Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment, and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Editors assume any liability for any injury and/or damage to persons or property arising out of or related to any use of the material contained in this book.

Ralph D. Feigin, M.D.

April 3, 1938–August 14, 2008

With great sadness, we dedicate this sixth edition of the *Textbook of Pediatric Infectious Diseases* to Ralph D. Feigin. As everyone in pediatrics and, in particular, pediatric infectious diseases, knows, Ralph was an extraordinary individual, and his untimely death leaves a void that will never be filled.

Ralph Feigin was born in New York City on April 3, 1938. He graduated from Columbia College in New York City in 1958 and received his M.D. from Boston University School of Medicine in 1962. He married Judith S. Zobel, a childhood friend, in 1960 while in medical school. Ralph completed his first two years of pediatric residency at Boston City Hospital and his third year at the Massachusetts General Hospital. He then fulfilled his military service requirement at the United States Army Research Institute of Infectious Diseases, Ft. Detrick, Frederick, Maryland. While at the United States Army Research Institute, he participated in significant studies relating to circadian periodicity and susceptibility to infections, as well as other studies that resulted in eight publications for which he was the first author. After completing his service commitment, he was Chief Resident at Massachusetts General Hospital during the 1967-68 academic year.

Ralph was recruited to Washington University in St. Louis by Phil Dodge in 1968, and soon thereafter he and one of us (JDC), who was then at St. Louis University, got together and forged an academic and personal friendship that continued until the time of his death. Almost 40 years ago, the two investigators recognized the need for a comprehensive book on pediatric infectious diseases, but because of their busy schedules the plan was put on hold, and in 1973 Jim moved to California. In 1976, the pediatric research meetings were held in St. Louis, and at this time Jim and Ralph met with W. B. Saunders representatives, and the book was conceived. The first edition of the textbook was published 5 years later in the fall of 1981. In comparison with this 6th edition, it was a modest effort, with 44 chapters and 124 contributors.

At Washington University and St. Louis Children's Hospital, Ralph developed one of the finest infectious diseases divisions in the country. His "Feigin Rounds" were an unparalleled learning experience and were legendary among medical students and residents. In 1977, Ralph moved to Houston, Texas, to accept the challenge of being the Chair of Pediatrics for Baylor College of Medicine and the Physician-in-Chief at Texas Children's Hospital. During the ensuing 30 years, the Department grew from 43 faculty members to almost 500. One of us (SLK) came under Ralph's spell in St. Louis and moved to Houston with him. The other one of us (GJD-H), an intern in Houston in 1977, was waiting for Dr. Feigin when he arrived.

In Houston, Ralph served as the Chair of Pediatrics for Baylor College of Medicine and the Physician-in-Chief at Texas Children's Hospital for 31 years. For 7 years of his tenure, he also served as President and CEO of Baylor College of Medicine. In addition to his commitments in Houston, Ralph served in leadership roles on more than 100 local, regional, and national committees and professional societies. His efforts in persuading government officials of all ranks helped children in Texas, the United States, and in all parts of the world. Many consider him to be the foremost pediatrician in the world.

As will be noted in the table of contents of this 6th edition of Feigin and Cherry, Ralph made his usual contributions to the text. In spite of his illness, he contributed to the book and made decisions relating to it until right before his death. Not only was Dr. Feigin a powerhouse of energy, speed, and unsurpassed accomplishments, but he also was a gentleman, full of compassion, warmth, and kindness, and a man who kept people and patients first in his heart and mind. He was a loving husband to his wife, Judy, and a proud father to his three children, Susan, Debra, and Michael; doting grandfather to his six grandchildren, Rebecca, Matthew, Sarah, Rachel, Jacob, and Eli; and a mentor to so many of us in the field of pediatrics and pediatric infectious diseases. Ralph Feigin is missed by everyone who knew him, particularly by Judy Feigin and the family as well as by the three of us.

JDC
SLK
GJD-H

To our spouses—
Judith Feigin, Jeanne Cherry, Neil Harrison, and Marsha Kaplan

our children—
Susan Feigin Harris and Jonathan Harris, Michael and Barbara Feigin,
Debra Feigin Sukin and Steven Sukin;
James Cherry, Jeffrey Cherry and
Kass Hogan, Susan Cherry, Kenneth and Jennifer Cherry;
Emily Demmler Wolfe and Joshua Wolfe, Matthew Demmler, Amy Demmler, Anna Rose Demmler,
Kelly Harrison, and Haley Harrison;
and Lauren Kaplan, Mindy Kaplan Langland and Lance Langland

and our grandchildren—
Rebecca and Sarah Harris, Matthew and Rachel Feigin, Jacob and Eli Sukin; Ferguson,
Dennis, and Siena Rose Cherry; and Reece Langland

CONTRIBUTORS

John G. Aaskov, Ph.D.
School of Life Sciences, Queensland University of Technology, Brisbane, Queensland, Australia
Alphaviruses: Ross River Virus Arthritis; Flaviviruses: Murray Valley Encephalitis

Susan M. Abdel-Rahman, Pharm.D.
Associate Professor of Pediatrics, University of Missouri at Kansas City School of Medicine; Director, Pharmacokinetic and Pharmacodynamic Care Laboratory, Children's Mercy Hospital and Clinics, Kansas City, Missouri
The Pharmacokinetic-Pharmacodynamic Interface: Determinants of Anti-infective Drug Action and Efficacy in Pediatrics

Christoph Aebi, M.D.
Head, Pediatric Infectious Diseases Unit, Department of Pediatrics and Institute for Infectious Diseases, University of Bern, Bern, Switzerland
Flaviviruses: Tick-Borne Encephalitis

Marvin E. Ament, M.D.
Professor of Pediatrics, David Geffen School of Medicine at UCLA; Chief, Division of Gastroenterology, Mattel Children's Hospital UCLA, Los Angeles, California
Esophagitis

Marsha S. Anderson, M.D.
Assistant Professor of Pediatrics, University of Colorado Denver School of Medicine; Attending Physician, Children's Hospital, Aurora, Colorado
Meningococcal Infections

Stephen S. Arnon, M.D.
Founder and Chief, Infant Botulism Treatment and Prevention Program, California Department of Health Services, Richmond, California
Infant Botulism

Ann M. Arvin, M.D.
Vice Provost and Dean of Research, Stanford University; Professor of Microbiology and Immunology and Lucile Salter Packard Professor of Pediatrics, Stanford University School of Medicine, Stanford; Attending Physician, Lucile Packard Children's Hospital, Palo Alto, California
Herpes Simplex Viruses 1 and 2

Jane T. Atkins, M.D.
Consultant, Pediatric Infectious Diseases, and Hospital Epidemiologist, Methodist Children's Hospital of South Texas, San Antonio, Texas
Cyclosporiasis, Isosporiasis, and Microsporidiosis

Robert L. Atmar, M.D.
Professor, Departments of Medicine and Molecular Virology and Microbiology, Baylor College of Medicine; Chief, Infectious Diseases Service, Department of Medicine, Ben Taub General Hospital, Houston, Texas
Rhinoviruses

Carol J. Baker, M.D.
Professor of Pediatrics and Molecular Virology and Microbiology, Baylor College of Medicine; Attending Physician, Infectious Diseases Service, Texas Children's Hospital, Houston, Texas
Cervical Lymphadenitis; Group B Streptococcal Infections

Robert S. Baltimore, M.D.
Professor of Pediatrics, Epidemiology, and Public Health, Yale University School of Medicine; Attending Physician in Pediatrics and Associate Hospital Epidemiologist, Yale–New Haven Children's Hospital, New Haven, Connecticut
Epidemiology of Infectious Diseases

Stephen J. Barenkamp, M.D.
Professor of Pediatrics and Molecular Biology, St. Louis University School of Medicine; Director, Division of Pediatric Infectious Diseases, Cardinal Glennon Children's Medical Center, St. Louis, Missouri
Haemophilus influenzae; Other *Haemophilus* Species (*aphrophilus, ducreyi, haemolyticus, influenzae* Biogroup Aegyptius, *parahaemolyticus,* and *parainfluenzae*)

Elizabeth D. Barnett, M.D.
Associate Professor of Pediatrics, Boston University School of Medicine; Section of Pediatric Infectious Diseases, Boston Medical Center, Boston, Massachusetts
Malaria

Robert D. Basow, M.D.
Community Preceptor Attending, Department of Community Pediatrics, University of Massachusetts Medical Center, Worcester, Massachusetts
Streptobacillus moniliformis (Rat-Bite Fever); *Spirillum minus* (Rat-Bite Fever)

William R. Beisel, M.D.
Adjunct Professor (retired), W. Harry Feinstone Department of Molecular Microbiology and Immunology, Johns Hopkins School of Hygiene and Public Health, Baltimore, Maryland
Metabolic Response of the Host to Infections

Beth P. Bell, M.D., M.P.H.
Associate Director for Epidemiologic Science, National Center for Immunization and Respiratory Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia
Hepatitis A Virus

Gil Benard, M.D., Ph.D.
Medical Researcher, Faculty of Medicine, University of São Paulo, São Paulo, Brazil
Paracoccidioidomycosis

David I. Bernstein, M.D., M.A.
Professor, Department of Pediatrics, University of Cincinnati College of Medicine; Director, Division of Infectious Diseases, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio
Rotaviruses

Kathrin M. Bernt, M.D.
Pediatrician, Boston, Massachusetts
Interaction of Infection and Nutrition

Andrea A. Berry, M.D.
Fellow, Department of Pediatrics, Division of Infectious Diseases and Tropical Pediatrics, University of Maryland School of Medicine, Baltimore, Maryland
Diarrhea-Causing and Dysentery-Causing *Escherichia coli*

Charles D. Bluestone, M.D.
Eberly Professor of Pediatric Otolaryngology, Department of Otolaryngology, University of Pittsburgh School of Medicine; Director, Department of Pediatric Otolaryngology, Children's Hospital of Pittsburgh, Pittsburgh, Pennsylvania
Otitis Media

Jeffrey L. Blumer, M.D., Ph.D.
Professor of Pediatrics and Pharmacology, Case Western Reserve University; Director, Rainbow Regional Network Development, Rainbow Babies and Children's Hospital, Cleveland, Ohio
Antibiotic Resistance

Robert Bortolussi, M.D., F.R.C.P.C.
Professor of Pediatrics and Microbiology and Immunology, Dalhousie University Faculty of Medicine; Staff Consultant, IWK Health Centre, Halifax, Nova Scotia, Canada
Listeriosis

Bobby L. Boyanton, Jr., M.D.
Medical Director, Clinical Microbiology, William Beaumont Hospital, Royal Oak, Michigan
Bacterial Laboratory Diagnosis

Kenneth M. Boyer, M.D.
Woman's Board Professor of Pediatrics, Rush Medical College; Chairman, Department of Pediatrics, Rush Children's Hospital of Rush University Medical Center, Chicago, Illinois
Nonbacterial Pneumonia; Congenital Toxoplasmosis; *Borrelia* (Relapsing Fever); Toxoplasmosis

John S. Bradley, M.D.
Director, Division of Infectious Diseases, Rady Children's Hospital–San Diego, San Diego, California
Peritonitis and Intra-abdominal Abscess; Retroperitoneal Infections; Outpatient Intravenous Antimicrobial Therapy for Serious Infections

Michael T. Brady, M.D.
Chair and Professor, Department of Pediatrics, College of Medicine, The Ohio State University; Physician-in-Chief, Nationwide Children's Hospital, Columbus, Ohio
Pseudomonas and Related Genera

William J. Britt, M.D.
Professor of Pediatrics and Microbiology, The University of Alabama at Birmingham School of Medicine; Attending Physician, Children's Hospital of Alabama, Birmingham, Alabama
Transmissible Spongiform Encephalopathies (Creutzfeldt-Jakob Disease, Gerstmann-Sträussler-Scheinker Disease, Kuru, Fatal Familial Insomnia, New Variant Creutzfeldt-Jakob Disease, Sporadic Fatal Insomnia)

Annemarie Broderick, M.D.
Consultant/Clinician-Scientist, Our Lady's Hospital for Sick Children, Dublin, Ireland
Hepatitis B and D Viruses

David E. Bronstein, M.D., M.S.
Department of Pediatrics, Southern California Permanente Medical Group, Palmdale, California
Aseptic Meningitis and Viral Meningitis; Encephalitis and Meningoencephalitis

David A. Bruckner, Sc.D.
Department of Pathology and Laboratory Medicine, David Geffen School of Medicine at UCLA, Los Angeles, California
Nomenclature for Aerobic and Anaerobic Bacteria; Classification of Fungi; Fungal Laboratory Analysis: Specimen Collection, Direct Detection, and Culture; Parasitic Laboratory Diagnosis

Steven C. Buckingham, M.D.
Associate Professor, Department of Pediatrics, Division of Pediatric Infectious Diseases, University of Tennessee Health Science Center; Attending Physician, Le Bonheur Children's Medical Center, Memphis, Tennessee
Other Anaerobic Infections

Ana Burgos, M.D.
Pediatric Hematology/Oncology, Duke University Medical Center, Durham, North Carolina
Aspergillus and Aspergillosis

Carrie L. Byington, M.D.
Professor of Pediatrics and Associate Chair for Clinical Research, University of Utah School of Medicine, Salt Lake City, Utah
Streptobacillus moniliformis (Rat-Bite Fever); *Spirillum minus* (Rat-Bite Fever)

Judith R. Campbell, M.D.
Associate Professor of Pediatrics, Section of Pediatric Infectious Diseases, Baylor College of Medicine; Attending Physician, Pediatric Infectious Diseases Service, Texas Children's Hospital, Houston, Texas
Parotitis; Peritonitis and Intra-abdominal Abscess

Samson Cantu, M.D.
Fellow, Pediatric Gastroenterology, Hepatology, and Nutrition, Baylor College of Medicine, Houston, Texas
Helicobacter pylori

Mariam R. Chacko, M.D.
Professor of Pediatrics, Section of Adolescent Medicine and Sports Medicine, Baylor College of Medicine; Attending Physician, Texas Children's Hospital; Medical Director, Baylor Teen Health Clinics, Houston, Texas
Genital Infections; *Calymmatobacterium granulomatis; Trichomonas* Infections

Louisa E. Chapman, M.D., M.S.P.H.
Captain, U.S. Public Health Service, and Medical Epidemiologist, National Center for Zoonotics, Vector-Borne and Enteric Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia
Hantaviruses

Rémi N. Charrel, M.D., Ph.D.
Associate Professor of Virology, Unité des Virus Emergents, Faculté de Médecine, Université de la Méditerranée, Marseille, France
Lymphocytic Choriomeningitis Virus Infection; Arenaviral Hemorrhagic Fevers; Toscana Virus

Tempe K. Chen, M.D.
Pediatric Family Center, Long Beach, California
Adenoviruses

James D. Cherry, M.D., M.Sc.
Professor of Pediatrics, David Geffen School of Medicine at UCLA; Member, Division of Infectious Diseases, Mattel Children's Hospital UCLA, Los Angeles, California
The Common Cold; Pharyngitis (Pharyngitis, Tonsillitis, Tonsillopharyngitis, and Nasopharyngitis); Herpangina; Pharyngoconjunctival Fever; Sinusitis; Mastoiditis; Epiglottitis; Croup (Laryngitis, Laryngotracheitis, Spasmodic Croup, Laryngotracheobronchitis, Bacterial Tracheitis, and Laryngotracheobronchopneumonitis); Acute Bronchitis; Aseptic Meningitis and Viral Meningitis; Encephalitis and Meningoencephalitis; Cutaneous Manifestations of Systemic Infections; Roseola Infantum (Exanthem Subitum); *Mycoplasma* and *Ureaplasma* Infections of the Neonate; Pertussis and Other *Bordetella* Infections; Tetanus; Human Parvovirus B19; Human Bocaviruses; Adenoviruses; Smallpox (Variola Virus); Monkeypox and Other Poxviruses; Enteroviruses and Parechoviruses; Reoviruses; Rubella Virus; Measles Virus; Mumps Virus; Human Metapneumovirus; *Mycoplasma* and *Ureaplasma* Infections

P. Joan Chesney, M.D.
Professor of Pediatrics, Division of Infectious Diseases, University of Tennessee, Memphis, College of Medicine; Active Staff, Department of Pediatrics, Le Bonheur Children's Medical Center; Director, Office of Academic Programs, St. Jude Children's Research Hospital, Memphis, Tennessee
Toxic Shock Syndrome

Madhuri C. Chilakapati, M.D.
Staff Physician, Kelsey Seybold Clinic, Houston, Texas
Ocular Infectious Diseases

