chile and some of the Caribbean Islands), however, are free of the disorder. In endemic countries, the disease's distribution is uneven, and most cases occur in individuals living in regions corresponding to the humid tropical and subtropical forests. The endemic area is centered in Brazil; 7000 of the about 10,000 patients described to date were natives of this country.[18,24,80,103,105,106,117,142,216] Although paracoccidioidomycosis has been reported in patients not living in endemic areas, prior residence in Latin America has been documented in every case.[96,109,171] In some of these patients, the interval between residence in the endemic area and clinical manifestations of the disease has been 10 to 40 years.[103,171] Within endemic areas, 10 to 50 percent of healthy adult individuals react to the intradermal administration of paracoccidioidin, suggesting previous contact or subclinical infection with *P. brasiliensis*.[25,29,33,48,95,107,156]

Molecular biology studies have indicated the existence of at least five different groups of *P. brasiliensis* strains and their close correspondence with the borders of the various endemic countries.[145] Recently, this fungus was described as having at least three distinct, previously unrecognized species: S1 (species 1 with 38 isolates), PS2 (phylogenetic species 2 with six isolates), and PS3 (phylogenetic species 3 with 21 isolates). Genealogies of four of the regions studied strongly supported the PS2 clade, composed of five Brazilian isolates and one Venezuelan isolate. The second clade, PS3, was composed solely of 21 Colombian isolates. The remaining 38 individuals formed S1. Two of the three lineages of *P. brasiliensis*, S1 and PS2, are sympatric across their range, suggesting barriers to gene flow other than geographic isolation.[122] Despite the apparently restricted ecologic niche, the habitat of the etiologic agent has not been determined precisely.[170,173]

PATHOGENESIS AND PATHOLOGY

The initial stages of the host-parasite interaction are unknown because of our inability to detect the precise moment when infection does occur.[79] In the past, traumatic implantation of the fungal propagules into skin and mucosa was thought to cause primary lesions, whereas other manifestations were regarded as secondary. However, through the study of many cases, including autopsies, what has become apparent is that pulmonary lesions are primary, with the infection taking place by inhalation of fungal propagules.[29,84] In experimental animals, the inhalatory route has been shown to give rise to disseminated disease.[124] In most cases, the initial pulmonary infection does not cause undue symptoms.[79,105] Once the conidia reach the terminal bronchi or the alveolar spaces, yeast transformation ensues.[124] In some cases, the fungus promptly disseminates by the lymphohematogenous route, producing distant subclinical and quiescent foci. Apparently, the local defenses are capable of controlling fungal spread, but some viable yeast cells may remain dormant in such foci in the pulmonary and mediastinal lymph nodes. Rarely, the initial pulmonary infection outweighs the host's immune defenses, causing an acute-subacute disease, the juvenile type, with predominant involvement of the reticuloendothelial system.[80] The disease in children falls into this category. Often, the quiescent foci remain so throughout life, as demonstrated by the high

*See references 24, 29, 80, 105, 106, 142, 172, 210.
†See references 11, 14, 46, 102, 105, 106, 107, 126, 142, 167, 216.

number of subclinical infections compared with the low disease incidence of this mycosis in the endemic regions.[77,216] Nonetheless, the most common clinical presentation of the disease is the chronic form, or adult-type disease, thought to result from fungal reactivation in these foci.[93] This reactivation frequently occurs when the patient has left the endemic area, as demonstrated by the cases reported outside Latin America, in countries where paracoccidioidomycosis is considered an imported disease.[46] Of note is that these cases may be manifested decades after leaving the endemic area, leading to difficult and delayed diagnosis.[91,123,198,212]

Thus, in the acute or subacute form, the initial lung infection may pass unnoticed but is followed by prompt dissemination to other organs and tissues.[11] In the chronic form, lung disease frequently occurs. Disease is restricted to the lungs in some of these patients, but in most, other organs also are afflicted. This spread may be caused by lymphohematogenous dissemination from reactivated pulmonary foci or directly from foci at virtually any organ. Actually, paracoccidioidomycosis, in the acute, subacute, or chronic forms, is more frequently a disseminated disease, even though clinical manifestations appear to be restricted to a sole organ.[80,126,142] However, determination of the degree of dissemination certainly is influenced by the availability of diagnostic procedures. After appropriate therapy, residual lesions, mostly fibrotic, become established.[79,126]

As already mentioned, the disease in children is acute or subacute and progressive (the juvenile form).[15,45,107] The time that elapses between infection and the onset of symptoms is not known precisely but has been estimated to be short, a few months.[79,80] In such patients, paracoccidioidomycosis is a severe, systemic disorder that involves preferentially the reticuloendothelial system to such an extent that it is the hallmark of the process.[8,15,107]

In adults, pulmonary lesions as seen on chest plain films may be defined as micronodular or miliary, nodular, infiltrative or interstitial, cavitary, fibrotic, and mixed types.[126,211] Emphysematous areas, pleural thickening, and enlarged hilar and mediastinal lymph nodes also can be observed. Right ventricular hypertrophy may be found in cases of long duration.[211] Lung involvement probably is secondary to a chronic lymphangitic process provoked by the fungus itself and to the host's response represented by formation of granulomata and fibrosis, which predominates at the perihilar region. This aspect correlates with the butterfly-like (perihilar) micronodular and interstitial infiltration observed on plain films.[210] Obstruction and reversal of lymphatic flow lead to the spread of the inflammatory process throughout the lungs. The pulmonary lesions as seen on computed tomographic imaging have been recently reassessed.[200]

In children and adolescents, the pulmonary component tends to pass unnoticed, and neither clinical examination nor radiologic studies reflect the real damage.[84] Only a minor proportion of the cases reported have had lung symptoms.[107] However, lack of notification may be more apparent than actual because the weight of the extrapulmonary lesions tends to minimize the less intense respiratory manifestations. Frequently, the mycosis is misdiagnosed, especially with tuberculosis and certain lymphomatous disorders.[107] Nonetheless, a careful search of pulmonary samples, including induced sputum, may reveal the characteristic multiple budding *P. brasiliensis* yeast cells.[107,169] Moreover, gallium scanning and computed tomography have allowed detection of incipient or discrete interstitial pulmonary lesions not revealed by plain radiographs.[34,81,218]

Lesions in the oropharyngeal and laryngeal mucosa occur frequently in the chronic form. They may be infiltrative, ulcerated, nodular, or vegetative and usually have a granulomatous aspect and may mimic squamous cell carcinoma.[21,126,130,186] The base of the ulcerated lesions usually is covered by small abscesses (the mulberry-like lesions) that probably represent fungal dissemination through the lymphatic system because they usually are accompanied by regional lymph node involvement.[44]

In children, such mucosal lesions are rather exceptional, but skin involvement occurs more commonly and tends to be multiple, in contrast with the adult chronic form.[118] In the adult chronic form, lesions are represented mostly by contiguous involvement of the periorificial mucosal lesions or draining lymph nodes. In children or young adults, and eventually in adults with the chronic severe disseminated disease, they represent hematogenous spread of the fungus. In this case, the lesions may appear as ulcerated or ulcerovegetative lesions, papules, or crust-covered ulcers and warts, usually at the same stage of development. Reports of septic shock caused by septicemia by *P. brasiliensis* show that the fungus can be blood borne.[126,209]

The reticuloendothelial system is the target organ in both children and young adults.[8] Almost every child with paracoccidioidomycosis exhibits involvement of the superficial or deep lymph node chains. Lymph nodes vary in size, number, consistency, and location; with time, they may liquefy, forming abscesses or fistulas. The spleen and liver frequently are involved in these same groups. Abdominal lymph node involvement also is a common occurrence in children.[8,107] Hypertrophied lymph nodes, usually generalized but particularly periaortic, around the hepatic hilum, and retroperitoneally, can be detected by ultrasonography, computed tomography, or magnetic resonance imaging.[119] Coalescent masses may become palpable and may result in disease caused by extrinsic compression of adjacent structures, such as jaundice by compression of the biliary duct,[25] pancreatitis,[25] or an intestinal obstruction.[120]

Splenic lesions are nodular or miliary. Gross hepatic lesions may not be apparent, but histopathologic examination regularly reveals fungal invasion of this organ.[8,15,107,133] In a series of fatal cases of paracoccidioidomycosis, 56.7 percent revealed the presence of yeast cells in the liver, associated with a granulomatous tissue response. Thirty percent of the cases had only widening of the portal tracts by fibrosis (31.6%), whereas 11.6 percent had an essentially normal liver.[203]

The intestinal mucosa may be affected, but similar to the lungs, its involvement is secondary to blockade of the regional lymphatic flow, with retrograde progression of *P. brasiliensis* to the mucosa, a process resulting in mycotic enteritis.[25,76,120] In this case, the submucosal inflammatory process is granulomatous; fungal cells are visualized; and the intestinal changes may vary from dilated loops, edema, congestion, and nodule formation to multiple mucosal ulcers.[76,120]

Studies also have shown bone marrow infiltration mainly, but not exclusively, in the acute-subacute form of the disease; 25.7 percent of the patients examined during active disease and 36.4 percent of those who died of paracoccidioidomycosis revealed this type of involvement.[164] The histologic pattern was variable, but appropriate staining always displayed fungal cells. Bone marrow invasion frequently is associated with marked eosinophilia.[164,192] In addition, bone and joint lesions are frequent occurrences in the acute-subacute form of the disease[3,15,66,107,209] and appear closely related to bone marrow infiltration.[164]

The adrenals often are involved in patients with the chronic form of the mycoses, many of whom suffer from adrenal hypofunction or insufficiency (Addison disease). The glands contain multiple granulomatous foci, and diffuse necrosis may be seen in the most severe cases. Hyperplasia of the adrenal glands also occurs commonly.[126]

On histologic examination, formation of granulomata is the rule, except in patients with severe disseminated disease, such as those with the acute-subacute form.[80] The granulomatous inflammation is associated with a mixed pyogenic component, especially in the case of ulcerated skin lesions or ruptured lymph nodes. Caseation and central necrosis may be present. In compact granulomata, abundant epithelial cells, Langerhans or foreign body

giant cells, plasmacytes, and lymphocytes are seen; often, phagocytosis of the yeast cells can be observed. $CD4^+$ lymphocytes dominate over $CD8^+$ lymphocytes and appear as peripheral mantles around aggregates of macrophages and histiocytes.[136] In the juvenile disseminated disease, the inflammatory reaction is diffuse, with abundance of both mononuclear and yeast cells but sparse formation of compact granulomata.[14,45,167] Loose granulomata appear unable to circumscribe fungal antigens, and at their periphery, *P. brasiliensis* antigens may permeate throughout the intercellular space.[185] Skin and mucous membrane lesions usually exhibit pseudoepitheliomatous hyperplasia and intraepithelial microabscesses.[133,153,154,185]

An interesting aspect drawn from the previously described histologic studies is the frequent description of areas of extremely active disease characterized by pyogenic reaction and loose granulomata, rich in budding fungal cells, intermingled with areas with compact granulomata, rare fungal cells, and variable degrees of fibrosis. This mixed aspect can be observed in lymph nodes, skin, or pulmonary lesions, suggesting that the disease evolves through localized new bouts of fungal multiplication and tissue invasion, whereas the adjacent older lesions are on the way to fibrotic resolution. Computed tomographic imaging of the lung confirmed this aspect by depicting areas with alveolar condensation along with fibrotic and emphysematous zones in one study and the simultaneous presence of features of more recent and chronic lesions.[81,200]

Tissue reactions are nonspecific; thus, diagnosis depends on finding *P. brasiliensis*. If the parasite is abundant, it may be identified by hematoxylin and eosin stains. Special fungal stains (e.g., Grocott silver methenamine) always should be employed, however, especially when granulomata are examined. The typical multiple budding yeast cells must be found to establish a diagnosis. The presence of fungal cells of different sizes (2 to 40 μm) suggests the presence of *P. brasiliensis*. In some cases, short chains and cells with single buds also are observed, and in these patients, differentiation of *P. brasiliensis* from *Cryptococcus neoformans*, *Blastomyces dermatitidis*, and even *Histoplasma capsulatum* must be made. When the disease is chronic, most of the fungal cells are found inside the macrophages, but free yeast cells predominate in disseminated cases. Internalized yeast cells exhibit altered morphology.[133,171]

CLINICAL MANIFESTATIONS

Paracoccidioidomycosis is a polymorphic disorder that at a particular time may involve more than one organ or system. Thus, making a topographic classification is unrealistic, and the classification of the mycosis currently accepted takes into consideration not only the organs involved but also the host's immune condition and the disease's natural history.[79] The infection is categorized as a *subclinical form*, and the overt process is subdivided into *acute-subacute* or *chronic disease*. The acute-subacute pattern predominates in children and young adults who are at greater risk than are patients exhibiting the chronic disease. According to the severity of the process, juvenile patients are assigned to two subgroups, severe and moderate. The adult type, which is the chronic progressive form of paracoccidioidomycosis, may be localized to pulmonary lesions, the unifocal disease, or disseminated from its primary foci, the multifocal process. Disseminated disease is characterized by involvement of the skin, mucosa, reticuloendothelial system, adrenal glands, and, less frequently, the gastrointestinal or the genitourinary tract, bones, and central nervous system.[8,23,84,118,126,133,167] The chronic form can be mild, moderate, or severe.[79]

Patients with acute or subacute disease develop signs and symptoms of a wasting process. Fever, malaise, listlessness, weight loss, and emaciation are recorded frequently. The severity of these symptoms is proportional to the degree of the organic involvement. Londero and associates[107] gathered the information published up to 1994 and found 269 cases in children younger than 14 years; however, sufficient clinical data for analysis of the prominent organic involvement were provided for only 77 children. The clinical characteristics exhibited by these children and by other patients described more recently, including the series of patients reported at two centers, are shown in Table 214–2. These findings support the notion that juvenile paracoccidioidomycosis is a disease of the reticuloendothelial system resulting in damage of the corresponding organs caused by severe macrophage dysfunction, as suggested previously.[80] Superficial lymph node enlargement was the predominant sign (81.6%) in these cases. Cervical and submandibular lymph node chains were involved most commonly, followed by those of the supraclavicular and axillary regions; however, any chain can be affected (Fig. 214–1). Lymph nodes may vary in size from slightly enlarged to

TABLE 214–2 Clinical Findings on Admission Diagnosis in Children with Paracoccidioidomycosis

Clinical Findings	No. of Children (%)
Lymph node enlargement	
Superficial	81.6
Thoracic	25
Abdominal	36.6
Abdominal masses	19.9
Hepatomegaly or splenomegaly	60.7
Ascites	19.1
Jaundice	10.5
Diarrhea, vomiting, abdominal pain, or distention	19.1
Joint or bone lesions	37.8
Skin lesions	29.1
Respiratory symptoms	9.1
Pulmonary consolidations or infiltrates	10.2
Pleural effusion	5.1
Oral and upper respiratory tract mucosa lesions	9.2

Total number of children investigated for each clinical finding varied from 98 to 199. Data from references 3, 34, 49, 66, 75, 107, 131, 146, 157, 166.

Figure 214–1 An 11-year-old boy with a 5-month history of fever and cervical and axillary lymph node enlargement, with fistulization. *(See companion Expert Consult web site for color version.)*

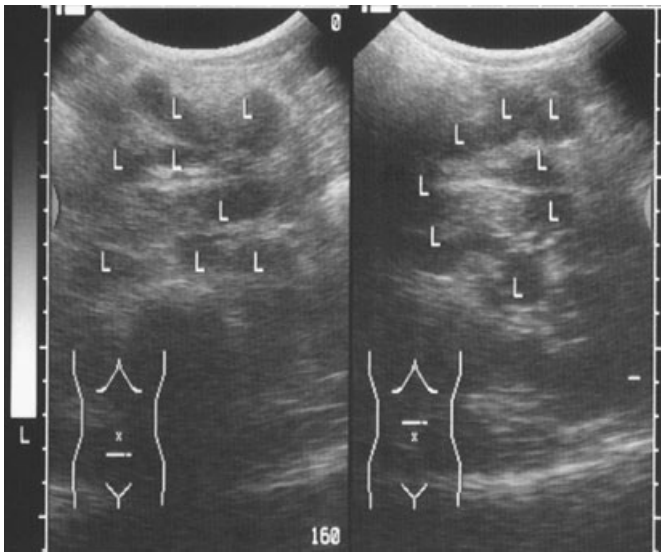

Figure 214–2 Extensive mesenteric lymph node enlargement in a 10-year-old boy (L) as shown by ultrasonography imaging.

large, painful, coalescent masses; they may be mobile and of elastic consistency or fixed to the adjacent tissues; hypertrophied nodes may progress to fistulization and discharge purulent material rich in *P. brasiliensis* yeast cells.

The next most important finding was hepatomegaly or splenomegaly (60.7%), which usually was asymptomatic. Jaundice is an infrequent occurrence and more closely relates to extrinsic compression of the biliary tree.[25] Liver enzymes, especially alkaline phosphatase, were abnormal in some cases but not markedly increased.[25,146] Portal hypertension also was a rare occurrence. Findings and complaints relating to the abdomen and digestive tract, such as abdominal masses, lymph node enlargement, diarrhea, vomiting, abdominal distention or pain, and ascites, also have also been recorded in a sizable proportion of patients (Fig. 214–2; see Table 214–2). Signs and symptoms of an acute abdomen, caused by masses formed by hypertrophied lymph nodes or perforation, also have been reported; this problem may lead to intestinal occlusion, blockage of lymphatic drainage, and, later, ascites.[8,15,107,147,158]

In a series comprising predominantly patients with the juvenile form of the disease, abdominal radiographic studies (double-contrast barium study) revealed ileal and jejunal alterations in 42 to 51 percent.[76,120] The main findings were distortion and coarsening of the mucosal pattern and loop dilation. However, part of these alterations was probably nonspecific because jejunal biopsies performed in a small number of patients revealed neither granulomatous response nor *P. brasiliensis* yeast cells.[120] On the other hand, histopathologic examination of autopsy specimens (probably the more severe cases) showed a specific granulomatous enteritis in 80 percent.[76] In addition, in a magnetic resonance imaging study of patients, mostly with the juvenile form, 48 percent had abdominal lymph node enlargement, even if no abdominal signs and symptoms had been recorded.[119] This lymph node involvement causes mesenteric lymphatic stasis and enteric mucosal edema that may progress to fungal enteritis accompanied by abnormal intestinal function, such as reduced absorption of fat.[121,147,158] Computed tomography and magnetic resonance imaging have proved helpful in determining the extent and nature of abdominal involvement.[119] These consequences of the primary fungal process adversely affect the health status of the patient.[12,193] Abdominal complications continue to be reported occasionally in the most recent series.[147,158]

Bone damage and articular problems also were important components (37.8%) of disseminated disease, especially in younger children. This proportion is higher than in earlier observations[121] and may be explained by the more frequent active search for bone lesions, irrespective of the presence or absence of symptoms in the more recent reports.[147,158] In these patients, the long bones frequently were affected, with the lytic lesions located at the diaphyseal or metaphyseal-epiphyseal regions,[3] probably because of their higher vascularization, emphasizing the hematogenous dissemination that typically occurs in this form of the disease (Fig. 214–3). Ribs, skull, phalanges, and vertebral lytic lesions also have been documented (see Fig. 214–3). Different from the painful, motion-restriction joint lesions, the bone lesions usually were silent.[3,15,66,132] A pathologic fracture occasionally may occur.[132]

Skin lesions were noted in 29.1 percent of the juvenile cases, with a tendency toward higher frequency with increasing age of the patient. Distribution of cutaneous lesions was variable, but face and trunk were involved more frequently.[118] Lung abnormalities were recorded in a smaller proportion of cases. However, even in the absence of clinical and radiologic involvement, colonization of the lung by *P. brasiliensis* can be demonstrated by direct examination and by culture.[169] When chest radiographs were abnormal, enlarged hilar lymph nodes and miliary infiltrates predominated.[84,107,169] In contrast with the adult form of the disease, in which adrenal involvement is a serious concern, it is an uncommon manifestation in children. A recent survey of adrenal function before and after treatment in 23 children has shown normal adrenal function.[159]

Anemia, increased erythrocyte sedimentation rate, severe hypoalbuminemia, and hypergammaglobulinemia with high IgG serum concentrations are found regularly.[8,15,80,146] Nonetheless, anti–*P. brasiliensis* antibodies may prove undetectable in some patients.[58,59] Eosinophilia and elevated IgE antibody titers have been detected in most patients.[146,192,219]

The association between human immunodeficiency virus (HIV) infection and paracoccidioidomycosis was reviewed.[11] The youngest patient described was a 15-year-old boy who had enlargement of superficial and mediastinal lymph nodes, skin nodules, and pulmonary infiltrates.[47] The mycosis also was diagnosed occasionally in other patients whose immune function was depressed by certain conditions or medications.[115] Of interest, however, is that the incidence of this mycosis has not increased in HIV-infected patients, as would have been expected.[11] No report of paracoccidioidomycosis and HIV co-infection in children has been published so far.

In the chronic, progressive, adult form of paracoccidioidomycosis, signs and symptoms differ substantially from those found in children. Descriptions of the disease in adults are beyond the scope of this text but are referenced.[80,126,142,172,186]

DIAGNOSIS

The diagnosis of paracoccidioidomycosis frequently is established by the direct examination of the clinical sample and confirmed by culture or serologic tests. Specific diagnosis depends solely on laboratory confirmation. The recommended way of diagnosing this mycosis, in the mycology laboratory, is the direct microscopic observation of the characteristic *P. brasiliensis* in a drop of physiologic saline or potassium hydroxide test (Fig. 214–4).[102] Usually, the sources of clinical specimens are sputum, secretion, and scraps or debris from ulcerated skin and mucosal lesions, draining material from suppurating lymph nodes or abscesses, bronchioalveolar fluid, biopsy tissue, and the like. Bronchioalveolar, articular, cerebrospinal, or other fluids must be centrifuged before examination. Draining material from suppurating lymph nodes usually is rich in fungal cells with multiple buds. The large

The chest radiograph (**A**) shows mediastinal lymph node enlargement and mild bilateral infiltrates in the middle and lower fields. Osteolytic lesions of long bones: humerus (**B**) and tibia and fibula bilaterally (**C**).

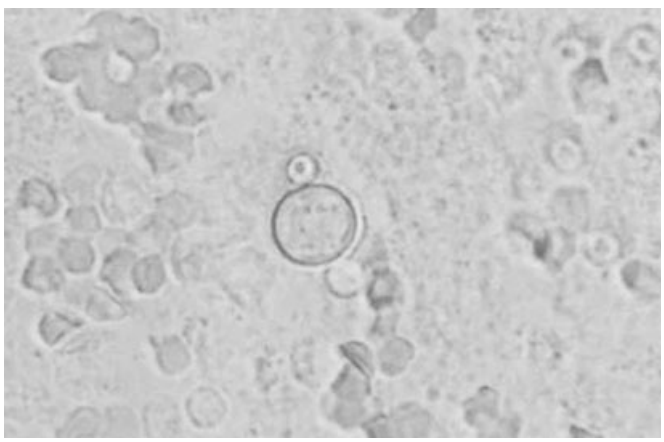

Figure 214–4 Direct examination of a potassium hydroxide mount of a patient's sputum specimen showing a budding *Paracoccidioides brasiliensis* yeast form–like cell.

cell, with multiple exosporulation, resembling a pilot's wheel, is pathognomonic of the disease. Sputum is one of the most important specimens used for diagnosis, and various procedures are used to improve the detection of the organism in this specimen. A cell block preparation method for sputum proved more sensitive (93%) than simple direct examination,[204] but few laboratories have employed it routinely. When the first examination of the sputum is negative, it can be homogenized with an equal volume of *N*-acetyl-L-cysteine and then centrifuged again. Four percent sodium hydroxide can be used, but only in direct examination because this treatment reduces the fungus isolation. The sensitivity of the direct examination (wet mount, smears, and histopathologic examination) varies from 80 to 100 percent or less and depends on the laboratory.[29,102] Biopsy samples should be taken only when routine direct examinations have failed, and the specimen should be placed in two separate flasks: one with sterile saline and the other with formalin for mycologic and histopathologic examinations, respectively. As the morphologic appearance of the parasitic forms of *P. brasiliensis* is pathognomonic, the diagnosis of the mycosis can be established by histopathologic examination of a biopsy specimen and confirmed by either culture or serology. If the parasite is abundant, it may be identified by hematoxylin and eosin stain and confirmed by a special fungal stain such as periodic acid–Schiff or Gomori methods.[102,133] Pereira and colleagues[161] established the diagnosis of 63 children with paracoccidioidomycosis by the identification of *P. brasiliensis* in lymph node biopsy (84%), bone biopsy (9%), or skin biopsy (7%) specimens.[158]

When the disease is chronic, most of the fungal cells are found inside the macrophages, but free yeast cells predominate in disseminated cases. Pauciparasitic forms of the *P. brasiliensis* granuloma that show a sarcoidic pattern with rare yeast forms may appear. In these cases, the diagnosis may rely on epidemiologic data plus serologic and molecular diagnostic tools such as PCR on paraffin-embedded tissue.[128,129] Visualization of the multiple budding yeast cells, in which the buds are connected to the parent cells by a narrow bridge with a well-defined refringent double wall, is mandatory because the *P. brasiliensis* yeast cells may range from a few microns to 30 to 40 μm. Sometimes, in the lesions, the parasite is present as diminutive yeast cells, measuring about 3 to 5 μm.[103] *P. brasiliensis* blastoconidia may be confused with *B. dermatitidis*, capsule-deficient *C. neoformans*, endospores and small *Coccidioides immitis* empty spherules, large *H. capsulatum* yeast cells,[29,103] or even *Pneumocystis carinii*.[194] For this reason, the multiple budding structures always should be found for specific diagnosis. In these cases, the molecular tests such as PCR and immunocytochemistry with specific polyclonal or monoclonal anti–*P. brasiliensis* antibody could be used.[40,184]

Disseminated and pulmonary paracoccidioidomycosis both can be confused with tuberculosis, histoplasmosis, leukemia, malignant neoplasms, or Hodgkin disease. When the skin or mucous membranes are affected, paracoccidioidomycosis must be differentiated from histoplasmosis, leishmaniasis, leprosy, syphilis, lupus erythematosus, and a variety of malignant neoplasms. In children, tuberculosis, acute abdominal syndrome, intestinal obstruction, osteomyelitis, and rheumatic fever also are important considerations in the differential diagnosis of this disorder.

Recently, several *P. brasiliensis* DNA sequences of potential diagnostic use have been reported, but few have been applied to clinical samples, needing further study before they are introduced in diagnosis. Until now, *P. brasiliensis* DNA sequences of potential diagnostic use are a species-specific 110-bp DNA fragment derived from the rat β-actin gene,[85] the 5.8S rRNA gene and its flanking internal transcribed spacer regions,[93,104,134] and the gp43 gene.[20,87] In addition, a species-specific 14-base DNA probe originating from the 28S ribosomal gene was used for in situ hybridization to detect *P. brasiliensis* in oral biopsy specimens from patients with paracoccidioidomycosis. However, this probe detected only 2 to 3 percent of the fungal cells present in the tissues; consequently, this technique exhibited low sensitivity for routine diagnostic purposes.[56,184] A PCR assay based on sequence of the gene coding for the gp43 antigen presented the highest sensitivity and specificity and gave a single band of 600 bp in sputum from a patient with chronic paracoccidioidomycosis. In addition, a PCR assay based on the 5′ nuclease assay using a fluorescent probe could detect at least 10 copies of this DNA sequence, providing sufficient accuracy to be useful for diagnosis of paracoccidioidomycosis.[188] Morais and colleagues[135] showed that some sequences of gp43 could undergo substitutions and need further testing to verify their universality and specificity for *P. brasiliensis*. Recently, the species-specific gp43 gene of *P. brasiliensis* was detected by loop-mediated isothermal amplification in DNA extracted from a paraffin-embedded tissue sample of paracoccidioidomycosis, suggesting that this method may achieve clinical application.[69] The primers reported by San Blas and colleagues[183] in 2005 produced positive identification bands, mainly in sputum samples; however, experiments with serum and blood samples were unsuccessful. Interestingly, the molecular test produced results that preceded, by 1 week or more, the information of classic tests as well as detected *P. brasiliensis* in a cerebrospinal fluid sample. Further experience will be necessary to include molecular tests in routine diagnosis.

Culture samples should be obtained to support the diagnosis and to establish the viability of the fungus. However, they are not always positive because the presence of other, more rapidly growing microorganisms in the samples renders isolation difficult. Culture methods, although essential for establishing the diagnosis in some cases, have limitations for rapid diagnosis, namely, insensitivity, need for invasive procedures, and delayed growth. At room temperature, *P. brasiliensis* is a slow-growing fungus that can be overgrown readily by bacteria, yeasts (especially *Candida*), and contaminant molds. Isolation should be attempted by the concomitant use of modified Sabouraud agar and yeast extract agar plus antibiotics and cycloheximide. In noncontaminated samples, the use of brain-heart infusion agar plus blood and antibiotics (without cycloheximide), a hemoglobin-containing agar incubated at 37° C, or both also is advisable. Cultures should be observed for 4 to 6 weeks, depending on temperature of incubation, with a definitive classification being accomplished only in the yeast phase.[29,103,142,172] The isolation rate of the fungus in culture varies from 80 to 100 percent but may be less in other nonspecialized centers.[29,102] As the mycelial form is not characteristic, subcultures in brain-heart infusion plus blood, Fava Netto's agar, or peptone–yeast extract–glucose agar, for up to 14 days at 35° C to 37° C, allow yeast conversion to occur and definitive diagnosis to be established.[102] Several sequences of *P. brasiliensis* DNA are of use in the identification of the fungus, as is the exoantigen test with specific antiserum, mainly for atypical isolates.[99] The 110-bp DNA fragment, a 14-base DNA probe, sense PbITS1s, and antisense PbITS3a have been used as a diagnostic marker for the identification and classification of different *P. brasiliensis* isolates.[85] Two primers, sense PbITS1s and antisense PbITS3a, were capable of identifying 29 strains of *P. brasiliensis* by means of a specific 418-bp fragment.[93] In addition, primers OL5 and OL3, specifically designed for 5.8S and 28S ribosomal DNA regions, were able to discriminate between *P. brasiliensis* and other human pathogenic fungi by PCR. OL5 was used in combination with primer ITS1 and OL3 with primer UNI-R in nested PCR and generated a 203-bp fragment present only in *P. brasiliensis*.[134] Universal fungal primers ITS1 and ITS4, directed to the conserved regions of ribosomal DNA, were found to be highly specific and could distinguish yeast-like organisms.[104] The species-specific gp43 gene of *P. brasiliensis* was detected by loop-mediated isothermal amplification in DNA from *P. brasiliensis* strains in 3 hours, suggesting that this method may be applied to rapid identification of this fungus.[69] Recently, the identity of the *P. brasiliensis* typical and atypical strains could be confirmed by its dimorphism, by the expression of gp43, and by PCR using specific primers for gp43 as well as ribosomal internal transcribed spacer regions.[26,51] However, an important note is that one sequence (483 bp) of the *Lacazia loboi* gp43-like gene had 85 percent identity at the nucleotide level and 75 percent identity with the deduced amino acid sequences of the *P. brasiliensis* gp43 protein.[215]

Patients with paracoccidioidomycosis not only have a polyclonal B cell activation but also produce large amounts of anti–*P. brasiliensis* antibodies, which are long-lasting and generally correlate with the severity of the disease.[7,13,22,108,219] Assessment of the serologic response has long been used in paracoccidioidomycosis. It has been used as a diagnostic tool mainly because, in a significant proportion of the patients, it is difficult to obtain clinical specimens for visualization or cultivation of the fungus when only deep-sited lesions are present. On some occasions, a serologic result is the first indication of the mycotic nature of the patient's illness. In recent years, a great interest has been generated in the development of techniques to improve paracoccidioidomycosis diagnosis. These developments have come in the fields of either antibody or antigen detection. Thus, serologic tests are of value for the diagnosis and may be useful in monitoring the evolution of the disease and its response to treatment. Antibodies are encountered in patients with clinical symptoms, and generally the titers of antibodies can be related to the severity of the disease. Patients with paracoccidioidomycosis have a polyclonal activation of the humoral system with high serum concentrations of specific IgA, IgG, and IgE isotypes.[7,19,22,108,129] However, antibodies usually are impaired or absent in some patients with severe juvenile forms and in immunocompromised individuals.[58,214] On occasion, titer fluctuations may result in values below the level of detection by current methods, which may result in false-negative results. Experience over the years has resulted in various highly sensitive and widely employed serologic tests; the frequency of positive test results in patients with paracoccidioidomycosis varies from 70 to 95 percent and may even reach 100 percent in particular cases, depending on the type of test used and the stage of the disease. Of note is that discrepancies between serologic tests performed in different laboratories represent a problem because of the variation in reagents used, laboratory procedures adopted, and varying criteria used for evaluation of the results obtained. Some of the most critical reasons for discrepancies are variations in the type of antigenic preparations, different strains, and, indeed, the mycelial or yeast cell phase chosen. Culture filtrates, cytoplasmic extracts, and antigens derived from the cell wall have been used as reagents in serologic tests for

paracoccidioidomycosis, although culture filtrates are used in most laboratories.[17,59,94,128]

Various fractions that have been cloned, sequenced, and applied to the diagnosis include HSP60,[53] gp43,[208] 29-kd,[161] and 27-kd fractions[50] as well as the combinations of the previously described 27-kd recombinant antigen and the 87-kd heat shock protein.[63] The main diagnostic antigen of paracoccidioidomycosis is the 43-kd glycoprotein[162] because 100 percent of these patients' sera display antibodies against it, depending on the test.[40,82] This fraction has been extensively and successfully employed as an antigen in establishing the serologic diagnosis of paracoccidioidomycosis.

Many serologic tests have been developed and extensively studied. Agar gel immunodiffusion, complement fixation, and counterimmunoelectrophoresis tests have been employed extensively.[129] Complement fixation tends to be used less often because it is a difficult and time-consuming technique. Also available are indirect immunofluorescence, indirect hemagglutination, enzyme-linked immunosorbent assay (ELISA), and dot-blot immunobinding and immunoblotting.[129,201] Some of the newer tests have employed purified antigens, such as glycoprotein 43, which are well characterized and more specific.[208] Immunodiffusion and counterimmunoelectrophoresis, which employ crude antigens derived from the yeast phase, can detect 90 percent or more of active cases.[59] Most authorities recommend the use of two different tests because none of these tests guarantees more than 90 percent sensitivity when it is employed alone. Immunodiffusion, for instance, is very simple and specific. Three precipitin bands, two of which are specific for *P. brasiliensis*, have been identified.[19,34]

A conjoint effort of several diagnostic centers assessing the value of this test with use of a reference crude antigen (Ag7) demonstrated it to be 84.3 percent sensitive and 98.9 percent specific[213]; but 15 percent represented false-negative results and constituted a failure of this diagnostic test, or they may be related to the production of low-avidity IgG2 antibodies directed against carbohydrate epitopes.[144] Patients with very localized, benign disease may present negative results in these tests, but with more sensitive techniques (e.g., immunoblotting or gp43-ELISA), a diagnosis usually is reached. In our laboratory, three tests (immunodiffusion, counterimmunoelectrophoresis, immunoblotting) are used in a routine serologic diagnosis. The sensitivities of these tests were 85.3 percent, 92.9 percent, and 100.0 percent, respectively, evaluated against 120 paracoccidioidomycosis sera. Limitations of these tests include cross-reactivity to other mycotic disorders, especially histoplasmosis and *Lacazia loboi* antigens, mainly in more sensitive tests,[162] and difficulties in standardization of the various tests and reagents.[39] The gp43 cross-reactivities were predominantly attributed to periodate-sensitive carbohydrate epitopes containing galactosyl.[162]

The value of serologic tests in the follow-up of patients undergoing treatment also has been addressed by several centers. The value of these tests in monitoring patients also is problematic, partly because of the diversity and complexity of the humoral response in patients with paracoccidioidomycosis. Serial serologic evaluations, usually done 3 months apart, together with the clinical, mycologic, and radiologic surveys can guide the treatment schedule, and two negative results in two of the serologic tests routinely employed is an additional criterion that helps in the difficult decision of therapy discontinuation.[173] The immunodiffusion, complement fixation, counterimmunoelectrophoresis, and ELISA tests were shown to be able to document the decline in antibody levels that parallels the clinical improvement; serum antibodies are cleared 1 to 2 years after cessation of therapy, depending on the clinical form.[30,59,129] Conversely, in these circumstances, rising antibody levels mean a relapse. Nonetheless, a considerable number of patients maintain, sometimes all their lives, the so-called healing titers (i.e., the persistence of low serologic titers in the tests). This is seen more frequently in patients with the acute form or the chronic multifocal form of the disease.[59] The debate on the clinical relevance of this phenomenon—whether it represents the persistence of residual active lesions, thus predicting possible future relapses—is inconclusive. During treatment of paracoccidioidomycosis, an important consideration is to be able to establish cure or remission criteria. A significant fall in reactivity of anti-gp43 antibodies has been shown to correlate with clinical improvement. During relapses, the levels of specific antibodies rose, and some patients considered cured exhibited a residual reactivity. Some patients have a negative immunodiffusion and counterimmunoelectrophoresis test result but a residual reactivity with gp43 and gp70 by immunoblotting.[29,59,67,129,142,172]

On the other hand, gp43 and gp70 can be detected in the biologic fluids. Furthermore, several studies have shown that the detection of antigens in blood and urine instead of antibodies is a potent means of establishing a diagnosis, monitoring treatment, and maintaining cure control.[88,111,112,129,213] They allow a more precise diagnosis to be established for patients with disseminated childhood and adult multifocal disease, in which antibodies are undetectable because of their coupling to excess antigen or their incapacity to raise antibodies. Antigenemia follow-up studies permit a more precise determination of improvement as antigen load decreases with treatment response. The detection of circulating antigen may represent a more practical approach to the early and rapid diagnosis of the disease. It also will be very helpful in establishing the diagnosis of immunocompromised patients, especially those with acquired immunodeficiency syndrome (AIDS), in whom searching for an antibody response is not a completely reliable diagnostic tool.

The skin test with paracoccidioidin is not considered a diagnostic test because 30 to 50 percent of the patients prove nonreactive when they are tested initially.[19,22,80,85] Conversely, a positive skin test result indicates previous contact with the fungus but not necessarily active disease. When histoplasmin skin test material is used, cross-reactions have been verified.[19,32,80,85] When the result of the skin test with paracoccidioidin is negative and the patient is treated, the skin test result may become positive, in which case the patient's prognosis is considered good.[29,142]

TREATMENT

The treatment of paracoccidioidomycosis usually is divided into two phases: attack and maintenance. Two different drugs can be used for each phase, or the same drug can be used for the two phases but at different dosages. Among the reasons for this two-phase prolonged treatment are the chronic progressive nature of the disease and the knowledge that all currently available drugs, albeit with apparently different efficacies, are only fungistatic. Thus, an adequate humoral and cellular immune response is required to control the mycosis. Cellular immunity, however, may be impaired in a large number of patients because of malnutrition or the disease process itself.[8,15,137] Provision of supportive therapy, therefore, is imperative. Rest, adequate nutrition, correction of anemia, and treatment of other concomitant infections are essential.[127] Paracoccidioidomycosis is the only fungal disease that can be treated successfully with sulfa drugs. Until 1958, when amphotericin B was introduced, no other treatment was available. In children, sulfadiazine can be provided orally at daily doses of 60 to 100 mg/kg divided into four to six equal parts; in adults, a maximum daily dose of 6 g can be used. Water intake and urine alkalinization (usually by bicarbonated water intake) should be encouraged during therapy to prevent crystalluria and tubular deposits of sulfadiazine.[127,191] Duration of the attack treat-

ment is dictated by the patient's response after clinical and serologic improvement has been attained; in general, in the chronic form, 2 to 6 months are required. A slow-acting sulfa drug (sulfamethoxypyridazine or sulfadimethoxine) can be provided as maintenance treatment, at a maximum daily dosage of 1 g.

In children, the precise total duration of therapy varies according to the severity of the disease, and it should also be dictated by the clinical and serologic responses of the patient to treatment. The importance of continuous treatment must be emphasized because relapses occur if the drug is not taken regularly. Moreover, if the drug is interrupted prematurely, the patient's isolate may become resistant to sulfonamides.[127,166] Sulfonamides can be used by patients with mild or moderately severe disease. They also can be used for patients who have been treated initially with amphotericin B.[127] Brazilian physicians most often employ trimethoprim-sulfamethoxazole (80 mg of trimethoprim and 400 mg of sulfamethoxazole per tablet) given at a dose of two tablets and administered orally at 12-hour intervals with satisfactory results. This drug also is used in association with amphotericin B. Tolerability is good; myelotoxicity (leukopenia), the main side effect, can be monitored and controlled by folinic acid administration without modification of the therapeutic regimen. In general, children should be given half the dose given to adults.[8,127] A Brazilian consensus on paracoccidioidomycosis recommends 8 to 10 mg/kg of trimethoprim daily.[190] This combination has the advantage of permitting alternative parenteral administration whenever necessary. Serum concentrations of sulfonamides should be determined when this drug is used and should not be less than 50 μm/mL. Duration of the acute treatment with this drug varies in each case, but it usually lasts for 6 months. Maintenance treatment in these cases can be achieved by using half the dose of the attack treatment or by using a slow-acting sulfa. Development of resistance to trimethoprim-sulfamethoxazole has been documented in an adult patient with the subacute form.[90]

Amphotericin B is effective but should be reserved for severely disseminated cases.[15,127] It also can be used by patients who relapse during the course of or after treatment with a sulfonamide or any orally administered drug because gastrointestinal involvement may impair drug absorption in these cases. The effectiveness of therapy with azoles has curtailed the need for more aggressive regimens. Amphotericin B should be provided as described in other chapters of this book. More than one course of therapy may be required in some patients.

Some investigators have suggested the use of a combined amphotericin B–sulfonamide treatment. In adults, a total cumulative dose of amphotericin B of 1 to 2 g followed by sulfa drugs, given as indicated previously, usually is sufficient.[116] With this drug combination, clinical improvement can be achieved in approximately 75 percent of patients; approximately 10 percent do not respond as well, and the remainder die during treatment. Relapses may be expected in approximately 10 to 15 percent of optimally treated patients.[127] Data regarding effectiveness of the new amphotericin B lipid formulations in paracoccidioidomycosis are insufficient.[62]

The use of oral ketoconazole has improved greatly the prognosis of patients with the progressive forms of this disease.[60,64,110,116] A comparative study of ketoconazole with amphotericin B plus sulfonamides showed equivalent to better responses in the ketoconazole group.[116] Ketoconazole is not as toxic as amphotericin B and does not require parenteral administration. Adults have been treated with 200 to 400 mg once daily for periods of 6 to 12 months with no problems and have shown a lower relapse rate (10%).[127,172] However, other studies have indicated that patients may need 18 months or more of treatment to achieve good results.[59,64,110,116] The use of ketoconazole for treatment of childhood paracoccidioidomycosis has been reported recently, with good results.[147] However, the role of ketoconazole in treating this mycosis remains uncertain because relatively few children have been treated to date. The results available suggest that the drug is effective. Children may be treated with doses varying from 5 to 8 mg/kg/day, in accordance with the manufacturer's indications. Children treated with ketoconazole should be monitored for changes in liver enzymes.[116,126,142] In adults, liver toxicity and gonadal changes also should be evaluated, especially during prolonged therapy.[127]

Ketoconazole no longer is considered the therapy of choice because of its side effects and numerous drug interactions. When the new triazole derivatives for oral administration (itraconazole, fluconazole) became available, they were tested in patients with paracoccidioidomycosis.

Today, more experience has been gained with itraconazole.[127,141,147,158,172] This triazole is more potent and less toxic than ketoconazole and is equally effective as or even more effective than the parent compound. A good experience in treating children with disseminated histoplasmosis has been reported.[205] It is administered in 100-mg capsules that should be given with or shortly after a meal. One or two capsules, depending on the severity of the fungal process, taken daily for 6 months have been shown to be effective in reducing all active lesions. Most (98%) of the patients, including children and young adults, respond.[127,141] Post-therapy observations indicate variable proportions (ranging from 2.1% to 21%) of relapses, depending on the severity of the disease, duration of therapy, and time of follow-up.[114,206] Side effects have been few and include transient elevation of hepatic enzymes.[127,141,142,206] At present, several well-conducted (but noncomparative) trials have been reported favoring this new triazole, which has become the first choice for the treatment of paracoccidioidomycosis in many reference centers. As for ketoconazole, the experience in treating childhood paracoccidioidomycosis with itraconazole still is limited compared with that with amphotericin B and trimethoprim-sulfamethoxazole, but the few reports are encouraging.[147,158] A randomized trial with sulfadiazine, ketoconazole, and itraconazole for the treatment of adult patients with disease of moderate severity failed to show higher efficacy of a particular regimen over the others.[191] However, long-term follow-up was not evaluated in this study. Itraconazole maintenance therapy is recommended at a dose of 5 to 10 mg/kg daily, with a maximum dosage of 200 mg twice daily. A liquid formulation of itraconazole in cyclodextrin was suggested initially as a promising alternative for treatment of children, but it has not been marketed in countries where the disease is endemic, and thus far no clinical experience could be gathered to support its recommendation.

Fluconazole is not as effective in this disorder; higher doses, up to 600 mg/day, and longer treatment periods are required. Recrudescence and relapse of disease occur more frequently than when itraconazole is used.[15,127,142] Fluconazole may be useful in severely ill patients who must be treated intravenously.[127] No experience in children is available. The literature has only one report of the successful use of terbinafine in an adult patient.[150]

Many questions remain to be answered about optimal treatment of paracoccidioidomycosis. The role of adjunct therapy with immunomodulators, such as cytokines, for cases refractory to conventional therapy remains to be investigated. α-Glucan obtained from *Saccharomyces cerevisiae* has been investigated.[125] The clinical and laboratory criteria that allow the transition from the attack to the maintenance treatment phase have not been standardized, nor have the parameters that could be used to end treatment with the assurance that the patient is cured. Progressive decrease in the titers of the serologic tests currently available is one of the laboratory parameters used most frequently; restoration of some cellular immunity responses, such as reactivity to the paracoccidioidin skin test, also is used. Newer methods (e.g.,

antigenemia detection and molecular biology approaches) are being standardized.[68,87,88,93,111,112,138] Tests for detection of antigenemia in serum have been developed in some centers and showed good efficacy in the follow-up of patients, but it has not yet become widely available.[88,111,112] Meanwhile, most specialists agree that treatment decisions need to be tailored according to the patient.

PROGNOSIS

Paracoccidioidomycosis is considered to be progressive in most cases and fatal if it is left untreated. However, residual lesions have been observed in a few patients with no known history of active mycotic infection.[79,84,126] Prognosis depends on the status of the patient at the time of diagnosis. Children and young adults in whom fungemia has taken place and who have multiple-organ involvement do not respond well to therapy. In less disseminated cases, the response to treatment depends on the severity of disease at the time of diagnosis. The fatality rate in young patients at one time was reported to be 31 percent,[45] but it now is much lower as a result of earlier diagnoses and better treatments. Nonetheless, it remains a life-threatening disease, with a rate of 9.5 to 13 percent fatalities in the most recent series. This rate was attributed to delayed diagnosis or searching for medical assistance, irregular treatment, or treatment not monitored. Abdominal complications, specially ascites, and malnutrition were associated with the lethal prognosis.[8,147,158] In the adult group, patients have a greater chance of survival because of the usually less severely disseminated nature of the chronic form. Once specific treatment is instituted, lesions regress promptly; skin lesions may heal completely in 2 to 4 weeks.[118,127] Complete remission is possible in most patients with the acute-subacute and chronic forms of the disease. Prognosis has improved as a result of establishing the diagnosis earlier, new antifungal drugs that facilitated compliance, and better knowledge of the disease; the last of the three has provided better clinical and laboratory follow-up and the notion that the disease needs prolonged surveillance, as shown by the decrease in positive mycological test results during and after therapy.[127,142,206] Some investigators consider the term *cure* inappropriate because of the inability to confirm complete eradication of the organism; the term *apparent cure* should be used instead.[127]

Paracoccidioidomycosis persists as a disease with a low mortality rate but high morbidity. Complications vary, and like the prognosis, their occurrence depends on the extent of fungal invasion. In the juvenile form, early complications that may lead to surgical intervention are intestinal obstruction and jaundice, both of which result from enlarged mesenteric lymph nodes. Disabsorptive syndromes may be associated, aggravating the nutritional status of the patients.[12,193] Patients also may present with ascites or chylothorax. Lymph nodes may suppurate, and fistulas can develop. A late complication that has been described recently is abdominal malakoplakia.[178] In the adult form, acute complications of mucosal involvement are dysphagia and dysphonia, edema of the glottis, respiratory insufficiency, and Addison disease, among others. Sequelae are not seen as commonly in children as in adults. In general, fibrosis is the cause of serious problems in patients who respond to therapy. Despite the newer, very effective therapies, these sequelae preclude, in many cases, the complete restoration of the patients' previous health status.[126,127,141,142,172,206] In the acute-subacute group, scarring and fibrosis of the affected nodes and residual pulmonary fibrosis have been noted.[107] Malabsorption syndrome probably is the most serious sequela in the juvenile form because of the enteric loss of proteins and inflammatory cells that results in immunodeficiency and opportunistic infections.[12,193] In adults, the sequelae described most frequently are microstomia, laryngeal stenosis leading to permanent tracheostomy, adrenal insufficiency, pulmonary fibrosis, dysphonia, and emphysema.[133,211,217]

Acknowledgments

We would like to deeply acknowledge Prof. Angela Restrepo for her invaluable contribution to this version of the chapter, and Drs. Maria Gorete Nogueira and Ricardo Pereira for their comments and sharing unpublished material.

CHAPTER 215

Cryptococcosis

Ana Moran ❂ Jerry L. Shenep ❂ Richard J. Hamill

Cryptococcosis is a life-threatening systemic fungal infection caused by the basidiomycetous yeast *Cryptococcus neoformans*. Historically, the disease has been referred to as *torulosis*, *European blastomycosis*, and *Busse-Buschke disease*. The organism and the disease that it causes were discovered independently more than a century ago. In 1894, Busse, a German pathologist, found the yeast in the tibial lesion of a 31-year-old woman who later died of systemic infection under the medical care of Buschke, her physician. Meanwhile, in 1895, Sanfelice, an Italian, had cultured for the first time the encapsulated yeast *Saccharomyces* (later *Cryptococcus*) *neoformans* from peach juice, suggesting that this organism is not an obligate human pathogen. Sanfelice pointed out the similarity between the isolates from Busse's case and the yeast from the peach juice. The first case in which *C. neoformans* was recognized as the cause of meningitis was reported in 1914 by Verse; in 1916, Stoddard and Cutler described the central nervous system (CNS) pathology of the organism.

Cryptococcosis involves predominantly the CNS, lungs, skin, and bones, but other organs also have been affected. Although most cases occur in immunocompromised patients, the systemic disease also may occur in seemingly immunocompetent individuals.

ORGANISM

Of the 19 species of *Cryptococcus*, *C. neoformans* causes almost all cryptococcal infections. Only rarely do other species of *Cryptococcus*, such as *Cryptococcus laurentii*[33] or *Cryptococcus albidus*,[14] cause disease. *C. neoformans* originally was thought to include two varieties: var. *neoformans* and var. *gattii*. *C. neoformans* var. *gattii* has been recognized more recently, however, as a separate species, *Cryptococcus gattii*.[35]

C. neoformans is an encapsulated, basidiomycetous yeast, measuring 4 to 10 μm in diameter. Based on capsular agglutination reactions, the five serotypes of *C. neoformans* are A, B, C, D, and AD hybrid.[38] Molecular studies and genome sequences have detected significant genetic variability between serotypes A and D, and more recently, serotype A has been distinguished as a new variety, var. *grubii*.[24] Currently, the organism is classified into two varieties: *C. neoformans* var. *neoformans* (serotype D) and var. *grubii* (serotype A), and *C. gattii* (serotypes B and C).

C. neoformans has two forms of life cycle: asexual and sexual. In the asexual stage, it replicates by budding, and haploid unicellular yeasts are recovered from the environment and human infections. In the sexual cycle, the organism has two mating types,

"alpha" and "a," which, when placed in contact, undergo conjugation. The end product is a basidia form that undergoes meiosis and produces basidiospores, thought to be infectious propagules that can convert to a yeast form when located in the lungs.[38]

A feature of all *C. neoformans* strains is the mucopolysaccharide capsule surrounding the cell wall. This capsule may vary in size from twice the diameter of the yeast to a barely detectable thickness. The presence of this capsule may be recognized with the use of a mucicarmine stain or with negative staining using India ink. The Fontana-Masson stain detects melanin precursors and is useful in identifying *C. neoformans* in fixed tissues.[48]

C. neoformans forms smooth, mucoid colonies on solid media. Initially cream-colored, the colonies become dry and tan, pinkish, or yellow with aging. The fungus produces urease, is nonfermentative, and uses several carbohydrates. Species of the genus are separated with carbohydrate assimilation tests and potassium nitrate. The organism grows at 37° C, is lactose-negative, and does not produce pseudomycelia on cornmeal agar. It does not grow well at room temperature (25° C). *C. neoformans* serotypes can be identified by growth on agar containing canavanine, glycine, and thymol-blue indicator, which serves to differentiate serotypes B and C from A and D. Changes in color occur with serotypes B and C, but not with serotypes A and D.[42] Antibodies that distinguish differences in capsular structures are commercially available now. Serotypes also can be identified on the basis of DNA sequence polymorphisms detected by polymerase chain reaction (PCR) fingerprinting, amplified fragment length polymorphism, restriction fragment length polymorphism, and multilocus sequence typing analysis.[38]

EPIDEMIOLOGY

Cryptococcosis occurs worldwide as a sporadic infection but not in epidemics. It is found in soil, especially in sites enriched with avian guano. Serotypes A, D, and AD of *C. neoformans* are found worldwide and usually associated with pigeon excreta, whereas serotypes B and C more often are located in tropical and subtropical countries and have not been isolated from bird guano. Serotype B has been found in the environment of the river red gum tree (*Eucalyptus camaldulensis*).[20] Naturally acquired infections occur in domestic animals, such as cats, dogs, cattle, pigs, rabbits, sheep, and horses, but neither animal-to-human nor human-to-human infections have been reported.[10] The clinical presentation of cryptococcosis in animals differs from disease in humans.[10] Subclinical infection and nasal colonization are known to occur in cats and dogs.[17]

Limited serologic data indicate that most children and adults have had subclinical or mild cryptococcal infection, possibly manifested as a brief respiratory illness with cough.[35] *Cryptococcus* can be found transiently as part of the flora, and isolation from the flora does not indicate disease. Clinical cryptococcal infections occur sporadically and usually are self-limited in immunocompetent individuals.

The initial cryptococcal infection is acquired by inhalation of the yeast into the lungs from an environmental source, such as soil contaminated with avian guano[10] (*C. neoformans* var. *neoformans* and var. *grubii*) or eucalyptus trees and decaying wood (*C. gattii*).[9] In avian nesting areas, the yeast has a minimal capsule and can be aerosolized more easily and inhaled to the level of the alveoli. Viable *Cryptococcus* has been isolated from dried soil particles measuring less than 2 μm in diameter.[51,58] These small particles become airborne easily and are capable of alveolar deposition. The organism can colonize the respiratory tract without producing any symptoms and can be cleared or enter a dormant stage. From the lungs, hematogenous dissemination may occur. Systemic infection may occur in otherwise normal individuals, but most cases of cryptococcosis occur in immunosuppressed individuals. Some underlying immunosuppressive conditions include leukemia, lymphoma, Hodgkin disease, systemic lupus erythematosus, corticosteroid therapy, sarcoidosis, organ transplantation, diabetes mellitus, congenital immunodeficiency disorders, idiopathic $CD4^+$ T-lymphocytopenia, and human immunodeficiency virus (HIV) infection.[10,18,29,43] The acquired immunodeficiency syndrome (AIDS) epidemic has become a major factor in the increased prevalence of cryptococcosis since 1980.[16] Cryptococcosis occurs in an estimated 8 percent of patients with AIDS in the United States.[43] For reasons that are not understood, almost all cryptococcal infections in AIDS patients are caused by *C. neoformans* var. *neoformans*, even in areas where *C. neoformans* var. *gattii* is environmentally prevalent.[34,60]

An active, population-based surveillance from 1992 to 2000 in two U.S. cities showed the incidence of cryptococcosis to decrease from 5 cases per 100,000 population in 1993 to 1.3 cases per 100,000 population in 2000.[14] Of 1491 cases, 89 percent occurred in patients known to be HIV-infected. Only 10 of the patients with cryptococcosis were younger than 16 years old.[29,43] Cryptococcal infections occur much less frequently in children than in adults. It primarily affects HIV-infected children aged 6 to 12 years old, in whom the reported prevalence is 0.5 to 1 percent,[1,27,69] and most frequently in children whose $CD4^+$ cell counts indicate profound immunosuppression.[1,27,28] Surveillance studies in children show a 0.85 to 1 percent frequency of cryptococcal infection in HIV-infected children.[27,37] The reasons for the disparity in the frequency of cryptococcal disease between the adult and the pediatric population are unknown. Some researchers have postulated that the difference might be explained by the lack of exposure to *C. neoformans*.[13] The lower frequency of cryptococcal disease among children compared with adults seems unlikely to reflect differences in exposure because serologic surveillance performed in one U.S. city showed a 70 percent seroprevalence among children 15 years or younger.[2]

PATHOPHYSIOLOGY

Considerable evidence suggests that *C. neoformans* becomes airborne from soil or dried pigeon excreta. These organisms, or fomites, usually measure less than 2 μm in diameter and are of a size that easily can reach the lung parenchyma through the airways of the lower respiratory tract.[23] After being inhaled, the yeast may colonize the host respiratory tract without producing any disease. Infection typically is asymptomatic, and it can either be cleared or enter a dormant, latent form.[53] Impaired cell-mediated immunity of the host, virulence of the strain, and size of the inoculum are the major determinants in the infection and progression to disease. When host immunity is compromised, the dormant form can reactivate and disseminate hematogenously to cause systemic infection.[38,53] Early lesions are characterized by collections of encapsulated yeasts surrounded by a gelatinous-like material.

Four basic patterns of reaction are seen in the lung: (1) one or more peripheral granulomas, (2) granulomatous pneumonia with intra-alveolar organisms and varying degrees of inflammatory response, (3) diffuse invasion of organisms within alveolar capillaries and interstitial tissues with little or no inflammation, and (4) massive intra-alveolar and intravascular organisms.[26] The lesions of the brain and meninges are cystlike, especially in the cerebral cortex. They represent masses of yeast forms, and little inflammatory reaction, in which macrophages predominate, and *C. neoformans* may be found in the cytoplasm of these cells. Granulomatous lesions are uncommon findings in the brain. The meninges may be thickened with the gelatinous polysaccharide of the yeast capsule.[53] Bone lesions are found in approximately 5 percent of cases of disseminated cryptococcosis. Acute and

chronic inflammation is seen and often is associated with giant cells and granulomata.[3]

The variety of *C. neoformans* may be a factor in the pathology of the infection. Some studies show that infection with *C. gattii* (serotypes B and C) more often is associated with immunocompetent individuals with cerebral mass lesions (with or without hydrocephalus) and pulmonary lesions than is infection with *C. neoformans* var. *neoformans*. The histopathologic features are indistinguishable, however.[44]

The most important virulence factors of *C. neoformans* are polysaccharide capsule, production of melanin, and growth at 37° C. The extracellular polysaccharide capsule is composed of glucuronoxylomannan and galactosylomannan, and has been shown to interfere with various immunologic functions.[8,12] *C. neoformans* sheds capsular polysaccharide into tissue during infection, interfering with local neutrophil migration, cytokine production, and phagocytosis; systemically, polysaccharide shedding elicits decreased antibody responses.[53] *C. neoformans* also synthesizes melanin, which is produced in human tissues during infection and contributes to virulence by protecting the organism from oxidative antifungal mechanisms of host immune effector cells and may down-regulate T-cell response.[30]

Studies in rats show that *C. neoformans* penetrates the lung parenchyma shortly (2 hours) after infection occurs, and that control of infection and decreased fungal burden are temporarily associated with a granulomatous tissue reaction.[53] The cryptococcal capsule inhibits phagocytosis,[32] which is the main defense against the organism. Monoclonal antibodies to the capsular polysaccharide are protective against experimental infection in mice, confirming the importance of the capsule in the pathogenesis of *C. neoformans* infection.[47] The high susceptibility of athymic (nude) mice and T cell–depleted mice to *C. neoformans* is consistent with the importance of cell-mediated immunity in the defense against *C. neoformans* infection. In contrast, when normal mice are challenged with *C. neoformans*, the infection is limited by $CD4^+$ and $CD8^+$ T cells.[45]

More recent evidence indicates that *C. neoformans* is killed primarily by $CD4^+$ T cells via the effector molecule granulysin.[72] In the presence of antibody and complement, *C. neoformans* is ingested by phagocytes. With production of polysaccharide within the phagocyte, however, the yeast can survive as a facultative intracellular pathogen.[21] *C. neoformans* can transform in vivo to a more pathogenic mucoid phenotype, which may be responsible for some cases of reactivation of disease in immunocompromised hosts.[25] Despite persistent infection of pulmonary macrophages in experimental mice, a vigorous immune response to secondary challenge shows that cell-mediated immunity is not impaired systemically during persistent infection.[39]

In humans, containment of the infection in the lung is associated with the formation of a granulomatous subpleural nodule.[5] Macrophages are considered the main effector cells against *C. neoformans*. They ingest and kill the organism and produce proinflammatory cytokines, such as interleukin-12. T cells contribute as well with a T-helper (T_H1)–polarized response that activates macrophages.[53] Humoral immunity also may play a role because specific antibodies can provide opsonins for promoting efficient phagocytosis, enhancing natural killer cell function, and clearing capsular polysaccharide.[71]

At a molecular level, the enzyme inositol phosphosphingophospholipase C is crucial to the yeast's resistance to pulmonary macrophages.[65] Production of melanin by *C. neoformans* also is protective against host immune defense mechanisms.[11] Glycosphingolipid glucosylceramide is essential for the growth of *C. neoformans* in alveolar spaces and in the bloodstream.[61]

A key pathogenic feature of *C. neoformans* is its ability to grow at 37° C. The disaccharide trehalose is a stress protectant, and the trehalose synthesis pathway is essential to permissive growth at body temperature.[54] Because this pathway also is important to the pathogenicity of *C. neoformans* in homeotherms, it is thought to have a role beyond protection from temperature stress.

The genome of *C. neoformans* was sequenced more recently.[41] This information, coupled with new insight into the life cycle of the pathogen,[38] should lead to advances in understanding of the pathogenesis of cryptococcosis.

CLINICAL MANIFESTATIONS

Two primary sites of infection by *C. neoformans* are the lungs and the CNS. In HIV-negative patients infected with *C. neoformans*, 36 percent of infections affect the lung only, and 51 percent of infections have CNS involvement.[52] In HIV-infected patients, CNS and extrapulmonary infection are more frequent.[53] In a pediatric systemic fungal infection surveillance conducted in Houston, Texas, nine cases of cryptococcosis were identified over the course of 9 years. Three children presented with meningitis: two with cutaneous disease, two with overwhelming fungemia, one with gastroenteritis, and one with pulmonary involvement (Table 215–1) (R. J. Hamill et al., 2002, data not published).

Bone and joint involvement occur in 5 percent or more of cases of extrapulmonary cryptococcosis. Acute and chronic inflammation occurs, often associated with giant cells and granulomata; sarcoidosis frequently is an underlying condition.[6,53] Other sites of dissemination include skin, eye, urinary tract, adrenal, liver, lymph nodes, sinuses, gastrointestinal tract, breasts, and the female reproductive system.

PULMONARY INVOLVEMENT

Although the lung is the most common portal of entry for infection, pulmonary cryptococcosis is uncommon in children.[69] One third of pulmonary infections are asymptomatic. Approximately half of patients have cough or chest pain, however, and smaller percentages have sputum production (32%), weight loss (26%), fever (26%), and hemoptysis (18%).[50] In immunocompromised hosts, the onset may be more severe, and the course more rapid.[53] Radiographic lesions in non-immunosuppressed hosts include well-defined, noncalcified, single or multiple nodules, masslike infiltrates, hilar lymphadenopathy, pleural effusions, and lung cavitations.[53,73] In immunosuppressed hosts, radiographic findings include alveolar and interstitial infiltrates as well.[53] A comprehensive review of pediatric pulmonary cryptococcosis revealed that most affected children were immunocompromised, and almost half of them were asymptomatic. Chest radiographs showed a lower lobe nodular pattern in most cases.[69]

CENTRAL NERVOUS SYSTEM INVOLVEMENT

Meningitis occurs in more than half of cryptococcal infections affecting HIV-infected children.[27,37] Headache and fever are the most common symptoms. Nausea and vomiting occur in half of cases. Stiff neck is seen in 75 percent of patients who are not immunocompromised and in 33 percent of patients with AIDS. Other, less frequent, manifestations include alteration of consciousness, impaired mental function, cranial nerve lesions, visual deficits, papilledema, seizures, diplopia, focal neurologic deficits, photophobia, and abnormal cerebellar signs.[1,28,53] The duration of symptoms before a diagnosis is established ranges from less than 1 week to 18 months and tends to be shorter in patients with AIDS.

TABLE 215–1 Clinical Manifestations of Cryptococcal Infections in Children

Age	Comorbid Condition	Clinical Presentation	Treatment	Outcome	Reference
14 yr	AIDS ($CD4^+$ = 3/μL)	Meningitis	AMB, then FLU	Survived, residual blindness	*
6 yr	Acute lymphocytic leukemia	Cutaneous	LAMB + 5-FC, then FLU	Resolved	*
3 yr	Unknown	Cutaneous	Unknown	Survived	*
18 yr	Neurocysticercosis, ventriculoperitoneal shunt	Meningitis, peritoneal pseudocyst	FLU, shunt removal	Survived	*
4 yr	Unknown	Disseminated	Unknown	Unknown	*
9 yr	AIDS	Disseminated	FLU	Died	*
13 yr	AIDS, hemophilia	Meningitis	FLU	Survived	*
15 yr	Tuberculosis	Pulmonary	None	Survived	*
16 yr	None	Pulmonary	AMB, then FLU	Survived	47
11-16 yr	AIDS ($CD4^+$ = 15/μL)	Pulmonary (1), disseminated (3)	AMB + 5-FC, then FLU	All survived	22
5 mo-16 yr	HIV ($CD4^+$ = 0-386/μL, median 54/μL)	Meningitis, disseminated, pulmonary	None, AMB, AMB + 5-FC, then FLU	Died (23%)	1
5 mo-12 yr	HIV ($CD4^+$ count not done)	Disseminated	AMB (8/15 patients received treatment)	Died (46%)	23
13 yr	Systemic lupus erythematosus	Meningitis	AMB + FLU	Survived	31
3-17 yr	Acute lymphoblastic leukemia	Meningitis (5), cutaneous (2), disseminated (2)	AMB + 5-FC, then FLU	All survived	28

**R. J. Hamill et al.: 2002, data not published.*
AIDS, acquired immunodeficiency syndrome; AMB, amphotericin B; 5-FC, flucytosine; FLU, fluconazole; HIV, human immunodeficiency virus; LAMB, liposomal amphotericin B.

Figure 215–1 Purpuric and papular skin lesions in a 3-year-old boy who presented with acute lymphoblastic leukemia and disseminated cryptococcosis. (See companion Expert Consult web site for color version.)

CUTANEOUS LESIONS

Various skin lesions caused by *C. neoformans*, including ulcers,[70] nodules,[36] vesicles, abscesses, papules, cellulitis, acneiform plaques, and purpuric and sinus tracts, have been described (Fig. 215–1; see Fig. 64–24). Skin lesions usually represent metastases to the skin of a disseminated infection and are difficult to diagnose clinically, given the multiple presentations. Histologic examination and culture are essential to identify specifically the cryptococcal skin lesion.

EXTRAPULMONARY CRYPTOCOCCOSIS IN IMMUNOCOMPROMISED INFANTS AND CHILDREN

The extent of knowledge about cryptococcosis in infants and children is reflected by reports and reviews.[36,37] From 1966 to 1997, only 22 immunosuppressed children without AIDS and 30 children with AIDS and extrapulmonary cryptococcosis were reported. Aspects of these cases are summarized in Table 215–1.

DIAGNOSIS

The diagnosis is established by showing *C. neoformans* during the disease state. *C. neoformans* may be shown by direct examination of clinical specimens from cerebrospinal fluid (CSF), urine, sputum, bronchoalveolar lavage fluid, or aspirates of skin lesions using India ink preparations, Gram staining of smears of cytocentrifugated specimens, or mucicarmine and Masson-Fontana silver stains, which distinctively show the cell wall and the capsule of the organism; by histologic examination; by isolation in culture; and by the detection of cryptococcal antigen. During cryptococcal meningitis, the India ink CSF preparation reveals the yeast in 80 percent of cases in patients with AIDS and 50 percent of cases in patients not infected with AIDS[53]; the culture yields the organism in 87 to 100 percent, and the cryptococcal antigen test is positive in 83 to 100 percent of cases. The leukocyte count of the CSF may be normal or increased to low levels, rarely exceeding 100 cells/mm^3, and the glucose is less than 50 mg/dL in 65 to 75 percent of patients.[62]

C. neoformans can be isolated in most routine mycologic or bacteriologic media, especially chocolate agar, 3 to 7 days after being inoculated into the media.[53] Sabouraud agar and Niger seed agar medium can be used, and cultures are maintained at 30° C to 32° C (not 37° C or 25° C). The sediment from centrifuged CSF or urine specimens is spread on several plates or slants.

Alternatively, 2 to 5 mL of CSF can be inoculated into Sabouraud broth and incubated on a shaker. Cycloheximide should not be used because it may inhibit the growth of *C. neoformans*. Blood can be cultured using the automated and the lysis-centrifugation procedure (Isolator tube; Dupont, Wilmington, DE). Although blood cultures may become positive within 3 days, they should be held for 3 to 4 weeks before being considered sterile.

Detection of cryptococcal antigen by latex agglutination and enzyme immunoassay in CSF, serum, and urine offers a highly sensitive and specific diagnostic tool. Latex agglutination uses hyperimmune rabbit immunoglobulin anti–*C. neoformans* antibodies bound to latex particles. Titers of 1:4 and greater suggest cryptococcal infection. Commercial kits detect 10 ng of cryptococcal antigen and have a sensitivity rate of approximately 95 percent in experienced hands. Enzyme immunoassays use monoclonal or polyclonal antibody to detect antigen. Close agreement between latex agglutination and enzyme immunoassays has been shown.[22] There are very few false-positive results, such as the cross-reactive polysaccharide of *Trichosporon asahii* (*beigelii*) or IgM antibody complexes (i.e., rheumatoid factor). False-negative results also are unusual and may be caused by low titers, early infection, presence of immune complexes, prozone effect of high titers, or "unencapsulated" strains with low production of polysaccharide.[53]

Despite the good diagnostic utility of the cryptococcal antigen tests for screening febrile, high-risk patients, such as patients with HIV infection, they are not recommended as treatment response indicators. High titers (≥1:1024) generally reflect, however, high burden of yeasts, a poor host immune response, and a greater likelihood of therapeutic failure.[53]

TREATMENT

Three factors must be considered in guiding the treatment of cryptococcosis: (1) the degree of immunosuppression, (2) extent of infection (pulmonary or extrapulmonary with and without neural involvement), and (3) choice of drugs. Untreated, cryptococcal infection in immunosuppressed patients is uniformly fatal. Controlled studies of treatment for cryptococcal disease in pediatric populations are scarce, and most of the recommendations are obtained from the adult literature.[46,63] Several antifungal agents with therapeutic efficacy are available and include amphotericin B or one of its lipid-associated formulations, flucytosine, fluconazole, and itraconazole. Other agents include voriconazole and posaconazole, although no in vitro or clinical studies have evaluated their use in children (Table 215–2).