Javier Chinen, M.D., Ph.D.
Assistant Professor, Department of Pediatrics, Baylor College of Medicine; Attending Physician, Allergy and Immunology Service, Texas Children's Hospital, Houston, Texas
Primary Immunodeficiencies

Natascha Ching, M.D.
Assistant Clinical Professor of Pediatrics, David Geffen School of Medicine at UCLA; Attending Physician, Division of Pediatric Infectious Diseases, Mattel Children's Hospital UCLA, Los Angeles, California
Arcanobacterium haemolyticum

H. Fred Clark, D.V.M., Ph.D.
Research Professor, Department of Pediatrics, University of Pennsylvania School of Medicine; Adjunct Professor, Wistar Institute, Philadelphia, Pennsylvania
Rabies Virus

Thomas G. Cleary, M.D.
Professor of Pediatrics, Division of Pediatric Infectious Diseases, University of Texas–Houston Medical School; Professor of Pediatrics, Department of Pediatric Infectious Diseases, Memorial Hermann Children's Hospital, Houston, Texas
Bacillus cereus; Shigella; Salmonella

David K. Coats, M.D.
Professor of Ophthalmology and Pediatrics, Department of Ophthalmology, Baylor College of Medicine; Chief, Ophthalmology Service, Texas Children's Hospital, Houston, Texas
Ocular Infectious Diseases

Armando G. Correa, M.D.
Assistant Professor of Pediatrics, Baylor College of Medicine; Attending Physician, Infectious Diseases Service, Texas Children's Hospital, Houston, Texas
Acinetobacter

J. Thomas Cross, Jr., M.D., M.P.H.
Vice President for Education, MedStudy Corporation, Colorado Springs, Colorado
Fungal Meningitis; Other Mycobacteria

William B. Cutrer, M.D.
Fellow, Pediatric Critical Care, Baylor College of Medicine; Attending Physician, Texas Children's Hospital, Houston, Texas
Bacterial Meningitis beyond the Neonatal Period

Ronald Dagan, M.D.
Professor of Pediatrics and Infectious Diseases, Faculty of Health Sciences, Ben-Gurion University of the Negev; Director, Pediatric Infectious Disease Unit, Soroka University Medical Center, Beer-Sheva, Israel
Pneumococcal Infections

David E. Dassey, M.D., M.P.H.
Acute Communicable Disease Control Program, Los Angeles, California
Public Health Aspects of Infectious Disease Control

Jeffrey P. Davis, M.D.
Adjunct Professor, Departments of Pediatrics and Preventative Medicine, University of Wisconsin Medical School; Chief Medical Officer and State Epidemiologist for Communicable Diseases, Bureau of Public Health, Wisconsin Division of Health, Madison, Wisconsin
Toxic Shock Syndrome

Gail J. Demmler-Harrison, M.D.
Professor of Pediatrics, Baylor College of Medicine; Attending Physician, Infectious Diseases Service, and Director, Diagnostic Virology Laboratory, Texas Children's Hospital, Houston, Texas
Hepatitis; Viral Infections of the Fetus and Neonate; Yeast and Fungal Infections of the Fetus and Neonate; Opportunistic Infections in Kidney Transplantation; Human Papillomaviruses; Cytomegalovirus; Antiviral Agents

Penelope H. Dennehy, M.D.
Professor of Pediatrics and Vice Chair for Academic Affairs for Pediatrics, The Warren Alpert Medical School of Brown University; Director, Division of Pediatric Infectious Diseases, Hasbro Children's Hospital, Providence, Rhode Island
Active Immunizing Agents

Minh L. Doan, M.D.
Assistant Professor of Pediatrics, Uniformed Services University of the Health Sciences F. Edward Hébert School of Medicine, Bethesda, Maryland; Pediatric Pulmonologist, Tripler Army Medical Center, Honolulu, Hawaii
Children's Interstitial Lung Disease and Hypersensitivity Pneumonitis

Simon R. Dobson, M.D., F.R.C.P.C.
Clinical Associate Professor, University of British Columbia Faculty of Medicine; Division of Infectious and Immunological Diseases, British Columbia Children's Hospital, Vancouver, British Columbia, Canada
Syphilis

Jan E. Drutz, M.D.
Professor of Pediatrics and Director, Pediatric Continuity Training Program, Baylor College of Medicine, Houston, Texas
Arthropods

Paul H. Edelstein, M.D.
Professor of Pathology and Laboratory Medicine, University of Pennsylvania School of Medicine; Director, Clinical Microbiology Laboratory, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania
Legionnaires' Disease, Pontiac Fever, and Related Illnesses

Kathryn M. Edwards, M.D.
Professor of Pediatrics, Vanderbilt University School of Medicine; Attending Physician, Monroe Carell Jr. Children's Hospital at Vanderbilt, Nashville, Tennessee
Bartonella (Cat-Scratch Disease)

Morven S. Edwards, M.D.
Professor of Pediatrics, Baylor College of Medicine; Attending Physician, Infectious Diseases Service, Texas Children's Hospital, Houston, Texas
Mediastinitis; Anthrax; Rickettsial and Ehrlichial Diseases; Animal Bites

B. Keith English, M.D.
Professor of Pediatrics, University of Tennessee Health Science Center; Chief, Division of Infectious Diseases, Le Bonheur Children's Medical Center, Memphis, Tennessee
Enterococcal and *Viridans* Streptococcal Infections

Dora Estripeaut, M.D.
Professor of Pediatrics and Infectious Diseases, University of Panama School of Medicine; Attending Physician in Pediatric Infectious Diseases, Hospital del Niño, Panama City, Panama
Perinatal Bacterial Diseases

Leland L. Fan, M.D.
Professor of Pediatrics, Baylor College of Medicine; Attending Physician, Pulmonary Service, Texas Children's Hospital, Houston, Texas
Children's Interstitial Lung Disease and Hypersensitivity Pneumonitis

Ralph D. Feigin, M.D.
Formerly J. S. Abercrombie Professor and Chairman, Department of Pediatrics, and Distinguished Service Professor, Baylor College of Medicine; Physician-in-Chief, Texas Children's Hospital; Physician-in-Chief, Service of Pediatrics, Ben Taub General Hospital; Chief, Pediatric Service, The Methodist Hospital, Houston, Texas
Metabolic Response of the Host to Infections; Interaction of Infection and Nutrition; Bacterial Meningitis beyond the Neonatal Period; Fever without Source and Fever of Unknown Origin; Diphtheria; *Aeromonas;* Tularemia; Leptospirosis; Rickettsial and Ehrlichial Diseases

George D. Ferry, M.D.
Professor of Pediatrics, Baylor College of Medicine; Chief, Inflammatory Bowel Disease Center, Texas Children's Hospital, Houston, Texas
Antibiotic-Associated Colitis

Anthony E. Fiore, M.D.
Deputy Branch Chief, Epidemiology and Prevention Branch, Influenza Division, National Center for Immunization and Respiratory Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia
Hepatitis A Virus

Philip R. Fischer, M.D.
Professor of Pediatrics, Mayo Clinic; Medical Director, Mayo Eugenio Litta Children's Hospital, Rochester, Minnesota
Cestodes; Trematodes; Schistosomiasis

Randall G. Fisher, M.D.
Associate Professor of Pediatrics, Eastern Virginia Medical School; Medical Director, Division of Infectious Diseases, and Attending Physician, Children's Hospital of The King's Daughters, Norfolk, Virginia
Miscellaneous Gram-Positive Cocci; *Erysipelothrix rhusiopathiae;* Miscellaneous Gram-Positive Bacilli; *Citrobacter; Enterobacter; Klebsiella; Morganella morganii; Proteus; Providencia; Serratia;* Miscellaneous Enterobacteria; *Vibrio vulnificus;* Miscellaneous Non-Enterobacteriaceae Fermentative Bacilli; *Achromobacter (Alcaligenes); Eikenella corrodens; Elizabethkingia* and *Chryseobacterium* Species

Patricia M. Flynn, M.D., M.S.
Professor, Departments of Pediatrics and Preventive Medicine, University of Tennessee Health Science Center; Member, Department of Infectious Diseases, St. Jude Children's Research Hospital, Memphis, Tennessee
Candidiasis

Thomas R. Flynn, D.M.D.
Associate Professor of Oral and Maxillofacial Surgery, Harvard School of Dental Medicine; Associate Visiting Surgeon, Department of Oral and Maxillofacial Surgery, Massachusetts General Hospital; Boston, Massachusetts
Infections of the Oral Cavity

Lisa M. Frenkel, M.D.
Professor of Pediatrics, Division of Infectious Diseases, and Professor of Laboratory Medicine, Division of Virology, University of Washington School of Medicine; Co-Director, Virology Clinic, and Associate and Attending Physician, Division of Pediatric Infectious Diseases, Seattle Children's Hospital, Seattle, Washington
Dientamoeba fragilis Infections

Ellen M. Friedman, M.D.
Professor of Otolaryngology and Pediatrics and Bobby Alford Chair of Pediatric Otolaryngology, Baylor College of Medicine; Chief, Otolaryngology, Speech, Language and Learning, and Auditory Services, Texas Children's Hospital, Houston, Texas
Otitis Externa

Richard A. Friedman, M.D., M.B.A.
Professor of Pediatrics, Baylor College of Medicine; Chief, Arrhythmia and Pacing Services, and Chief, Cardiology Clinic, Texas Children's Hospital, Houston, Texas
Infectious Pericarditis

Lynne S. Garcia, M.S., M.T.
Director, LSG & Associates, Santa Monica, California
Classification and Nomenclature of Human Parasites; Leishmaniasis; Trypanosomiasis

Patrick J. Gavin, M.D.
Department of Pathology and Laboratory Medicine, Evanston Northwestern Healthcare, Evanston, Illinois
Naegleria, Acanthamoeba, and *Balamuthia*

Michael A. Gerber, M.D.
Professor of Pediatrics, University of Cincinnati College of Medicine; Division of Infectious Diseases, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio
Group A, Group C, and Group G Beta-Hemolytic Streptococcal Infections

Anne A. Gershon, M.D.
Professor of Pediatrics, Columbia University College of Physicians and Surgeons; Attending Physician, Morgan Stanley Children's Hospital, New York, New York
Varicella-Zoster Virus

Mark A. Gilger, M.D.
Professor of Pediatrics, Baylor College of Medicine; Chief of Service, Gastroenterology, Hepatology, and Nutrition, Texas Children's Hospital, Houston, Texas
Whipple Disease; *Helicobacter pylori*

Susan L. Gillespie, M.D., Ph.D.
Assistant Professor, Department of Pediatrics, Baylor College of Medicine; Baylor International Pediatric AIDS Initiative, Houston, Texas
Human Retroviruses: Oncoviruses (Human T-Cell Lymphotropic Viruses) and Lentiviruses (Human Immunodeficiency Virus Type 2)

Daniel G. Glaze, M.D.
Professor of Pediatrics and Neurology, Baylor College of Medicine; Director of Sleep Clinic and Sleep Laboratory, Texas Children's Hospital, Houston, Texas
Parainfectious and Postinfectious Disorders of the Nervous System

W. Paul Glezen, M.D.
Professor, Departments of Molecular Virology and Microbiology and Pediatrics, Baylor College of Medicine; Courtesy Staff, Infectious Diseases Service, Texas Children's Hospital, Houston, Texas
Influenza Viruses

Mary P. Glodé, M.D.
Professor of Pediatrics, University of Colorado Denver School of Medicine; Professor of Pediatric Infectious Diseases, Children's Hospital, Aurora, Colorado
Meningococcal Infections

Donald A. Goldmann, M.D.
Professor of Pediatrics, Harvard Medical School; Senior Associate in Infectious Diseases, Children's Hospital Boston, Boston, Massachusetts
Health Care–Associated Infections; Programs to Prevent and Control Health Care–Associated Infections

Ellie J. C. Goldstein, M.D.
Clinical Professor of Medicine, David Geffen School of Medicine at UCLA, Los Angeles; Director, R. M. Alden Research Laboratory, Culver City, California
Human Bites

Nira A. Goldstein, M.D.
Assistant Professor, Division of Pediatric Otolaryngology, State University of New York Downstate Medical Center College of Medicine; Attending Physician, Division of Pediatric Otolaryngology, University Hospital of Brooklyn, Long Island College Hospital, and Kings County Hospital Center, Brooklyn, New York
Peritonsillar, Retropharyngeal, and Parapharyngeal Abscesses

Edmond T. Gonzales, Jr., M.D.
Professor of Urology, Scott Department of Urology, Baylor College of Medicine; Head, Department of Surgery, and Chief, Pediatric Urology Service, Texas Children's Hospital, Houston, Texas
Renal Abscess; Prostatitis

Mark P. Gorman, M.D.
Instructor, Harvard Medical School; Assistant in Neurology, Children's Hospital Boston, Boston, Massachusetts
Parainfectious and Postinfectious Disorders of the Nervous System

Michael D. Green, M.D., M.P.H.
Professor of Pediatrics and Surgery, University of Pittsburgh School of Medicine; Attending Physician, Division of Infectious Diseases, and Director, Infectious Diseases Research Laboratories, Children's Hospital of Pittsburgh, Pittsburgh, Pennsylvania
Opportunistic Infections in Liver and Intestinal Transplantation

David Greenberg, M.D.
Lecturer, Faculty of Health Sciences, Ben-Gurion University of the Negev; Senior Physician, Specialist in Pediatrics and Infectious Diseases, Soroka University Medical Center, Beer-Sheva, Israel
Pneumococcal Infections

Andreas H. Groll, M.D.
Infectious Disease Research Program, Department of Pediatric Hematology/Oncology, Children's University Hospital, Münster, Germany
Antifungal Agents

Charles Grose, M.D.
Professor, Department of Pediatrics, University of Iowa Carver College of Medicine; Director of Infectious Diseases, Children's Hospital, Iowa City, Iowa
Bacterial Myositis and Pyomyositis; Human Herpesviruses 6, 7, and 8

Duane J. Gubler, M.D.
Professor and Chair, Department of Tropical Medicine and Medical Microbiology, John A. Burns School of Medicine, University of Hawaii at Manoa, Honolulu, Hawaii
Flaviviruses: Yellow Fever

Roberto A. Guerrero, M.D.
Pediatric Gastroenterologist, Loxahatchee, Florida
Whipple Disease

Javier Nieto Guevara, M.D.
Department of Pediatrics, Hospital del Niño, Panama City, Panama
Parameningeal Infections

Kathleen M. Gutierrez, M.D.
Assistant Professor, Stanford University School of Medicine, Stanford; Assistant Professor of Pediatrics, Lucile Packard Children's Hospital, Palo Alto, California
Herpes Simplex Viruses 1 and 2

Caroline Breese Hall, M.D.
Professor of Pediatrics and Medicine, University of Rochester School of Medicine and Dentistry, Rochester, New York
Parainfluenza Viruses; Respiratory Syncytial Virus

Scott B. Halstead, M.D.
Director, Supportive Research and Development, Pediatric Dengue Vaccine Initiative, International Vaccine Institute, Seoul, Korea
Alphaviruses: Chikungunya; Flaviviruses: Dengue and Dengue Hemorrhagic Fever

Shinjiro Hamano, M.D., Ph.D.
Department of Parasitology, Faculty of Medical Sciences, Kyushu University, Fukuoka, Japan
Amebiasis

Richard J. Hamill, M.D.
Professor, Departments of Medicine and Molecular Virology and Microbiology, Baylor College of Medicine; Staff Physician, Infectious Diseases Section, Michael E. DeBakey Veterans Affairs Medical Center, Houston, Texas
Cryptococcosis

Margaret R. Hammerschlag, M.D.
Professor of Pediatrics and Medicine, State University of New York Downstate Medical Center College of Medicine; Director, Division of Pediatric Infectious Diseases, State University of New York Downstate Medical Center, Kings County Hospital Center, Brooklyn, New York
Peritonsillar, Retropharyngeal, and Parapharyngeal Abscesses; *Chlamydia trachomatis* Infections in the Neonate; *Chlamydia* Infections

I. Celine Hanson, M.D.
Professor of Pediatrics, Section of Allergy and Immunology, Baylor College of Medicine; Chief, Allergy and Immunology Clinic, Texas Children's Hospital, Houston, Texas
Chronic Bronchitis; Human Retroviruses: Impact of Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome

Nada Harik, M.D.
Assistant Professor, Department of Pediatrics and Department of Microbiology and Immunology, Division of Pediatric Infectious Diseases, University of Arkansas for Medical Sciences, Little Rock, Arkansas
Nocardia