Standardized methods for in vitro susceptibility testing are available. The clinical utility of in vitro susceptibility testing is not clearly defined, however. Detection of resistance in vitro seems to correlate with clinical resistance[3]; however, most reported cases are relapse isolates, rather than isolates associated with initial infection.[7,68]

TREATMENT OF CRYPTOCOCCOSIS IN IMMUNOCOMPETENT HOSTS

Pulmonary and Non–Central Nervous System Disease

Some patients with normal immunocompetence and cryptococcosis of limited extent and nonprogressive disease may recover without receiving treatment. Pulmonary cryptococcal infection may resolve without treatment in immunocompetent hosts, and observation has been suggested as a reasonable course of management.[50] Given the potential for dissemination, the seriousness of CNS involvement, and the availability of effective and well-tolerated antifungal agents, however, this approach should be considered only when the patient can be followed closely and reliably.

In most infants and children, excluding extrapulmonary dissemination is difficult, and treatment is warranted. Performing a lumbar puncture is essential in all cases of pulmonary disease. Immunocompetent patients with asymptomatic and mild-to-moderate disease should be treated with fluconazole, 3 to 6 mg/kg/day for 3 to 6 months for asymptomatic disease or 6 to 12 months for mild-to-moderate disease. Itraconazole is an alternative drug for patients unable to take fluconazole (see Table 215–2). If oral azoles cannot be taken, or progression of the disease occurs, amphotericin B, 0.4 to 0.7 mg/kg/day, is recommended. Severe pulmonary disease is treated similar to CNS disease.

Central Nervous System Disease

For CNS disease, the combination of amphotericin B, 0.7 to 1 mg/kg/day, and flucytosine, 100 mg/kg/day, is used as induction therapy for 2 weeks, followed by fluconazole, 12 mg/kg/day, for a minimum of 10 weeks. Alternatively, the amphotericin B and flucytosine combination may be continued for 6 to 10 weeks. To avoid development of neutropenia, the dosage of flucytosine should be adjusted to achieve a serum level of 30 to 80 μg/mL, measured 2 hours after administration of the dose. The CSF should be examined after the first 2 weeks of therapy, at which time 60 to 90 percent of patients have sterile CSF. A positive culture at this point is an indication for extending the treatment course beyond the minimum recommendation. Fluconazole, 3 to 6 mg/kg/day, should be administered for a minimum of 10 weeks.[55,64]

Intraventricular and intrathecal amphotericin B may be needed for refractory cases. Lipid formulations of amphotericin B can be used in place of amphotericin B in patients with renal dysfunction, with similar therapeutic efficacy. Regardless of the initial regimen, some experts recommend a subsequent course of fluconazole, 3 to 6 mg/kg/day for 6 to 12 months. Treatment outcome is poor if CNS disease is not recognized and treated early.[4,19]

TABLE 215–2 Therapeutic Agents Available for Treatment of Cryptococcosis*

Drug	Dose	Route	Excretion	Major Side Effects
Amphotericin B	0.5-1.0 mg/kg/day	IV	Renal—40% over 7 days; biliary—minimal; dialysis—poorly dialyzable	Infusion-related reactions, hypokalemia, hypomagnesemia, renal impairment, renal tubular acidosis, anemia, thrombophlebitis
Flucytosine	100 mg/kg/day	PO	Renal—>90%	Nausea, vomiting, anemia, leukopenia, thrombocytopenia, hemorrhagic colitis, hepatotoxicity
Fluconazole	12 mg/kg/day	IV, PO	Renal—80%	Hepatotoxicity, nausea, headache, skin rash

**Other drugs with in vitro efficacy against C. neoformans include itraconazole, voriconazole, and posaconazole.*

TREATMENT OF CRYPTOCOCCOSIS IN IMMUNOCOMPROMISED HOSTS WITH ACQUIRED IMMUNODEFICIENCY SYNDROME

Cryptococcal Pneumonia

All HIV-infected patients with pulmonary cryptococcal infection must be treated because they are at high risk for developing disseminated infection. For children with mild-to-moderate disease, treatment with fluconazole alone is appropriate and should be followed by lifelong suppressive therapy. An alternative to fluconazole is itraconazole.[46] AIDS-infected patients responding with immune reconstitution after receiving effective highly active antiretroviral therapy (HAART) may not require lifelong maintenance therapy. For patients with severe pneumonia, amphotericin B should be used until the patient is asymptomatic, at which time fluconazole can be substituted for maintenance therapy. Patients with cancer and pulmonary cryptococcosis treated with fluconazole monotherapy generally had good outcomes.[31]

Cryptococcal Meningitis

For meningeal cryptococcosis, induction therapy consists of a combination of amphotericin B (0.7-1.0 mg/kg body weight/day) and flucytosine (25 mg/kg/dose four times daily) for a minimum of 2 weeks.[63] Induction is followed by consolidation treatment with fluconazole (12 mg/kg/daily) for a minimum of 10 weeks, or until CSF cultures are sterile.[59] Management principles of elevated intracranial pressure in children with cryptococcal meningitis are the same as for adults and include measurement of the CSF pressure and frequent therapeutic lumbar punctures or ventricular shunting for hydrocephalus and prolonged clinical or microbiologic failures.[63]

Because of the relapse rate of 50 percent, maintenance therapy is important after an acute episode of meningitis in HIV-infected individuals. Fluconazole given daily is the preferred drug for maintenance, but intravenous amphotericin B one to three times a week is a reasonable alternative, although this form of maintenance therapy may be complicated by bacterial infections related to vascular access.[57] Fluconazole has a more rapid clearance and shorter half-life in children than in adults; higher doses are recommended. Oral itraconazole or amphotericin B given one to three times weekly are alternative maintenance regimens. HIV-infected patients who are treated initially with fluconazole are at risk of relapse despite continued fluconazole.[7] Neurosurgical procedures may be required in severe cases to control cerebral edema. A ventricular shunt may be required to treat hydrocephalus.

The safety of discontinuation of secondary prophylaxis in children treated with HAART has not been studied extensively. Data from adult studies show that after successful treatment of cryptococcal meningitis, secondary prophylaxis can be discontinued in individuals who have a satisfactory response to HAART ($CD4^+$ cell count >100 to 200 cells/μL for at least 6 months).[49]

Immune reconstitution inflammatory syndrome has been described in adult and pediatric patients co-infected with HIV and *C. neoformans* who are treated with HAART.[59,66] Patients with *C. neoformans*–related immune reconstitution inflammatory syndrome present with higher CSF opening pressures, glucose levels, and cell counts.

PROGNOSIS

Based on the reports of extrapulmonary cryptococcosis in immunosuppressed infants and children, the prognosis for severe systemic cryptococcosis is reasonably good. Of the 13 children with AIDS and cryptococcosis,[37] 2 untreated patients died, and 10 of the 11 treated patients had a clinical response to amphotericin B with or without flucytosine, although 7 of the 10 had died of HIV infection at the time of the report. Of the 15 non–AIDS-infected but immunosuppressed patients reviewed by Leggiadro and associates,[36] responses also were favorable but difficult to evaluate clearly because of the presence of other diseases and complications.

Factors that suggest poor prognosis in cryptococcal meningitis are burden of yeast at presentation, patient's level of sensorium at presentation, high cryptococcal antigen titer (1:1024) and low cell count in CSF (<20 cells/mm^3), and inability to manage underlying disease.[15,56] Among patients receiving organ transplants, patients receiving liver transplants have a particularly unfavorable prognosis.[67] Patients receiving a calcineurin inhibitor have a significantly better prognosis than patients receiving other immunosuppressive therapies.[67]

PREVENTION

Immunocompromised individuals should avoid exposure to dust, especially in areas contaminated with bird droppings, particularly pigeon droppings. Long-term prophylactic therapy with fluconazole is effective in preventing recurrent cryptococcal infection. Prophylaxis with fluconazole should be considered for patients who continue to be severely immunocompromised at the end of therapy for cryptococcal infection. Prophylaxis generally is not needed by patients with cancer who experience remission and immune recovery, but should be considered until such time. Prophylaxis is indicated for patients with AIDS who have had cryptococcosis, as discussed earlier.

CHAPTER 216

Histoplasmosis

Martin B. Kleiman

Histoplasmosis is the most common pulmonary and systemic mycosis in humans and affects millions of people.[200,460] Although most infections occur in areas in which the etiologic agent, *Histoplasma capsulatum*, is endemic, increasingly it is being reported from areas not previously known to be endemic. A substantial proportion of infections occur in the United States, where approximately 500,000 individuals are infected annually.[429] Of these, an estimated 55,000 to 200,000 infected individuals become symptomatic, and 1500 to 4000 require hospitalization.[275] The public health significance of *H. capsulatum* as an opportunistic infection has escalated in proportion to the increasing numbers of individuals who are immunosuppressed.[268]

H. capsulatum was described[367] first in 1906 by Darling, a pathologist in the Panama Canal Zone,[73] while examining autopsy specimens of a man from Martinique who had died of a chronic, wasting illness. Darling observed an organism within histiocytes and thought it to be an encapsulated plasmodium; the illness caused by this new pathogen was named *reticuloendothelial cytomycosis*.[271] In 1932, Dodd and Tompkins[96] showed intracellular *H. capsulatum* in the peripheral blood smear of a febrile child, and DeMonbreum[90] subsequently grew the organism from this same child and correctly classified it as a fungus. In 1944, Christie and Peterson[59] developed histoplasmin and, after subcutaneous inoculation, showed a positive cutaneous reaction in a child with histoplasmosis.

In 1945, Parsons and Zarafonetis[306] characterized the disease as rare and usually fatal after studying 71 patients with disseminated histoplasmosis. With the use of histoplasmin skin testing, however, Christie and Peterson[59] soon showed histoplasmosis to be a common and usually a mild disease. They correctly recognized that histoplasmosis was the cause of pulmonary calcifications in large numbers of patients who were presumed to have tuberculosis, but in whom tuberculin skin tests were negative. Further characterization of the natural habitat and transmission of the fungus occurred in the late 1940s and early 1950s with demonstration of the organism in soil and air samples.[3,111,339,430]

ORGANISM

H. capsulatum var. *capsulatum*, the anamorphic (asexual) form of the organism, is a thermally dimorphic, saprophytic fungus of the class Ascomycetes, family Gymnoascaceae, subdivision Ascomycotina. The mold form displays heterothallic sexual reproduction with plus (+) and minus (–) mating types. Ninety percent of infections are caused by the minus type. The ascomycetous teleomorph produced by mating opposite types was isolated in 1972 and termed *Emmonsiella capsulata*[218]; the current taxonomy of this perfect (sexual) form is *Ajellomyces capsulatus*.[261,340] Because the fungus is isolated in the laboratory as the anamorph, the more common name *H. capsulatum* is used in this text.

At temperatures of 25° C to 30° C, the mold form grows as a fluffy colony with an aerial mycelium that varies from white to buff brown. Mycelia, small oval microconidia (3 to 5 μm) that are attached laterally to hyphae, and tuberculate and nontuberculate macroconidia (8 to 16 μm) are seen microscopically (Fig. 216–1).[423] The organism grows slowly, with 1 to 2 weeks required for laboratory strains and 8 to 12 weeks for growth from clinical specimens. When cultured at 37° C on enriched media containing cysteine, the mold transforms to the yeast form in 7 to 10 days.[275] The small, heaped, yellow-white, pasty colonies appear microscopically as ovoid, budding yeasts (1 to 3 μm × 3 to 5 μm) with rare pseudohyphae.[275,297]

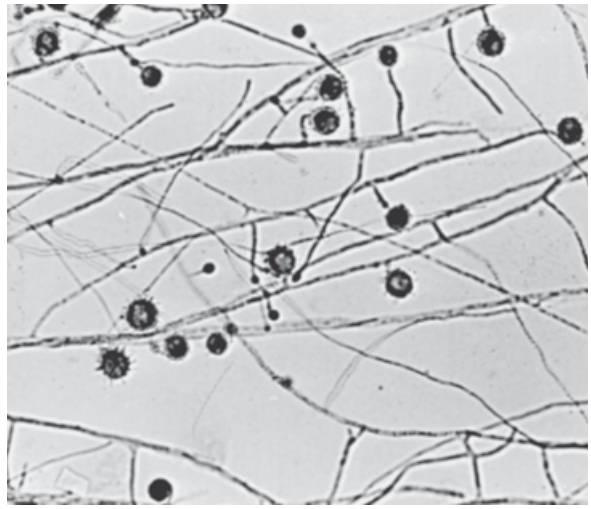

Figure 216–1 Culture of *Histoplasma capsulatum* from sputum illustrating tuberculate macroaleuriospores and microaleuriospores (lactophenol cotton blue, ×52).

In its natural habitat, the soil, *H. capsulatum* exists as mycelia and spores. It survives best in moist (95 to 100% humidity), nitrogen-rich soil at temperatures of 37° C or greater and can be found 1 mile below the soil surface.[417,429] The droppings in roosting sites of chickens, blackbirds, and starlings contain nutrients that promote fungal growth and, at least in the case of chickens, may contain substances that discourage the growth of competitive organisms in the soil.[376] Many species of colonial New World bats become infected and excrete the fungus in their guano; bat guano also contains substances that encourage growth of the fungus.[110,244,392,393] Although birds excrete the fungus in droppings, they remain uninfected, probably because of their high body temperature. *H. capsulatum* can remain viable in droppings or other contaminated sites for many years.[475]

Early techniques used to differentiate strains of *H. capsulatum* included serotyping and chemotyping.[97] Examinations of restriction fragment length polymorphisms of DNA have delineated three broad classes that exhibit geographic and possibly clinical differences.[103,207,420] Class 2 strains are found most frequently in North America, and class 3 strains are found in Central and South America. Class 1 strains are isolated almost exclusively from immunocompromised patients. Individual strains within each class have been examined further with additional nucleic acid–based and genome-wide approaches to reveal considerable genetic diversity.[50,183] Such strain differences are useful for molecular epidemiologic investigations.[183,195,279,337,394,493] Studies have suggested that patients with acquired immunodeficiency syndrome (AIDS) may be infected with less virulent, temperature-sensitive variants of *H. capsulatum*.[381] Additional investigations using molecular methodology have suggested that genetic differences in the pathogen may underlie clinical differences.[168,195]

Histoplasma duboisii, the cause of African histoplasmosis, was reclassified as a variant of *H. capsulatum* when investigators

showed that mating of isolates from each type produced cleistothecia and ascospores identical to those of *E. capsulata* (now termed *A. capsulatus*).[219,339] *H. capsulatum* var. *duboisii* is indistinguishable from *H. capsulatum* var. *capsulatum* in its mycelial stage, but its tissue phase is much larger and consists of thick-walled oval yeast forms that are 10 to 15 μm in diameter. Infections caused by *H. capsulatum* var. *duboisii* have been described across central and western Africa, and cases occur along with histoplasmosis caused by *H. capsulatum*.[155,297] A more recent phylogeographic analysis[196] of both varieties that cause human disease and another, *H. capsulatum* var. *farciniminosum* (an Old World horse pathogen), using DNA sequencing of four independent protein-coding genes questioned the validity of the classification.

EPIDEMIOLOGY

Histoplasmosis is acquired almost exclusively when environmental sites that are contaminated with *H. capsulatum* are disturbed, and spores become aerosolized and are inhaled. Early understanding of its epidemiology was influenced heavily by analyses of point-source outbreaks of acute infection among small groups of people exposed to relatively large inocula. Because most infections are either asymptomatic or mild and self-limited, however, such investigations skewed the true epidemiology. A more comprehensive understanding was achieved when the results of skin test epidemiology; cultures of environmental sources, birds, and other animals; and careful analysis of the history of exposure also were considered.[49]

Histoplasmosis has been reported worldwide in tropical, subtropical, and, most frequently, temperate areas.[118] Regions with a high incidence of infection are termed *endemic*, and most infections occur in these areas. Most infections occur sporadically and cannot be associated with exposure to a specific site or activity. They are presumed to result when environmental conditions are conducive to growth of the fungus, and dry windy weather or other events or activities facilitate the airborne transmission of spores. Although early reports emphasized that the infection usually was associated with occupational exposure in primarily rural environments, infection is recognized commonly in urban areas,[184,249,356] where it may affect numerous people.[468] Infections occur commonly in children and frequently remain unrecognized because, as investigations of outbreaks have shown, children often remain asymptomatic.[37,157,177] In a skin test survey of a highly endemic area in Tennessee, skin test reactivity was found in 80 percent of children 10 years old.[494]

The incidence of human infection varies widely in endemic regions. Within short distances of areas in which residents show only a moderate incidence of skin test reactivity, reactivity may be hyperendemic in areas in which the incidence of infection is considerably higher. Still more localized and very heavily contaminated sites, termed *microfoci*, may be found in which localized, sometimes severe, outbreaks occur. Because the droppings of birds and bats[92] accelerate the growth of the fungus in the environment, sites that have been implicated in localized outbreaks have included blackbird and pigeon roosting areas, chicken houses, bat-infested caves,[21,251] attics, chimneys, old buildings, and decaying woodpiles and trees. Activities that disturb these types of sites have been implicated in localized outbreaks.[177,321,429] Infections in children have been associated with exploring caves; playing in barns or hollow trees; cleaning abandoned buildings; cutting firewood or decayed tree stumps; renovating the walls, attics, or basements of older homes; digging in contaminated sites; being downwind of the excavation/demolition of buildings; cleaning seldom-used fireplaces; and being in indoor environments contaminated by fungal aerosols gaining access to air intakes.[55,249]

Edwards and colleagues[105,106] described the geographic distribution of *H. capsulatum* in the United States by performing histoplasmin skin testing on 275,558 Navy recruits between 1958 and 1965. The highest incidence of reactivity was found in residents of the Ohio-Mississippi-Missouri, the St. Lawrence, and the Rio Grande River Valleys.[275] In four states (Arkansas, Kentucky, Missouri, and Tennessee), the percentage of positive adult reactors ranged from 57 to 68 percent. In the adjacent states (Illinois, Indiana, Ohio, and Oklahoma), skin test reactivity ranged from 50 to 73 percent among adults in farm areas. Of the other seven states in the endemic area, lifetime prevalence rates exceeding 50 percent were shown in one or more counties.[2] Epidemiologic studies of this scale have not been repeated, and, as has been shown with other endemic mycoses,[224] population shifts and changes in land use may alter these patterns.

Numerous histoplasmosis outbreaks have been documented and offer some means of assessing the epidemiology and clinical spectrum of infections acquired in point-source and sustained outbreaks. The largest sustained outbreak was reported to occur in Indianapolis, Indiana, where it involved an estimated 100,000 individuals within a 400-square-mile area and lasted nearly 1 year.[468] Symptomatic cases were identified in 435 individuals (including 49 <15 years old), and disseminated disease developed in 46. Individuals 15 to 34 years old were more likely to become infected than were other age groups. An equal sex distribution of cases occurred before puberty; males predominated in a 3:1 ratio in older individuals. Localized outbreaks related to high-risk sites and activities[44,351,414] are well documented. Isolated cases may not be associated readily with such activities. Infections acquired during travel[19,116,190,191,305,452] to endemic regions[18,114,131,428] are being reported more frequently. Infections acquired in areas not previously recognized to be endemic, such as occurred in a large group of college students whose only known common exposure was vacationing at a hotel in Mexico,[278] require consideration of the diagnosis of histoplasmosis in patients presenting with compatible clinical findings.[16,41,47,350] Rarely, infections may occur in non-endemic areas and result from reactivation of quiescent infection in patients who become immunosuppressed.[180,405]

Although various wild and domestic animals may become infected, transmission of histoplasmosis to humans does not occur.[272] Infection of an infant after exposure to a pillow that contained contaminated feathers has been reported.[48] Although a case of sexual transmission that resulted from exposure to the mucosal lesions of a patient with disseminated histoplasmosis has been reported,[374] human-to-human transmission is extremely rare. Transmission has been confirmed, with the use of molecular typing methodology, in the recipients of two cadaveric organs transplanted from a donor who had resided in an endemic area.[235] Infections caused by direct inoculation of contaminated material in the environment or from laboratory accidents are rare.

PATHOPHYSIOLOGY

H. capsulatum has unique biologic interactions with human macrophages, dendritic cells, and neutrophils,[288] the outcome of which contributes to its success as a human pathogen. Key among these interactions are its ability to infect and gain access to macrophages[484]; to alter the intracellular environment, allowing it to survive, replicate, and disseminate; to remain viable during clinically unapparent infection; and to become reactivated when host immune factors permit.[45,485] The onset of infection results in a brisk innate immune response that is followed by an acquired immune response after about 2 weeks. During these events, the fungus induces an orderly modulation of the host inflammatory and cytokine responses. Production of cytokine begins within 24 hours of primary infection and continues for approximately 3 weeks, bridging the innate and acquired immune reactions. Suc-

cessful clearance of the infection[20,192,296,332,496] depends primarily on the functional integrity of cellular immunity. The clinical manifestations and outcome of the infection are determined by this complex interplay of events.

The incubation period of histoplasmosis varies depending on the size of the inoculum, the integrity of the host immune response, the presence of immunity from previous infection, and strain-to-strain differences in fungal virulence.[143,213] Although the range of incubation periods is reported to be 1 to 3 weeks in non-immune hosts, it is based largely on data gathered from point-source outbreaks in which the time of exposure is readily determined. In these settings, the size of the infecting inoculum probably is larger, however, than that resulting in sporadic infections.[49] Because most infections occur sporadically and either are asymptomatic or result in nonspecific flulike illnesses that are not diagnosed, the upper range may be longer. In patients who retain specific cellular (protective) immunity from previous infection, re-exposure results in less severe symptoms and shorter incubation periods, usually approximately 4 to 7 days.[49] Infants and individuals with a primary or acquired deficiency in cellular immune function are more likely to experience symptomatic illness after exposure.[143]

In experimental animals, acute pneumonitis develops after inhalation of *H. capsulatum* microconidia or mycelial fragments.[24] Because of their smaller size, microconidia gain access to the terminal alveoli and bronchioles more readily than macroconidia do. Within 2 to 3 days after being inhaled, spores germinate and convert to the yeast form of the fungus. This step apparently is a critical determinant of virulence because chemical blockage of the conversion from the mycelial to the yeast phase impairs virulence[285] in a murine model.[270] Progress in understanding the molecular cell biology and genetics of the mold-to-yeast transition has been reviewed more recently.[178] Molecular techniques also have identified two genes (*URA5*, *CBP1*) that have a role in pathogenesis.[483,485]

Additional determinants of fungal virulence have been described and include a role for α-1,3-glucan.[333] In the first week, a neutrophil response occurs at the site of the infection[24]; it is followed in approximately 2 weeks by the accumulation of helper T lymphocytes and macrophages.[323] The yeast forms attach to integrins of the CD11/CD18 group of cell surface receptors and enter neutrophils[363] and macrophages.[40,100] This process may be an adaptive microbe entry mechanism that enables the organism to evade the host oxidative burst response associated with host-directed opsonophagocytosis.[485] Human neutrophils possess fungistatic activity that resides within azurophilic granules.[38,290] Neutrophils have been shown to play a role in the primary immune response in a murine model[498]; however, depletion of neutrophils in a systemic model of secondary infection did not alter the course.

Traditional opsonophagocytosis facilitated by binding to complement or to immunoglobulin after the development of humoral immunity also occurs.[485] This process exposes the yeast to the full array of antimicrobial defense mechanisms.[484] Microbe-directed binding using a specific ligand (adhesin) on the yeast's surface has been identified as *H. capsulatum* HSP 60.[15,42,245] This heat-shock protein also has been shown to induce immunity to lethal and sublethal infection in a mouse model, a complex effect related to its ability to stimulate $CD4^+$ T lymphocytes.[82]

Yeast seems to have a competitive advantage within the membrane-bound vacuoles of macrophages,[286,287] and the asylum seems to protect it from pulmonary collectin-mediated killing.[260] In mouse models, additional strategies used by the organism to survive and replicate in this ordinarily hostile environment include increasing the alkalinity, tolerating nutrient starvation, and resisting the toxic effects of host reactive oxygen and nitrogen intermediates, degradative enzymes, and antimicrobial peptides.[485] Mouse macrophages differ from human macrophages because the latter mount a respiratory burst without the need for opsonization, as is required for murine macrophages. Lysis of infected cells results in the release of additional yeasts and infection of additional macrophages. During this period of fungal sequestration and replication, lymphohematogenous dissemination distributes yeast from the lungs to the reticuloendothelial system and to other organs.[286] Without the development of specific cellular immunity, unrestricted growth of the fungus is lethal.[287,323]

Although infection usually results in a brisk antibody response, humoral immunity does not contribute substantially to primary or secondary immunity.[255,294,352] A mouse model has shown, however, that antibodies to a cell surface protein of the fungus altered the intracellular fate of the fungus and mediated protection.[17,291] Human dendritic cells that reside in the lung link the innate and adaptive immune responses. More efficient antigen-presenting cells than alveolar macrophages, dendritic cells use the fibronectin receptor, phagocytose and rapidly degrade the organism, present *H. capsulatum* antigen for lymphocyte proliferation, and facilitate the induction of cell-mediated immunity.[137,287] Dendritic cells also have been shown to present exogenous antigen through uptake of apoptotic macrophage-associated fungal antigens (cross-presentation).[237] Some of the strategies used by the yeast that facilitate its survival and replication within macrophages, such as prevention of phagolysosomal fusion, do not occur in dendritic cells. The resultant rapid destruction of yeast within human dendritic cells constitutes an important role for these cells in the innate immune response[287] and seems to result from exposure to lysosomal hydrolases.[136]

After they participate in the innate immune response, several endogenous cytokines induced by the development of acquired cellular immunity[287] activate macrophages, which act as the primary cellular effectors that control the infection.[286] Cytokines that play key roles in the resolution of primary or secondary infection (protective immunity) in animal models include tumor necrosis factor-α (TNF-α),[8,10,11,78,80,488,498] interferon-γ (IFN-γ),[8,9,64,222,419] interleukin-4 (IL-4),[78] IL-12,[9,46,499,500] IL-1,[86] and granulocyte-macrophage colony-stimulating factor.[7,9,10,80,85,377] The effect of IL-12 results from its induction of IFN-γ; it is active in primary infection, but not in re-infection.[9] Deficiency of IL-10 has been shown to confer a salutary effect on histoplasmosis in a mouse model.[83] Apoptosis, a crucial element of protective immunity in the mouse model, when inhibited, is accompanied by elevated production of IL-4 and IL-10 and exacerbation of the severity of infection.[6]

Cytokines that activate human macrophages and induce them to become fungistatic are granulocyte-macrophage colony-stimulating factor, macrophage-stimulating factor, and IL-3[78,289]; the mechanisms by which the colony-stimulating factors stimulate fungistatic activity are not fully elucidated, but have been shown to not require acidification to kill and degrade yeast.[291] TNF-α[43,78,84,226,482] is a central and critical mediator of resistance in mice and humans, although its effect on cellular targets differs.[161] Human macrophages also express antifungal activity that is not cytokine-dependent. The latter mechanism is stimulated by attachment of macrophages to type 1 collagen matrices and is mediated at least partly by overcoming the ability of yeasts to inhibit phagolysosomal fusion.[292]

In addition to macrophages, specific T-cell subpopulations also are capable of killing *H. capsulatum*. $CD4^+$ cells have been shown to be essential for fungal clearance in mouse models.[79,140,236] The importance of these cells in human infection is supported by observations showing that the risk of severe histoplasmosis developing in adults with human immunodeficiency virus (HIV) infection increases when the $CD4^+$ count decreases to less than 200/μL.[447] $CD8^+$ cells also mediate immunity in mice,[236] but their contribution is not as significant as that of $CD4^+$ cells. $CD8^+$ cell clearance of *H. capsulatum* involves perforin-dependent and

perforin-independent mechanisms.[497] Perforin also plays an independent and essential role in primary immunity in a mouse model.[497] Cytokines such as IFN-γ and TNF-α also work in concert with cytolytic mechanisms to provide protective immunity against *H. capsulatum*.[497] The role of natural killer cells has been studied in murine models.[308] Natural killer cells participate to a limited degree in the immune response in immunocompetent animals and play a more substantial role in animals depleted of T cells.[287]

In immunocompetent hosts, cellular immunity is suppressed[312] early in the course of histoplasmosis, especially in disseminated histoplasmosis of infancy.[61,296] Cellular immune function returns to normal after 4 to 6 weeks of treatment. In the mouse model, *H. capsulatum* infection is associated with the generation of suppressor T-cell activity; this activity depresses the production of T cell–dependent, delayed-type hypersensitivity, mitogen-induced lymphocyte transformation, and cytotoxic activity.[20] T-cell immunity develops approximately 10 to 21 days after exposure, and splenic suppressor T-cell numbers decrease, while helper T cells increase.

In a study of the cellular immune response of patients infected with HIV-1 and with recent onset of histoplasmosis, all had nonreactive skin tests. Lymphoproliferative responses and IFN-γ production were depressed in patients with $CD4^+$ counts of 200 to 500 cells/mm^3; lymphoproliferative responses approached normal in patients with $CD4^+$ counts greater than 500 cells/mm^3.[412] In addition to having defective cellular immunity resulting from decreased numbers of $CD4^+$ cells, patients with HIV infection have macrophages that show a diminished ability to control *H. capsulatum*. These macrophages have a profound defect in their ability to recognize and bind to yeast and show permissiveness for intracellular growth of the fungus.[56] The HIV envelope glycoprotein gp120 seems to play a role in inhibiting phagocytosis of *H. capsulatum* by macrophages, but it is not responsible for the capacity for accelerated growth of yeast within macrophages.[57]

PATHOLOGY

With the exception of patients who have severe progressive disseminated infection, particularly patients with preexisting primary or acquired cellular immune dysfunction, histopathologic findings in histoplasmosis are characterized by granulomatous inflammation, usually in association with caseating and noncaseating granulomata. The mature granuloma serves the host by isolating the inflammation, protecting adjacent healthy tissues, inhibiting growth of the organism, and preventing systemic dissemination. The effectiveness of this pathologic response is underscored by the wide prevalence of asymptomatic and self-limited infections in geographic regions where skin test reactivity exceeds 90 percent. At the same time, a benefit that accrues to the pathogen in this microenvironment is long-term latency, sometimes ending with reactivation in the setting of late, acquired immune dysfunction.[171] An animal model that permits investigation of this interface between the pathogen and its host has been described.[171]

Typical granulomata appear after the development of an effective acquired immune response; the cellular elements in these lesions consist primarily of mononuclear phagocytes and lymphocytes, largely T cells. Langerhans giant cells often are present, and typical yeast forms occasionally, but not consistently, are visible within macrophages. Inflammation ultimately progresses to fibrosis and often is accompanied by calcification.[143] The rate of calcification is age-dependent, and it may occur within months in children and over several years in adults.[143,385] Exuberant granulomatous inflammation or fibrosis or both can result in obstruction or dysfunction of adjacent mediastinal or, less commonly, abdominal[335] structures. Although viable yeasts remain in quiescent granulomata, they are few in number and rarely seen. In areas endemic for histoplasmosis, old granulomata in the lung, bone marrow, or other sites may be seen as incidental findings, the significance of which depends on clinical assessment. Yeasts almost never are observed in histologic sections of extensive fibrosis in late histoplasmosis.

In patients with acute progressive manifestations of histoplasmosis, especially patients with preexisting cellular immune dysfunction,[118,274] or in infants, the inflammatory response is impaired, and granuloma formation is poor.[145] In these instances, extensive parasitization of macrophages by yeasts occurs, and organisms may be seen readily in various reticuloendothelial structures, especially the bone marrow, and sometimes within leukocytes in the peripheral blood.[296] Many other organ systems are involved. The histopathologic findings in central nervous system (CNS) infection consist of granulomatous basilar meningeal and vascular inflammation, perineural inflammatory changes in cranial nerves, and the presence of many organisms at the periphery of mass lesions.[437] In disseminated infections, the adrenals frequently are affected,[154,217,390] and a wide spectrum of pathologic abnormalities of the gastrointestinal tract is seen.[22,221]

CLINICAL MANIFESTATIONS

Approximately 95 percent of infections caused by *H. capsulatum* occur in normal individuals, and either are asymptomatic or cause brief, self-limited illness with no sequelae. The only residual findings are the incidental radiographic demonstration of typical granulomata in the lung parenchyma or calcifications in the hilar/mediastinal lymph nodes or the spleen. In immunocompetent hosts, the size of the inoculum probably is the principal determinant of whether infection is accompanied by clinical symptoms. After exposure to small inocula, only 1 percent of individuals develop symptoms, but after heavy exposure, 50 to 100 percent become ill.[429] Additionally, the symptoms that develop are more severe in individuals who are exposed to large inocula. Severity may be reduced by preexisting immunity derived from previous infection. Protection is incomplete, however, and severe disease can occur after re-exposure to a heavy inoculum.

A crucial determinant of susceptibility and severity also is host-dependent. Individuals with primary or acquired disorders of cellular immunity and otherwise normal infants younger than 1 year have a disproportionately high risk for developing symptoms after exposure. These groups also are at far greater risk for progression of early fungal dissemination. The higher risk for dissemination during infancy is thought to result from age-related, relative immaturity of immune function, rather than a primary immunodeficiency disorder.

As with the other endemic mycoses, histoplasmosis begins as an acute inflammatory pneumonitis, undergoes self-limited or progressive dissemination, and requires an effective host immune response for its control. Clinical manifestations (Table 216–1) vary because they result from any or all of the following: the nonspecific systemic effects caused by the infection, symptoms resulting from either the primary inflammatory focus or perturbation of function of anatomic structures adjacent to primary sites of inflammation, hypersensitivity phenomena resulting from the acquired immune response, symptoms caused by hematogenously infected sites, life-threatening multisystem symptoms resulting from progressive parasitization of the reticuloendothelial and other organ systems, symptoms caused by chronically progressive forms of pneumonitis or dissemination, or exacerbation of quiescent disease. Recognition, confirmation of the diagnosis, and selection of prudent therapeutic options require understanding of these diverse clinical manifestations. Aside from patients with preexisting conditions or receiving therapy that

TABLE 216–1 Clinical Manifestations of Histoplasmosis

Asymptomatic infection
Pulmonary disease
Acute (mild, moderate, severe forms)
Mediastinal adenitis
Mediastinal granuloma*
Obstruction/dysfunction of contiguous mediastinal structures by granulomatous inflammation of lymph nodes
Pericarditis
Chronic disease with cavitation†
Broncholithiasis†
Lithoptysis†
Mediastinal fibrosis‡
Progressive disseminated infection
Acute
Infancy (PDH of infancy) with or without meningitis
Immunocompromised (non-HIV)
HIV
Subacute†
Chronic†
Presumed ocular histoplasmosis†
Primary cutaneous infection†
Isolated meningitis†

**Complications similar to those of mediastinal adenitis, but presentation either unassociated with acute infection or following asymptomatic or unrecognized infection.*
†*Rare in children.*
‡*Infrequent manifestation during childhood.*
HIV, human immunodeficiency virus; PDH, progressive disseminated histoplasmosis.

impairs immune function, all patients with serious infections, disseminated disease, persistent antigenuria after the completion of therapy, relapse, or recurrent infection should undergo comprehensive assessment of immune function.

PULMONARY HISTOPLASMOSIS

The most common symptoms of acute primary histoplasmosis encompass a spectrum[441] of respiratory and systemic complaints of varying severity. Eighty percent of infections that are accompanied by symptoms are mild, undifferentiated, flulike illnesses with cough, myalgia, headache, and variable low-grade fever. Symptoms usually are self-limited and resolve in 3 to 5 days.[429] In cases of more significant fungal exposure, fever is present, and symptoms can include headache, myalgia, chills, persistent cough, and nonpleuritic chest pain.[143] Illness may persist for 2 weeks and be associated with nausea, asthenia, weight loss, or fatigue. This manifestation also is self-limited, although fatigue and weight loss improve slowly after the fever resolves.

In primary infections that last longer than 2 weeks, fever persists and is accompanied by greater weight loss, chills, night sweats, fatigue, and chest pain. The chest pain that occurs in histoplasmosis typically is nonpleuritic, may be substernal or lateralized, usually is brief in duration, and recurs frequently. This pattern of chest pain may last 1 week to a few months.[143] Wheezing may be an early symptom.[43,427] Hepatosplenomegaly occasionally is present, although its occurrence should raise suspicion of early dissemination. In these prolonged illnesses, resolution without treatment may occur, but with the safe and effective oral antifungal agents available, most experts recommend treatment with antifungal therapy.

Finally, in acute primary infections that occur after intense exposure to numerous spores, the resulting diffuse pneumonitis may be associated with dyspnea or adult respiratory distress syndrome early in the infection. In these instances, the ordinarily self-limited early dissemination has a high risk of becoming progressive, and treatment is required. After development of the respiratory complaints that accompany primary infection, rheumatologic syndromes may be seen within several months of infection. They usually consist of erythema multiforme,[269] erythema nodosum,[143,242,304,368] acute migratory polyarthritis, or any combination of these conditions.[63,345] Although histoplasmosis-induced erythema nodosum is seen during childhood and adolescence, arthritis is uncommon. The rheumatologic symptoms are immune-mediated and usually self-limited or respond to anti-inflammatory therapy.

Various symptoms may result from complications arising from intrathoracic or, less commonly, intra-abdominal lymphadenitis caused by *H. capsulatum*. One of the most problematic, often termed *mediastinal lymphadenitis*, is acute primary infection accompanied by fever, weight loss, and a mediastinal mass visible on chest radiograph. This scenario and the presence of mediastinal lymphadenopathy in the absence of any recognized clinical symptoms often require definitive diagnosis to exclude neoplasm, especially lymphoma.[127,456,487] Pediatric series that have examined the definitive diagnosis of such manifestations have found rates of histoplasmosis to range from 1 to 57 percent,[33,127,426,487] a discrepancy best explained by considering whether the study population lived in an endemic region. In a highly endemic region, the cause of a mass within the middle mediastinum was histoplasmosis if the *Histoplasma* complement-fixation (CF) titer was greater than 1:16.[127]

Complications of acute primary histoplasmosis may be seen when granulomatous lymphadenitis results in inflammation, compression, or obstruction of contiguous structures within the thorax; this manifestation occasionally is termed *mediastinal granuloma*. Structures most commonly affected are, in decreasing order of frequency, the bronchi, trachea, pericardium, pulmonary vasculature and great vessels, lymphatics,[407] esophagus, and nerves.[102,307,338,486] Symptoms include bronchial compression or obstruction, or both,[383] which sometimes is associated with distal pneumonitis; pericarditis; pulmonary infarction; esophageal diverticula, fistula formation, or dysmotility, alone or in combination; tracheoesophageal fistula formation; and phrenic or recurrent laryngeal nerve palsy. Presumably because of their more pliable airways, children are more susceptible than adults to tracheobronchial compression as a result of encroachment by enlarged lymph nodes.[129] The risk of involvement of contiguous structures by such mediastinal granulomata may be related to the thickness of the capsule, rather than the overall size of the node.[143]

In highly endemic regions, histoplasmosis is the cause of 25 percent of acute pericarditis cases; approximately one fourth of patients have symptoms of tamponade,[430] although it rarely is seen in children. In almost all instances, pericardial effusion results from inflammation caused by infected lymph nodes adjacent to the pericardium, and not by frank fungal pericarditis.[492] The pericardial fluid is exudative, bloody, and almost always sterile.[468] Most patients with *Histoplasma* pericarditis quickly improve with administration of nonsteroidal anti-inflammatory drugs, and neither acute drainage nor pericardiectomy is needed. Rarely, contiguous adenitis or broncholiths erode through the pericardium and cause fungal contamination of the pericardial space.[143,492] Pleural effusions occur very rarely in children with histoplasmosis, and, similar to pericarditis, seem to result from pleural inflammatory reactions to adjacent granulomata; cultures of pleural fluid are negative.[329] Broncholithiasis may result from calcifications that erode through bronchi,[28] but they rarely occur in children. Lower cervical[262,430] or supraclavicular adenitis is an infrequent manifestation of histoplasmosis and usually is seen in association with mediastinal involvement. Lymphadenitis occasionally affects the intra-abdominal lymph nodes and has been reported to cause biliary tract obstruction[309,335] in children.

Subacute or chronic manifestations of intrathoracic histoplasmosis may occur in children, although they most commonly affect older adults. Of these entities, mediastinal fibrosis may

affect adolescents. In these rare instances, granulomatous inflammation progresses to dense fibrosis and may cause stenosis, obstruction, or malfunction of contiguous critical mediastinal structures. Although symptoms are similar to those caused by active granulomatous inflammation that impairs the function of these structures, the fibrosis is progressive and irreversible and responds to neither antifungal therapy nor anti-inflammatory agents.[248] Common complications include the superior vena cava syndrome and stenosis or obstruction of the trachea, bronchi, pulmonary artery, or esophagus.[161]

Late constrictive pericarditis was reported[143] to develop in 14 percent of adults with *Histoplasma* pericarditis, but data have been descriptive. Long-term data in children are lacking; however, a 30-year experience in a highly endemic area has failed to identify histoplasmosis-induced constrictive pericarditis during childhood (M. Kleiman, 2007, personal experience). Additional late complications of intrathoracic histoplasmosis seen primarily in adults include pulmonary histoplasmomas (lung nodules), which are granulomata in the peripheral lung fields that become encased in dense fibrous tissue, often with concentric layers of calcification. They enlarge over several years and may cause symptoms of a mass lesion[146] or manifest as an isolated pulmonary mass. Endobronchial lesions characteristically manifest with stricture, obstruction, or hemoptysis, and mimic bronchogenic neoplasms.[194,346]

Cavitary (also termed *chronic*) pulmonary histoplasmosis rarely has been reported in a child,[27,95] and typically is seen in adults with underlying chronic obstructive pulmonary disease. Symptoms include episodes of low-grade fever, productive cough, weakness, weight loss, and fatigue.[148,200] Early pulmonary findings consist of apical interstitial pneumonitis that eventually progresses to fibrosis, cavitation, and gradual spread to uninvolved areas of the lung.[460] If chronic histoplasmosis goes untreated, the disease is fatal.[200] Disseminated infection eventually develops in approximately 80 percent of patients with this disorder.[123,348]

PRIMARY CUTANEOUS HISTOPLASMOSIS

Numerous reports[298,418] describe apparently immunocompetent patients who present with mucosal,[132,273,344,374] corneal,[401] or cutaneous ulcerated lesions that show characteristic pathologic changes and morphologic and cultural documentation of *H. capsulatum* and resolve without treatment. These lesions have been considered to be primary, localized infections.[399] Aside from several cases that reasonably may be attributed to documented instances of direct inoculation,[216,374] many of these reports fail to provide sufficient evidence[113,225] to exclude confidently low-grade, chronic dissemination with histoplasmosis.[460] Comprehensive clinical and laboratory evaluation and long-term follow-up[69,491] are needed to attribute with confidence mucocutaneous lesions to localized infections with *H. capsulatum*.

PROGRESSIVE DISSEMINATED HISTOPLASMOSIS

Progressive disseminated histoplasmosis (PDH) occurs most frequently in immunodeficient patients and patients at the extremes of age.[145,358,460] The clinical entity is defined as an illness that is accompanied by active replication of *H. capsulatum* in multiple organ systems. Symptoms are prolonged and usually last longer than 3 weeks. Laboratory evidence of dissemination may include anemia, thrombocytopenia, or leukopenia; persistent antigenuria or antigenemia or both; demonstration of granulomas in extrapulmonary tissue; histopathologic demonstration of compatible yeast; or growth of the fungus in culture.[452] This definition excludes the transient fungal dissemination that uniformly occurs in early primary infection and is aborted by the host's acquired cellular immune response. It does encompass, however, the rare instance in which intense exposure to a large fungal inoculum results in severe primary infection that overwhelms the host's ability to mount an effective cellular immune response, allowing the usually self-limited primary dissemination to progress.

Distinct clinical presentations of PDH in adults permit subclassification into acute, subacute, and chronic forms. In contrast, PDH in children occurs almost exclusively as an acute, progressive, life-threatening infection.[186] Most of these infections develop in immunocompetent infants younger than 1 year, or in children with acquired or primary cellular immunodeficiency. Rarely, PDH occurs in an immunocompetent child.[74] Transplacental infection has been reported to occur in infants of women with PDH complicating HIV infection.[474]

PDH may result from exogenous exposure of a susceptible or immune host or from reactivation of endogenous quiescent foci of infection. Precise differentiation of these mechanisms of pathogenesis is complicated by the risk for re-exposure in endemic areas and the relative unavailability of a method that easily distinguishes strain differences in isolates. Although reactivation of infection may occur in an immunosuppressed host,[180,405] epidemiologic data in immunosuppressed individuals who reside in areas highly endemic for histoplasmosis favor exogenous exposure as the most common mechanism. Supporting evidence consists of observations showing that rates of PDH in immunocompromised patients increase only during periods in which infection rates increase in the general population and do not increase in interepidemic periods.[314,362,413,471] Using the results of histoplasmin skin testing obtained at the time of diagnosis of malignancy in a large cohort of children, Hughes[176] found that skin test reactivity was absent in all children in whom PDH subsequently developed, and that in none of those known to be skin test positive at the time of diagnosis of neoplastic diseases did PDH develop later.

Progressive Disseminated Histoplasmosis of Infancy

PDH of infancy usually affects children younger than 1 year and has been reported to occur in a 6-week-old infant.[229,296] Rare instances of transplacental[474] infection have been reported. It usually is a subacute illness in which symptoms often are reported to have been present for 1 to 12 weeks before the patient undergoes an initial evaluation; as the disease progresses, patients eventually become profoundly ill and usually die unless treated. Early symptoms include variable fever, failure to thrive,[382] and hepatosplenomegaly in almost all instances. Pallor, cough, tachypnea, oropharyngeal ulcerations, lymphadenopathy, gastrointestinal bleeding, or hemorrhagic skin lesions may develop. Abnormalities that are seen frequently in laboratory studies, and inexorably worsen, include anemia, thrombocytopenia, leukopenia,[145,229] disseminated intravascular coagulopathy, and marked depression of immunoregulatory cells[61,296]; these abnormalities reflect the overwhelming fungal parasitization of the reticuloendothelial system and often suggest the diagnosis of a lymphoreticular malignancy.[1] The chest radiograph may show signs of focal pneumonitis, mediastinal adenopathy, or miliary disease, but more than 50 percent of chest radiographs are normal at the time the diagnosis is made. Organs commonly affected are the spleen, liver, bone marrow, lymph nodes, gastrointestinal tract, and adrenal glands.[52,154,232] Abnormalities in the cerebrospinal fluid (CSF) were found in 62 percent of a large series of PDH cases in Costa Rican infants.[296]

PDH of infancy was uniformly fatal before effective antifungal agents became available[229]; survival rates are now excellent. In a series of Costa Rican children that included some infants with malnutrition, 90 percent of patients treated with amphotericin B survived; of the four who died, two had received amphotericin B for either 33 or 35 days and thereafter were treated with keto-

conazole orally. Both families declined further treatment and were lost to follow-up (C. Odio, 2007, personal communication); each returned, within 5 weeks of discharge, with massive gastrointestinal hemorrhage and recurrent dissemination. The other two were gravely ill and died after having received only either two or three doses. Survival was 100 percent in an Indiana series of PDH of infancy (M. Kleiman, 2008, unpublished data).

Progressive Disseminated Histoplasmosis in Immunocompromised Hosts

Immunocompromised individuals, including individuals in whom the primary medical condition or therapy[246] has depressed cellular immunity, are at risk for dissemination if they acquire histoplasmosis.[176] Common predisposing conditions include AIDS, primary immunodeficiency disorders,[174] immunosuppressive therapy for reticuloendothelial malignancies,[176] organ transplantation,[263] and chronic renal failure. More recently, an increased number of severe PDH infections has been recognized in patients treated with TNF-α antagonists for inflammatory disorders.[482] This effect seems to be associated most closely with the use of infliximab,[108,226] a chimeric mouse monoclonal IgG1 antibody directed against soluble and cellular TNF-α that blocks it from binding with its endogenous cell surface TNF-α receptor.[78,126]

In children who are receiving chemotherapy for malignancies, disseminated histoplasmosis can occur during either remission or relapse.[1,176] The most common initial symptom is persistent fever, often without localizing symptoms and unassociated with toxicity. As the illness evolves, fever continues, and liver and spleen enlargement may occur. Laboratory abnormalities include progressively worsening anemia, leukopenia, and thrombocytopenia; disseminated intravascular coagulopathy may ensue eventually. The chest radiograph may be normal.[176] *Histoplasma* antibody assays usually are negative, and the diagnosis can be confirmed most readily using *Histoplasma* antigen assay of urine or serum.

Another common symptom complex consists of respiratory complaints and tachypnea. In these instances, persistent fever is followed in several days by dyspnea. Chest radiographs, although occasionally normal at the onset of symptoms, show diffuse interstitial infiltrates[1] that progressively worsen. Hypoxemia usually accompanies the symptoms and is progressive. This clinical complex is not specific for histoplasmosis, however, and may be indistinguishable from that caused by *Pneumocystis jiroveci*, cytomegalovirus, various viral respiratory pathogens, other opportunistic fungi, and bacterial septicemia.[152]

The diagnosis of histoplasmosis may be established noninvasively with the urine antigen assay. If this assay is negative, lung biopsy and culture are the most sensitive and specific diagnostic methods and often provide diagnostic information about other potential causes. Examination of bronchoalveolar lavage (BAL)[159] fluid for *Histoplasma* antigen is sensitive and specific in adults, but has not been studied adequately in children.

A subacute form of PDH is seen primarily in adults,[460] although in one report of 19 cases, it was found in 7 infants and 1 child.[145] The principal clinical features that distinguish the subacute from the acute form of PDH are more prolonged symptoms at initial evaluation, a higher frequency of focal lesions, less pronounced fever, and fewer hematologic abnormalities in subacute infection. Early complaints are nonspecific and may be present for 1 to 6 months; malaise and weight loss occur frequently. Hepatosplenomegaly is seen almost uniformly, and intestinal ulceration,[192] sometimes with perforation, occurs commonly.

Gastrointestinal histoplasmosis displays protean manifestations that may occur as a result of mediastinal histoplasmosis[189] or in the setting of PDH.[452] The terminal ileum often is involved, and findings may mimic Crohn's disease.[51,383a] Colonic lesions may result in bleeding or obstruction,[172] or mimic neoplasms.[227] Isolated colonic lesions without evidence of dissemination are rare.[179] Oropharyngeal ulcerations occur and are large and deep and can mimic neoplasms.[113,145,273] Seventy-five percent of patients have adrenal involvement, sometimes unilateral[390]; adrenal insufficiency occurs less frequently, but is reported in 15 percent of adults.[145,149,378] CNS infections are seen occasionally and may be manifested as chronic meningitis, focal mass lesions, or focal areas of cerebritis. Endovascular infections occur and may involve abnormal or normal native valves. The aortic or mitral valves or prosthetic valves[5,29,58,109,133] most commonly are affected. Valvular disease generally is typical of fungal endocarditis, with large vegetations and a high frequency of embolic phenomena.[89]

Numerous isolated lesions[29,72,257,401,481] have been described; some occur in the setting of PDH, and others are found to be isolated manifestations of infection.[189] Vaginal and penile ulcers, soft tissue nodules, recurrent panniculitis, tenosynovitis, carpal tunnel syndrome, osteomyelitis and arthritis, enteropathies, immune hemolytic anemia, and epididymitis all have occurred.[188,202,210,302,324,345,374,386,427] Although the progression of subacute PDH is slower than that seen in acute PDH, it is nonetheless a progressive infection that is fatal in 2 to 24 months if untreated.[145]

Chronic disseminated histoplasmosis is seen almost exclusively in adults in association with cavitary pulmonary lesions.[145] Oropharyngeal ulcers are accompanied by chronic, mild, intermittent constitutional symptoms. A chronic relapsing disseminated form of the disease has been described in two younger patients, 9 and 20 years old, with chronic mucocutaneous candidiasis[118,274,310] and in a child with IFN-γ receptor-1 deficiency.[496]

Progressive Disseminated Histoplasmosis in Human Immunodeficiency Virus–Infected Patients

Histoplasmosis is an AIDS-defining opportunistic infection,[54] and commonly occurs in HIV-infected patients residing in endemic areas. Disseminated infection develops in more than 90 percent of HIV-infected adults with histoplasmosis.[447] In 1988, less than 0.5 percent of adult patients with AIDS had disseminated disease.[147] In endemic areas, it has been reported in approximately 5 percent of patients,[163,258,266] and in 21 to 53 percent during epidemic periods.[32,447,469,470]

In a multivariate analysis of risk factors for the development of histoplasmosis in HIV-infected adults residing in endemic areas, receipt of antiretroviral therapy and triazole drugs was associated independently with decreased risk[164,267]; one study found the risk to be increased with positive baseline serology, $CD4^+$ cell counts less than 150/μL, and exposure to chicken coops.[266] Risk factors for death in two large cohorts of adults also have been determined.[70,89,439] Mortality rates were greater in HIV-infected individuals with PDH treated with antifungal therapy compared with HIV-negative patients with PDH; in HIV-positive patients receiving highly active antiretroviral (HAART) therapy along with antifungal therapy, clinical outcomes were similar to those of patients with PDH unassociated with HIV infection.[402] Comparable studies have not been done in children. In Arkansas, a highly endemic area, histoplasmosis was the AIDS-defining illness in 8 percent of 40 children who acquired HIV in the perinatal period.[366] Histoplasmosis occasionally is seen in non-endemic regions, perhaps because of reactivation of quiescent foci of infection.[19,47,116,353,355]

In HIV-infected adults with disseminated histoplasmosis, symptoms often are nonspecific; prolonged unexplained fever and weight loss are seen almost uniformly, and respiratory complaints occur in approximately half of patients.[158,186,355,447] Features are not distinctive, and in areas in which *Penicillium marneffei* also is endemic, clinical, laboratory, and radiographic findings overlap.[277] Gastrointestinal symptoms[189] are reported commonly and usually are nonspecific; abdominal pain, weight loss, and diarrhea occur in 50 to 70 percent of patients.[22,162,165,221,387]

Multiple intestinal pathogens may be present along with *H. capsulatum*.[319] Enlargement of the liver and spleen is found in approximately 25 percent of patients. Ten percent of patients are initially gravely ill with signs of a septic shock–like syndrome.[447] Mucocutaneous lesions occur in approximately 10 percent of adult patients and include nonspecific maculopapular rash, papules, nodules, pustules, ulcerative lesions, acneiform lesions, mucosal ulcers, and vegetative plaques[153,160]; histopathologic examination of skin biopsy specimens often is diagnostic. The frequency of skin lesions in a cohort of Brazilian patients was 66 percent, a difference attributed to geographic strain differences.[198]

CNS involvement, including meningitis, encephalitis, and focal brain lesions, occurs in approximately 18 percent of patients with PDH complicating HIV infection.[14,15,32,185,254,355,437] Symptoms include headache, encephalopathy, or complaints arising from focal neurologic abnormalities.[437] Published reports of histoplasmosis complicating HIV infection in children are few; in four HIV-infected children in Indiana, fever was present in all, and cutaneous lesions were absent; hepatosplenomegaly was found in one child, and an abdominal mass caused by an infected abdominal lymph node was seen in one child. In adults, initial chest radiographs are normal in approximately 40 percent, show diffuse interstitial or reticulonodular infiltrates in approximately 50 percent, and show localized lesions in approximately 5 percent. Diffuse abnormalities frequently appear during treatment of individuals whose chest radiographs initially were normal.[355]

With the widespread use of HAART for treating advanced HIV infections, an immune reconstitution inflammatory syndrome has been described.[71,280,372] The immunopathogenesis of immune reconstitution inflammatory syndrome is presumed to result from interaction between HAART-induced improvement of host immune function and residual microbial antigens.[240,342] *H. capsulatum* is among other granuloma-inducing pathogens reported to induce immune reconstitution inflammatory syndrome.[36,372]

Central Nervous System Infection

CNS manifestations occur in 5 to 10 percent of adults with PDH,[437,466] but they also may occur as chronic meningitis without other signs of apparent dissemination.[212,348,358,378,437,466] Acute or chronic meningitis occurs in 60 percent of CNS infections; single or multiple focal lesions affecting the brain or spinal cord, stroke syndromes, and encephalitis constitute the balance of manifestations. Symptoms of meningitis often are present 1 to 6 months before the diagnosis is established, but they have been reported to be present for 7 years.[134] Meningitis has been reported to occur years after apparent total resolution of PDH.[36,401] This situation may result from failure of antifungal agents to penetrate the CNS compartment sufficiently to eradicate the infection fully from this sequestered site.[23,402] Symptoms include headache, decreased level of consciousness, confusion, and cranial nerve deficits in 28 to 56 percent of cases.[437]

Diagnosis is most problematic in patients with meningitis and no features of localized or disseminated infection. It is suspected ante mortem in only 40 percent of cases; symptoms and findings mimic those caused by other granulomatous infections, sarcoidosis,[437] cerebral vasculitis,[384] neoplasms,[193] or conditions leading to normal-pressure hydrocephalus. CSF findings are nonspecific and include mild pleocytosis, elevated protein, and depressed glucose. The diagnosis is confirmed by isolating *H. capsulatum* from CSF, detecting *Histoplasma* antigen or antibody in CSF, or identifying the organism in non-CNS sites. Although the specificity of culture and antigen detection are high, sensitivity is variable. CSF antigen sensitivity is 38 percent in non–HIV-infected patients and 67 percent in HIV-infected patients. CSF antibody sensitivity ranges from 80 to 89 percent, but cross-reactions with *Cryptococcus* occur in 28 percent of cases.[466]

CNS infection in children is unusual and, when seen, usually is reported in association with dissemination[365,370]; in one series,[296] meningitis was found in 62 percent of cases of PDH of infancy. A chronic, progressive infection of the CNS has been reported in a child.[341] Other reports describe isolated meningitis with focal neurologic abnormalities occurring after an acute respiratory illness,[26] cerebellar ataxia that was diagnosed only presumptively as histoplasmosis,[371] and cerebellar and medullary lesions.[421] A child has been described with a symptom complex of cervical lymphadenopathy, CSF pleocytosis, arthritis, and interstitial nephritis.[427]

Presumed Ocular Histoplasmosis Syndrome

The entity termed *presumed ocular histoplasmosis syndrome* consists of a triad of findings: (1) discrete atrophic choroidal scars in the macula or midperiphery (histo spots), (2) peripapillary atrophy, and (3) choroidal neovascularization that can lead to loss of central vision.[60,361] In contrast to the acute endophthalmitis[142] or choroiditis[303] that occurs as a manifestation of disseminated infection, the abnormalities seen with presumed ocular histoplasmosis syndrome occur in the absence of inflammatory changes in the vitreous or anterior chambers.

Commonly diagnosed in endemic areas, the cause-and-effect relationship of the findings in presumed ocular histoplasmosis syndrome and histoplasmosis has been based largely on a weak epidemiologic association with histoplasmin skin test reactivity. The clinical syndrome also occurs in individuals residing in non-endemic regions, however.[301,389,425] Little pathologic evidence exists to support histoplasmosis as its cause.[209,300,326] Only a single report detected *H. capsulatum* DNA in cells of an enucleated eye from an affected patient; however, this report used a nonstandardized polymerase chain reaction–based methodology (see section on molecular diagnosis). Presumed ocular histoplasmosis does not seem to occur in children younger than 10 years, although among patients included in a review of the operative management of this entity were 11 children 12 to 18 years old and one child 7 years old.[408]

ILLNESS CAUSED BY INFECTION WITH *HISTOPLASMA CAPSULATUM* VAR. *DUBOISII*

In patients infected with *H. capsulatum* var. *duboisii*, focal lesions are seen more commonly in bones (usually the femur, ribs, or skull) and skin (cutaneous or subcutaneous). The lungs, gastrointestinal tract, liver, spleen, and lymph nodes rarely are involved. A progressive disseminated form of infection with *H. capsulatum* var. *duboisii* occurs and is associated with pyogranulomatous inflammation involving multiple organs.[65,250,476]

RADIOGRAPHIC FINDINGS

The radiographic findings seen most commonly in children with histoplasmosis are not pathognomonic[211] and may mimic the findings seen in tuberculosis or other granulomatous processes and, in some cases, neoplastic conditions, especially lymphoma.[127] After small or moderate degrees of fungal exposure, the plain chest radiograph is normal in approximately 75 percent of skin test converters.[143,473] Computed tomography (CT) is more sensitive and likely to reveal parenchymal infiltrates that are invisible on plain radiographs. The most common pulmonary parenchymal changes are "soft" single or multiple, poorly defined areas of airspace consolidation[156] often found in the basilar portions of the lungs (Fig. 216–2). They either may fully resolve or may consolidate into granulomata that persist, with or without calcification,

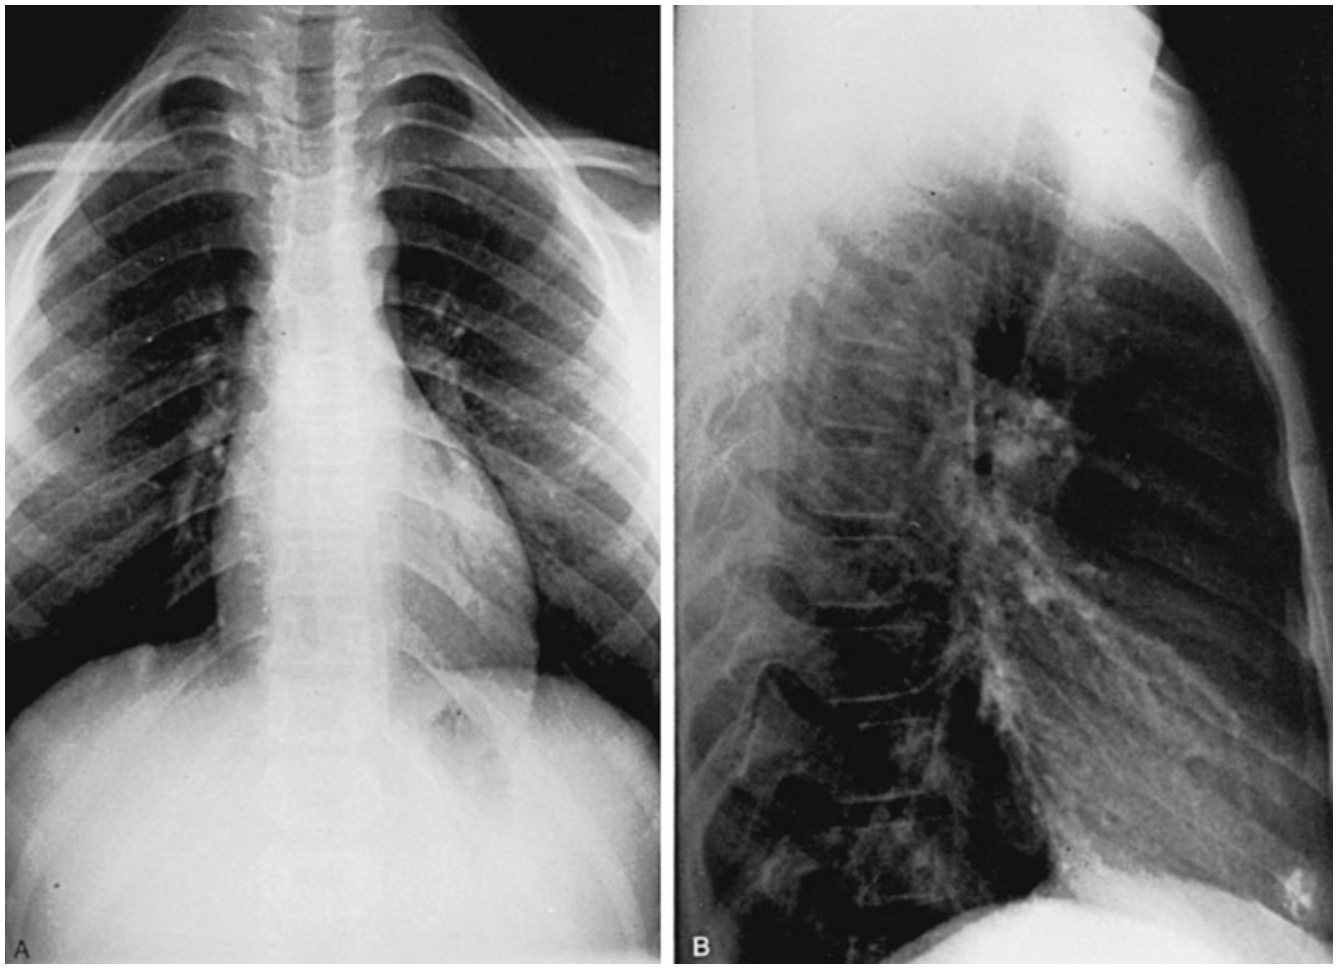

Figure 216–2 **A** and **B,** Chest radiograph of an asymptomatic boy shows in the right lower lobe a calcification overlying the diaphragm between ribs 10 and 11 in the posteroanterior view **(A)** and overlying the apex of the heart in the lateral view **(B)**. These films also showed punctate calcifications overlying the spleen and right axilla (not shown here).

as common findings in residents of or travelers to endemic areas.[299]

The appearance of enlarged hilar/mediastinal nodes, either in association with pulmonary infiltrates or as isolated findings, also is a common radiographic finding of acute pulmonary histoplasmosis. Isolated hilar or mediastinal adenopathy occurs in 20 percent of cases, 80 percent of which are asymptomatic.[67] With CT, low signal intensity within nodes sometimes is shown, although frank suppuration is unusual. Infected nodes may enlarge sufficiently to compress or obstruct adjacent structures. Nodes usually have reached their maximal size at the time of diagnosis and become smaller or return to normal in several months; calcification may, but does not consistently, occur. In infants and young children, clusters of small infiltrates occasionally coalesce into a larger bronchopneumonic lesion.[143] Although small pleural effusions are present in 10 percent of adults with acute histoplasmosis,[468] they occur infrequently in children.[1,327,407] Isolated calcifications may be seen in the spleen or liver months to years after infection. These calcifications result from the self-limited fungal dissemination that occurs during primary infection and often are appreciated as incidental findings in individuals who have lived in endemic regions.

Three distinct chest radiographic patterns have been described in individuals who have had intense exposure to the fungus.[143] Individuals from non-endemic areas initially may have scattered infiltrates that later evolve into "buckshot" calcifications. The second and most common pattern is the presence of smaller, nodular lesions (Fig. 216–3). This form is seen in individuals from endemic and non-endemic areas. Finally, a diffuse miliary or interstitial pattern (Fig. 216–4) may occur, often in a patient with protective immunity.

In PDH, the chest radiograph in adults may show abnormalities in only 25 to 50 percent of patients.[66] Diffuse abnormalities commonly appear during treatment of individuals for whom chest radiographs initially were normal.[355] Diffuse interstitial or reticulonodular infiltrates are present in approximately 50 percent, and localized lesions are present in the remainder. In immunocompromised children, diffuse interstitial infiltrates are the most common radiographic findings; they worsen rapidly and in concert with progressive hypoxemia, especially in patients with HIV infection or patients receiving immunosuppressive therapy.[66] The presence of interstitial infiltrates at admission has been reported in 60 percent of children with PDH of infancy[296] in a Costa Rican series, but chest radiographs were uniformly normal in a series of Indiana patients (M. Kleiman, 2007, unpublished data). Abdominal ultrasound or CT, or both, may show evidence of adrenal enlargement in chronic disseminated disease in adults.[247,480]

Fibrosing mediastinitis caused by histoplasmosis is seen radiographically as pronounced thickening of the mediastinum that often compresses or obstructs the superior vena cava, major

Figure 216–3 CT scan of the chest of a teenage girl from Tennessee complaining of right arm pain when swimming. A nodular density is seen in the periphery of the right lung field *(arrow)*, and the right hilum is enlarged slightly. Serologic tests and needle biopsy of the lesion were nondiagnostic, but excisional biopsy showed necrotizing granulomata with numerous histoplasmal yeast forms.

Figure 216–4 CT scan of the chest of a 16-year-old with a history of recent demolition and renovation in the home. The patient developed fever, cough, and progressive respiratory failure requiring maximal ventilatory support using an oscillator. CT scan shows diffuse interstitial infiltrates and a pleural effusion. A urine *Histoplasma* antigen assay was strongly positive.

TABLE 216–2 Interpretive Guidelines for Laboratory Tests in Children with Acute Histoplasmosis

		Interpretation*	
Test	**Result**	***Normal Host***	***Immunocompromised Host***
Complement fixation antibody assay†	≤1:8	–	(–)
	1:16	+	(–)
	≥1:32	++	++
Immunodiffusion antibody assay†	M bands and H bands negative	–	(–)
	M bands present only	+	+
	H bands present only	++	++
	M bands and H bands present	++	++
Urine antigen‡	Negative	(–)‖	(–)‖
	Positive (low) 0.6-4 ng/mL	+	+
	Positive >4 ng/mL	++§	++§¶
Histologic findings			
Node/mass	Negative	(–)	(–)
Infected organ	Granulomata, no yeast form	++	++
	Granulomata, yeast forms	+++	+++
Bone marrow/blood	No yeast forms	(–)	(–)
	Yeast forms seen	+++¶	+++¶
Culture any site	Negative	(–)	(–)
	Positive	+++	+++
Bone marrow/blood culture	Positive	+++¶	+++¶

**(–), does not exclude infection; –, recent infection unlikely (≤5% probability); +, recent infection possible, ++, strongly suggestive of acute or recent infection; +++, confirms current infection.*
†Seroconversion confirms acute/recent infection.
‡Positive urine antigen tests should be confirmed, especially if additional laboratory examinations do not strongly support active infection.
§Compatible with early infection or disseminated infection.
¶Strongly suggestive of progressive disseminated infection or acute primary infection.
‖Progressive disseminated infection unlikely.

bronchi, esophagus, or other critical structures. It can be found in a localized pattern that frequently contains calcification. It must be carefully differentiated from idiopathic fibrosis or fibrosis not induced by infection, which may cause similar symptoms.[373] CT and magnetic resonance imaging help differentiate active inflammation from fibrosis and aid in monitoring progression.[343,347]

DIAGNOSIS

Several laboratory tests play key roles in establishing the diagnosis of histoplasmosis. Although each has value, their optimal use depends on an understanding of their differing sensitivities and specificities in various clinical settings.[436] Table 216–2 provides general guidelines for their interpretation.

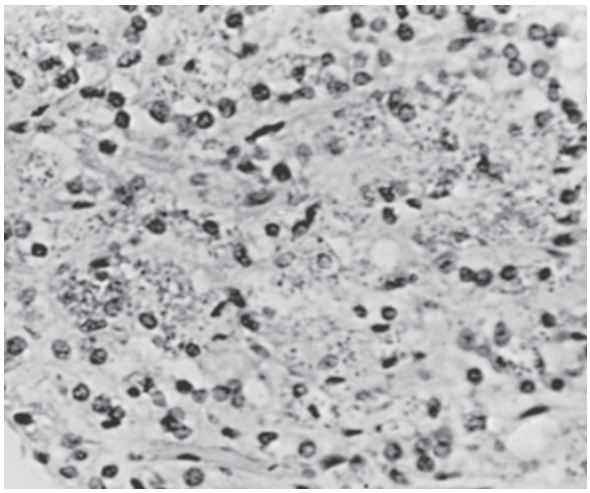

Figure 216–5 Histoplasmosis of the adrenal gland illustrating the histiocytic response with numerous cells of *Histoplasma capsulatum* within the cytoplasm (hematoxylin and eosin, ×52).

TABLE 216–3 Sensitivity of Diagnostic Studies in Different Histoplasmosis Syndromes

Test	Acute Pulmonary	Subacute Pulmonary	Progressive Disseminated
Antigen (%)	75-81	19-34	91-92
Antibody (%)	40-80	78-89	63-81
Histopathology (%)	47	9-38	12-43
Culture (%)	34	9-15	75-85

ORGANISMS SHOWN ON HISTOLOGY

In clinical and epidemiologic settings compatible with histoplasmosis, observation of 2- to 4-μm typical yeast forms in histopathologic specimens is strong supportive evidence of histoplasmosis (Fig. 216–5). Rarely, typical yeast may be observed but result from past infection.[436] Care must be taken to differentiate *H. capsulatum* from the intracellular pathogens *Leishmania donovani* and *Toxoplasma gondii*, small variants of *Blastomyces dermatitidis*, endospores and young spherules of *Coccidioides immitis*, *P. marneffei*, and the yeast forms of *Cryptococcus neoformans*. Giemsa and hematoxylin and eosin stains show intracellular yeasts in sputum, blood smears, bone aspirates, and biopsy specimens. The Gomori methenamine silver stain is the most sensitive reagent and has the advantage that calcification artifacts dissolve during the staining procedure[297,423]; its disadvantage is that it does not provide adequate cellular detail.

Although observation of typical yeast forms in specimens provides important diagnostic information, it requires either a body fluid with a large fungal load or tissue that must be obtained by biopsy. Test sensitivity (Table 216–3) is better in disseminated forms of histoplasmosis, in which yeasts are shown easily in bone marrow, in affected tissue, and often in blood smears.[185] It is less sensitive in self-limited primary infections,[477] including acute pulmonary infection following heavy exposure, in which cytology and histopathology sensitivities are 25 percent.[436] Histopathologic demonstration of typical yeast forms was 18 to 62 percent in three large Indianapolis outbreaks.[436] The technique usually is unrewarding in patients with calcified and fibrotic lesions.[253,258,477]

CULTURE

Normally, sterile specimens and minced or homogenized tissue can be inoculated onto suitable media, such as brain-heart infusion agar, inhibitory mold agar, Sabouraud's glucose (dextrose) agar, and enriched broth such as brain-heart infusion broth. The optimal method for recovery of *H. capsulatum* from blood is the lysis-centrifugation technique, which lyses white blood cells, inhibits complement, and prevents coagulation; after processing is completed, the resulting concentrate is transferred to culture media. Specimens from nonsterile sites should be cultured on media that inhibit bacteria and saprophytic fungi; non-cycloheximide–containing media also should be used to permit the growth of other opportunistic pathogens.[423] Cultures are incubated aerobically at 25° C to 30° C and held for at least 12 weeks before being considered negative. Most isolates grow in 3 to 4 weeks.[456] Use of the lysis-centrifugation system for blood culture has shortened the time for identification of a positive culture from approximately 16 days to 9 days.[31,311] The fungus is recovered in its mycelial form, and confirmation of identification requires that it be converted to the yeast form, be shown to produce the H or M exoantigen, or react positively with a specific nucleic acid probe (AccuProbe; Gen-Probe, Inc., San Diego, CA).[384] Laboratory-based rapid identification and differentiation of fungal pathogens using polymerase chain reaction methodology have been developed, but they are not yet available in clinical laboratories.[325,328]

Recovery of *H. capsulatum* from a clinical specimen obtained from a symptomatic patient confirms the diagnosis of active histoplasmosis. The only exception is the infrequent event in which an incidental granuloma is found to be culture-positive, but histoplasmosis is not a likely cause of the clinical symptoms. The sensitivity of culture depends heavily on the severity of the infection and the fungal burden (see Table 216–3).[478] In primary acute, self-limited histoplasmosis, 40 percent of patients have positive cultures when obtained from sputum (23%), BAL fluid (39%), lung, and extrapulmonary sites (37%).[436] In contrast, cultures are positive in 75 to 85 percent of adults with PDH. In the latter patients, sites from which *H. capsulatum* commonly is recovered include the lower respiratory tract, blood, bone marrow, CSF, liver, spleen, skin lesions, and synovium.[12,296] The highest yield in PDH is from bone marrow, which is positive in 75 percent of instances.[358,430] Urine is positive in 40 to 70 percent, and sputum is positive in 60 percent.[378] In adults with PDH, rates of positive lysis-centrifugation cultures of peripheral blood are 90 to 100 percent in acute dissemination and 50 percent in subacute dissemination; positive cultures are very rarely seen in chronic dissemination.[247]

In forms of pulmonary histoplasmosis other than low-inoculum infection, sputum may be a reliable site for recovery of the organism in culture, but not the best choice of diagnostic methods. High-inoculum infection after exposure to heavily contaminated sites usually results in moderate-to-severe infection in which patients seek medical attention within 2 weeks of inhaling spores. In these instances, the fungal burden is high, and respiratory secretions or lung tissue may show the organism, allowing the diagnosis to be made promptly; culture also may be positive, but the 2- to 4-week delay in achieving growth renders culture less desirable than other diagnostic methods, especially antigen detection. In adults with chronic cavitary pulmonary infection, sputum culture is positive in 50 to 85 percent of instances.[144,434] The sensitivity of sputum culture may be increased with multiple sampling.[454]

Bronchoscopy with BAL may be helpful in patients with pulmonary disease. In a study of bronchoscopy in 71 adults, BAL was positive in only 4 percent of individuals with a single pulmonary nodule, but it increased to 55 percent in the remainder of the patient group. The highest yield of 88 percent (7 of 8)

was in patients with infiltrates or cavitary disease.[327] Bronchoscopy did not seem to be helpful in evaluating patients with adenopathy, chronic pleural effusion, or bronchopleural fistulas. In children, culture plus staining of BAL fluid has been rewarding in diagnosing high fungal burden infection in patients with HIV, but it is less sensitive than lung biopsy in other immunocompromised patients, especially patients receiving chemotherapy for reticuloendothelial malignancy. In patients with mediastinal granuloma and fibrosis, cultures were positive in only 3.8 to 10 percent.[91,248]

Cultures usually are negative in rheumatologic manifestations of histoplasmosis, such as arthritis, erythema nodosum, erythema multiforme, and pericarditis, because these reactive manifestations generally occur months after low-burden infection in patients whose acquired cellular immune response has controlled fungal replication. Isolated CNS infection is uncommon in children, but meningitis was reported to occur in 25 of 40 cases of PDH of infancy; yeasts were observed in the CSF, and *H. capsulatum* was recovered in culture from 4 patients.[296] Recognizing CNS infection in adults is difficult, unless concurrent dissemination, which occurs in approximately 20 to 40 percent of cases, is present.[434,437,466] Invasive procedures sometimes are needed to confirm the diagnosis. Culture is positive in 27 to 65 percent of CSF specimens and in 50 percent of cultures obtained from other sites in adults.[434] The number of organisms in CSF is small, so the yield is improved substantially by culturing large volumes (10 to 20 mL in adults) on at least two occasions.[466] In isolated CNS infections, culture is usually unrewarding.

ANTIBODY AND ANTIGEN DETECTION

The serologic methods that are used most commonly for the diagnosis of histoplasmosis are immunodiffusion (ID) and CF. These tests are useful because, despite documentation of skin test reactivity in 50 to 70 percent of young healthy adults residing in an endemic area, seropositivity in this population has been found to be 0.5 percent by ID and 2 percent by CF using the mycelial antigen, and 4 percent with the yeast antigen.[453] These tests serve to make the probability of histoplasmosis high in a patient with a compatible illness and elevated titers.

Both methods have equal sensitivity (75 to 85%); however, ID is slightly more specific (>95% versus 85 to 90%).[430,431] In immunocompetent patients, either or both tests are positive in 95 percent of patients with acute primary pulmonary infection. CF titers often become positive 2 to 4 weeks earlier, usually by 4 to 6 weeks after exposure.[430] In patients with CF antibody, 25 percent have a negative ID result; only 1 percent of patients reactive by ID are CF-negative.[75] When the ID test is reactive, however, it remains so for a longer time. In addition to the 4- to 6-week lag in developing elevated titers, an important limitation of both serologic assays is their reduced sensitivity in immunosuppressed patients. Only 50 percent of immunosuppressed children and adults with disseminated histoplasmosis are seropositive.[76,176] Of immunocompetent infants and young children with severe PDH during infancy and early childhood, 93 percent had elevated antibody titers.[296]

Cross-reactivity with other fungal antigens affects CF and ID assays.[456] CF cross-reactivity occurs most commonly with *B. dermatiditis* (40%) and C. *immitis* (16%).[456] Cross-reactions also rarely occur with candidiasis, tuberculosis, aspergillosis, and cryptococcosis.[253,456] Cross-reactions with blastomycosis are common in the histoplasmosis CF assay, in which titers of 1:8 to 1:16 frequently are observed[205]; comparison of results of a single serum sample performed in the same assay often reveals CF antibody concentrations to be higher for the homologous infection. In these instances, ID tests sometimes are corroborative because the blastomycosis ID method is more specific and less likely to cross-react in histoplasmosis.[239] ID has been noted to show false-positivity in 5 percent of other fungal infections, however.[456] Cross-reactivity also is seen occasionally in patients with chronic cavitary tuberculosis, although simultaneous infection with tuberculosis and fungal pathogens can occur.[125,456] Variability in the specificity of commercial reagents has been reported to cause false-negative results.[230]

Complement Fixation

CF uses sensitized sheep red blood cells, killed whole *H. capsulatum* yeast cells, and histoplasmin, a soluble mycelium-form filtrate antigen.[275] In a common-source outbreak of acute primary pulmonary histoplasmosis, the titer becomes positive in 6 percent of individuals at 3 weeks, 73 percent at 4 weeks, and 77 percent at 6 weeks.[75,456] With resolution of infection, titers decrease to 1:8 to 1:16 within 4 to 6 months and become undetectable (<1:8) by 9 months in most instances. Reported sensitivities for a single titer vary from 70 to 95 percent and depend on the threshold for considering a result positive. Single titers of 1:32 performed by an experienced laboratory are strong supportive evidence of acute or recent infection, especially when the accompanying clinical symptoms are compatible. One report[398] showed that 12 of 28 patients with non-*Histoplasma* febrile pneumonia had false-positive CF titers of 1:32 or greater, so other laboratory and clinical data need to be considered.

The presence of a fourfold increase between acute and convalescent sera is the best serologic evidence of recent infection. The individual yeast (CF-Y) and mycelial (CF-M) phases can be measured. CF-Y is more sensitive than CF-M for recent or active infection. In a series of 11 children with acute pulmonary histoplasmosis, CF-Y was 1:32 or greater in 9, but CF-M was 1:32 or greater in only 3 children.[487] In endemic regions, background low-titer CF serologic reactions may be present in 5 to 15 percent of adults,[283] but they have been reported to occur in 30 percent.[135,143,247,457]

The serologic response seems to correlate with the severity of disease in immunocompetent individuals with acute infection.[429] In an outbreak of histoplasmosis, seropositivity was 90 to 100 percent in severe acute histoplasmosis, 86 percent in moderate histoplasmosis, 75 percent in mild histoplasmosis, and 18 percent in asymptomatic histoplasmosis.[223] Twenty-five percent of patients with acute histoplasmosis have CF titers that could be considered borderline positive, between 1:8 and 1:16.[75] Although they may result from previous infection, these titers should not be disregarded if clinical symptoms suggest acute infection. In adults with chronic pulmonary histoplasmosis, the CF titer is greater than 1:32 in almost all patients.[199] In children who present with middle mediastinal masses caused by histoplasmosis, 67 percent have CF titers of 1:32 or greater.[127]

The serologic diagnosis of patients with isolated meningitis caused by *H. capsulatum* often is problematic[466] because no single test exhibits high sensitivity. CF and ID can be positive in CSF, but half of patients with other chronic fungal meningeal infections may show false-positive results.[322,455] CF-M antibody seems to be the most sensitive and specific test for the diagnosis of meningitis caused by histoplasmosis. In one study, no false-positive CSF CF-M titers occurred in patients with cryptococcal meningitis, but CF-Y was false-positive in 5 of 18 patients.[455] Individuals with fibrosing mediastinitis or mediastinal granuloma generally have negative or very low levels of CF antibody.[429]

Immunodiffusion

The micro-ID method[204] detects precipitins (reported as bands) against the H and M glycoprotein antigens of *H. capsulatum*.[275,457] The M band is present in 25 percent of infections by the fourth week of infection and in 50 to 86 percent by the sixth week.[25,75,315]

It can persist for 18 to 36 months after recovery, but eventually becomes nonreactive. In endemic areas, in which serologic surveys show that 24 percent of healthy adult blood donors have CF-Y titers of 1:8 or 1:16, ID serology is positive in less than 1 percent.[135] Because it is more specific, ID can be of value to confirm the diagnosis of histoplasmosis in patients with *Histoplasma* CF titers in the borderline 1:8 to 1:16 range.[424]

The H band is present infrequently in patients with histoplasmosis; when seen, it is transient, and its presence suggests active infection.[143] In patients with active pulmonary histoplasmosis, one half to three fourths have an M band alone. The H band is present in only 10 to 20 percent of acute infections,[12,148,205,457] and only 10 percent of individuals have M and H bands present.[12] The latter finding is highly suggestive of active histoplasmosis.[204] The H band is detected less consistently in children with histoplasmosis.[427] In adults with disseminated disease, both bands are present in 25 percent of individuals.[12] The M band has been detected in 52 percent and 57 percent of patients with chronic pulmonary and disseminated disease.[148] The ID test is not approved for use in CSF specimens and has not been evaluated as a test for the diagnosis of meningitis.[436]

Antibody Detection by Radioimmunoassay and Enzyme Immunoassay

Antibody detection methods that use radioimmunoassay and enzyme immunoassay have been developed. They can detect antibody slightly earlier than is possible with ID and CF, can detect antibody to histoplasmin and yeast antigens, and can measure IgG-specific and IgM-specific *Histoplasma* antibodies.[75,220,315,457,461,501] The disadvantages of cross-reactivity,[456] complexity and cost of the methodology, poor reproducibility, and negligible clinically relevant superiority over standard serologic methods have restricted their commercial availability. Neither radioimmunoassay nor enzyme immunoassay is recommended for diagnosis.

Antigen Detection

The development in 1986[462] and further refinements of the *Histoplasma* antigen assay fill an important gap in laboratory diagnosis. When performed on serum, urine, or other selected body fluids, antigen detection provides rapid, accurate, noninvasive, diagnostic information for the most serious manifestations of disease. It is especially useful for the evaluation of infection in an immunocompromised host, in whom serologic methods often are negative.[462] Although evaluated almost exclusively in adults, antigen detection occupies the same diagnostic niche for managing infection during childhood.

Antigen detection is most sensitive in infections accompanied by high fungal burdens.[478] These include progressive disseminated infections in intensely exposed or immunocompromised hosts and primary pulmonary infection, in whom antigen detection reflects the early hematogenous dissemination that occurs before it is aborted by the cellular immune response. In addition to its usefulness in diagnosis, antigen assay provides a parameter with which to assess the adequacy of response to therapy and, after treatment, a monitor to predict relapse in patients who are at high risk for recurrence.[444,448-450]

The sensitivity of urine antigen detection (see Table 216–3) in patients with acute primary pulmonary infection is 75 to 81 percent, with the highest rates seen in patients tested within a few weeks of exposure, in patients with intense exposure, and in patients with extensive pulmonary involvement.[434,477] Sensitivity is less in subacute pulmonary and chronic cavitary infection in adults. The sensitivity of antigen detection is very high in progressive disseminating forms of histoplasmosis. In adults with disseminated histoplasmosis, antigen is detected in 91 to 92 percent of immunosuppressed and non-immunosuppressed patients and in 95 percent of patients with AIDS.[434] In 22 children with PDH, urinary antigen testing was positive in 100 percent.[119] From 1991 through 2006 at Riley Hospital for Children in Indianapolis, urine antigen testing was positive in all instances of disseminated histoplasmosis (M. Kleiman, unpublished data).

Measurement of antigen initially was developed using radioimmunoassay technology and was replaced with an enzyme-linked immunoassay.[104] Two generations of refinement of the enzyme-linked immunoassay have greatly increased its sensitivity and specificity. The results of these semiquantitative assays were reported in "antigen units" that were determined by comparison with a negative control. Assay-to-assay variability with radioimmunoassay and enzyme-linked immunoassay required that sequential specimens were stored and retested in the same assay to determine whether a significant change had occurred in response to therapy. A fully quantitative, third-generation assay, introduced in 2006, has eliminated this need, but has altered recommendations for follow-up of patients using antigen assay.

Although *Histoplasma* antigen may be detected in serum, the sensitivity is less than that of urine. Of immunosuppressed adults with disseminated histoplasmosis, antigen was found in 50 percent of serum samples and 92 percent of urine specimens. Similarly, in patients with disseminated histoplasmosis complicating AIDS, antigenuria was seen in 95 percent versus 85 percent in serum.[462,477] Antigen often is found in BAL fluid of patients after intense exposure and in immunocompromised patients with hematogenous dissemination and lung involvement.[447,451] In adults with isolated meningitis, antigen detection in CSF may be the sole basis for confirming the diagnosis.[462,463,466] The range of antigen positivity in all cases of meningitis is 40 to 66 percent; the highest rates are found in severe infections with heavy fungal burdens, especially infections that occur in immunosuppressed patients.[466] In patients with clinical findings suggestive of meningitis but in whom antigen is not present in CSF, antigen found in extrameningeal sites sometimes can confirm the diagnosis.

Antigen levels in blood or urine decrease during treatment and should clear completely in infections that are treated adequately.[459] Conversely, the persistence of moderate antigenuria has been associated with a risk of recrudescence. This risk has been shown best in patients with AIDS and histoplasmosis, in whom significant antigenuria often persists after cessation of therapy.[448,449,465] Monitoring urine antigen in such patients has shown that increasing urine antigen concentrations foretell recurrence.[448] The sensitivity of the antigen assay is high, however, and the pattern of antigen clearance has not been established firmly in other clinical settings. Infants with PDH who have been treated adequately, have had a good clinical response, and in whom urine antigen levels have substantially decreased during therapy often have persistence of low levels of urine antigen after completion of amphotericin B therapy. In these infants, all of whom were immunocompetent, no relapse has been observed after treatment with a total dose of 30 mg/kg of amphotericin B (M. Kleiman, 2007, unpublished data). Residual excretion of urine antigen continues to decrease and eventually ceases; monitoring is recommended to confirm resolution.[119]

With the introduction in 2006 of the third-generation quantitative *Histoplasma* antigen method,[436] interassay variability was reduced by extrapolating antigen concentrations from a calibration curve that was created using the results of assays of known quantities of antigen. Because this calibration curve is linear at values less than a concentration of 40 ng/mL, measurements in excess of this are reported as greater than 39 ng/mL, and changes cannot be determined until they fall below this value. Although the quantitative method has increased precision and eliminates the need to evaluate current specimens in tandem with earlier specimens,[436] as required in earlier enzyme-linked immunoassays, it also has necessitated changes in recommendations

for using the antigen assay to monitor the effectiveness of therapy.[448]

Although urine samples could be used conveniently for this purpose with the older, semiquantitative methods, urine antigen concentrations measured with the quantitative assay often exceed the upper end of the calibration curve, especially in disseminated infections. If urine concentrations are found to exceed 39 ng/mL, monitoring patients for adequacy of response is more informative if serum antigen concentrations are initially followed because maximum serum concentrations are lower than the concentrations of concomitant urine samples and more likely to fall within the range in which differences in concentration could be measured accurately. When antigenemia is resolved, urine concentrations can be followed with the quantitative assay. Testing should be performed at 3- to 4-month intervals during treatment, at the end of therapy, if symptoms recur, and periodically for another year to monitor for relapse.

Antigen concentration decreases during effective therapy. If the baseline value is less than 20 ng/mL, antigen concentration should decline at least 3 ng/mL during the first month and during subsequent 3-month intervals. If the baseline antigen is greater than 20 ng/mL, the concentration should decrease by at least 15 percent during similar time periods. Failure of the antigen concentration to decline or documentation of progressive increase may indicate treatment failure. It is unknown whether treatment should be continued until antigenuria clears completely; some patients who have stopped therapy despite having low levels of antigenuria (<4 ng/mL) seem to have done well.

Cross-reactions in the *Histoplasma* antigen assay occur in paracoccidioidomycosis, African histoplasmosis caused by *H. capsulatum* var. *duboisii*, blastomycosis, and infections caused by *P. marneffei*.[472] Because these infections have distinguishing epidemiologic and clinical features, and supportive diagnostic tests may aid further in differentiating them from histoplasmosis, cross-reactions usually create little difficulty in interpreting positive test results. Treatment is similar for these endemic mycoses, so appropriate therapy may be given while confirmatory data are sought. Blood, urine, BAL fluid, and CSF specimens yield reliable results in the antigen assay. False-positive results may occur with pleural fluid and other high protein–containing body fluids, such as peritoneal, synovial, and pericardial fluids; these fluids and tissue specimens are unsuitable specimens. The test is commercially available (MiraVista Diagnostics, Indianapolis, IN).

SKIN TESTING

A skin test for histoplasmosis has been a valuable epidemiologic and investigational tool, but has little diagnostic usefulness[143]; it no longer is commercially available. Skin testing is performed with standardized histoplasmin antigen prepared from mycelial-phase culture filtrate. After intradermal administration, an area of induration of 5 mm or larger at 48 hours is considered positive and indicative of cellular immunity.[275] Skin test reactivity usually develops within 2 to 4 weeks after infection.[123] In chronic pulmonary disease, including cavitary disease, the skin test is positive in three fourths of patients.[123] In contrast, individuals with disseminated disease seldom have positive results.[13] Eighty percent of children who are older than 12 years and reside in endemic areas may be reactive.[429] Cutaneous reactivity may diminish, wax, or wane with re-exposure,[143,429,494] but it usually persists indefinitely in most individuals. The problem of serologic boosting by skin testing also has limited its diagnostic use.[12,13,39,173,203,206,275] Cross-reactions occur in patients with blastomycosis and coccidioidomycosis.[105-107]

MOLECULAR METHODS

Epidemiologic studies have used restriction fragment length polymorphisms of DNA. Nucleic acid–based and genome-wide approaches have been used to explore the genetic diversity of the pathogen.[207,420] Molecular methods also have been used to examine strains recovered from patients who have failed therapy[464] and to identify relatedness in isolates recovered after organ transplantation.[235]

Sensitive and specific oligonucleotide probes for yeastlike fungi have been developed and hold promise for application to clinical specimens.[238] Molecular methods that reliably detect *H. capsulatum* in clinical samples have yet to show superiority, however, to standard diagnostic tests.[58] Polymerase chain reaction methodology has been evaluated for identifying *H. capsulatum* in tissue and body fluids, but false-negative results were encountered in a third of specimens.[30] Polymerase chain reaction methodology used with clinical specimens (urine, serum, BAL, CSF) containing urine antigen showed specificities of 80 to 100 percent, but sensitivities of only 0 to 22 percent.[436]

TREATMENT

Most patients with symptomatic histoplasmosis recover without receiving antifungal therapy.[143] Treatment almost always is required for patients with severe symptoms, prolonged illness, or evidence suggestive of progressive dissemination. Evidence-based, consensus practice guidelines for treatment of histoplasmosis have been published[467] and revised in 2007[452] to include recommendations for treatment of children.

No controlled therapeutic trials have been conducted in children. Chronic pulmonary infection and subacute and chronic dissemination syndromes rarely occur in children. Table 216–4 summarizes recommendations for treating the clinical manifestations of histoplasmosis seen most frequently in children. These recommendations have been derived from anecdotal published reports, clinical experience, and extrapolation from experience in adults. Surgical management of histoplasmosis rarely is indicated.

MEDICAL MANAGEMENT FOR MANIFESTATIONS REQUIRING ANTIFUNGAL THERAPY

Because most patients with light or moderate exposure to fungal spores recover without treatment, the first decision is to determine whether to observe the patient carefully or to begin administering an antifungal agent. The criteria that are key to making this decision are clinical assessment of the character, severity, and duration of symptoms, and assessment of the adequacy of the patient's cellular immunity. When treatment with antifungals has been elected, a regimen is selected that is appropriate for the initial findings. Manifestations of histoplasmosis in children that most often require antifungal treatment are severe or protracted symptoms resulting from acute primary pulmonary infection, mediastinal adenitis that is causing compression of adjacent structures, disseminated infection of infancy,[119,296] and infection in an immunocompromised host.[1,388] Treatment recommendations are summarized in Table 216–4.

The antifungal agents that play primary roles in medical management include amphotericin B deoxycholate,[357] liposomal amphotericin B,[187] amphotericin B lipid complex,[316] and itraconazole.[93,458] Amphotericin B is fungicidal for *H. capsulatum*, whereas itraconazole is fungistatic. Combinations of the two agents are not synergistic. Based largely on the results of its superiority in animal studies[68] and its faster clearance of fungemia in patients

TABLE 216–4 Summary of Treatment Recommendations for Children with Histoplasmosis

Manifestation	Treatment	
	Severe Illness	***Moderate or Mild Illness***
Acute pulmonary	AmB,* 1-2 wk, then Itr for 12 wk†; use of concomitant steroids is controversial	Symptoms <4 wk, none; persistent symptoms for >4 wk, Itr for 6-12 wk
Disseminated (non-HIV) ± meningitis	AmB,‡or AmB for 2 wk, then Itr for 6 mo‡	Itr† for 6-8 mo or same as for severe§
Disseminated (with HIV)	AmB,‡¶ or AmB followed by Itr§	Same as for severe; Itr secondary prophylaxis if immune dysfunction persists (see text for criteria)
Meningitis, isolated	AmB¶ for 3 mo, then Itr for 12 mo	Some as for severe because of poor outcome
Fibrosing mediastinitis	Itr for 3 mo¶	Same as for severe
Pericarditis	Pericardial drainage for severe tamponade + NSAID for 2-12 wk**	NSAID for 2-12 wk
Rheumatologic	NSAID for 2-12 wk	Same as for severe
Compression of contiguous structures by mediastinal adenitis/granuloma	Prednisone 2 mg/kg/day, concurrent Itr (see text)	

**Amphotericin B deoxycholate is preferred, 1 mg/kg/day.*
†In severe manifestations, itraconazole may be given at 150% of the recommended dose in three divided doses for the first 3 days of treatment only. Itraconazole levels are recommended for severe infections, and in patients in whom clinical response is suboptimal. Serum levels of 2 μg/mL are recommended when steady state is reached (approximately 2 weeks). Itraconazole dose is 5 to 10 mg/kg/day divided twice a day.
‡If amphotericin B is used for the entire course of treatment, 30 to 40 mg/kg should be given over 4 to 6 weeks.
§Therapy should continue until Histoplasma *urine antigen concentrations are stable and <4 ng/mL; prolonged low-level excretions may persist (see text).*
¶Liposomal amphotericin B (3 to 5 mg/kg/day) may be superior to amphotericin B deoxycholate in patients with HIV (see text).
¶Probably ineffective if fibrotic; when granulomatous mediastinitis could be present, it may be considered.
***Prompt administration of NSAID may obviate need for drainage in non–life-threatening manifestation of pericarditis.*
AmB, amphotericin B; HIV, human immunodeficiency virus; Itr, itraconazole; NSAID, nonsteroidal anti-inflammatory drug (indomethacin 1 to 3 mg/kg/day).
Modified from Wheat, L. J., Freifeld, A., Kleiman, M. B., et al.: Practice guidelines for management of patients with histoplasmosis. Clin. Infect. Dis. 45:807-825, 2007.

with AIDS,[187] amphotericin B is more effective for severe disease than itraconazole.[458] Amphotericin B is used most commonly as "induction" therapy; after substantial improvement has occurred, it is stopped, and step-down therapy with itraconazole is used to complete treatment. Monotherapy with itraconazole is effective for treating patients who have mild or moderately severe symptoms. In addition to regimens that are used to treat acute infections, suppressive (secondary prophylactic) regimens have been developed for treating patients with AIDS because the rate of relapse is high if antifungal treatment is stopped, and immune function has not been improved by HAART.[447] Primary prophylactic regimens also have been developed for use by patients with AIDS who live in highly endemic areas.[267]

Chapter 252 contains a detailed discussion of the antifungal agents used to treat histoplasmosis. Amphotericin B deoxycholate usually is well tolerated and very effective in children. Its lipid formulations, although less nephrotoxic, are substantially more expensive.[395] Liposomal amphotericin B is the best evaluated of the lipid preparations. A comparative trial of amphotericin B deoxycholate and liposomal amphotericin B in adults with disseminated histoplasmosis and AIDS showed faster improvement and lower mortality rates with the liposomal preparation.[187] Liposomal and standard amphotericin B formulations clear fungemia faster than itraconazole does.[440]

If amphotericin B is used as monotherapy for severe or disseminated infection in a normal or immunocompromised host, a dosage of 1 mg/kg/day administered for 4 to 6 weeks is recommended. Failures of 30 and 35 mg/kg total dose have been reported in PDH of infancy,[296] and because relapse has been observed in immunosuppressed patients,[176] close follow-up, preferably with monitoring of urine antigen concentrations, is required after completion. When amphotericin B is used as induction therapy in severely ill children, it should be continued for 2 to 4 weeks and until substantial improvement in clinical and laboratory findings is achieved. Short courses of therapy for PDH of infancy have been successful.[120,229,241] One report described cure in five infants[120] (only two with microbiologic confirmation and another in which PDH was highly probable) with an initial dose of 0.25 mg/kg, 0.5 mg/kg given on the second day, and 1 mg/kg/day administered for 7 to 11 days thereafter. Insufficient data are available to recommend short courses of amphotericin B for treatment as monotherapy, and because of the availability of itraconazole, such regimens seldom are needed.

Itraconazole generally is well tolerated by children and, in adults, is more effective[142] and less likely to induce resistance than the other azoles.[112,128,166,169,283,318,379,416] Although clinical trials using itraconazole have not been conducted in children, clinical experience has confirmed its effectiveness as the oral azole of choice.[452] The erratic bioavailability of the capsule form can be improved when it is taken with liquids with low pH and caloric content (concomitant food and a cola drink are recommended).[181] Serum levels should be monitored,[138] particularly if symptoms persist. The liquid solution of itraconazole is better absorbed, but may have adverse gastrointestinal effects that affect compliance. The liquid solution is better absorbed when taken on an empty stomach. The 90 percent minimal inhibitory concentration (MIC_{90}) of itraconazole for *H. capsulatum* is less than 0.01 μg/mL; the optimal therapeutic level has not been determined, but serum concentrations greater than 2 μg/mL should be effective, easily achieved, and well tolerated.[168] With its long half-life, serum concentrations vary little after steady state is achieved (approximately 2 weeks). When used as monotherapy, or as step-down treatment after amphotericin B induction to treat mild to moderately severe infections in adults, a loading dose consisting of 150 percent of the total daily dose is recommended for the initial 3 days of therapy. Itraconazole is quite expensive. As with the other azoles, important drug-drug interactions need to be considered in patients receiving agents known to affect excretion of the azole or whose excretion is affected by the antifungal.

Fluconazole was less effective than itraconazole in treating adults with chronic pulmonary histoplasmosis[265] or disseminated histoplasmosis.[464] It also has been associated with relapse in disseminated infection,[465] is less effective than itraconazole for secondary prophylaxis in adults with disseminated infection,[267] and clears fungemia more slowly in adults with disseminated

infection than itraconazole.[444] Fluconazole is recommended for use in patients who either do not tolerate itraconazole or fail to absorb it. When fluconazole is used, careful follow-up with urine antigen monitoring is needed to detect relapse. Because itraconazole does not enter the CSF easily, fluconazole may be considered in patients with CNS infection. The relationship between CSF concentrations and outcome has not been determined, however.[467] Antagonism is a concern when fluconazole is used in conjunction with amphotericin B to treat meningitis.[231] Fluconazole is reliably absorbed and metabolized, and drug monitoring seldom is needed.[465]

Ketoconazole is less well tolerated than either itraconazole or fluconazole.[35,88,170,233,406] It is reasonably effective in adults with chronic pulmonary infection[94,233,282,375] and in patients with disseminated infection, although relapse is common.[330] In histoplasmosis complicating AIDS, the response to ketoconazole was only 9 percent versus 74 to 88 percent with amphotericin B and 85 percent with itraconazole.[284,411,433] Ketoconazole is inexpensive and may be an alternative consideration for treatment if high cost precludes the use of itraconazole.

The newer azoles, voriconazole and posaconazole, have activity against *H. capsulatum* in vitro. Posaconazole has shown greater activity[446] and seems to be more active in experimental models.[68] Resistance that seems to have been induced by fluconazole when used in patients with AIDS also was accompanied by increase in MIC values to voriconazole,[446] suggesting that resistance may emerge during treatment with voriconazole.[445] Voriconazole[4,121,175,281,404] and posaconazole[336] have been effective in isolated reports describing differing manifestations of infection. These agents and fluconazole remain second-line alternatives to itraconazole.[62,320,452] If these agents are elected for use, therapeutic drug monitoring is recommended.[452] Echinocandins have been examined in vitro with conflicting results; human data are lacking.

Primary Pulmonary Infection

Primary pulmonary histoplasmosis that occurs after intense exposure to spores may result in life-threatening illness with high fever, diffuse pulmonary infiltrates, hypoxemia, and adult respiratory distress syndrome.[99,143,145,432,467] Infection of this severity should be treated promptly, and induction with amphotericin B is recommended until substantial clinical improvement occurs. Only anecdotal evidence indicates that concomitant use of corticosteroids may be beneficial in treating patients with severe inhalation and adult respiratory distress syndrome.[150,197,397,490] After improvement results from amphotericin B induction, itraconazole should be continued for at least 3 months. In patients who may not appear as ill, but in whom laboratory or clinical evidence is suggestive of progressive primary dissemination, empiric therapy should be initiated.

Patients without respiratory distress but in whom severe systemic complaints, such as high fever, fatigue, and weight loss, persist for 2 to 4 weeks or longer also are candidates for antifungal therapy. In these instances, firm criteria to guide the timing of this decision are not established, and treatment must be individualized. Still, as observed when amphotericin B was the only effective treatment, and its toxicity and inconvenience resulted in deferring therapy for longer than currently practiced, a significant proportion of these symptoms could be expected to undergo spontaneous resolution. The convenience of oral antifungal agents renders the decision less problematic because these protracted but mild to moderately severe symptoms may be treated with itraconazole. Itraconazole should be used for at least 6 weeks in these instances (see Table 216–4). No clinical studies have been conducted to show whether treatment shortens the duration of symptoms or prevents later complications.[452]

Mediastinal Adenitis

One of the most common initial presentations is mediastinal adenitis that is associated with acute pulmonary infection. In this setting, affected nodes enlarge, coalesce and compress, or obstruct adjacent structures. Bronchi and the trachea are most often affected; less commonly, the superior vena cava and esophagus are affected. The phrenic or recurrent laryngeal nerves rarely are affected. Symptoms usually associated with airway compression are cough, mild tachypnea, exertion with activity, wheezing, and nonpleuritic chest pain. The superior vena cava syndrome may accompany obstruction of the superior vena cava. Fever is an uncommon manifestation, unless secondary bacterial pneumonitis caused by obstruction is present. The illness generally is self-limited, but may persist for several weeks. Although only anecdotal evidence supports the benefit of treatment, itraconazole may be helpful in patients with active inflammation. An elevated erythrocyte sedimentation rate and CF titer could be considered markers compatible with active inflammation. As also shown in a study involving dogs with mediastinal granuloma,[364] adjunctive treatment with steroids sometimes is beneficial[150,397] and, if effective, results in prompt improvement. If steroids are used, they should be given with an antifungal agent because of the risk of dissemination resulting from steroid-induced suppression of cellular immunity. Itraconazole should be continued for 6 to 12 weeks. Although fibrosing mediastinitis is a late complication of histoplasmosis, no evidence has shown that mediastinal adenitis is its precursor, and that antifungal therapy would prevent its occurrence.

The clinical entity termed *mediastinal granuloma* affects adults and is seen less frequently in children. Mediastinal granuloma describes a large (3 to 10 cm in adults) mass of mostly caseous lymph nodes that coalesce into a single lesion usually located in the right paratracheal region (Fig. 216–6). Lesions often are asymptomatic and discovered as incidental findings in imaging studies. Symptoms may result from compression of bronchi,

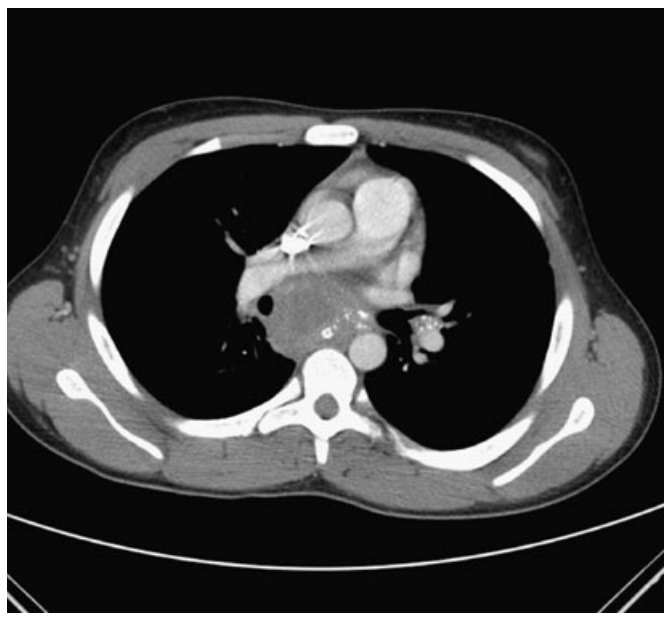

Figure 216–6 A 16-year-old boy was present when a barn was cleaned using a power blower. One week later, he developed a low-grade fever followed by intermittent, nonpleuritic, right parasternal chest pain. CT scan of the chest shows a subcarinal mass with low signal intensity centrally. There is scattered calcification. Histoplasmosis was confirmed by the laboratory, and was compatible with re-exposure to the fungus.

esophagus, or vena cava. Drainage of caseous material may occur spontaneously and result in fistulous tracts to the esophagus,[383] bronchi, or skin. Treatment with itraconazole is appropriate, although efficacy is unproven. Operative intervention sometimes is indicated in the event that compression of the superior vena cava or esophagus occurs. No evidence indicates that this entity is a precursor to mediastinal fibrosis (see section on surgical treatment).

Disseminated Infection

Progressive disseminated infections in children occur in several settings, and all require antifungal therapy.[229,241] Among immunocompetent children, they occur primarily in infants younger than 1 year old and infrequently in children at any age after intense exposure.[296] Among immunocompromised children, dissemination is seen most often in patients who are receiving immunosuppressive agents that impair the cellular immune system, in patients with AIDS, and less commonly in patients with primary disorders of cellular or combined immunity.[174,496] Table 216–4 summarizes treatment recommendations.

Immunocompetent Patients and Immunosuppressed Patients without Human Immunodeficiency Virus Infection

If not treated with antifungal agents,[145,229,241,445] patients with acute progressive disseminated histoplasmosis have a mortality rate approaching 100 percent.[93,122,187,458] Treatment with amphotericin B results in survival of more than 90 percent of infants with PDH.[119,176,229,296] In contrast to adults, in whom monotherapy with itraconazole for patients with nonsevere dissemination has been successful,[93,458] only one report[403] has described the outcome of itraconazole monotherapy in children with disseminated histoplasmosis. Seven children 2 to 14 years old were treated. One child died shortly after treatment was stopped at 1 month. "Marked improvement" was noted in patients treated for 3 months (four patients) and 6 months (one patient), and complete resolution was reported in one patient after 12 months of therapy. Monotherapy with itraconazole is not recommended for disseminated histoplasmosis.[452] Based largely on its demonstrated effectiveness in clinical trials in adults, however, and its ease of administration and tolerability in children, itraconazole is recommended for step-down therapy after induction with amphotericin B. Serum levels of itraconazole should be monitored (see section on antifungal therapy) along with serum/urine antigen concentrations during therapy and in follow-up to ensure that the fungal burden is decreasing. If amphotericin B is elected as monotherapy, a total dose of 30 to 40 mg/kg over 4 to 6 weeks is recommended.

Disseminated Infection in Patients with Acquired Immunodeficiency Syndrome

The severity of the initial signs of illness heavily influences the outcome and recommended treatment regimens for patients with disseminated histoplasmosis complicating HIV infection (see Table 216–4). Regimens are based on trials conducted in adults. Amphotericin B was effective in 74 to 88 percent of all cases,[433,447] whereas patients treated for infections that were sufficiently severe to require hospitalization had a 50 percent mortality rate.[433] In patients with moderate-to-severe disseminated histoplasmosis, liposomal amphotericin B provided a survival benefit compared with amphotericin B deoxycholate.[187] Adults with only mild or moderate symptoms were treated successfully with itraconazole monotherapy in 85 percent of instances.[458]

Recommendations for children are similar to the recommendations for adults; amphotericin B deoxycholate usually is well tolerated in children and is recommended as monotherapy at a dose of 1 mg/kg/day given for 4 to 6 weeks. Alternatively, it may be used for 2 weeks as induction therapy and followed thereafter by itraconazole, 5 to 10 mg/kg/day for 12 months. Liposomal amphotericin B, a more costly preparation, may be substituted for the deoxycholate preparation with either regimen in the event of renal complications. Serum followed by urine antigen monitoring[293,448] (see section on antigen detection) is recommended during therapy and for 1 year after its completion to monitor response and to assess for relapse. After the completion of therapy, the significance of low levels of antigenuria in the absence of antigenemia and clinical symptoms is unclear and not an indication for prolonged therapy. Prolonged follow-up is recommended in these instances.

Because of a high rate of relapse after cessation of therapy in patients with AIDS in whom there is persistently impaired immune function, long-term maintenance therapy (secondary prophylaxis) is recommended.[186,438,447,469] In adults with mild to moderately severe disseminated infection, amphotericin B (50 mg weekly or biweekly) is effective in 81 to 97 percent of cases,[264,447] and itraconazole is effective in 90 percent.[168,459] Itraconazole is the azole of choice for mildly or moderately ill patients, in whom it may be used as induction therapy and secondary prophylaxis. Fluconazole is not recommended for secondary prophylaxis (see section on medical management), but may be considered if patients received amphotericin B as induction therapy, if itraconazole is poorly tolerated, or if itraconazole's cost precludes its use.

A prospective observational study[139] of adults with AIDS and disseminated histoplasmosis found it safe to discontinue secondary prophylaxis after 12 months of primary antifungal therapy and demonstration of sustained immunologic improvement resulting from HAART therapy. Specific criteria for withholding secondary prophylaxis include negative blood cultures, *Histoplasma* urine antigen concentration of less than 4 ng/mL, and $CD4^+$ T-cell counts greater than 150 cells/mm^3 in patients continuing to receive HAART.[139] Primary prophylaxis with itraconazole is effective for patients with AIDS who live in hyperendemic areas[267] (areas in which the incidence of histoplasmosis is >5 cases per 100 patients per year).

Prophylaxis of Immunosuppressed Patients

Clusters of infection occasionally are reported in high-risk populations, sometimes in geographic regions with low background rates.[121] Based on the results of a large clinical trial, however, the need for prophylaxis for patients residing in a hyperendemic area and who are undergoing immunosuppression for management of neoplasms, inflammatory syndromes, or transplantation of allogeneic bone marrow or solid organs seems to be low.[413] Included were patients with CF titers to *H. capsulatum* of 1:8 or 1:16, positive M bands by ID, or radiographic evidence suggestive of past infection (calcified splenic or lung nodules). In contrast, patients receiving TNF-α antagonists seem to be at greater risk of developing disseminated histoplasmosis,[422,482] perhaps attributable to reactivation of latent infection. Active histoplasmosis during the 2 years preceding the need for immunosuppression may be a basis for consideration of prophylaxis. Although firm evidence is lacking, criteria for such evidence may include chest radiographic abnormalities compatible with histoplasmosis, *Histoplasma* antigenuria, or anti-*Histoplasma* antibody titers 1:32 or greater. Duration is unclear, but 12 to 24 weeks has been recommended.[452]

Central Nervous System Infection

With the exception of CNS infections that accompany PDH, histoplasmosis of the CNS in children[175] rarely is seen.[296] Adults with CNS infections[23,360,466] can present with meningitis, focal infection of the brain[212] or spinal cord, thrombotic events caused by focal vasculitis or emboli, or diffuse encephalitis. As with children, some infections occur in association with disseminated infection, others occur as an isolated illness, and others occur in the context of relapse in a sequestered site that is penetrated inadequately by antifungal agents.[466] Mortality is almost uniformly invariable if untreated. Treatment is effective in only 20 to 40 percent of patients with meningitis, and 50 percent of responders relapse after cessation of treatment.[437]

Although amphotericin B deoxycholate and liposomal amphotericin B enter the CSF poorly,[101,151,228] liposomal amphotericin B concentrations are higher in brain tissue in animal models.[228] Comparative studies of these agents for the treatment of CNS infections caused by histoplasmosis have not been performed. In a more recent report,[360] five adults were treated initially with amphotericin B deoxycholate at doses of 40 mg/kg for 8 weeks followed by fluconazole, 200-400 mg/day for 1 year, resulting in cure of four patients and minor residual sequelae in one. These reports, the ability of liposomal amphotericin B to achieve higher brain tissue levels than occur with amphotericin B deoxycholate, and the superiority of itraconazole over fluconazole in an animal model all contribute to the basis for the recommendation[221] that adults with CNS infections receive liposomal amphotericin B (5 mg/kg/day) for 4 to 6 weeks followed by itraconazole for 1 year.

Meningitis was present in 25 of 40 children in a series[296] of progressive disseminated histoplasmosis. All children received 40 mg/kg of amphotericin B deoxycholate followed by ketoconazole for 3 months. The overall mortality rate in the series was 10 percent; however, two deaths were in children who failed to complete therapy, and two died within 4 days of presentation, suggesting that this regimen cured meningitis in most cases. In the rare setting in which meningitis is found in a child as an isolated infection, recommendations reasonably might include the use of liposomal amphotericin B (in place of amphotericin B deoxycholate) followed by itraconazole for 12 months.

The role of combination therapy for CNS infection has not been examined in humans. Antagonism has been shown in an animal model[167] that used a regimen of fluconazole and amphotericin B. In another animal model of CNS infection, itraconazole in association with amphotericin B provided no benefit compared with amphotericin B alone.[231]

Despite isolated case reports that have reported success with ketoconazole, itraconazole, fluconazole, the combination of itraconazole and fluconazole, and voriconazole,[404,452] the efficacy of azole monotherapy for the treatment of CNS infections has not been adequately studied. Posaconazole[320,336] has been used successfully as salvage therapy in one patient after therapeutic failure with several prior regimens. The evidence is insufficient to recommend azole monotherapy for CNS infection.

MEDICAL MANAGEMENT OF MANIFESTATIONS THAT DO NOT REQUIRE ANTIFUNGAL THERAPY

Several common and uncommon manifestations of histoplasmosis do not require antifungal treatment. Apart from mild primary pulmonary infection, one of the most common is pericarditis. Because it rarely is associated with frank fungal infection of the pericardium, it usually resolves spontaneously or with nonsteroidal anti-inflammatory drugs. Indomethacin usually is effective[492] in rapidly reducing inflammation and can reverse signs of impending tamponade. Steroids have been reported to be effective, but, if used, should be accompanied by antifungal therapy. Rheumatologic symptoms of arthritis, with or without erythema multiforme or erythema nodosum, also respond to nonsteroidal anti-inflammatory drugs.[368] Fibrosing mediastinitis is a late complication of histoplasmosis, but it occurs occasionally in children. When granulomatous lesions evolve to become densely fibrotic, antifungal and anti-inflammatory therapies are ineffective. The clinical and laboratory criteria that are used to assess whether active inflammation is present are inexact, however, and a trial of antifungal therapy often is warranted if clinical features or laboratory evidence of active inflammation, or both, is present. Treatment with antifungals almost always is unsuccessful, but improvement has been reported.[409] Presumed ocular histoplasmosis is seen almost exclusively in adults and does not improve with antifungal therapy; its management has been reviewed extensively.[60]

SURGICAL TREATMENT

Operative intervention rarely is needed to manage patients with histoplasmosis. In a review of 94 patients, 10 to 40 years old, the most common reason for evaluation was obstruction of thoracic structures by mediastinal masses.[129] Seventy-five patients underwent surgery or endoscopy to relieve obstruction of the pulmonary artery, superior vena cava, bronchus, or esophagus. Recurrent pneumonia, tracheoesophageal fistula, hemoptysis, and broncholithiasis were other indications for surgical procedures.[129,214,495] Because attempts to excise caseous nodes completely sometimes can damage contiguous structures, the preferable approach is to incise and evacuate debris from such lesions and leave the adherent portion of the capsule intact.[117,129,313,479]

Surgery has little place in the management of fibrosing mediastinitis resulting from histoplasmosis. The dense fibrous consolidation of mediastinal structures coupled with the hypervascularity of mediastinal tissues renders the risk for development of serious hemorrhage and other life-threatening surgical complications high.[259] Excisional biopsy carries a prohibitive risk.[77] Bronchoscopy coupled with coagulation of hyperemic vessels within bronchi in individuals presenting with hemoptysis has been useful.[256] When calcification has occurred in fibrosing mediastinitis, surgical repair is not feasible,[253] and the fibrosis continues after surgery. Some success has been achieved with relief of vascular obstruction by percutaneous placement of intravascular stents,[98,400] but complications occur.[334] An intravascular stent has been used successfully to relieve obstruction in a child with superior vena cava syndrome (M. Kleiman, unpublished observation, 2008). Prophylactic excision of large mediastinal nodes has not been shown to prevent fibrosis, and patients with large mediastinal lymph nodes who are otherwise asymptomatic rarely progress to develop mediastinal fibrosis.[429]

PROGNOSIS

Histoplasmosis is either unrecognized or self-limited in most individuals who sustain this most common of the endemic mycoses. Histoplasmosis results in serious illness in infants, immunocompromised patients, and older individuals, particularly individuals with emphysematous pulmonary disease.[34,275] The cure rate for children who receive therapy for serious acute manifestations is high. Little prospective information is available about the long-term outcome in acute pulmonary histoplasmosis. A study that examined pulmonary function in six children and their parents after intense exposure found restrictive (three patients) and obstructive (two patients) patterns and a reduction in carbon monoxide diffusing capacity in five of six tested. At 2 years, a diffusing capacity abnormality remained in three children, and hypoxemia persisted in the most severely affected

patient.[215] No data that can be used to predict the occurrence of long-term complications, such as mediastinal fibrosis, are available. When it does occur, mediastinal fibrosis is progressive, and therapeutic options are few; because by definition mediastinal fibrosis invades the airways and pulmonary vasculature, its prognosis is influenced heavily by whether it affects one or both lungs.[77] The prognosis is poor in the latter instance.

PREVENTION

Complete prevention of histoplasmosis is currently impossible, but reasonable precautions can decrease greatly the risk to individuals who are highly likely to experience serious complications if they become infected. Individuals with impaired cellular immunity who reside in, or plan travel to, endemic regions should be counseled about the potentially serious consequences of infection. Counseling should include education about the sites likely to be contaminated with *H. capsulatum* and the activities that potentially may expose them to spores; primary prophylactic regimens using itraconazole may be considered for HIV-infected patients with exposure to soil mixed with bird or bat droppings (see section on epidemiology).[164] If such activities are unavoidable, the use of National Institute for Occupational Safety and Health (NIOSH)–certified high-efficiency mask filtration devices[410] should be encouraged; however, devices appropriate for use by small children may be unavailable. Sterilization of sites by formaldehyde spray[53,410] have been attempted, but the toxicity of this agent renders its use undesirable and, in some settings, ineffective. When potentially contaminated sites are disturbed, aerosols containing spores can be reduced substantially by thoroughly dampening the material with water before it is manipulated. Although educating and counseling high-risk patients afford some protection against acquiring infection from microfoci, some of which can result in intense exposure, they do not protect against "sporadic" infections. For the general population, education in endemic areas also is beneficial, particularly for protecting individuals whose occupational and recreational activities may expose them to *H. capsulatum*.

A vaccine for prevention of histoplasmosis has not been developed, although active investigation in animal models[295,354] is under way to identify potential vaccine targets[81,87,485,489] and delineate the regulatory elements needed for immunity against *H. capsulatum*.[82,359] An intriguing area of inquiry is identifying vaccine targets integral to dimorphism, a requisite for the pathogenicity of all of the endemic fungi.[285] Other areas of inquiry have explored the feasibility of developing vaccines against invasive fungal pathogens in the setting of severe immunodeficiency, including individuals with $CD4^+$ T-cell deficiency.[489] A recombinant protein vaccine has been made from cloned sequences of DNA coding for the cell wall glycoprotein HSP 60, which has been found to be protective in mice against a lethal intravenous inoculum of *H. capsulatum*.[141] This vaccine protected mice in a model of pulmonary infection.

CHAPTER 217

Sporotrichosis

Bernhard L. Wiedermann

Sporotrichosis is an infection caused by the fungus *Sporothrix schenckii* that is manifested most commonly as an ulcerating nodule at a site of local trauma, with spread occurring along regional lymphatic channels. Infection of other tissues or widespread dissemination is rare. It is an uncommon problem in children, but young adults seem to be infected more frequently, presumably owing to more frequent exposure to soil, plants, and decaying vegetable matter that harbor the organism. The disease was described first by a medical student, Schenck, in 1898, and most of what is known about the clinical syndrome has been learned from studies of large outbreaks, particularly one occurring in gold miners near Johannesburg, South Africa, in the early 1940s.[77,87]

ORGANISM

S. schenckii is a dimorphic fungus found principally in decaying vegetable matter or plant debris, although it does not seem to be a plant pathogen. A molecular phylogenetic study of 60 isolates from South America and Europe showed three major clades that tended to group according to geographic origin.[57] The organism grows well on most culture media and is resistant to cycloheximide. Preferred culture media are Sabouraud glucose agar and blood agar, incubated at 25° C to 27° C. Most isolates grow readily from clinical material within 3 to 5 days, although occasional instances of slow growth have been reported, and cultures should be held at least 4 weeks before being considered negative. Incubation on blood agar at higher temperatures (37° C) allows growth of the yeast phase, which is necessary for specific identification of the organism in culture.[72]

EPIDEMIOLOGY

Most cases of sporotrichosis are reported from Central and South America, especially from Mexico and Brazil, and cases in the United States appear to cluster in the Midwest, particularly along the Mississippi and Missouri River areas.[32,66] Disease in humans usually results from inoculation of minor wounds by debris containing *S. schenckii*, and gardeners and nursery workers, forestry workers, miners, and other individuals exposed to contaminated plant materials are at higher risk for acquiring the disease.[12,16] Disseminated disease has been the initial presentation of some human immunodeficiency virus–infected individuals.[2] Laboratory personnel working with the organism have become infected after incurring needle-stick injuries.[86] The large South African epidemic in the gold mines of Transvaal probably resulted from the miners' brushing against rotting timbers in the mines, and a cluster of cases that occurred after a brick-throwing incident in Florida was traced to *S. schenckii* in the packing straw of the bricks.[75,87] Contaminated hay was the source of one outbreak linked to a Halloween haunted house.[22] Pulmonary disease may result from inhalation of spores.[66] Uncommonly, transmission of disease from animals, particularly domestic cats with cutaneous disease, or from family members occurs.[24,28,29,70] One adult

acquired the disease after being bitten by a squirrel.[76] In South America, armadillo hunters are at risk for developing sporotrichosis, but it is acquired from the decaying plant debris in armadillo nests, rather than from the animals themselves.[56] Cats have been implicated in a large outbreak in Brazil.[78] Molecular typing of isolates can be useful in investigations of outbreaks.[15,59,60]

PATHOGENESIS AND PATHOLOGY

As indicated, the most common mode of acquisition of sporotrichosis is by inoculation of the organism into skin structures, although disease also may develop from inhalation of spores of the organism. The incubation period varies considerably, commonly ranging from 7 to 30 days after cutaneous inoculation, but possibly as long as 6 months.[72] The disease usually remains localized; of the 2825 cases of sporotrichosis in the Transvaal mine epidemic, none had systemic spread.[87]

S. schenckii, similar to other yeasts, seems to bind specifically to the glycosphingolipid lactosylceramide, which is present on the cell surface of animal cells.[41] This mechanism may be one by which the organism establishes a foothold in the host. Cell-mediated immune responses probably are important for containment of infection. One study documented intact responses in patients with cutaneous forms of the disease, whereas patients with systemic sporotrichosis had impaired cell-mediated immunity.[65] This study is supported by the observation that systemic disease tends to occur in individuals with underlying diseases that alter cell-mediated immunity.

Histopathologic examination of primary cutaneous lesions usually reveals changes in the epithelium, with hyperkeratosis, parakeratosis, and pseudoepitheliomatous hyperplasia. Intraepidermal microabscesses may be seen as well. In more established lesions, the pathologic process involves the dermis and below, with inflammatory infiltrate extending perivascularly.[53] The classic lesion on microscopic examination is a granuloma with an asteroid body at the center, although this picture is not pathognomonic for sporotrichosis. The asteroid body is an antigen-antibody complex deposited on the surface of the organism.[52] Showing fungi in tissue sections often is difficult, even with special staining techniques, because of the paucity of organisms in tissue. They may be seen on Gram stain as gram-positive, but irregularly staining bodies, sometimes as cigar-shaped, 3- to 5-μm yeast forms. Periodic acid–Schiff and silver stains probably are better suited for detection of fungi in tissue sections.[53,72] Immunohistochemical staining techniques may prove superior to standard methods.[58,63]

CLINICAL MANIFESTATIONS

Sporotrichosis can occur in cutaneous and extracutaneous forms, with the cutaneous varieties accounting for approximately 80 percent of all cases.[72] These categories can be broken down further into the organ system involved (Table 217–1).

TABLE 217–1 Clinical Forms of Sporotrichosis

Cutaneous	Extracutaneous
Lymphocutaneous	Osteoarticular
Fixed cutaneous	Pulmonary
	Muscular
	Ocular
	Genitourinary
	Central nervous system

Data from references 1, 35, 36, 49, 66, 73.

CUTANEOUS SPOROTRICHOSIS

Cutaneous disease with *S. schenckii* can be either lymphocutaneous or fixed cutaneous, the latter of which occurs less frequently. In lymphocutaneous cases, the initial lesion appears as a firm, slightly tender subcutaneous nodule. It progresses along local lymphatic channels, with multiple nodules appearing. The lesions typically enlarge, and may ulcerate and suppurate (Fig. 217–1). Untreated, they may heal slowly over months or persist; recurrences are frequent. Differential diagnosis includes cutaneous nocardiosis, atypical mycobacterial disease, leishmaniasis, rosacea, syphilis, pyoderma gangrenosum, and disseminated *Acanthamoeba* disease, and cutaneous manifestations of other fungal diseases.[20,47,69,85,94]

The fixed cutaneous form of the disease is just as the name implies, with no evidence of lymphatic spread. The primary lesions are identical to the lesions seen in the lymphocutaneous form. Although some researchers have suggested that sporotrichosis in children is more likely to appear in the fixed cutaneous form, compared with adults, this theory has not been borne out in prior studies. Table 217–2 shows results from six reports of series of cases of sporotrichosis in children. The 60 percent rate for the lymphocutaneous form may not differ much from the 90 percent figure quoted for adults when one takes into account that many pediatric studies are reports of small numbers of cases and may have resulted from selection bias. A large series of patients from Peru documented a disproportionate number of children with facial lesions (86 of 143 children versus 23 of 95 adults) but did not classify fixed versus lymphocutaneous forms by age.[64] Fixed cutaneous disease in children has been confused with

Figure 217–1 Cutaneous lymphatic sporotrichosis of both arms. Note the characteristic involvement of lymphatics that drain the sites of the primary lesions. *(Courtesy of G. Medoff and G. S. Kobayashi.)*

TABLE 217–2 Summary of 42 Cases of Pediatric Sporotrichosis

Duration of symptoms before diagnosis	3-10 wk
Lymphatic involvement	28/47*
Culture-positive	39/44*
Relapse after therapy	1/21*

**Numerator is number of patients positive; denominator is number of patients tested. Data from references 10, 13, 18, 31, 54, and 61.*

impetigo.[10] A study from Peru also documented a predilection of children to develop lymphocutaneous lesions on the face and neck.[55] Risk factors for disease in children in this study included playing in fields, ownership of a cat, and residence in a house with dirt floors.

EXTRACUTANEOUS SPOROTRICHOSIS

Sporotrichosis occurring in extracutaneous sites either may be localized (related to an unusual area of trauma) or may represent disseminated disease. In the absence of trauma, the presence of extracutaneous sporotrichosis should raise suspicion of disseminated disease and consideration of immunodeficiency states. Overall, infection of bones and joints is the most common form of extracutaneous disease.[92] Sporotrichal arthritis usually is an indolent and slowly progressive disease that may occur with or without cutaneous or lymphatic disease, suggesting a hematogenous route of infection for most cases. Diagnosis generally requires synovial biopsy with culture for showing the organism.[79,92] Two studies showed diagnostic delays averaging 17 and 25 months from the onset of symptoms.[5,17] Sporotrichal osteomyelitis usually occurs with concomitant arthritis, but isolated bone involvement has been recorded. Lytic lesions and periosteal changes are noted most frequently.[34,92]

Pulmonary sporotrichosis seldom occurs with cases of disseminated disease and probably develops after inhalation of spores, as with primary pulmonary histoplasmosis.[66] The presence of cavitary lesions in the upper lobes often leads to a diagnosis of tuberculosis, and fungal culture of sputum, bronchoscopic specimens, lung tissue, or gastric aspirate usually is needed for establishing the diagnosis.[25,66,90] Pleural involvement is uncommon (3 of 47 cases in one review), and complications such as massive hemoptysis rarely occur.[26,37,66]

Sporotrichosis has been found to involve virtually every organ system in the body as part of disseminated disease.[92] Most commonly, underlying immunodeficiency states, such as diabetes, prolonged steroid therapy, alcoholism, tumor necrosis factor-α antagonist therapy, and acquired immunodeficiency syndrome, are present.[1,27,33,35,38,49,84,92] Fungemia in the absence of disseminated disease has been documented in one otherwise healthy adult with a lysis-centrifugation blood culture system, and laryngeal and cutaneous sporotrichosis have been reported in a healthy child.[46,48] Dissemination in patients with neoplasia seldom occurs.

DIAGNOSIS

A high index of suspicion is necessary to establish the diagnosis of sporotrichosis. In the largest outbreak in the United States, which occurred in 1988 among horticulturists and forestry workers, only 15 percent of cases were diagnosed at the time of initial presentation to a physician.[14] Culture is the gold standard for diagnosing sporotrichosis. Although organisms occasionally are seen on pathologic specimens, the yield is low enough to render biopsy unnecessary. If the diagnosis is suspected, scrapings of cutaneous lesions for culture should be sufficient to establish the diagnosis.[72]

A skin test antigen has been available for many years, but, as with the histoplasmin skin test for histoplasmosis, it is useful mainly as an epidemiologic tool. Polymerase chain reaction may prove useful in diagnosis in the future.[42] Serodiagnosis has been explored in a few studies. Immunoprecipitation or commercially available slide latex agglutination can be useful when material for culture is difficult to obtain, or cultures are negative, such as with sporotrichal meningitis.[21,80] Similarly, an enzyme-linked immunosorbent assay has been used for diagnosis. Antibody titers in cerebrospinal fluid tend to decrease with successful therapy, and such tests might prove useful for monitoring response to therapy.[6,80] Western blotting has been used to detect sporotrichal antibody.[81] Using a crude antigen preparation, Scott and Muchmore[81] determined that detection of antibody to three antigens, 32 kd, 40 kd, and 70 kd, seems to be sensitive and specific for diagnosis of active sporotrichosis. Patients with extracutaneous disease seemed to form antibody to a greater number of *S. schenckii* organisms than patients with cutaneous disease. Further studies of the immune response in sporotrichosis should enable development of better serodiagnostic tests than those that now are routinely available.

TREATMENT AND PROGNOSIS

Sporotrichosis may resolve spontaneously, but treatment is indicated in most circumstances.[4,67] The Mycoses Study Group of the Infectious Diseases Society of America has published practice guidelines for management of patients with sporotrichosis.[45]

Heat applied to the site of cutaneous disease has been reported anecdotally to cause resolution of lesions in patients in whom medical therapy was contraindicated.[30,73,88] One prospective study showed good results using benzene pocket warmers for heat therapy of facial lesions in children.[39] Surgical removal of infected skin and soft tissue has been used, but skin grafting may be required.[9] This form of treatment usually is unnecessary with the availability of medical management except possibly for some cases of pulmonary infection (particularly if it is confined to one lobe) and other extracutaneous disease.[17,34,66] Hyperthermia remains an option for treating sporotrichosis in pregnancy, for which other agents may be contraindicated.[42]

A saturated solution of potassium iodide (SSKI), a proteolytic agent for which the mechanism of action in sporotrichosis is unclear,[51] can be used for uncomplicated sporotrichosis. The in vitro growth of *S. schenckii* is not inhibited appreciably by iodide, but free iodine has a marked inhibitory effect on growth.[91] The small amount of free iodine in a saturated solution of potassium iodide may be sufficient to cause resolution of disease. The pediatric dosage of a saturated solution of potassium iodide is empiric; it usually is given three times daily in juice or milk, starting at a low dose (e.g., 1 to 2 drops per year of age) and increasing the dose over the course of several days to a maximum of 30 to 40 drops per dose.[13,54,61] For younger children, lower dosages may be acceptable.[54,68] Treatment is continued until a few weeks after all lesions have resolved. Adverse reactions, such as salivary gland swelling, excessive lacrimation or salivation, nausea, vomiting, and abdominal pain, may resolve with temporary cessation of therapy followed by re-institution at a lower dosage. SSKI currently is only an alternative treatment for lymphocutaneous and cutaneous forms of the disease.[42]

In vitro susceptibility testing is not used widely, and results may not always agree with clinical response.[74,89] Itraconazole, an oral azole derivative, is the drug of choice for treatment of cutaneous, lymphocutaneous, and osteoarticular forms of sporotrichosis.[8,40-42,83] Restrepo and colleagues[71] showed clinical cures in all 17 patients with cutaneous forms of sporotrichosis treated with itraconazole (100 mg/day), with no major side effects. Borelli[7] reported a treatment failure, however, in a patient treated with 100 mg/day, who subsequently responded when the dose was increased to 200 mg/day. Systemic disease also has been treated with itraconazole with favorable clinical responses, although all information is from cases in adults.[3,50,62,83,93]

Intravenous amphotericin B remains the drug of choice for treating patients with disseminated or severe sporotrichosis.[42,92] Duration of therapy in children has not been studied but probably should require 30 mg/kg as a total dose. Occasionally, intra-articular amphotericin B is used for treating sporotrichal arthritis

if response to other therapy is poor.[23] Amphotericin B therapy in patients with pulmonary sporotrichosis is less effective than with other forms of sporotrichosis, which has prompted many clinicians to use a combined medical-surgical approach.[45,66] Itraconazole is an alternative therapy and may be useful for long-term suppression.[45] Amphotericin B seems to be effective in treating sporotrichal meningitis when it is given early in the course of the disease, but adjunctive therapy with flucytosine or rifampin might be helpful.[79] Itraconazole and fluconazole also may have roles in treating meningitis.[40,45]

S. schenckii does not seem to be particularly susceptible to ketoconazole in vitro, and clinical experience with ketoconazole treatment of sporotrichosis has been mixed.[11,19,82] Possibly, relatively large doses of ketoconazole are needed to produce a good clinical response. Terbinafine, an allylamine, cured five adults with cutaneous sporotrichosis, but further experience with this agent is needed.[40]

Prognosis for cutaneous forms of disease is excellent, but the extracutaneous forms are associated with significant morbidity and mortality, in part related to the underlying conditions predisposing these patients to disseminated disease. Many cases of osteoarticular disease result in permanent disability.[17]

PREVENTION

The key to prevention of sporotrichosis is the elimination of exposure to the organism, particularly with regard to skin surfaces and mucous membranes. Usually, elimination of exposure can be accomplished by the use of protective clothing during high-risk activities, such as working with sphagnum moss or other decaying, moist plant material.[12,14] Nursery workers should be educated about the hazards and early signs of sporotrichosis, and physicians and veterinarians should be aware of the uncommon circumstances of spread of the infection from family members and domestic cats. The epidemic in the Transvaal gold mines was stopped when timbers in the mine shafts were sprayed with a fungicide.[87] Although reporting of individual cases of sporotrichosis is not required in the United States, reporting of clusters of cases can aid epidemiologic investigations and stop the spread of the disease.

CHAPTER 218

ZYGOMYCOSIS

Theoklis E. Zaoutis ✪ William J. Steinbach

Zygomycosis (formerly *mucormycosis* or *phycomycosis*) is a relatively new term that refers to a group of uncommon but frequently fatal mycoses caused by the fungi of the class Zygomycetes. Organisms of the class Zygomycetes have been reported to cause disease in humans in publications since the 1800s. Platauf[86] is credited with providing the first description of zygomycosis in humans in his paper entitled "Mycosis Mucorina." In this German language manuscript, Platauf[86] described a case of disseminated mycosis in a patient with cancer. The first English language description of the disease appeared in 1940 when Wade[120] described a case of cutaneous mucormycosis infection of the face.

The class Zygomycetes is divided into two orders, the Mucorales and the Entomophthorales.[94] The Mucorales organisms are responsible for most of the disease seen in humans, predominately affecting immunocompromised hosts and often characterized by a rapidly evolving clinical course with tissue destruction and invasion of blood vessels. The mycoses caused by Entomophthorales historically have been limited to immunocompetent patients residing in tropical and subtropical areas of the world. Infections caused by Entomophthorales usually are chronic, subcutaneous, and limited without blood vessel invasion.[94] This chapter focuses on the more relevant infections caused by Mucorales, with a brief description of infections caused by Entomophthorales.