Rick E. Harrison, M.D.
Professor of Pediatrics, David Geffen School of Medicine at UCLA; Medical Director, Mattel Children's Hospital UCLA, Los Angeles, California
Tetanus

C. Mary Healy, M.D.
Assistant Professor, Department of Pediatrics, Section of Infectious Diseases, Baylor College of Medicine; Attending Physician, Infections Diseases Service, Texas Children's Hospital, Houston, Texas
Cervical Lymphadenitis

Ulrich Heininger, M.D.
Professor of Pediatrics, University of Basel Medical School; Chair, Division of Pediatric Infectious Diseases and Vaccines, University Children's Hospital, Basel, Switzerland
Pertussis and Other *Bordetella* Infections

Gloria P. Heresi, M.D.
Professor of Pediatrics, Section of Pediatric Infectious Diseases, University of Texas Health Science Center at Houston; Attending Physician, Memorial Hermann Hospital and Lyndon Baines Johnson General Hospital, Houston, Texas
Campylobacter jejuni

Peter W. Hiatt, M.D.
Associate Professor of Pediatrics, Baylor College of Medicine; Attending Physician and Medical Director, Infant Pulmonary Diagnostic Laboratory, Texas Children's Hospital, Houston, Texas
Cystic Fibrosis; Acute Respiratory Distress Syndrome in Children

Harry R. Hill, M.D.
Professor of Pathology and Pediatrics, Department of Pathology, University of Utah School of Medicine, Salt Lake City, Utah
Immunomodulating Agents

David C. Hilmers, M.D., M.P.H.
Assistant Professor of Pediatrics and Internal Medicine, Baylor College of Medicine; Attending Physician, Texas Children's Hospital, Houston, Texas
Nonvenereal Treponematoses

Jill A. Hoffman, M.D.
Associate Professor of Pediatrics, Keck School of Medicine of the University of Southern California; Division of Infectious Diseases, Children's Hospital Los Angeles, Los Angeles, California
Infections in Pediatric Lung Transplantation

Ellis K. L. Hon, M.B.B.S.
Assistant Professor, Department of Paediatrics, Chinese University of Hong Kong; Honorary Medical Officer, Prince of Wales Hospital, Shatin, Hong Kong, China
Coronaviruses and Toroviruses, Including Severe Acute Respiratory Virus Syndrome

Margaret K. Hostetter, M.D.
Jean McLean Wallace Professor and Chair, Yale School of Medicine, New Haven, Connecticut
Infectious Disease Considerations in International Adoptees and Refugees

Peter J. Hotez, M.D., Ph.D.
Distinguished Research Professor and Walter G. Ross Professor and Chair, Department of Microbiology, Immunology, and Tropical Medicine, George Washington University School of Medicine and Health Sciences; President, Sabine Vaccine Institute, Washington, D.C.
Blastocystis hominis Infection; *Entamoeba coli* Infection; *Balantidium coli* Infection; Parasitic Nematode Infections; Drugs for Parasitic Infections

Walter T. Hughes, M.D.
Lecturer, Department of Pediatrics, Johns Hopkins University School of Medicine, Baltimore, Maryland; Emeritus Chairman, Department of Infectious Diseases, St. Jude Children's Research Hospital, Memphis, Tennessee
Pneumocystis Pneumonia

Kristina G. Hulten, Ph.D.
Assistant Professor of Pediatrics, Baylor College of Medicine; Attending Physician, Texas Children's Hospital, Houston, Texas
Staphylococcus aureus Infections (Coagulase-Positive Staphylococci)

David A. Hunstad, M.D.
Assistant Professor of Pediatrics and Molecular Microbiology, Washington University in St. Louis School of Medicine, St. Louis, Missouri
Molecular Determinants of Microbial Pathogenesis

Eugene S. Hurwitz, M.D.
Clinical Assistant Professor, Department of Pediatrics, Emory University School of Medicine; Respiratory Disease Management Associates, LLC, Atlanta, Georgia
Reye Syndrome

W. Charles Huskins, M.D., M.Sc.
Assistant Professor of Pediatrics, Mayo Medical School; Consultant, Pediatric Infectious Diseases, and Hospital Epidemiologist, Mayo Eugenio Litta Children's Hospital, Mayo Clinic, Rochester, Minnesota
Health Care–Associated Infections; Programs to Prevent and Control Health Care–Associated Infections

David Y. Hyun, M.D.
Assistant Professor of Pediatrics, Division of Infectious Diseases, Children's National Medical Center, Washington, D.C.
Coagulase-Negative Staphylococcal Infections; *Vibrio parahaemolyticus*

Mary Anne Jackson, M.D.
Professor of Pediatrics, University of Missouri–Kansas City School of Medicine; Section Chief, Pediatric Infectious Diseases, Children's Mercy Hospital, Kansas City, Missouri
Bacterial Skin Infections

Michael R. Jacobs, M.B. B.Ch., Ph.D.
Professor of Pathology, Case Western Reserve University; Director of Clinical Microbiology, University Hospitals of Cleveland, Cleveland, Ohio
Pneumococcal Infections

Richard F. Jacobs, M.D., F.A.A.P.
Horace C. Cabe Professor of Pediatrics and Professor and Chairman, Department of Pediatrics, University of Arkansas for Medical Sciences; President, Arkansas Children's Hospital Research Institute; Attending Physician, Pediatric Infectious Diseases, Arkansas Children's Hospital, Little Rock, Arkansas
Pleural Effusions and Empyema; Lung Abscess; Fungal Meningitis; Other Mycobacteria; *Nocardia; Actinobacillus actinomycetemcomitans;* Actinomycosis

Jenifer L. Jaeger, M.D.
Epidemic Intelligence Service Officer, Bureau of Communicable Disease Control, Centers for Disease Control and Prevention, Albany, New York
Active Immunizing Agents

Ravi R. Jhaveri, M.D.
Assistant Professor of Pediatrics, Molecular Genetics, and Microbiology, Division of Pediatric Infectious Diseases, Duke University School of Medicine, Durham, North Carolina
Hepatitis E Virus

Samantha Johnston, M.D.
Physician, Doctors without Borders, New York, New York
Smallpox; Monkeypox and Other Poxviruses

Maureen M. Jonas, M.D.
Associate Professor of Pediatrics, Harvard Medical School; Senior Associate Physician in Medicine, Division of Gastroenterology, Children's Hospital Boston, Boston, Massachusetts
Hepatitis B and D Viruses; Hepatitis C Virus

Meena R. Julapalli, M.D.
Physician-in-Training, Department of Dermatology, Baylor College of Medicine and Texas Children's Hospital, Houston, Texas
Viral and Fungal Skin Infections

Edward L. Kaplan, M.D.
Professor of Pediatrics, Department of Pediatrics, University of Minnesota Medical School; Attending Physician, Department of Pediatrics, Fairview University Medical Center, Minneapolis, Minnesota
Group A, Group C, and Group G Beta-Hemolytic Streptococcal Infections

Sheldon L. Kaplan, M.D.
Professor and Vice-Chairman of Clinical Affairs and Head, Section of Pediatric Infections Diseases, Department of Pediatrics, Baylor College of Medicine; Chief, Infectious Diseases Service, Texas Children's Hospital, Houston, Texas
Infectious Pericarditis; Renal Abscess; Prostatitis; Pyogenic Liver Abscess; Bacteremia and Septic Shock; Infections in Pediatric Heart Transplantation; *Staphylococcus aureus* Infections (Coagulase-Positive Staphylococci); Coagulase-Negative Staphylococcal Infections

Saul J. Karpen, M.D., Ph.D
Associate Professor of Pediatrics and Molecular and Cellular Biology, and Faculty, Translational Biology and Molecular Medicine, Baylor College of Medicine; Director, Texas Children's Liver Center, Texas Children's Hospital, Houston, Texas
Cholangitis and Cholecystitis

Gregory L. Kearns, Pharm.D., Ph.D.
Professor of Pediatrics, University of Missouri–Kansas City School of Medicine; Professor of Pharmacology, University of Missouri–Kansas City School of Pharmacy; Marion Merrell Dow/Missouri Chair of Medical Research and Chairman, Department of Medical Research, Children's Mercy Hospitals and Clinics, Kansas City, Missouri
The Pharmacokinetic-Pharmacodynamic Interface: Determinants of Anti-infective Drug Action and Efficacy in Pediatrics

Margaret A. Keller, M.D.
Professor of Pediatrics, David Geffen School of Medicine at UCLA, Los Angeles; Chief, Pediatric Infectious Diseases, Harbor-UCLA Medical Center, Torrance, California
Passive Immunization

Chaouki K. Khoury, M.D., M.S.
Assistant Professor and Assistant Residency Program Director, Department of Neurology, University of Oklahoma Health Sciences Center, Oklahoma City, Oklahoma
Cyclosporiasis, Isosporiasis, and Microsporidiosis

Martin B. Kleiman, M.D.
Professor, Department of Pediatric Infectious Diseases, Indiana University School of Medicine; Director, Pediatric Infectious Diseases, Riley Hospital for Children, Indianapolis, Indiana
Histoplasmosis

Jerome O. Klein, M.D.
Professor of Pediatrics, Boston University School of Medicine; Division of Pediatric Infectious Diseases, Maxwell Finland Laboratory for Infectious Diseases, Boston, Massachusetts
Otitis Media; Bacterial Pneumonias

Mark W. Kline, M.D.
Professor and Head, Retrovirology Section, Department of Pediatrics, Baylor College of Medicine; President, Baylor International Pediatric AIDS Initiative, Texas Children's Hospital, Houston, Texas
Primary Immunodeficiencies

Katherine M. Knapp, M.D.
Assistant Professor, Department of Pediatrics, University of Tennessee Health Science Center; Assistant Member, Department of Infectious Diseases, St. Jude Children's Research Hospital, Memphis, Tennessee
Candidiasis

Heidi M. Kokkinos, M.T.(ASCP), B.S.
Core Technologist, Mycology Laboratory, University of California, Los Angeles; Clinical Laboratory Scientist, Department of Pathology and Laboratory Medicine, UCLA Medical Center, Los Angeles, California
Classification of Fungi

Peter J. Krause, M.D.
Associate Research Scientist, Department of Epidemiology and Public Health, Yale School of Medicine, New Haven; Division of Pediatric Infectious Diseases, Connecticut Children's Medical Center, Hartford, Connecticut
Babesiosis

Leonard R. Krilov, M.D.
Professor of Pediatrics, State University of New York Stony Brook School of Medicine, Stony Brook; Chief, Pediatric Infectious Disease, and Vice-Chairman, Department of Pediatrics, Children's Medical Center, Winthrop University Hospital, Mineola, New York
Chronic Fatigue Syndrome

Paul Krogstad, M.D., M.S.
Professor of Pediatrics and Molecular and Medical Pharmacology, Department of Pediatrics, David Geffen School of Medicine at UCLA; Attending Physician, Mattel Children's Hospital UCLA, Los Angeles, California
Esophagitis; Osteomyelitis; Septic Arthritis; Enteroviruses and Parechoviruses

Thomas L. Kuhls, M.D.
Consultant, Pediatric Infectious Diseases, Norman Regional Hospital, Norman; Consultant, Pediatric Infectious Diseases, Baptist Medical Center, Oklahoma City, Oklahoma
Appendicitis and Pelvic Abscess; Pancreatitis; *Kingella* Species

Xavier de Lamballerie, M.D., Ph.D.
Professor of Virology, Unité des Virus Emergents, Faculté de Médecine, Université de la Méditerranée, Marseille, France
Lymphocytic Choriomeningitis Virus Infection; Arenaviral Hemorrhagic Fevers; Toscana Virus

Timothy R. La Pine, M.D.
Adjunct Professor of Pathology and Pediatrics, Department of Pathology, University of Utah School of Medicine, Salt Lake City, Utah
Immunomodulating Agents

Matthew B. Laurens, M.D., M.P.H.
Research Associate, Pediatric Infectious Diseases and Tropical Pediatrics, University of Maryland School of Medicine, Baltimore, Maryland
Cholera

Charles T. Leach, M.D.
Professor of Pediatrics, University of Texas Health Science Center at San Antonio; Attending Physician, CHRISTUS Santa Rosa Children's Hospital and University Hospital, San Antonio, Texas
Epstein-Barr Virus

Robert J. Leggiadro, M.D.
Professor of Clinical Pediatrics, Weill Medical College of Cornell University; Chairman, Department of Pediatrics, Lincoln Medical and Mental Health Center, Bronx, New York
Other *Campylobacter* Species; Bioterrorism

Diana R. Lennon, M.B.Ch.B., F.R.A.C.P.
Professor of Population Health of Children and Youth, University of Auckland; Pediatrician in Infectious Diseases, Starship Children's Hospital, Auckland, New Zealand
Acute Rheumatic Fever

Carolyn Lentzsch-Parcells, M.D.
Pediatrician, Pearland, Texas
Fever: Pathogenesis and Treatment

Eric Leroy
Institut de Recherche pour le Developpement, Université de la Méditerranée, Marseille, France; Centre International de Recherches Medicales de Franceville, Franceville, Gabon
Filoviral Hemorrhagic Fever: Marburg and Ebola Virus Fevers

Chi Wai Leung, M.B.B.S.
Honorary Clinical Associate Professor, Department of Paediatrics and Adolescent Medicine, University of Hong Kong; Consultant Paediatrician and Head of Paediatric Infectious Diseases, Department of Paediatrics and Adolescent Medicine, Princess Margaret Hospital, Hong Kong, China
Coronaviruses and Toroviruses, Including Severe Acute Respiratory Syndrome

Moise L. Levy, M.D.
Chief, Pediatric Dermatology, Dell Children's Medical Center, Austin, Texas
Viral and Fungal Skin Infections

Karen Lewis, M.D.
Medical Director, Bureau of Epidemiology and Disease Control, and State Tuberculosis Control Officer, Arizona Department of Health Services, Phoenix, Arizona
Mastoiditis

Phyllis T. Losikoff, M.D., M.P.H.
Clinical Assistant Professor of Pediatrics, The Warren Alpert Medical School of Brown University, Providence; Medical Director, Rhode Island Training School, Cranston, Rhode Island
Active Immunizing Agents

Timothy Edward Lotze, M.D.
Assistant Professor of Pediatrics and Neurology, Baylor College of Medicine; Attending Physician, Neurology Service, Texas Children's Hospital, Houston, Texas
Parainfectious and Postinfectious Disorders of the Nervous System

Adam W. Lowry, M.D.
Instructor, Department of Pediatrics, Baylor College of Medicine; Air Transport Physician, Critical Care Service, Texas Children's Hospital, Houston, Texas
Leptospirosis

Timothy Mailman, M.D.
Associate Professor, Department of Pediatrics, Dalhousie University Faculty of Medicine; Staff Consultant, IWK Health Centre, Halifax, Nova Scotia, Canada
Listeriosis

Susan A. Maloney, M.D.
Chief Epidemiologist and Special Studies, Division of Global Migration and Quarantine, Centers for Disease Control and Prevention, Atlanta, Georgia
International Travel Issues for Children

Laurene Mascola, M.D., M.P.H.
Chief, Acute Communicable Disease Control, Los Angeles County Department of Health Services, Los Angeles, California
Public Health Aspects of Infectious Disease Control

Edward O. Mason, Ph.D.
Professor, Department of Pediatrics and Department of Molecular Virology and Microbiology, Baylor College of Medicine; Director, Infectious Disease Laboratory, Texas Children's Hospital, Houston, Texas
Staphylococcus aureus Infections (Coagulase-Positive Staphylococci)

David O. Matson, M.D., Ph.D.
Director, Graduate Program in Public Health, and Professor of Health Professions and Pediatrics, Eastern Virginia Medical School and Old Dominion University, Norfolk, Virginia
Caliciviruses

Alan N. Mayer, M.D., Ph.D.
Instructor, Department of Pediatrics, Harvard Medical School; Assistant, Division of Gastroenterology, Children's Hospital Boston, Boston, Massachusetts
Hepatitis C Virus

Marc A. Mazade, M.D.
Pediatric Infectious Diseases Consultant, Cook Children's, Fort Worth, Texas
Infections Related to Craniofacial Surgical Procedures

James B. McAuley, M.D., M.P.H.
Associate Professor of Pediatrics and Internal Medicine, Rush Medical College; Director, Section of Pediatric Infectious Diseases, Rush Children's Hospital of Rush University Medical Center, Chicago, Illinois
Congenital Toxoplasmosis; Toxoplasmosis

George H. McCracken, Jr., M.D.
Glaxosmithkline Distinguished Professorship of Pediatric Infectious Diseases, Sarah M. and Charles E. Sey Chair in Pediatric Infectious Diseases, and Professor, Department of Pediatrics, University of Texas Southwestern Medical School; Attending Physician, Children's Medical Center of Dallas, Dallas, Texas
Antibacterial Therapeutic Agents

Kenneth McIntosh, M.D.
Professor of Pediatrics, Harvard Medical School; Emeritus Chief, Division of Infectious Diseases, Children's Hospital Boston, Boston, Massachusetts
Coronaviruses and Toroviruses, Including Severe Acute Respiratory Syndrome

James E. McJunkin, M.D.
Professor of Pediatrics, West Virginia University Health Sciences Center–Charleston Division; Professor of Pediatrics, Women and Children's Hospital, Charleston Area Medical Center, Charleston, West Virginia
La Crosse Encephalitis and Other California Serogroup Viruses

Kelly T. McKee, Jr., M.D.
Vice President, Public Health and Government Services, Quintiles Transnational Corporation, Durham, North Carolina
Hantaviruses

Rima L. McLeod, M.D.
Jules and Doris Stein RPB Professor, Department of Visual Sciences, Pathology, Committees of Molecular Medicine, Genetics, and Immunology, University of Chicago Pritzker School of Medicine; Attending Physician, Department of Medicine, University of Chicago Hospitals; Attending Physician, Department of Ophthalmology, Medical Reese Hospital and Medical Center, Chicago, Illinois
Toxoplasmosis

Valérie A. McLin, M.D.
Assistant Professor of Pediatrics, Baylor College of Medicine; Texas Children's Liver Center, Texas Children's Hospital, Houston, Texas
Cholangitis and Cholecystitis

Maria José Soares Mendes-Giannini, M.D.
Professor, School of Pharmaceutical Sciences, Araraquara, São Paulo State University, São Paulo, Brazil
Paracoccidioidomycosis

Wayne M. Meyers, M.D., Ph.D., D.Sc. (Hon)
Visiting Scientist, Department of Environmental and Infectious Disease Sciences, Armed Forces Institute of Pathology; Registrar for Leprosy, American Registry of Pathology, Washington, D.C.
Leprosy and Buruli Ulcer: The Major Cutaneous Mycobacterioses

Marian G. Michaels, M.D., M.P.H.
Professor of Pediatrics and Surgery, University of Pittsburgh School of Medicine; Director, Pediatric HIV Center; Co-Director, Infectious Diseases Clinical Research Unit; and Attending Physician, Division of Infectious Diseases, Children's Hospital of Pittsburgh, Pittsburgh, Pennsylvania
Opportunistic Infections in Liver and Intestinal Transplantation

Ian C. Michelow, M.D.
Pediatrician, Massachusetts General Hospital, Boston, Massachusetts
Antibacterial Therapeutic Agents

Vladana Milisavljevic, M.D., M.S.
Assistant Clinical Professor, Department of Pediatrics, David Geffen School of Medicine at UCLA; Attending Physician, Mattel Children's Hospital UCLA, Los Angeles, California
Mycoplasma and *Ureaplasma* Infections of the Neonate

Aaron M. Miller, M.D.
Staff Physician, Houston Eye Associates, Tomball, Texas
Ocular Infectious Diseases

James N. Miller, Ph.D.
Professor Emeritus on Recall, Department of Microbiology, Immunology, and Molecular Genetics, David Geffen School of Medicine at UCLA, Los Angeles, California
Nonvenereal Treponematoses

Marjorie J. Miller, Ph.D.
Senior Specialist, Virology, Department of Pathology and Laboratory Medicine, UCLA Medical Center, Los Angeles, California
Classification and Nomenclature of Viruses; Viral Laboratory Diagnosis

James N. Mills, Ph.D.
Chief, Medical Ecology Unit, Special Pathogens Branch, Division of Viral and Rickettsial Diseases, National Center for Zoonosis, Vector-Borne, and Enteric Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia
Hantaviruses

Linda L. Minnich, M.S.
Adjunct Assistant Professor, Robert C. Byrd Health Sciences Center, Charleston Division; Virologist, Charleston Area Medical Center, Charleston, West Virginia
La Crosse Encephalitis and Other California Serogroup Viruses

Ann Moran, M.D.
Assistant Professor, Department of Medicine, Baylor College of Medicine; Staff Physician, Infectious Diseases Section, Michael E. DeBakey Veterans Affairs Medical Center, Houston, Texas
Cryptococcosis

James R. Murphy, Ph.D.
Professor, Department of Pediatrics, Section of Pediatric Infectious Diseases, University of Texas Health Science Center, Houston, Texas
Campylobacter jejuni

Pratip K. Nag, M.D., Ph.D.
Assistant Professor of Pediatrics, Pediatric Emergency Medicine Section, Baylor College of Medicine; Attending Physician, Texas Children's Hospital, Houston, Texas
Diphtheria; Tularemia

Joseph J. Nania, M.D.
Department of Pediatrics, Division of Infectious Diseases, Vanderbilt University School of Medicine, Nashville, Tennessee
Bartonella (Cat-Scratch Disease)

James P. Nataro, M.D., Ph.D., M.B.A.
Professor of Pediatrics, Medicine, Microbiology and Immunology, and Biochemistry and Molecular Biology, Center for Vaccine Development, University of Maryland School of Medicine; Vice Chair, Department of Pediatrics, University of Maryland Hospital for Children, Baltimore, Maryland
Diarrhea-Causing and Dysentery-Causing *Escherichia coli;* Cholera

Roger K. Nicome, M.D.
Assistant Professor of Pediatrics, Pediatric Emergency Medicine Section, Baylor College of Medicine; Attending Physician, Emergency Medicine Department, Texas Children's Hospital, Houston, Texas
Aeromonas

Karin Nielsen-Saines, M.D., M.P.H.
Assistant Professor of Pediatrics, David Geffen School of Medicine at UCLA; Member, Division of Infectious Diseases, Mattel Children's Hospital UCLA, Los Angeles, California
Leishmaniasis

Delma J. Nieves, M.D.
Assistant Professor of Pediatrics, David Geffen School of Medicine at UCLA; Member, Division of Infectious Diseases, Mattel Children's Hospital UCLA, Los Angeles, California
The Common Cold

Richard A. Oberhelman, M.D.
Professor of Tropical Medicine and Pediatrics, Tulane School of Public Health and Tropical Medicine, New Orleans, Louisiana
Bacillus cereus

Theresa J. Ochoa, M.D.
Assistant Professor of Pediatrics, Universidad Peruana Cayetano Heredia, Lima, Peru; Assistant Professor of Epidemiology, University of Texas School of Public Health, Houston, Texas
Shigella; Salmonella; Cryptosporidiosis

Christopher M. Oermann, M.D.
Associate Professor, Department of Pediatrics, Baylor College of Medicine; Attending Physician, Pulmonary Medicine Service, Texas Children's Hospital, Houston, Texas
Acute Respiratory Distress Syndrome in Children

Alina Olteanu, M.D., Ph.D.
Assistant Professor of Pediatrics, Tulane University School of Medicine, New Orleans, Louisiana
Metabolic Response of the Host to Infections

Gary D. Overturf, M.D.
Professor of Pediatrics and Pathology, University of New Mexico School of Medicine; Medical Director, Infectious Diseases, TriCore Reference Laboratories, Albuquerque, New Mexico
Plague *(Yersinia pestis);* Clostridial Intoxication and Infection; Antimicrobial Prophylaxis

Debra L. Palazzi, M.D.
Assistant Professor of Pediatrics, Pediatric Infectious Diseases Section, Baylor College of Medicine; Attending Physician, Texas Children's Hospital, Houston, Texas
Fever without Source and Fever of Unknown Origin

Pia S. Pannaraj, M.D.
Assistant Professor of Pediatrics, Keck School of Medicine of the University of Southern California; Attending Physician, Children's Hospital Los Angeles, Los Angeles, California
Group B Streptococcal Infections

Janak A. Patel, M.D.
Professor of Pediatrics and Director, Division of Pediatric Infectious Diseases and Immunology, Children's Hospital, University of Texas Medical Branch; Consultant, Shriners Burn Hospital for Children, Galveston, Texas
Infections in Burn Patients

Christian C. Patrick, M.D., Ph.D.
Chief Medical Officer and Senior Vice President for Medical and Academic Affairs, Miami Children's Hospital, Miami, Florida
Opportunistic Infections in Hematopoietic Stem Cell Transplantation; Coagulase-Negative Staphylococcal Infections

Evelyn A. Paysse, M.D.
Associate Professor of Ophthalmology and Pediatrics, Department of Ophthalmology, Baylor College of Medicine; Clinical Physician, Department of Pediatric Ophthalmology and Strabismus, Texas Children's Hospital, Houston, Texas
Ocular Infectious Diseases

Norma Pérez, D.O.
Assistant Professor, Baylor College of Medicine; Staff Scientist, University of Texas Health Science Center, Houston, Texas
Campylobacter jejuni

C. J. Peters, M.D.
Professor of Microbiology, Immunology, and Pathology, University of Texas Medical Branch–Galveston, Galveston, Texas
Hantaviruses; Other Bunyaviridae: Rift Valley Fever

William A. Petri, Jr., M.D., Ph.D.
Professor of Medicine, Microbiology, and Pathology; Chief, Division of Infectious Diseases and International Health; Wade Hampton Frost Professor of Epidemiology, University of Virginia School of Medicine; Attending Physician, University of Virginia Hospitals, Charlottesville, Virginia
Amebiasis

Brandon Lane Phillips, M.D.
Instructor in Pediatrics, Mayo College of Medicine, and Fellow, Division of Pediatric Cardiology, Mayo Clinic, Rochester, Minnesota
Pneumococcal Infections

Larry K. Pickering, M.D.
Senior Adviser to the Director, National Center for Immunization and Respiratory Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia
Approach to Patients with Gastrointestinal Tract Infections and Food Poisoning

Joseph F. Piecuch, D.M.D., M.D.
Clinical Professor, Department of Oral and Maxillofacial Surgery, University of Connecticut School of Dental Medicine, Farmington; Director, Oral and Maxillofacial Surgery Section, Hartford Hospital, Hartford, Connecticut
Infections of the Oral Cavity

Francisco P. Pinheiro, M.D.
Department of Arbovirus, Instituto Evandro Chagas, Belém, Brazil
Other Bunyaviridae: Oropouche Fever

Stanley A. Plotkin, M.D.
Emeritus Professor of Pediatrics, University of Pennsylvania School of Medicine and Wistar Institute; Former Chief, Division of Infectious Diseases, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania; Adjunct Professor of International Health, Johns Hopkins University, Baltimore, Maryland; Former Medical and Scientific Director, Aventis Pasteur; and Executive Advisor to the CEO, Sanofi Pasteur, Swiftwater, Pennsylvania
Rabies Virus

Scott L. Pomeroy, M.D., Ph.D.
Bronson Crothers Professor of Neurology, Harvard Medical School; Neurologist-in-Chief, Children's Hospital Boston, Boston, Massachusetts
Parainfectious and Postinfectious Disorders of the Nervous System

Alice Pong, M.D.
Attending Physician, Division of Pediatric Infectious Diseases, Rady Children's Hospital–San Deigo, San Diego, California
Retroperitoneal Infections

David L. Pugatch, M.D.
Clinical Professor of Pediatrics, University of California, San Francisco, School of Medicine, San Francisco; Medical Director, Pediatric Infectious Diseases, Children's Hospital of Central California, Madera, California
Active Immunizing Agents

Joan S. Purcell, M.D.
Chair, Department of Pediatrics, The Woodlands Memorial Hospital; Vice President, Step Pediatrics, The Woodlands, Texas
Trichomonas Infections

Ramya Ramraj, M.D.
Pediatrician, Sugarland, Texas
Mimiviruses

Jack S. Remington, M.D.
Professor Emeritus, Department of Medicine, Stanford University School of Medicine; Palo Alto Medical Foundation, Palo Alto, California
Toxoplasmosis

Carina A. Rodriguez, M.D.
Postdoctoral Fellow, University of Tennessee, Memphis, College of Medicine, and Department of Infectious Diseases, St. Jude Children's Research Hospital, Memphis, Tennessee
Coagulase-Negative Staphylococcal Infections

José R. Romero, M.D.
Horace C. Cabe Professor of Pediatrics and Chief, Pediatric Infectious Diseases, Arkansas Children's Hospital/University of Arkansas for Medical Sciences; Director, Clinical Trials Research, Arkansas Children's Hospital Research Unit, Little Rock, Arkansas
Flaviviruses: West Nile Virus

Benjamin A. Ross, M.D.
Pediatric Neurologist, Denver, Colorado
Parainfectious and Postinfectious Disorders of the Nervous System

Lawrence A. Ross, M.D.
Professor of Clinical Pediatrics, Keck School of Medicine of the University of Southern California; Attending Physician, Division of Infectious Diseases, Children's Hospital Los Angeles, Los Angeles, California
Trypanosomiasis

Judith L. Rowen, M.D.
Associate Professor of Pediatrics and Assistant Dean for Educational Affairs, University of Texas Medical Branch–Galveston, Galveston, Texas
Miscellaneous Mycoses

Charles E. Rupprecht, V.M.D., Ph.D.
Chief, Rabies Program, Division of Viral and Rickettsial Diseases, Centers for Disease Control and Prevention, Atlanta, Georgia
Rabies Virus

Xavier Sáez-Llorens, M.D.
Professor of Pediatrics and Infectious Diseases, University of Panama School of Medicine; Vice-Chairman and Head of Infectious Diseases, Hospital del Niño, Panama City, Panama
Parameningeal Infections; Perinatal Bacterial Diseases

Lisa Saiman, M.D., M.P.H.
Associate Professor of Clinical Pediatrics, Department of Pediatrics, Columbia University College of Physicians and Surgeons; Associate Attending Pediatrician, Department of Pediatrics, and Hospital Epidemiologist, Department of Pediatrics and Epidemiology, Children's Hospital of New York, New York, New York
Cystic Fibrosis

Joseph W. St. Geme III, M.D.
Professor of Pediatrics and Molecular Genetics and Microbiology and Chair, Department of Pediatrics, Duke University School of Medicine; Chief Medical Officer, Duke University Hospital, Durham, North Carolina
Molecular Determinants of Microbial Pathogenesis

Pablo J. Sánchez, M.D.
Professor, Department of Pediatrics, Division of Neonatal-Perinatal Medicine and Pediatric Infectious Diseases, University of Texas Southwestern Medical School; Division of Neonatal-Perinatal Medicine and Pediatric Infectious Diseases, Parkland Health and Hospital Systems and Children's Medical Center of Dallas, Dallas, Texas
Viral Infections of the Fetus and Neonate; Syphilis

Laura A. Sass, M.D.
Assistant Professor of Pediatrics, Eastern Virginia Medical School; Attending Physician, Division of Pediatric Infectious Diseases, Children's Hospital of The King's Daughters, Norfolk, Virginia
Enterobacter

Carlos A. Sattler, M.D.
Senior Director, Medical Affairs and Policy, Merck Vaccines and Infectious Diseases, West Point, Pennsylvania
Stenotrophomonas (Xanthomonas) maltophilia

Danica J. Schulte, M.D.
Clinical Instructor, Department of Pediatrics, David Geffen School of Medicine at UCLA; Attending Physician, Division of Pediatric Infectious Diseases, Immunology, and Allergy, Cedars-Sinai Medical Center, Los Angeles, California
Human Parvovirus B19

Gordon E. Schutze, M.D.
Professor of Pediatrics, Section of Retrovirology, Baylor College of Medicine; Vice President, Baylor International Pediatric AIDS Initiative, Texas Children's Hospital, Houston, Texas
Human Retroviruses: Oncoviruses (Human T-Cell Lymphotropic Viruses) and Lentiviruses (Human Immunodeficiency Virus Type 2); Blastomycosis

Filiz O. Seeborg, M.D.
Assistant Professor of Pediatrics, Section of Pediatric Allergy and Immunology, Baylor College of Medicine; Attending Physician, Allergy and Immunology Service, Texas Children's Hospital, Houston, Texas
Human Retroviruses: Impact of Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome

Eugene D. Shapiro, M.D.
Professor of Pediatrics, Epidemiology, and Public Health and Investigative Medicine, Yale School of Medicine; Associate Chairperson, Yale–New Haven Children's Hospital, New Haven, Connecticut
Epidemiology of Infectious Diseases; Epidemiology and Biostatistics