ORGANISMS

The organisms of the class Zygomycetes are ubiquitous in nature and have a wide geographic distribution. The class consists of

Figure 218–1 Classification of Zygomycetes. *(From Ribes, J. A., Vanover-Sams, C. L., and Baker, D. J.: Zygomycetes in human disease. Clin. Microbiol. Rev.* 13*:236, 2000.)*

two orders, Mucorales and Entomophthorales, each containing several species reported to cause disease in humans (Fig. 218–1).[94] The most common causative organisms in humans are the *Mucor*; *Rhizopus*, *Absidia*, and *Rhizomucor* genera of the Mucoraceae family. These organisms grow readily on common laboratory media, but are inhibited by cycloheximide. On solid media, members of Mucorales show rapid growth of woolly colonies, often with spores seen as tiny dark dots to the naked eye. Hyphae characteristically are large (10 to 30 μm in diameter), nonseptate, and, often, twisted or ribbon-like. The lack of septation and the tendency of hyphae to branch at right angles usually serve to distinguish them from *Aspergillus* spp., which are septate, are smaller, and branch at acute angles. Genera usually are differentiated from one another by examination of mycelia. Differentiating the members of Zygomycetes into species often is difficult.

Growth of members of Entomophthorales also occurs readily on solid media, but appears as flat, gray, or pale yellow waxy colonies with velvety white mycelia on the surface.[94,96] The hyphae often are septate, and differentiation between genera and among species is based on morphologic characteristics of cultured organisms.

EPIDEMIOLOGY

All members of Zygomycetes are ubiquitous in nature and are found in all parts of the world, regardless of climate or other factors. Most reported human disease caused by members of Mucorales is concentrated in North America, perhaps because of a concentration of immunocompromised hosts.[7] Infections caused by the Entomophthorales genera *Basidiobolus* and *Conidiobolus* occur predominantly in Africa, India, and the Far East, although a few cases have been reported in North and South America.[94]

These fungi are found commonly in soil, in decaying organic material such as vegetation, bread, seeds, and fruits, and in manure. Many of them are animal pathogens. Members of Mucorales also are isolated occasionally from the hospital environment.[51,54,94,125,128] Studies have suggested that a relationship exists between activities involved in hospital construction and development of zygomycosis in immunocompromised hosts.[54,99,128] *Rhizopus* spp. frequently are found in moldy bread and fruits.[94] Members of Entomophthorales commonly are found in feces of reptiles and other animals and in decaying vegetable matter, and some are insect pathogens.[94]

The ubiquitous nature of these organisms, coupled with the paucity of human disease associated with them, is strong evidence for their saprophytic characteristics. Infections caused by the Zygomycetes are rare, occurring at an annual rate of 1.7 infections per 1 million population in the United States.[91] Since the 1990s, the frequency and incidence of zygomycosis have increased, however, particularly among hematopoietic stem cell transplant (HSCT) recipients and patients with hematologic malignancies (Fig. 218–2).[32,52,65] Despite these increases since the 1990s, Zygomycetes were seen at autopsy in 1.9 percent of patients dying of malignancy, contrasting with the high incidence of aspergillosis at autopsy (19.6%) at the same center.[53]

The incidence of zygomycosis complicating HSCT was 2.5 percent in one study; it may be less common than other molds because evaluation of indoor environments shows Zygomycetes rarely are isolated.[57] A review of 1500 patients who underwent HSCT over the course of 26 years at one center found only 0.9 percent of patients had zygomycosis.[74] In the largest systematic review of reported cases of zygomycosis, *Rhizopus* spp. and

E., et al.: Zygomycosis in a tertiary-care cancer center in the era of Aspergillus-active antifungal therapy: A case-control observational study of 27 recent cases. J. Infect. Dis.* 191*:1350, 2005.)*

Mucor spp. were the causative organisms most commonly reported, being identified in 47 percent and 18 percent of cases.[98] The review included 157 published cases of pediatric zygomycosis, and a similar distribution of species causing infection was seen in children and adults.[133]

Infection with zygomycetes commonly manifests as an opportunistic infection in patients with underlying risk factors. Predisposing risk factors include immunosuppression, metabolic disorders, breakdown of skin or soft tissue integrity such as occurs in burn patients or surgical patients, and prematurity (Table 218–1).[51,53,98,133] The underlying conditions most commonly reported for adults and children are diabetes mellitus and neutropenia.[53,98,133] More recent evidence has suggested that the increasing use of voriconazole as prophylaxis and as empiric, preemptive, and targeted therapy for invasive aspergillosis is associated with an increased risk for development of zygomycosis.[40,52,66,105] One hypothesis is that voriconazole, because of its lack of activity against Zygomycetes, has exerted selection pressure favoring the emergence of zygomycosis.[128]

MUCORMYCOSIS

PATHOGENESIS AND PATHOLOGY

Mucormycosis usually is acquired by humans after inhalation of spores from environmental sources, and the organisms may colonize the sinuses and nasopharynx of some patients.[94] Occasionally, mucormycosis results from cutaneous inoculation of spores secondary to trauma, as has occurred with contaminated elastic adhesive tape[24,34,94] and ingestion of fermented milk or dried bread products.[55,78] After airborne spores are inhaled, primary infection usually develops in the upper and lower respiratory tract and later by contiguous or hematogenous dissemination. Disseminated disease most commonly arises from the lungs and spreads hematogenously to the central nervous system, kidneys, gastrointestinal tract, and heart. Dissemination also can occur from cutaneous or subcutaneous sites of infection.[24,34,109] Person-to-person transmission has not been documented.

TABLE 218–1 Underlying Diseases Commonly Associated with Increased Risk for Mucormycosis

Pediatric-Specific Risk Factors	Risk Factors Seen in Adults and Children
Prematurity	Neutropenia or neutrophil dysfunction
Methylmalonicaciduria	Diabetes mellitus
Malnourishment	Malignancy
	Organ transplantation
	Corticosteroid therapy
	HIV infection
	Diabetes mellitus
	Deferoxamine therapy
	Intravenous drug use
	Trauma or surgery
	Burns

The immune status of the host is fundamental to production of disease. In normal hosts, Zygomycetes are killed by mononuclear cells and neutrophils via the generation of oxidative metabolites and cationic peptide defensins.[25,121,123] The neutrophil seems to be the primary component of the immune response against these organisms and may serve to prevent germination of inhaled spores.[25] Neutropenia and qualitative deficiencies of neutrophil function are associated with an increased risk of development of zygomycosis.[17,109] In addition, corticosteroid treatment impairs the ability of macrophages to prevent germination of the spores.[122] Zygomycosis reported in patients with acquired immunodeficiency syndrome (AIDS) tends to occur in intravenous drug users and may reflect direct inoculation as the risk factor, rather than the immunodeficiency itself.[75,107] Disease may follow a less fulminant course in patients with AIDS compared with other immunocompromised populations.[8]

Diabetes mellitus, in particular diabetic ketoacidosis, is the most common underlying disease in patients with mucormycosis.[50,51,98] Serum from patients with diabetic ketoacidosis does not inhibit the growth of *Rhizopus* spp., but serum from those same patients after treatment of the ketoacidosis does show inhibitory properties similar to those of normal human serum.[3,17,33,94] Hyperglycemia and acidosis, commonly seen in diabetic patients, are known to impair the ability of phagocytes for chemotaxis and to kill the organisms by oxidative and non-oxidative mechanisms.[17]

Iron levels in serum also may play a role in the pathogenesis and immune response to the organisms. Patients treated with the iron chelator deferoxamine have a markedly increased risk of developing invasive mucormycosis, as shown by the tendency for deferoxamine therapy to result in progression of natural and experimental mucormycosis.[11,12,22,23,36,93,101,117] This phenomenon seems to occur commonly, particularly in patients undergoing hemodialysis.[10,11,131] Studies in experimental animals suggest that deferoxamine may serve as a siderophore for *Rhizopus* spp., with resultant increased fungal growth and increased mortality rates in a guinea pig model.[9,23,117] In diabetic patients, the presence of systemic acidosis can lead to elevated levels of serum iron, likely

as a result of the release of iron from binding proteins.[3] In vitro data conflict, however, on the exact effects of iron or deferoxamine on promoting the growth of members of Mucorales.[80] Much remains to be understood about the pathogenesis of mucormycosis, and a unifying concept would have to incorporate the effects of steroids, acidosis, and iron on host neutrophils and macrophages in failing to suppress fungal replication.

The hallmark of histologic examination of mucormycosis is vascular invasion with resultant thrombosis and tissue necrosis and accompanying acute and chronic inflammation.[14,39,109] Most of the clinical findings of progressive disease can be related to these effects on blood vessels. Septic emboli may affect all parts of the body. Perineural invasion also occurs commonly.[31] In the rhinocerebral form, the disease may progress along nerve roots during intracranial spread. Although sparse, hyphal forms may be seen in tissue on routine hematoxylin and eosin staining more commonly than with silver or other special fungal stains (Fig. 218–3).[96]

CLINICAL MANIFESTATIONS

The clinical forms of zygomycosis are best considered by type of organ system involvement (Table 218–2). The primary site of infection at the time of initial diagnosis varies as a function of the host population (Table 218–3). Rhinocerebral, cutaneous, and pulmonary diseases are the most common clinical manifestations of zygomycosis.[98] Other forms of invasive zygomycosis include gastrointestinal, disseminated, and other rare presentations.[51,98]

Acute Rhinocerebral Mucormycosis

The acute rhinocerebral form of mucormycosis, including sinus and sino-orbital infections, is the most common presentation of zygomycosis and occurs most often in the setting of diabetes mellitus.[53,98] Rhinocerebral zygomycosis spreads from the nares, palate, or sinuses to the paranasal sinuses, and then to the retro-orbital region and brain by hematogenous spread. Symptoms include facial pain and headache; physical examination reveals brownish, blood-tinged nasal discharge; black eschar on the palate; proptosis; or cranial nerve involvement.[29] Involved tissues become red, then violaceous, and finally black as vessels are thrombosed, and tissues undergo necrosis. Extension into the periorbital region can be manifested as proptosis or orbital edema, and ocular or optic nerve involvement can be suggested by pain, blurring, or loss of vision.[108] Initial symptoms of invasive rhinocerebral disease include bloody nasal discharge,[94] seizures,[79] and cerebrovascular accident.[68] The mortality rate for rhinocerebral disease is greater than 50 percent.[98]

TABLE 218–3 Patterns of Zygomycosis by Host Population

Predisposing Condition	Predominant Sites of Infection*
Diabetes mellitus	Rhinocerebral, pulmonary, sino-orbital cutaneous
Malignancy (neutropenia)	Pulmonary, sinus, cutaneous, sino-orbital
Hematopoietic stem cell transplantation	Pulmonary, disseminated, rhinocerebral
Solid organ transplantation	Sinus, cutaneous, pulmonary, rhinocerebral, disseminated
Intravenous drug use/abuse	Cerebral, endocarditis, cutaneous, disseminated
Malnutrition	Gastrointestinal, disseminated
Deferoxamine therapy	Disseminated, pulmonary, rhinocerebral, cerebral, cutaneous, gastrointestinal
No underlying condition	Cutaneous, pulmonary, sino-orbital, rhinocerebral, gastrointestinal

Cutaneous Mucormycosis

Cutaneous zygomycosis represents approximately 20 percent of reported cases in adults and a slightly higher proportion of pediatric cases.[98,133] Primary cutaneous infection usually occurs at the site of trauma, burns, or adhesive dressings, or invasive procedures in immunocompromised hosts.[20,34,49,114,129,130] Among neonates, the skin is the most common point of entry, with involvement of adhesive tape, monitor leads, or central venous access sites predominating. Premature infants represent most neonatal cases, and the overall mortality rate reported in the literature is 75 percent.[60,81,97] Secondary cutaneous disease results from hematogenous dissemination.[49] Primary disease may be very invasive locally and by direct extension affect adjacent bone and tissue. With vessel invasion, frankly disseminated disease may arise.

Primary cutaneous disease has lesions, which appear erythematous and indurated and progress to form black eschars (Fig. 218–4). In contrast, cutaneous disease arising from disseminated disease usually manifests in patients as nodular subcutaneous lesions, which may ulcerate.[94] Cutaneous zygomycosis can be evidence of disseminated disease, but primary cutaneous zygomycosis associated with occlusive bandages, burns, or wounds rarely extends beyond local involvement.[42] Most cutaneous cases are caused by *Rhizopus* and manifest with lesions that typically are black necrotic ulcers surrounded by erythematous and indurated painful cellulitis.[43] There can be rapid progression and skin

Figure 218–4 Cutaneous zygomycosis in a child with neutropenia. (See companion Expert Consult web site for color version.)

necrosis caused by hyphae invading the vasculature and causing tissue infarction.[58] Cutaneous zygomycosis should be considered when skin necrosis continues despite administration of appropriate antibiotics.[83]

Pulmonary Mucormycosis

Pulmonary zygomycosis may develop as a result of inhalation or by hematogenous or lymphatic spread. The clinical manifestations of pulmonary zygomycosis are similar to the manifestations of invasive pulmonary aspergillosis and often are indistinguishable.[16] Mucormycotic pneumonia typically develops in severely immunocompromised patients, such as patients with malignancy and neutropenia,[65,74,109] but it also has occurred in patients with juvenile diabetes mellitus and in normal hosts.[18,45,98] Patients with pulmonary zygomycosis often present with fever, cough, chest pain, and rapidly progressive dyspnea.[111] Angioinvasion results in necrosis of lung tissue, which may lead to cavitation and hemoptysis. Massive pulmonary hemorrhage may result from vascular erosion.[37,127] Chest radiographs and computed tomography (CT) scans may reveal a lobar pneumonia pattern, isolated masses, nodular disease, cavitation, or wedge-shaped areas of infarction.[48,64,68,111] Because of the lack of inflammatory cells that are capable of infiltrating the lung in neutropenic patients, however, radiography may not be dramatically abnormal.

Distinguishing pulmonary zygomycosis from invasive pulmonary aspergillosis is a clinical challenge. In patients with hematologic malignancies, clues for distinguishing pulmonary zygomycosis are the presence of concomitant pansinusitis, a history of antifungal prophylaxis with *Aspergillus*-active agents such as voriconazole and echinocandins, and possibly the repeated absence of detectable *Aspergillus* galactomannan antigen in serum. In addition, the presence of multiple nodules (>10) and, to a lesser degree, pleural effusions on CT scans favors the diagnosis of pulmonary zygomycosis over invasive pulmonary aspergillosis in patients with cancer.[16] Some atypical presentations of pulmonary zygomycosis include chronic infection with constitutional symptoms in relatively immunocompetent hosts.[71] Rarely, fungus balls have been noted within a preexisting lung cavity.[94] Hypersensitivity pneumonitis caused by *Rhizopus* spp. has been described in farm workers and Scandinavian sawmill workers (so-called wood trimmer's disease).[27] The disease usually is fulminant, but may be milder in hosts with less severe immunocompromise.

Gastrointestinal Mucormycosis

Gastrointestinal involvement probably results from ingestion of fungal spores, either from the environment or from colonized upper airways. Occasionally, hematogenous or direct extension routes result in intestinal tract involvement. Malnutrition, prematurity, uremia, and underlying gastrointestinal disease, such as typhoid fever or amebiasis, are predisposing factors.[59,70,72,78] Gastrointestinal zygomycosis is the most common clinical manifestation among neonates, representing two thirds of neonatal cases.[133] Most gastrointestinal disease in neonates is seen in premature neonates, some occurring in association with progressive necrotizing skin lesions and others manifesting with necrotizing enterocolitis.[115,132] All sites along the intestinal tract can be involved, with the stomach and colon being the most common sites.[78] Nonspecific abdominal pain with hematemesis, hematochezia, or melena may occur. Dissemination to other sites may occur by hematogenous routes. Perforation after bowel wall necrosis is common. Diagnosis usually is made at autopsy.

Disseminated Mucormycosis

Disseminated mucormycosis occurs in the most severely immunocompromised patients and usually is diagnosed post mortem.[42,118] Clinical findings are nonspecific, and a high index of suspicion and readily accessible tissue for biopsy are needed to establish the diagnosis. The pulmonary system is affected most commonly, followed by the central nervous system, but virtually any organ can be involved. A subacute form of disseminated disease with a protracted but fatal course has been reported.[82] The combination of severe immunocompromise and subtle clinical findings renders this form of mucormycosis the most difficult to treat.

Miscellaneous Forms of Mucormycosis

A variety of case reports of mucormycosis involving isolated areas of the body are found in the literature and include reports of endocarditis,[71,100,134] brain abscess,[98] peritonitis,[15,76,87] osteomyelitis,[28] mediastinitis,[67] tracheitis,[103] corneal infection,[112] otitis externa,[112] superior vena cava syndrome,[13] and renal disease.[62] Common to these disease manifestations is some type of local accidental or surgical trauma that results in a ready access site for invasion of fungal organisms. Outcome varies and depends on the underlying condition of the host and the extent of disease.

DIAGNOSIS

The presence of Zygomycetes in clinical specimens need not always represent clinically significant isolates. The spores from asexual reproduction are easily airborne and may be laboratory contaminants of culture medium or a result of oral ingestion in food or nasal inhalation of air before patient sampling. A positive culture linked to hyphal identification in cytologic specimens or tissue sections is considered diagnostic.[4,94] One study showed that the isolation of Zygomycetes from a patient with malignancy with no risk factors or clinically evident infection probably represents colonization; however, the pretest probability of a culture positive for Zygomycetes in a patient with leukemia was high.[53]

In most patients, the clinical presentation is assumed to be invasive aspergillosis, and in one series of 185 cases of disseminated zygomycosis, the correct diagnosis was made ante mortem in only 17 cases.[42] In the largest single-center review of zygomycosis, chest radiographs were abnormal in all patients with pulmonary zygomycosis, showing patterns such as focal consolidation (30%), cavitation (24%), widespread infiltrates (24%), or nodules (18%).[53] Cavitation is a common finding on chest radiograph, but the "air crescent sign" is seen less frequently than in patients with

invasive aspergillosis. In acidotic patients, pulmonary findings mostly manifest as lobar consolidation that may cavitate to form a lung abscess.[19] In one series, most manifestations in patients with pulmonary involvement were nodular or cavitary lesions.[74]

Noninvasive diagnostic procedures for zygomycosis are nonspecific, and a tissue diagnosis must be sought, even in situations in which other infectious agents have been isolated. Cultures of blood and bodily fluid rarely detect the disease. Immunofluorescent antibody staining of formaldehyde-fixed tissue is available through the mycology section of the Centers for Disease Control and Prevention, which might be helpful in confirming a suspected diagnosis.[29,42] Many specimens, including blood, sputum, gastric fluid, or nasal swabs, are either difficult to culture or of no diagnostic value, and invasive zygomycosis is correctly diagnosed with tissue biopsy.[29]

Antemortem respiratory tract specimens from autopsy-confirmed cases found zero of eight positive results in patients, including blood, urine, and cerebrospinal fluid cultures.[85] Cultures of lower respiratory specimens, including bronchoalveolar lavage and sputum specimens, were negative for zygomycosis in 75 percent of cases of histopathologically proven pulmonary zygomycosis, possibly owing to the high incidence of concomitant pulmonary infections.[53] Pulmonary zygomycosis has been diagnosed by fine-needle aspiration,[5] and an analysis of 87 cases of zygomycosis revealed that 40 percent of pulmonary disease was diagnosed by transbronchial biopsy, and 20 percent required open lung biopsy or surgical resection for diagnosis.[56]

Serologic diagnostic tests for detecting zygomycosis are not clinically useful. Antibody tests lack specificity, whereas several antigen detection systems have been used in tissue specimens. Very few molecular techniques are in use for establishing the diagnosis of zygomycosis, and techniques that are available are still experimental. Polymerase chain reaction amplification of the 18S rRNA sequences may be useful in epidemiologic studies of outbreaks, but little is currently being offered for primary diagnosis.[94] Primers from ribosomal DNA for Zygomycetes most implicated in clinical infection have been designed for use in a polymerase chain reaction assay for rapid and accurate identification.[95,119]

TREATMENT

Of overall great importance is the combination of early and aggressive surgical excision of the necrotic lesions, restoration of immune function, and intense antifungal therapy. Because tissue infarction is a prominent feature, removal of devitalized tissue is crucial because antifungals alone, especially in the setting of continued immunosuppression, would not elicit cure.[57,85] All necrotic-appearing tissue should be removed, and often patients require repeated surgical procedures for removal of devitalized tissue. Surgical débridement alone may be sufficient to cure localized cutaneous disease.[89]

Currently, the recommended antifungal therapy for zygomycosis is amphotericin B, given at maximal dosages of 1 to 1.5 mg/kg/day, based on the individual's tolerance of side effects.[51] Amphotericin B lipid complex also has been used successfully.[84] Whether lipid formulations of amphotericin B confer any advantage over conventional amphotericin B for mucormycosis is unclear,[53,84] but avoiding the nephrotoxicity associated with conventional amphotericin B may prove beneficial in delivering a longer duration of therapy.

Most azoles, including fluconazole and voriconazole, have no meaningful activity against Zygomycetes fungi. This point is crucial because voriconazole is an excellent antifungal against invasive aspergillosis, but has no clinical activity against zygomycosis. Posaconazole, a more recently approved orally available triazole, does possess potent activity against Zygomycetes.[113] In several more recent salvage therapy reports and studies, the overall success rate was 60 to 70 percent in patients with refractory disease.[90,116,104] The drug was well tolerated with only minimal gastrointestinal side effects. These encouraging results suggest that posaconazole may be a significant advance in the treatment of zygomycosis, but dedicated prospective clinical trial data are lacking. Echinocandins lack significant activity against Zygomycetes in vitro, and several cases of breakthrough zygomycosis have occurred in patients receiving echinocandin-based therapy.[52] This is a second crucial treatment point because the echinocandins also possess antifungal activity against invasive aspergillosis, but are not clinically useful against zygomycosis.

Hyperbaric oxygen therapy has been used as an adjunct to surgical and antifungal therapy for some patients in an attempt to limit the extent of gangrene and tissue necrosis.[21,30,46,88] The increased oxygen pressure achieved with hyperbaric therapy seems to improve the ability of neutrophils to kill organisms and inhibits fungal growth in vitro.[6] Although this regimen is apparently promising, the number of patients evaluated with this form of treatment is much too small to permit making any firm conclusions on its benefit. The role of other adjunctive therapies for zygomycosis has not been well studied. Granulocyte transfusions or cytokines that enhance phagocytic activity, such as interferon-γ and granulocyte-macrophage colony-stimulating factor, have been used occasionally to treat patients with zygomycosis.[1,35,106] Case reports have indicated favorable outcomes in patients treated with these adjunctive therapies,[1,106] but further studies are warranted before these therapies are recommended routinely.

PROGNOSIS AND PREVENTION

The disease site and host factors are key determinants of prognosis for zygomycosis. The reported mortality rate is highest for disseminated disease (100%) followed by gastrointestinal (85%), cerebral (79%), pulmonary (76%), and rhinocerebral (46%) disease.[98] Localized cutaneous disease is associated with a low mortality rate of 10 percent. Significant risk factors for mortality include disseminated disease and renal failure. Patients who undergo surgery as primary therapy and patients who receive antifungal therapy are significantly more likely to survive.[98] Among children, age younger than 1 year is associated with higher mortality.[133]

ENTOMOPHTHOROMYCOSIS

PATHOGENESIS AND PATHOLOGY

Entomophthoromycosis presumably develops through inhalation of spores to cause sinus disease or cutaneous inoculation to cause cutaneous or subcutaneous infection. The exact mechanisms are unclear, however, and no specific animal model has been developed. The organisms are of extremely low virulence, as manifested by the rare occurrence of these infections despite the ubiquitous nature of the fungi. Although discrete clinical syndromes have been assigned to the two genera causing disease, this distinction is artificial, and one should recognize that either group could cause either form of entomophthoromycosis or even a syndrome more suggestive of mucormycosis.[94,102,124,126]

Histopathologic examination of affected tissues shows some similarities to mucormycosis. Areas of acute and chronic inflammation are found in association with broad hyphal elements that may or may not display septations. The hyphae are more visible with hematoxylin and eosin staining than with more specific fungal stains.[94] The tendency for vascular invasion typical of mucormycosis does not occur with entomophthoromycosis, however, and necrosis is uncommon. Instead, a Splendore-

Hoeppli phenomenon, likely consisting of hyphae surrounded by eosinophilic material in a stellate pattern, occurs.[94] This feature is not pathognomonic of entomophthoromycosis, however, and has been seen in cases of mucormycosis.

CLINICAL MANIFESTATIONS

Chronic Rhinofacial Zygomycosis

Chronic rhinofacial zygomycosis, also called *entomophthoromycosis conidiobolae* because most infections are caused by *Conidiobolus coronatus*, is an indolent subcutaneous infection involving the face.[38,73,77] Typically, bilateral intranasal swelling eventually progresses to invasion of the sinuses and soft tissue swelling of the face, unaccompanied by fever or pain. One infant developed orbital involvement from *C. coronatus* dacryocystitis.[61] Symptoms commonly persist for weeks or months, but deep tissue progression is unlikely to occur.

Chronic Subcutaneous Zygomycosis

Chronic subcutaneous zygomycosis, also known as *entomophthoromycosis basidiobolae*, is similar to chronic rhinofacial disease with the exception that the lesions usually are on the trunk or extremities. The etiologic agent is *Basidiobolus ranarum*. Painless subcutaneous nodules may progress to invade deeper soft tissues, and massive soft tissue swelling may develop. Facial infection similar to that of chronic rhinofacial zygomycosis also may occur.[26] *Conidiobolus incongruus* has caused orbitofacial disease in a child residing in the Middle East.[2] With rare exceptions, most cases of subcutaneous zygomycosis are slowly progressive.[44,94]

Gastrointestinal Basidiobolomycosis

Gastrointestinal basidiobolomycosis is an extremely rare condition resulting from *B. ranarum* infection of the gastrointestinal tract. A cluster of cases was identified in Arizona in the late 1990s, suggesting a possible emerging infection in the region. In a case-control study including seven adult patients in Arizona, infected patients tended to be more likely to use ranitidine and to have resided in Arizona for a longer time compared with controls.[63] Clinical features included abdominal pain, leukocytosis, and eosinophilia. Combined surgical resection and itraconazole seemed to be effective treatment.

DIAGNOSIS

Entomophthoromycosis often can be diagnosed presumptively on the basis of clinical presentation and geographic origin of the patient, but usually biopsy is required.[94] More recent work on serodiagnosis by immunodiffusion has had promising results.[41,47] Onchocerciasis, filariasis, and Burkitt lymphoma sometimes are in the differential diagnosis.[44,94]

TREATMENT

Evaluating therapy for this group of diseases is difficult because of occasional reports of spontaneous resolution. Many agents have been tried with variable success. Taylor and colleagues[110] treated a young man with rhinofacial disease with amphotericin B, corticosteroids, miconazole, and multiple surgical procedures before noting resolution months after any therapy had been given. Susceptibility testing of the isolate on the patient showed minimal inhibitory effects of amphotericin B and no benefit of adding flucytosine or rifampin; miconazole, ketoconazole, and potassium iodide did not have impressive in vitro activity. Other investigators recommend potassium iodide therapy, with trimethoprim-sulfamethoxazole as an alternative.[92]

Other anecdotal reports of efficacy of trimethoprim-sulfamethoxazole, ketoconazole, or itraconazole raise hopes for the future development of effective therapy, but such hope must be tempered by the fact that only small numbers of patients have been treated.[38,63,110] Currently, no antifungal is the preferred treatment for this condition, although some type of medical therapy seems indicated for all cases. Data regarding the activity of posaconazole against this group of fungi are unavailable. The role of surgery is less for this group of disorders than for mucormycosis, but patients with well-circumscribed areas, such as nodular lesions, may benefit from surgical excision. Despite surgery, recurrence of disease after surgery commonly occurs in such patients.[110]

PROGNOSIS AND PREVENTION

Mortality caused by entomophthoromycoses is unlikely to occur, but morbidity and disfigurement are common. The efficacy of medical and surgical therapy is unclear, but all patients likely should receive attempts at treatment because the natural history of the disease is one of slow progression. Specific means for preventing disease are unavailable because so little is known about factors predisposing individuals to these chronic zygomycotic syndromes.

CHAPTER 219

Miscellaneous Mycoses

Judith L. Rowen

ENTITIES

Fungi other than the classic mycoses generally cause disease in two distinct ways: (1) Organisms present in the environment are inoculated accidentally into the host, and (2) immunocompromised hosts cannot defend against the ubiquitous fungi and acquire systemic infection with organisms that rarely are seen as pathogens in a normal host. When the infection is caused by inoculation, several distinct entities occur that may be caused by many different fungi. Table 219–1 lists etiologies reported for these clinical syndromes.

TABLE 219–1 Selected Miscellaneous Fungi Implicated in Common Clinical Syndromes

Clinical Syndrome	Genus	References
Keratitis	*Acremonium*	76, 93
	Alternaria	37, 181
	Aureobasidium	86
	Bipolaris	86
	Blastoschizomyces	125
	Curvularia	181
	Exophiala	6
	Fusarium	181
	Geotrichum	183
	Lasiodiplodia	231
	Metarrhizium	55
	Paecilomyces	181
	Penicillium	181
	Phoma	203
	Scedosporium/ Pseudoallescheria	37, 100, 180
	Scopulariopsis	37
Mycetoma/soft tissue infection	*Acremonium*	75, 93, 249
	Alternaria	34
	Curvularia	207
	Exophiala jeanselmei	249

	Trichosporon	45, 58, 150, 245
Sinusitis	*Acremonium*	76
	Alternaria	62, 159
	Bipolaris	62, 247
	Curvularia	62, 106, 165
	Exserohilum	2, 62
	Fusarium	62
	Pseudallescheria	245
	Scopulariopsis	67, 119
	Ulocladium	184

NOTE: The fungi listed are those within the purview of this section on "miscellaneous mycoses." Many of these syndromes are commonly caused by Candida, Aspergillus, and the Zygomycetes as well.

MYCOTIC KERATITIS

In a review of 51 cases of microbial keratitis in children, 18 percent were attributed to fungal pathogens.[52] The proportion of cases of keratitis caused by fungal pathogens is higher in adults, and the outcome generally is worse than in children.[231] *Fusarium* and *Aspergillus* are the most commonly isolated fungi, followed by *Curvularia* and *Alternaria*.[181,231] Corneal infection with fungi often occurs after trauma to the eye (e.g., by a nylon-line trimmer, frequently with contamination of the injury by organic matter).[48,181,231] More recently, contact lens use has been implicated in numerous cases of mycotic keratitis.[109] The diagnosis often is delayed because the child has been presumptively treated with antibacterial, antiviral, or corticosteroid drops before the acquisition of corneal scrapings.[181] The most common manifestations include a grayish surface and anterior chamber reaction; serrated margins, raised slough, satellite lesions, and any color other than yellow suggests a fungal rather than bacterial etiology.[231,232]

Gram stain or potassium hydroxide wet-mount examination of eye drainage or scrapings frequently results in a proper diagnosis.[231,238] Appropriate therapy with topical or oral antifungal agents, or both, is successful in most cases; surgical therapy is required for patients with large areas of infiltrate or who have failed medical treatment.[81,86] Natamycin, a topical polyene, is used most frequently, but successful treatment with topical and systemic voriconazole is reported increasingly.[37,231] New products, such as collagen shields soaked in antifungal medications, may improve drug delivery over drops, which must be applied at frequent intervals.[231]

SOFT TISSUE INFECTION, INCLUDING MYCETOMA

Smoldering infection may occur when environmental fungi are inoculated directly into normal tissue. The classic manifestation of this process is mycetoma, a chronic granulomatous disorder affecting all the soft tissues in the area of inoculation and occasionally involving bone and distant organs.[249] The incubation period ranges from months to years after the original trauma occurs.[132] The condition is characterized by abscesses, nodules, and sinuses that may drain characteristic granules. Figure 219–1 depicts a characteristic granule.

Approximately two thirds of mycetomata actually are caused by bacteria, such as *Nocardia* spp., whereas the remaining third (also referred to as *eumycetoma*) are caused by fungi.[38] In the United States, the pathogen found most frequently is *Scedosporium apiospermum* (sexual phase, *Pseudallescheria boydii*),[38] but in the subtropics, where the condition is more prevalent, the organism isolated most frequently is *Madurella mycetomatis*.[249] The disease occurs more commonly in men than women and is more likely to affect adults than children.[249] In one case series, however, 4.5 percent of cases occurred in children.[29] The age and gender differences in the incidence of disease have been ascribed to hormonal influences, although another potential contributing factor is increased occupational exposure in male farm workers.[29] The lower extremity, especially the foot, is the body part most commonly involved, followed by the thorax, but cases have been reported that involve all body areas.[38,249]

The differential diagnosis includes cutaneous tuberculosis, tumor, osteomyelitis, and sporotrichosis.[249] Examination of exudates from draining sinuses may reveal the diagnosis, but surgical biopsy might be required.[38,249] Therapy should be directed at the pathogen isolated; itraconazole has shown some promise in selected cases.[30,249]

FUNGAL PERITONITIS

Patients undergoing peritoneal dialysis are compromised hosts because of direct violation of the mucocutaneous barrier by the dialysis catheter and the immunosuppressive effect of the underlying renal disease.[19] Fungal peritonitis develops after contamination of the dialysis system occurs. *Candida* spp. are the most common causative agents,[246] but several other yeasts and filamentous fungi have been reported as the etiology (see Table 219–1). Fungi are responsible for 2.9 percent of episodes of peritonitis that occur in children undergoing peritoneal dialysis.[246] Treatment includes removal of the dialysis catheter and initiation of antifungal therapy, but the ideal timing for removal of the catheter is unclear.[27,246] Amphotericin has very poor penetration into the dialysate when given intravenously[27] and is irritating when given intraperitoneally.[74] Penetration of fluconazole into

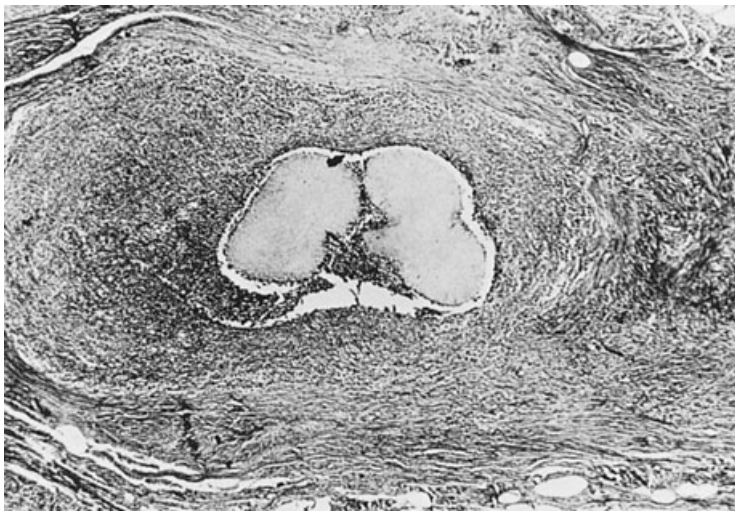

Figure 219–1 Large granule of *P. boydii* in the sinus tract of a mycetoma. Extensive fibrosis is seen in the periphery of the tract, and the tract is filled with a mixed granulomatous and pyogenic infiltrate (hematoxylin and eosin, ×100). *(Courtesy of Centers for Disease Control and Prevention.)*

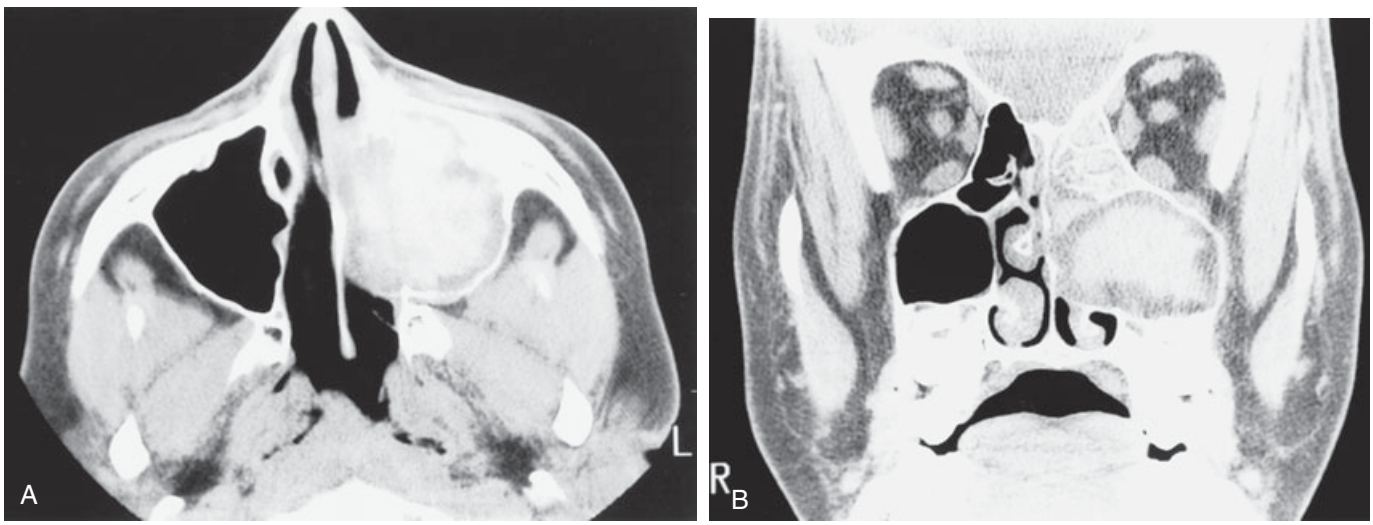

Figure 219–2 Allergic *Curvularia* sinusitis in a 12-year-old girl. **A,** CT scan shows a large space-occupying mass involving the left maxillary sinus with expansion of its medial and lateral posterior walls. The mass has high density centrally with a peripheral zone of decreased density. **B,** Coronal image shows the mass with centrally increased density and low density in the periphery. Additionally, the ethmoid air cells are involved. *(Photos courtesy of Eric Hendrick, M.D.)*

dialysate is rapid and efficient.[27] Fluconazole and itraconazole have been used successfully as therapy.[27,43,83,156,245] The outcome of fungal peritonitis may be better in children than adults, with a larger percentage successfully continuing peritoneal dialysis.[246]

FUNGAL SINUSITIS

Fungal sinusitis apparently is a spectrum of diseases ranging from a purely allergic condition through invasive forms that may progress to brain abscess as erosion through the sinus walls continues.[59] Noninvasive sinusitis takes two forms: allergic fungal sinusitis and sinus mycetoma. In allergic fungal sinusitis, the sinus (most commonly a maxillary sinus) fills with a gelatinous material often described as having the consistency of peanut butter or cottage cheese.[59] This material consists of mucin, eosinophils, Charcot-Leyden crystals, and sparse fungal hyphae.[62] Patients have signs and symptoms of chronic sinusitis, and proptosis and distortion of facial features may develop, more commonly in children.[62,143,165] Most case series include children, with the youngest patients being early elementary school age.[62,120,211] The disease is more common in humid, coastal areas.[59] The fungi implicated most commonly include *Curvularia* and *Bipolaris* spp.[50,62,211]; *Aspergillus*, *Exserohilum*, and *Alternaria* spp. also have been reported.[50,59]

The diagnosis of allergic fungal sinusitis should be suspected in patients with chronic sinusitis, especially patients with a history of atopy. Nasal polyps are found frequently, and many patients may recall production of nasal casts.[62,211] Computed tomography (CT) and magnetic resonance imaging (MRI) may highly suggest the diagnosis; on non–contrast-enhanced CT, the sinuses contain areas of high attenuation, and by MRI, areas of T2-weighted signal void are seen.[133] Figure 219–2 shows a typical CT scan from a patient with allergic fungal sinusitis. Many patients show loss of bony margins; this loss is not from invasive destruction, but from bone compression caused by a mass effect.[62] The diagnosis is confirmed by histopathology; to meet the criteria for allergic fungal sinusitis, the patient must be immunocompetent; have radiographic evidence of sinusitis; and have histologic

specimens with eosinophil-rich allergic mucin, positive fungal stain or culture, and no evidence of invasion.[62]

Treatment predominantly is surgical, usually endoscopic removal of the allergic mucin and improvement in aeration and drainage.[59,62,120,137] The pathophysiology is assumed to be similar to that of allergic bronchopulmonary aspergillosis, in that the disease is the result of the host's response to inhaled fungi that lodge in the sinuses, rather than the result of true infection.[50] Elevated IgE is noted frequently.[62,211] Systemic and nasally inhaled corticosteroids are administered after surgical drainage has been performed.[59,137,212] Immunotherapy with fungal allergens also has been used by some clinicians.[137] Recurrences are common, especially if use of corticosteroids is stopped prematurely.[212] Itraconazole has been reported to be helpful in treating allergic bronchopulmonary aspergillosis[224]; it has been used in some cases of allergic fungal sinusitis, but its utility is yet unproven.[13]

The other form of noninvasive fungal sinusitis is sinus mycetoma, which essentially is a fungus ball in the sinuses, usually the maxillary sinuses.[60,117] The patient initially has nasal obstruction, facial pain, and a fetid odor (cacosmia).[59,60] Similar to allergic fungal sinusitis, distortion of the bony margins may occur,[60] although one large series noted this finding in only 4 percent of patients.[117] Although *Aspergillus fumigatus* is the fungus most frequently implicated, *Pseudallescheria* and *Alternaria* also are reported.[60,117] Claylike, cheesy material, similar in appearance to the material present in allergic fungal sinusitis, but without the findings of allergic mucin on histopathology, is seen at surgery.[59] Although hyphae are sparse in allergic fungal sinusitis, they are abundant in mycetoma, but frequently fail to grow on culture.[59] Treatment is surgical, with wide opening of the sinuses and removal of the mycetoma; recurrences are rare.[117]

Acute, fulminant invasive fungal sinusitis is associated most frequently with Zygomycetes or *Aspergillus* in immunocompromised individuals.[59] Reports of this entity increasingly implicate other fungi, however, such as *Pseudallescheria*, *Fusarium*, *Alternaria*, and *Scopulariopsis*.[59,67,119,159] Affected patients usually are immunocompromised as a result of having cancer, transplantation, or poorly controlled diabetes mellitus.[61] Four percent of children treated at one center for hematologic or lymphoid malignancies developed invasive fungal sinusitis; all were neutropenic for a prolonged period (mean 21.3 days).[184] Initial signs and symptoms may be limited to fever or facial pain, with some patients developing headache and epistaxis; careful physical examination or nasal endoscopy may reveal nasal mucosal ulcers or eschars.[59,184] The hallmark of this entity is histopathologic evidence of invasion into the mucosa or other tissues.[59,61] The disease may progress rapidly and lead to orbital apex syndrome and further intracranial involvement.[59] Therapy includes wide surgical excision and administration of amphotericin B; lipid formulations of amphotericin B and combination therapy may be useful in treating this syndrome.[59,184]

ETIOLOGIES

The taxonomy of fungi has undergone significant revision with the addition of molecular techniques to the classic morphologic methods. When presented with a patient with a fungal infection, the clinician rarely can identify the taxonomic group of the invading organism until final culture results are available. Instead, the appearance of the organism in tissue specimens is what is appreciated first. In the following discussion of infection caused by specific pathogens, the organisms are grouped by their appearance in tissue. For detailed review of fungal taxonomy, the reader is referred to several excellent resources.[228,254]

YEASTS

In contrast to the filamentous fungi, which tend to invade locally at the site of initial inoculation, with later dissemination if at all, yeasts tend to cause disease after hematogenous dissemination without significant local disease. End-organ deposition may lead to focal disease, however, after hematogenous spread. In addition to *Candida* and the classic dimorphic fungi of endemic infections, several yeastlike pathogens have emerged as significant pathogens.

Malassezia Species

Also known by the obsolete term *Pityrosporum*, *Malassezia* spp. are most familiar as the cause of a minor skin infection, tinea versicolor. *Malassezia* spp. also have a putative role in neonatal cephalic pustulosis, seborrheic dermatitis, and atopic dermatitis.[17] *Malassezia furfur* and *Malassezia pachydermatis* also cause bloodstream infection, usually in association with central venous catheters. *M. furfur* is obligatorily lipophilic, which probably explains the concordance of systemic disease with the use of intravenous lipid emulsions. Systemic infection with *Malassezia* was described first in 1981 by Redline and Dahms[199]; the patient was an extremely low-birth-weight infant, which is typical for this disease. Catheter-related *Malassezia* fungemia also has been described in older children and adults with immunocompromising conditions.[20] In a review of 55 cases in neonates, the most common underlying condition was prematurity, followed by short-gut syndrome; all infants were receiving lipid supplementation.[136] In contrast, *M. pachydermatis* does not require lipids for growth. This organism is most familiar as a causative agent of otitis externa in dogs, and at least one nursery outbreak has been associated with colonized pets of health care workers.[44]

Adults are colonized nearly universally with *Malassezia* organisms.[136] Colonization in neonates varies from 30 to 100 percent of those sampled and occurs early in life.[5,123,194,216] Factors correlated with colonization include length of hospitalization, lower gestational age, time in an isolette, and use of occlusive dressings.[136] The organisms resist superficial cleaning and may persist on plastic surfaces for prolonged periods of at least 3 months, which may facilitate outbreaks within an intensive care nursery.[239]

Clinically, infected infants have fever (53%), respiratory distress (53%), lethargy, poor feeding, bradycardia, and hepatosplenomegaly.[136] Thrombocytopenia occurs in 48 percent. Frequently, blood drawn directly from the central catheter is culture-positive, with negative peripheral blood cultures. The laboratory should be alerted that *Malassezia* is suspected because lipid supplementation may enhance recovery of the organism.[173] The 2.5- to 6-μm yeasts may be seen on a smear of blood drawn through the catheter.[91,135] Treatment should include removal of the implicated central catheter. Antifungal therapy usually is provided, although testing suggests only moderate susceptibility to amphotericin B.[135] Most infants recover; however, infants dying of infection frequently have heavy involvement of the lungs and heart at autopsy.[135,136]

Trichosporon Species

Most infections caused by *Trichosporon* are attributed to *Trichosporon beigelii* in the literature; however, revision of the genus has suggested that most invasive disease is caused by *Trichosporon asahii*, with other species implicated predominantly in superficial disease, such as white piedra.[228] White piedra affects the shafts of terminal hairs and results in nodules or coalescent concretions; one epidemiologic survey found it in 40 percent of men and 14 percent of women tested.[112] Invasive disease usually affects cancer patients with neutropenia or neonates.[10,78,95,99,102] Table 219–2

TABLE 219–2 Summary of Reported *Trichosporon* Infections

Type of Infection	Underlying Condition	References
Bloodstream	Burns	94
Cholangitis	Natural killer cell deficiency	111
Disseminated	Hemophagocytic syndrome	56, 101
Endocarditis	Repaired congenital heart disease	15

Septic arthritis	Acute myelogenous leukemia	149
Shunt infection	Arachnoid cyst	18
Urinary tract infection	Renal transplant	128

summarizes other reports of *Trichosporon* infection causing unusual manifestations of disease or affecting patients with other underlying conditions.

Trichosporon is isolated from blood cultures as a yeast that is germ tube–negative and urease-positive. In tissue sections, hyaline hyphae with septations and rectangular arthroconidia (2 to 4 μm × 3 to 7 μm) are seen, with pseudohyphae and blastoconidia noted occasionally.[228] The organism may be found in soil, water, vegetation, and animal excreta.[102,228] *Trichosporon* shares a heat-stable antigen with *Cryptococcus neoformans*, which may cause the latex agglutination test for cryptococcal capsular polysaccharide to be positive in the setting of disseminated *Trichosporon* infection.[148] The results of the cryptococcal antigen test have been followed in an experimental model and in patients to document response to therapy; however, the initial antigen testing may be negative despite disseminated disease.[94,227,243]

Most affected neonates have been less than 1000 g birth weight and born between 23 and 25 weeks' gestational age.[78,209,229,256] Disease was identified most frequently in the second week of life, with the bloodstream and skin being the sites most commonly involved. Respiratory cultures usually are positive, suggesting the lung as a possible portal of entry.[209] Most of these infants died of their infection.

The incidence of trichosporonosis in patients with hematologic malignancies has been reported to be 0.4 percent.[90] Immunocompromised hosts frequently have fever during periods of neutropenia. Skin involvement occurs with disseminated disease and is described as papular, purpuric, or necrotic lesions.[70,108] The organism is recovered from blood cultures, skin lesions, urine, sputum, and liver and kidney biopsy specimens, indicating the organism's widespread involvement.[70,102] Isolated fungemia (including catheter sepsis) and infection limited to the lungs also have been reported.[9,118,157] Mortality rates are high; one cancer center reported 53 percent crude mortality.[70,102,118] Although most immunocompromised hosts with *Trichosporon* infection have been patients with cancer, infection also has been reported in patients with congenital immunodeficiencies, such as chronic granulomatous disease[162]; see Table 219–2 for other examples.

Although amphotericin B often is used, some experts recommend therapy with one of the newer azoles. The organism has been described as tolerant to amphotericin B,[244] but animal models have shown good efficacy with fluconazole.[10,243] Voriconazole has good activity in vitro, and reports of successful clinical use are increasing.[16,134,141,146] Successful therapy with lipid-based amphotericin B and with posaconazole has been reported.[54,229] Echinocandins are not sufficiently active against *Trichosporon*, and breakthrough infections have occurred in patients receiving these drugs for antifungal prophylaxis.[92,141]

Penicillium marneffei

Occasional reports describe opportunistic infection with *Penicillium* molds,[130] but the major pathogen in this genus is *Penicillium marneffei*, which is the only species that is a dimorphic fungus. At 25° C, *P. marneffei* grows as a filamentous mold and produces a diffusible red pigment, whereas at 37° C, it grows as a yeast form that reproduces by fission rather than budding.[49] The hyphae are septate and hyaline, and the yeast forms are 3 to 5 μm in size, similar to the size of *Histoplasma*.[228] Initial reports confused the organism with *Histoplasma*; one histopathologic feature that may be helpful is that the yeasts of *P. marneffei* frequently have visible cross walls that form during fission.[49,57] Adding to the potential confusion, infection with *P. marneffei* may lead to a false-positive *Histoplasma* antigen test.[49]

The fungus was isolated first from bamboo rats captured in Vietnam, and the disease is endemic to Southeast Asia, including areas of Myanmar, Cambodia, southern China, Indonesia, Laos, Malaysia, Thailand, and Vietnam.[171] Disease caused by *P. marneffei* was listed as an acquired immunodeficiency syndrome (AIDS)–defining condition in 1992, and it is the third most common opportunistic infection in the Chiang Mai region of Thailand, with 16 percent of all patients infected with human immunodeficiency virus (HIV).[49] The exact mode of transmission is unclear; bamboo rats and humans are thought to be infected from a common source, rather than transmission being from rats to humans.[63] An inhalational route of infection is supported by an infection in a physician from Africa who was HIV-positive and whose only possible exposure was during a visit to the Pasteur Institute, where other laboratory workers were handling the fungus.[171] The incubation period may be only 2 weeks or very prolonged; the first recognized human case was in a U.S. missionary with Hodgkin disease who had traveled in Southeast Asia 2 years before the discovery of his infection.[171]

In most cases, the disease is disseminated, with prominent involvement of the skin by umbilicated papules reminiscent of molluscum contagiosum (Fig. 219–3).[49] As with the other endemic mycoses caused by dimorphic fungi, the disease is thought to disseminate from a pulmonary source.[240] In a review of 21 children with HIV and penicilliosis, the initial signs and symptoms included generalized lymphadenopathy (90%), hepatomegaly

Figure 219–3 Skin lesions from *P. marneffei*. *(Photograph courtesy of S. Chiewchanvit, provided by www.doctorfungus.org.)*

(90%), fever (81%), skin lesions (67%), splenomegaly (67%), failure to thrive (52%), severe anemia (43%), and thrombocytopenia (21%).[222] The infection was manifested at a later age than most opportunistic infections in this population (32 months of age versus 7 months of age). In adults, fever, weight loss, and anemia also are prominent, and a painful cough is noted frequently.[63] The organism usually is isolated from blood cultures; skin biopsy cultures also frequently yield the organism.[63,222]

More focal involvement of lymph nodes may occur. In children with HIV, mesenteric adenitis with prolonged fever and abdominal pain may mimic acute appendicitis.[237] Chronic lymphadenopathy resembling scrofula has been reported in a previously healthy child.[257] This child and another without underlying disease had transient lymphocyte abnormalities that resolved after treatment of the infection.[121,257]

The diagnosis depends primarily on isolation of the organism from cultures or characteristic findings on histopathologic examination with a consistent clinical history. Bone marrow aspirates, touch smears of skin, or lymph node biopsy specimens can be Wright stained for rapid, presumptive diagnosis.[240] Occasionally, the organism is seen on peripheral blood smears.[240] Serologic and DNA amplification tests have been devised, but remain experimental.[63,171,240] The antibody used in galactomannan assays may cross-react with *P. marneffei.* Amphotericin B followed by itraconazole is the usual mode of therapy. As with many fungal infections in patients with HIV, relapse occurs frequently when therapy is halted.[225] In a placebo-controlled trial of itraconazole maintenance therapy, relapse did not occur in the treatment arm, whereas 20 of 35 placebo recipients relapsed at a mean of 24 weeks after therapy.[226]

Pichia Species

Pichia anomala (formerly known as *Hansenula anomala*) and *Pichia angusta* (formerly known as *Hansenula polymorpha*) are rare causes of human disease. *P. anomala* is the teleomorph, or sexual stage, of *Candida pelliculosa.* It characteristically has one to four hat-shaped ascospores when asci are produced.[228] It may colonize the human gastrointestinal tract and is found in pigeon excreta, plants, and fruit.[14] Another species, *Pichia ohmeri* (synonym, *Kodamaea ohmeri*) has been reported to cause disease, with several reports in pediatric patients.[190]

Human infection has been reported primarily in immunocompromised hosts and premature neonates.[8,14,147,161,166,213,220,233,255] Nursery outbreaks with high levels of colonization have been described.[14,166,220] Neonates with fungemia are lethargic and have mottling, apnea, bradycardia, and an increased need for ventilatory support.[166] Abscesses may occur at the site of insertion of peripheral intravenous catheters.[166] Jaundice and fever also have been described.[14] Almost every patient reported had recently received broad-spectrum antibiotics and had a central catheter in place, frequently for parenteral nutrition.[14] The organism often is isolated from blood cultures and the catheter tip.[8,255] Other infections have included ventriculitis, lymphadenitis, and necrotizing enteritis.[147,161,166]

Despite the fragile nature of the patients affected, disease caused by *Pichia* rarely is fatal. Most reported cases have been treated with amphotericin B plus 5-flucytosine and removal of central venous catheters. Although many isolates are susceptible to fluconazole, elevated minimal inhibitory concentrations (MICs) have been found in patients' isolates associated with poor clinical response to this drug.[8,255]

Rhodotorula Species

Rhodotorula grows as glistening pink-to-red colonies. Usually, no pseudohyphae are formed; the yeast cells are ovoid or elongate (2 to 5.5 μm × 2.5 to 14 μm).[228] The organism is urease-positive and does not ferment carbohydrates.[228] It can be found colonizing normal human skin, mucous membranes, shower curtains, bathtubs, and toothbrushes, and can be isolated from cheese, milk, air, soil, and water.[116,218,228] Most human infections have been associated with catheters in patients with cancer or HIV.[116,218,242] Endocarditis in a child with presumed underlying rheumatic heart disease also has been described, as have nursery outbreaks.[169,189] The pathogen seems to be of low virulence, with few deaths attributable to infection. Resistance to fluconazole is seen frequently, and disease has been reported in patients receiving fluconazole prophylaxis; in vitro testing suggests that most strains are susceptible to voriconazole, itraconazole, and amphotericin B, with ravuconazole having the highest activity of the newer agents.[71,116,127] Clinical cases have been treated successfully with amphotericin B or 5-flucytosine monotherapy and by removal of catheters, without antifungal therapy.[116,169]

Saccharomyces cerevisiae

Saccharomyces cerevisiae is a yeast best known as baker's yeast or brewer's yeast. Strains (often called *Saccharomyces boulardii*) also have been used as a biotherapeutic agent for severe diarrhea, especially *Clostridium difficile*–associated diarrhea.[97] The yeast is distributed ubiquitously in the environment and may be found as a commensal in the human gastrointestinal tract.[254] Clinical isolates have enhanced virulence compared with environmental strains when evaluated in animal models.[193] *Saccharomyces* is responsible for 3 percent of cases of fungal vaginitis, especially in women with a history of recurrent or chronic vaginitis.[193,223] Invasive infection develops in patients with multiple medical problems, usually with a central venous catheter in place.[9,77,156,234] The source of infection is presumed to be via translocation from the gastrointestinal tract or from indwelling venous lines.[234] Mortality rates with these infections are high, with reports ranging from 35 to almost 50 percent.[68,77,163]

Organisms have been isolated from nearly every body site.[68,77,163] Infections associated with the use of *S. boulardii* (actually not a separate species) seem to be less clinically devastating, although septic shock developed in one patient, who later recovered.[68,97,192] Environmental sampling has indicated that the organisms can be isolated from the air, environmental surfaces, and the hands of caretakers opening packets for administration to the patient, so direct contamination of central venous catheters may be the source, although gut translocation also has been postulated.[97,192] In a review of 60 cases, probiotic use was noted in 43 percent.[163] The authors recommend caution when considering probiotics in immunosuppressed or critically ill patients. Therapy

includes removal of implicated catheters and administration of antifungal agents. MICs are low for amphotericin B and 5-flucytosine, and itraconazole and voriconazole seem to have better activity than fluconazole.[71,234]

Blastoschizomyces capitatus

Blastoschizomyces capitatus was formerly known as *Trichosporon capitatum* and *Geotrichum capitatum*. It may be found in soil and beach sand and as part of the normal human flora of the gastrointestinal tract.[228] Infection has been seen predominantly in immunocompromised hosts, especially patients with hematologic malignancies; one European consortium reported an incidence of 0.5 percent in their patients.[90] In a review of 99 patients with *Blastoschizomyces* infection, blood cultures were positive in 77 percent.[90] In another case series, 8 patients had lesions comparable to those seen with hepatosplenic candidiasis, and the fungus grew from liver specimens.[139] Focal lesions of the brain and kidney also have been described.[90,139] Chronic meningitis that developed in a patient after bone marrow transplantation has been described.[89] Organisms have been isolated from the blood, heart, lungs, liver, spleen, cerebrospinal fluid (CSF), skin, stomach, urine, kidneys, and intracerebral lesions.[15,89,139] The lung lesions may resemble lesions of an aspergilloma, with cavitation and a typical crescent sign.[139] In tissue, pleomorphic yeasts that are 3 to 8 μm in diameter and septate hyphae are seen. Successful therapy generally requires recovery from neutropenia. Amphotericin B with and without 5-flucytosine and fluconazole have been used. A patient with chronic meningitis responded clinically to a prolonged course of fluconazole, but fungi were noted in the meninges at autopsy, so the infection was not eradicated.[89] Voriconazole has better activity in vitro than the other azoles do; clinical correlation has not been reported.[71,90] The mortality rate is high, reported at 56 percent in a large case review.[90]

MOLDS

In contrast to the pathogens found in tissues as yeasts, molds rarely are part of the normal human flora and instead have arisen from the environment. A portal of entry, be it a minor wound, a central catheter, or the lungs, often is recognizable. With increasing numbers of immunocompromised hosts, the variety of fungi assuming greater clinical importance has expanded similarly. In tissue specimens, making a definitive diagnosis of the particular mold involved rarely is possible. One useful differentiation is between the "black molds," or dematiaceous fungi, which lead to clinical infections collectively known as *phaeohyphomycoses*, and the hyaline molds, which cause hyalohyphomycoses. Dematiaceous fungi contain melanin in their cell walls, which can be seen in tissue sections, especially with Masson-Fontana staining. Table 219–3 lists the genera included in this group. In addition to phaeohyphomycosis, other clinical syndromes associated with the dematiaceous fungi, such as mycetoma (discussed previously) and chromoblastomycosis, are sufficiently unique to be discussed separately.

TABLE 219–3 Dematiaceous Fungi

Alternaria*	***Madurella***
Aureobasidium	*Microascus*
Bipolaris	*Mycocentrospora*
Botryomyces	*Nigrospora*
Byssoascus	*Ochroconus*
Cephalotrichum	*Oidiodendron*

Trichoderma
Tritirachium
Volutella

**The most frequently implicated genera are listed in bold type.*

Agents of hyalohyphomycosis are listed in Table 219–4. In tissue section, the hyaline molds may be presumed to be *Aspergillus* or *Candida*. Although the distinction is difficult to make, a few characteristics may allow differentiation of these molds from the more common *Aspergillus*. The hyphae are septate, frequently with marked variation in diameter.[126] Whereas *Aspergillus* nearly uniformly branches at 45 degrees, the hyaline molds may exhibit 45-degree and 90-degree branching.[126] Careful investigation frequently reveals evidence of adventitious sporulation through the presence of phialoconidia and phialides; *Aspergillus* generally undergoes in vivo sporulation only in aerated spaces, such as lung cavities.[126] Confusion with *Zygomycetes* occurs less commonly, but the hyphae of hyaline molds are narrower and more frequently septate than those of Zygomycetes and are less likely to twist in a ribbon-like pattern.[126]

Phaeohyphomycosis

The range of clinical diseases attributed to the phaeoid, or dematiaceous, fungi is broad. The term *phaeohyphomycosis* literally means "condition of fungi with dark hyphae," and does not reflect

the disease produced, but rather the pathogen producing the disease. The presence of melanin in the cell wall may act as a virulence factor, as has been shown for *Wangiella dermatitidis* in animal models.[142] Focal diseases attributed to this group of fungi include bone and joint infection after local trauma, sinusitis, peritonitis associated with dialysis, and keratitis. Implicated genera include *Alternaria*, *Curvularia*, *Bipolaris*, *Exserohilum*, and *Exophiala*.[2,34,75,142] Allergic bronchopulmonary pneumonitis also has been described.[2]

Phaeohyphomycosis has been termed an *emerging disease*,[200] and increasing reports of health care–associated acquisition have appeared. Bloodstream infections with *Exophiala* were associated with contaminated hospital water, and disseminated disease with *Phialemonium* was seen in a group of patients undergoing hemodialysis who had been dialyzed on the same unit.[177,195] Another outbreak involved *Exophiala* infections of the central nervous system (CNS) traced to contaminated injectable steroids.[69]

Phaeomycotic brain abscess often is caused by *Cladophialophora bantiana* (formerly named *Xylohypha bantiana*) or *Ochroconus gallopavum* (formerly named *Dactylaria gallopavum*).[142,221] In the Middle East, *Ramichloridium mackenziei* is a prominent pathogen.[69] *Bipolaris* also has been reported as a cause of brain abscess and granulomatous meningoencephalitis.[2,160] Many of these patients are immunocompetent, without underlying disease. Brain abscess caused by *C. bantiana* is manifested as chronic headache, fever, and hemiparesis.[142] Boys are affected predominantly, and the frontal lobes are involved most frequently. Lumbar puncture reveals elevated opening pressure, high protein and depressed glucose levels, and negative cultures. CSF eosinophilia may be seen.[201] Abscess cultures must be obtained.[142] CNS disease also may manifest as meningitis, encephalitis, myelitis, or arachnoiditis.[201]

Disseminated disease usually occurs in the setting of altered host immunity. Most patients have hematologic malignancies with resultant neutropenia. In a review of 72 cases of disseminated phaeohyphomycosis, the mortality rate was 79 percent.[200] Fever was present in 76 percent, with skin manifestations in 33 percent, CNS symptoms in 31 percent, gastrointestinal symptoms in 31 percent, and apparent sepsis in 11 percent.[200] Blood cultures were positive in more than half of the patients.[200] Fungemia with *Exophiala jeanselmei* has been described in association with central venous catheters.[176] Eosinophilia may be a hint that disseminated phaeomycosis is the cause of fever in an immunocompromised host, although it was noted in only 11 percent of such patients.[200]

Infection in organ transplant recipients is manifested differently from infection in patients with hematologic malignancies. The length of time post-transplant until the development of symptomatic disease is prolonged, with a median time of 22 months.[221] Skin, soft tissue, or joint infection develops in most organ transplant recipients, with *Exophiala* being the pathogen implicated most frequently.[221] The second most common manifestation is brain abscess, which occurs much earlier in the course, at a mean of 3 months post-transplant.[221]

Premature neonates are another population of immunocompromised hosts susceptible to acquiring unusual pathogens. Infection caused by the agents of phaeohyphomycosis in premature infants predominantly have been in the form of invasive fungal dermatitis with necrotic ulcers. Two cases caused by *Curvularia* and one caused by *Bipolaris* have been described.[36,75,206] Endocarditis caused by *Acremonium* also has been reported in a premature neonate.[87]

Skin lesions attributed to phaeohyphomycosis may take many forms, including papules, plaques, pustules, nodules, and nonhealing ulcers, most commonly on the extremities.[221] In a review of 89 cases of cutaneous alternariosis, the lesions were noted to be shallow-based, nonhealing ulcers that evolved from nodules, subcutaneous noninflammatory cysts, verrucous lesions, and confluent scaly patches.[129] In the setting of disseminated disease, skin manifestations may take the form of a rash rather than discrete lesions.[199]

Therapy for phaeohyphomycosis depends on the site of infection. If surgical resection is feasible, it should be pursued. Complete resection, rather than aspiration, of brain abscesses has been associated with improved outcome.[201] Generally, amphotericin B does not have good activity, whereas itraconazole has more consistent activity.[200] In vitro results of 15 species of dematiaceous fungi showed low MICs for itraconazole and terbinafine.[145] Itraconazole led to clinical improvement, remission, or stabilization in 11 of 17 patients.[215] Cases of successful treatment with posaconazole and terbinafine also have been reported.[3,170]

STACHYBOTRYS

A cluster of 10 cases of pulmonary hemorrhage and hemosiderosis in infants in Cleveland, Ohio, initially was attributed to environmental exposure to *Stachybotrys chartarum* (also referred to as *Stachybotrys atra*).[66,73] This mold produces trichothecene mycotoxins, so researchers postulated that the disease in infants was caused by exposure to mycotoxins from fungi growing in water-damaged households. Further evaluation by the Centers for Disease Control and Prevention found that the association was not substantiated.[40] If similar outbreaks recur, more careful analysis of the role of fungi and mycotoxins is warranted.