Nina L. Shapiro, M.D.
Associate Professor, Division of Head and Neck Surgery, David Geffen School of Medicine at UCLA; Attending Physician, Division of Head and Neck Surgery, UCLA Medical Center, Los Angeles, California
Sinusitis; Mastoiditis

William T. Shearer, M.D., Ph.D.
Professor, Departments of Pediatrics and Immunology, and Head, Section of Pediatric Allergy and Immunology, Baylor College of Medicine; Chief, Allergy and Immunology Service, Texas Children's Hospital, Houston, Texas
Chronic Bronchitis; Primary Immunodeficiencies; Human Retroviruses: Impact of Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome

Ziad M. Shehab, M.D.
Professor of Clinical Pediatrics and Pathology, University of Arizona Health Sciences Center, Tucson, Arizona
Coccidioidomycosis

Jerry L. Shenep, M.D.
Professor of Pediatrics, University of Tennessee Health Science Center; Member, Department of Infectious Diseases, St. Jude Children's Research Hospital, Memphis, Tennessee
Enterococcal and Viridans Streptococcal Infections; Cryptococcosis

W. Donald Shields, M.D.
Professor of Neurology and Pediatrics, David Geffen School of Medicine at UCLA; Member, Division of Neurology, Mattel Children's Hospital UCLA, Los Angeles, California
Encephalitis and Meningoencephalitis

Robyn Shimizu-Cohen
University of California, Los Angeles, School of Medicine; Clinical Laboratory Scientist, University of California, Los Angeles, Healthcare, Los Angeles, California
Parasitic Laboratory Diagnosis

Stanford T. Shulman, M.D.
Virginia H. Rogers Professor of Pediatric Infectious Diseases, Feinberg School of Medicine, Northwestern University; Chief, Division of Infectious Diseases, Children's Memorial Hospital, Chicago, Illinois
Kawasaki Disease

Constantine Simos, D.M.D.
Attending Physician, Oral and Maxillofacial Surgery, Robert Wood Johnson University Hospital and Saint Peter's University Hospital, New Brunswick, New Jersey
Infections of the Oral Cavity

Arnold L. Smith, M.D.
Professor, Department of Pathobiology, University of Washington School of Public Health; Member, Department of Bacterial Pathogens, Seattle Biomedical Research Institute, Seattle, Washington
Meningococcal Infections

Jason S. Soden, M.D.
Assistant Professor of Pediatrics, University of Colorado Denver School of Medicine; Attending Physician, Pediatric Gastroenterology, The Children's Hospital, Denver, Colorado
Cholangitis and Cholecystitis

Mary Allen Staat, M.D., M.P.H.
Associate Professor, Department of Pediatrics, University of Cincinnati College of Medicine; Director, International Adoption Center, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio
Genital Infections; Rotaviruses

Jeffrey R. Starke, M.D.
Professor and Vice-Chairman of Pediatrics, Baylor College of Medicine; Chief of Pediatrics, Ben Taub General Hospital; Infection Control Officer, Texas Children's Hospital, Houston, Texas
Infective Endocarditis; Tuberculosis

Barbara W. Stechenberg, M.D.
Professor of Pediatrics, Tufts University School of Medicine, Boston; Vice-Chair, Department of Pediatrics, and Director, Pediatric Infectious Diseases, Baystate Children's Hospital, Springfield, Massachusetts
Eosinophilic Meningitis; *Moraxella catarrhalis;* Diphtheria; *Pasteurella multocida;* Bartonellosis; *Borrelia* (Lyme Disease)

William J. Steinbach, M.D.
Assistant Professor of Pediatrics, Duke University School of Medicine; Division of Pediatric Infectious Diseases, Duke University Medical Center, Durham, North Carolina
Aspergillus and Aspergillosis; Zygomycosis

Paul G. Steinkuller, M.D.
Associate Professor of Ophthalmology and Pediatrics, Baylor College of Medicine; Clinical Staff, Ophthalmology Service, Texas Children's Hospital, Houston, Texas
Ocular Infectious Diseases

E. Richard Stiehm, M.D.
Professor of Pediatrics, David Geffen School of Medicine at UCLA; Attending Pediatrician, Mattel Children's Hospital UCLA, Los Angeles, California
Passive Immunization

Stephanie H. Stovall, M.D.
Assistant Professor of Pediatrics, University of Arkansas for Medical Sciences; Medical Director, Clinical Microbiology and Virology Laboratory, and Co-Director, Antimicrobial Stewardship, Arkansas Children's Hospital, Little Rock, Arkansas
Blastomycosis

Jeffrey Suen, M.D.
Assistant Professor, Department of Pediatrics, David Geffen School of Medicine at UCLA; Member, Division of Infectious Diseases, Mattel Children's Hospital UCLA, Los Angeles, California
Toxic Shock Syndrome

Ciro V. Sumaya, M.D.
Dean, School of Rural Public Health, and Professor and Cox Endowed Chair in Medicine, Department of Pediatrics, Texas A & M Health Science Center, College Station; Attending Physician, Scott and White Hospital and Clinic, Temple, Texas
Epstein-Barr Virus

Andrea P. Summer, M.D.
Associate Professor of Pediatrics, Medical University of South Carolina, Charleston, South Carolina
Cestodes; Trematodes; Schistosomiasis

Douglas S. Swanson, M.D.
Associate Professor of Pediatrics, University of Missouri–Kansas City School of Medicine; Children's Mercy Hospital, Kansas City, Missouri
Indigenous Flora

Tina Q. Tan, M.D.
Associate Professor of Pediatrics, Feinberg School of Medicine, Northwestern University; Attending Physician, Infectious Diseases; Co-Director, Pediatric Travel Medicine Clinic; and Director, International Adoptee Clinic, Children's Memorial Hospital, Chicago, Illinois
Infections Related to Prosthetic or Artificial Devices; Giardiasis; *Naegleria, Acanthamoeba,* and *Balamuthia*

Herbert B. Tanowitz, M.D.

Zygomycosis

PREFACE

Morbidity and mortality rates related to infectious diseases decreased dramatically during the first half of the 20th century in the developed world because of major improvements in public health (e.g., clean water, adequate sanitation, and vector control) and personal health. Further major reduction in morbidity and mortality rates occurred in the second half of that century following the introduction of antimicrobial therapy, as well as active and passive immunization efforts. Despite theses advances in the 20th century, infectious diseases in the developed world remain the leading cause of morbidity in infants and children in the early 21st century. Children continue to experience three to nine respiratory infections and one to three gastrointestinal illnesses annually, requiring visits to physicians that outnumber the visits made for the purpose of well-child care. Infectious diseases also are the most common cause of school absenteeism. In more recent years, the emergence of resistance to multiple antibiotics by a large number of bacterial microorganisms (i.e., community-associated methicillin-resistant *Staphylococcus aureus*) has contributed to the morbidity and mortality related to infectious diseases processes, as have new infectious agents (i.e., bocavirus, SARS coronavirus). The developing world is confronted with the same present-day problems seen in the developed world (antimicrobial resistance and new infectious agents), and these challenges are compounded by malnutrition and lack of adequate public health services and antimicrobial agents.

The first edition of our text was written because we and many of our colleagues were concerned that no single reference text existed that comprehensively covered infectious diseases in children and adolescents. With each subsequent edition, including this one, our goal has been to provide comprehensive coverage of all subjects pertinent to the study of infectious diseases in these populations. Any attempt to summarize our present understanding of infectious diseases for serious students of the subject is a formidable task. In many areas, new information continues to accrue so rapidly that material becomes dated before it can appear in a text of this magnitude. Nonetheless, we have endeavored with the help of many of our colleagues to provide the most comprehensive and up-to-date discussion of this field. The new edition will be available online as well as in print. Purchasers can access the online version by registering their PIN number (found on the inside front cover of the book) at www.expertconsult.com. Online access includes not only fully searchable text, photos, illustrations, and tables but references linked to Pub Med access.

To provide a text as comprehensive and authoritative as possible, we have enlisted contributions from a large number of individuals whose collective expertise is responsible for whatever success we may have had in meeting our objective. We offer our most profound appreciation to the 284 fellow contributors from 108 universities or institutions in 15 countries for their professional expertise and devoted scholarship. Their cooperation and willingness to work with us leave us deeply in their debt.

Once again, infectious diseases are discussed according to organ systems that may be affected, as well as individually by microorganisms. In all sections in which diseases related to specific agents are discussed, emphasis has been placed, to the greatest extent possible, on the specificity of clinical manifestations that may be related to the organism causing the disease. Detailed information regarding the best means to establish a diagnosis and explicit recommendations for therapy are provided.

The entire text has been revised extensively. This edition continues the format that was initiated in the fourth edition in that infections with specific microorganisms have been organized to provide appropriate emphasis on the common features that may relate specific microorganisms to one another. Thus, all gram-positive coccal organisms are presented sequentially and are followed by gram-negative cocci, gram-positive bacilli, enterobacteria, gram-negative coccobacilli, Treponemataceae, anaerobic bacteria, and so forth. In addition, special sections of the text have been devoted to discussions of each of the following: molecular determinants of microbial pathogenesis; immunologic and phagocytic responses to infection; metabolic response of the host to infections; interaction of infection and nutrition; pathogenesis and treatment of fever; indigenous flora; epidemiology of infectious diseases; infections of the compromised host; Kawasaki disease; chronic fatigue syndrome; international travel issues for children; infectious disease problems of international adoptees and refugees; nosocomial infections; prevention and control of infections in hospitalized children; pharmacology and pharmacokinetics of antibacterial, antiviral, antifungal, and antiparasitic agents; immunomodulating agents; active and passive immunizing agents; public health considerations; infections in daycare environments; and use of the bacteriology, mycology, parasitology, virology, and serology laboratories. The section on infections in the compromised host has been divided into nine chapters including opportunistic infections in children with bone marrow transplantation, infections in pediatric heart transplant recipients and lung transplant recipients, opportunistic infections in children with liver and intestinal transplantation, opportunistic infections in children with kidney transplantation, infections related to prosthetics or artificial devices, infections related to craniofacial surgical procedures, and infections related to burns. This reorganization has been necessitated by the large number of individuals, particularly post-transplantation recipients, who now serve as the source of many infectious disease problems and constitute a large part of the consulting practice of many pediatric infectious disease physicians.

With some sadness, we have retained a section on bioterrorism, which is necessitated by the current state of world affairs. The section on immunomodulating agents and their potential use in the treatment of infectious diseases has been expanded because information on this subject has become more extensive since the publication of the last edition. Specific sections also have been

devoted to human and animal bites. The subject of biostatistics as applicable to the subspecialty of infectious diseases also has been included. New chapters on human bocavirus and mimiviruses have been added, and the chapters on human metapneumovirus, coronaviruses, and monkeypox have been expanded.

This project could not have been brought to fruition without the help and assistance of many people whose names do not appear in the text. No words are sufficient to adequately convey our gratitude appropriately; we hope that they know they have our heartfelt thanks.

We would like to single out certain individuals for specific mention. We cannot adequately convey our appreciation for the thousands of hours devoted by Dr. B. Lee Ligon, who edited and also proofread every word of the text that was submitted, as well as the page proofs. We are equally indebted to Mary Campbell, who spent an equivalent amount of time and who was specifically responsible for the coordination of the editorial effort, correspondence with our contributors and with the publishers, and coordination of the manuscript preparation process. She also typed and retyped many sections of the text. We also extremely appreciate the efforts of Laura Wennstrom Sheehan, who oversaw and coordinated all events in Los Angeles. In particular, the work of Tiki Valentino and the students in the UCLA office (Lilit Gevorgyan, Judy Diep, Wendy Monteon, Robin Nguyen, Narges Moaddel, Margarita Santiago, Kelley Shin, and Karla Ortiz) deserves much praise.

We also appreciate the assistance provided to Mary Campbell and to the editors by Carrel Briley in Dr. Feigin's office.

Also appreciated were the help and support of Judith Fletcher, Melissa Dudlick, and Lee Ann Draud at Elsevier.

Finally, we thank the Baylor College of Medicine and Texas Children's Hospital in Houston, Texas, and the David Geffen School of Medicine at UCLA and the Mattel Children's Hospital UCLA in Los Angeles, California, for providing an environment that is supportive of intellectual pursuits.

CHAPTER 1

Molecular Determinants of Microbial Pathogenesis

David A. Hunstad ✪ Joseph W. St. Geme III

Despite the availability of antibiotics and expansion of vaccination programs, infectious diseases remain a leading cause of morbidity and mortality worldwide. Numerous factors, including an increase in the prevalence of antimicrobial resistance, an increase in global travel, and an increase in the number of individuals with altered immunity, contribute to the continuing importance of infectious agents. In recent years, several microorganisms have been implicated in diseases previously considered noninfectious, and a variety of new and emerging pathogens have been recognized.

Pathogens are defined as microorganisms that are capable of causing disease. Not all pathogens are equal, however, with respect to their pathogenic potential (i.e., their virulence). Many pathogens are commensal organisms and live in harmony with their host under most conditions, causing disease only when normal immune mechanisms are disrupted or absent. Other pathogens produce disease even in the setting of intact immunity and almost always cause symptoms.

For a given pathogen, pathogenic potential is determined by the specific array of virulence-associated genes. Some species of bacteria are capable of natural transformation and readily acquire fragments of DNA from other organisms, expanding or altering their genetic composition, occasionally with consequences related to virulence. Many microorganisms carry virulence-associated genes on mobile genetic elements, including plasmids, transposons, and bacteriophages. These elements may equip the organism with genetic information that facilitates rapid adaptation to an unfavorable or changing environment. Comparison of genomes from pathogenic and nonpathogenic members of a single genus or species has led to the identification of *pathogenicity islands*—large blocks of chromosomal DNA that are present in pathogens and absent from related nonpathogens. These blocks are flanked by insertion sequences or repeat elements and differ in nucleotide composition relative to the surrounding genome, suggesting acquisition by horizontal exchange. Pathogenicity islands contain clusters of virulence-associated genes that encode a variety of factors, including protein secretion systems, secreted effector molecules, adhesins, and regulatory proteins.

To be successful, a pathogen must enter the host, find an appropriate niche, and multiply. Often the pathogen induces damage to the host and then spreads to other tissues, either nearby the initial site of infection or more distant. Ideally, the pathogen stops short of causing death to the host and produces symptoms, such as cough or diarrhea, that facilitate spread to another host.

This chapter addresses several key steps in the pathogenic process. In each case, we present examples that highlight pathogens and paradigms of relevance to infectious diseases in children. As a reflection of our personal bias, we focus primarily on bacterial pathogens.

COLONIZATION

Most infectious diseases begin with microbial colonization of a host surface—typically the skin, the respiratory tract, the gastrointestinal tract, or the genitourinary tract. Although colonization is insufficient for an organism to produce disease, it is a necessary prerequisite. The process of colonization requires specialized microbial factors, called *adhesins*, which promote adherence to host structures and enable the organism to overcome local defenses, such as mucociliary function, peristalsis, and urinary flow. The cognate receptors for these interactions generally are either carbohydrate or protein structures—in some cases expressed on host cells, and in others present in mucosal secretions or in submucosal tissue.

PILUS ADHESINS

Perhaps most common among bacterial adhesins are hairlike fibers called *pili* (also called *fimbriae*). Pili are polymeric structures containing a major structural subunit that usually ranges in size from 15 to 25 kd. Because of their size and morphology, most pili can be seen by negative-stain transmission electron microscopy.

The prototype example among adhesive pili is the P (or Pap) pilus, which is expressed by uropathogenic *Escherichia coli* (UPEC) and has been strongly associated with pyelonephritis. P pili recognize globoseries glycolipids, host molecules that are characterized by a core structure consisting of Gal-α1,4-Gal. The globoseries glycolipids are especially abundant in renal epithelium,[20] accounting for the predilection of P-piliated *E. coli* to adhere to kidney tissue and cause pyelonephritis. As shown in Figure 1–1, P pili are composite structures and consist of two subassemblies, including a thick rod that emanates from the bacterial surface and a thin tip fibrillum that extends distally.[141,226] The pilus rod is a right-handed helical cylinder and comprises repeating PapA subunits, whereas the tip fibrillum has an open helical configuration and contains mostly repeating PapE subunits. The two subassemblies are joined to each other by the PapK adapter protein. PapG contains the adhesive moiety and is located at the distal end of the tip fibrillum, joined to PapE by the PapF adapter.[123]

P pili are assembled in a process that involves a periplasmic chaperone, called *PapD*, and an outer membrane usher, called *PapC* (see Fig. 1–1).[50,142] The crystal structures of PapD alone and PapD interacting with the PapK pilin subunit have been solved, revealing significant insights into PapD interaction with Pap subunits and the mechanism of P pilus assembly.[225] PapD consists of two immunoglobulin-like folds oriented in an L shape with an intervening cleft. The PapK subunit consists of a single immunoglobulin-like fold but lacks the seventh, C-terminal β-strand (strand G1). The absence of this strand leaves a deep groove along the surface of PapK and exposes its hydrophobic core, predisposing the subunit to aggregation and degradation.