Chromoblastomycosis

Chromoblastomycosis is a chronic infection of skin and subcutaneous tissue; the agent isolated most commonly is *Fonsecaea pedrosoi*; other implicated fungi are *Cladophialophora carrionii* and *Phialophora verrucosa.* The disease is limited to the tropical and subtropical regions of the world, usually in warm, humid areas.[28] Infection begins with inoculation of the organism, typically through minor trauma, such as a splinter or thorn.[72] Most affected patients are men, frequently farmers.[28] The median age of affected patients is 35 years, but pediatric patients have been reported.[28] The mean duration of illness before initial medical evaluation is sought is 3 years, attesting to the slow-growing nature of this process.[28]

The lesions are markedly hyperkeratotic and may be nodular, verrucous, or psoriaform (Fig. 219–4).[28] Common symptoms include pruritus and pain.[28] Scratching the lesions may be the mode of spread for the frequent development of satellite lesions.[144] Bacterial superinfection is a common complication; the fungi

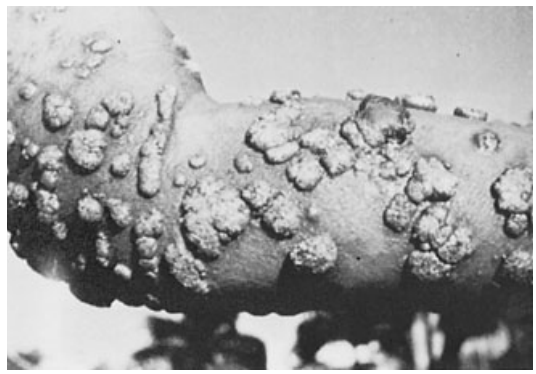

Figure 219–4 Chromoblastomycosis. The warty-like growth of epidermis and dermis is a result of traumatic implantation of the etiologic agent and subsequent autoinoculation from scratching. The agent was *Fonsecaea pedrosoi.*

usually do not disseminate to deeper tissues, although brain involvement has been reported.[28,144] A late complication is fibrosis leading to lymphatic obstruction and a clinical picture similar to that of elephantiasis.[144]

Most cases can be diagnosed by direct potassium hydroxide smears, which reveal the pathognomonic sclerotic bodies.[28] Sclerotic bodies also have been referred to as muriform cells and Medlar bodies. They are round to polyhedral, chestnut brown, thick-walled cells that are 5 to 12 μm in diameter with horizontal or vertical septa.[144] If biopsy is performed, the sclerotic bodies are noted, and the dermis reveals granulomata.[28,144] The fungi readily grow in culture, but colonies may not be evident for a few weeks. A new polymerase chain reaction assay holds promise for more rapid diagnosis.[53] The differential diagnosis includes verrucous cutaneous tuberculosis, sporotrichosis, mycetoma, leishmaniasis, coccidioidomycosis, psoriasis, hyperkeratotic tinea, blastomycosis, leprosy, and tertiary syphilis.[28,144] Differentiating features include the distinct margins and frequent satellite lesions of chromoblastomycosis.[144] Treatment has included local excision when feasible, with some practitioners using either cryosurgery or the application of heat.[28,144] Surgery plus antifungal therapy with itraconazole or terbinafine is considered the standard of care.[72]

SCEDOSPORIUM/PSEUDALLESCHERIA

Classification of these organisms as agents of phaeohyphomycosis versus hyalohyphomycosis has been controversial.[142] *Scedosporium prolificans* is listed more commonly as dematiaceous, and *Scedosporium apiospermum* infection usually is listed as a hyalohyphomycosis. *S. apiospermum* is the asexual anamorph of *Pseudallescheria boydii*; other obsolete names for this fungus include *Petriellidium boydii*, *Monosporium apiospermum*, and *Allescheria boydii. S. prolificans* previously was referred to as *Scedosporium inflatum*, but was found to be conspecific with a fungus named *Lomentospora prolificans* isolated from the soil of potted plants in a Belgian greenhouse; the previously assigned specific nomenclature was adopted.[25] The two species differ morphologically, with *S. prolificans* having annellides with a distinctive, swollen base.[253] In addition, *P. boydii* grows on Sabouraud agar containing cycloheximide, whereas *S. prolificans* does not.[253]

Both species of *Scedosporium* cause disseminated disease in immunocompromised hosts, but differences in the form of localized disease most associated with the species do occur. In the United States, *P. boydii* is the causative agent most commonly isolated from mycetoma.[38] *P. boydii* is distributed widely in soil, sewage, and contaminated water.[228] Its presence in polluted water most likely is responsible for the unique occurrence of brain abscess caused by this fungus in patients who have survived near-drowning. In a review of 38 cases of CNS infection, most of the patients had immunocompromising conditions, but 28 percent had sustained near-drowning.[174] The time of onset from the near-drowning episode to symptoms ranges from 7 to 135 days (mean 37 days).[182] Abscesses may be single or multiple.[174] Although the fungus may be isolated from CSF, direct inspection of brain tissue usually is required to establish the diagnosis.[115] Near-drowning victims with CNS involvement often have evidence of pulmonary disease, suggesting the lung as a portal of entry.[113] Even in immunocompetent patients, mortality is high (70%), perhaps related to a delay in establishing the diagnosis.[113,182]

P. boydii may be isolated from respiratory secretions in the absence of disease.[235] In patients with cystic fibrosis, 8.6 percent had *S. apiospermum* isolated from sputum cultures, the most frequent filamentous fungus after *A. fumigatus.*[46] Two of the patients had signs and symptoms compatible with allergic bronchopulmonary disease occurring after chronic colonization with *S. apiospermum.*[46] Invasive pulmonary disease also develops in immunocompetent and immunocompromised hosts.[110,164,235] Clinically, it may resemble aspergillosis. In addition to pulmonary infection, other focal forms of the disease have included endocarditis related to an indwelling catheter, osteomyelitis, surgical wound infection, sinusitis, and olecranon bursitis.[80,235,250]

S. prolificans initially was recognized as a cause of focally invasive disease, especially musculoskeletal infections occurring after penetrating trauma or surgery.[253] More recently, the organism has been recognized as an emerging pathogen of immunocompromised hosts.[188,193] Some clusters of cases have occurred in association with hospital renovation, suggesting a possible environmental source, but this source has not been conclusively shown.[25] Because many of the cases have been reported from Spain, Australia, and California, some researchers have suggested that climactic factors may influence the likelihood of infection. Cases in California have been suspected to be coccidioidomycosis.[175]

The usual finding of disseminated *S. prolificans* infection is fever unresponsive to broad-spectrum antibiotics, followed by pulmonary involvement and later neurologic manifestations, skin lesions, and, finally, widespread involvement with frequent renal failure.[193,197] In a review of 16 cases of disseminated infection, chest radiographs were abnormal in 12 patients, with bilateral focal infiltrates in 6, diffuse infiltrates in 5, and a solitary pulmonary nodule in 1.[25] The skin lesions usually are multiple and may be erythematous or nodular or have necrotic centers.[25,175] One patient had intense myalgias preceding the eruption of skin lesions.[175] Meningoencephalitis may occur; one case was attributed to direct inoculation during lumbar puncture for intrathecal chemotherapy.[131] At autopsy, the fungus is found most commonly in the kidney, lung, brain, and spleen.[25] The mortality rate is very high—87.5 percent in one series.[25] Blood cultures frequently are positive, with the organism growing in 9 to 15 days in routine blood culture detection systems, but much more rapidly in fungal isolator tubes.[25]

Both clinically important species of *Scedosporium* are resistant to amphotericin B.[25,71] Therapy usually includes wide surgical débridement whenever possible. Some joint infections apparently have responded to débridement plus administration of intra-articular amphotericin B; the high local concentration may improve its effectiveness.[253] As with most mold infections, recovery of neutrophil counts in immunocompromised hosts is crucial for improvement. *P. boydii* is susceptible to some of the newer triazoles, such as posaconazole, ravuconazole, and voriconazole.[193] Some strains of *S. prolificans* also were susceptible, and successful treatment with voriconazole combined with terbinafine has been described.[193,251] Successful treatment of *P. boydii* with voriconazole and with posaconazole has been reported.[151,164,174] Itraconazole has some activity and has proved effective in localized disease, but decreased concentrations in brain tissue may limit its effectiveness.[81,174] Adjuvant treatment with interferon-γ, granulocyte colony-stimulating factor, and granulocyte-monocyte colony-stimulating factor also has been reported.[1,251]

Hyalohyphomycosis

FUSARIUM SPECIES

Fusarium initially was recognized as a plant pathogen that caused crown rot on cereal grains.[172] The organisms are distributed widely in soil and vegetation and in all climates, and they may be airborne.[172] Pathogenic species also have been isolated from hospital water systems, suggesting the possibility of nosocomial acquisition.[12] The species most commonly associated with invasive human disease are *Fusarium solani*, *Fusarium oxysporum*, and *Fusarium verticilloides* (also known as *Fusarium moniliforme*).[98]

The first human disease states attributed to *Fusarium* were secondary not to invasion, but to elaboration of mycotoxins. Alimentary toxic aleukia was responsible for epidemics in the Soviet

Union during World War II.[172] This disease results from the consumption of grains colonized with *Fusarium sporotrichioides* after overwintering. The fungus elaborates a toxin designated T-2, which is a potent protein synthesis inhibitor. The disease begins with a burning sensation from the mouth to the stomach, followed by vomiting and diarrhea, abdominal pain, headache, and fatigue. Progressive leukopenia develops, and hemorrhage and necrosis eventually may lead to death. A similar disease known as scabby grain intoxication, or akakabi-byo, has occurred in Japan.[172] Mycotoxins have never been shown conclusively during invasive fusariosis, but they have been postulated to contribute to virulence through further suppression of the host's immune system.[172] Other possible virulence factors include production of enzymes and adherence and invasion of prosthetic materials.[172]

In immunocompetent hosts, *Fusarium* may cause localized disease. Onychomycosis from *Fusarium* may result in a characteristic milky discoloration of the nail.[172] Burn wounds also are colonized frequently with *Fusarium*.[188] In central Africa, *Fusarium* is a frequent cause of mycotic external otitis.[172] Bone and joint infections have been reported after traumatic inoculation has occurred,[32,172] and hematogenous osteomyelitis has been described in an adolescent with leukemia.[35] Peritonitis associated with continuous ambulatory peritoneal dialysis catheters also may occur.[79,114,172]

Fusarium is the most common fungal etiology of keratitis in the United States.[172] Corneal injury accompanied by contamination with fungal material may progress to keratitis, possibly aided by the elaboration of proteases by *F. solani*.[172,181] The organism can survive on contact lenses, affording another possible mode of entry.[172] In 2005 to 2006, an epidemic of *Fusarium* keratitis in wearers of contact lenses was associated with use of a specific storage solution.[23] The isolates were genetically diverse, suggesting multiple sources of contamination.[178] In vitro studies showed that conditions simulating noncompliant use of contact lenses (e.g., overnight wear) enhanced the risk for having corneal damage and fungal overgrowth.[39,124,205,258]

The incidence of infection caused by *Fusarium* has been increasing, most probably in concert with the increased use of immunosuppressive regimens. Most cases are described in patients with hematologic malignancies, but other underlying conditions include aplastic anemia, AIDS, solid tumors, and burns.[138] Eight percent of all non-*Candida* fungal infections occurring after bone marrow transplantation are caused by *Fusarium*.[158] Most patients are neutropenic at the time infection is acquired. In a review of 81 cases, the infection was disseminated in 88 percent.[138] Common sites of infection were the skin (79%), lungs (42%), and upper respiratory tract, including the sinuses (22%).[138] Localized disease, specifically onychomycosis, precedes disseminated infection in many cases, underscoring the need for careful inspection and treatment of local infection before the institution of immunosuppressive therapy.[138,172] Infection in patients after receiving solid organ transplants usually is localized and occurs at a median of 9 months post-transplant.[210]

In immunocompromised hosts, skin involvement is characteristic (Fig. 219–5). The lesions are found predominantly on the extremities and begin as tender, erythematous papules that may become vesicular and later develop a necrotic center reminiscent of ecthyma gangrenosum.[85,167,172,210] The lesions usually occur in the setting of disseminated disease with hematogenous spread, but they also may follow direct inoculation. Nasal lesions may resemble the lesions of zygomycosis or aspergillosis, with painless, black necrotic eschars.[85]

Infection also has been reported in neonates. One 28-week-gestation infant has been described with a fungal mass in the renal pelvis akin to renal fungus balls seen after candidiasis; the infant recovered after resection of the mass.[168] Endocarditis, most likely related to a central venous catheter, has been described in a term neonate.[104]

In a large case series, histopathology or blood cultures, or both, were positive in 80 percent of cases; blood cultures were positive in 47 percent.[138] This prevalence is in contrast to aspergillosis, in which positive blood cultures are distinctly unusual. The high rate of positive blood cultures in fusariosis most likely is related to the production of adventitious unicellular propagules and the vasoinvasive nature of the fungus.[188,193] In tissue sections, the fungi often have a perivascular distribution, with frank vascular invasion leading to thrombosis and necrosis.[85,172] The fungus grows rapidly in culture, and mature colonies develop by 4 to 5

Figure 219–5 Skin lesions of disseminated fusariosis in an immunocompromised host. The lesions often resemble ecthyma gangrenosum. *(Photograph courtesy of D. Graybill, provided by www.doctorfungus.org.)*

days.[85] Sickle-shaped or banana-shaped macroconidia are noted, and the reverse is deeply pigmented.[85]

Mortality rates from *Fusarium* infection are high: 76 percent in one case series, 57 percent in another, and 26 percent in a third report.[98,138,198] The outcome seems to be better in patients with solid organ transplants than in patients with bone marrow transplants, with resolution achieved in five of six patients in one series.[210] Therapy generally has been disappointing in neutropenic patients, and recovery of neutrophil counts seems to be mandatory for clinical resolution.[85] Catheter-related infections respond well with removal of the catheter and administration of antifungal therapy; however, most reported cases also had normal neutrophil counts.[241] In burn patients, very high-dose topical nystatin therapy has been reported to be effective.[22] Whenever feasible, wide surgical resection is necessary.

Antifungal therapy for disseminated infection has been disappointing. The organisms are resistant to amphotericin in animal models.[11] The activity of amphotericin B may be enhanced, however, by the addition of agents providing synergy; a more recent report describes encouraging in vitro results with the combination of amphotericin B plus azithromycin.[35] Amphotericin B lipid complex has been used to achieve levels above the MIC.[33,187] Because neutrophils are clearly critical to recovery, granulocyte transfusions and colony-stimulating factors have been used.[26,33,88,187,193,198] In vitro testing shows the activity of voriconazole to be similar to that of amphotericin B and itraconazole against *Fusarium*.[71]

PAECILOMYCES SPECIES

Paecilomyces lilacinus and *Paecilomyces variotii* have been reported as human pathogens. The organisms are widely distributed in soil and decomposing vegetation. They were classified previously with *Penicillium* and bear some resemblance microscopically, but never have the blue-green coloration frequently seen in *Penicillium* colonies. *P. lilacinus* has a faint violet, mauve, or reddish gray tint, whereas *P. variotii* has powdery colonies that initially are buff, but eventually turn yellowish brown.[228] Localized infection, such as peritonitis complicating continuous ambulatory peritoneal dialysis and keratitis, has been described.[51,140,181,202,245] Resistance to commonly used disinfectants has contributed to outbreaks from contaminated solutions and topical agents; an outbreak occurring after implantation of intraocular lenses was traced to contaminated bicarbonate solution, and skin infection in immunocompromised patients was linked to contaminated moisturizing lotion.[107,248] Cases of sinusitis, endophthalmitis, endocarditis after placement of cardiac grafts, orbital cellulitis, pulmonary infection, and cutaneous and subcutaneous infection have been reported.[188,230]

In a review of 119 cases of *P. lilacinus* infection, 51 percent affected the eye, and 35 percent were cutaneous/subcutaneous.[186] Infection has been noted in patients with underlying hematologic malignancies, chronic granulomatous disease, and diabetes mellitus, and after receiving bone marrow transplants.[107,208,219,230,252] Even in immunocompromised hosts, the infection usually remains localized, but dissemination has been described.[107,188] Skin lesions may resemble the lesions seen in fusariosis, and they range from erythematous macules to nodules, pustules, vesicular lesions, and necrotic crusts.[107] Blood cultures may be positive, especially in infection related to indwelling vascular access devices.[188,220] Skin biopsy samples frequently yield positive cultures.[107] In contrast to most fungi, biopsies may reveal evidence of sporulation, allowing presumptive diagnosis before culture results are known.[186] Clinical outcome was poor in 30 of 47 cases reviewed.[230] Removal of vascular devices and surgical débridement are recommended.[188,234]

Speciation is important when devising optimal therapy because *P. lilacinus* is frankly resistant to amphotericin B and fluconazole. Clinical success has been reported with voriconazole, and posaconazole has the lowest MIC values in vitro.[186] *P. variotii* generally is susceptible to amphotericin B and the azoles, although breakthrough infection during voriconazole prophylaxis has been reported.[4,42]

ACREMONIUM SPECIES

Acremonium previously was named *Cephalosporium*, and this name for the genus is the one most familiar to clinicians; cephalosporin was isolated first from *Acremonium chrysogenium*.[93] The organisms are widely distributed in soil, plant debris, and rotting mushrooms.[93] The most common form of infection caused by *Acremonium* is focally invasive disease after trauma, with mycetoma and keratitis predominating.[76,93] Other reported manifestations include hypersensitivity pneumonitis, fungus balls, sinusitis, bone and joint infection, arteriovenous fistula infection, peritonitis, empyema, meningitis, and endocarditis.[76] Many patients have had recent surgery, injury, intravenous drug injection, or immunosuppressive therapy as predisposing factors.[76] In immunocompromised hosts, fungemia, including catheter-related fungemia, and papular rashes have been reported.[93,204] Recovery usually depends on restoration of normal neutrophil function.

Acremonium is resistant to most antifungals when tested in vitro; amphotericin B has the best activity.[93] Many different therapeutic regimens have been attempted, with variable success.[93] Catheter-related fungemia has responded to removal of the catheter followed by liposomal amphotericin B.[204]

"MYCOSES" CAUSED BY ORGANISMS OTHER THAN FUNGI

Three diseases—protothecosis, rhinosporidiosis, and pythiosis—generally were considered mycoses until molecular genetic techniques revealed the true nature of the pathogens. Protothecosis is caused by an achlorophyllic alga, and rhinosporidiosis and pythiosis more recently have been attributed to protistan parasites.

Rhinosporidiosis

Rhinosporidiosis consists of warty, vegetative growths, usually found in the nose or eyes (Fig. 219–6). The growths do not cause pain, and grow very slowly. Epidemiologically, the disease is associated with exposure to stagnant pools or fresh water. Of cases, 88 percent are reported from India; however, cases also are reported from South America and the United States.[7,84] The lesions may resemble nasal polyps, but mucous cysts are absent, and histopathology reveals the characteristic "sporangia." The spherules of *Rhinosporidium seeberi* are visible with most commonly used tissue stains. The spherules also stain with mucicarmine, which stains *C. neoformans* as well. The only known therapy to date is surgical removal, which may lead to copious bleeding and secondary infection. The organism never has been grown in culture, but more recent evaluation of 18S ribosomal RNA has revealed that *R. seeberi* is most closely related to the DRIP clade (named for *Dermocystidium* rosette agent, *Ichthyophonus*, and *Psorospermium*) clade of aquatic protistan parasites; close phylogenetic relatives include known fish parasites.[82] Further evaluation of these related parasites may result in better understanding of the natural history of infection and the ideal approach to therapy.

Protothecosis

The algae responsible for protothecosis grow readily on Sabouraud agar, unless cycloheximide is incorporated.[228] The species most commonly implicated is *Prototheca wickerhamii*, but *Prototheca zopfii* and *Prototheca stagnora* also have been reported.[105] Forms of infection include cutaneous or subcutaneous infection,

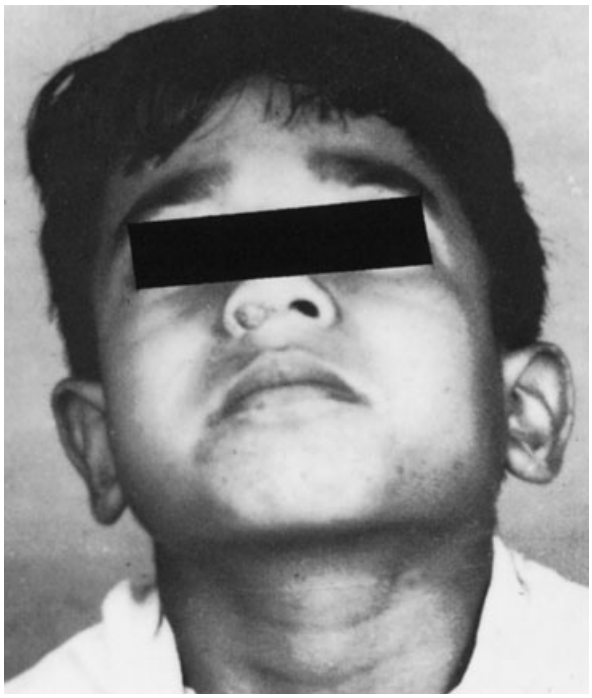

Figure 219–6 Rhinosporidiosis. Polyps are developing in the nose. *(Courtesy of S. Banerjee.)*

olecranon bursitis, catheter-related infection, and systemic disease.[105] Half the reported patients have an underlying immunocompromising condition.[105] Infection frequently occurs after local trauma. Histologically, granulomata often are noted.[106] Disseminated disease usually involves the abdominal cavity, with the development of multiple nodular lesions.[105] The organisms usually are susceptible to amphotericin B, so treatment generally is surgical excision (if feasible), followed by administration of amphotericin B, although olecranon bursitis frequently is treated with bursectomy alone.[105,229]

Pythiosis

Pythiosis is best known as a veterinary condition characterized by chronic subcutaneous granulomas; the equine form of the disease is referred to as *swamp cancer* and *Florida horse leeches*.[96,229] The aquatic organism seems to grow hyphae in culture, but the cell walls do not contain ergosterol.[96] Motile zoospores also are produced, with an affinity for attachment to plant stems and human hair.[96] Most human disease has been reported in tropical and subtropical areas, including the United States. Many cases have been reported from Thailand, usually affecting patients with thalassemia and related hemoglobinopathies.[196] The disease usually manifests with cutaneous, subcutaneous, vascular, or ophthalmic involvement; pneumonia with subsequent development of pleural and pericardial infection has been reported in a child with leukemia.[96] Patients often report contact with swampy water or with horses.[196,236] In tissue specimens, the organisms may resemble Zygomycetes, and misidentification as such has been reported.[31,152,217] Silver stains show the hyphae, but the organisms are not well visualized with periodic acid–Schiff stains.[236] Successful therapy usually includes surgical débridement; given the absence of ergosterol, treatment with standard antifungal agents would not be expected to be useful, but survival has been reported after use of various agents, including terbinafine, itraconazole, amphotericin B (deoxycholate and liposomal forms), and potassium iodide, alone and in combination.[31,96,196,217]

SECTION XXII

Parasitic Diseases

CHAPTER 220

Classification and Nomenclature of Human Parasites

Lynne S. Garcia

Although common names frequently are used to describe parasitic organisms, these names may represent different parasites in different parts of the world. To eliminate these problems, a binomial system of nomenclature in which the scientific name consists of the genus and species is used. These names generally are of Greek or Latin origin. In certain publications, the scientific name often is followed by the name of the individual who originally named the parasite. The date of naming also may be provided. If the name of the individual is in parentheses, it means that the person used a generic name no longer considered to be correct.

On the basis of life histories and morphologic characteristics, systems of classification have been developed to indicate the relationship among the various parasite species. Closely related species are placed in the same genus, related genera in the same family, related families in the same order, related orders in the same class, and related classes in the same phylum, one of the major categories in the animal kingdom. As one moves up the classification schema, each category becomes broader; however, each category still has characteristics in common.

Parasites of humans are classified in five major divisions: (1) the Protozoa (amebae, flagellates, ciliates, sporozoans, coccidia, and microsporidia); (2) the Platyhelminthes or flatworms (cestodes, trematodes); (3) the Acanthocephala or thorny-headed worms; (4) the Nematoda or roundworms; and (5) the Arthropoda (insects, spiders, mites, ticks). Although these categories seem to be well defined, often considerable confusion occurs in attempting to classify parasitic organisms. One of the primary reasons is the lack of known specimens. Some organisms recovered from humans are very rare; difficulty arises in determining morphologic and physiologic variation among such groups. Type specimens must be deposited for study before a legitimate species name can be given. Even when certain parasites are numerous, they may represent strains or races of the same species with slightly different characteristics.

Generally, reproductive mechanisms are a valid concept in determining definitions of species, but so many exceptions exist within parasite groups that taking into consideration properties such as sexual reproduction, parthenogenesis, and asexual reproduction is difficult. Another difficulty in recognizing species is the ability and tendency of the organisms to alter their morphologic forms according to age, host, or nutrition, which often results in several names being given to the same organism. An additional problem involves alternation of parasitic and free-living phases in the life cycle. These organisms may be very different and difficult to recognize as belonging to the same species. Despite these difficulties, newer, more sophisticated molecular methods of grouping organisms often have confirmed taxonomic conclusions reached hundreds of years earlier by experienced taxonomists.

As investigations continue in parasitic genetics, immunology, and biochemistry, the species designation is expected to be defined more clearly. Originally, these species designations were determined primarily by morphologic differences, resulting in a phenotypic approach. With the use of highly sophisticated molecular techniques, the approach is expected to continue to be more genotypic. Benefits of these studies also include the development of highly specific and sensitive diagnostic tests and the ability to diagnose parasitic infections based on molecular parameters, rather than merely phenotypic characteristics.

Although gaps in knowledge concerning classification of all human parasites remain, the binomial system has allowed the classification of 1.5 million species of organisms in the animal kingdom such that all published information can be retrieved, regardless of the language spoken. The difficulty for the clinician arises when one considers the rapid increase in information concerning microbiology that has transpired in recent years and the changing considerations such as the role of immunosuppression in the host-parasite interaction and the modified definitions of "normal flora" and "nonpathogenic" in this patient population.

The classification of parasites is presented in tabular form. Although certain designations of species may be controversial, this classification scheme is designed to provide some order and meaning to a widely divergent group of organisms. No attempt has been made to include every possible organism, and only organisms considered clinically relevant in the context of human parasitology are included. The main groups that are presented include protozoa, nematodes (roundworms), cestodes (tapeworms), and trematodes (flukes). Some relevant information on arthropods is presented in Tables 220–1 and 220–2. It is hoped that this information will provide some insight into the parasite groupings, leading to a better understanding of parasitic infections and the appropriate diagnostic and clinical approach.

PROTOZOA

AMEBAE—INTESTINAL

These organisms are characterized by having pseudopods (motility) and trophozoite and cyst stages in the life cycle and include some exceptions in which a cyst form has not been identified. Amebae usually are acquired by humans through fecal-oral transmission or mouth-to-mouth contact (*Entamoeba gingivalis*).

TABLE 220–1 Human Vector-Borne Infections

Infection (Disease)	Causative Agent	Vector (Common Name)
Protozoal		
Malaria	*Plasmodium* species	Mosquitoes
Leishmaniasis	*Leishmania* species	Sandflies
Chagas disease	*Trypanosoma cruzi*	Triatomid bugs
East African trypanosomiasis	*Trypanosoma brucei rhodesiense*	Tsetse flies
West African trypanosomiasis	*Trypanosoma brucei gambiense*	Tsetse flies
Babesiosis	*Babesia* species	Ticks
Helminthic		
Filariasis	*Wuchereria bancrofti*	Mosquitoes
Filariasis	*Brugia malayi*	Mosquitoes
Filariasis	*Dirofilaria* spp.	Mosquitoes
Filariasis	*Mansonella persans*	Biting midges
Filariasis	*Mansonella streptocerca*	Biting midges
Filariasis	*Mansonella ozzardi*	Biting midges
Onchocerciasis	*Onchocerca volvulus*	Black flies
Loiasis	*Loa loa*	Deer flies
Dog tapeworm infection	*Dipylidium caninum*	Dog lice and fleas, human fleas
Rat tapeworm infection	*Hymenolepis diminuta*	Rat fleas, beetles, grain beetles
Dwarf tapeworm	*Hymenolepis nana*	Grain beetles (rare)

TABLE 220–2 Medically Important Arthropods

Local or Systemic Problems	Vector (Common Name)	Local or Systemic Problems	Vector (Common Name)
Skin reaction to bites	Sucking lice	Painful sting, potential anaphylaxis	Honeybees
	Bedbugs		Bumblebees
	Kissing bugs		Wasps, hornets, yellow jackets
	Biting midges		Fire ants
	Sandflies		Scorpions
	Black flies	Dermatitis, ulcerations	Fleas
	Mosquitoes	Nodular ulceration with subsequent secondary infection	Chigoe flea
	Deer flies		
	Tsetse flies		
	Soft ticks	Blistering of skin after contact with adult beetles	Blister beetles
	Hard ticks		
Painful bite	Horseflies	Bite, usually painless, delayed systemic reaction	Black widow spiders
	Fire ants		
	Centipedes		
Intense itching	Human itch mites	Initial blister followed by extensive necrosis and slow healing	Brown recluse spiders
	Chiggers		South American brown spider

Current Name
*Entamoeba histolytica**
*Entamoeba dispar**
Entamoeba hartmanni†
Entamoeba coli
Entamoeba polecki
Entamoeba gingivalis
Endolimax nana
Iodamoeba bütschlii
*Blastocystis hominis**

**E. histolytica* is being used to designate the true pathogen, whereas *E. dispar* now is being used to designate a nonpathogen. Unless trophozoites containing ingested red blood cells (*E. histolytica*) are seen, the two organisms cannot be differentiated on the basis of morphology seen in permanent stained smears of fecal specimens and are reported as *E. histolytica/E. dispar*. Immunoassays are available commercially for differentiating *E. histolytica* from *E. dispar*. Because the differences in pathogenicity are genetic and not just phenotypic, the decision to treat must be made by the physician. Finding of organisms in the *E. histolytica/E. dispar* group in patient specimens must continue to be reported to state and county Departments of Public Health (follow your particular state reporting regulations).

†*E. hartmanni* is nonpathogenic and is totally different from *E. histolytica*. "Small race *E. histolytica*" is incorrect and should not be used at any time to designate *E. hartmanni*.

FLAGELLATES—INTESTINAL

These organisms move by means of flagella and are acquired by fecal-oral transmission. With the exception of *Dientamoeba fragilis* (internal flagella) and species in the genera *Trichomonas* and *Pentatrichomonas*, they have the trophozoite and cyst stages in the life cycle. *D. fragilis*, *Trichomonas*, and *Pentatrichomonas* spp. do not have a cyst stage.

*The taxonomic position of *Blastocystis* has always been confusing, but it has been placed in the kingdom Chromista (plantlike organisms, mainly algae), and this group lies close to the sporozoans and ciliates.

Current Name

*Giardia lamblia**
Chilomastix mesnili
Dientamoeba fragilis
Pentatrichomonas hominis
Trichomonas tenax
Enteromonas hominis
Retortamonas intestinalis

Ciliates—Intestinal

These organisms, which move by means of cilia, are acquired by humans through fecal-oral transmission. They have the trophozoite and cyst forms in the life cycle.

Current Name

Balantidium coli

COCCIDIA, MICROSPORIDIA—INTESTINAL

These organisms are acquired by humans by ingestion of various meats or through fecal-oral transmission via contaminated food or water.

Current Name

COCCIDIA

Cryptosporidium hominis
Cryptosporidium parvum
Cryptosporidium spp.
Cyclospora cayetanensis
Isospora belli
Sarcocystis hominis
Sarcocystis suihominis
Sarcocystis bovihominis

MICROSPORIDIA†

Enterocytozoon bieneusi
Encephalitozoon (Septata) intestinalis‡

AMEBAE, FLAGELLATES—OTHER BODY SITES

The amebae are pathogenic, free-living organisms that may be associated with warm, fresh-water areas. They have been found in the central nervous system, the eye, and other sites. *Trichomonas vaginalis* usually is acquired by sexual transmission. This particular flagellate is found in the genitourinary system.

Current Name

AMEBAE

Naegleria fowleri
Acanthamoeba spp.
Hartmannella spp.
Balamuthia mandrillaris
Sappinia diploidea

FLAGELLATES

Trichomonas vaginalis

COCCIDIA, MICROSPORIDIA, UNDECIDED CLASSIFICATION—OTHER BODY SITES

These organisms are particularly important in immunocompromised patients. They also may infect many individuals who have no apparent symptoms. On the basis of several RNA studies, *Pneumocystis jiroveci* is linked more closely to the fungi and has been reclassified with those organisms. Consequently, it is removed from the list.

Current Name

COCCIDIA

Toxoplasma gondii

MICROSPORIDIA

Nosema ocularum
Brachiola connori
Brachiola algerae
Brachiola vesicularum
Vittaforma corneae
Pleistophora ronneafiei
Trachipleistophora hominis
Trachipleistophora anthropophthera
Encephalitozoon hellem
Encephalitozoon cuniculi
*Encephalitozoon (Septata) intestinalis**
Enterocytozoon bieneusi†
Microsporidium africanum‡
Microsporidium ceylonensis‡

SPOROZOA, FLAGELLATES—BLOOD AND TISSUES

All of these organisms are arthropod-borne. Diagnosis may be more difficult to make than is diagnosis of the intestinal protozoa, particularly if automated blood differential systems are used. The *Leishmania* spp. have undergone extensive revisions in classification. From a clinical perspective, however, recovery and identification of the organisms still are related to body site. Recovery of the organisms is limited to the site of the lesion in infections other than those caused by the *Leishmania donovani* complex (visceral leishmaniasis).

Current Name

SPOROZOA (MALARIA, BABESIOSIS)

Malaria
Plasmodium vivax
Plasmodium ovale

*Although some individuals have changed the species designation for the genus *Giardia* to *G. intestinalis* or *G. duodenalis*, no consensus exists. For this listing, we retain the name *Giardia lamblia*.
†The microsporidia are now thought to be more closely related to fungi than to protozoa; however, parasitologists have been reluctant to part with this group, whereas mycologists have been equally reluctant to accept it. Consequently, the microsporidia are retained within this listing for parasites.
‡Formerly called *Septata intestinalis*.

*Formerly called *Septata intestinalis*.
†*E. bieneusi* has been recovered from sites other than the intestinal tract.
‡This designation is now written as a true genus but remains a "catch-all" for organisms that have not been (or may never be) identified to the true genus or species levels.

Plasmodium malariae
Plasmodium falciparum

Babesiosis
Babesia microti
Babesia divergens
Babesia gibsoni
Babesia spp.

FLAGELLATES (LEISHMANIASIS, TRYPANOSOMIASIS)

Leishmaniasis
Leishmania tropica complex (cutaneous leishmaniasis)
Leishmania mexicana complex (cutaneous leishmaniasis)
Leishmania braziliensis complex (mucocutaneous leishmaniasis)
Leishmania donovani complex (visceral leishmaniasis)

Trypanosomiasis
Trypanosoma brucei gambiense (West African trypanosomiasis)
Trypanosoma brucei rhodesiense (East African trypanosomiasis)
Trypanosoma cruzi (American trypanosomiasis)
Trypanosoma rangeli

NEMATODES

INTESTINAL

These organisms normally are acquired by ingestion of eggs or penetration of the skin by larval forms from the soil.

Current Name

Ascaris lumbricoides
Enterobius vermicularis (pinworm)
Ancylostoma duodenale (Old World hookworm)
Necator americanus (New World hookworm)
Strongyloides stercoralis
Strongyloides fuelleborni
Trichostrongylus spp.
Trichuris trichiura (whipworm)
Capillaria philippinensis
Oesophagostomum spp. (*O. bifurcum* most common in humans—West Africa)
Ternidens diminutus (80% in Zimbabwe)

TISSUE

For the most part, these organisms rarely are seen within the United States; however, the first three are more important.

Current Name

Trichinella spiralis
Trichinella spp.
Toxocara canis or *Toxocara cati* (visceral or ocular larva migrans)
Ancylostoma braziliense or *Ancylostoma caninum* (cutaneous larva migrans)
Baylisascaris procyonis (severe systemic visceral larva migrans, neural larva migrans)
Dracunculus medinensis
Angiostrongylus cantonensis
Angiostrongylus costaricensis
Gnathostoma spinigerum
Gnathostoma spp.
Anisakiasis (larvae from salt-water fish)
Anisakis spp.
Phocanema spp.
Contracaecum spp.
Pseudoterranova spp.
Hysterothylacium spp.
Porrocaecum spp.
Capillaria hepatica
Thelazia spp.

FILARIAL WORMS—BLOOD, OTHER BODY FLUIDS, SKIN

These organisms also are arthropod-borne. The adult worms tend to live in the tissues of lymphatics. Diagnosis is made on the basis of the recovery and identification of the larval worms (microfilariae) in the blood, other body fluids, or skin. Elephantiasis may be associated with some of the organisms listed.

Current Name

Wuchereria bancrofti
Brugia malayi
Brugia timori
Loa loa
Onchocerca volvulus
Mansonella ozzardi
Mansonella streptocerca
Mansonella perstans
Dirofilaria immitis ("coin" lesion in the lung) (dog heartworm)
Dirofilaria spp. (may be found in subcutaneous nodules)

CESTODES

INTESTINAL

The adult form of these organisms is acquired by humans through ingestion of the larval forms contained in poorly cooked or raw meats or fresh-water fish. In the case of *Dipylidium caninum*, infection is acquired by the accidental ingestion of dog fleas. *Hymenolepis nana* and *Hymenolepis diminuta* are transmitted by ingestion of certain arthropods (fleas, beetles). Also, *H. nana* can be transmitted through ingestion of eggs (life cycle can bypass the intermediate beetle host). Humans can serve as the intermediate and definitive hosts in *H. nana* and *Taenia solium* infections.

Current Name

Diphyllobothrium latum (broad, fish tapeworm)
Dipylidium caninum (dog tapeworm)
Hymenolepis (Rodentolepis) nana (dwarf tapeworm)
Hymenolepis diminuta (rat tapeworm)
Taenia solium (pork tapeworm)
Taenia saginata (beef tapeworm)
Taenia asiatica (Taiwanese variant of *T. saginata*)

LARVAL FORMS—TISSUE

The ingestion of certain tapeworm eggs or accidental contact with certain larval forms can lead to the diseases shown in parentheses.

Current Name

Taenia solium (cysticercosis)
Echinococcus granulosus (hydatid disease)
Echinococcus multilocularis (alveolar hydatid disease)
Echinococcus oligarthrus (polycystic hydatid disease)
Multiceps multiceps (coenurosis)

Diphyllobothrium spp. (sparganosis)
Spirometra mansonoides (sparganosis)

TREMATODES

INTESTINAL

These organisms are uncommon within the United States except for four species of *Alaria*, which are endemic within North America.

Current Name

Fasciolopsis buski (giant intestinal fluke)
Echinostoma ilocanum
Eurytrema pancreaticum
Heterophyes heterophyes
Metagonimus yokogawai
Alaria spp.

LIVER AND LUNG

These organisms are not seen commonly within the United States; however, some Southeast Asian refugees do harbor some of these parasites.

Current Name

Clonorchis (Opisthorchis) sinensis (Chinese liver fluke)
Opisthorchis viverrini
Fasciola hepatica (sheep liver fluke)
Paragonimus westermani (lung fluke)
Paragonimus spp.
Metorchis conjunctus (North American liver fluke)

BLOOD

The schistosomes are acquired by penetration of the skin by the cercarial forms that are released from fresh-water snails. Although they are not endemic within the United States, occasionally patients are seen who may have these infections.

Current Name

Schistosoma mansoni
Schistosoma haematobium
Schistosoma japonicum
Schistosoma intercalatum
Schistosoma mekongi

ARTHROPODS

See Tables 220–1 and 220–2.

SUBSECTION 1

Protozoa

A. Amebae

CHAPTER 221

AMEBIASIS

Shinjiro Hamano ✪ William A. Petri, Jr.

Diarrheal diseases continue to be major causes of morbidity and mortality in children in developing countries. In Bangladesh, 1 in 30 children dies of diarrhea or dysentery by age 5 years.[75] Amebiasis is an infection caused by the protozoan parasite *Entamoeba histolytica*. Infection occurs via ingestion of the parasite's cyst from fecally contaminated food, water, or hands. Approximately 50 million illnesses and 100,000 deaths occur annually from amebiasis, rendering it the third leading cause of death by parasitic disease in humans.[75] Long-term consequences of amebiasis in children include malnutrition and reduced cognitive

abilities.[69,93] Although amebiasis is present worldwide, it occurs most commonly in underdeveloped areas, especially Central and South America, Africa, and Asia. In the United States and other developed countries, cases of amebiasis are most likely to occur in immigrants from and travelers to endemic regions, but it can affect populations of the developed world, as shown by the epidemic that occurred in Tbilissi, Republic of Georgia, caused by contaminated municipal water.[13] Currently, there is no vaccine to prevent the childhood morbidity and mortality resulting from infection with *E. histolytica*.

ETIOLOGY

E. histolytica is named for the pathologic evidence of "lysis" of tissues. The first demonstration of the organism in human tissues was made by Lambl in 1859 in the postmortem examination of the colon of a child who died as a result of having excessive diarrhea.[16,71] No connection of the organism with the disease was made until 1875, when Losch, in St. Petersburg, Russia, found the organism at autopsy in the colon of a woodcutter. Losch induced diarrhea and ulcerations in a dog given feces from the patient.[59] He did not think, however, that a connection existed between the organism and the disease. The first patient described in the United States was a physician treated by Osler for an amebic liver abscess in 1890.[71] Councilman and Lafleur described the organism and the disease in 1891.[20,42] Further investigation of the disease was delayed until a better understanding of the life cycle of *E. histolytica* could be obtained.[26] In recent years, the application of modern molecular biology techniques to the study of *E. histolytica* and *Entamoeba dispar* has resulted in an explosion of information about the mechanisms of virulence, pathogenicity, and immune responses to these organisms.[85,87]

E. histolytica is the pathogenic species, having the capacity to invade tissue and cause symptomatic disease, whereas *E. dispar* (and *E. histolytica*) is associated with the asymptomatic carrier state.[6,85] More recently, a study revealed that all genotypes of *E. histolytica* are not equally capable of causing disease.[6] Morphologically distinct members of the genus *Entamoeba*, such as *Entamoeba coli* and *Entamoeba hartmanni*, also are nonpathogenic. *Dientamoeba fragilis* and *Entamoeba polecki* have been associated with diarrhea, and *Entamoeba gingivalis* has been associated with periodontal disease.

Members of the genus *Entamoeba*, which are protozoan organisms belonging to the subphylum Sarcodina and close to *Dictyostelium discoideum* on one of the lowest branches of the eukaryotic tree, have trophozoite and cyst forms.[37] The cysts of *E. histolytica* and *E. dispar* are almost spherical, being surrounded by a cell wall composed of chitin. The cysts may have one to four nuclei, although quadrinucleate cysts are most typical. This feature allows differentiation from *Escherichia coli*, which usually has 6 to 8 nuclei in the cysts and may have 32 nuclei.[72] Cysts of *E. histolytica* are 5 to 20 μm in diameter (average 12 μm) and have a greenish tint in the unstained condition.[60] Young cysts contain chromatoid bodies, which are composed of ribosome particles in crystalline arrays.[12] The cysts of *E. hartmanni* appear identical to those of *E. histolytica* except for being a smaller size (4 to 10 μm). *E. histolytica* cysts can survive for days in the dried state at 30° C or for months at 0° C to 4° C. They can be killed by temperatures greater than 50° C retained for 5 minutes.[42] They are completely resistant to the concentrations of chlorine used in water supplies, but may be killed with hyperchlorination or with iodine solutions.[60,72] They are filtered from water supplies that pass through a sand filtration phase. They resist acids well.

When these quadrinucleate cysts are ingested, they resist the acid pH of the stomach and ultimately excyst in the alkaline environment of the bowel. The process of excystation results in the release of four trophozoites that divide by binary fission to produce eight trophozoites. The usual trophozoites have a diameter of 25 μm (range 10 to 60 μm).[26,85] They have a single nucleus that is 3 to 5 μm in diameter and contains fine peripheral chromatin with a slightly eccentric karyosome. They have a granular endoplasm that typically contains vacuoles in which bacteria and debris can be seen. Some glycogen is present and can be stained with periodic acid–Schiff stain.

Although amebae were thought to lack organelles, such as mitochondria, endoplasmic reticulum, and Golgi apparatus, evidence to the contrary is coming to light. The existence of nuclear-encoded mitochondrial genes and a remnant mitochondrial organelle was reported more recently.[61,94] The presence of ingested erythrocytes is a characteristic feature of *E. histolytica*, but not *E. dispar*.[85] Movement is accomplished by extension of clear pseudopodia. Replication is by binary fission. These protozoa live in the colon of humans and other mammals. Trophozoites die quickly outside the body and are quite sensitive to acid—they generally are not considered to be infective.[31] When cooled (as when feces are expelled and gradually cooled from body temperature) or stimulated by as-yet-undefined luminal conditions, the trophozoites form cysts that can remain viable for weeks to months on excretion.[85]

Trophozoites of *E. coli* are 15 to 50 μm in diameter; have much more sluggish motility than the trophozoites of *E. histolytica*; and have blunt pseudopodia, rather than the sharp, finger-like pseudopodia of *E. histolytica*. Trophozoites of *E. hartmanni* are 4 to 14 μm in diameter and have much less glycogen than the trophozoites of *E. histolytica*.[26]

EPIDEMIOLOGY

Amebiasis is distributed throughout the world. The number of people infected with either *E. histolytica* or *E. dispar* per year is estimated to be 500 million. Although most individuals remain asymptomatic, perpetuating the natural cycle of the organism through fecal excretion of infective cysts, approximately 50 million people experience the severe morbidity associated with invasive disease, with an estimated 100,000 dying annually.[75,92] In the United States, 50 percent of amebiasis is observed in Hispanic/Asian/Pacific Islanders. Travelers from developing countries, men, and residents of institutions for the mentally retarded are considered to be at higher risk for amebiasis (Table 221–1).

During the 1990s, enough evidence had accumulated to support the formal separation of two morphologically identical species of ameba: the nonpathogenic *E. dispar* from the potentially pathogenic *E. histolytica*.[1,14,29,30,36,92] Morbidity and mortality data in absolute numbers that existed before this time pertaining to cases of invasive disease were not greatly affected by this reclassification because all invasive disease was known to be caused by *E. histolytica*.[92] Because most prevalence and incidence data previously collected pertained to asymptomatic individuals, however, and it was clear that most asymptomatic individuals with cysts detected in their stool were infected with nonpathogenic *E. dispar*, the true prevalence and incidence of *E. histolytica* became a matter of speculation.[92]

TABLE 221–1 Risk Factors for Amebiasis in the United States

Hispanic/Asian/Pacific Islanders—50% of U.S. cases reported to CDC
Travelers—0.3% incidence in one study
Institutions for mentally retarded
Men who have sex with men
Men—90% amebic liver abscesses in men, but rare in children

CDC, Centers for Disease Control and Prevention.

Estimates of *E. histolytica* infections have been based primarily on examinations of stool for cysts and parasites, but these tests are insensitive and cannot differentiate *E. histolytica* from morphologically identical species that are nonpathogenic, such as *E. dispar* and *Entamoeba moshkovskii*.[5,22] Specific and sensitive means to detect *E. histolytica* in stool are now available and include antigen detection and polymerase chain reaction (PCR).[34,41,56]

A prospective study of preschool children in a slum of Dhaka, Bangladesh, showed *E. histolytica*–associated diarrhea in 9 percent and *E. histolytica*–associated dysentery in 3 percent of the children annually.[39] Not all individuals are equally susceptible to amebiasis, with certain HLA-DR and HLA-DQ alleles associated with resistance to infection and disease.[23] The annual incidence of amebic liver abscess was reported to be 21 cases per 100,000 inhabitants in Hue City, Vietnam.[14] Carefully conducted serologic studies in Mexico, where amebiasis is endemic, showed antibody to *E. histolytica* in 8.4 percent of the population.[17] In the urban slum of Fortaleza, Brazil, 25 percent of all individuals tested carried antibody to *E. histolytica*; the prevalence of antiamebic antibodies in children 6 to 14 years old was 40 percent.[15]

PATHOGENESIS AND PATHOLOGY

The cysts are transported through the digestive tract to the intestine, where they release their mobile, disease-producing form, the trophozoite. *E. histolytica* trophozoites can live in the large intestine and form new cysts without causing disease. They also can invade the lining of the colon, killing host cells and causing diarrhea, amebic colitis, acute dysentery, or chronic diarrhea. The trophozoites also can be carried through the blood to other organs, most commonly the liver and occasionally the brain, where they form potentially life-threatening abscesses (Fig. 221–1). Important virulence factors include the trophozoite cell surface galactose and *N*-acetyl-D-galactosamine (Gal/GalNAc)–specific lectin that mediates adherence to colonic mucins and host cells,[74,86] cysteine proteinases that likely promote invasion by degrading extracellular matrix and serum components, and amoebapore pore-forming proteins involved in killing of bacteria and host cells.[57,88]

The interface of the Gal/GalNAc lectin with the host mucins lining the intestine is the defining moment of the infection.[19] If the parasite lectin attaches to the host mucin glycoproteins that line the intestinal lumen, a noninvasive gut infection ensues. The life cycle continues as the trophozoites reproduce by clonal expansion in the mucin layer. Subsequently, the Gal/GalNAc lectin, along with mucin glycoproteins or other gut bacteria, initiates the developmental pathway leading to encystment.[25,92]

Colitis is caused when the trophozoite penetrates the intestinal mucous layer, which otherwise acts as a barrier to invasion by inhibiting amebic adherence to the underlying epithelium and by slowing trophozoite motility.[19] Invasion is mediated by the killing of epithelial cells, neutrophils, and lymphocytes by trophozoites, which occurs only after the parasite lectin engages host GalNAc on O-linked cell surface oligosaccharides.[75] The interaction of the lectin with glycoconjugates is stereospecific and multivalent.[100] The identity of the high-affinity intestinal epithelial cell receptor is unknown. Secretion of amoebapore, a 5-kd pore-forming protein, by the ameba may contribute to killing.[55] Activation of human caspase 3, a distal effector molecule in the apoptotic pathway, occurs rapidly after amebic contact, and caspases are required for cell killing in vitro and for the formation of amebic liver abscesses in vivo.[45,99]

Interaction of the parasite with the intestinal epithelium causes an inflammatory response marked by the activation of nuclear factor κB and the secretion of cytokines.[24,89] The development of this epithelial response may depend on trophozoite virulence factors, such as cysteine proteinase, and leads to intestinal abnormalities through neutrophil-mediated damage. Neutrophils also can be protective, and activation of neutrophils or macrophages by tumor necrosis factor-α or interferon-γ kills amebae in vitro and limits the size of amebic liver abscesses.[7,21] In contrast to the intense inflammatory response, typical of early invasive amebiasis, inflammation surrounding well-established colonic ulcers and liver abscesses is minimal, given the degree of tissue damage.[16]

The initial lesions of clinical amebiasis often are small interglandular ulcers with a diameter of approximately 1 mm. They extend only to the muscularis mucosa.[16,64] The margins may be hyperemic, and slight edema of the surrounding mucosa is present. *E. histolytica* organisms seen in these ulcers stain well with periodic acid–Schiff stain.[76] Bleeding and friability are not prominent at this stage, although proctoscopic examination may find mucus coming from these ulcers, with an abundant number of amebae present.

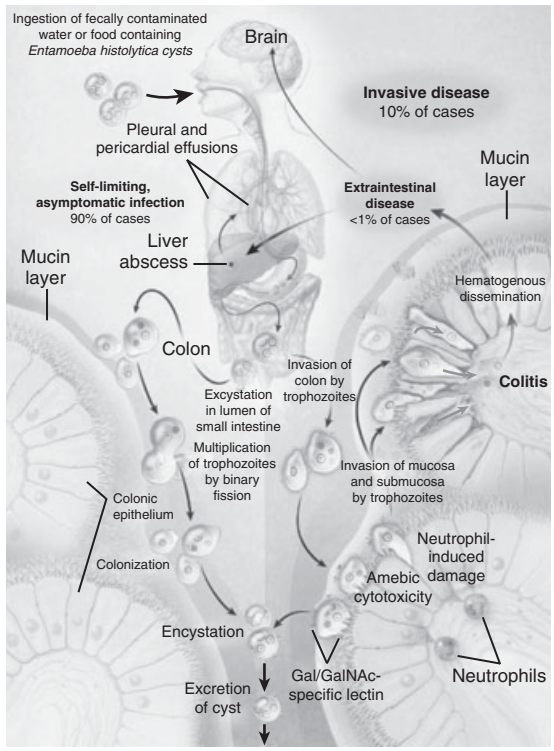

Figure 221–1 Life cycle of *Entamoeba histolytica*. Infection normally is initiated by the ingestion of fecally contaminated water or food containing *E. histolytica* cysts. The infective cyst form of the parasite survives passage through the stomach and small intestine. Excystation occurs in the bowel lumen, where motile and potentially invasive trophozoites are formed. In most infections, the trophozoites aggregate in the intestinal mucin layer and form new cysts, resulting in a self-limited and asymptomatic infection. In some cases, adherence to and lysis of the colonic epithelium, mediated by the galactose and *N*-acetyl-D-galactosamine (Gal/GalNAc)–specific lectin, initiates invasion of the colon by trophozoites. Neutrophils responding to the invasion contribute to cellular damage at the site of invasion. When the intestinal epithelium is invaded, extraintestinal spread to the peritoneum, liver, and other sites may follow. Factors controlling invasion, as opposed to encystation, most likely include parasite "quorum sensing" signaled by the Gal/GalNAc-specific lectin, interactions of amebae with the bacterial flora of the intestine, and innate and acquired immune responses of the host. (See companion Expert Consult web site for color version.) *(From Haque, R., Huston, C. D., Hughes, E., et al.: Amebiasis. N. Engl. J. Med.* 348*:1565-1573.)*

The next stage of intestinal disease is the production of deeper ulcers. These "buttonhole" ulcers may be 1 cm in diameter and may extend into the submucosa.[16,76] The ulcer often extends laterally under normal-appearing mucosa, forming a characteristic flask shape. Occasional perforation through the serosa leads to peritonitis or pneumoperitoneum.[91] Extensive necrosis may be present, but usually only very little inflammation occurs. The edema is more intense, but the mucosa between ulcers is normal, in contrast to the marked inflammatory response seen in bacterial enteritis. When ulceration is more extensive, the edema surrounding the ulcers becomes confluent, and the mucosa appears gelatinous. In young children, this condition can progress to a fulminant necrotizing colitis associated with transmural necrosis. The pathologic events associated with this phenomenon are not understood. Rarely, an inflammatory response is present, resulting in granulation of the tissue with a fibrous outer wall.[72] It is given the name *ameboma*. Occasionally, an ameboma fills a significant portion of the lumen, which causes stricture or obstruction. Other complications of intestinal amebiasis result from direct extension of the ulcers. This extension may result in cutaneous involvement of the perianal area or lesions of the penis, vulva, vagina, or cervix.[2,72] Cutaneous and ophthalmologic amebiasis also is caused by fecal contamination of the face.[67]

Amebas disseminate to the liver in 50 percent of patients with fulminant amebiasis.[2,3] Dissemination to other organs directly from the intestine probably does not occur, but dissemination from the liver to lung, heart, brain, spleen, scapula, larynx, stomach, and aorta has been described.[16] Amebic abscess of the liver occurs more often in men than in women by a ratio of 16:1, but occurs equally often in prepubertal children of both sexes.[3,16] Abscesses occur more commonly in adults, but occur in children as young as 4 months of age.[70] These abscesses vary from microscopic lesions to massive necrosis of 90 percent of the liver. Fever, right upper quadrant pain, and the presence of serum antibodies to amebae point to hepatic amebic abscess.[84] Examination of the fluid from such an abscess frequently reveals a reddish, "anchovy paste" fluid that rarely may appear white or green. The fluid is acidic, with a pH ranging from 5.2 to 6.7.[82] Amebas are found in the walls of the abscess and only rarely in the fluid of the abscess. Many patients with amebic liver abscess also have anaerobic bacteria in the abscess fluid.[83] The walls are composed of a thin connective tissue capsule. The right lobe of the liver is involved with amebic liver abscess about six times as often as the left lobe. Abscesses in the right lobe can perforate and cause disease below the diaphragm or in the thoracic cavity. Abscesses in the left lobe can lead to pericardial effusions, which are less common than pleural effusions.[32,47]

Pleural effusions can remain loculated or lead to cutaneous fistulas or to bronchopleural fistulas. Drainage from these fistulas is acidic, in contrast to the neutral secretions in the normal lung. Seeding of the cardiac valves and of the brain has been described.[16] Cerebral abscesses have the same microscopic findings as do liver abscesses, with a thin capsule of connective tissue surrounding a fluid with little or no associated inflammatory response.

IMMUNITY

Protection from amebiasis, including acquired immunity to infection and invasion by *E. histolytica*, is associated with a mucosal IgA antibody response against the carbohydrate recognition domain of the parasite Gal/GalNAc lectin.[37,35,43,53] Cell-mediated immunity in protection from invasive amebiasis, but not infection per se, also has been shown. There is substantial evidence from in vitro, animal model, and most recently human studies of an important role for interferon-γ in protection from amebic colitis, acting in part by activating of macrophages to kill the parasite.[40,44] Invasive amebiasis rarely occurs in individuals with human immunodeficiency virus/acquired immunodeficiency syndrome, even in areas where amebiasis is common, suggesting an important role also exists for natural immunity or innate immune responses, or both, in protection from infection.[7,34]

CLINICAL MANIFESTATIONS

INTESTINAL AMEBIASIS

Asymptomatic Intraluminal Amebiasis

The most common type of amebic infestation is an asymptomatic cyst-passing carrier state. All *E. dispar* infections and 90 percent of *E. histolytica* infections are asymptomatic, manifesting with only *Entamoeba* cysts in the feces.[29,78] Some investigators have suggested that stools of these individuals generally are more liquid than stools of individuals without trophozoites.[26]

Entamoeba histolytica–Associated Diarrhea

Diarrhea is the most common manifestation of amebic disease, present in 9 percent of children in the Mirpur cohort each year, compared with only 3 percent of children having amebic colitis each year.[39] *E. histolytica*–associated diarrhea is defined as three or more unformed stools in a 24-hour period accompanied by a new episode of *E. histolytica* infection. This definition was validated previously in the cohort by (1) showing that diarrhea was approximately five times more common in the setting of a new infection (age-adjusted odds ratio for the association of new *E. histolytica* infection with diarrhea of 4.7; 95% confidence interval 2.9 to 7.6), and (2) showing by a complete bacteriologic, virologic, and parasitic work-up that only 32 percent of *E. histolytica*–associated diarrhea cases were co-infected with another pathogen compared with identification of an enteropathogen in 59 percent of all cases of diarrhea.[37]

Acute Amebic Colitis

Amebic dysentery was defined as a diarrheal stool sample containing occult or gross blood that was positive for *E. histolytica* antigen. Seventy percent of patients have a gradual onset of symptoms over 3 or 4 weeks after infestation, with increasingly severe diarrhea as the primary complaint, accompanied by general abdominal tenderness. Occasionally, the onset may be acute or may be delayed for several months after infestation. This onset differs from bacterial causes of dysentery, in which patients usually have only symptoms of 1 to 2 days' duration. The diarrhea is usually associated with pain in children. Pain may be of such severity that an acute abdomen is suspected.[2,10,48,76] The stools contain blood and mucus in virtually all cases.[2,76,77] Fever is present in only a few patients with amebic colitis. Abdominal distention and dehydration occur in less than 10 percent of patients. In young children, intussusception, perforation, peritonitis, or necrotizing colitis may develop rapidly.[10,48,91]

Ameboma

Unusual manifestations of amebic colitis include toxic megacolon (0.5% of cases, usually requires surgical intervention), ameboma (granulation tissue in colonic lumen mimicking colonic cancer in appearance), and a chronic nondysenteric form of infection that can manifest as years of waxing and waning diarrhea, abdominal pain, and weight loss (easily misdiagnosed as inflammatory bowel disease).

EXTRAINTESTINAL AMEBIASIS

Amebic Liver Abscess

The typical patient with an amebic liver abscess in the United States is an immigrant, usually a Hispanic/Asian/Pacific Islander; male; 20 to 40 years old; who presents with fever, right upper quadrant pain, leukocytosis, abnormal serum transaminases and alkaline phosphatase, and a defect on hepatic imaging study. Roughly 90 percent of patients with liver abscess are men. The abscess usually is single and is in the right lobe of the liver 80 percent of the time.[49] Most frequently, patients present with liver abscess without concurrent colitis. Amebae are seen infrequently in the stool at the time of diagnosis of liver abscess.[3] Liver abscess can manifest acutely with fever and right upper abdominal tenderness and pain, or subacutely, with prominent weight loss and less frequent fever and abdominal pain. The peripheral white blood cell count is elevated, as is the alkaline phosphatase level, in many patients.

Early evaluation of the hepatobiliary system with ultrasound or computed tomography (CT) is essential to show the abscess in the liver. The differential diagnosis of the lesion in the liver includes pyogenic abscess, hepatoma, and echinococcal cyst. Aspiration of the abscess occasionally is required to diagnose amebiasis (although amebae are visualized in the pus in only a few cases; if the abscess is pyogenic, the responsible bacteria are seen or cultured). Antibodies to *E. histolytica* are present in the serum of 92 to 97 percent of patients on acute presentation with amebic liver abscess and are very useful diagnostically. Unusual extraintestinal manifestations of amebiasis include direct extension of the liver abscess to pleura or pericardium and brain abscess. In a patient who presents with right upper quadrant pain, ultrasound, CT, or magnetic resonance imaging (MRI) should be performed to examine the liver and gallbladder.

If a space-filling defect in the liver is observed, the differential diagnosis includes (1) amebiasis (most common in men with a history of travel or residence in a developing country); (2) pyogenic or bacterial abscess (suspect in women, patients with cholecystitis, elderly individuals, individuals with diabetes, and patients presenting with jaundice); (3) echinococcal abscess (an incidental finding because echinococcal abscess should not cause pain or fever); and (4) cancer. Most patients with amebic liver abscess have detectable circulating antigen in serum and serum anti-amebic antibodies.[34]

In children, abdominal pain is reported infrequently with amebic liver abscess.[33,68] More commonly, high fever, abdominal distention, irritability, and tachypnea are noted. Some children are admitted to the hospital with a fever of unknown origin. Hepatomegaly occurs frequently, but elicitation of hepatic tenderness is not well documented. In one report, four of five children younger than 5 years died with amebic liver abscesses because the diagnosis was not suspected.[54] Death usually results from rupture of the liver abscess into the peritoneum, thorax, or pericardium, but may follow extensive hepatic damage and liver failure.[3,81]

Metastatic Amebiasis

Extra-abdominal amebiasis presumably follows direct extension from liver abscesses, rather than direct dissemination from the intestine.[3,16] Thoracic amebiasis is the most common type of extra-abdominal amebiasis and occurs in approximately 10 percent of patients with amebic liver abscess.[16,47] Symptoms depend on the type of involvement. Empyema, bronchohepatic fistulas, or extension of a pleuropulmonary abscess into the pericardium may occur.

Pericardial amebiasis is the next most common form of extraintestinal involvement and may result from rupture of a liver abscess in the left lobe of the liver into the pericardium or through extension of the right-sided pleural amebiasis.[16,27,28,32] It is estimated to occur in 3 percent of patients with hepatic abscesses.[28] It manifests as acute pericarditis with tamponade and, occasionally, as pneumopericardium.[27] Amebic liver abscess in the left lobe also may rupture directly into the left chest.[63]

Cerebral amebic abscesses were found in 8 percent of patients with amebic infections discovered at autopsy in one study.[58] In other studies, lower rates of 0.66 to 4.7 percent of patients with amebic liver abscess having brain abscesses were reported.[46] Patients with cerebral amebiasis frequently are so ill from the intestinal, liver, and possibly lung involvement that neurologic signs are not always assessed easily. In 18 patients with proven cerebral amebiasis, initial neurologic examination was normal in 13, and only 1 patient later developed seizures.

Other foci of infection are rare findings, but amebic rectovesical fistula formation and involvement of pharynx, heart, aorta, and scapula have been reported. Cutaneous extension after the adherence of perforated, inflamed bowel to the skin is an extremely painful and rare complication.[16,72] This situation also may arise after invasion of the skin by trophozoites emerging out from the rectum occurs.

DIAGNOSIS

A heightened suspicion of amebiasis should be present if the patient has been in a developing country as a resident or traveler. The diagnosis of amebiasis should be considered in any child who is passing diarrhea, bloody stools, or stools with mucus; any child with a hepatic abscess; and any febrile child with right upper quadrant pain, abdominal distention, or tachypnea.[54,68] In a patient with diarrhea, if blood is present in the stool (grossly bloody or occult blood positive), infectious (Shiga toxin–producing *E. coli*, *Salmonella*, *Shigella*, *Campylobacter*, and *E. histolytica*) and noninfectious (inflammatory bowel disease, diverticulosis, arteriovenous malformations, cancer) causes should be considered.

IMMUNOLOGIC OR MOLECULAR EXAMINATION OF STOOL OR SERA

E. histolytica infection was defined as a positive test for antigen in stool. Antigen was detected using the TechLab (Blacksburg, VA) *E. histolytica* II stool antigen detection test, which specifically detects *E. histolytica* and does not cross-react with *E. dispar* or *E. moshkovskii*. The antigen test is 95 percent sensitive and specific compared with the "gold standard" of *E. histolytica* culture and zymodeme determination. It also is 80 percent sensitive compared with real-time PCR for *E. histolytica* DNA in stool. Although real-time PCR is excellent in sensitivity and specificity, real-time PCR still is not practical for the measurement of infection in the thousands of stool samples analyzed in this prospective study, so we usually use the less sensitive but highly specific antigen detection test, recognizing that in doing so we may underestimate the incidence of amebiasis.[41,56] In addition, immunohistochemical staining of amebae is useful in a difficult-to-diagnose case. Serologic tests for anti-amebic antibodies also are a very useful tool in diagnosis, with sensitivity of 70 to 80 percent early in disease and approaching 100 percent sensitivity on convalescence. The combined use of serology and stool antigen detection test offers the best diagnostic approach.

MICROSCOPIC EXAMINATION OF STOOL

Before the development of new antigen detection and PCR tests, amebiasis was diagnosed by examining a stool sample through a microscope to determine whether *E. histolytica* cysts were present. This method often requires more than one specimen, however, because the number of cysts in the stool varies greatly. In addition, stool microscopy has limited sensitivity and specificity. The body's own immune system produces macrophage cells that can look like the amebae. Three different amebae—*E. histolytica*, which causes amebiasis, and *E. dispar* and *E. moshkovskii*, which do not cause disease—look identical under a microscope.[22]

NONINVASIVE DIAGNOSIS OF EXTRAINTESTINAL AMEBIASIS

Amebiasis outside the intestine has been even more difficult to diagnose. Clinical manifestations of extraintestinal disease vary widely, and less than 10 percent of individuals with amebic liver abscesses have identifiable *E. histolytica* in their stools. The TechLab *E. histolytica* II test, which differentiates the true pathogen *E. histolytica* from *E. dispar*, was reported to detect Gal/GalNAc lectin in the sera of 22 of 23 (96%) patients with amebic liver abscess tested before treatment with the anti-amebic drug metronidazole and 0 of 70 (0%) controls. After 1 week of treatment with metronidazole, more than 80 percent of patients became serum lectin antigen–negative. Detection of *E. histolytica* Gal/GalNAc lectin in the sera using the TechLab *E. histolytica* II kit is sensitive to diagnose hepatic and intestinal amebiasis before the institution of metronidazole treatment.[38]

Noninvasive diagnostic procedures such as ultrasound, CT, and MRI can detect extracolonic amebiasis in the liver, paracecal masses, brain, and other sites, but they cannot distinguish between abscesses caused by amebae and those caused by bacteria, hampering proper treatment of the condition. Most patients with amebic liver abscess have a single abscess in the right lobe of the liver, although multiple lesions also can occur.[4] Chest radiographs show elevation of the right diaphragm in 56 percent of patients with hepatic abscess.[3] The diagnosis of cerebral amebiasis requires careful neurologic evaluation and radiographic evaluation with either CT or MRI.[16,46,58] Because of the risk for perforation, barium studies are relatively contraindicated in patients with amebic colitis.

BIOPSY STUDIES

The colonic and rectal mucosa in amebic colitis usually reveals ulcerations with a diameter of 1 to 10 mm. Amebic trophozoites often are at the periphery of these necrotic areas, which can be sampled through a biopsy specimen taken during sigmoidoscopy or colonoscopy.[42,49] Because of the potential for perforation, colonoscopy should be undertaken with caution.

In patients with amebic liver abscesses, amebic trophozoites are found near the capsule of the abscess. Until more recently, the most accurate diagnostic test involved the examination of a sample collected from the abscess tissue by needle aspiration, a procedure that is painful, potentially dangerous, and relatively insensitive, identifying amebic trophozoites only 20 percent of the time.

DIFFERENTIAL DIAGNOSIS

Invasive amebic colitis may resemble ulcerative colitis, Crohn disease of the colon (inflammatory bowel disease), bacillary dysentery, or tuberculous colitis.[11,18,42,89] Stool examinations, colonoscopic examination with biopsies, and serologic examination should be able to differentiate amebic colitis from these diseases. Histologic examination of involved colonic mucosa should differentiate amebic colitis, with its lack of inflammation and rare granulation tissue, from the inflammatory responses seen in ulcerative colitis, bacillary dysentery, and Crohn disease of the colon. Tuberculous colitis and Crohn disease are more likely to show granuloma formation than amebiasis. Ileocecal or small bowel involvement as seen on barium studies would suggest Crohn disease or tuberculosis of the gastrointestinal tract, rather than amebiasis. Tuberculous colitis usually is associated with pulmonary tuberculosis and with a strong reaction to tuberculin skin testing. In some cases, differentiating between invasive amebic colitis and inflammatory bowel disease may be impossible. If a patient with this differential diagnosis is placed on corticosteroids and deteriorates, the corticosteroids should be stopped, and repeat investigation for amebiasis should be performed.[18,68,72]

Amebic liver abscess must be differentiated from pyogenic abscesses and neoplastic lesions. Detection of *E. histolytica* Gal/GalNAc lectin in the sera using the TechLab *E. histolytica* II kit is quite helpful to diagnose hepatic and intestinal amebiasis before the institution of metronidazole treatment.[38] Total leukocyte counts and cultures of blood may help to differentiate pyogenic and amebic abscesses. Many children with pyogenic liver abscesses have negative blood cultures, however. Often, amebic and pyogenic liver abscesses show similar features on CT and MRI. Occasionally, nuclear imaging with gallium is helpful because, in contrast to a pyogenic abscess, very few neutrophils are contained within an amebic liver abscess.[85,87] Gallium scanning of an amebic liver abscess may reveal a cold spot, possibly with a bright rim. Several investigators recommend a trial using an appropriate drug for amebic abscess for 3 or 4 days while serologic and culture results are awaited.[68,98] Patients with amebic liver abscess should respond to treatment in this length of time by becoming afebrile. No change in size of the liver or size of the abscess should be noted at this time because resolution of the abscess usually takes 2 months to several years.[4,79,80,90,97]

COMPLICATIONS

Complications of amebiasis may be prevented by early establishment of diagnosis and initiation of treatment with appropriate agents.[46,68] When complications occur, the prognosis generally is poor.

Invasive intestinal amebiasis has been associated most commonly with perforation and peritonitis,[8,10,48,68,91,96] which apparently are an end result of "necrotizing" or "toxic" amebic colitis. In children, perforation may be heralded by the appearance of an acute abdomen or pneumoperitoneum, with rapid progression to death, presumably from sepsis.[8,68,96] Surgical resection and therapy for endotoxic shock improve the prognosis.[96] This complication is not rare and accounts for more than 30 percent of deaths from amebiasis in children.[11,50] Massive intestinal hemorrhage causes approximately 3 percent of deaths from amebiasis. Intussusception occasionally occurs and can be reduced with gentle barium enema. Multiple colonic strictures also can occur and cause obstructive symptoms. Fistulas to other organs or to the skin may develop.

Liver abscesses and their resultant complications account for approximately 40 percent of deaths from amebiasis.[50] Liver abscess also was found in 13 percent of patients with amebiasis who had postmortem examinations. Liver abscess with rupture into the abdomen was present in 8 percent of patients who died with amebiasis, and rupture of a liver abscess into the right pleural space was found in 12 percent.[50] Many patients with amebic liver abscess also have anaerobic bacteria in the abscess fluid.[83] In cases free of bacterial contamination, the fluid has few

inflammatory cells and an acidic pH. Amebic pericarditis or pneumopericardium occurs rarely and is found in only 1 percent of patients whose deaths were caused by amebiasis.[27,28,32,50] The fluid is similar to that found in the pleural space. A cerebral abscess was found in 4 percent of patients with amebiasis who died.[50] It has been reported in fewer than 10 children, only one of whom survived.[9,16,46,58] Other complications include infections of the retroperitoneal space, stomach, spleen, esophagus, and duodenum.[58]

TREATMENT

INTESTINAL AMEBIASIS

Asymptomatic Intraluminal Amebiasis

Therapy for asymptomatic and noninvasive infection differs from therapy for invasive infection. Asymptomatic infections may be treated with intraluminal agents, such as paromomycin or diloxanide furoate. Each agent has a high rate of success for eradication of cyst passage.[65,66] Paromomycin is a nonabsorbable aminoglycoside that is active against the cyst and trophozoite stages. High cure rates have been reported with a 7-day oral dose of paromomycin at 25 to 35 mg/kg/day in three divided doses (Table 221–2). Diloxanide furoate (Furamide) is a poorly absorbed agent that is quite active against only intraluminal amebiasis, but treats symptomatic and asymptomatic disease.[62,98] Cure rates have been greater than 90 percent with a 10-day oral course of diloxanide furoate at 20 mg/kg/day in three divided doses (maximum dose of 1500 mg/day).[65,66,73]

Acute Amebic Colitis

Nitroimidazoles, particularly metronidazole, are the mainstay of therapy for invasive amebiasis.[37] The oral dosage of metronidazole is 35 to 50 mg/kg/day (to a maximum of 2250 mg/day) in three divided doses for 7 to 10 days for severe intestinal or extraintestinal amebiasis. Metronidazole is concentrated in the ameba, probably via reduction of its nitro group by ferredoxin or flavodoxin-like electron transport proteins, which maintain a gradient for the entry of the unchanged drug. Metabolic intermediates of metronidazole damage DNA and possibly other macromolecules, and they deprive the organism of reducing equivalents by acting as an electron sink. Nitroimidazoles with longer half-lives (tinidazole, secnidazole, and ornidazole) are better tolerated and allow shorter periods of treatment.[38] The oral dosage of tinidazole is 60 mg/kg/day (to a maximum of 2000 mg/day) for 5 days for severe intestinal or extraintestinal amebiasis (see Table 221–2) (see http://www.medletter.com/).