In the PapD-PapK complex, the G1 strand of PapD occupies the groove in PapK and completes the immunoglobulin-like fold, a phenomenon termed *donor strand complementation* (Fig. 1–2A). This interaction shields the hydrophobic core of the subunit and stabilizes the protein. Within the groove, the G1 strand of PapD interacts on one side with the C-terminal, F strand of PapK.[225] Ultimately, PapD delivers PapK and other Pap subunits to the PapC usher, which forms a dimer with twin pores in the outer membrane.[148] As the pilus is assembled on the bacterial surface, the N-terminal strand of a neighboring subunit (the one most

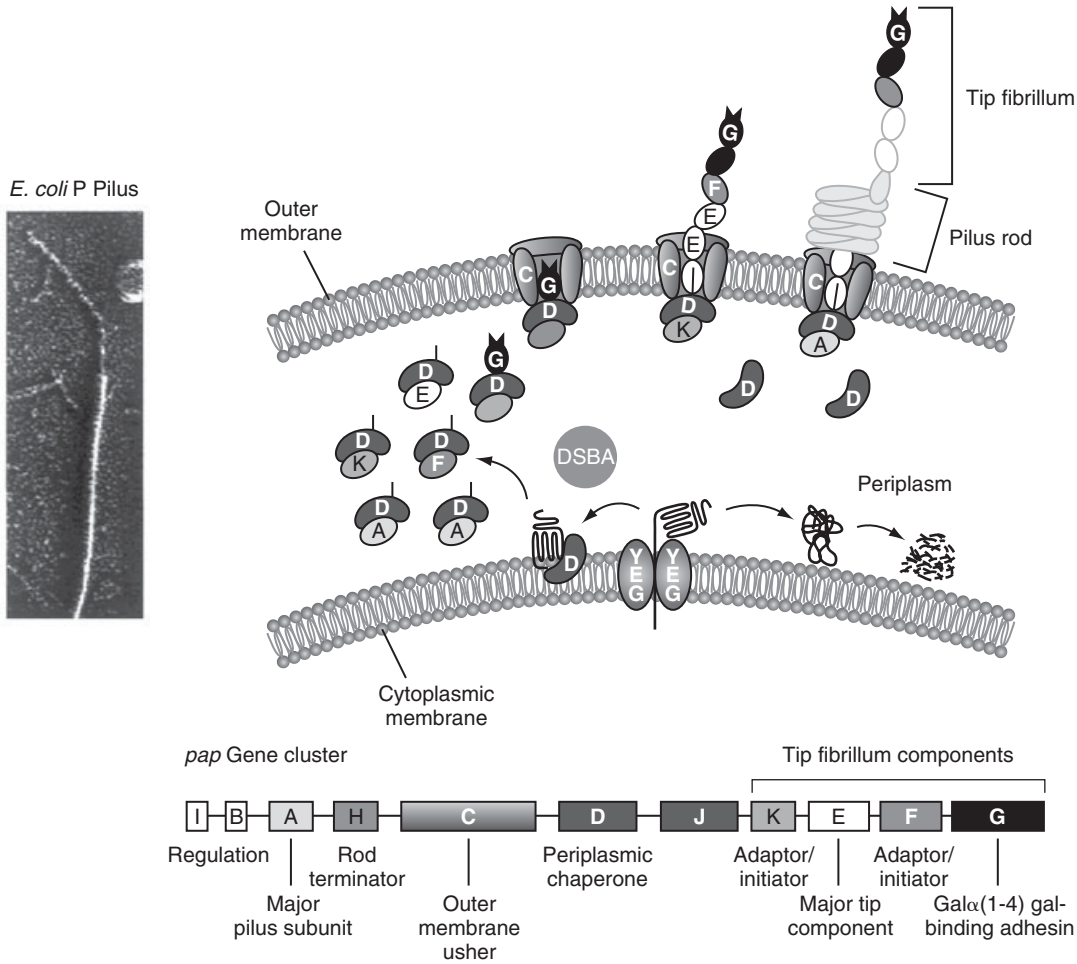

Figure 1–1 Biogenesis and structure of *Escherichia coli* P pili. The *pap* gene cluster and the function of each of the gene products are indicated in the lower portion of the figure. Nascent pilin subunits are complexed with the PapD chaperone and added to the base of the developing pilus via the PapC usher. The mature pilus rod is composed of repeating units of PapA; the tip fibrillum contains the adhesin PapG. The ultrastructure of the pilus is shown in the electron micrograph at the left side of the figure. DSBA, disulfide oxidoreductase that resides in the periplasm; YEG, sec machinery that facilitates protein export from the cytoplasm to the periplasm. *(Courtesy of S. J. Hultgren and F. J. Sauer.)*

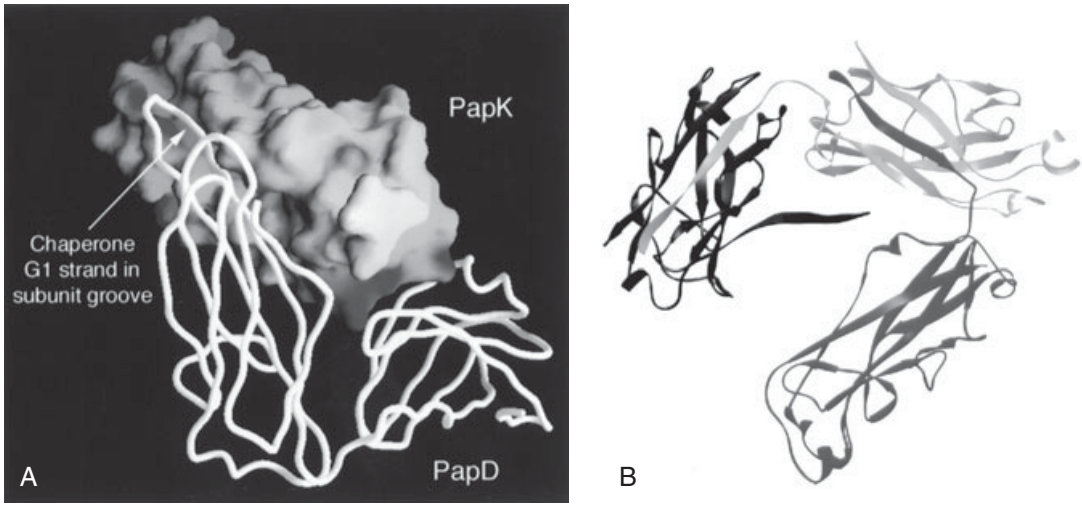

Figure 1–2 **A,** The G1 strand of the PapD chaperone completes the immunoglobulin-like fold of the PapK pilin subunit (donor strand complementation). **B,** The mature P pilus rod comprises a helix (3.28 subunits per turn) of repeating PapA subunits; each subunit is completed by a strand donated by its neighbor. *(Courtesy of S. J. Hultgren and F. J. Sauer.)*

recently added to the pilus base) replaces the G1 strand of PapD in a process called *donor strand exchange*. In the mature pilus, each subunit completes the immunoglobulin-like fold of its neighbor (see Fig. 1–2B).[117] The PapA major subunit employs an intramolecular "hinge" first to exit the usher vertically and then to adopt its final conformation within the helical cylinder that forms the pilus fiber.[176]

More than 30 different bacterial adhesive structures are assembled via the chaperone-usher pathway with a PapD-like chaperone and a PapC-like usher. These PapD-like chaperones can be divided into two distinct subfamilies based on conserved structural differences that occur near the subunit binding site.[118] One subfamily is involved in the assembly of rodlike pili similar to P pili, and the second subfamily participates in the biogenesis of more atypical filamentous structures. The nature of the chaperone is linked directly to the architecture of the adhesive appendage.[239]

Type 4 pili represent a second class of pili, distinguished by a methylated first amino acid (usually phenylalanine), a short positively charged leader sequence, a conserved hydrophobic amino terminal domain, and a tendency to form bundle-like structures. Type 4 pili have been identified in numerous gram-negative bacterial pathogens, including *Neisseria gonorrhoeae*, *Neisseria meningitidis*, enteropathogenic *E. coli* (EPEC), *Vibrio cholerae*, *Pseudomonas aeruginosa*, *Kingella kingae*, *Eikenella corrodens*, *Moraxella* spp., and *Dichelobacter nodosus* (formerly *Bacteroides nodosus*).*

Although the mechanism of assembly of type 4 pili is still being elucidated, existing data suggest that the process is complex. Twenty to 40 gene products are required for the assembly of *P. aeruginosa* type 4 pili, and at least 15 plasmid-encoded proteins are involved in the biogenesis of EPEC type 4 pili.[107,247] Based on studies of *P. aeruginosa*, EPEC, *Neisseria* spp., and *V. cholerae*, the presence of an inner membrane pre-pilin peptidase seems to be a general prerequisite for type 4 pilus biogenesis.[132,144,186] The involvement of at least one protein with a canonical nucleotide binding domain is another common feature. Many of the other proteins required for type 4 pilus assembly resemble proteins from filamentous phage biogenesis systems and DNA uptake and transfer systems, suggesting that similar transport and assembly mechanisms are used.[108,221] More recent evidence indicates that type 4 pili often are glycosylated, with carbohydrate decoration affecting function in at least some cases and perhaps serving to obscure antigenic epitopes.[26,157,234,268]

Despite marked differences in the assembly pathways for type 4 pili and P pili, examination by electron microscopy suggests that, in some cases, significant structural similarities may exist. Gonococcal type 4 pili are composed predominantly of PilE structural subunits polymerized into a helical rod.[195] A minor phase-variable adhesive protein called PilC is displayed at the tip of the pilus and is essential for pilus-mediated binding to epithelial cells.[127,220] These observations suggest that *N. gonorrhoeae* pili may be composite structures with a tip-associated adhesin, analogous to P pili and other pili assembled by the chaperone-usher pathway.

Although adhesive pili are more prevalent in gram-negative bacteria, they also are found in some gram-positive species. One example is *Streptococcus parasanguis*, an oral pathogen and a member of the sanguis streptococcal family. This organism binds to calcium phosphate (the primary mineral component of tooth enamel) and to other oral bacteria, epithelial cells, platelets, and fibronectin. Several adhesins, including pili referred to as *long fimbriae*, mediate these binding functions.

Based on studies of *S. parasanguis* strain FW213, long fimbriae are fashioned primarily from Fap1, a 200-kd protein that includes an unusually long (50 amino acids) signal sequence and a cell wall sorting signal typical of other gram-positive bacterial surface proteins.[283,284] Specific glycosylation of Fap1 seems to be critical to the adhesive function of this fimbrial protein.[246] Similar to gram-negative bacterial pili, long fimbriae seem to have a composite structure with a pilus tip. The tip contains an additional adhesin called FimA, which in purified form is capable of blocking bacterial adherence to saliva-coated hydroxyapatite.[61,191] In work by Burnette-Curley and coworkers,[23] disruption of the *fimA* gene resulted in a 7-fold to 20-fold reduction in the incidence of endocarditis after intravenous inoculation of rats. A second gram-positive organism capable of expressing pili is *Streptococcus agalactiae* (group B streptococcus), a common cause of neonatal pneumonia, sepsis, and meningitis. In *S. agalactiae*, at least two genomic islands encode pilus components, including a major pilin, a pilus-associated anchor, and a pilus-associated adhesin.[55,219]

NON-PILUS ADHESINS

Beyond pili, a variety of non-pilus adhesins exist. In most cases, non-pilus adhesins are proteinaceous and are monomeric or oligomeric surface structures, although isolated examples of carbohydrate and lipid-containing adhesive structures have been identified. Generally, these molecules are difficult to visualize by electron microscopy, even with high-resolution techniques. Similar to pili, for the most part non-pilus adhesins can be classified according to their mechanism of secretion and presentation on the bacterial surface.

Among the best characterized bacterial non-pilus adhesins is filamentous hemagglutinin (FHA), a surface protein expressed by *Bordetella pertussis* and other *Bordetella* species. FHA is synthesized as a large precursor protein with a calculated molecular mass of 367 kd. A cleavage event occurs to eliminate the C-terminal third of the protein and produce the mature 220-kd species.[52] The export of FHA to the surface of the organism occurs via the so-called two-partner secretion pathway, a conserved strategy in which a secreted (TpsA) protein interacts, via specific determinants within its N-terminus, with a cognate outer membrane transporter (TpsB).[109] In *B. pertussis*, the TpsA-type protein FHA is transported by a TpsB-type outer membrane protein called *FhaC*, which has β-barrel pore-forming properties and facilitates translocation of FHA across the outer membrane.[279] Homologous TpsB proteins in other species include those that export the hemolysins of *Serratia marcescens*, *Proteus mirabilis*, and *Haemophilus ducreyi*; the *Haemophilus influenzae* heme:hemopexin binding protein (HxuA); and the *H. influenzae* HMW1 and HMW2 adhesins, among others.[7,36,194,207,264] Although crystallographic data are lacking, the C-terminal portion of FhaC is predicted to form a β-barrel pore in the outer membrane, whereas the FhaC N-terminus may participate in specific recognition of FHA on the periplasmic side.[167]

Examination of purified FHA by transmission electron microscopy and circular dichroism spectroscopy showed that the FHA molecule is 50 nm in length and adopts the shape of a horseshoe nail. It has a globular head, a 37 nm long shaft that averages 4 nm in width but tapers slightly from the head end, and a small flexible tail (Fig. 1–3).[130,156] In the crystal structure of the N-terminus of FHA (the so-called two-partner secretion domain that interacts with FhaC), a series of 19-residue repeat motifs forms a β-helix that is central to the overall structure of full-length FHA (see Fig. 1–3).[30]

Consistent with its large size, FHA contains at least four separate binding domains, three of which have been localized. The region involved in adherence to sulfated saccharides has been mapped to the N-terminus of the FHA molecule.[170] Sulfated saccharides, such as heparin and heparan sulfate, are major components of mucus and extracellular matrix in the respiratory tract

*See references 59, 78, 160, 172, 208, 214, 228, 249, 260, 272.

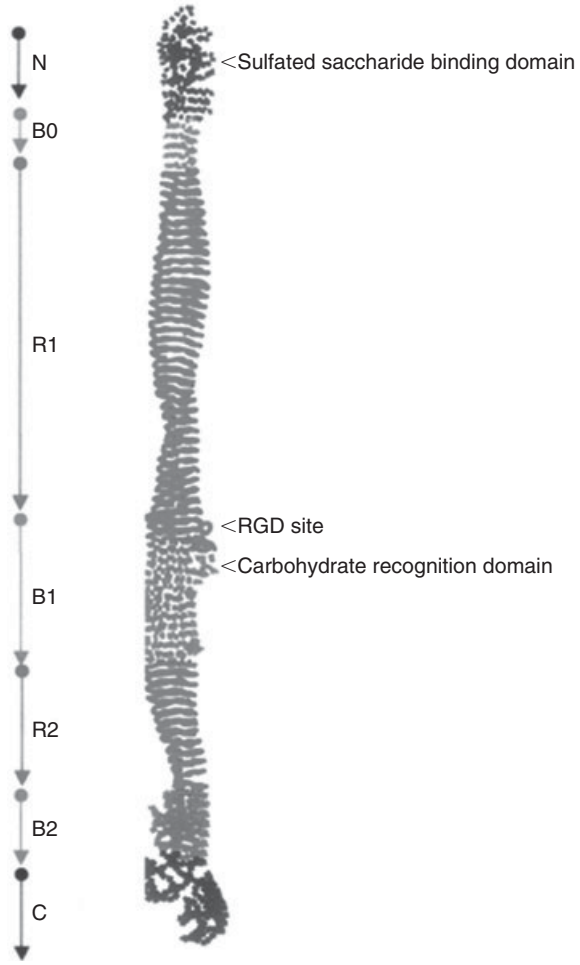

Figure 1–3 Ribbon representation model structure of filamentous hemagglutinin from *Bordetella pertussis*. There are five regions that are assigned β-helical coils, designated B0, R1, B1, R2, and B2. The N-terminus of the protein is designated with "N," and the C-terminus of the protein is designated with "C." The locations of the sulfated saccharide binding domain, the carbohydrate recognition domain, and the arginine-glycine-aspartic acid (RGD) tripeptide are noted. (See companion Expert Consult web site for color version.) *(From Kajava, A. V., Cheng, N., Cleaver, R., et al.: Beta-helix model for the filamentous haemagglutinin adhesin of* Bordetella pertussis *and related bacterial secretory proteins. Mol. Microbiol.* 42*:279-292, 2001.)*

and are found on the surface of epithelial cells.[162,287] The region that recognizes lactosylceramides and promotes adherence to ciliated respiratory epithelial cells and macrophages has been localized to amino acids 1141 to 1279 (the carbohydrate recognition domain).[209] An arginine-glycine-aspartic acid (RGD) tripeptide is located at amino acids 1097 to 1099 and interacts with leukocyte response integrin, a leukocyte integrin that stimulates up-regulation of complement receptor type 3 (CR3).[122] Finally, FHA recognizes CR3 (CD11b/CD18), allowing organisms to be ingested by macrophages without stimulating an oxidative burst.[215,282] The location of the CR3-binding domain is unknown.