Approximately 90 percent of patients who present with mild-to-moderate amebic dysentery have a response to nitroimidazole therapy. In the rare case of fulminant amebic colitis, adding broad-spectrum antibiotics to treat intestinal bacteria that may spill into the peritoneum is prudent; surgical intervention occasionally is required for acute abdomen, gastrointestinal bleeding, or toxic megacolon.[37] Agents such as metronidazole that are active against invasive and extraintestinal amebiasis are well absorbed and do not stay in the lumen long enough to have an effect on intestinal amebiasis. Parasites persist in the intestine in 40 to 60 percent of patients who receive nitroimidazole. Nitroimidazole treatment should be followed with paromomycin or the second-line agent diloxanide furoate to cure luminal infection.[38] Metronidazole and paromomycin should not be given at the same time because the diarrhea that is a common side effect of paromomycin may render assessing the patient's response to therapy difficult.[50-52]

EXTRAINTESTINAL AMEBIASIS

Amebic Liver Abscess and Metastatic Amebiasis

Extraintestinal and severe intestinal amebiasis must be treated with the tissue-active agents. Metronidazole (35 to 50 mg/kg/day in three divided doses for 7 to 10 days) is the preferred drug because it is effective and relatively free of serious side effects (see Table 221–2).[2,3,62,85,87,98] It is effective for extraintestinal amebiasis in any location, although amebic brain abscesses usually are not treated successfully with any medications. Most patients with amebic liver abscess respond to metronidazole within 72 hours. For amebic colitis, follow-up therapy with a luminal agent is very important because of the high rates of asymptomatic intestinal colonization in patients with amebic liver abscess.

Therapeutic aspiration of an amebic liver abscess occasionally is required as an adjunct to antiparasitic therapy. Drainage of the abscess should be considered in patients who have no clinical response to drug therapy within 5 to 7 days or patients with a high risk of experiencing rupture of the abscess, as defined by a cavity with a diameter of more than 5 cm or by the presence of lesions in the left lobe.[95] Because many patients with amebic liver abscess also have anaerobic bacteria in the abscess fluid,[83] addition of antibiotics, drainage, or both to the treatment regimen in the absence of a prompt response to nitroimidazole therapy is reasonable. Imaging-guided percutaneous treatment (needle aspiration or catheter drainage) has replaced surgical intervention as the procedure of choice for reducing the size of an abscess.[95]

PROGNOSIS

Invasive disease develops in 50 million people each year, and 50,000 to 100,000 deaths per year are caused by the invasive disease.[78,84,85] The case-fatality ratio is between 1 in 500 and 1 in 1000 diagnosed cases. Among patients with illness severe enough to require hospitalization, the case-fatality ratio is higher. One small study in children reported a 9 percent mortality rate and a 27 percent morbidity rate.[68]

Bowel necrosis or perforation is the cause of death from purely intestinal amebiasis, and early surgical intervention can reduce the mortality rate of these complications from 100 to 28 percent.[96] Amebic liver abscess has a case-fatality rate of 10 to 15 percent in combined figures of adults and children.[54,70,81] The mortality rate when pleural involvement is noted is 14 percent.[47,54] Amebic pericarditis has a case-fatality rate of 40 percent.[32] Cerebral amebiasis has a case-fatality rate of 96 percent.

TABLE 221–2 Pediatric Dosage of Drugs for Amebiasis

Symptomatic	Paromomycin	25-35 mg/kg/day in 3 doses × 7 days
Mild-to-moderate intestinal disease	Metronidazole	35-50 mg/kg/day in 3 doses × 7-10 days
	Trinidazole	50 mg/kg (maximum 2000 mg) qd × 3 days
Severe intestinal and extraintestinal disease	Metronidazole	35-50 mg/kg/day in 3 doses × 7-10 days
	Trinidazole	60 mg/kg/day (maximum 2000 mg) × 5 days

FUTURE

In a perfect world, amebiasis would be prevented by eradicating fecal contamination of food and water. Providing safe food and water for all children in developing countries would require massive societal changes and monetary investments. An effective vaccine would be much less costly, and for several reasons, a vaccine is a desirable and feasible goal. The high incidence of amebiasis in more recent community-based studies suggests that an effective vaccine would improve child health in developing countries.

The fact that humans naturally acquire partial immunity against intestinal infection indicates that barriers to stimulating an effective acquired immune response should not be insurmountable. Aiding vaccine design is the demonstration that several recombinant antigens, including the Gal/GalNAc-specific lectin, provide protection in animal models of amebiasis, and that human immunity is linked to intestinal IgA against the lectin.[35,37,43] The high degree of sequence conservation of the Gal/GalNAc-specific lectin suggests that a vaccine could be broadly protective. Finally, the absence of epidemiologically significant animal reservoirs suggests that herd immunity could interrupt fecal-oral transmission in humans. The challenges will be to design vaccines capable of eliciting durable mucosal immunity, to understand the correlates of acquired immunity, and, most important, to enlist the continued support of industrialized nations to combat diarrheal diseases of children in developing countries.

CHAPTER 222

BLASTOCYSTIS HOMINIS INFECTION

Peter J. Hotez

Blastocystis hominis is one of the most common gastrointestinal protozoa of humans, with a worldwide prevalence that may be greater than 50 percent.[26,27] Other *Blastocystis* spp. have been described from numerous other vertebrates and insects.[27] Although new information about the molecular and cell biology of this organism has been acquired in recent years, considerable controversy regarding its true taxonomy and life cycle remains.[4,26,27,29,30] The pathogenicity of *B. hominis* and its ability to cause gastrointestinal illness in humans are equally controversial.[10,11,13,16,24]

ETIOLOGY AND PATHOGENESIS

Since its discovery in the early part of the 20th century by Alexeieff[1] and then Brumpt,[6] *B. hominis* has been assigned to many different phyla in animal and plant kingdoms. Early on, it was identified by various workers as vegetable material, a yeast, a fungus, or a protozoan. Although the organism was identified as a protozoan parasite in 1967, its subphylum status bounced between the Sporozoa and the Sarcodina.[4] Nucleic acid sequencing data now suggest that *B. hominis* does not belong to either category,[13,14] but instead probably constitutes its own group (class Blastocystea) more closely related to the Straemenopiles, a heterogeneous group of unicellular and multicellular protists that includes slime nets, water molds, and brown algae.[27] Additional molecular taxonomic data suggest that the intraspecific variation among stocks of *B. hominis* is sufficiently different to warrant multiple separate species assignments for the organism.[5,27] This observation ultimately may have a bearing on the current controversies surrounding the pathogenicity of the organism and different modes of transmission (i.e., zoonotic and human-to-human).[27]

Ultrastructural data gathered from light and electron microscopy on organisms obtained from in vitro culture and from fresh fecal material indicate the existence of several different parasite forms, including cyst forms; ameboid forms; and the so-called granular, avacuolar, and vacuolar forms.[4] The *B. hominis* vacuolar cell is the most distinctive and appears as a thin peripheral band of cytoplasm surrounding a large membrane-enclosed central vacuole.[4] The central vacuole may have a storage function. Although *B. hominis* is thought to have predominantly anaerobic metabolism, structures that look like mitochondria have been identified on transmission electron microscopy. *Blastocystis* mitochondria may function only in lipid biosynthesis and not oxidative phosphorylation.[4,29] Alternatively, what appears to be a *Blastocystis* mitochondrion on electron microscopy actually may be a hydrogenosome.[4]

Several highly speculative life cycles of *B. hominis* have been proposed.[4,14] The infective stage probably is a dormant cyst form that undergoes excystation in response to host gastric acid and intestinal enzymes. Excystation may result in the release of avacuolar forms that can undergo facultative transformation to either an ameboid or a multivacuolar form. The multivacuolar form either may encyst to an infective stage or may coalesce to the vacuolar form.[4] These stages are thought to predominate in the large intestine, although organisms also have been recovered from duodenal aspirates. Which, if any, of these life cycle stages invades tissue or causes disease is unknown. Acquisition of knowledge in this area has been hampered by lack of a suitable animal model, although infection of gnotobiotic guinea pigs with this organism was reported to result in mild intestinal hyperemia and superficial invasion of *B. hominis* into the mucosa of the cecum. Nonspecific inflammation (infiltration of lymphocytes and plasmocytes) and edema of the colonic mucosa have been seen during sigmoidoscopy with biopsy in some patients.[4] So far, no serologic antibody response to the organism has been shown[7] except in a subset of patients with irritable bowel syndrome who reportedly show elevated IgG2 antibody.[12] The possibility remains that *B. hominis* is entirely commensal in humans.

EPIDEMIOLOGY AND CLINICAL MANIFESTATIONS

B. hominis has a worldwide distribution in tropical and temperate regions, with infection rates of 54 percent occurring among some populations.[2-4,8,9,20,21,24,28] High rates of infection also have been reported in individuals with a recent history of travel,[23] with exposure to pets or farm animals,[8] and living in institutionalized settings.[4] In many of these individuals, however, *B. hominis* probably is a commensal parasite. Although *B. hominis* is found commonly in preschool-age and school-age children,[20-22] children overall do not seem to be at increased risk for acquisition of infection.[4]

Most studies investigating the association between *B. hominis* infection and disease are based primarily on clinical laboratory isolates of the organism in patients exhibiting gastrointestinal symptoms. Common clinical complaints include abdominal discomfort, bloating, cramping, diarrhea, and vomiting.[2] As noted earlier, IgG2 seroconversion to *B. hominis* has been linked to irritable bowel syndrome.[12] Weight loss associated with a protein-losing enteropathy also has been described. Infective arthritis also has been reported.[16] Because *B. hominis* commonly is found in symptomatic and asymptomatic individuals, some investigators have proposed that only very heavy infections result in disease.[17,25] Many of these studies were not controlled, however.

Shlim and colleagues[25] conducted a large prospective controlled study among a population of expatriates and tourists in Katmandu, Nepal, who were at high risk for developing traveler's diarrhea. They concluded that *B. hominis* in high concentrations was not associated with diarrhea, and the presence of higher concentrations of the organism in stool was not associated with more severe symptoms.[25] In a subsequent editorial, several design features were cited that may "weaken the authors' conclusions."[15] At least four other prospective trials have been conducted, with one supporting *B. hominis* as a cause of diarrhea, one arguing against it, and two others that were inconclusive.[23] The confusion may be resolved partly by the identification of separate human "demes" of *Blastocystis*,[5,14] which might lead to improved molecular diagnostic techniques for distinguishing pathogenic from nonpathogenic species. This situation is analogous to the morphologically identical species of *Entamoeba* (*Entamoeba histolytica* and *Entamoeba dispar*), only the former of which causes colitis.

DIAGNOSIS

Light microscopy of wet preparations of fresh or concentrated stool usually identify *B. hominis*. Staining of preparations with iodine or trichrome also is beneficial. Many laboratories attempt to identify the characteristic vacuolar forms, which may be underrepresented in clinical material.[4] Under these circumstances, the services of an experienced technologist are required to identify the less distinctive fecal cyst form.[27] Organisms also can be recovered from biopsy material obtained during sigmoidoscopy and colonoscopy.

TREATMENT

Given the controversy surrounding the pathogenicity of *B. hominis*, a prudent approach is to refrain from treating asymptomatic immunocompetent individuals.[18] In individuals who have gastrointestinal illness and in whom other pathogens have been excluded, administering a course of antiprotozoal chemotherapy may be reasonable. Some investigators have reported symptomatic improvement in patients receiving either metronidazole or tinidazole.[4,9] Using an in vitro assay that employed metabolic labeling, researchers found that the drugs emetine, satranidazole, furazolidone, and quinacrine were superior in activity to either metronidazole or tinidazole.[4] The authors caution, however, that the in vitro assay does not take into account the pharmacokinetic properties of the drugs. Furazolidone is available in suspension and may be suitable for pediatric use.[11] In two prospective, randomized, double-blind, placebo-controlled studies, children and adults who received 500 mg of nitazoxanide were shown to respond significantly better to treatment parasitologically and

clinically compared with placebo controls.[23] Trimethoprim-sulfamethoxazole also has been reported as an alternative regimen.[19]

CHAPTER 223

ENTAMOEBA COLI INFECTION

Peter J. Hotez

Until more recently, *Entamoeba coli* was considered to be entirely nonpathogenic and was of interest to the clinician only because of its morphologic similarities to *Entamoeba histolytica* that might result in misdiagnosis. In 1991, several case reports from northern Europe appeared, however, that implicated *Entamoeba coli* as a possible cause of infectious diarrhea.[2,5,7] Two cases of diarrhea associated with *Entamoeba coli* have been described in children.[2]

ETIOLOGY AND PATHOGENESIS

Entamoeba coli, similar to other members of the genus *Entamoeba*, has trophozoite and cyst forms. The trophozoite is similar in size to *E. histolytica* (15 to 50 μm), but has a more sluggish motility with short pseudopodia.[4] The cytoplasm is described as granular, coarse, or frothy, and contains numerous bacteria, yeasts, and other food materials.[4,6] Occasionally, red blood cells are seen in the cytoplasm, but their occurrence is not nearly as common as in pathogenic strains of *E. histolytica*. During passage through the colon, the trophozoite rounds up and synthesizes a chitin-containing cyst wall. *Entamoeba coli* cysts measure 10 to 35 μm and usually contain 8 to 16 nuclei, although occasionally 32 nuclei are seen.

Transmission of *Entamoeba coli* infection occurs through the fecal-oral route in the same manner as *E. histolytica* infection. On cyst ingestion, the total number of excysting trophozoites usually is fewer than eight.[4] The *Entamoeba coli* trophozoites colonize the lumen of the large intestine. Very little is known about the events by which *Entamoeba coli* trophozoites occasionally cause human gastrointestinal illness. Even with a pathogenic *Entamoeba coli* strain, the invasive potential of this organism is presumed not to be nearly as great as that of *E. histolytica* because diarrheal disease in patients infected with *Entamoeba coli* is not associated with dysentery or accompanied by a leukocytosis or elevated serum IgA.[7]

EPIDEMIOLOGY AND CLINICAL MANIFESTATIONS

Entamoeba coli is worldwide in distribution, although it occurs more commonly in warmer climates and in some populations of homosexual men.[4] In 1991, Wahlgren[7] described eight patients from Sweden with mild or persistent diarrhea who harbored *Entamoeba coli*. Before receiving specific anti-amebic chemotherapy, all eight patients had their stools examined repeatedly by (1)

light microscopy, to exclude other protozoa and helminths; (2) electron microscopy, to exclude the presence of some pathogenic viruses; and (3) aerobic and anaerobic culture, to exclude pathogenic bacteria. These patients typically complained of a long history of loose but not watery stools (without blood or mucus), flatulence, and colicky pain. One patient was a parasitology laboratory technician who had symptoms for more than 15 years. Every patient responded to specific anti-amebic chemotherapy.[7] Two children with similar symptoms who also responded to anti-amebic chemotherapy subsequently were described in Ireland.[2]

DIAGNOSIS AND TREATMENT

Entamoeba coli sometimes is difficult to distinguish from *E. histolytica*, particularly because the nuclear structures of their trophozoite stages are similar.[3] Some differences exist, however, including the karyosome, which is eccentric in *Entamoeba coli*, but central in *E. histolytica*, and the cytoplasm, which is coarse and seldom contains red blood cells in *Entamoeba coli*, in contrast to *E. histolytica*.[3] The differences between the cyst stages of *Entamoeba coli* and *E. histolytica* (and *Entamoeba dispar*) are more apparent. The *Entamoeba coli* cyst typically has two to four times more nuclei than cysts in *E. histolytica*. The *Entamoeba coli* cyst has been reported to become more refractive during fixation so that it often is visualized better in a wet preparation.[4]

Generally, *Entamoeba coli* still is regarded by most investigators as a commensal organism. In patients with persistent diarrhea whose diagnostic fecal evaluation reveals only the presence of *Entamoeba coli*, administering a course of specific anti-amebic therapy is reasonable.[1] All of the Swedish patients were reported to respond to a 10-day course of diloxanide furoate in a dose of 500 mg three times daily.[7] Children also may respond to an equivalent pediatric dose of 20 mg/kg/day in three divided doses for 10 days. As of 1994, diloxanide furoate was available in the United States from the Centers for Disease Control and Prevention Drug Service. Alternatively, two children from Ireland (where diloxanide furoate was unavailable) were treated successfully for *Entamoeba coli*–associated diarrhea with metronidazole.[2]

B. Flagellates (Intestinal)

CHAPTER 224

GIARDIASIS

Tina Q. Tan

Giardiasis is caused by an infection with the flagellated, binucleated protozoan parasite *Giardia lamblia* (also known as *Giardia duodenalis* or *Giardia intestinalis*). Worldwide, *G. lamblia* is one of the most prevalent and important infectious causes of diarrheal illness in humans. Van Leeuwenhoek first described the parasite when examining his own stool under a microscope in 1681. Lambl described the trophozoite in 1859, and Grassi described the cyst in 1879.[64] This flagellated parasite, which belongs to the family Hexamitidae, is one of the most ancient eukaryotes and lacks many organelles, including Golgi apparatus and mitochondria.[30] Mitochondrial genes have been discovered in the organism more recently, however, and the organism has been shown to possess specialized membrane structures that perform the respiratory chain activities of the inner mitochondrial membrane. This finding lends support to the theory that *Giardia* organisms have become highly evolved and have lost many of their ancestral characteristics.[1,4,59,60] For centuries, *Giardia* were thought to be nonpathogenic organisms; however, during the past 30 years, data have shown that *G. lamblia* can be a pathogen that causes sporadic and epidemic disease.[40]

ETIOLOGIC AGENTS

G. lamblia has two morphologic forms: the infectious cyst, which is resistant to chemicals and environmental stresses, and the trophozoite, which is responsible for the disease. The trophozoite is pear-shaped, with a dorsal convexity and a spiral organelle on its ventral surface. The spiral organelle or sucking disk is the means by which the organism attaches to mucosal surfaces. The trophozoite usually measures 10 to 21 μm in length and 5 to 15 μm in width. It has four pairs of flagella and two symmetric nuclei. Trophozoites live in the small intestine and divide by binary fission. The cyst form usually is seen in stool samples and is oval-shaped, measuring 8 to 12 μm in length and 5 to 10 μm in width. It contains two to four nuclei and remnants of organelles. Cysts can remain viable for long periods (≥3 months) in cold water and are resistant to killing by iodine and chlorine; however, they can be destroyed by heating to 50° C and by desiccation.[2]

Six species of *Giardia* have been identified based on the morphologic characteristics of the trophozoite: *G. duodenalis*, *G. agilis*, *G. muris*, *G. ardeae*, *G. psittaci*, and *G. microti*. *G. lamblia*, also called *G. duodenalis*, is the primary pathogenic species in humans and other mammals. All the other species infect primarily animal species and cause no significant disease in humans. The species that infects humans is morphologically indistinguishable from that of other mammals.[2,40] Isoenzyme and genetic analyses indicate that isolates from infected individuals exhibit high levels of genetic diversity and comprise a large number of genotypes that can be placed into four groups.[13] The different isolates within groups show some specificity for infection in various mammals

versus humans, but no consistent genetic differences have been identified between isolates that cause symptomatic versus isolates that cause asymptomatic disease. The genotypes are grouped into two major genetic assemblages: assemblage A and assemblage B. More recent studies have shown that in symptomatic infection a strong correlation exists between isolate assemblage type and the severity of infection; however, the infectivity and pathogenicity of *Giardia* genotypes seem to vary depending on the age of the host.[2,44,69,77]

EPIDEMIOLOGY

Giardia infections are ubiquitous, and outbreaks occur in developed and underdeveloped countries throughout the world. Cross-transmission and infection occur between domestic and wild animals and humans and between humans.[20] Transmission involves the fecal-oral, water-borne, and food-borne transmission of cysts; the level of sanitation and a high intradomiciliary/peridomiciliary concentration of domestic animals are related directly to the prevalence of infection.[6,24,46,51,61,84,85]

G. lamblia is one of the most common parasites in the United States, affecting individuals of all ages, and is found in 4.2 to 7 percent of specimens submitted to the laboratory for examination.[50] The populations that are affected most frequently include children 0 to 5 years old, adults 31 to 40 years old, backpackers, campers, hunters, and travelers to areas where the disease is endemic.[45] Data from the National Giardiasis Surveillance System of the Centers for Disease Control and Prevention estimate that 2.5 million cases occur each year in the United States.[103] Cases per 100,000 population range from 1.4 to 30, with seven states reporting more than 15 cases per 100,000 population. In 2005, Vermont had the highest incidence, with 30 cases per 100,000 population. Cases are more prevalent in males, and rates are highest in children 1 to 4 years old (children in daycare centers and their close contacts), followed closely by children 5 to 9 years old and adults 31 to 40 years old. Most cases are reported in the early summer through early fall.[103]

Giardia is a frequent cause of diarrhea in daycare centers around the world, with infection rates of 1 to 55 percent.[3,8,53,70,73,75] Most children are symptomatic, and chronic passage of cysts in some preschool-age children in daycare centers may persist for 5 to 6 months after the initial diagnosis is established. Transmission from these infants and children to adult family members is common; 25 percent of the children have *Giardia*-positive stools. The prevalence rates are highest in centers with many non–toilet-trained children and staff members who change diapers and prepare food without adequate handwashing. Prevalence rates decline after children are toilet trained.[8]

Sexual transmission may occur with heterosexual and homosexual contact; however, male homosexual behavior is an established risk factor for acquiring *G. lamblia* infection, with cyst passage rates reaching 20 percent.[43,52,57] Other individuals at risk include campers, backpackers, hunters, and other travelers to national parks, wilderness areas, and disease-endemic areas because of vertical transmission from animals and ingestion of untreated drinking water.[99] Patients who were infected during travel had longer exposure times in countries where the prevalence was high.[48] In addition, many outbreaks have been reported in municipal water supplies that have not been treated with flocculation or filtration.

From 1985 to 1994, *Giardia* was responsible for 44 percent of the outbreaks of water-borne diarrheal illness in which an etiology could be determined. Sixty-four percent of these outbreaks were associated with unfiltered water. According to a sample survey of 66 reservoir sites in Canada and the United States, 81 percent contained *Giardia* cysts at a concentration of 3 cysts per liter before treatment and 1.7 cysts per liter after treatment.[54,55] Treatment of water with iodine preparations kills most cysts, but they are resistant to chlorination. Swimming pools may be another source of infection when used by diapered infants and developmentally delayed individuals.[76] A less common mode of transmission is through ingestion of contaminated food, in which only 10 cysts may be required to establish infection.[66,79]

PATHOGENESIS

Humans are infected by the oral ingestion of 10 to 25 cysts.[79] Excystation occurs in the stomach and small intestine, and the trophozoites are found in large numbers in the upper part of the small intestine, where they closely apply their sucking disks to the mucosa (Fig. 224–1). They may penetrate into the secretory tubules of the mucosa and sometimes are found in the gallbladder

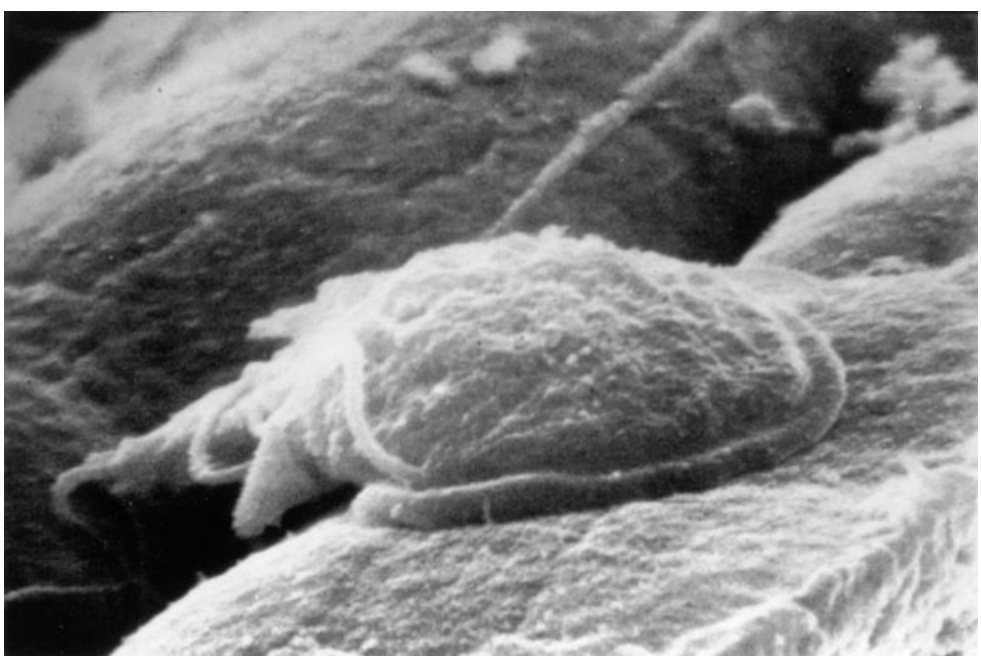

Figure 224–1 Trophozoite of *Giardia lamblia* adhering to the intestinal surface.

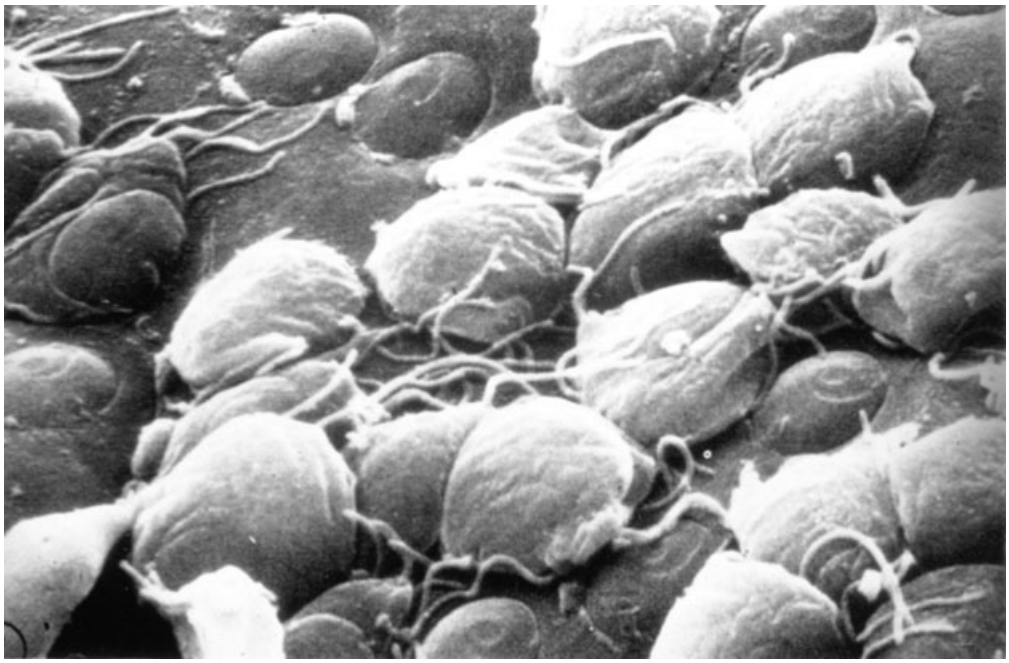

Figure 224–2 Scanning electron micrograph of trophozoites of *Giardia lamblia* from an intestinal biopsy specimen. Note the indentations left on the mucosal surface by the parasite's sucking disk.

and in the biliary drainage. Scanning electron micrographs of the intestinal mucosa (Fig. 224–2) show the mechanical damage caused by the presence of the organisms on the mucosal surface.

The histologic changes seen in the tissues do not always correlate with the presence or absence of symptoms. Biopsy specimens of the small intestine in children and adults show normal histology despite the presence of diarrhea and other symptoms.[82] Flattening of the brush border, damage to mucosal epithelial cells, and slight flattening of the villi with increased mitotic index, increased goblet cells, alteration of bile content or duodenal flora, and infiltration with inflammatory cells also may be present.[19,71,80,102] Studies have shown that *Giardia* disrupts tight junctional zona occludens, increases permeability, and induces apoptosis in small intestinal epithelial cells. Disruption of the intestinal epithelial cell brush border may explain the lactose intolerance that commonly develops.[11,15] In vivo and in vitro studies have established that *Giardia* causes malabsorption of glucose, sodium, and water, and reduces disaccharidase activity owing to loss of epithelial absorptive surface area.[10] Disruption of digestion by bile and proteases may produce malabsorption, diarrhea, and resulting malnutrition.

The causes of symptoms are not well understood. Hypotheses include (1) the parasite as a physical barrier to absorption, (2) disruption of the brush border with loss of enzymatic activity, (3) elaboration of toxins by the parasite, (4) changes in fat absorption in the small intestine, and (5) activation of cytokines after damage to enterocytes.

Host immunity, including the humoral and the cellular components, is important in the clearance and protection against reinfection with *Giardia*. Persistence of infection in nude mice suggests a role for T-cell activity.[81,89] Humans produce serum IgG, IgM, IgA, and IgE in response to infection.[31,34,74,87,97] Studies have shown that IgM and IgG antibody with complement is lethal to *Giardia* trophozoites. In the intestinal lumen, the secretory IgA response seems to play a role in the modulation of infection, as does the migration of infiltrating lymphocytes in the intestinal mucosa. The absence of secretory IgA is associated with the inability to clear *Giardia* infection and is associated with the development of chronic giardiasis in humans.[14] In a study of human volunteers, 84 percent of volunteers self-cured in 18.4 days, whereas the remainder became chronically infected.[79] Human milk has been shown to kill the trophozoites of *G. lamblia* by generating toxic lipolytic products.[30,31,78]

Infection may be severe and difficult to eradicate in immunodeficient individuals with antibody deficiencies (e.g., common variable immunodeficiency, X-linked agammaglobulinemia) or in patients with reduced gastric acidity. Giardiasis long has been associated with hypogammaglobulinemia, nodular lymphoid hyperplasia of the small intestine, and chronic diarrhea.[41] Patients with hypogammaglobulinemia, absence of plasma cells in the intestinal lamina propria, cystic fibrosis, protein-calorie malnutrition, and human immunodeficiency virus (or acquired immunodeficiency syndrome), and patients who are receiving immunosuppressive therapy are more likely to develop chronic giardiasis than individuals with X-linked hypogammaglobulinemia, selective IgA deficiency, and Wiskott-Aldrich or Nezelof syndrome.[47,72,86]

CLINICAL MANIFESTATIONS

Infection with *Giardia* organisms can result in asymptomatic infection (5 to 15%), an acute self-limited diarrheal illness (25 to 50%), or chronic diarrhea and malabsorption depending on host susceptibility and pathogen genotype virulence.[38,45] The incubation period for giardiasis is 7 to 14 days. Symptoms vary from mild abdominal discomfort and diarrhea to severe cramping; bloating; and severe, explosive, watery, greasy, foul-smelling diarrhea (Table 224–1).[43] Patients and caregivers describe a constellation of signs and symptoms, including abdominal bloating, flatulence, and frequent foul-smelling diarrhea. Young infants may exhibit anorexia, weight loss, or a malabsorption syndrome that resembles sprue. Symptoms usually last more than 7 to 10 days and in most cases clear spontaneously. Patterns of stools vary from normal to mushy, foul-smelling diarrhea (Table 224–2). Gross blood, pus, and mucus usually are not present in the stool, and signs of inflammatory diarrhea, such as tenesmus and bloody diarrhea, do not occur. A few patients develop persistent, chronic infection that is associated with severe malaise, headache, weight

TABLE 224–1 Symptoms in Patients with Giardiasis

Symptom	Frequency (%)
Diarrhea	89
Malaise	84
Nausea	58-68
Foul-smelling stool	57-72
Flatulence	56-74
Abdominal cramps	55-80
Bloating	55-69
Weight loss	48-64
Anorexia	40-64
Abdominal distention	31
Belching	30
Fever	17-28

Stool Characteristic	Frequency (%)
Mushy	52
Formed	33
Watery	12
Mucus	3
Bloody	0

loss, and diffuse abdominal and epigastric discomfort that is exacerbated by eating.

Episodes of diarrhea typically alternate with periods of normal bowel movements and may persist for months. Lactose intolerance may develop in 20 to 40 percent of cases and persist for weeks after the infection has been eradicated.[86,100] Children with symptomatic giardiasis may develop steatorrhea and malabsorption of vitamin A, vitamin B_{12}, protein, D-xylose, and iron.[33,88] Anecdotal reports have attributed various other symptoms, including rash, urticaria, arthralgia, reactive arthritis, constipation, biliary tract disease, and gastric infection, to giardiasis, but no firm evidence supports *G. lamblia* as the cause of these symptoms.

Individuals passing cysts may be asymptomatic and may serve as a reservoir of infection for others. This fact is particularly important for outbreaks among food handlers and in daycare centers. Severe prolonged illness that requires hospitalization is found in 2 per 100,000 cases, which is similar to that for shigellosis.[56] Young children and pregnant women usually are admitted to the hospital because of volume depletion and failure to thrive.[88]

Parasitic infection, including giardiasis, should be considered in the evaluation of a child who fails to thrive and in immunocompromised infants and children who have diarrhea or gastrointestinal complaints. It also should be considered in the differential diagnosis of any child who is in a daycare center or who has traveled outside of the United States and has gastrointestinal symptoms.[39,70]

DIAGNOSIS

Obtaining a thorough travel and potential exposure history is important in establishing the diagnosis of giardiasis. Recent travel to the wilderness or a national park and travel to developing areas or other endemic areas of the world where fecal-oral hygiene is a problem are important parts of the history in any patient with persistent diarrhea. Demonstration of trophozoites or cysts in the stool on ova and parasite examination is the traditional standard for establishing the diagnosis.[65] Examination of preserved fecal specimens reveals cysts or trophozoites in most infections. Organisms are excreted in a highly variable pattern; multiple samples taken on different days are required for detection.[18] A single stool sample misses 20 to 40 percent of the infections, whereas three stool samples miss less than 10 percent of infections.[42]

Commercially available tests to detect antigen by enzyme-linked immunosorbent assay (ELISA) have been shown to be rapid and highly sensitive and specific, but are qualitative and are unable to distinguish between genotypes or detect low levels of infection.[49,98] ELISA may be particularly useful in screening mass outbreaks and assessing cure. Monoclonal antibodies usually are employed to detect antigen either by ELISA or by immunofluorescence assay. Some of these assays have a sensitivity of 91 to 95 percent and specificities of greater than 98 percent.[22,62,98] Antigen may be detected best when the stool is preserved in formalin.[22] These tests do not replace microscopic examination of the stool, which is considered to be the standard, because of the possibility of infection with multiple organisms in travelers.

Molecular techniques such as polymerase chain reaction (PCR) are alternative methods that may be used for the specific detection of *Giardia* organisms in the stool. PCR in combination with restriction fragment length polymorphism or nested PCR may be used to genotype the organisms. The sensitivity of detection by PCR is greater than that of microscopy and is much better for detection of low numbers of parasites in stool samples.[7] The use of real-time PCR is a more recent advancement in PCR-based technology for the detection of *G. lamblia* in stool. This method, using dual-labeled fluorescent probes targeting the β-giardin gene, is sensitive and rapid and may be used to detect *G. lamblia* in stool and to differentiate the major genotypes of the organism. It can be adapted to high-throughput detection to screen large numbers of samples, especially in outbreak situations.[12,36]

Even with the available diagnostic tests, infections may be missed in some patients, and in cases with a high index of suspicion, the organism may be recovered by duodenal biopsy or duodenal aspiration. Invasive techniques may be an important diagnostic adjunct in immunosuppressed individuals and in patients with sprue, for whom histology of the bowel also may be important in planning therapy.

TREATMENT

All patients with either cysts or trophozoites in the stool should be treated. Multiple classes of drugs are available for the treatment of giardiasis, each with different clinical properties and efficacies (Table 224–3).[5,27,101] The nitroimidazole class of agents includes metronidazole, tinidazole, ornidazole, and secnidazole and is the mainstay of treatment for giardiasis. These drugs are administered orally in their inactive probiotic form.[27]

Of the nitroimidazoles, metronidazole has been the one most extensively studied and widely used worldwide. The mechanism of killing of *Giardia* organisms by the nitroimidazoles involves the use of the anaerobic metabolic pathways of the organism. The drug diffuses into the trophozoite, where it is activated and inhibits trophozoite respiration and causes cellular damage by the production of toxic radicals and loss of DNA helical structure resulting in trophozoite death.[32,94]

Of the nitroimidazoles, tinidazole and metronidazole have shown the greatest in vitro activity.[17,35] Metronidazole is considered the drug of choice for treatment, with tinidazole being an alternative.[25,27] Although albendazole has been shown to be curative in single doses or a 5-day course, it is not approved for use in giardiasis in the United States.[37,105] Quinacrine, which is inexpensive and has excellent efficacy, also is no longer available in the United States.[27] It may cause hemolysis in children with

TABLE 224–3 Drugs for the Treatment of Giardiasis

Drug	Dosage	Efficacy (%)	Side Effects
Metronidazole	15 mg/kg/day PO divided tid × 5-10 days (maximum 750 mg/day)	80-100	Metallic taste, headache, nausea, vomiting, rash, peripheral neuropathy, neutropenia, disulfiram-like effects
Tinidazole	50 mg/kg, single dose (maximum 2 g)	80-96	Metallic taste, nausea, vomiting, headache, rash, peripheral neuropathy, neutropenia, disulfiram-like effects
Ornidazole*	40-50 mg/kg, single dose (maximum 2 g)	96-100	Metallic taste, nausea, vomiting, headache, rash, peripheral neuropathy, neutropenia, disulfiram-like effects
Secnidazole	30 mg/kg, single dose (maximum 2 g)	90	Nausea, anorexia, abdominal pain
Albendazole†	15 mg/kg/day × 5-7 days (maximum 400 mg)	94-100	Anorexia, constipation, neutropenia, elevated liver function tests
Furazolidone	6-8 mg/kg/day PO divided qid × 1-10 days	81-96	Allergic reactions, headache, nausea, vomiting, diarrhea, brown discoloration of urine, hemolysis, disulfiram-like effects
Paromomycin	30 mg/kg/day divided tid × 5-10 days (maximum 2 g/day)	55-88	Nausea, vomiting, ototoxicity, nephrotoxicity
Quinacrine*	6 mg/kg/day divided tid × 7 days	92-95	Nausea, vomiting, dizziness, headache, yellow/orange skin and mucous membrane discoloration, hemolysis, toxic psychosis
Nitazoxanide	1-3 years old—200 mg/day divided bid × 3 days 4-11 years old—400 mg/day divided bid × 3 days ≥12 years old—1000 mg/day divided bid × 3 days	85-90	Nausea, abdominal pain, diarrhea, anorexia, flatulence, headache, yellow eyes, discolored urine, increased creatinine and serum alanine aminotransferase

**No longer produced in the United States; can be obtained from Panorama Pharmacy, Panorama City, CA.*
†Not approved by the Food and Drug Administration for this indication in the United States.

glucose-6-phosphate dehydrogenase deficiency. Furazolidone is an effective alternative and is available in a liquid form. Furazolidone is administered four times a day for 7 to 10 days and is associated with side effects including rash, nausea, and vomiting. Tinidazole has been shown to eliminate the parasite after single-dose therapy.[25] Secnidazole, another member of the 5-nitromidazoles, has been shown to be well tolerated at a dose of 30 mg/kg/day (maximum 2 g) and is an option for therapy.[32] Paromomycin, an aminoglycoside that is not well absorbed, is the only drug that can be used in pregnancy. It is not as effective as other medications in eradicating the parasite, but may induce clinical improvement.

A 3-day course of a new drug licensed by the U.S. Food and Drug Administration, nitazoxanide (Alinia), has been shown to treat successfully 85 percent of children with diarrhea caused by *Giardia*.[23,83] Although outbreaks of *Giardia* in daycare centers are common, treating all children in the daycare center is not efficacious because recurrence rates are high, and a chance of a drug reaction always exists. Treatment is reserved for symptomatic children.

Treatment failures and the development of drug resistance have been reported with all of the common agents used to treat *Giardia*, including albendazole, furazolidone, metronidazole, and quinacrine.[5] The prevalence of clinical metronidazole-resistant cases is reported to be 20 percent[9,21,90,93,96] with recurrence rates reaching 90 percent.[104] Metronidazole-resistant *Giardia* strains also have manifested cross-resistance to tinidazole.[90,93,96] Furazolidone-resistant *Giardia* spp. can be induced in vitro and in vivo, and this may induce the organism to become resistant more easily to quinacrine.[63,91,95] *Giardia* resistant to albendazole has been reported to develop rapidly in vitro. Albendazole resistance also develops more easily in *Giardia* strains that are furazolidone-resistant, giving rise to multidrug-resistant phenotypes.[57,92]

Patients with clinically resistant strains have been treated with longer repeat courses or higher doses of the initial agent[28,68]; however, the most effective means of eradicating these infections seems to be the use of an anti-*Giardia* agent from a different class to avoid potential cross-resistance.[16,29] For *Giardia* strains that are phenotypically considered to be multidrug-resistant, administration of anti-*Giardia* drugs in combination may be used for the successful treatment of the infection.

CHAPTER 225

DIENTAMOEBA FRAGILIS INFECTIONS

Lisa M. Frenkel

Dientamoeba fragilis is a protozoan that may inhabit the human gastrointestinal tract. In 1918, *D. fragilis* was recognized as a distinct species by Jepps and Dobell, who considered it to be a rare intestinal commensal.[36] In unpreserved feces, the morphologic characteristics of *D. fragilis* do not persist, which most likely accounts for its perceived rarity in some surveys. Careful studies using preserved and stained fecal specimens have found an association between *D. fragilis* infection and acute and chronic gastrointestinal symptoms, which has led to its recognition as a pathogenic protozoan.

ORGANISM

D. fragilis, in contrast to most other intestinal protozoa, has no known cyst form. The trophozoite was classified initially in the genus *Entamoeba*. The similarity of *D. fragilis* to flagellates, however, specifically to *Histomonas meleagridis*, the cause of "blackhead" enterohepatitis in fowl, was noted on careful examination under the light microscope.[18] *H. meleagridis* is a flagellate when it is found in the cecum of fowl; however, its flagella are lost when it invades tissues.[18] *D. fragilis* in the binucleate form resembles the tissue form of *Histomonas*.[18] *D. fragilis* has not been found to invade tissues, however. Antigenic and ultrastructural relatedness to *Histomonas* has been based on fluorescent antibody,[12] electron microscopic,[19] and molecular[19] studies.[15,27,65] *D. fragilis* was reclassified in 1974 by Honigberg as a nonflagellate trichomonad of the order Trichomonadida, family Monocercomonadidae, subfamily Dientamoebinae, and genus *Dientamoeba*.[8,21] Genetic studies confirmed recent evolution with trichomonads,[15,27,65] with two genotypes detected in DNA encoding ribosomal RNA.[38] Genotype 1 seems to predominate in epidemiologic studies.[13,38,54,69,79]

D. fragilis infects the mucosal crypts of the large intestine in close proximity to mucosal epithelium from the cecum to the rectum. The organism ranges in size from 3 to 18 μm in diameter, but it usually is 7 to 12 μm. The pseudopodia of *D. fragilis* have a delicate, leaflike appearance and serrated margins.[35] This protozoan is seen to move actively in fresh feces, but quickly becomes rounded after standing. *D. fragilis* is easy to isolate and grow in vitro in media containing solid rice-starch.[18] Cultures should be maintained at 37° C to 38° C (98.6° F to 100.4° F) because the organism rounds up and stops moving and feeding at lower temperatures. *D. fragilis* thrives in temperatures up to 41° C (105.8° F). This organism feeds on bacteria and starch grains and ingests human red blood cells.

D. fragilis reproduces by binary fission.[18] Although the organisms are found most commonly in the binucleate form, approximately 20 percent are in the uninucleate form, and a few are multinucleate.[35,36,41,78,83] Each nucleus contains a large, fragmented (four to eight granules) karyosome surrounded by a clear zone with no peripheral chromatin and a fine nuclear membrane.[36,82] Occasionally, aberrant forms may be found that usually are uninucleate and may be 20 μm. They do not reproduce. Humans seem to be the natural host of *D. fragilis*. *D. fragilis* infection has been reported in two simian species.[18] Multiple attempts to infect other animals have been unsuccessful so far. The atypical morphologic and biologic characteristics of the organism and the absence of an animal model have impeded classification and defining the epidemiology and pathogenicity of *D. fragilis*.[37]

EPIDEMIOLOGY AND TRANSMISSION

D. fragilis was thought to be uncommon until improved techniques for preserving the organism were used.[25,30,63] The tropho-

zoites of *D. fragilis* have been noted to be quite sensitive to an aerobic environment.[12] They die and disintegrate within 1 hour in an isotonic salt solution at room temperature; when smeared on slides, they round up and become granular within 15 minutes during microscopic examination at room temperature and low humidity.[12]

D. fragilis has been reported worldwide with a prevalence in selected populations of 1.4 to 38 percent.* Higher prevalence rates of 19 to 69 percent have been reported in crowded living situations, such as institutions and communal groups[5,45,47,48,75] and in individuals traveling outside the United States.[42,59,68,71] A serologic survey in Canada using indirect immunofluorescence techniques detected antibodies to *D. fragilis* in 87 to 100 percent of healthy children 1 to 19 years old,[10] suggesting that infection occurs in most individuals during childhood. Although the antibodies detected in this survey did not absorb when incubated with *Klebsiella pneumoniae* or *Bacteroides vulgatus*, known to contaminate the antigen source of *D. fragilis*, additional studies are needed to confirm the specificity of the assay and to define the seroprevalence in other populations.

The mode of transmission of *D. fragilis* is unknown; however, two mechanisms have been postulated. One hypothesis is that *D. fragilis* is transmitted in the eggs of *Enterobius vermicularis* (pinworm) in a manner similar to the transmission of *H. meleagridis* in the eggs of the avian nematode *Heterakis gallinae*.[6,18,76,81] In support of this theory, many investigators have noted a high frequency of concomitant infection with *D. fragilis* and *E. vermicularis*.[6,18,31,76] Ockert[51] provided the most convincing support for this theory when, by ingesting eggs of *E. vermicularis*, which he had washed with water and exposed to pepsin and hydrochloric acid, he became infected with *E. vermicularis* and *D. fragilis*. Other investigators, noting a high rate of concomitant infection of *D. fragilis* with organisms causing intestinal infections[44,45,48,81] and negative tests for *E. vermicularis*,[14,69] suggest fecal-oral transmission.

CLINICAL MANIFESTATIONS

Gastrointestinal and, less frequently, systemic symptoms have been reported to occur in association with *D. fragilis* in the fecal specimens of children and adults.† Symptomatic infections occur in 15 to 85 percent of infected individuals.‡ Acute watery diarrhea and a chronic recurrent abdominal pain syndrome have been associated with *D. fragilis* in children and adults.§

Individuals with acute diarrhea also have reported abdominal pain, anorexia, nausea, and vomiting, and, less frequently, fever, weight loss, headache, malaise, fatigue, irritability, and weakness.¶ The stools have been described as greenish brown, mushy or sticky, with a foul odor, and sometimes bloody and with mucus.[39,40] Abdominal tenderness has been found commonly on physical examination[14,39,67] and may mimic appendicitis.[64,76]

When symptomatic, *D. fragilis* infection is associated most frequently with chronic abdominal pain,[14,46,66,67] which may persist for months to years.[32,83] The pain is described commonly as dull, achy, crampy, or colicky, and usually is located in the lower abdominal quadrants.[63,67,83] Complaints of flatulence, fatigue, and alternating diarrhea and constipation are common in individuals with *D. fragilis* infections.[36,67] Laboratory and radiologic studies usually are normal. Eosinophilia, not usually seen with protozoal infections, has been reported in infected children and adults, most commonly in association with chronic symptoms.[14,66,67,72] Eosinophilia has not been observed by others, however.[39] The high prevalence of *D. fragilis* in fecal surveys generally without symptoms and the nonprogressive nature of symptomatic infections should steer clinicians to look for alternative diagnoses in seriously ill children.

DIAGNOSIS

Infection with *D. fragilis* should be considered when abdominal pain or diarrhea or both persist beyond 1 week, particularly if the child lives in an institution, has lived or traveled to a location where sanitary practices are poor, or is infected with pinworms. Investigation for *D. fragilis* infection should include the collection of at least three stool specimens that are immediately placed in a stool preservative such as polyvinyl alcohol stool preservative to retain the morphologic characteristics of the delicate trophozoite.[63] Diagnosis also can be made by permanent stained smear of a fresh or purged fecal specimen.[6,30,78] Detection of the organism seems not to be compromised by use of "environmentally friendly" mercury-free stool preservative and stain (EcoFix and EcoStain, Meridian Diagnostics, Inc., Cincinnati, Ohio).[26]

Three fecal specimens properly collected and stained leads to the identification of this intestinal protozoan in 70 to 93 percent of infected individuals.[34,62] Stool specimens should be collected on alternate days because excretion of *D. fragilis* seems to manifest a cyclic pattern.[16] Stool samples should be collected before radiologic studies with barium are done because barium interferes with detection of the protozoa.[24] Other medications interfering with parasite identification include antibiotics, mineral oil, antimalarials, antiprotozoan agents, nonabsorbable diarrheal preparations, and bismuth.[24] These substances may interfere with the detection of parasites for 3 weeks.[24]

After arrival in the laboratory, stool specimens are processed with the use of a formalin-ether sedimentation concentration technique and stained with either iron hematoxylin or trichrome and examined by qualified and experienced individuals for the proper identification of *D. fragilis*.[22,26] Garcia and associates[24,25] reported 92.2 percent of *D. fragilis* trophozoites were determined solely on the basis of the trichrome-stained smear, and subsequent studies indicate a comparable sensitivity with the use of Ecostain.[26] Diagnostic characteristics of *D. fragilis* on a permanently stained smear include a high percentage of binucleate trophozoites and nuclei without peripheral chromatin, but with four to eight chromatin granules in a central mass.[21] Detection of *D. fragilis* by indirect immunofluorescence[11] or by culture[61,85] seems promising in limited investigations. Assays using polymerase chain reaction that are sensitive and specific for detection of *D. fragilis* have been described.[54,70] One serologic test has been developed; however, the high seroprevalence of *D. fragilis* precludes its use as a diagnostic tool.[10]

TREATMENT

Several different agents have been used in the treatment of *D. fragilis* infection. Presently, one of four drugs is recommended for the treatment of *D. fragilis* infection: iodoquinol, tetracycline, paromomycin, or metronidazole.[2,11,43,67,80] However, owing to a paucity of clinical studies, tetracycline and paromomycin are considered investigational by the U.S. Food and Drug Administration.[1,2] Among newer agents, secnidazole[28] and ornidazole[90] seem effective in limited studies, and tinidazole is active in vitro.[23]

Iodoquinol, 650 mg three times a day for 20 days, is recommended for adults and 40 mg/kg/day divided three times a day

*See references 3-5, 9, 12, 13, 20, 42, 44-46, 49, 53, 55, 58, 60, 73-75, 78, 79, 81, 84, 88.
†See references 7, 11, 13, 14, 17, 29, 31-36, 39, 40, 47, 48, 52, 53, 56, 57, 59, 67-69, 74, 77-79, 83, 86, 89.
‡See references 39, 43, 44, 47, 53, 59, 66-68, 86, 88.
§See references 13, 14, 17, 30-36, 45, 46, 48, 50, 52, 53, 55, 56, 61-64, 66, 69, 73, 74, 83.
¶See references 14, 16, 17, 32, 39, 40, 56, 64, 66, 67, 83, 89.

for children. The tablets should be taken with meals. Side effects include abdominal discomfort, diarrhea, anal irritation and pruritus, headache, and dysesthesias of the hands and feet. Paromomycin in a dosage of 500 mg three times a day for adults and 25 to 35 mg/kg/day in three divided doses in children for 7 days may be more effective than iodoquinol.[87] Adverse reactions to paromomycin include nausea, abdominal cramps, and diarrhea. It is absorbed poorly after oral administration and is no longer available in syrup form in the United States.

Recrudescence or relapse has been reported after one or more 7-day courses of paromomycin in a few treated children.[80] Alternative therapy is tetracycline hydrochloride or metronidazole. Tetracycline is recommended at a dosage of 500 mg four times a day for adults and 40 mg/kg/day in four divided doses for children for 10 days. Tetracycline may cause gastrointestinal and central nervous system symptoms. It should not be given to children younger than 9 years old because it may cause discoloration of the teeth. Metronidazole treatment is recommended at a dosage of 500 to 750 mg three times daily for 10 days for adults and 20 to 40 mg/kg/day divided into three doses for children. Treatment with metronidazole may cause gastrointestinal and central nervous system symptoms. Because of the adverse reactions associated with these drugs, the clinician should evaluate carefully the need for therapy in each case and discuss treatment options with the child's family.

CHAPTER 226

TRICHOMONAS INFECTIONS

Joan S. Purcell ❁ Mariam R. Chacko

Trichomonas spp. are found in animals and humans. The most widely studied member of this species is *Trichomonas vaginalis* because it is the trichomonad most relevant to human disease. Donne first described *T. vaginalis* in 1836 as motile microorganisms in the purulent frothy leukorrhea of women with vaginal discharge and genital irritation.[17] Epidemiologic information concerning *Trichomonas* infection is most detailed in the adult population; nonetheless, studies that document the epidemiology of *T. vaginalis* in children and adolescents are available.*

BACTERIOLOGY

Trichomonads are acellular flagellated protozoans. The Trichomonadidae family is characterized as mononucleate with an axial organelle that has an undulating membrane.[73] The *Trichomonas* genus includes protozoans that have organelles with three to four anterior flagella and an undulating membrane composed of the posterior flagellum.[73] Five *Trichomonas* spp. infect humans, and three *Trichomonas* spp. infect animals. In humans, the five species of *Trichomonas* include *T. tenax*, *T. ardin delteili*, *T. faecalis*, *T. hominis*, and *T. vaginalis*.[73]

T. vaginalis is the most clinically relevant human trichomonad; the other four species are nonpathogenic. *T. vaginalis* consists of four anterior flagella and a posterior flagellum incorporated into the undulating membrane. *T. vaginalis* can survive but cannot multiply at room temperature. In contrast, *T. hominis* has five anterior flagella and a trailing posterior flagellum, and can survive and multiply at room temperature. Only *T. hominis* can survive in media without serum and in feces for 24 hours.[73]

PATHOGENESIS

Virulence factors associated with *T. vaginalis* infection have been defined and include adherence, contact-independent factors, hemolysis, and host macromolecule acquisition. Epithelial cell

*See references 9, 11, 18, 22-24, 27, 28, 36, 38, 39, 50, 58, 69.

adherence depends on an intact cytoskeleton and *Trichomonas* protein ligands and proteases, which are necessary to activate adherence molecules.[12,19] Cell contact-independent factors include pH variability and cell-detaching factor, which in vitro inhibit reorganization of cells infected with *T. vaginalis*. *T. vaginalis* produces lactic and acetic acid as by-products of glucose metabolism.[12] These acids lower the pH, which is cytotoxic to epithelial cells. Another metabolic by-product of *T. vaginalis* is cell-detaching factor, which has a cytopathic effect on epithelial cells and increases subepithelial vascularity, producing the clinical sign of "strawberry cervix."[12] The activity of cell-detaching factor is optimal at pH 5.0 or greater. Hemolysis is seen only in the presence of live trichomonads. Cysteine proteases seem to be important for hemolysis because introduction of their inhibitors in vitro eliminates hemolysis by *T. vaginalis*.[10,12,30]

The addition of metronidazole reduces levels of hemolysis by 50 percent.[12] The hemolytic activity of *T. vaginalis* is temperature-dependent, with maximal hemolysis at 37° C. Hemolysis is inhibited via separation of trichomonads from erythrocytes by a 3-μm filter, suggesting a contact-dependent mechanism.[12] As a parasite, *T. vaginalis* also depends on host macromolecules for nutrition, including plasma proteins and lactoferrin.

The host responds to *T. vaginalis* infection at the cellular level with polymorphonuclear cells and lymphocyte activity. *T. vaginalis* secretes proteases that are chemotactic to polymorphonuclear leukocytes, with resultant phagocytosis and killing of the trichomonad by oxidative mechanisms.[12] *T. vaginalis* secretions are mitogenic to lymphocytes; they enhance phagocytosis by polymorphonuclear cells and may suppress the host immune response if numerous suppressor lymphocytes are activated.

Clinically, *T. vaginalis* infection has gender differences. Women are largely symptomatic, whereas only a few men have symptoms with *T. vaginalis* infection, many of which undergo spontaneous cure. Estrogen levels in females directly correlate with infection at peak estradiol levels. In an early study of premenarcheal vaginitis in children 3 months to 9 years old, *T. vaginalis* infection accounted for only 2.8 to 4.4 percent of cases of vaginitis in unestrogenized vaginas compared with 50 percent of infections in fully estrogenized vaginas of patients nearing puberty.[20] In asymptomatic males infected with *T. vaginalis*, the prostate gland serves as a reservoir. Men may remain asymptomatic because of the concentration of zinc salts in prostatic fluid, which is cytocidal for trichomonads.[34] In vitro, testosterone decreases the growth of *T. vaginalis* as well.[19] In symptomatic males, *T. vaginalis* may be isolated in specimens from urine, urethral discharge, and semen.[29]

In the host, trichomonads may serve as a vector for bacteria and viruses, as shown by the high co-infection rate with *T. vaginalis* and human papillomavirus. Although bacteria contaminate trichomonads externally, trichomonads are thought to ingest virus-infected cells and destroy them, with the active virus left intact.[22] *T. vaginalis* has been implicated in pelvic inflammatory disease via ascension from the vagina to the fallopian tubes. In vitro studies have shown *Escherichia coli* strains, a part of the normal vaginal flora, intimately attached to trichomonads by glycoprotein strands.[30] Trichomonads contaminated with bacteria serve as a vector for the bacteria to produce pelvic infection on reaching the uterus, fallopian tubes, or peritoneum.[30] Likewise, a more recent study involving Dutch women attending a sexually transmitted infection treatment clinic found that 71 percent of the women infected with *T. vaginalis* were co-infected with *Mycoplasma hominis*. Because of the small sample size, however, whether infection with *T. vaginalis* predisposes females to infection with *M. hominis*, or whether this co-infection reflects the sexual behavior of the individual, remains unclear.[6]

In contrast, vaginal colonization with *Lactobacillus* spp. was thought to inhibit trichomonal invasion by lowering vaginal pH. In a study of 336 African women 15 to 49 years old, 199 of whom were pregnant, 31 percent were culture-positive for *T. vaginalis*, whereas only 40 percent of the patients tested positive for *Lactobacillus*. Although the rate of *Lactobacillus* colonization in these African women was low, the high rate of *T. vaginalis* infection was not related to the absence of *Lactobacillus*. Trichomonads may not alter the vaginal flora substantially.[45] In women infected with *T. vaginalis* in the lower genital tract, however, the aggressive inflammatory response with resultant punctate hemorrhages allows transmission and infection with human immunodeficiency virus (HIV)-1.[63]

A spectrum of severity of disease exists in patients infected with *T. vaginalis*. Some patients are asymptomatic, whereas others experience severe symptomatic inflammation and discomfort. The virulence of *T. vaginalis* isolates varies; whether this variance is caused by the host response or inherent properties of the parasite is unknown. The Golgi apparatus in *T. vaginalis* is a prominent structure and seems to be a key station in the production of adhesins.[7] Evidence indicates, however, that the dramatic heterogeneity that exists on the surface of the parasite leads to antigenic diversity among different isolates of *T. vaginalis*. In one study, prominent immunogens absent on the surface of *T. vaginalis* isolates led to an enhanced ability of the parasite to cause cytoadherence-dependent killing of HeLa cells in monolayer culture. In addition, only the adherent parasites possessed adhesins, which directly affected cytoadherence and cytotoxicity of the parasites.[11] The cysteine proteases of *T. vaginalis* may be responsible for the cytoadherence, nutrient acquisition, and cytotoxicity of *T. vaginalis*. These proteinases are shed during the life cycle and growth of *T. vaginalis*. One hundred percent of sera from women infected with *T. vaginalis*, but none from normal uninfected women, possessed IgG to numerous trichomonad cysteine proteinases. This serum antiproteinase antibody disappeared after the women received effective therapy for the infection.[3]

IMMUNOLOGY

The interaction between *T. vaginalis* and host immunoglobulins is unclear. In women infected with *T. vaginalis*, specific local antibodies, IgG and IgA, are seen in vaginal secretions. IgA may serve to increase opsonization of the parasite by IgG and result in enhanced phagocytosis. IgG specific for *Trichomonas* cysteine proteases and surface proteins is seen, but it does not help rid the host of infection.[3] *T. vaginalis* synthesizes high-molecular-weight proteins with variable surface expression.[2] Of samples obtained from women infected with *T. vaginalis*, 70 percent of vaginal washes and 80 percent of vaginal mucus samples had IgG to a specific *T. vaginalis* surface protein immunogen with a molecular mass of 230,000 d (P230). In contrast, no antibody to P230 was detected in uninfected women or in detergent extract depleted of P230, suggesting a highly specific antibody.[2] Clinically, this finding may account for the lack of resistance to repeated *Trichomonas* infections and variable host antibody titers in infected individuals.

EPIDEMIOLOGY

As noted previously, five species of *Trichomonas* have been identified in humans; the most clinically important one is *T. vaginalis*. *T. vaginalis* is not part of the normal flora, but is found in the human vagina, urethra, and prostate. Inoculation experiments with *T. vaginalis* in the mouth and intestines failed to establish infection in these sites.[73] *T. tenax* is found in the mouth, whereas *T. hominis*, *T. ardin delteili*, and *T. faecalis* are found in the bowel. *T. tenax* is detected in approximately 5 percent of patients with *T. vaginalis*.[73] *T. tenax*, *T. ardin delteili*, and *T. faecalis* are part of the normal flora and are nonpathogenic.[73] *T. hominis* can infect

humans and is associated with gastrointestinal dysentery.[73] The incidence of *T. hominis* in humans is 0.4 to 3.5 percent. *T. hominis* is found only rarely in the stools of patients who concomitantly have *T. vaginalis*.[73]

T. vaginalis infection may be the most commonly encountered sexually transmitted disease. A vast amount of international prevalence data on *T. vaginalis* sexually transmitted infections stems from research done in clinics and populations in Africa.[4,13] The prevalence of *T. vaginalis* urogenital infection varies from 5 to 65 percent in different studies conducted predominantly in adults. Many of the studies of urogenital trichomoniasis are biased because of lack of random sampling, variance in the sensitivity and specificity of the diagnostic tests used, and sample selection, often from sexually transmitted disease clinics.[43] One of the reasons for the high prevalence of *T. vaginalis* infection is its rate of asymptomatic carriage; reliance on clinical symptoms alone would cause a practitioner to miss 80 percent of infections.[48]

Trichomonal infection is found in all age groups, from neonates to adults. It has been detected in newborns and infants, presumably from contamination on passage through an infected birth canal.[58] Most of the cases reported have involved premature infant girls. Vertical transmission of the organism occurs as the infant passes through the infected maternal birth canal.

T. vaginalis is seen most commonly in postmenarcheal sexually active adolescent girls and women; however, *T. vaginalis* vaginitis is noted occasionally in children.[22] *T. vaginalis* in a prepubertal girl or non–sexually active adolescent girl must raise suspicion of sexual abuse and prompt an evaluation for other sexually transmitted diseases.[18,50,73] In a study of 409 children suspected of having been sexually abused, *T. vaginalis* was diagnosed in 4 children, 10 to 12 years old, by wet-mount examination of vaginal secretions. This study may have underrepresented cases of *T. vaginalis* in patients suspected of having been sexually abused because a saline wet-mount preparation was available in only 18 of the 409 children.[72] One study of 54 premenarcheal girls (median age 5.8 years) with vulvovaginitis failed to identify *T. vaginalis*.[48,72] Lang and others[23,39] found *T. vaginalis* in 3.6 percent of 9- to 12-year-old girls. In adolescents, the prevalence of *T. vaginalis* is 5.5 to 34 percent.[18]

Trichomonal infections can be found in males and females, although the incidence is greater in females. The incidence of *T. vaginalis* infection is 10 to 25 percent in sexually active adolescent girls and women worldwide. Approximately 180 million women worldwide may be infected with *T. vaginalis*; prevalence data depend on the population studied. The prevalence of *T. vaginalis* is 5 to 74 percent in women, and 5 to 29 percent in men.[1,2] In men attending a sexually transmitted disease clinic, the prevalence of *T. vaginalis* was 22 percent in sexual contacts of women with trichomoniasis and 6 percent in homosexual men attending the same clinic.[32] *T. vaginalis* was found in 58 percent of 85 young black men 16 to 22 years old who were sexually active.[57] Sixty-nine percent previously had a sexually transmitted infection.

The rate of infection with *T. vaginalis* is increased in black women and in women with other sexually transmitted diseases. It also is increased in women who have gonococcal cervicitis with a vaginal pH shift greater than 4.5 and in women who are pregnant, and it may be increased around the time of menarche and after menopause.[16,47,73] Trichomoniasis apparently does not have a seasonal pattern of infection.[43] Urogenital trichomoniasis is seen more commonly in inner-city patients and patients in the 20- to 30-year-old age group.[43]

Infection with *T. vaginalis* increases in direct relation to number of sexual partners. An increased number of sexual partners also increases the risk of co-infection with other sexually transmitted organisms, including, but not limited to, *Chlamydia trachomatis*, *Neisseria gonorrhea*, *M. hominis*, and HIV.[3] Oral contraceptives diminish the rate of infection with *T. vaginalis* compared with an intrauterine device or tubal ligation.[43] The use of nonoxinol 9 spermicidal cream was not related significantly to a decrease in *Trichomonas* infection.[5]

In another study of 226 women attending a sexually transmitted disease clinic, trichomonal infection was noted in 44 percent of the patients.[47] No association was found among patient age, frequency of coitus, date of most recent coitus, day of menstrual cycle, antibiotic use, contraceptive methods, or symptoms of discharge or pruritus.[47] Other risk factors for women may involve a change in the normal vaginal flora, such as overgrowth of *Gardnerella vaginalis*, *Bacteroides*, or *Peptostreptococcus*. These bacteria may serve as sources of nutrients for trichomonads and allow them to thrive. In men, sexual contact with a woman infected with *T. vaginalis*, nongonococcal urethritis, or nongonococcal nonchlamydial urethritis was associated with an increased risk for acquiring infection with *T. vaginalis*.[35] In trichomoniasis, lactobacilli are absent from the vagina. This absence promotes alkalinity of the vaginal pH, enhancing the overgrowth of anaerobes and trichomonads.[65] Another study performed in Africa failed to show a significant role for *Lactobacillus* in patients with *T. vaginalis* infection.[15,45]

T. vaginalis usually is transmitted sexually in adolescents and adults. Large numbers of trichomonads are found in the prostatic secretions of husbands of women with recurrent *T. vaginalis* infection. In a clinic for patients with sexually transmitted diseases, 60 percent of husbands of women who had chronic, repeated *T. vaginitis* infection were culture-positive for *T. vaginalis*, in contrast to 8 percent in a control group of men attending the same clinic.[70] In a study from the United Kingdom of child and adolescent sexual assault victims, *T. vaginalis* was found in 1 of the 16 girls who were 12 years or younger.[28] These data support the concept of sexual transmission of *T. vaginalis*.

Nonsexual transmission of *T. vaginalis* has been reported. In rural India, a point prevalence survey of random samples from preadolescent and adolescent girls complaining of leukorrhea revealed that 76 percent were infected with *T. vaginalis*. Of the girls who were infected, 38 percent were younger than 12 years old. In this study, poor genital hygiene and underwear use were correlated with a higher incidence of infection. In addition, a significantly higher risk occurred in girls who washed or bathed in tanks or rivers versus girls who used pipe or well water. In the tropics, nonsexual transmission may account for infection with *T. vaginalis* in preadolescent and adolescent girls.[11] *T. vaginalis* can survive on toilet seats for 1 hour, on wet clothes for 3 hours, in fresh water for 30 minutes, in warm mineral water for 2 or 3 days, and in urine for hours. According to the literature, transmission of *Trichomonas* may occur via fomites (washcloths, towels), particularly when people are living together in crowded, confined spaces.[50]

CLINICAL MANIFESTATIONS

Trichomonas has been isolated from the tracheal aspirates in preterm neonates with respiratory failure and from nasal secretions in a full-term newborn with suppurative nasal discharge and respiratory distress.[55,67,68] The vagina of an infant may serve as a reservoir of infection that goes unnoticed until the infant is evaluated 5 to 6 weeks after birth for fever. Motile trichomonads and pyuria are seen on examination of the urine. Symptoms resolve after treatment with metronidazole.[58] Premenarcheal girls have diffuse bubbly leukorrhea and pruritus.[39] Vaginitis with a purulent foul-smelling discharge is the most common manifestation of infection with *T. vaginalis* in girls; in some patients, trichomonads may be found in the urine initially, with the development of frank signs of vaginitis 7 to 28 days later.[27]

Fifty percent of girls and women and 90 percent of boys and men infected with *T. vaginalis* are asymptomatic.[66] When one controls for co-infection with other organisms, *T. vaginalis* infection is associated significantly with purulent discharge, vulvar itching, colpitis macularis (strawberry cervix), and vaginal and vulvar erythema. The sensitivity of the other signs and symptoms of *Trichomonas* vaginitis, including vaginal burning, dysuria, urinary frequency, dyspareunia, frothy discharge, and cervical friability, is low.[72] Although frothy leukorrhea was associated most frequently with *Trichomonas* infection, 29 percent of the patients with frothy discharge in one study did not have *Trichomonas* infection.[72] Strawberry cervix was pathognomonic of *T. vaginalis* infection, but it was noted in only 2 to 3 percent of patients. One cannot depend on this finding to establish a clinical diagnosis of *T. vaginalis* vaginitis in most patients.[16] The diagnosis of *Trichomonas* infection should be considered in any girl or woman with a vaginal discharge.

Trichomonads may ascend the fallopian tubes and, if contaminated with bacteria, can produce the syndrome of pelvic inflammatory disease.[9,30] In HIV-infected girls and women, the risk of developing pelvic inflammatory disease increases significantly with *T. vaginalis* vaginitis.[49] Vaginal *Trichomonas* has been associated with adverse pregnancy outcomes, primarily premature rupture of membranes, preterm labor, and low-birth-weight infants.[31]

In boys and men, *T. vaginalis* may be manifested as symptomatic urethritis with dysuria secondary to urethral inflammation and discharge. On examination, the discharge often is not visualized. When a discharge is present, it is clear to cloudy, but not grossly purulent. On microscopy, numerous inflammatory cells are seen.[32,37] *T. vaginalis* also may be a cause of chronic nonbacterial prostatitis and may be manifested as chronic prostatitis resistant to standard therapy.[26,37] In addition, *T. vaginalis* has been reported to be an etiologic agent of epididymitis in men, with purulent urethral discharge, scrotal swelling, and enlargement of the epididymis.[16] Although rare, *T. vaginalis* has been reported to infect the median raphe of the penis.[64]

DIAGNOSIS

CLINICAL EXAMINATION

In girls and women, the presence of a frothy purulent discharge, vulvar/vaginal erythema, and a strawberry cervix should suggest *Trichomonas* infection. Boys and men tend to be asymptomatic or, if symptomatic, have a purulent urethral discharge and urethral inflammation. If the physician relies on clinical examination alone, 80 percent of infections may be missed.[17,65]

WET-MOUNT EXAMINATION

The diagnosis of trichomoniasis in women usually is made by wet-mount examination of vaginal secretions. Wet-mount preparations are obtained by swabbing the lateral and anterior vaginal fornices to obtain discharge material with vaginal epithelial cells; the secretions are placed in a tube with normal saline and mounted on a slide. These preparations are easy to prepare, and the method is cost-effective, but in women its sensitivity is only approximately 60 to 70 percent.[10] This method also may be used for urethral specimens in men, but it is insensitive. In addition, the validity of the result depends on the technical skill of the examiner and the rapidity with which the specimen is examined; cooling greatly affects the motility of trichomonads, which may hinder identification.[36] Wet-mount examinations are tests now regulated by Clinical Laboratory Improvement Amendments, which may be a barrier in performing them in office-based laboratories.

PAPANICOLAOU SMEAR

Conventional Papanicolaou smears can detect trichomonads and have the advantage of being fixed and read at a later time. This method is considered unreliable, however, for the diagnosis of trichomoniasis. *T. vaginalis* does not always appear in its typical pear-shaped morphology after fixation on the slide. Rather, it may appear to be more rounded, similar to a polymorphonuclear leukocyte. Cytopathologic diagnostic criteria for *Trichomonas* infection include the presence of perinuclear halos and a dirty granular background. These features are nonspecific, however, and a similar background and halos can be found with certain other conditions.

The sensitivity of Papanicolaou smears for diagnosing *Trichomonas* in culture-proven infection is 56 percent.[34] In a study of 1199 women, *T. vaginalis* infection would have been diagnosed falsely in 37 percent based on Papanicolaou smear results. In a second study, *T. vaginalis* infection would not have been diagnosed in 44 percent of patients with culture-proven infection because of negative Papanicolaou smear findings.[54] More recent data show the liquid-based Papanicolaou smears as being highly specific for the diagnosis of *T. vaginalis* and may warrant treatment without confirmation. Compared with culture, the liquid-based test has a low sensitivity of 61 percent. It has a specificity equal to culture (99%).[40]

STAINING TECHNIQUES

Acridine orange is a compound that differentially stains DNA (yellow-green) and RNA (bright red). *T. vaginalis* stains brick-red with an oval, yellow-green nucleus. The flagella do not stain. Unfixed smears are kept at room temperature for 24 hours; fixed slides may be kept 5 days. Acridine orange stains may permit a rapid, accurate diagnosis of *T. vaginalis* infection. The diagnosis can be confirmed by other diagnostic methods in 93 percent of cases.[46] Acridine orange staining seems to be at least as sensitive as wet-mount examination.[8,59]

CULTURE

Diagnosis of *T. vaginalis* by culture continues to be considered the gold standard. Although generally used in clinical research, this diagnostic method should be considered strongly when trichomoniasis is suggested, but cannot be confirmed by other easily available methods. Secretions are collected from the vagina or urethra with a cotton-tipped swab and placed directly on culture media. The reformulated media currently prepared commercially are Diamond, Kupferberg, and Lash media.[61] These media contain antibiotics to inhibit bacterial overgrowth and may contain yeast extract, horse or sheep serum, or both.[60] Cultures are incubated for 7 days, and a drop of sediment from the culture tube is placed on a slide, and a wet-mount examination is performed.

Culture of *T. vaginalis* on these media detected less than 10 trichomonads; cultures were not affected by douching in the previous 24 hours. In contrast, the sensitivity of wet-mount preparations decreased from 57 to 22 percent after douching.[17] Limitations of culture include the failure of culture media to support the growth of trichomonads in some cases by culture day 7. Growth in culture media also is inoculum-dependent; less sensitive media require higher inocula of trichomonads.[60] In men, the combination of prostatic massage before collection of the speci-

men and culture of urethral samples and urinary sediment has a sensitivity of 94 to 98 percent.[35,57]

The plastic envelope or pouch method is a simplified and now standard commercially available method of culture for *T. vaginalis*. The most common test is the InPouch (Biomed Diagnostics, San Jose, CA). Vaginal secretions are placed in a liquid medium contained in a pouch with the growth medium. The medium allows the organism to grow so that it can be visualized on direct microscopy for 5 days. Compared with wet-mount examination, the pouch method can increase *T. vaginalis* detection rates by twofold. The sensitivity and specificity of culture via the pouch method are 94 percent and 96 percent; sensitivity and specificity of vaginal wet-mount examination are 58 percent and 100 percent.[41,51]

DIRECT IMMUNOFLUORESCENCE AND ENZYME IMMUNOASSAYS

Direct immunofluorescence and enzyme immunoassays are more sensitive than the wet-mount preparation and give fairly rapid results. They are not readily available, however. The sensitivity of direct fluorescent antibody (DFA) staining approaches 86 percent compared with culture and is not related to the number of trichomonads seen on wet-mount examination. The sensitivity of DFA staining is superior to that of wet-mount examination or acridine orange staining in women who have *T. vaginalis* infection and is comparable to the sensitivity of these techniques in women infected with multiple organisms.[7,32,59] Interpretation of DFA staining may be accomplished in less than 1 hour.[32] In a study of high-risk men who underwent prostatic massage before collection of the specimen, DFA staining on urethral samples had a sensitivity of 63 percent.[57]

A monoclonal-based enzyme-linked immunosorbent assay was developed for use with a monoclonal antibody specific for a 65-kd surface polypeptide of *T. vaginalis*. Polyclonal rabbit anti–*T. vaginalis* antibody labeled with horseradish peroxidase was used as the probe. In a limited study of 36 women, this enzyme-linked immunosorbent assay had a sensitivity of 89 percent and a specificity of 97 percent.[42]

NUCLEIC ACID HYBRIDIZATION AND AMPLIFICATION TESTS

Rapid diagnostic tests such as DNA hybridization techniques are now available for clinical use with vaginal secretions. Two point-of-care tests have been approved by the U.S. Food and Drug Administration: OSOM Trichomonas Rapid Test (Genzyme Diagnostics, Cambridge, MA), an immunochromatographic capillary flow dipstick technology, and the Affirm VP III (Becton Dickinson, San Jose, CA), a nucleic acid probe test that evaluates for *T. vaginalis*, *G. vaginalis*, and *Candida albicans*. The results with these tests can be obtained in 10 minutes and 45 minutes. Although the sensitivity of both tests on vaginal secretions is greater than 83 percent, and the specificity is greater than 97 percent, false-positive tests might occur in low-prevalence populations[6] available for clinical use. Several primer sets have been described, and sensitivities using vaginal swabs have ranged from 8.5 to 100 percent.[10,25] In contrast, the sensitivity of using a urine specimen to detect trichomoniasis is 64 percent.[41]

No Food and Drug Administration–approved nucleic acid hybridization and amplification tests such as a polymerase chain reaction test for *T. vaginalis* are available in the United States. Research has shown that sensitivities using polymerase chain reaction vaginal swabs have ranged from 8.5 to 100 percent, in contrast to the 64 percent sensitivity of a urine specimen used to detect trichomonas.[41]

TREATMENT

T. vaginalis infection in girls and women should be treated to relieve symptoms, prevent further transmission of disease, and prevent chronic inflammation of the Bartholin and Skene glands.[69] In boys and men, chronic infection may lead to prostatitis or urethral stricture.[13] Adolescent boys and men who are asymptomatic may re-infect their partners. Male partners of women infected with *T. vaginalis* should be treated.[70]

Metronidazole or tinidazole are the treatments of choice for *T. vaginalis* infection and are available for treatment of trichomoniasis in the United States. Worldwide, other drugs used for trichomoniasis include nifuratel, nimorazole, secnidazole, and carnidazole. Despite the availability of these other drugs, metronidazole remains the standard therapy for trichomoniasis. Metronidazole enters the trichomonad via passive diffusion, and its nitro group is reduced to a cytotoxic intermediate that reacts with DNA and causes cell death. Metronidazole is 93 to 95 percent bioavailable, and after oral administration, peak serum levels are attained in 1 to 3 hours, and a steady state is attained in 2 to 3 days. Metronidazole is metabolized by the liver, with only 20 percent being protein-bound; the drug is distributed well in the body.[44]

Side effects reported with the use of metronidazole include nausea, vomiting, anorexia, a metallic taste, headache, dizziness, diarrhea, and darkening of the urine. Urticaria, reversible peripheral neuropathy, seizures, and ataxia have been reported with intravenous use. The side effects tend to be dose-related and self-limited.[44] In a study of 1199 women with *T. vaginalis* infection treated with metronidazole, only 4 to 5 percent experienced symptoms of nausea, coated tongue, dryness of the mouth, anorexia, or diarrhea. All symptoms disappeared within a few days of completion of treatment, and in only one case was treatment discontinued because of side effects. In addition, relative and absolute leukopenia was not observed in these subjects. Metronidazole enhances or reactivates the growth of *C. albicans* in the vagina.[54] Metronidazole may potentiate the actions of anticonvulsants and warfarin. Because a significant disulfiram-like effect is produced when the drug is combined with moderate intake of alcohol,[44] alcohol should be avoided during and for 48 hours after completion of a course of therapy with metronidazole.

In the United States, two treatment regimens are recommended for treatment of *T. vaginalis*. The first is metronidazole, 2 g orally in a single dose in adolescents and adults. This regimen is 90 to 95 percent effective.[10] Metronidazole vaginal suppositories are not recommended for the treatment of trichomoniasis. The second regimen is tinidazole, 2 g orally in a single dose. This regimen is 86 to 100 percent effective. An alternative regimen is metronidazole, 500 mg twice daily for 7 days. Some strains of *T. vaginalis* have reduced susceptibility to metronidazole, with low-level metronidazole-resistant strains reported in 2 to 5 percent of infected cases. Although rare, higher level resistance also has been reported.[42,61,62] Treatment options for metronidazole-resistant cases are limited. If the infection fails to respond to metronidazole, it should be re-treated with tinidazole or metronidazole, 500 mg twice daily for 7 days.[10] If treatment failure continues, the patient can be re-treated with 2 g of metronidazole or tinidazole once daily for 5 days.[10]

Metronidazole is a pregnancy category B drug. To date, studies have been unable to show consistently an association between metronidazole use during pregnancy and teratogenic effects in infants.[9] In addition, although some data suggest increased risk of having a premature or low-birth-weight infant after undergoing metronidazole treatment, limitations of the studies prevent definitive conclusions regarding risks of treatment.[10,31] Treatment during pregnancy may relieve symptoms and prevent pregnancy and perinatal complications. The Centers for Disease Control and Prevention[10] recommends counseling

TABLE 226–1 Dosing of Metronidazole in Children

Age (yr)	Weight (kg)	Metronidazole Administered (mg)	
		*Orally**	*Locally*†
0-1	10	150	10
1-6	20.5	250	50
7-12	40	500	150
>12	>40	500-1000	250-500

**Oral dose = one third of the total dose administered every 8 hours for 5 to 10 days.*
†*Local dose = total dose administered intravaginally once daily or half the total dose administered twice daily for 5 to 10 days.*
Adapted from Kurnatowska, A., and Komorowska, A.: Urogenital trichomoniasis in children. In *Honigberg, B. M. (ed.): Trichomonads Parasitic in Humans. New York, Springer-Verlag, 1989, p. 268.*

patients on the potential risks and benefits of treatment. In symptomatic women, some specialists offer treatment during the first trimester, and some do so after the first trimester. In asymptomatic women, some clinicians defer treatment to after 37 weeks of gestation.

Tinidazole is a pregnancy category C drug, and its safety in pregnancy has not been evaluated. It is not offered during pregnancy.[10] A breast-fed infant consumes approximately 1 percent of a single 2 g oral dose of metronidazole; infants of mothers who are breast-feeding and who are treated with a single dose of metronidazole for trichomoniasis should be removed from the breast for at least 24 hours after treatment.[10,44] In the case of treatment with tinidazole, breast-feeding can be resumed 3 days after the last dose.

In children with infections of the genital organs, local therapy with metronidazole is preferred because it has fewer systemic side effects. Cotton-tipped swabs saturated with metronidazole are introduced into the hymen and applied locally. In multifocal infections, genital infections that fail to respond to local therapy, and infections in newborn or infant boys, oral therapy with metronidazole is given (Table 226–1).[38] Before administering oral or intravenous metronidazole to children, the clinician should obtain baseline hematologic, renal, and liver function tests to monitor changes as therapy continues. Resolution of the signs and symptoms of infection indicates a response to treatment. Eradication of *T. vaginalis* should be confirmed by wet-mount examination or culture (if available) 3 to 5 days after completion of treatment in children.[38]

PROGNOSIS

If untreated, *T. vaginalis* can lead to chronic inflammation of the Bartholin and Skene glands in women and to prostatitis and urethritis with urethral stricture formation in men.[62] Complete resolution of symptoms plus eradication of *T. vaginalis* usually is noted when treatment is provided promptly.

C. Ciliates (Intestinal)

CHAPTER 227

BALANTIDIUM COLI INFECTION

Peter J. Hotez

Balantidium coli is the largest protozoan parasite and the only ciliate to infect humans.[6,9,15] The organism has a worldwide distribution, but it usually is found in the less developed nations of the tropics. Because pigs are the principal animal reservoir, most human infections have been reported in tropical regions where swine have close contact with humans, such as the islands of the South Pacific (including Papua New Guinea) and Central and South America.[10] Balantidiasis occurs in areas where other swine-associated parasitic zoonoses (e.g., taeniasis, trichinellosis, ascariasis) also are prevalent, although infection with *B. coli* occurs rarely. In Iran where pig raising no longer is permitted, wild boar serve as an animal reservoir.[11] Less than 1000 cases of human balantidiasis are reported in the literature.[9] The organism first was described in 1857 by Malmsten, who observed the ciliates from two patients in Sweden.[3]

ETIOLOGY AND PATHOGENESIS

The organism has trophozoite and cyst stages. The trophozoite is a large, pear-shaped organism covered with cilia. Estimates of size range from 50 to 100 μm in length and 40 to 70 μm in width.[6] This enormous protozoan organism typically can be seen by light microscopy using only low-power magnification.[6] Subcellular organelles, such as a cytostome and many large vacuoles containing bacteria and debris, are visualized under higher magnifica-

tion. Similar to many other ciliates, *B. coli* trophozoites have a macronucleus and a micronucleus. The trophozoites colonize the large intestine, where ultimately they round up and secrete a cyst wall as they pass down the lumen. The cysts measure 50 to 70 μm and contain a macronucleus and a micronucleus. The cyst stages can survive in the outside environment and are infectious to a wide range of animals, including humans (discussed later).

Frequently, *B. coli* does not invade human tissues and does not cause clinical disease. Under conditions that are not understood well, however, *B. coli* also has the potential for highly aggressive invasion and destruction of tissue. Whether the invasive potential of *B. coli* results from parasite virulence, compromised host defenses, or some combination of these two factors is unclear. The observation that invasive disease occurs more commonly in debilitated patients and in patients with polyparasitism suggests that host defenses have an important role in limiting tissue destruction by *B. coli*.[1,9]

When parasite invasion occurs, it begins in the colonic mucosa, where ulcerations and secondary microabscesses can result. Extensive tissue damage in the cecum and appendix results in clinical presentations of typhlitis and appendicitis.[4,5,9] Histopathologic examination of these tissues reveals flask-shaped ulcerations and necrosis with an extensive inflammatory infiltrate composed predominantly of polymorphonuclear leukocytes.[4,9] *B. coli* probably creates mucosal ulcerations through the release of histolytic enzymes similar to those described from *Entamoeba histolytica*.[12] Ulcerations can lead to hemorrhage or even colonic perforation. A second type of histopathology has been reported wherein patients harboring *B. coli* develop inflammatory polyposis of the rectum and sigmoid colon.[8]

When tissue invasion is extensive, the organism can metastasize to extraintestinal sites and cause hepatic and pulmonary involvement. Polymorphonuclear inflammatory cell infiltration results in abscesses at these sites.[3,5,8] Most patients with metastatic balantidiasis have recognizable defects in host defenses.[8]

EPIDEMIOLOGY

As noted earlier, human balantidiasis has a worldwide distribution, but epidemic foci have been reported in the swine-producing areas of Papua New Guinea, Micronesia, the Seychelles Islands, and Central and South America.[3,10,13] Incidence rates can be high among swine farmers and slaughterhouse workers. The potential for development of human *B. coli* infections is thought to be high in areas of poor hygiene where extensive contact occurs between humans and pigs. A notorious outbreak of human balantidiasis occurred after a devastating typhoon on the Pacific island of Truk caused widespread contamination of ground and surface water supplies with pig feces.[13] Many other animals, including nonhuman primates, guinea pigs, horses, cattle, and rats, also potentially can serve as reservoir hosts. *B. coli* also colonizes many great apes, including baboons, orangutans, chimpanzees, and gorillas, and clinical balantidiasis has been reported in these primates when they are maintained in captivity.[9] Human epidemics also have been described in institutional settings, especially where crowding mixes with low levels of personal hygiene.[13] In these instances, human-to-human spread has been postulated. Although *B. coli* is not known as an opportunistic pathogen in patients infected with human immunodeficiency virus, at least one case of *B. coli* in this setting has been described.[3]

CLINICAL MANIFESTATIONS

ASYMPTOMATIC INFECTION

Most infections are asymptomatic or cause occasional loose stools. This situation probably accounts for 85 percent of patients harboring *B. coli*.[9] Asymptomatic infection may occur more commonly in children than in adults.[14]

DIARRHEA

The next most frequent presentation of *B. coli* infections is in patients who have intermittent diarrhea, abdominal pain, and weight loss.[14] Sometimes, discrete ulcerations can be observed during sigmoidoscopy.[9] Chronic diarrhea has been described in a patient with acquired immunodeficiency syndrome.[2] A subset of patients with balantidiasis develop invasive disease subsequently.

INVASIVE COLONIC BALANTIDIASIS

The hallmark of *Balantidium* colitis is dysentery with bloody and mucous stools, colonic tenderness, leukocytosis, and fever. Sigmoidoscopy and colonoscopy of these patients reveal ulcerations and formation of mucosal granulomata.[1,9,13] Involvement of the large intestine can be diffuse, although in some cases, right-sided colonic lesions predominate. Right-sided colonic lesions can progress to typhlitis or appendicitis.[4,5,9] Transmural involvement of the colon frequently results in intestinal obstruction, hemorrhage, and balantidial peritonitis. Colonic perforation is an ominous complication that is associated with extremely high mortality.[9]

METASTATIC BALANTIDIASIS

Highly invasive balantidiasis leading to metastatic disease of the mesenteric lymph nodes, liver, and lung is a rare complication that can occur in malnourished, debilitated, and immunocompromised patients.

DIAGNOSIS

Stools from patients harboring *B. coli* have been described as having a pigpen odor.[14] The examination of wet preparations of fresh or concentrated stools usually reveals cyst and trophozoite forms of *B. coli*. Cilia motility and rapid rotary motion of the trophozoites occasionally can be appreciated under low-power magnification. Because the organism takes up heavy concentrations of dye, stained preparations typically do not reveal internal structures or even cilia.[6] These large organisms can be confused with helminth ova, especially on stained preparations.[6] As an adjunct to direct fecal examinations, sigmoidoscopy can show ulcerations from which abundant trophozoites may be obtained for diagnosis.[14]

TREATMENT

For the treatment of intestinal balantidiasis, numerous chemotherapeutic regimens have been tried, usually with some improvement. In many cases, the parasite is not eradicated, however.[9] For children older than 8 years, tetracycline (40 mg/kg/day in four doses for 10 days [maximum 2 g/day]) is the treatment of choice. Tetracycline is considered to be investigational for this condition by the U.S. Food and Drug Administration. Also considered investigational for balantidiasis are the drugs iodoquinol (30-40 mg/kg/day in three doses for 20 days) and metronidazole (35 to 50 mg/kg/day in three doses for 5 days).[7] Alternative chemotherapeutic agents that have been tried with variable success include paromomycin and chloroquine.[9] Surgical intervention

often is required for gastrointestinal invasive complications of *B. coli*, such as typhlitis, appendicitis, and peritonitis.

D. Coccidia, Inicnosporidia (Intestinal)

CHAPTER 228

CRYPTOSPORIDIOSIS

Theresa J. Ochoa ✪ A. Clinton White, Jr.

Cryptosporidium is an important cause of acute diarrhea in normal hosts worldwide, of persistent diarrhea in children in developing countries, and of chronic diarrhea in immunocompromised hosts including patients with acquired immunodeficiency syndrome (AIDS).[42,56,64,91] These protozoan parasites were identified first in the stomach of mice in 1907,[229] and for decades were considered to be veterinary pathogens. The first human cases of cryptosporidiosis were reported in 1976.[151,170] In the early 1980s, large numbers of cases were noted with the emerging epidemic of AIDS.[11,52] Thereafter, *Cryptosporidium* was identified in animal handlers and children[52,244] and was associated with large waterborne outbreaks of diarrhea.[55,140] Studies have shown that *Cryptosporidium* is a common cause of diarrheal disease in immunocompetent and immunocompromised hosts.

MICROBIOLOGY

Cryptosporidium spp. are ubiquitous, small (2 to 6 μm) obligate intracellular protozoan parasites that infect the epithelium of the gastrointestinal tract of vertebrates. The genus *Cryptosporidium* has been classified within the subclass Coccidia (coccidia) along with *Eimeria*, *Isospora*, *Cyclospora*, *Sarcocystis*, and *Toxoplasma*. Species names were given according to the animal that they infected.[250] Initial cross-transmission studies revealed that little host specificity exists.[66,230] Subsequent genetic studies have identified at least 13 accepted species of *Cryptosporidium* and more than 30 *Cryptosporidium* genotypes.[249] Most human infections are caused by separate species, *Cryptosporidium hominis* (formerly *Cryptosporidium parvum* genotype 1) and *Cryptosporidium parvum* (formerly *C. parvum* genotype 2). *C. hominis* is found only in humans (but can infect gnotobiotic pigs), and *C. parvum* is found in a wide range of animals (particularly cattle and sheep) and in humans.[164,180,248] The relative frequency of *C. hominis* and *C. parvum* in humans differs in geographic regions, probably as the result of differences in transmission routes. In European countries, *C. parvum* is found more commonly in human cases than *C. hominis*, although a more recent study in the United Kingdom has shown a comparable rate for both pathogens.[134] In the rest of the world, *C. hominis* is the predominant species in humans.[31,32,248] Humans also can be infected rarely with *Cryptosporidium meleagridis*, *Cryptosporidium canis*, *Cryptosporidium felis*, *Cryptosporidium muris*, *Cryptosporidium suis*, and *Cryptosporidium andersoni*.[62,76,77,147,179,228,247]

LIFE CYCLE

Cryptosporidium spp. can complete their entire life cycles, including asexual (merogony) and sexual (sporogony) reproductive cycles, within a single host (homoxenous). The life cycle is characterized by six major developmental stages: (1) excystation, or release of infective sporozoites; (2) merogony, or asexual replication in the host; (3) gametogony, or the formation of microgametocytes and macrogametocytes; (4) fertilization, or the union of microgametocytes and macrogametocytes; (5) oocyst formation; and (6) sporogony, or the formation of infectious sporozoites within the oocyst wall (Fig. 228–1).[51,100]

The life cycle begins with ingestion of the infectious oocyst. The oocysts are activated in the stomach and upper intestines, which allows the organisms to excyst, releasing four infective sporozoites.[69,174] The motile sporozoites bind to receptors on the surface of the intestinal epithelium, inducing actin polymerization and protrusion of the intestinal epithelial cell membrane.[41,61] The membrane surrounds the sporozoite and fuses to form the parasitophorous vacuole, which remains in the microvillus layer on the surface of the epithelium. Inside the parasitophorous vacuole, the parasites undergo asexual reproduction (merogony). They enlarge into trophozoite forms and divide to form type I meronts, which mature and rupture to release the motile merozoites. The merozoites bind to receptors on the epithelial cells and are engulfed by the cells. They then either repeat the process of merogony or undergo sexual differentiation (sporogony).

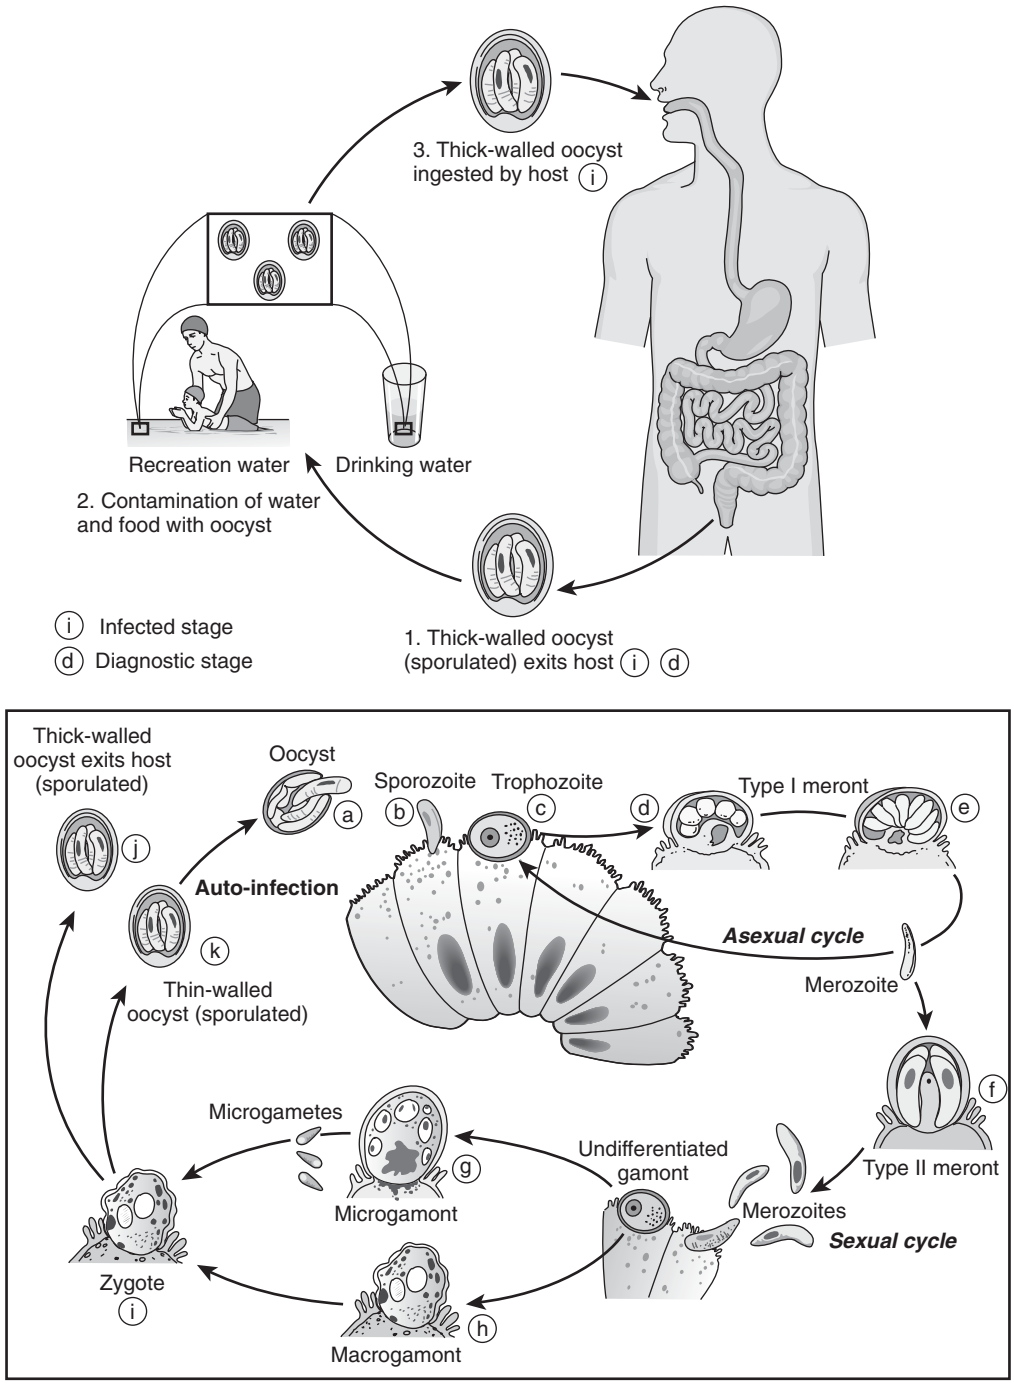

Figure 228–1 Life cycle of oocyst. After ingestion, the oocysts (a) release the sporozoite (b), which attach to and are engulfed by the epithelial cell. Inside the parasitophorous vacuole, the organisms enlarge to form trophozoites (c) and divide to form meronts (d, e, f). After reinvasion, they may differentiate into the sexual forms (macro- and microgamont, g, h), which fuse to form the zygote (i). The zygote releases the thin-walled oocysts (k), which cause autoinfection, or thick-walled oocysts (j), which are the infectious form.

In the case of sexual differentiation, the merozoites differentiate into the microgametocytes and macrogametocytes. The microgametocyte releases the microgametes, which penetrate the cells infected with macrogametocytes. The macrogametocyte and microgametes fuse to form the zygote form, which then undergoes meiosis to form the oocyst, containing four sporozoites. Two morphologic forms of the oocyst have been described: thin-walled oocysts, which excyst within the same host in a process of self-infection, and thick-walled oocysts, which are shed into the environment.[100]

EPIDEMIOLOGY

Cryptosporidium is distributed worldwide. Infection generally is more common in warm, humid months. Prevalence rates generally are higher in developing countries than in industrialized countries. Older surveys not involving patients with human immunodeficiency virus (HIV) documented oocysts in 1 to 3 percent of specimens from industrialized countries of Europe and North America and in 5 to 10 percent of specimens from developing countries.[91] Most studies on the prevalence of infection

have relied on detection of oocysts in fecal samples. With the development of improved diagnostic techniques, more cases are being identified. Using direct immunofluorescence, *Cryptosporidium* was found in 19 percent of children with diarrhea in Brazil.[180] With the use of polymerase chain reaction, *Cryptosporidium* was found in 18 percent of hospitalized patients and schoolchildren in South Africa,[210] in 25 percent of children with diarrhea in Uganda,[228] and in 36 percent of children prospectively followed in an urban slum in Brazil.[31] The prevalence may be higher than suggested by earlier stool studies.

Cryptosporidium has been reported more frequently in children than in adults.[103] The prevalence of asymptomatic infection with *Cryptosporidium* in children younger than 5 years old is estimated to be generally less than 1 percent, but varies with geographic location. In a longitudinal study in Italy, asymptomatic infection was seen in 6 percent of immunocompetent children and 22 percent of immunodeficient children.[182] In a Peruvian cohort study, 36 of 57 children (63%) followed for 2 years had asymptomatic *Cryptosporidium* infection.[38] Infection is particularly common in the first 2 years of life. Young children in daycare centers are at high risk for acquiring infection. Outbreaks of cryptosporidiosis in daycare centers have been reported from the United States and many other countries.[12,48,67,82,153,237]

The seroprevalence of antibodies to *Cryptosporidium* is 25 to 35 percent in adults in industrialized countries of North America and Europe, and is 65 percent in developing countries of South America.[233,252] Most serosurveys have documented a seroprevalence of approximately 30 percent in U.S. adults. Studies from the United States–Mexico border showed seroprevalence rates of 80 percent, however, in urban border communities.[128] Seroprevalence increases progressively with age. In a study in Oklahoma, 31 percent of children were seropositive, with rates increasing from 13 percent in children younger than 5 years to 58 percent in children 14 to 21 years old.[125] In a study in rural communities of China, no detectable antibody was found in infants 2 to 6 months old, but the proportion that were seropositive steadily increased after they reached 1 year of age.[252] In a Brazilian shantytown, less than 90 percent of children seroconverted during the first year of life, showing the high prevalence of this infection.[252] In a Peruvian birth cohort study of diarrheal disease, the incidence rate of cryptosporidiosis determined by a serologic assay was higher than the rate determined by stool microscopy (0.77 versus 0.41 infection/child-year of surveillance).[187]

Cryptosporidium is a common cause of diarrhea in patients infected with HIV. Cryptosporidiosis occurs in an estimated 10 to 15 percent of patients with AIDS in developed countries and in 30 to 50 percent of patients with AIDS in developing countries.[91] Among patients with HIV, the infection rate is proportional to the $CD4^+$ cell count. In a longitudinal study of patients with HIV, the infection rate varied from 23 percent of patients with $CD4^+$ cell counts greater than 1000/μL to 46 percent of patients with $CD4^+$ cell counts less than 100/μL.[186] In recent years, the widespread use of highly active antiretroviral therapy has resulted in the restoration of immune function and a reduction in the incidence of cryptosporidiosis and other opportunistic infections.[133]

Cryptosporidium is a common cause of persistent diarrhea in immunocompetent and immunocompromised children, especially in developing countries.[168,171,220,227,228] A study in West African children investigated episode-specific determinants for the progression of an acute episode of diarrhea to chronic diarrhea; current infection with *C. parvum* was the most significant risk factor.[220] Among 243 children with persistent diarrhea in Uganda, 76 (31%) had *Cryptosporidium*.[227] Ninety-one of the 243 children had HIV, of whom 67 (74%) had *Cryptosporidium*. Children with $CD4^+$ cell counts less than 25 percent were more likely to have *Cryptosporidium*.[227]

Cryptosporidiosis also has been noted in other immunodeficient hosts, including patients with primary immunodeficiencies, organ transplantation, cancer, and diabetics.[104] A particularly high prevalence of cryptosporidiosis occurs in patients with X-linked hyper-IgM syndrome. In two case series of hyper-IgM syndrome, the prevalence of cryptosporidiosis was 24 percent.[95,135]

TRANSMISSION

Humans can acquire *Cryptosporidium* infections through several transmission routes, such as direct contact with infected individuals (person-to-person transmission) or animals (zoonotic transmission) and ingestion of contaminated water (water-borne transmission) and food (food-borne transmission). The relative importance of these transmission routes varies from country to country.[248,249]

The infectious dose of *Cryptosporidium* is low, but considerable variability exists among isolates, ranging from approximately 1000 oocysts (UCP strain) to less than 10 oocysts (Texas isolate).[60,173] Because the infectious dose is low, *Cryptosporidium* is transmitted easily from person to person. This route of transmission was recognized initially in outbreaks associated with contact with daycare centers[8,48,96,244] and with nosocomial transmission.[122,166,211] Secondary transmission within households also is common.[141] During the acute diarrheal illness, large quantities of oocytes are excreted in stool and are highly infectious. Asymptomatic shedding of oocytes may continue for 5 weeks after an acute episode of diarrhea.[222] Contact with an ill individual is a major risk factor for cryptosporidiosis.[189,193] Sexual transmission has been postulated to occur in association with anogenital sex.[97]

Numerous outbreaks have been attributed to animal contact.[158,184] *C. parvum* (bovine genotype) is thought to infect primarily domestic animals, with zoonotic transmission to people. In England, most endemic cases of cryptosporidiosis are caused by *C. parvum*.[147] In addition to cattle, sheep, pigs, and pets have been implicated in zoonotic infection.[36,147,159,246,247]

Cryptosporidium oocysts are resistant to environmental conditions; oocysts can remain infectious for at least 6 months if kept moist,[65] but viability decreases rapidly with desiccation.[194] Oocysts are killed by heat, pasteurization, hydrogen peroxide, ozone, and ultraviolet radiation.[63] Oocysts are highly resistant to chlorination, however.[123] Surveys have shown that most surface sources of drinking water are contaminated with oocysts before treatment,[131,200] and even a low-grade contamination has been documented in samples of treated water.[130,200]

Water-borne outbreaks of cryptosporidiosis have been linked to contaminated drinking water, such as water from artesian wells, surface water, and filtered public drinking water,[56,64] and to contaminated recreational water, such as swimming pools, water parks, lakes, rivers, beaches, and fountains.[22,64,132] The largest documented water-borne outbreak of diarrhea occurred in Milwaukee in 1993, affecting an estimated 400,000 individuals.[140] Many of the water-borne outbreaks, including the outbreak in Milwaukee, have been caused by *C. hominis*.

Food-borne infections occur less commonly. Outbreaks have been associated with contaminated apple cider, unpasteurized milk, chicken salad, and raw produce.[64,79,156,190] Oocysts are found commonly on vegetables in developing countries.[177] *Cryptosporidium* is associated with international travel[120] and causes approximately 2 percent of traveler's diarrhea.[110]

PATHOLOGY AND PATHOGENESIS

In immunocompetent hosts, the organisms are localized primarily to the distal small intestines and proximal colon. In immunodeficient hosts, the parasites have been identified throughout the gut, in the biliary tract, and in the respiratory tract.[46,85,118] Children with persistent cryptosporidiosis may have villous atrophy and a mild increase in lamina propria lymphocytes.[183] Heavier infection is associated with villous atrophy; crypt hyperplasia; marked infiltration with lymphocytes, plasma cells, and neutrophils[46,80,83,85,138]; and with extraintestinal involvement.

Cryptosporidium causes watery diarrhea and malabsorption. These symptoms are thought to be related to sodium malabsorption, electrogenic chloride secretion, and increased intestinal permeability. The profuse, watery diarrhea suggests a toxin-mediated illness. Some investigators have reported enterotoxic activity in fecal samples from patients with cryptosporidiosis.[89] No secretory activity has been detected in formal studies, however.[89,119]

Cryptosporidiosis also is characterized by defects in intestinal permeability. Increased permeability may result in decreased absorption of fluids and electrolytes and solute fluxes into the gut. *Cryptosporidium* infection directly induces defects in intestinal epithelial cell barrier function in vitro.[2,86,199] Studies in children with cryptosporidiosis have shown a correlation between the severity of disease and altered intestinal permeability.[251]

Infection of intestinal epithelial cells leads to activation of nuclear factor κB[43,146] and increased expression of proinflammatory cytokines and markers of inflammation, including tumor necrosis factor-α (TNF-α), interleukin-1β (IL-1β), IL-8, CXCL10, and lactoferrin.[5,116,121,126,196,214,245] The chemokines and cytokines recruit inflammatory and immune cells into the intestines. Infection also leads to increased expression of cyclooxygenase-2, production of prostaglandins by the epithelial cells, and production of neuropeptides by the inflammatory cells.[127,198] Prostaglandins are thought to mediate decreased sodium and to stimulate chloride secretion.[18,47,116,127] Prostaglandin inhibitors have not proven to be effective symptomatic therapy in human cryptosporidiosis, however. The neuropeptide substance P correlates with severity of diarrhea in patients with cryptosporidiosis and AIDS.[198] Octreotide, a substance P antagonist, partially suppresses diarrhea in patients with chronic cryptosporidiosis.[18,88]

Cryptosporidiosis leads to villous atrophy and crypt hyperplasia.[17,28,47,83,124,163,183] Increased epithelial cell apoptosis has been shown in cells from tissue cultures and in biopsy specimens from infected intestines.[138] Loss of villous surface area is associated with malabsorption.[46,83,124,215] Patients with AIDS and severe cryptosporidiosis have malabsorption of bile acids, vitamin B_{12}, and fatty acids,[83,191,213] which is partly responsible for the severe wasting seen in these patients.

IMMUNOLOGY

Innate and acquired immunity are important in the defense and clearance of *Cryptosporidium*. $CD4^+$ T cells play a key role in the control of cryptosporidiosis. Among patients with HIV infection, cryptosporidiosis is self-limited in patients with $CD4^+$ cell counts greater than 180/μL, chronic in patients with $CD4^+$ cell counts less than 100/μL, and fulminant in some patients with $CD4^+$ cell counts less than 50/μL.[27,68,93,144] Resolution of cryptosporidiosis in patients with AIDS in response to highly active antiretroviral therapy is associated with an influx of $CD4^+$ cells into the intestines.[212] The role of other cell populations has been less clear.

Hyper-IgM syndrome, owing to defects in CD40 ligand, is associated with increased frequency and severity of *Cryptosporidium* infection.[95,135] Hyper-IgM syndrome is associated with profound defects in the ability of antigen-presenting cells to produce IL-12 and TNF-α and to stimulate production of interferon-γ (IFN-γ).[107]

IFN-γ is an important mediator of the immune clearance of *Cryptosporidium*. Depletion of IFN-γ causes exacerbation of infection[39,231,234]; inactivation IL-12, the major factor stimulating production of IFN-γ, causes chronic infection.[33,235] Treatment of intestinal epithelial cell lines with IFN-γ can activate the cells directly to clear partially *C. parvum* infection.[185] Lymphocytes from individuals who have recovered from cryptosporidiosis produced IFN-γ after antigen stimulation in vitro.[81] Approximately half of volunteers challenged with *C. parvum* express IFN-γ in the intestinal mucosa.[239] IFN-γ production by cells from patients with HIV during active cryptosporidiosis and from Haitian children with active cryptosporidiosis was very low, however, despite the fact that they had self-limited disease.[81,121] Similarly, IFN-γ expression in normal volunteers was limited to the subset with evidence of prior exposure.[239] In seronegative, normal volunteers experimentally infected and in patients with AIDS recovering from cryptosporidiosis, control of infection was associated with expression of IL-15.[176,197] This effect likely is mediated by activation of natural killer cells.[54]

In murine models, inactivation of IFN-γ expression resulted in only a mild chronic infection in BALB/c mice and was associated with expression of IL-12, IL-4, and TNF-α.[126,149,219] In the absence of IFN-γ, IL-12 treatment worsened cryptosporidiosis.[218] IL-4 synergizes with IFN-γ in eliminating infection of epithelial cells; however, IL-4 treatment did not modulate infection in IFN-γ knockout mice.[4,129,218] By contrast, TNF-α limited infection in IFN-γ knockout mice, activated human epithelial cells to limit infection, and has been associated with control of infection in cattle.[126,185,245]

The role of antibody in the immune response to cryptosporidiosis is controversial.[192] Early studies noted cases of chronic cryptosporidiosis in patients with low antibody levels, but, in most cases, studies were not performed to exclude coexisting T-cell dysfunction. In animal models, inactivation of B cells did not affect clearance of cryptosporidiosis.[40,223] By contrast, treatment with high concentrations of anti-*Cryptosporidium* antibody did facilitate clearance.[20,111,181,192,206] High levels of serum and fecal antibodies to *C. parvum* have been found in patients with AIDS with chronic cryptosporidiosis and in volunteers challenged with *C. parvum*.[24,49] The presence and timing of antibody correlated with shedding of oocysts, however, rather than with clearance or resistance to infection. Similarly, cytokines such as transforming growth factor-β that stimulate IgA production often develop only after resolution of illness.[195] In a longitudinal study of diarrheal disease in Peruvian children, the magnitude of the antibody response (IgG) was related to the number of previous infections with *Cryptosporidium*.[188]

CLINICAL MANIFESTATIONS

The clinical spectrum of disease caused by *Cryptosporidium* is broad and depends on the immunologic status of the host (Table 228–1). Symptoms of cryptosporidiosis develop after a prepatent period, during which the parasites invade the intestinal epithelium and proliferate. The prepatent period is approximately 1 week (range 1 to 30 days).[113,140,173,175]

Regardless of the immunologic status of the patient, diarrhea is the most common manifestation of cryptosporidiosis. In developing countries, cryptosporidiosis accounts for 5 to 10 percent of cases of childhood diarrhea.[3,108,121,162,168,169,208,211,228] Children present with an acute diarrheal syndrome characterized by watery diarrhea and crampy abdominal pain with frequent, foul-smelling, bulky stools.[209] Other, less common clinical findings include low-grade fever, flatulence, nausea, and vomiting. The stools rarely contain blood and fecal leukocytes, with occasional

TABLE 228–1 Clinical Manifestation of Cryptosporidiosis

Host	Clinical Manifestations	Comments
Normal host	Acute watery diarrhea	Relapses are common Persistent diarrhea is common
Children in developing countries	Acute watery diarrhea Persistent diarrhea	Diarrhea more severe in children with malnutrition Persistent diarrhea affects nutritional status, growth, and intellectual function
Immunocompromised host	Acute watery diarrhea Relapsing diarrhea Persistent/chronic diarrhea Cholera-like illness Extraintestinal involvement	Transient, self-limited, similar to normal host Very common Usually found in patients with low CD4 or malnutrition Voluminous watery diarrhea, only with very low CD4 Respiratory tract, biliary tract, and pancreas

TABLE 228–2 Diagnosis of *Cryptosporidium* Infection

	Method	Comments
Microscopic examination of stools	Modified acid-fast stain of stools	Inexpensive and widely available diagnostic test
	Fluorescent stains (auramine O, auramine-rhodamine)	Faster than other acid-fast stains and may improve sensitivity
	Immunofluorescent assays (IFA)	More sensitive than acid-fast staining but also more expensive
Antigen-detection assays	Enzyme immunoassay (EIA), and immunochromatographic tests: direct and indirect immunofluorescence assay (DFA and IIF)	Good sensitivity (66-100%) and excellent specificity (93-100%), but occasional lots associated with false positive tests
Molecular methods	Polymerase chain reaction (PCR)	Increased sensitivity compared to microscopic or antigen-detection studies

mucus. In immunocompetent patients, the onset of diarrhea is abrupt, and the illness usually is self-limited. Recurrent symptoms develop in 40 percent of cases after initial resolution. Relapses may occur after a diarrhea-free period of several days to weeks.[140,141,168] Forty-five percent of cases develop diarrhea lasting more than 14 days.[169,220]

Cryptosporidium is one of the most common causes of persistent diarrhea in developing countries, causing about one third of cases.[168,209,220,228] Children with persistent diarrhea, especially if caused by *Cryptosporidium*, are at high risk for developing additional gastrointestinal infections after the initial illness, weight loss, and premature death.[3,9,136,161] Persistent diarrhea in children seriously affects nutritional status, growth, and intellectual function.[25,90] A long-term follow-up study of children with onset of cryptosporidiosis before age 1 year suggests an association with poorer physical fitness and poorer cognitive development that persists for years.[90] In a second study, long-term effects of early childhood malnutrition were noted, but no significant association with *Cryptosporidium* compared with other pathogens was found.[25]

Cryptosporidiosis is more severe in children with malnutrition. Malnourished children tend to have a protracted course and shed oocysts longer. They often require hospitalization, and their diseases may have a fatal outcome.* Prospective cohort studies of children followed from birth have shown significant differences in nutritional status before acquisition of *Cryptosporidium* infection.[3,37,160] In addition, the onset of cryptosporidiosis is associated with growth faltering. Older children eventually recovered and experienced catch-up growth, but children infected before 1 year of age often never recovered.[3,37,160] Asymptomatic infection can lead to malnutrition even without diarrhea.[38] *Cryptosporidium* infection causes acute malnutrition, and the long-term consequences of this interaction are likely to be worse in children infected in infancy or with prior malnutrition.

*See references 9, 104, 108, 109, 139, 168, 207, 209, 211, 228.

The clinical manifestations of cryptosporidiosis in patients with HIV vary. Four distinct gastrointestinal syndromes have been described in HIV-infected patients: (1) transient, self-limited diarrhea, similar to diarrhea in normal hosts, usually in patients with $CD4^+$ cell counts greater than 150/μL; (2) voluminous watery diarrhea or cholera-like illness that requires rehydration, seen in a few cases, usually in patients with $CD4^+$ cell counts less than 50/μL; (3) relapsing diarrhea; and (4) a chronic diarrheal illness resulting in wasting, usually in patients with $CD4^+$ cell counts less than 150/μL.[27,93,138,144] Other conditions associated with *Cryptosporidium* infection include cancer, hypogammaglobulinemia, severe combined immunodeficiency,[104] bone marrow and renal transplantation, and concurrent viral infections such as measles and cytomegalovirus. The severity and duration of illness generally depend on the degree of immunodeficiency.

In immunocompromised patients, extraintestinal involvement may occur in the respiratory tract, biliary tract, and pancreas.[45,93,137,154,236] Respiratory tract involvement often is asymptomatic, but may cause cough, shortness of breath, wheezing, croup, and hoarseness. *Cryptosporidium* has been reported as a cause of laryngobronchitis in children.[92] Biliary tract involvement in cryptosporidiosis has been limited to patients with profound immunodeficiency.[93,236] Patients may present with acalculous cholecystitis or cholangitis and, less frequently, with sclerosing cholangitis or hepatitis.[93,224,236] Pancreatitis is an uncommon finding, but it has been reported in adults and children infected with HIV.[94,137,157] Concomitant infection with cytomegalovirus can occur and frequently is associated with irregularities of the intrahepatic duct.[23,101,115]

DIAGNOSIS

Many laboratories do not test for *Cryptosporidium* unless the tests are specifically requested (Table 228–2). *Cryptosporidium* infection usually is diagnosed by microscopic examination of stools. Fresh, preserved, and frozen stools can be used for testing.[15,19]

Numerous concentration methods have been attempted to improve the yield, but all are laborious and are used mainly in research laboratories.[19,44]

Traditional approaches to stool examinations usually miss the organism because the oocysts are small, 4 to 6 μm in diameter, and similar in size and shape to yeast forms normally found in stool. Several special staining methods have been explored, including auramine-rhodamine, auramine-carbolfuchsin, Giemsa stain, safranin–methylene blue stain, aniline-carbolmethyl violet, and acridine orange.[50] The stains that are used routinely to detect other intestinal parasites (trichrome and iron hematoxylin) do not detect *Cryptosporidium*.

Traditionally, the method of choice for clinical laboratories to detect *Cryptosporidium* oocysts in stools has been the modified acid-fast stain.[16,19,142] Oocysts stain pink or red, whereas yeast cells and fecal debris are green or blue (Fig. 228–2). The stain used most frequently is a modification of the Ziehl-Neelsen stain.[15,19] Many other modifications that have been described include hot and cold techniques, incorporation of dimethyl sulfoxide, and use of detergent. The sensitivity of stool examination with acid-fast staining is poor, requiring an oocyst concentration of greater than 500,000/mL in formed stools,[238] with fewer cases detected than with fluorescent methods.[7,112] Fluorescent stains (e.g., auramine O, auramine-rhodamine) can be read more quickly than other acid-fast stains and may have improved sensitivity.[226] These assays can yield false-positive results, however; all of the acid-fast stains detect other parasites that may cause similar illnesses (e.g., *Isospora* and *Cyclospora*).[15,19]

Immunofluorescent assays employing oocysts specific for monoclonal antibodies can be used to test for cryptosporidiosis. Immunofluorescent assays have been reported to be 10 times more sensitive than acid-fast staining.[53,71,106] Direct immunofluorescent staining using monoclonal antibodies now is the gold standard for stool examination.

Antigen-detection assays are being used increasingly for diagnosis of stools. Commercial kits for *Cryptosporidium* are available in enzyme-linked immunosorbent assay (ELISA) and immunochromatographic formats. The ELISA kits for *Cryptosporidium* have good sensitivity (66 to 100%) and excellent specificity (93 to 100%).[19,53,71-73,217a] The sensitivity has been poor in some studies,[105,112,167] however, and pseudo-outbreaks from false-positive results have been reported.[14,58] Commercial ELISA kits also may test for *Giardia* and *Entamoeba* antigens.[72] Immunochromatographic tests are rapid tests for *Cryptosporidium* and *Giardia* antigen.[73,112] The sensitivity is less than with other assays, but the specificity is excellent, and results are available in minutes.[73,112] Antigen assays as a group have the advantage of not requiring skills in microscopic identification of organisms.

Polymerase chain reactions for *C. parvum* DNA also have been employed to detect organisms. They also have increased sensitivity compared with microscopic or antigen-detection studies of stool.[21,148,217a] In one study of children with primary immunodeficiencies, polymerase chain reaction was able to detect significantly more cases of biliary cryptosporidiosis than were detected by stool studies.[148]

Biopsy of the intestine typically is unnecessary for the diagnosis of intestinal infection, although the unique apical location within the intestinal epithelium is distinctive. The parasite can be visualized by light microscopy after staining with hematoxylin and eosin or by electron microscopy.[50]

MANAGEMENT

Replacement of fluids and electrolytes is a crucial first step in management, as with all cases of diarrhea. Oral rehydration is preferred, but severely ill patients may require parenteral fluids. Glutamine supplementation may improve fluid absorption.[34] Dietary management is crucial in cryptosporidiosis, especially if it is associated with persistent diarrhea. Supportive care should include initially a lactose-free diet because lactase activity is decreased on the apical border of epithelial cells.[183]

Cryptosporidiosis is associated with increased intestinal transit, which could interfere with absorption of fluids, electrolytes, and drugs.[29,215] Antimotility and antisecretory agents (i.e., tincture of opium, loperamide, octreotide, acetorphan) have roles in therapy, but their use generally is limited to refractory cases in adults with AIDS.[74,216] These agents may control the diarrhea, but they do not eradicate the parasite.

In immunocompromised hosts, management of intestinal cryptosporidiosis is problematic. For patients with AIDS with chronic cryptosporidiosis, effective antiretroviral therapy can result in dramatic improvement in diarrhea.[35,70,87,143,155,176] The HIV protease inhibitors have anticryptosporidial activity in vitro and reduced infection by 90 percent in an animal model,[102,152] and most of the studies reporting responses have used protease inhibitors. By contrast, cryptosporidiosis is associated with malabsorption of nucleosides.[30]

The role of antiparasitic therapy in cryptosporidiosis is controversial. Because cryptosporidiosis usually is self-limited in immunocompetent hosts and can be variable in compromised hosts, controlled trials are crucial. No agent has proven reliably curative in patients with advanced AIDS. A meta-analysis of seven randomized controlled clinical trials found no clear evidence for efficacy of antiparasitic agents in the management of cryptosporidiosis in compromised hosts.[1]

Nitazoxanide is a nitrothiazolyl-salicylamide derivative with a broad spectrum of antiprotozoal and antihelmintic activity.[241]

Nitazoxanide is active against *Cryptosporidium* in vitro and in animal models.[75,225] In the initial study in patients with AIDS and cryptosporidiosis, a 7-day course of nitazoxanide was associated with improvement in 7 of 12 patients, but diarrhea resolved completely in only 4.[59]

A placebo-controlled study of nitazoxanide in patients with cryptosporidiosis showed significant clinical improvement in apparently immunocompetent children and adults with persistent diarrhea.[202] By day 7, diarrhea had resolved in 39 of 49 (80%) patients treated with nitazoxanide compared with 20 of 49 (41%) treated with placebo. Nitazoxanide also reduced the duration of shedding of oocysts. In parallel randomized studies in severely malnourished HIV-infected and HIV-negative children in Zambia with chronic cryptosporidiosis, a 3-day course of therapy not only led to clinical and parasitologic improvement, but also improved survival in HIV-negative children.[10] All children were treated with nitazoxanide suspension (100 mg twice a day for 3 days) or matching placebo. Among non–HIV-infected patients, resolution by day 7 was noted in 14 of 25 (56%) of patients treated with nitazoxanide compared with 5 of 22 (23%) for the placebo group. Similar findings were reported in immunocompetent patients 12 years old and older. A good clinical response was seen in 27 of 28 (96%) patients receiving nitazoxanide compared with 11 of 27 (41%) receiving placebo.[204] Among the HIV-infected children, most with severe malnutrition, no significant response occurred.[10]

Higher doses and longer duration were effective in adults with HIV.[203] Among patients with $CD4^+$ cell counts greater than 50/μL, 10 of 14 (71%) responded to 1 g/day, and 9 of 10 (90%) responded to 2 g/day compared with 3 of 15 (20%) treated with placebo. The response was no better than placebo for patients with $CD4^+$ cell counts of 50/μL or less.[150] In expanded access programs, most patients improved on therapy.[201]

Nitazoxanide suspension was approved in the United States in 2002 for treatment of cryptosporidiosis and giardiasis in children. For most indications, it is dosed every 12 hours for 3 days. The recommended dose is 100 mg (5 mL) for children 12 to 47 months old, 200 mg for children 4 to 11 years old, and 500 mg for older children and adults (approximately 15 mg/kg/day).[240] Nitazoxanide generally is well tolerated; adverse events occur at a frequency similar to that for placebo and include abdominal pain, diarrhea, vomiting, and headache.[240]

Paromomycin is an orally administered nonabsorbable aminoglycoside. Initial in vitro studies noted poor activity against *C. parvum*. When patients with AIDS and cryptosporidiosis were treated with available antiparasitic drugs, however, some improved when treated with paromomycin.[78] Three randomized, controlled trials examined the effects of paromomycin in patients with AIDS and cryptosporidiosis.[98,117,242] Paromomycin was associated with a significant reduction in shedding of oocysts and decreased stool frequency, but not cure.[242] In another study, no significant difference was found between groups.[98]

Macrolide antibiotics including spiramycin, azithromycin, roxithromycin, and clarithromycin have some activity against *Cryptosporidium*.[26] In one study, children treated with spiramycin had shorter duration of symptoms and shedding of oocysts,[205] but a second trial showed no effect.[243] Case series noted improvement in cryptosporidiosis in patients with HIV and cancer treated with azithromycin,[57,99,114,165] but subsequent trials in patients with AIDS did not show changes in frequency of stools or shedding of oocysts.[26] A study in Egyptian schoolchildren suggested more rapid resolution of symptoms was achieved with azithromycin.[6] Roxithromycin treatment was associated with improvement in AIDS-associated cryptosporidiosis in two uncontrolled studies.[221,232]

Case reports noted improvement in chronic cryptosporidiosis in patients treated with oral anti-*Cryptosporidium* immunoglobulin preparations.[84] Two well-controlled trials with oral bovine anti-*Cryptosporidium* immunoglobulin preparations in cryptosporidiosis showed no significant decrease in symptoms or shedding of oocysts, however.[172]

PREVENTION

In hospitals and daycare centers, handwashing is the most important measure to prevent the spread of any enteric pathogen. In hospitals, enteric precautions (washing hands, wearing gloves, and wearing gowns if soiling is likely) are important measures to prevent nosocomial spread.

Swimming pools are an important source of infection. Contamination of treated recreational water, such as a fecal accident in a swimming pool, should prompt aggressive measures, including closing the pool temporarily. Recreational waters, such as lakes, may pose a danger for compromised hosts, who should avoid contact with untreated water.[145]

Control of water-borne transmission of cryptosporidiosis is a major public health concern. This issue is complicated by the ability of *Cryptosporidium* to escape the filtration system used in most public water facilities and its resistance to chlorination. The Centers for Disease Control and Prevention recommends that during outbreak situations, compromised patients boil tap water for 1 minute, filter tap water using a filtration system to remove particles 1 μ or smaller, or use bottled water prepared by distillation or reverse osmotic filtration. In situations not associated with an outbreak, no special measures are recommended. Routinely using the outbreak measures outlined earlier for severe immunosuppressed patients may be prudent, however.[13] The Centers for Disease Control and Prevention web site contains an excellent patient fact sheet about *Cryptosporidium* and its prevention at www.cdc.gov/ncidod/dpd/parasites/cryptosporidiosis/. Currently, no vaccine is available to protect against *Cryptosporidium*.

CHAPTER 229

Cyclosporiasis, Isosporiasis, and Microsporidiosis

Chaouki K. Khoury ✪ Jane T. Atkins

CYCLOSPORIASIS

Cyclospora cayetanensis is a coccidian parasite that infects the gastrointestinal tract of immunocompetent and immunocompromised patients.[73,137,207] This organism was described in feces from humans without enteritis in 1979.[7] The first documented cases of diarrheal disease attributed to *Cyclospora* were reported in 1986 in four immunocompetent patients who had traveled from the United States to either Haiti or Mexico.[164] At that time, it was referred to as an unsporulated, coccidian body or a fungal spore. Before the mid-1980s, reports of diarrheal illness caused by *Cyclospora* were rare. With the advent of the epidemic of acquired immunodeficiency syndrome (AIDS), this organism gained increasing recognition as an enteric pathogen.[137,159,207]

MICROBIOLOGY AND LIFE CYCLE

Cyclospora is a round-to-ovoid, variable acid-fast organism that measures 8 to 10 μm in diameter (Fig. 229–1).[130] It also has been referred to as a *Cyanobacterium*-like body, a blue-green alga, a coccidian-like body, *Cryptosporidium*-like, or big *Cryptosporidium*.[8,12,79,130,133,135,143,158,166] In 1993, Ortega and associates[130,133] assigned this organism to the family Eimeriidae and the genus *Cyclospora* and proposed the name *C. cayetanensis* for the species that infects humans. This classification was based on its sporulation characteristics, and the name was derived from the institution where the original research was performed (Universidad Peruana Cayetano Heredia in Lima, Peru).[206]

Cyclospora, similar to *Isospora*, sporulates exogenously and has two sporocysts per oocyst. It differs from *Isospora* in that it has two sporozoites per sporocyst, whereas *Isospora* has four per sporocyst. *Cyclospora* spp. are ubiquitous and infect various animals, including vipers, moles, rodents, and myriapods. Humans are the only known host of *C. cayetanensis*. Organisms resembling *C. cayetanensis* have been found in the stool of chimpanzees living in Uganda.[206]

Sexual and asexual stages of *Cyclospora* are found in jejunal biopsy specimens from infected individuals, showing that this coccidian parasite can complete its entire life cycle in a single host.[131] Infected patients pass unsporulated oocysts into the environment. A period outside the host is required for maturation into an infectious, sporulated oocyst. A warm, moist environment seems to favor sporulation in nature. In vitro, sporulation occurs 1 to 2 weeks after incubation in distilled water or 2.5 percent potassium dichromate at 25° C to 35° C.[163,169] Sporulation has been delayed by storage of oocysts at 4° C for 6 months or by storage at 37° C for 14 days, and can be completely aborted if oocysts are subjected to –20° C for longer than 24 hours or 60° C for longer than 1 hour.[162] In vivo, excystation of mature sporulated oocysts most likely occurs in the small bowel. In vitro, a combination of bile salts, sodium taurocholate, and mechanical pressure is required for excystation.[169]

EPIDEMIOLOGY AND TRANSMISSION

Cyclospora is distributed worldwide. Initial reports of cyclosporiasis involved residents of developing countries or travelers return-

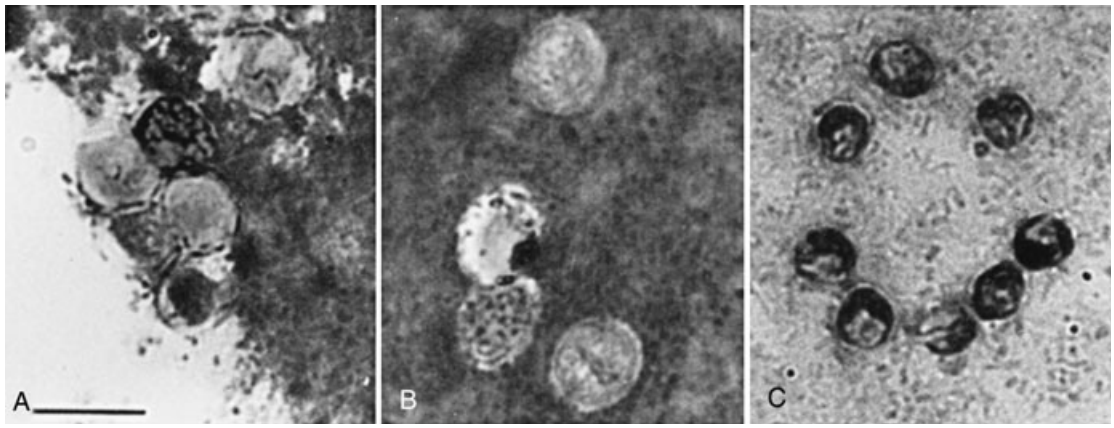

Figure 229–1 **A-C,** Modified acid-fast stain of *Cyclospora* sp. (**A**), *Cryptosporidium muris* (**B**), and *Cryptosporidium parvum* (**C**). Bar = 10 μm. *(From Ortega, Y. R., Sterling, C. R., Gilman, R. H., et al.:* Cyclospora *species: A new protozoan pathogen of humans. N. Engl. J. Med.* 328:*1308-1312, 1993.)*

ing from such countries.[78,130,133,143,158] It has been identified in individuals residing in or traveling to numerous geographic areas, including North, Central, and South America; the Caribbean islands; England; eastern Europe; Turkey; Egypt; India; eastern Asia; Nigeria; South Africa; and Australia.[3,4,15,48,152,163,169,209] In one study of diarrheic stool from subjects returning from tropical areas, *C. cayetanensis* was identified in 5 percent of samples, rendering it the second most common pathogen after *Giardia*.[186] Seasonal variation has been described. In Nepal, most cases occur during the rainy season, between May and October.[78] In Peru, the peak is during the fall, between April and June.[133] The prevalence in endemic regions varies with the age and immunologic status of the host. Prevalence rates in children from Peru and Nepal are reported to range from 2 to 18 percent.[77,133] In one series from Haiti, *Cyclospora* was reported in 11 percent of adults infected with human immunodeficiency virus (HIV), but was not detected in non–HIV-infected adults or infants younger than 6 months.[137]

Direct person-to-person transmission is unlikely to occur because a period outside the host is required for maturation into a sporulated oocyst.[169] The infectious dose of *Cyclospora* is unknown, but is hypothesized to be low, as with other coccidian parasites. Contamination of the environment with oocysts plays a major role in the transmission of *Cyclospora*. Food-borne and water-borne transmission of *Cyclospora* have been described.[169] Water-borne outbreaks have been reported in Chicago and in Nepal.[80,135,206] In one area of Egypt, the average prevalence of *Cyclospora* spores in stool samples was 5.6 percent in patients with diarrhea, in contrast to 2.3 percent in asymptomatic subjects, with higher prevalence in places with higher water contamination.[48] High levels of aquatic contamination also were documented in Hanoi (Vietnam), reaching 63.6 percent in certain areas, again emphasizing the important role of contaminated water in the spread of the pathogen.[118]

Food-borne transmission of this organism via the consumption of uncooked meat and poultry was suspected in 1979.[7] In recent years, an increasing number of cases of food-borne outbreaks have been reported.[73-75] Widespread recognition of this organism as a food-borne pathogen occurred in 1996 and 1997, when outbreaks of cyclosporiasis occurred in the United States and Canada and were associated with the consumption of raspberries imported from Guatemala.[73-75] Researchers postulated that the raspberries were contaminated with insecticide or fungicides that were mixed with contaminated water, or that the irrigation water was contaminated with *Cyclospora* oocysts.[134,163] During 1997, clusters of cases were identified in which fresh basil and mesclun lettuce were implicated.[144] Eleven food-borne outbreaks occurred in North America between 1990 and 2000, affecting 3600 people.[107] *Cyclospora* oocysts contaminating vegetables are not removed easily by routine washing.[132]

CLINICAL MANIFESTATIONS

Cyclospora causes disease in immunocompetent and immunocompromised patients.[133,137,143,158,206] *Cyclospora* spores also have been detected along with other pathogens, such as with *Giardia* in stool,[95] or rarely with tuberculosis in sputum.[82]

The incubation period typically is 2 to 11 days. In the Chicago outbreak, cases occurred 12 hours to 7 days after the suspected contamination of the water supply occurred.[135] In an immunocompetent host, diarrheal symptoms may last 7 weeks and may be remitting.[206] A cyclic, relapsing pattern of diarrhea alternating with constipation may occur.[163] Resolution of symptoms usually correlates with disappearance of the organism from the stool.[78,138] Asymptomatic excretion of cysts has been reported, however.[12,143] In one prevalence study in a Venezuelan community, *C. cayetanensis* spores were identified in 6.1 percent of subjects, with an asymptomatic carrier state in 84.6 percent of these.[26]

In immunocompromised hosts, the duration of diarrhea is highly variable, ranging from a few days to several months; in most cases, it is protracted. The illness is characterized by an abrupt onset of watery diarrhea. Flulike symptoms, including malaise, myalgia, and anorexia, also occur.[27,206] Low-grade fever is reported in approximately 25 percent of patients.[135,158,206] Vomiting may occur, but is less common than diarrhea. Other associated symptoms include abdominal cramping, heartburn, and indigestion.[163] Weight loss from malabsorption occurs in immunocompetent and immunocompromised patients.[78,164,207] Cyclosporiasis also was described in an infant, in whom it presented as irritability and refusal to feed.[83]

The median duration of disease in various U.S. outbreaks has been 10 to 20 days (range 1 to 60 days).[73] In HIV-infected patients, *Cyclospora* causes symptoms that are indistinguishable

from symptoms of *Cryptosporidium* and *Isospora* infection.[206] Biliary disease was reported in two patients with AIDS infected with *Cyclospora*. These patients had clinical and radiographic confirmation of biliary disease and did not have evidence of infection with other pathogens. Both patients had acalculous cholecystitis that was responsive to therapy with trimethoprim-sulfamethoxazole.[159] Finally, *Cyclospora* may play a role as a pulmonary pathogen in immunocompromised patients.[82]

DIAGNOSIS

Cyclospora, in contrast to *Cryptosporidium*, can be visualized by light microscopy after formol-ether concentration of the stool. In fresh stool, the oocysts are unsporulated. They appear as refractile spherical bodies measuring 8 to 10 μm and have a central greenish morula that contains six to nine refractile globules.[130] Safranin staining enhances the outline of the membrane, but does not stain internal structures. The sensitivity of wet mounts is 75 percent.[137] Oocysts exhibit bright blue autofluorescence when exposed to ultraviolet light. Staining is variable with modified Ziehl-Neelsen stain (see Fig. 229–1).[133] Fluorescence with auramine-rhodamine staining enhances the visualization of internal structures, but this stain usually is weak and irregular. Lacto-phenol cotton blue staining also allows visualization of the oocysts.[139] *Cyclospora* is not visualized by Gram, Giemsa, Grocott-Gomori methenamine–silver nitrate, Lugol iodine, periodic acid–Schiff, or hematoxylin and eosin staining.[139,206]

A direct comparison of formalin-ether sedimentation, direct smear examination, and sucrose centrifugal flotation yielded the highest recovery of *Cyclospora* oocysts in stool with the last method.[93] More recently, real-time polymerase chain reaction (PCR)[183,186] and flow cytometry[44] were advocated as an operator-independent, relatively rapid quantitative tool for the screening of stool samples for *Cyclospora* oocysts that seems to be more sensitive than microscopy. Real-time PCR may detect 1 oocyst/5 μL volume.[183]

TREATMENT

Disease seems to be self-limited in immunocompetent hosts. When treatment is indicated because of the severity or persistence of symptoms, trimethoprim-sulfamethoxazole is the drug of choice. In a small, uncontrolled study, therapy with trimethoprim-sulfamethoxazole resulted in resolution of symptoms and reduction of the duration of shedding oocysts from 9 to 13 days.[106] In a placebo-controlled trial involving travelers to Nepal, trimethoprim-sulfamethoxazole given for 7 days eradicated *Cyclospora* from the stool in 96 percent of patients.[78] In contrast, 88 percent of the placebo group still had detectable *Cyclospora* in the stool at the end of 7 days. Eradication of the organism correlated with resolution of symptoms. In one study, patients with *Cyclospora* did not improve when treated with empiric therapy (norfloxacin, tinidazole, quinacrine, nalidixic acid, and diloxanide furoate)[158] that was aimed at other enteric pathogens. Prophylaxis with trimethoprim-sulfamethoxazole 3 days a week seems to prevent recurrent episodes in HIV-infected patients.[137]

ISOSPORIASIS

Isospora belli is an enteric coccidian parasite that is related closely to *Toxoplasma*, *Cryptosporidium*, *Sarcocystis*, and *Cyclospora* (Fig. 229–2). Numerous species of *Isospora* infect reptiles, birds, and mammals. *I. belli* is the only species that infects humans.[49] *Isospora*, similar to the other enteric coccidian parasites, causes a self-limited diarrheal illness in immunocompetent hosts and a prolonged diarrheal illness in immunocompromised hosts. Cases of human isosporiasis were first reported in 1915.[200,205] Similar to the other enteric coccidian diseases, isosporiasis was reported infrequently before the AIDS epidemic.