A growing number of non-pilus adhesins belong to the so-called autotransporter family. These proteins are synthesized as precursor proteins with three functional domains: an N-terminal canonical signal sequence, an internal passenger domain, and a C-terminal outer membrane domain. The signal sequence directs the protein to the Sec machinery and is cleaved after it facilitates transport of the polypeptide from the cytoplasm to the periplasm. The C-terminal domain inserts into the outer membrane and forms a β-barrel with a central hydrophilic channel. Ultimately, the passenger domain is presented on the surface of the organism and influences interaction with host molecules.[100]

More recent studies have established that autotransporter proteins can be separated into two distinct groups, designated *conventional autotransporters* and *trimeric autotransporters* (Fig. 1–4).[42] In conventional autotransporters, the C-terminal outer membrane domain contains roughly 300 amino acids and is a monomeric β-barrel with a single N-terminal α-helix spanning the pore (Fig. 1–5A).[192,252] In trimeric autotransporters, the C-terminal outer membrane domain contains approximately 70 amino acids and forms heat-resistant, detergent-resistant trimers in the outer membrane. Each trimer forms a β-barrel with four strands from each of the three subunits and with three N-terminal α-helices spanning the pore (see Fig. 1–5B).[168]

An example of a conventional autotransporter adhesin is the *H. influenzae* Hap protein, which was discovered based on its ability to promote adherence and low-level invasion in assays with cultured epithelial cells.[240] Hap also promotes bacterial binding to extracellular matrix proteins and bacterial microcolony formation.[63,101] Examination of chimeric proteins and studies with purified protein have shown that the adhesive activity responsible for Hap-mediated adherence, invasion, binding to extracellular matrix proteins, and microcolony formation localizes to the passenger domain, referred to as Hap_S.[63,101] More detailed characterization of Hap_S has established that the region responsible for interaction with host epithelial cells and microcolony formation resides in the C-terminal 311 amino acids and may have utility as a vaccine antigen.[44,62,151] A prototype member of the trimeric autotransporter subfamily is the *H. influenzae* Hia adhesin. This protein is expressed in a subset of nontypeable *H. influenzae* strains and contains two homologous high-affinity trimeric binding domains, creating the potential for stable multivalent interaction with respiratory epithelial cells.[143,288]

Another group of non-pilus adhesins is typified by intimin, a protein expressed by EPEC, enterohemorrhagic *E. coli*, and the murine pathogen *Citrobacter rodentium*. Intimin contains a flexible N-terminus, a central β-barrel domain that integrates into the outer membrane, and a C-terminal binding domain that interacts with the translocated intimin receptor (Tir).[261] Tir is synthesized by the bacterium, translocated into the host cell cytoplasm via the EPEC type III secretion system,[134,281] and inserted into the host cell membrane, a process that has been modeled in vitro.[212]

The interaction between intimin and Tir triggers a series of host cell events, resulting in receptor clustering, dramatic rearrangement of the actin cytoskeleton, and formation of a distinctive pedestal referred to as an attaching and effacing (A/E) lesion (Fig. 1–6).[134,218] All of the genes essential for formation of A/E lesions are present within a 35-kb region of the EPEC chromosome termed the *locus of enterocyte effacement*, an example of a pathogenicity island.[53,163] This locus is highly conserved in content and organization across all A/E pathogens and contains the genes that encode intimin, Tir, and the EPEC type III secretion system, with a total of 41 open reading frames overall.

In recent years, investigators have identified a large family of non-pilus adhesins involved in adherence to host extracellular matrix proteins, including fibronectin, laminin, vitronectin, collagen, fibrinogen, and a variety of proteoglycans. These adhesins have been classified as *microbial surface components recognizing adhesive matrix molecules* (MSCRAMMs) and are especially prevalent among gram-positive bacteria.[199] In gram-positive organisms, these adhesins are covalently anchored to the cell wall peptidoglycan and have a characteristic primary amino acid sequence. In particular, the carboxy-terminus contains a segment rich in proline and glycine residues, an LPXTG motif (involved in sorting the protein to the cell wall), a hydrophobic

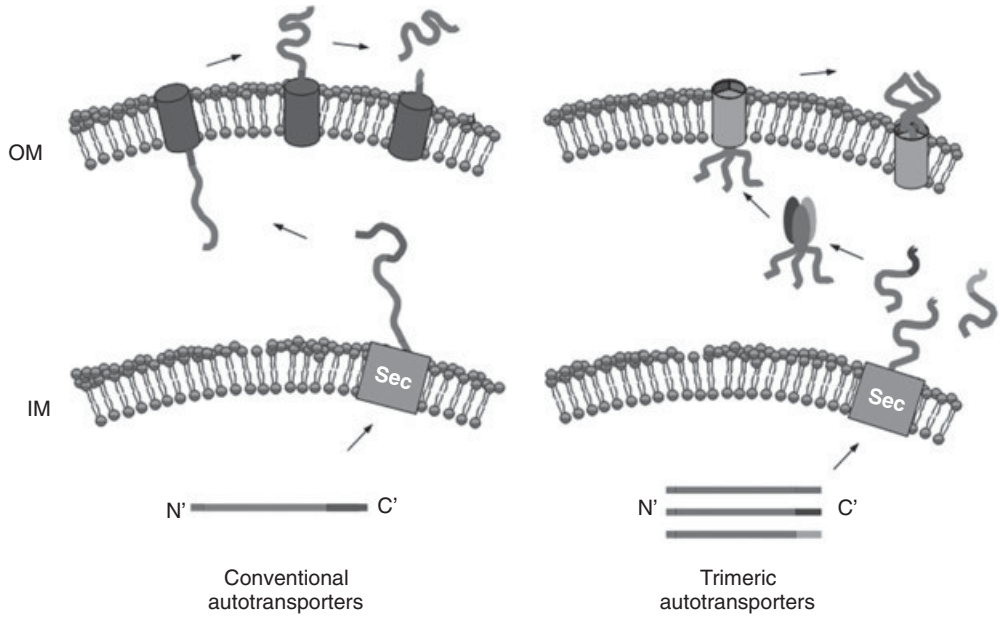

Figure 1–4 Autotransporter protein secretion pathway. Conventional autotransporter secretion is shown on the left, and trimeric autotransporter secretion is shown on the right. Autotransporter proteins are synthesized as preproteins with three functional domains, including an N-terminal signal sequence, an internal passenger domain, and a C-terminal outer membrane β-barrel domain. Protein secretion begins with export of the protein from the cytoplasm via the inner membrane Sec machinery (Sec). Most conventional autotransporters are cleaved on the bacterial surface. IM, inner membrane; OM, outer membrane. (See companion Expert Consult web site for color version.) *(From Cotter, S. E., Surana, N. K., and St. Geme, J. W., III: Trimeric autotransporters: A distinct subfamily of autotransporter proteins. Trends Microbiol.* 13*:199-205, 2005.)*

membrane-spanning domain, and a short, positively charged segment that resides in the cytoplasm and serves as a cell wall retention signal. Adhesive functions typically are located near the N-terminus.[65]

Staphylococcus aureus is a common gram-positive pathogen in children and is capable of producing a variety of MSCRAMMs, including collagen-binding protein (Cna), fibronectin-binding protein A (FnBPA), and clumping factor (ClfA). Strains recovered from patients with septic arthritis commonly express Cna, which mediates binding to cartilage in vitro and seems to play a key role in the pathogenesis of septic arthritis in experimental mice.[198,200,253] The current model of Cna binding suggests that the two major domains (N1 and N2) and an intervening linker polypeptide together form a spherical "hole" through which the bound collagen fiber passes.[294] FnBPA shares homology with *Streptococcus pyogenes* protein F and mediates binding to fibronectin and the gamma chain of fibrinogen.[271] This protein likely is important in *S. aureus* infections of implanted biomaterials, which become coated with fibrinogen and fibrin soon after implantation. ClfA was named based on the observation that it mediates bacterial clumping in the presence of soluble fibrinogen.[164] Similar to FnBPA, ClfA mediates binding to fibrinogen-coated surfaces in vitro and probably contributes to infections of artificial surfaces. The active domain of ClfA is designated region A and contains two amino acid residues (E526 and V527) shown more recently to mediate binding to soluble fibrinogen.[95] The crystal structure of region A shows an immunoglobulin-like fold common to other *S. aureus* MSCRAMMs.[49] Vaccination with ClfA was shown to protect against subsequent development of septic arthritis and death in a mouse model of intravenous *S. aureus* infection.[128]

OTHER MECHANISMS OF ADHERENCE

Candida albicans is a common inhabitant of mucosal surfaces and an important cause of systemic disease, especially in patients with compromised immunity. *Candida* blastospores are capable of efficient adhesion to epithelial cells, leading to budding and division. In addition, germ tube formation occurs, facilitating penetration through the epithelial barrier and dissemination to distant sites.[114] In recent years, several candidate *C. albicans* adhesins have been identified.[8,113,149,290] Of particular interest is a protein called INT1, which shares functional homology with the vertebrate integrin family.

Integrins normally are expressed by cells of the human immune system (neutrophils, monocytes, macrophages) and mediate cellular binding and shape-changing functions. Each integrin is a heterodimer of an alpha chain and a beta chain. Many different alpha and beta chains have been identified, and each combination displays a unique binding specificity. INT1 is an α-integrin–like protein that recognizes the RGD sequence of the C3 fragment iC3b on epithelial cells. In in vitro assays, short peptides encompassing the RGD sequence are capable of inhibiting *C. albicans* adherence by 50 percent, confirming that INT1 plays a significant role as an adhesin and suggesting that other adhesins also exist.[114] Beyond promoting adherence to epithelium, INT1 disguises organisms as leukocytes, allowing evasion of phagocytosis. Introduction of INT1 into *Saccharomyces cerevisiae* confers a capacity for adherence and results in germ tube formation, indicating the importance of this protein in morphogenesis.[73,74]

The adhesive properties of *C. albicans* are tied closely to its morphologic state. Adherence to buccal epithelial cells is greater by organisms bearing germ tubes than by yeast forms.[138] With this information in mind, Staab and coworkers[243] searched a germ tube cDNA library and identified a putative adhesin called *hyphal wall protein 1* (Hwp1), encoded by the *hwp1* gene. Examination of the predicted amino acid sequence of Hwp1 revealed similarity to proteins that are substrates for mammalian transglutaminase enzymes. These enzymes form a cornified envelope on squamous epithelial cells (including buccal epithelial cells) by cross-linking relevant substrates.[244] The interactions of germ tubes with buccal epithelial cells resist stresses (e.g., heating or treatment with sodium dodecylsulfate [SDS]) capable of dissociating most typical microbe-host adhesive pairs, and elimination of expression of Hwp1 results in a marked reduction in adhesion to buccal epithelial cells.[18,242] Hwp1 represents a unique adhesive strategy, employing host transglutaminase enzymes to cross-link Hwp1 (via a glycosyl phosphatidylinositol remnant anchor) directly to surface proteins on buccal epithelial cells.[241]

TISSUE TROPISM

Most microorganisms show restriction in the range of hosts, tissues, and cell types that they colonize. This restriction is referred to as *tropism* and generally reflects the specificity of the interaction between a given microbial adhesin and its cognate receptor. Tropism is determined by the distribution of the relevant host receptor.

P pili of uropathogenic *E. coli* serve as the platform for presentation of one of three different PapG variants, referred to as class I, class II, and class III PapG. All three variants recognize globoseries glycolipids, but each binds with a distinct specificity to the globoseries glycolipid isotypes. Class I PapG preferentially recognizes globotriosylceramide (GbO3, Gal-α1,4-Gal-β1,3-Glc-ceramide); class II PapG preferentially recognizes globoside (GbO4, GalNAc-β1,3-Gal-α1,4-Gal-β1,3-Glc-ceramide); and class III PapG preferentially interacts with Forssman antigen (GbO5, GalNAc-α1,3-GalNAc-β1,3-Gal-α1,4-Gal-β1,3-Glc-ceramide).[250] Globoside is the dominant globoseries glycolipid expressed in human kidney, and most human isolates of *E. coli* associated with pyelonephritis express class II PapG. In contrast, Forssman antigen is the most abundant globoseries glycolipid in dog kidney, and more than 50 percent of canine urinary isolates of *E. coli* express class III PapG.[286] *E. coli* expressing P pili with class II PapG are not found as a cause of urinary tract infection in dogs. The specificity of the PapG variant at the tip of the P pilus influences host range, favoring infection of either human or dog.

The crystal structure of class II PapG bound to Gal-α1,4-Gal was solved by Dodson and coworkers,[51] uncovering the structural basis of PapG binding specificity. The PapG receptor binding site is located on the side of the molecule and must be oriented with its N-terminal to C-terminal axis parallel to the host cell membrane to allow docking to the receptor. This orientation may be facilitated by the flexibility inherent in the tip fibrillum. The PapG binding site consists of two regions. The first forms a β-barrel, and the second is composed of a central antiparallel β-sheet that is flanked on one side by two 2-stranded β-sheets and on the other side by an α-helix. When class II PapG interacts with GbO4, the arginine residue at position 170 in PapG makes contact with the GbO4 side chain. In class I PapG, a histidine residue occupies position 170, interfering with potential contact with the GbO4 side chain. Similarly, class II PapG and class III PapG differ in amino acids required for interaction with the GbO5 side chain.[51]

Group A streptococcus (*S. pyogenes*) is a common cause of infections of skin and soft tissue, including impetigo, cellulitis, and necrotizing fasciitis. Adherence to host cells by *S. pyogenes* is influenced by non-pilus adhesins called *M protein* and *protein F*. M protein forms a fiber and consists of a C-terminal region that anchors the protein in the cell wall, a coiled-coil rod region extending approximately 50 nm from the cell wall, and a short non-helical domain extending more distally.[64] Protein F is a 120-

kd protein that is notable for a tandem repeat element consisting of six repeats of 32 to 44 amino acids adjacent to the C-terminus.[93,193] Based on experiments with a series of isogenic strains that differ in expression of M protein or protein F or both, M protein clearly promotes adherence to human keratinocytes via interaction with the CD46 molecule (also called *membrane cofactor protein*), whereas protein F mediates adherence to epidermal Langerhans cells, which are located in the basal layer of the epidermis.[189,190] M protein and protein F contribute to group A streptococcal adherence to the skin, but each protein directs interaction with a different population of epidermal cells.

Early studies showed that human immunodeficiency virus type 1 (HIV-1) infects $CD4^+$ cells and interacts with the CD4 molecule, but that CD4 alone is insufficient to permit infection. More recent observations have established that numerous host cell chemokine receptors, especially CCR5 and CXCR4, serve as co-receptors for HIV-1 and are required for viral entry into $CD4^+$ target cells. These co-receptors seem to influence the cellular tropism displayed by different HIV-1 variants.[48] All HIV variants are able to replicate in primary T cells, but only some also can replicate in primary macrophages or in immortalized T-cell lines. Asymptomatic HIV-infected individuals carry strains that generally use CCR5 as a co-receptor (termed M5 strains) and are non–syncytium-inducing in vitro. Such strains traditionally have been described as macrophage tropic (M-tropic), but more recent experiments have shown that these M5 strains also can infect $CD4^+$ T cells and peripheral blood mononuclear cells.[205] Rapid viral mutation caused by the error-prone HIV polymerase and HIV reverse transcriptase leads to the production within the host of syncytium-inducing, T cell–tropic (T-tropic) HIV-1 strains, which predominate in the circulation of patients with acquired immunodeficiency syndrome.[48] These variants generally are restricted to CXCR4 (expressed on T cells) as a co-receptor, although some primary syncytium-inducing variants can use CCR5 and CXCR4.[54,60,233] T-tropic, syncytium-inducing strains are characterized by positively charged residues at fixed positions of the V3 loop and changes in charge and length of the V2 region of the viral envelope glycoprotein gp120, which binds to CD4 and co-receptors before viral entry into host cells occurs.[66,67,86] Cellular tropism is closely aligned, but not synonymous, with HIV co-receptor usage.