MICROBIOLOGY AND LIFE CYCLE

I. belli is a monoxeonous coccidian parasite that is related closely to *Cyclospora*.[84] The mature oocyst of *I. belli* is oval-shaped, measures 10 to 20 × 20 to 33 μm, and has a translucent thin wall that contains two round sporoblasts, each with four crescent-shaped sporozoites (Fig. 229–3).[28] Infection occurs after the ingestion of a mature sporulated oocyst. Excystation occurs in the proximal part of the small intestine and results in the release of sporozoites that invade enterocytes of the distal duodenum and proximal jejunum and develop into trophozoites. The trophozoites reproduce asexually to form merozoites. The merozoites undergo asexual replication (schizogony or merogony) or sexual replication (gametogony) that results in the production of an immature unsporulated oocyst. This latter form is excreted in stool and requires 12 to 48 hours to mature into the infectious form, a sporulated oocyst.[17]

EPIDEMIOLOGY AND TRANSMISSION

The true prevalence of *I. belli* is unknown. It is more common in the tropical and subtropical regions[50a,104] of Africa, Southeast Asia, and Central and South America. In North America, it has been implicated as a cause of diarrhea in institutionalized patients[86] and as a cause of traveler's diarrhea.[66,157] Before the AIDS pandemic, *Isospora* was an uncommon cause of diarrhea, even in endemic regions. Between 1976 and 1980, *Isospora* oocysts were detected in 0.17 percent of stool specimens from 1139 Southeast Asian refugees.[17] *Isospora* is found in 3 to 18 percent of patients with AIDS from developing countries and in less than 0.2 percent of patients with AIDS from the United States and Europe.[81,136,165] In Haiti, *Isospora* accounts for 15 percent of chronic diarrhea in patients with AIDS.[37] It is thought to be the most frequent human coccidiosis.[39]

The consensus is that humans are the only host of *I. belli*, and that no animal reservoirs exist. Organisms resembling *I. belli* have been identified in the stool of dogs.[65] Transmission is by the fecal-oral route. Sexual transmission of *Isospora* also has been suggested.[55] Infection occurs after the ingestion of oocysts in fecally contaminated food or water or from environmental sources.[55,138,165] The incubation period is thought to be 3 to 14 days.[17,72] The infectious dose has not been established. In one investigation, symptoms developed in a single volunteer after 3000 organisms were ingested, but they failed to develop with a second challenge.[111] If untreated, the organism is shed in the stool for 11 to 120 days.[72] The oocysts of *I. belli* are highly resistant to commonly used disinfectants and may remain viable for months in a cool, moist environment.

PATHOPHYSIOLOGY

The pathologic findings in patients with isosporiasis are nonspecific. Histopathologic changes include shortening of the villi; hypertrophy of the crypts; and infiltration of the lamina propria with plasma cells, lymphocytes, polymorphonuclear leukocytes, and eosinophils.[17,20,28,136,176] All stages of the life cycle have been identified within the villous epithelium (Fig. 229–4) and always are enclosed within a parasitiferous vessel.[20,136,176] Extracellular

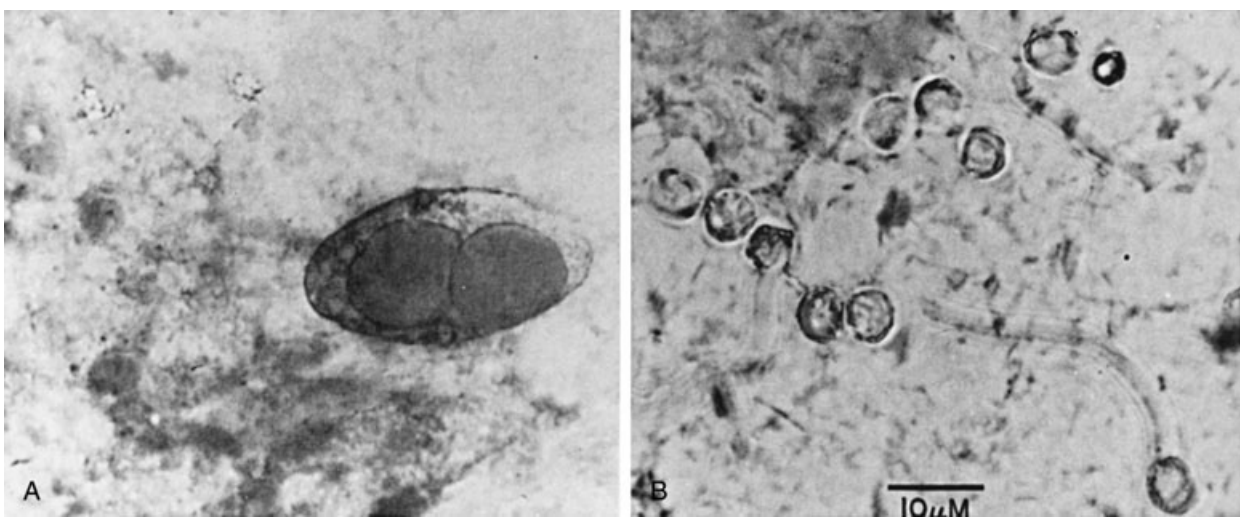

Figure 229–3 Unconcentrated fresh stool sample from two patients with AIDS stained with modified Kinyoun stain. **A,** *Isospora belli*. **B,** *Cryptosporidium*. Note the difference in size and shape of the two coccidian parasites; *Isospora* averages 25 × 15 μm and contains two sporoblasts, whereas *Cryptosporidium* averages about 5 μm in diameter. *(From DeHovitz, J. A., Pape, J. W., Boncy, M., et al.: Clinical manifestations and therapy of* Isospora belli *infection in patients with the acquired immunodeficiency syndrome. N. Engl. J. Med.* 315:87-90, *1986.)*

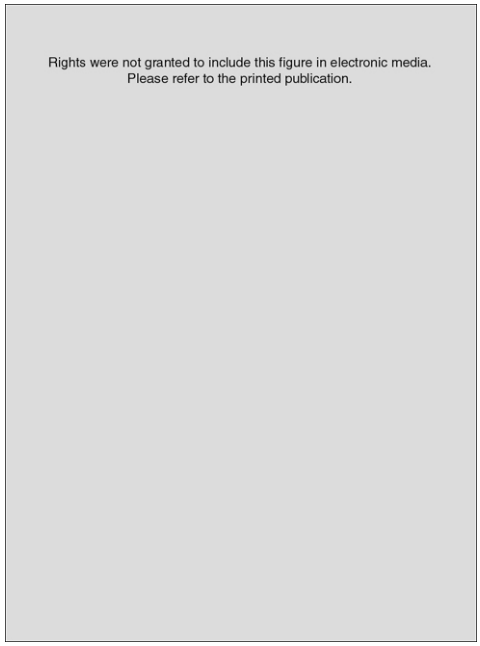

Figure 229–4 *Isospora* infecting the jejunum of a patient with severe diarrhea. Trophozoites (T) divide within enterocytes by schizogony to form merozoites (M). *(From Garcia, L. S., Owen, R. L., and Current, W. L.: Isosporiasis.* In *Balows, A., Hausler, W. J., Jr., Ohashi, M., and Turano, A. [eds.]: The Laboratory Diagnosis of Infectious Diseases: Principles and Practice. Vol. 1. New York, Springer-Verlag, 1988, pp. 899-903.)*

merozoites rarely are found in the intestinal lumen or the lamina propria.[28]

Isosporiasis is characterized by massive fluid loss suggestive of toxin-mediated hypersecretion, but no enterotoxin has been identified.[136] The pathophysiology of isosporiasis has not been defined; however, cell-mediated immunity seems to be important in the pathogenesis of villous changes. Activated T cells are mitogenic to enterocytes, and this mitogenic activity results in crypt hyperplasia, which leads to villous atrophy. Local T-cell activation results in the release of lymphokines, increase in intraepithelial lymphocytes, and enhanced expression of HLA-DR antigens on enterocytes of the villi and crypts. Intestinal mast cells also may play a role in the pathogenesis by releasing a collagen IV protease.[21]

CLINICAL MANIFESTATIONS

The clinical findings are indistinguishable from the findings of other enteric coccidian parasites. The spectrum of disease ranges from asymptomatic infection to severe, protracted, life-threatening diarrhea. Immunocompetent patients usually have a self-limited illness that resolves spontaneously over several weeks.[136,165,203] Headache, malaise, vomiting, fever, and dehydration may be noted. Recurrent symptoms and chronic illness may occur.[104] The disease is more severe in infants and children than in adults,[103,175] and intractable diarrhea has been reported in infants.[86]

In patients with HIV/AIDS, *I. belli* infections occur more frequently when the $CD4^+$ count is less than 200 cells/mm^3, and asymptomatic infection is uncommon in this patient population (2% of all infections).[25] These patients tend to have a more severe illness that may be life-threatening. Other conditions that predispose to a more severe illness include alpha-chain disease, acute lymphoblastic leukemia, Hodgkin disease, human T-cell lymphotropic virus type 1–related T-cell leukemia, and non-Hodgkin lymphoma.[147,150] In these patients, the onset of illness is insidious and associated with nonspecific symptoms, such as low-grade fever, headache, malaise, myalgia, and anorexia.[37,136] Nausea, vomiting, and diffuse crampy abdominal pain also are present. The stool is watery and may contain mucus, but does not contain blood or leukocytes. Chronic intermittent diarrhea with a mean duration of 7.9 months (range 2 to 26 months) is the major clinical manifestation.[138] Dehydration occurs in 70 percent of patients and requires intravenous fluids in 10 percent. The average daily fluid loss is 2 L, with some patients losing 20 L.[136] Malabsorption, steatorrhea, severe weight loss (>10% of body weight), and lactose intolerance have been reported.[20,37,176,201] Charcot-Leyden crystals are a common finding in stool. Peripheral eosinophilia occurs in more than 50 percent of patients.[85,138] Nonspecific radiographic findings include prominent mucosal folds, thickening of the intestinal wall, and disordered motility.[165]

Biliary disease and extraintestinal manifestations of *I. belli* are rare, but have been reported in patients with AIDS.[21,117,148] The organism has been identified in tracheobronchial, mediastinal, and mesenteric lymph nodes; the spleen; and the liver.[117,148] Acalculous cholecystitis has been reported.[11] A case of coccidial endometriosis in an immunocompetent patient also was attributed to *I. belli* based on the microscopic identification of intracytoplasmic oocysts that contain sporoblasts.[39]

DIAGNOSIS

The diagnosis is made by identifying oocysts in stool or by visualizing the parasite in biopsy specimens of the small intestine.[17,138,165] Similar to *Cryptosporidium*, *Isospora* can be detected in stool by using modified acid-fast or auramine-rhodamine stain. Organisms are sparse, so concentration techniques such as zinc sulfate, hypertonic sodium chloride, formalin-ether sedimentation, and Sheather sucrose solution are used to enhance recovery.[136,165] The oocysts also can be identified in stool by using lacto-phenol cotton blue staining.[139] The thin translucent wall of the oocyst may be difficult to identify in stool preserved in polyvinyl alcohol.[108]

Isospora oocysts are distinguished easily from *Cryptosporidium* oocysts. They are oval, contain one or two sporoblasts, and are 10 times larger than *Cryptosporidium* oocysts. In comparison, *Cryptosporidium* oocysts are round, contain four sporozoites, and measure 2 to 5 μm in diameter (see Fig. 229–3). The oocysts of *I. belli* exhibit autofluorescence with an ultraviolet epifluorescent illuminator (450 to 490 nm excitation filter).[108] The sensitivity of autofluorescence is significantly higher than that of light microscopy using iodine staining (95.7% versus 48.4%).[14] The sensitivity and specificity of the other methods for detection of *Isospora* in stool are unknown.[136] It is possible to detect the parasite by biopsy and not visualize oocysts in stool.[20] The parasite usually is found in the proximal part of the small bowel (Fig. 229–5). In patients with AIDS, it can be found in the small and large intestines.

TREATMENT

The treatment of choice is trimethoprim-sulfamethoxazole given four times a day for 10 days.[37,138,165,201] Patients who have been symptomatic for months usually have resolution in less than 1 week with this treatment. Pyrimethamine-sulfadoxine (Fansidar) is an alternative agent. For a sulfonamide-allergic patient, ciprofloxacin[185] and pyrimethamine[199] alone are alterna-

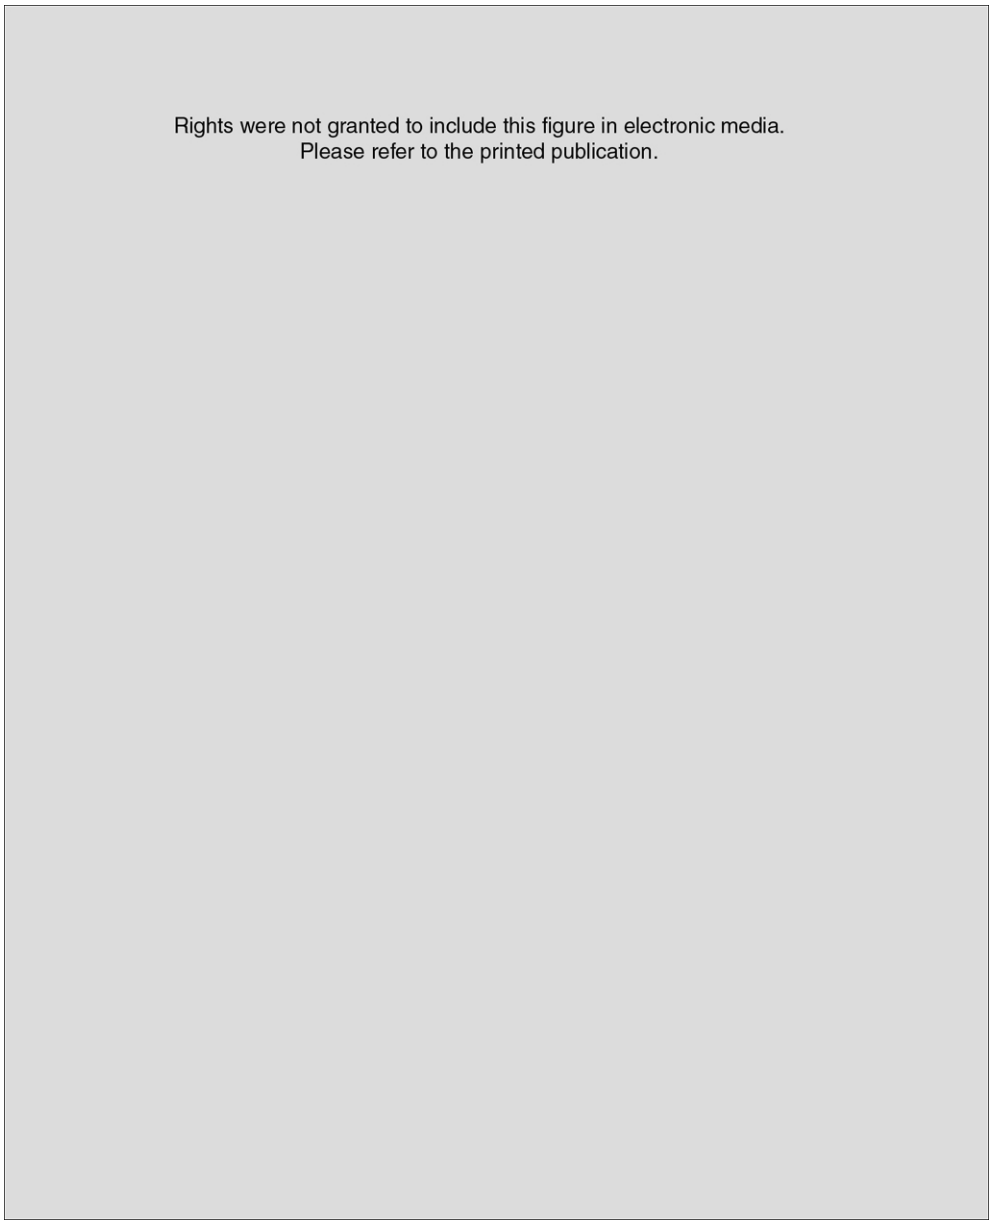

Figure 229–5 Jejunal biopsy from a patient with AIDS and severe diarrhea. Various developmental stages of the intestinal microsporidian *Enterocytozoon* infect almost every enterocyte. Stages include proliferative plasmodia *(1)*, early sporogonial plasmodia *(2)*, late sporogonial plasmodia *(3)*, and mature spores *(4)*. A spore *(arrow)* can be seen within a necrotic enterocyte, which appears ready to slough into the lumen. *(From Cali, A., and Owen, R. L.: Intracellular development of* Enterocytozoon*: A unique microsporidian found in the intestine of AIDS patients. J. Protozool. 37:145, 1990.)*

tive agents. Ciprofloxacin[185] is not as effective as trimethoprim-sulfamethoxazole and is not approved by the U.S. Food and Drug Administration for children younger than 18 years. Data on the use of macrolides and metronidazole are limited to uncontrolled studies.[55,104]

Fifty percent of patients with AIDS and isosporiasis have recurrences.[37,138] Prophylaxis with trimethoprim-sulfamethoxazole, (160 mg/800 mg) three times a week, or sulfadoxine-pyrimethamine, (500 mg/25 mg) once a week, is necessary to prevent relapse.[138] Ciprofloxacin can be used as an alternative prophylaxis agent for sulfonamide-allergic adolescent patients older than 17 years.[185] Pyrimethamine is an alternative prophylaxis agent, but data on its use are limited, especially in pediatric patients.[199]

MICROSPORIDIOSIS

Microsporidiosis is caused by an extensive group of obligate intracellular, phylogenetically ancient spore-forming parasites that infect vertebrate and invertebrate animals.[10,193] In humans, microsporidia were detected first in cerebrospinal fluid in 1959 in Japan in a child with seizures.[110] This infection has been reported infrequently in normal hosts. The number of cases described has increased since 1985, after recognition of the diarrhea and wasting syndrome in patients with AIDS. The pathogenic role in other immunocompromised individuals remains to be studied, as do the mode of transmission and sources of infection. The broad range of clinical manifestations includes kerato-

conjunctivitis, sinopulmonary infection, myositis, cholecystitis, hepatitis, and disseminated infection with tubulointerstitial nephritis.[193]

MICROBIOLOGY AND LIFE CYCLE

Microsporidians were reclassified more recently. Based on genomic and phylogenetic studies, they now are part of the domain Eukaryota, supergroup Opisthokonta, first rank subgroup Fungi, second rank subgroup Microsporidia.[2] They are characterized by the presence in the spore stage of an extrusion apparatus with a polar tubule that allows transfer of protoplasmic material into the host cell to occur.[155,193] The number of genera and species known to cause human disease increases as diagnostic abilities improve.[172] In addition, in vitro studies of a nonhuman microsporidian, *Tubulinosema ratisbonensis*, show that it is able to infect human cell lines, indicating that it could cause opportunistic zoonoses when the host immune defenses are impaired.[56] To date, nine genera have been identified that infect humans: *Enterocytozoon*, *Encephalitozoon*, *Nosema*, *Trachipleistophora*, *Vittaforma*, *Pleistophora*, *Anncaliia*, *Brachiola*, and *Microsporidium*.[38,109]

The genus *Microsporidium* groups together all unclassified microsporidia. Subclassification of these organisms traditionally has been based on morphologic characteristics of the stages of the parasite. More recent advances in differentiation are based on phenotypic (protein antigenic patterns) and genotypic characteristics as determined by PCR techniques, small-subunit ribosomal RNA patterns, restriction fragment length polymorphism, and subspecies-specific monoclonal antibodies.[36,70,120,153,173,187] These studies have allowed the genus *Septata* to be reclassified into the previously known *Encephalitozoon*.[36] *Encephalitozoon hellem* is differentiated from *Encephalitozoon cuniculi* by antigenic and molecular analysis.[123,151] A final taxonomic classification may develop after more precise molecular analysis is conducted.[193]

These spore-forming unicellular organisms are true eukaryotes. Historically, they were thought to lack mitochondria, and their small ribosomal RNA and ribosomes caused them to be thought of as an early phylogenetic group that diverged from prokaryotes before the endosymbiosis of mitochondria by the other eukaryotes. Nonetheless, their nuclear genes encode mitochondrial heat shock protein Hsp70, and anti-Hsp70 antibodies show localization within a small organelle with a double membrane, reminiscent of mitochondria, although it has lost its aerobic function.[202]

The asexual life cycle in the host cell is divided into two phases: the merogonic or proliferative vegetative phase and the sporogonic phase, which results in the production of mature spores.[155] Intracellular stages proliferate by binary or multiple fission and appear as multinucleated elements that can be in direct contact with the cell cytoplasm (e.g., *Enterocytozoon bieneusi*, *Nosema* spp.) or engulfed in a parasitiferous vacuole (*Encephalitozoon* spp.). In the case of *Encephalitozoon intestinalis*, septa are formed by a fibrillar structure.[193] The spore consists of a surrounding protective three-layered wall and internal infective nucleated material that is injected into the host cell by extrusion of a coiled polar tubule attached to an anchoring disk. The average size of the vegetative stages ranges from 2 to 6 × 1 to 3 μm, and the average size of the spores ranges from 0.7 × 1.64 μm (*E. bieneusi*) to 3 × 5 μm (*Nosema ocularum*). Cell culture systems are available for a few species, including *Nosema corneum*, *E. hellem*, and *E. intestinalis*.[36,70,122,156,180,196] These isolated organisms are useful for the development of specific antisera that may allow the microsporidial species to be differentiated.

EPIDEMIOLOGY AND TRANSMISSION

Precise data on the incidence, relevant reservoirs, source of infection, and mode of transmission are undefined. Symptomatic cases have been documented in non–AIDS-infected patients, and half of them had evidence of altered immune status.[68,191] Few cases of self-limited diarrhea have been reported in apparently normal hosts.[53,191] In HIV-infected patients, approximately 25 to 50 percent of cases of chronic diarrhea of undetermined etiology, or roughly 15 percent of the total cases of diarrhea, may be caused by these organisms.[16,97,123,181,182] The percentages have varied, depending on the population studied and the diagnostic techniques used. Young homosexual or bisexual adults[9,51,145,173] and severely immunosuppressed children with congenital HIV can be affected.[197] The prevalence of microsporidia (as detected by light microscopy) in the stool of HIV-infected patients is almost 4 percent in Lima, Peru.[171] *E. bieneusi* has been the most prevalent microsporidium and is found primarily in individuals with $CD4^+$ cell counts less than 100/mm^3.[3,41,51] Second in frequency are *E. intestinalis*, *E. hellem*, and *E. cuniculi*.[193] Asymptomatic infection and persistent carriage in immunosuppressed patients have been reported.[145] The other microsporidia infecting humans have been reported much less frequently.[40]

Microsporidia are ubiquitous in nature, and some of the species infecting humans are present in animals: *E. bieneusi* (pigs, nonhuman primates), *E. hellem* (parakeets), *E. cuniculi* (rabbits, dogs, horses), *E. intestinalis* (gorillas), and *Pleistophora* spp. (fish).[40,46,67,102] The major human microsporidian pathogens all have been identified in animals that commonly are in contact with human populations, such as pigeons in urban parks[69] or aquatic birds,[161] suggesting that microsporidiosis may be a zoonotic infection or may be transmitted via water, or both. The zoonotic potential of these organisms is supported by genotypic studies that show identical genotypes across species (e.g., human and monkey).[46]

Disease caused by contamination of water and food has been reported.[30] Ways of eliminating the infectivity of the microsporidian spores are being studied. Food that undergoes high-pressure processing of at least 345 MPa eliminates infectivity of the spores.[88] Similarly, treatment with commercial bleach, 70 percent ethanol, and the commercial disinfectants HiTor and Roccal also can eliminate spore infectivity. The duration of treatment necessary to do so increases as the solution used is diluted further.[87] Disinfection protocols for water also are being evaluated. They include filtration, coagulation, chlorination, gamma-radiation, and ozonation.[42]

An aerosol route of bronchopulmonary infection with species that are not found in the gut, such as *Encephalitozoon*, is supported by histopathologic findings in the bronchial tract.[196] Direct contact with conjunctival mucosa is postulated to be the source of ocular infections.[129] Serologic surveys using *E. cuniculi* antigens have found antibodies in multiple population groups, but they probably represent cross-reactivity with either various microsporidia species or other organisms.[155] *Nosema* is the only member of this group not reported in AIDS-infected patients; rather, it has been described as a disseminated infection in children with thymic aplasia and as local keratitis in normal hosts with or without previous trauma.[156,193] *Pleistophora* infection may be manifested as myositis infiltrating muscle fibers and may cause atrophy and degeneration.[99]

Co-infection with other opportunistic agents, including cytomegalovirus, *Mycobacterium avium–intracellulare*, *Cryptosporidium*,[113] and other parasites, has been reported in 5 to 60 percent of cases.[9,59,97,123,128,145] Unsuspected *Cryptosporidium* infection may be found in 20 percent of patients with microsporidia.[63]

PATHOPHYSIOLOGY

Despite the growing number of reports of microsporidiosis, the mechanism of disease in humans has remained largely unknown.[193] Latent asymptomatic infection or acute disease has not been described fully in humans. With the exception of local ocular disease, the parasite proliferates when immunologic defenses are defective, especially cell-mediated immunity.[45,122] The reason behind the different clinical pictures seen with the different microsporidioses also is unclear.[58] The immunopathogenic response of the human hosts to microsporidia has begun to be elucidated only more recently.

The portal of entry of the microsporidia into human cells always has been thought to be through cellular impalement by the deployed apical polar tube.[100] Some debate has ensued, however, about the role that parasite phagocytosis may play. Studies of *E. cuniculi* infection of human cell lines revealed that spores gain intracellular access through a parasitophorous vacuole more frequently than by polar tube impalement. Some of these spores would extrude their polar tube within the vacuole to gain access to the cytoplasm.[50,60] Whether or not this vacuole is a phagocytic vacuole is still debatable. Study of the membrane protein composition of the parasitophorous vacuole of *E. cuniculi* shows absence of host membrane proteins, especially markers of the endophagocytic pathway, 1 minute post-infection, the significance of which is unknown. If not phagocytic in nature, the origin of the parasitophorous vacuole remains to be elucidated.[50]

Other studies of human cell lines infected with *E. intestinalis* revealed that the parasite can gain access into mature cell lines only through impalement, where there was a modest role for phagocytosis into undifferentiated cell lines. The attachment of the parasite to the cell surface can be inhibited by chondroitin sulfate A (a sulfated glycan), and certain cells show a higher attachment propensity than others, which correlates with higher infectivity of these cells.[100] The use of exogenous nonsulfated glycans does not decrease attachment,[71] indicating a role for cell-surface sulfated glycosaminoglycans in mediating parasite attachment, which correlates with infectivity.[71,100] It is possible that the importance of cell membrane impalement with the polar tube as a means of entry into the host cells varies among the different microsporidian species.

As for the variability of the clinical picture with the different microsporidioses, cellular uptake studies showed a difference in the extent of uptake of microsporidian spores by different human cell lines, but all cell lines were able to internalize microsporidian spores. This finding suggests that a combination of cellular specificity and route of transmission might be at play in deciding what ensuing clinical picture might emerge.[58]

After entry into the cell, several pathogenic processes occur, the actual sequences of which remain to be elucidated. In vitro studies of infected macrophages revealed a specific pattern of inflammatory chemokine up-regulation 6 hours post-infection. These chemokines lead to a 2.9-fold increase in migration of naive cells about 48 hours post-infection. The different chemokines are involved in the recruitment of different cell types (monocytes, neutrophils, lymphocytes, eosinophils), consistent with the histopathologic observation of cell aggregates from different cell lines in patients with microsporidiosis. Neutralization of these chemokines resulted in blunting of the cellular chemotactic response. The fact that a delay occurs before the chemotactic response is noted could represent a parasitic immune-evasion characteristic, to provide enough time for invasion of and replication in human cells.[52]

Other studies showed that the different *Encephalitozoon* spp. inhibit caspase-3 cleavage and the activation of the p53 pathway, failing to activate the cellular apoptotic pathway, which allows it to replicate intracellularly.[38] The nitric oxide response similarly is inhibited.[57] Investigators also have shown that *E. cuniculi* expresses a microsporidial aquaporin (EcAQP) onto the surface of the spore and the infected cells. EcAQP is similar to the human aquaporin channel (AQP), but it lacks the cysteine residues that line AQP, which renders it resistant to mercury inhibition. This EcAQP is purported to mediate a rapid water influx into the spores, a step considered to be necessary for the infectious process.[64]

Finally, whether it is important for cell entry or extruded after entry into the cell, the polar tube plays an important role in the infectivity of the microsporidians. The polar tube of *E. hellem* consists of three proteins (PTP1, PTP2, and PTP3). PTP1 is the major protein. It is modified post-translationally by *O*-mannosylation, which seems to allow it to interact with some intracellular mannose-binding protein, which is essential for its infectivity because pretreatment of the cell culture with mannose decreased the infectivity of *E. hellem*. Presumably, this factor is due to competitive inhibition of the yet-to-be-identified cellular mannose-binding protein.[208]

These in vitro studies elucidate the first steps in understanding the microsporidioses. Whether the infected macrophages act as a carrier for dissemination of the microsporidians and what the subsequent steps are in the infection process remain to be elucidated.[52]

The different microsporidians exhibit diverse histopathologic characteristics. *E. intestinalis* can reach the submucosa; its presence in the kidneys and lower airways presumably results from systemic dissemination.[45,122] Mucosal injury, characterized by partial villus atrophy and crypt hyperplasia, correlates with xylose malabsorption and decreased activity of mucosal disaccharidases.[96]

Other types of encephalitozoonosis, including infection with *E. cuniculi* and *E. hellem*, have greater potential for dissemination.[153] *Encephalitozoon* infects macrophages and can disseminate to the liver, brain, kidneys, or sinuses and cause randomly distributed granulomatous lesions.[40] *E. cuniculi* has been reported in children with seizures,[13,110] hepatitis, peritonitis, and disseminated infection. It has been found in conjunctival and sinopulmonary infections associated with colonization of the intestinal tract.[61] The portal of entry for the organism in these cases is uncertain. *E. hellem* may involve the urinary tract, bronchial epithelium, and conjunctiva.[153] In sections of corneal scrapings, the cytoplasm of superficial epithelial cells contains vacuoles with the granular organisms, but these vacuoles cause minimal nuclear distortion.[22] *E. bieneusi* almost always is limited to the intestinal and biliary tract; it has a preference for enterocytes in the small intestine. The organism produces a limited inflammatory reaction and abnormalities in villi.[51] It rarely invades the lamina propria, but, exceptionally, respiratory epithelia may be infected.[195]

When infection occurs, the immune response that the host mounts determines the outcome. IgM antibodies against the polar tube seem to be protective. Their highest level is in young healthy adults, with levels decreasing with age. HIV-infected individuals with $CD4^+$ cell counts less than $250/mm^3$ do not produce these antibodies.[127]

CLINICAL MANIFESTATIONS

INTESTINAL AND BILIARY TRACT MICROSPORIDIOSIS

Typically, microsporidiosis manifests as chronic diarrhea and wasting syndrome in severely immunodeficient HIV-infected patients ($CD4^+$ cell count $<100/mm^3$).[9,52,123,173] AIDS-infected

patients with $CD4^+$ cell counts greater than 200/mm^3 tend to have self-limited diarrhea. In some cases, microsporidiosis is the AIDS-defining opportunistic infection.[112,128] Transplant recipients also are at risk for acquiring these pathogens.[30] The usual symptom is afebrile, loose to watery, nonbloody, nonmucoid diarrhea consisting of 3 to 20 bowel movements per day, which is worsened by food intake and associated with progressive weight loss, malabsorption, and anorexia.[9,129] Absorption of fat, D-xylose, and zinc is abnormal.[9,123] Persistent or intermittent symptoms may lead to severe cachexia by a combination of decreased intake and malabsorption.[173] Half of patients have abdominal pain; some complain of nausea and vomiting.[128] Affected children may have failure to thrive, chronic diarrhea, and intermittent abdominal pain.[197] Sporadic cases of *E. bieneusi* and *E. intestinalis* causing self-limited diarrhea with diffuse abdominal pain and nausea in immunocompetent individuals have been reported.[53,189,191]

Patients with cholangitis and acalculous cholecystitis have right upper quadrant abdominal pain. Imaging studies may reveal dilation of the intrahepatic and common bile ducts or irregularities of the bile duct and gallbladder wall. AIDS cholangiopathy is similar to cholangiopathy associated with cytomegalovirus and cryptosporidial infection.[142]

OCULAR INFECTION

Immunocompetent patients with histologically confirmed ocular infection with *Microsporidium ceylonensis*, *Nosema* spp. (*Nosema corneum* and *Nosema ocularum*), *Vittaforma corneae*, and *Trachipleistophora hominis* have been reported.[32,146,156,193] In India, the 2-year incidence of microsporidial keratoconjunctivitis in immunocompetent patients is approximately 0.4 percent, with a presentation duration of symptoms of approximately 1 week (range 1 day to 2 years). The infection in these patients is mostly unilateral and may be associated with previous trauma or bathing in contaminated water. The infection may lead to a progressive decrease in visual acuity secondary to severe corneal stromal disruption or corneal ulcer. The prognosis for full recovery usually is favorable.[91] The most common finding on slit-lamp examination in immunocompetent individuals is a stromal keratitis,[92] although atypical punctate epithelial keratitis with a mild nonpurulent conjunctivitis also has been reported.[91] Involvement of the posterior segment has been reported in a patient with longstanding psoriasis. She had sclerouveitis with retinal detachment caused by *Nosema*.[119]

Encephalitozoon spp. (in particular, *E. hellem*, but also others) are a cause of keratoconjunctivitis and scleritis in HIV-infected patients and other immunodeficient patients; symptoms in these patients include conjunctival inflammation, photophobia, blurred vision, a foreign body sensation, decreased visual acuity, and punctate epithelial keratopathy.[94,129,154] The lesion usually is bilateral and not associated with ocular trauma. Occasionally, ocular involvement is accompanied by evidence of disseminated infection.[68,94] Intrastromal keratitis caused by *Trachipleistophora anthropopthera* also has been reported in an HIV-infected patient.[140]

SYSTEMIC MICROSPORIDIOSIS

Disseminated systemic infection may develop in HIV-positive patients. *E. cuniculi* and *E. hellem* have been associated with tubulointerstitial nephritis, ureteritis, cystitis, conjunctivitis, and colonization or infection of the respiratory tract; these findings may occur in the absence of gastrointestinal symptoms.[36,68,187,191,196] Flank pain, hematuria, and dysuria are symptoms of urinary tract involvement, and progressive nonproductive cough, wheezing, and pleuritic pain are seen with lower respiratory involvement. Disseminated *E. cuniculi* infection involving the intestinal tract has been reported.[61] *E. intestinalis* infection usually is limited to the intestinal tract, although systemic manifestations consisting of urinary tract involvement (interstitial nephritis) and sinopulmonary dissemination may occur after invasion of the intestinal lamina propria.[45,68,122] Disseminated disease also may occur in other immunosuppressed, non–HIV-infected patients, such as kidney transplant recipients.[62] Serologic evidence (enzyme immunoassay and counterimmunoelectrophoresis) also shows that *E. intestinalis* causes central nervous system infection characterized by severe headache and seizures in HIV-infected patients.[182]

Disseminated *Nosema conorii* infection has been described in an immunodeficient athymic child with chronic diarrhea, fever, and weight loss. The parasite was found in the myocardium, diaphragm, kidney tubules, liver, and lungs.[155]

Severely immunosuppressed hosts may be predisposed to the development of myositis (caused by *Pleistophora ronneafiei*, *T. hominis*, or *Brachiola algerae*) with nonspecific symptoms of generalized muscle weakness or myalgias and elevated creatinine phosphokinase. The myocardium also may be involved, and the infection may be fatal in this instance. Muscle biopsy provides a definitive diagnosis.[23,24,31,33,101]

Sinusitis with a mucopurulent nasal discharge or lower respiratory tract involvement with bronchiolitis, pneumonia, and respiratory failure has been described with *E. bieneusi* and *Encephalitozoon* spp.[19,174,195] The source of the organism is unknown and may represent primary respiratory acquisition or secondary dissemination from other mucosal surfaces.[174]

DIAGNOSIS

A definitive diagnosis is made by direct morphologic demonstration of organisms in stool, body fluids (duodenal aspirates, bile, bronchoalveolar lavage fluid, nasal secretions, urine, conjunctival smears, cerebrospinal fluid), or tissue sections[46,68,122,123,193,194]; microsporidia sometimes can be cultured.[122] Light microscopy is reliable, although the small size and the staining properties of microsporidia render recognition difficult to establish. Electron microscopy usually is necessary to define the ultrastructural features of the different genera. Immunologic, molecular, antigenic, and biochemical analysis of isolated organisms can be performed if ultrastructure does not allow differentiation among similar species.[36,70,153,196]

Weber chromotrope–based stain,[192] with modifications[151] that allow better resolution from background, has shown good sensitivity and specificity for the analysis of unconcentrated stool samples and other body fluids, including urine.[9,35,41,45,68,196,198] Under oil immersion, the pinkish red spore wall of microsporidia must be differentiated morphologically from some yeast elements and bacteria.[173] Uvitex 2B[35,179,181] and calcofluor white[105] are useful, but fungi can give false-positive results.[41] Giemsa stain seems less satisfactory for stool analysis.[173] It is unclear whether intermittent shedding occurs, so multiple stool samples are needed for detection.[10,123] Acid-fast staining has been attempted with some success in the cytologic examination of centrifuged fluids.[142] In corneal scrapings, potassium hydroxide with calcofluor white and acid-fast stains yield the highest accuracy (96.7% and 93.3%).[89]

Recognition of microsporidia by light microscopy[96,123,195] in paraffin-embedded tissue sections has been reported with routine techniques, including hematoxylin and eosin,[129,153] tissue Gram,[129,153,173] periodic acid–Schiff, silver,[51] and Giemsa stains.[149,173] The accuracy of each technique is related to the intensity of infection[181] and the level of training of the individual performing the analysis. The spores often are on the surface of the villi; the multinucleated sporogonial stage appears as a col-

lection of granules that is confused easily with cytoplasmic organelles.[128,129] Some workers prefer touch preparations of small intestine stained with Giemsa.[10,123,160] Histologic examination of ultrathin plastic sections stained with toluidine blue or methylene blue azure II fuchsin stain may increase the sensitivity.[129,173] Differentiation of the spores by immunofluorescence assay may allow investigators to identify the species.[6,63,154,192,196] Monoclonal antibodies produced against isolated microsporidia may permit speciation in cytologic and histologic analysis.[5,187] Cross-reactivity of *Encephalitozoon* antisera has been used in establishing the diagnosis of *E. bieneusi* infection in stool and intestinal biopsy tissue.[5,210] In ocular microsporidiosis, conjunctival and corneal scrapings or biopsy samples prepared with Giemsa and other routine histologic stains can be used in establishing a diagnosis.[22,129] Less invasive conjunctival swabs may be positive, with the same stains as used for stool samples.[122,196]

Electron microscopy of stool, body fluids, and tissue sections[68,122,129,142,145,173,196] is considered the gold standard for confirmation of infection; it allows evaluation of the multiple stages of the parasite in tissues. The sensitivity may be lower than that of other techniques for the detection of spores in stool and urine specimens.[34] Successful isolation of *Encephalitozoon* and *N. corneum* is possible with the use of several cell lines.[36,70,122,156,180,196]

Serologic tests were available first for *E. cuniculi* infection.[13] The sensitivity and specificity are unknown, and cross-reactivity is likely. Presumed *E. intestinalis* infection has been diagnosed in AIDS-infected patients by enzyme-linked immunosorbent assay and counterimmunoelectrophoresis techniques.[182] Another method that has been applied to the rapid identification of whole organisms and spores is the matrix-assisted desorption ionization time of flight mass spectroscopy, which identifies unique spectral markers of each of the different species.[124] PCR testing also is helpful in establishing the diagnosis of microsporidiosis[59,76,121] and in identifying the different species in clinical samples, whether on intestinal biopsy specimens in disseminated disease,[36,187,196] on corneal scrapings or biopsy sample in microsporidial keratitis,[29,90] or on stool samples in patients with diarrhea.[1,98,204] Differential hybridization, in conjunction with PCR, can allow specific species identification with high sensitivity and specificity (95% and 100%).[126,178,188] When DNA extraction uses the FTA filter method (whatman Bioscience, Cambridge, United Kingdom) the PCR sensitivity reaches 100 percent.[170] In addition, real-time PCR can be used to monitor response to treatment and to monitor dissemination to blood or serum.[114,115] Direct comparison of PCR with light microscopy revealed that lower spore levels, such as seen in asymptomatic cases, can be detected by PCR, but are missed with light microscopy.[125] The sensitivity and specificity of light microscopy is approximately 86.7 percent and 100 percent.[170]

TREATMENT

In ocular infection, keratoplasty often is required to clear the infection. Keratoplasty usually is followed by systemic (albendazole, itraconazole) and usually topical (fumagillin, propamidine isothionate) therapy.[54,140,168,184] In systemic disease, control of HIV infection is the most effective means of controlling infections caused by microsporidia. In patients who fail to respond to antiretroviral therapy, other measures may be necessary.

At present, albendazole is the only treatment that may be useful for enteric and systemic infections caused by *E. intestinalis* and other *Encephalitozoon* spp.[9,47,51,121,122,167,198] It binds tubulin-inhibiting microtubule assembly.[177] Intestinal *E. bieneusi* infection responds inconsistently to albendazole.[16,189] Treatment with albendazole may lead to improvement in diarrhea without eradication of spores in the stool specimens obtained; diarrhea eventually may recur.[122,123,198] Stool volume and frequency are reduced with a low-fat, low-residue diet.[9] Fumagillin, an antibiotic made by *Aspergillus fumigatus*, is an effective topical therapy for microsporidial corneal disease, and an oral preparation (not available in the United States) is the drug of choice for intestinal *E. bieneusi* infection.[43] Fumagillin is an inhibitor of the microsporidian methionine aminopeptidase type 2 (MetAP2), which is essential for microsporidia growth.[177] Given this lack of effective therapies, a search is on for novel treatments. They include the following:

1. Glycosaminoglycan inhibitors would inhibit spore binding to the cell surface.[100]
2. Anti–polar tube antibodies, especially against the post-translational *O*-mannosyl moiety of PTP1, have been shown to be protective.[208] One potentially could devise vaccines that lead to the production of these antibodies.[141]
3. Microsporidian aquaporin inhibitors would impair spore germination.[64]
4. Growth inhibitors, such as inhibitors of MetAP2, would be less toxic than fumagillin[18,177,190] or inhibitors of aspartyl protease, another enzyme essential for microsporidia growth. This latter enzyme was identified as a potential therapeutic target when it was noted that HIV-positive patients treated with protease inhibitors showed disease clearance beyond what would be expected from immune reconstitution alone.[116]
5. Competitive inhibitors of chitin synthesis would be helpful, chitin being an essential element in the wall of these organisms. In vitro studies of polyoxin D and nikkomycin Z seem promising, with the former being 10-fold more effective.[167]
6. Flavonoids and isoflavones have been shown in in vitro studies to be effective against microsporidia, either alone or in conjunction with other drugs to augment their efficacy.[113]

CHAPTER 230

BABESIOSIS

Peter J. Krause

The first reference to babesiosis may have been in the Bible, where a widespread murrain or plague in cattle and other domestic animals is described in Exodus, Chapter 9, Verse 3: "Behold, the hand of the Lord is upon thy cattle which is in the field, upon the horses, upon the asses, upon the camels, upon the oxen, and upon the sheep: there shall be a very grievous murrain." The word "murrain" still is used to describe red-water fever, a form of babesiosis found in cattle in parts of Ireland.[23] Babesiosis long has been recognized as an important disease in livestock, having a significant economic impact in many parts of the world; the health burden of babesiosis in humans has been recognized only more recently.[23,33,56]

Babesiosis is a disease caused by an intraerythrocytic protozoon that is transmitted by ticks and has many clinical features similar to those of malaria. The parasite first was described in animals in 1888 by Babes.[4] In 1893, it became the first microorganism shown to be transmitted by arthropods when Smith and Kilbourne[115] identified a tick as the vector for a species of babesiosis (*Babesia bigemina*) in Texas cattle. The first human case was described in 1957.[112] During the past 30 years, the epidemiology of the disease has changed from a few isolated cases to the establishment of endemic areas in southern New England, New York, and the north-central Midwest, and reports have come from a wide geographic range in North America, Europe, Asia, Africa, and South America. Evidence indicates that the disease is more common in children and adults than is currently reported.[58,61]

EPIDEMIOLOGY

Worldwide, more than 70 species in the genus *Babesia* infect a wide variety of wild and domestic animals. *B. bigemina*, *Babesia bovis*, *Babesia divergens*, and *Babesia major* are found in cattle; *Babesia equi* is found in horses; *Babesia canis* is found in dogs; *Babesia felis* is found in cats; and *Babesia microti* is found in rodents.[68] Each species previously was thought to be host-specific, but the host range of some species now is recognized to be quite broad.[43,67,68,119,125] Some confusion has occurred in taxonomy because the identification of different *Babesia* spp. has been based largely on morphology and the vertebrate host.[41] Most *Babesia* spp. are small (1 to 5 μm in length) and pear-shaped, round, or oval.[67] Seven *Babesia* spp. have been found to cause disease in humans: *B. microti*, *Babesia duncani*, *B. divergens*, EU1, MO1, KO1, and TW1.[21a,44,44a,45,64,90,110,129a]

Human babesiosis is a zoonotic disease transmitted by a tick vector from an infected animal reservoir (Fig. 230–1). Humans are an uncommon and terminal host for *Babesia* spp., which depend on other species for survival. The primary reservoir for *B. microti* in eastern North America is the white-footed mouse (*Peromyscus leucopus*), but the parasite also has been found in shrews, chipmunks, voles, and rats.[42,119,126] Two thirds of *P. leucopus* have been found to be parasitemic in endemic areas.[120] *Babesia* spp. are transmitted by hard-bodied (ixodid) ticks. The primary vector in the northeastern United States is *Ixodes scapularis* (also known as *Ixodes dammini*), which is the same

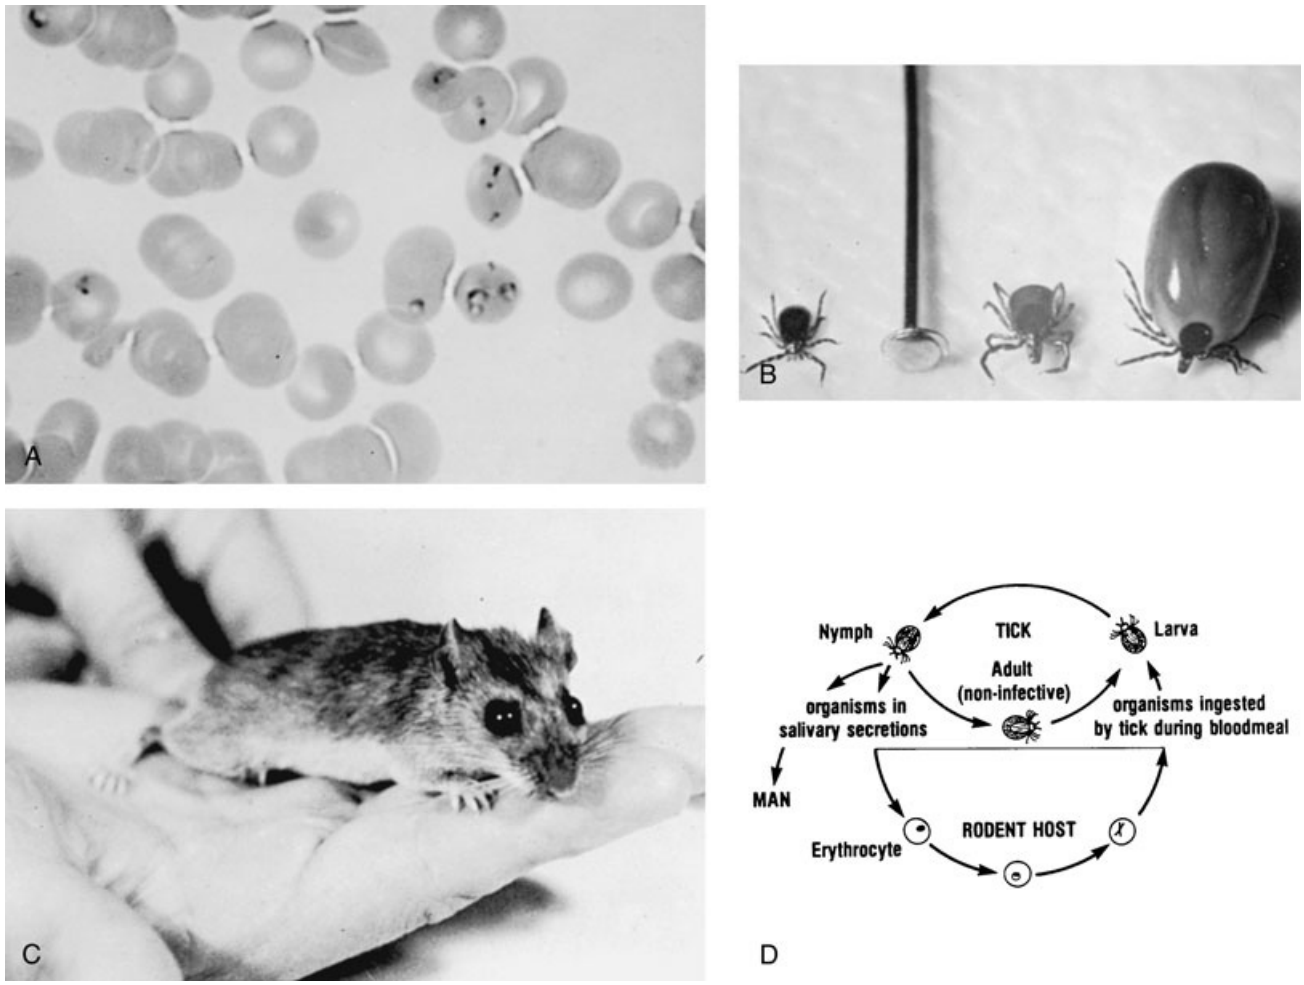

Figure 230–1 Life cycle of *Babesia microti*. **A,** Ring forms of *B. microti* in human blood film (original magnification ×1000). **B,** *Ixodes dammini* ticks and a common pin. The ticks are an adult male, an adult female, and an engorged female. **C,** White-footed mouse (*Peromyscus leucopus*). **D,** Life cycle of *B. microti*. *(**B** courtesy of Mike Frigione, Pfizer, Inc., New York, NY; **D** modified from Ruebush, T. K., II: Babesiosis.* In *Strickland, G. T. [ed.]: Hunter's Tropical Medicine. Philadelphia, W. B. Saunders, 1984.)*

tick that transmits *Borrelia burgdorferi*, the etiologic agent of Lyme disease, and the agent of human granulocytic anaplasmosis.[51,53,116-121,124,130] *I. scapularis* ticks may be infected simultaneously with *B. burgdorferi*, *B. microti*, and the agent of human granulocytic anaplasmosis.[73,86,130] Clinical and laboratory evidence exists for simultaneous human infection with two or more of these pathogens.[7,61,64,70,79,127]

Each of the three active stages in the life cycle (larva, nymph, and adult) of *I. scapularis* takes a blood meal from a vertebrate host to mature to the next stage. Ingested babesial organisms infect intestinal tissue of the tick and subsequently travel to the salivary glands, from which they may be introduced into a new vertebrate host.[87] *Babesia* spp. are transmitted to the subsequent tick stage (transstadial passage). In some species of *Babesia*, such as *B. bovis*, the organisms may invade the ovaries and pass transovarially to the larvae. The tick transmission cycle begins in late summer, when newly hatched larvae ingest the parasite with a blood meal from an infected rodent and maintain the parasite to the nymphal stage. Nymphs transmit the *Babesia* spp. to rodents in late spring and summer of the following year.[117,120] Larvae, nymphs, and adults can feed on humans, but the nymph is the primary vector.[87] All active tick stages also feed on the white-tailed deer (*Odocoileus virginianus*), which is an important host for the tick, but is not a reservoir for *B. microti*.[88,120] An increase in the deer population during the past few decades is thought to be a major factor in the spread of *I. scapularis* and the resulting increase in human cases.[40,117,120] Domestic animals such as the dog may carry the adult *I. scapularis*, but do not seem to be important hosts for the tick and are not infected with *B. microti*.[105,118]

Since the 1980s, human babesiosis has been described with increasing frequency at mainland sites, and more recent studies suggest that the endemic range continues to expand. In certain sites, in certain years of high transmission, babesiosis may constitute a significant public health burden.[58] *B. microti* has been identified in rodent populations in several regions of the United States,[2,3,34,100,119] and human cases have been reported in Connecticut, Massachusetts, Rhode Island, New York, Minnesota, Wisconsin, and New Jersey.[15,24,27,62,77,100,122]

Human babesiosis caused by organisms that morphologically are distinct from *B. microti* has been reported in Georgia and Mexico, although the precise species in these cases have not been identified.[43,109,129a] Moderately severe illness caused by *B. duncani*

occurs in Washington state and California.[84,90] *B. duncani* morphologically is indistinguishable from *B. microti*, but is antigenically and genotypically distinct.[84,90] A case of human babesiosis caused by MO1, a species that is similar to *B. divergens*, has been described in Missouri.[44] In Europe, *B. divergens* and EU1 infections are thought to be transmitted by the cattle tick *I. ricinus*, and human cases have been reported in the former Yugoslavia, France, Ireland, Great Britain, and Russia.[31,32,44a,45,129a,140] Human cases also have been reported in Asia, Africa, and South America.[11,95,110,131] An absence of clinical cases of babesiosis in the tropics may be due to cross-immunity from other endemic protozoal diseases.[52]

Most human cases of babesiosis occur in the summer and in areas where the vector tick, rodents, and deer are in close proximity to humans.[117,119,122] Rarely, babesiosis is acquired through blood transfusions.[29,32a,37,49,66a,71,114,134] Whole blood, frozen erythrocytes, and platelets have been implicated. The incubation period in these cases seems to be 6 to 9 weeks. Transplacental/perinatal transmission of babesiosis also has been described.[26,29]

PATHOGENESIS AND PATHOLOGY

Understanding of the pathogenesis and pathology of babesiosis in humans is incomplete and is based largely on information gathered from studies of babesiosis in other animals. The early cellular events of babesial entry into erythrocytes were investigated by Jack and Ward,[48] who presented data suggesting that *Babesia rodhani* penetrates the erythrocyte by activation of the alternative complement pathway. These authors found that the C3b receptor plays a key role in modification of the parasite or red blood cell, allowing entry of the parasite into the cell. Rudzinska and colleagues[53,97,98] studied the life cycle of *B. microti* in erythrocytes using electron microscopy. After adhesion and entry into the erythrocyte occur, the organism multiplies by asexual budding into two to four daughter cells, or merozoites. In contrast to *Plasmodium* spp. merozoites, which are released from the erythrocytes all at once (synchrony), *Babesia* spp. merozoites are released at varying intervals. New erythrocytes are infected, and the cycle is repeated.

It is unknown whether the initial merozoite release leads to destruction of the host erythrocyte, but alteration of the erythrocyte membrane and eventual lysis occur.[97,123] Erythrocyte lysis is associated with many of the clinical manifestations and complications of the disease, including fever, hemolytic anemia, jaundice, hemoglobinemia, hemoglobinuria, and renal insufficiency. The absence of synchrony decreases the possibility of massive hemolysis and may explain why patients heavily parasitized with *Babesia* spp. may be less ill than patients with *Plasmodium* spp.[123]

Babesia spp. are intraerythrocytic protozoa, and extracellular forms are seen only in heavily parasitized cases.[1,123] *Babesia* organisms do not invade fixed tissue, and evidence in animals suggests that disease results from the excessive production of proinflammatory cytokines (e.g., tumor necrosis factor), as is thought to occur with malaria.[20,65a] A more recent report of fatal human babesiosis with cerebral involvement that was not associated with erythrocyte adherence and vascular occlusion is consistent with this hypothesis.[19] Release of a molecule similar to endotoxin has been hypothesized to trigger the release of proinflammatory cytokines in patients with babesiosis. These cytokines subsequently stimulate release of downstream mediators, such as nitric oxide, which kill parasites, but also may cause direct cellular damage if produced in excess.[18,20,65a]

In addition to proinflammatory cytokine release, obstruction of blood vessels by parasitized erythrocytes with accompanying ischemia and necrosis possibly may result in cerebral abnormalities, hepatomegaly and hepatic dysfunction, and splenomegaly.[23,94,102] Clinical manifestations such as hypotension, vascular congestion, and anoxia also may result from the activation of fibronectin, kallikreins, and complement.[25,50,137,138]

Innate and adaptive immune mechanisms limit the severity of babesial infections, but immunity is incomplete because parasitemia may exist for months to years in animals and up to 27 months in humans after recovery from the initial illness.[60] Reinfection may occur, although it is uncommon. Age is an important factor in host defense against babesial disease in animals and humans. Most clinically apparent cases are reported in adults, but serologic surveys indicate that children are equally susceptible to infection and presumably are exposed to ticks to the same extent.[61,100,105] Almost all of the pediatric cases reported have been in neonates.[29,74,134]

More recent data from a murine model of babesiosis have suggested that resistance to *B. microti* infection conferred by the adaptive immune system is genetically determined and associated with age.[129] Alternatively, the increased severity of babesiosis observed in elderly patients and in neonates may result from impaired splenic function. The spleen plays a critical role in protection against *Babesia* spp. by (1) removing parasites from infected erythrocytes through a process known as "pitting," (2) ingesting parasites by resident reticuloendothelial cells and mononuclear phagocytes, and (3) producing antibabesial antibody.[13,22,25,96,134,137] It long has been known that splenectomized animals have more severe babesiosis than animals with intact spleens. Animals that have recovered from babesiosis and have had negative blood smears have developed parasitemia again after undergoing splenectomy.[69,106] Most fatal cases of babesiosis in humans have occurred in splenectomized individuals, although asplenia does not always result in death or even severe illness.[12,96] Other host defense mechanisms that may help limit babesial infection include macrophages and macrophage products, such as tumor necrosis factor,[20,25,137] B lymphocytes,[76] T lymphocytes,[13,76,99,135] polymorphonuclear leukocytes,[111] antibody,[13,50,65b] and complement,[7,137,151]

CLINICAL MANIFESTATIONS

Clinical manifestations of babesiosis range from subclinical illness to fulminating disease resulting in death. Overt signs and symptoms begin after an incubation period of 1 to 6 weeks from the beginning of tick feeding.[105] The unengorged *I. scapularis* nymph is about 2 mm in length, and the patient often has no recollection of having a tick bite. In most cases, the patient has a gradual onset of malaise, anorexia, and fatigue followed by intermittent fever as high as 40° C (104° F) and one or more of the following: chills, sweats, myalgia, arthralgia, nausea, and vomiting.[1,31,57,64,74,100,104,122] Less commonly noted are emotional lability and depression, hyperesthesia, headache, sore throat, abdominal pain, conjunctival injection, photophobia, weight loss, and nonproductive cough.[55,102,122,123] In contrast to other tick-borne illnesses, such as Lyme disease, Rocky Mountain spotted fever, or tularemia, rash seldom is noted.[24] Ecchymoses and petechiae have been described.[54,123] Erythema chronicum migrans has been noted in patients with babesiosis, but these patients likely had babesiosis and Lyme disease co-infection.[6]

The findings on physical examination generally are minimal, often consisting only of fever.[1,44,64,104,122] Mild splenomegaly, hepatomegaly, or both are noted occasionally.[102,134] Slight pharyngeal erythema, jaundice, and retinopathy with splinter hemorrhages and retinal infarcts also have been reported.[55,74,82] Several abnormal laboratory findings in patients with babesiosis reflect the invasion and subsequent lysis of erythrocytes by the parasite.[55,74,100,102] Mild to moderately severe hemolytic anemia occurs, with an elevated reticulocyte count. Elevated liver enzyme levels may be detected in serum.[100] The leukocyte count is normal to slightly decreased, with a "left shift." Thrombocytopenia may occur.[102] The

erythrocyte sedimentation rate is elevated. Proteinuria and an elevated blood urea nitrogen and creatinine also may be noted.[55,72,102] The illness usually lasts a few weeks to several months, with prolonged recovery taking up to 18 months.[1,6,60,102,104,122] Parasitemia may continue even after the patient feels well. Persistent parasitemia and relapse of illness, as noted with malaria, has been described 27 months after the initial episode.[60]

Some patients, especially patients who are immunocompromised or patients with *B. divergens* or *B. duncani* infection, have a more severe form of the disease consisting of fulminant illness lasting approximately 1 week and ending in death or a prolonged convalescence.[32,39,54,70,82,123] Signs and symptoms include high fever, hemolytic anemia, hemoglobinemia and hemoglobinuria, jaundice, ecchymoses, petechiae, congestive heart failure, pulmonary edema, renal failure, adult respiratory distress syndrome, and coma.[35,36,39,54,122,123,132] Patients with babesiosis who are co-infected with Lyme disease also have more severe acute illness than patients with babesiosis alone.[38,64,70,127] Co-infected patients usually experience moderate to severe acute illness often followed by persistent fatigue. In a recent case-control study, patients with severe immunosuppression who became infected with *B. microti* developed a prolonged, relapsing course of illness despite multiple courses of antibabesial therapy. Recurrent illness sometimes lasted more than a year and a fifth of these patients died.[65b]

Inapparent infection occurs in approximately a quarter of adults and half of children.[58] Serosurveys provide evidence of asymptomatic infection because of the disparity between seroprevalence rates and the number of indigenous reported cases of babesiosis. In a survey on Nantucket Island in Massachusetts, 2 percent of 577 random blood samples and 7.5 percent of 133 blood samples from patients with a history of tick bite or fever had *B. microti* indirect immunofluorescent antibody (IFA) titers of 1:64 or greater.[104] A survey of adults living on Shelter Island, New York, showed that 6 of 136 (4.4%) and 7 of 102 (6.9%) had *B. microti* IFA titers of 1:64 or greater.[28] In a survey of Massachusetts blood donors, 29 of 779 (37%) from Cape Cod had *B. microti* IFA titers of 1:16 compared with 7 of 148 (4.7%) from metropolitan Boston.[89] In a serosurvey in Connecticut, 72 of 735 (9.5%) residents who were seropositive for *B. burgdorferi* had positive *B. microti* IFA titers of 1:64 compared with 8 of 299 (2.7%) seronegative for *B. burgdorferi*.[62] Serosurveys in Mexico, Nigeria, and Taiwan also showed high *B. microti* seroprevalence rates compared with the number of indigenous reported cases of babesiosis.[37a,46,66,83]

DIAGNOSIS

Specific diagnosis of babesiosis is made by microscopic identification of the organism by Giemsa or Wright stains of thick or thin blood smears and by detection of babesial antibodies by one of several serologic tests. *Babesia* spp. are round, oval, or pear-shaped and have a blue cytoplasm with a red chromatin. The ring form is most common and is similar to the rings of *Plasmodium falciparum*.[41] *Babesia* spp. can be distinguished from *Plasmodium* spp. by (1) the absence of pigment, which is present in older trophozoites of *Plasmodium* spp.; (2) the absence of schizonts and gametocytes; (3) the absence of synchronous stages within the erythrocytes; and (4) the presence of the infrequently noted tetrad or Maltese cross forms, in which four compact masses, each containing nuclear material, are joined by strands of cytoplasm.[41]

Multiple thick and thin blood smears should be examined because only a few erythrocytes are infected in the early stage of the illness, when most people seek medical attention.[41] Rapid automated differential blood analyzers may fail to distinguish erythrocytic inclusions.[10] In thick smears, the *Babesia* organism appears as a tiny red-to-purple nucleus with a thin tail of light blue cytoplasm. Maximum erythrocyte infection is approximately 10 percent in normal hosts, but up to 85 percent in asplenic individuals.[122] Usually less than 1 percent of erythrocytes are parasitized early in the course of the illness, and the laboratory investigation of possible babesiosis should include more than an examination of blood smears.

In cases in which the presence of *Babesia* spp. is suspected but not shown by blood smears, babesial DNA can be amplified and detected using the polymerase chain reaction.[65,85] Blood from the patient also can be injected by the intravenous or intraperitoneal route into small laboratory animals such as hamsters or gerbils. If present in the patient, *B. microti* usually appears in the blood of the inoculated animal within 2 to 4 weeks.[8] This diagnostic technique is less sensitive and more time-consuming and costly than the polymerase chain reaction.[65]

Numerous serologic tests have been developed to detect babesial antibodies. Of the commonly used serologic tests, the IFA assay is the most reliable.[16,59,63,102] The IFA test is simpler, less expensive, and more rapid than the complement-fixation test. IgG and IgM IFAs can be detected.[16,59,63] During the acute phase of the illness, titers usually exceed 1:1024, but decline to 1:64 or less within 8 to 12 months. A babesial IFA titer of 1:1024 or greater usually signifies active or recent infection.[16,103] Although cross-reactions occur to different *Babesia* spp. and *Plasmodium* spp. with the IFA test, these titers almost always are low (≤1:16).[16,17] The problem of cross-reactivity with *Plasmodium* spp. is minimized in areas that have no indigenous malaria. A reliable immunoblot assay for detection of *B. microti* antibody has been developed.[108] Enzyme-linked immunosorbent assays for detection of *B. divergens* and *B. major* have been found to be superior to complement fixation and IFA procedures.[9,93,125,128]

PREVENTION AND TREATMENT

The combination of either atovaquone plus azithromycin or clindamycin plus quinine for 7 to 10 days is the initial therapy that should be considered for patients with babesiosis. Clindamycin and quinine should be given to patients with severe babesiosis. In such patients, clindamycin should be administered intravenously rather than orally, and exchange transfusion should be considered. The dosage recommendations are as follows:[14,29,35,91,136]

- Atovaquone—children, 20 mg/kg every 12 hours (maximum of 750 mg per dose); adults, 750 mg orally every 12 hours
- Azithromycin—children, 10 mg/kg once per day on day 1 (maximum of 500 mg per dose) and 5 mg/kg once per day (maximum of 250 mg per dose) and orally thereafter; adults, 500 to 1000 mg on day 1 and 250 mg orally once per day thereafter; immunocompromised adults, 600 to 1000 mg/day
- Clindamycin—children, 7 to 10 mg/kg given intravenously or orally every 6 to 8 hours (maximum of 600 mg per dose); adults, 300 to 600 mg every 6 hours intravenously or 600 mg every 8 hours orally
- Quinine—children, 8 mg/kg given orally every 8 hours (maximum of 650 mg per dose); adults, 650 mg every 6 to 8 hours orally

The clindamycin and quinine combination was first used in a case of babesiosis in an 8-week-old infant girl who contracted the disease from a blood transfusion.[134] Initially, she was thought to have malaria. Clindamycin and quinine were given after failure with chloroquine. Her favorable outcome suggested the prospective use of this combination in adults. Numerous children and adults subsequently have been treated with clindamycin and quinine, with prompt clearing of parasitemia and resolution of clinical signs and symptoms.[14,15,74,122]

The successful use of atovaquone and azithromycin for the treatment of malaria and for babesiosis in hamsters prompted a

clinical trial to determine whether the combination would be effective in human babesiosis.[47,133] In the first prospective trial of antibabesial therapy in humans, atovaquone and azithromycin were compared with clindamycin and quinine in adults.[57] Adverse effects were reported in 15 percent of subjects who received atovaquone and azithromycin compared with 72 percent of subjects who received clindamycin and quinine. In approximately one third of subjects taking clindamycin and quinine, the apparent drug reactions were severe enough that the drugs were discontinued or the dosages decreased compared with only 2 percent of subjects taking atovaquone and azithromycin. Both drug combinations were equally effective in clearing symptoms and parasitemia. Although the combination of atovaquone and azithromycin has had limited use in children, the mild course of disease in children and the favorable safety profile of this combination justify its use in children who have mild to moderate disease.[29,91]

Other antimicrobial agents that have been used to treat babesiosis generally are ineffective. Although chloroquine may give some symptomatic relief of fever and myalgia by its antiinflammatory action, it often fails to clear parasitemia in guinea pigs and humans and is not recommended.[14,78] Other antimalarial drugs, such as quinacrine, primaquine, pyrimethamine, pyrimethamine and sulfadoxine, sulfadiazine, and tetracycline, have no effect on parasitemia in animals. Pentamidine isothionate has been found to decrease fever and parasitemia, but the organisms are not eradicated, and the drug has proved to be ineffective in animals and humans.[30] Diminazene aceturate was effective in clearing parasitemia and clinical symptoms in one patient, but he developed Guillain-Barré syndrome during recovery, possibly as a result of receiving the drug.[107] Pentamidine and trimethoprim-sulfamethoxazole were used successfully to treat a case of *B. divergens* infection in France.[92]

Partial or complete red blood cell exchange transfusion can decrease the degree of parasitemia rapidly and remove toxic byproducts of babesial infections.[12,49,123] Exchange transfusion is indicated for patients with severe babesiosis, as indicated by high-grade parasitemia (≥10%); significant hemolysis; or renal, hepatic, or pulmonary compromise. No data are available to determine whether partial exchange transfusion is preferable to whole-blood exchange transfusion.[136]

Babesiosis can be prevented by avoiding areas in May through September where ticks, deer, and mice are known to thrive. It is especially important for asplenic individuals in endemic areas to avoid tall grass and brush where ticks may abound. Use of clothing that covers the lower part of the body and that is sprayed or impregnated with diethyltoluamide, dimethyl phthalate, or permethrin (Permanone) is recommended for individuals who travel into the foliage of endemic areas.[23,113] A search for ticks on people and pets should be carried out and the ticks removed as soon as possible.[23] Tick removal is accomplished best with tweezers by grasping the mouth parts without squeezing the body of the tick.[24,81] Attempts to reduce the tick, mouse, or deer populations in endemic areas have either been unsuccessful or have encountered opposition.[74,113,117,120a,132a] It is recommended that prospective blood donors who reside in endemic areas and who present with a history of fever within the preceding 1 to 2 months be excluded from giving blood to prevent transfusion-related cases.[101] The American Red Cross defers blood donors who have had a history of babesiosis.[75] Effective *B. bovis* and *B. bigemina* vaccines have been developed for use in cattle, but no *B. microti* vaccine has been developed.[80,139]

Babesiosis is a tick-borne zoonosis that is endemic in parts of North America (*B. microti*) and Europe (*B. divergens*). It commonly manifests as a viral-like illness, and the incidence in the United States and throughout the rest of the world likely is greater than currently recognized. The clinical symptoms of babesiosis usually are nonspecific, and detecting the organism in blood smears may be difficult. Although fatalities have been reported in patients experiencing babesial infection (primarily in immunocompromised hosts), complete recovery with antibabesial chemotherapy is the rule.