New HIV-1 infection is selectively established by M-tropic HIV-1 strains, even if the transmitting host harbors more pathogenic non–M-tropic strains as well.[265,292] CCR5 also is expressed on the surface of rectal and vaginal epithelial cells, which may be sites of initial encounter between HIV-1 and the human host.[291] The importance of CCR5 in HIV-1 binding to $CD4^+$ cells is underscored by the observation that individuals homozygous for a 32-bp deletion in CCR5 (the $\Delta 32$ allele) are resistant to infection with HIV-1.[116,152] The $\Delta 32$ heterozygous state does not protect against acquisition of HIV-1, although HIV disease in heterozygous patients may follow an attenuated course.

This allele is found frequently (10 to 14 percent) in white populations, leading to speculation that it provided a survival advantage during one or more historical epidemics of infectious diseases.[185] More recent data suggest, however, that the $\Delta 32$ allele may confer immunodeficiency in the face of challenge with certain viral pathogens, such as West Nile virus.[79,80] CCR5 may have a role in controlling the development of malignancy, including lymphoma, raising some concern about developing anti-HIV pharmacologic agents that target CCR5 function.[146] Finally, co-evolution of viral determinants and host cell receptors may determine the spectrum of tissue and organ involvement within the host. The chemokine receptor CCR8 may facilitate the entry of neurotropic HIV-1 strains into brain cells,[126] and envelopes derived from brain isolates of HIV are adapted to infect cells with low-level CD4/CCR5 expression, such as neuroglia and brain macrophages.[204]

BIOFILMS

After attachment to a particular surface, many pathogens are capable of forming *biofilms*—structured communities of microbial cells enclosed in a self-produced exopolysaccharide matrix.[210] Although most studies of biofilms have involved a single species, it is likely that biofilms relevant to human infection often involve multiple species sharing the advantages of biofilm existence. Human infections associated with biofilms include dental caries, lower airway infection with *P. aeruginosa* in patients with cystic fibrosis, and foreign body infection in patients with prostheses and implanted devices. In addition, formation of biofilms likely occurs during osteomyelitis and endocarditis.[39]

P. aeruginosa is a model organism for the study of biofilms; it forms pillars of stationary (sessile) bacteria held together by an extracellular polysaccharide called *alginate*. Interposed among these pillars are channels that facilitate the flow of nutrients and provide pathways for motile (planktonic) organisms to move about (Fig. 1–7A). In experiments directed at defining the early steps of *P. aeruginosa* biofilm formation, O'Toole and Kolter[187] established that flagella are required for initial bacterial attachment, presumably because these appendages promote movement toward the relevant surface (see Fig. 1–7A). After attachment occurs, type 4 pili and pilus-mediated twitching motility promote formation of microcolonies. In the context of microcolonies, transcription of *algC*, *algD*, and *algU* is activated, resulting in synthesis of alginate.[46] The alternative sigma factor σ^{22} positively regulates the *alg* genes and negatively regulates expression of flagella. Consistent with this observation, pulmonary isolates from patients with cystic fibrosis often are highly mucoid (reflecting expression of alginate) and lack flagella.[71,76]

Development of the complex community present within a biofilm requires intercellular communication. In the case of *P. aeruginosa*, this communication occurs via the LasR-LasI *quorum sensing* system, which involves the acyl-homoserine lactone called *N*-(3-oxododecanoyl)-L-homoserine lactone (3OC12-HSL).[47,196] 3OC12-HSL is synthesized in a reaction catalyzed by LasI and accumulates with increases in population density. Ultimately, 3OC12-HSL reaches a critical concentration and then interacts with LasR, serving to activate transcription of numerous genes. Host inflammatory pathways also are induced directly by accumulated 3OC12-HSL.[238] Organisms with a mutation in *lasI* are capable of attachment and microcolony formation, but the resulting microcolonies remain thin, undifferentiated, and sensitive to dispersion by detergents. Addition of the missing lactone signal to the *lasI* mutant restores development into structured, thick, biocide-resistant biofilms, analogous to biofilms observed with wild-type organisms.[47] Mutation in *lasI* impedes establishment of pulmonary infection in mice.[202,285]

Biofilms constitute a protected mode of growth that allows survival in a hostile environment, such as in the presence of host immune mechanisms or antimicrobial agents.[39] Based on studies of *P. aeruginosa*, sessile bacteria release antigens and stimulate production of antibodies, but these antibodies are ineffective in killing organisms within biofilms.[31] Similarly, sessile *P. aeruginosa* stimulate a diminished oxidative burst and are refractory to phagocytic uptake. In addition, organisms within biofilms are resistant to the effects of many antibiotics—in part because antibiotic agents are unable to diffuse through the biofilm, in part because these bacteria may exist in a slow-growing state, and possibly because these organisms adopt a distinct and protected phenotype.[39] Progress in understanding the mechanisms by which biofilms develop, such as the solution of the

LasI crystal structure,[84] are likely to yield novel approaches to antimicrobial therapy, aimed at disrupting biofilm formation or persistence.

INVASION, INTRACELLULAR SURVIVAL, AND CELL-TO-CELL SPREAD

After adherence to a host surface occurs, many pathogenic organisms are able to invade and survive inside epithelial cells and other non-professional phagocytes (e.g., M cells in intestinal Peyer patches). In addition, some pathogens are able to survive inside professional phagocytes (macrophages and neutrophils). Invasion may represent a mechanism to breach host mucosal barriers and gain access to deeper or more distant tissues. Alternatively, invasion may provide the organism with a special niche, protected from the host's immune mechanisms. Generally, the process of invasion involves a class of molecules called *invasins*, which mediate microbial adherence and entry. Invasion is an active event that relies on underlying host cell functions and is associated with rearrangement of the host cell cytoskeleton. When inside the host cell, the invading or ingested organism usually is localized within a membrane-bound vacuole that contains lysosomal enzymes. In some cases, the pathogen escapes from this vacuole and enters the cytoplasm, a more permissive environment. In others, the pathogen remains in the vacuole and neutralizes lysosomal enzymatic activity. The processes of invasion into cells, survival within cells, cell-to-cell spread, and entry into the circulation define the extent of infection and dissemination.

INVASION

In considering the molecular mechanisms of microbial invasion, perhaps best characterized pathogenic bacteria are the enteropathogenic *Yersinia* species—*Yersinia pseudotuberculosis* and *Yersinia enterocolitica*. These organisms usually are acquired by ingestion of contaminated food or water and typically cause self-limited enteritis or mesenteric adenitis. In infants and other individuals with compromised immunity, they sometimes produce systemic disease. The primary determinant of *Y. pseudotuberculosis* and *Y. enterocolitica* invasion is an adhesive outer membrane protein, invasin, which is encoded by a chromosomal locus called *inv* and binds tightly to a family of β_1-integrins expressed on host cells, including $\alpha_3\beta_1$ integrin on the surface of intestinal M cells.[121] The interaction between invasin and β_1-integrins initiates a cascade of signaling steps in the host cell, resulting in actin rearrangement and formation of large complexes of cytoskeletal elements (e.g., talin, vinculin, α-actinin) called *focal adhesions*.[120] Bacterial entry into the host cell occurs via a "zipper-like" mechanism, with the plasma membrane zippering around the invading organism.

Beyond invasin, two additional proteins called YadA and Ail also influence invasion by enteropathogenic *Yersinia* species. YadA is a 45-kd surface protein that is encoded by the 70-kb *Yersinia* virulence plasmid. It is highly expressed under environmental conditions (e.g., temperature of 37° C) in which invasin is repressed.[57] YadA reaches the bacterial surface via the autotransporter pathway and exists in a trimeric form that is essential for its adhesive activity.[41] Similar to invasin, YadA promotes invasion through binding to β_1-integrins on the host cell surface, but its binding occurs indirectly via extracellular matrix molecules, including collagens, laminin, and fibronectin.[58] Based on studies using a mouse oral infection model, in *Y. enterocolitica*, YadA is essential for survival and multiplication in Peyer patches, whereas in *Y. pseudotuberculosis*, YadA is dispensable for full virulence.[17] Ail is a 17-kd outer membrane protein that also is encoded by a chromosomal locus (*ail*) and mediates high levels of adherence and low levels of invasion in assays with cultured epithelial cells. Ail also mediates resistance to complement-mediated serum killing, independent of an effect on invasion.[14]

Similar to *Y. enterocolitica* and *Y. pseudotuberculosis*, *Listeria monocytogenes* invades epithelial cells via a zipper-like mechanism. Invasion is mediated by proteins called *internalin A* (InlA) and *internalin B* (InlB), which are required for virulence in animal models. InlA interacts with E-cadherin, a host cell transmembrane protein with an intracellular domain that interacts with the cytoskeleton.[169] InlB interacts with C1q on host cells and promotes invasion by activating the PI-3 kinase pathway.[19] Uropathogenic strains of *E. coli* also invade epithelial cells via a zipper-like mechanism, mediated by the FimH adhesin expressed on the tip of type 1 pili. In experiments with cultured bladder epithelial cells, FimH is necessary and sufficient for entry, as shown by examination of a *fimH*$^-$ mutant and of latex beads coated with purified FimH.[161] In vitro experiments suggest further that FimH-mediated bacterial binding to a mannose-coated surface is strengthened by shear forces, such as fluid flow over the surface.[257,258] After FimH-dependent invasion into superficial epithelial cells of the murine bladder occurs, uropathogenic *E. coli* multiply rapidly to form intracellular bacterial communities, which display some features of biofilms (see Fig. 1–7B).[5,129,131] Bacteria derived from this intracellular niche ultimately form a quiescent bacterial reservoir within the epithelium, possibly serving as a seed for recurrent infections.[179]

Salmonella enterica serovar Typhimurium (*S. typhimurium*) is an example of a pathogen that invades cells by a mechanism distinct from zippering. On contact with the epithelial cell surface, *S. typhimurium* triggers a dramatic host cell response characterized by actin rearrangement, calcium and inositol phosphate fluxes, and membrane ruffling. Bacterial entry into the cell occurs rapidly, with organisms appearing in membrane-bound vacuoles within a few minutes of initial contact with the host cell.

The determinants of *S. typhimurium* invasion are encoded by a pathogenicity island called SPI-1, located at centisome 63 on the bacterial chromosome.[72] Especially important is a type III secretion system, which forms a needle-like complex on the bacterial surface and serves to translocate bacterial proteins directly into the host cell, ultimately disrupting the host cell cytoskeleton.[33] Studies of the structure of the needle-like complex have established that the base spans the inner and the outer membranes and is approximately 40 nm in diameter, whereas the needle itself is 8 nm wide and approximately 80 nm long (Fig. 1–8).[35] The base is composed of proteins PrgH, PrgK, and InvG, with InvG playing a key role in pore formation in the bacterial outer membrane. The needle is composed of PrgI, and its length is influenced by a protein called InvJ.[139,140]

The proteins secreted through the *S. typhimurium* needle complex (and other type III secretion systems) and into the host cell are referred to as *effector proteins*. SopE is an effector protein that mediates the initial rearrangement of actin and ruffling of the host cell membrane. It functions as a guanyl-nucleotide exchange factor and activates two host cell Rho guanosine triphosphatase (GTPase) proteins called Rac and Cdc42.[28,92,94] SptP is an effector protein that functions as an antagonist of SopE, mediating reversal of actin rearrangement by converting Rac and Cdc42 to the inactive forms (guanosine diphosphate forms). Consistent with these functions, SopE and SptP directly antagonize each other when co-injected into Ref52 cells.[70] Other effector proteins secreted by the *S. typhimurium* type III secretion system include the inositol phosphate phosphorylase SopB, which disrupts normal host cell signaling mechanisms,[184] and AvrA, which inhibits the nuclear factor (NF)-κB signaling pathway in host cells, down-regulating host inflammatory responses.[34]

Important accessory and regulatory genes also are present in SPI-1. The *sicA* gene is just upstream of the *sipB* and *sipC* genes and encodes an accessory protein with chaperone activity essential for stabilization and translocation of SipB, SipC, and SopE.[263] Other chaperones encoded by SPI-1 are involved in the stabilization and translocation of other effector proteins. The genetic and environmental factors that regulate the expression of type III secretion machinery and secreted proteins also are beginning to be understood.[4]

INTRACELLULAR SURVIVAL

When an organism invades a non-professional phagocyte or is ingested by a professional phagocyte, there are several potential outcomes. Often, the organism is killed. Some pathogens have developed strategies to survive and replicate inside host cells, however, in some cases within a vacuole and in others by escaping from the vacuole.

General agreement is that *S. typhimurium* resides within a membrane-bound vacuole in professional and non-professional phagocytes. The vacuole lacks several lysosomal markers typical of the main endocytic pathway (the mannose-6-phosphate receptor pathway), however, and seems to be distinct from this pathway. Insight into the molecular determinants of intravacuolar survival came in 1996, when two independent groups reported the discovery of a second *Salmonella* pathogenicity island, now called *SPI-2*.[102,188] This island maps to centisome 31 and encodes another type III secretion system, including structural proteins (*ssa* locus),[102] effector proteins (*sse* locus), and accessory proteins (*ssc* locus). In addition, this region encodes a two-component regulatory system consisting of proteins SsrA (formerly SpiR) and SsrB. SsrA is a membrane-located sensor kinase, and SsrB is a transcriptional regulator.[188] Mutations in SPI-2 result in reduced

survival inside macrophages, with no effect on adherence and invasion in assays with intestinal epithelial cells.[188]

Salmonella SPI-2 mutants show reduced virulence in experimental mice (10^4-fold reduction in 50 percent lethal dose), suggesting that survival inside macrophages is a key factor in the pathogenesis of disease.[229] Expression of SPI-2 genes within the macrophage vacuole depends at least partly on the acidic intravacuolar environment. Inhibition of macrophage vacuolar acidification using bafilomycin A1 (an inhibitor of the vacuolar proton adenosine triphosphatase [ATPase]) results in a sharp attenuation in transcription of SPI-2 genes. This effect is not reproduced by low pH alone outside the vacuole, suggesting that other environmental effects within the vacuole play a role.[29] More recent work indicates that *Salmonella* SPI-2 transcription is activated before invasion occurs, apparently preparing the pathogen for the hostile intracellular environment.[21] As a group, the SPI-2 genes seem to modulate host endocytic and exocytic transport mechanisms.[1]

A third *Salmonella* pathogenicity island called *SPI-3* also influences survival inside macrophages. This island is located at centisome 82 and was discovered by examining the *Salmonella selC* locus, a tRNA gene in which pathogenicity islands reside in some strains of *E. coli*.[10,12] SPI-3 contains the *mgtBC* operon, which permits *S. typhimurium* to grow in environments with low concentrations of Mg^{2+}, including macrophages. In particular, mutation of the *mgtBC* operon abolishes the ability of *S. typhimurium* to replicate in low Mg^{2+} liquid media and in macrophages, and addition of Mg^{2+} to the medium after phagocytosis restores the ability to survive intracellularly. Homologous *mgtBC* genes have been found in other organisms with intracellular lifestyles, such as *Brucella melitensis* and *Yersinia pestis*.[11] In *Salmonella*, the *mgtBC* genes are expressed after internalization into host cells occurs under control of the PhoP-PhoQ two-component regulatory system, a complex that directs expression of many virulence determinants.[158]

The ability to survive within phagocytic cells may provide *Salmonella* with a means to exploit an intrinsic host pathway and disseminate to distant sites. In particular, certain phagocytes express the β_2-integrin CD18, which mediates leukocyte migration in response to various stimuli. During *S. typhimurium* infection, CD18-expressing phagocytes transfer organisms from the intestine to the spleen. Bacterial loads in the liver and spleen are reduced after oral inoculation in CD18-deficient mice, compared with infection in wild-type mice.[266] On the one hand, this function of CD18 facilitates initiation of a systemic immune response and benefits the host. On the other hand, it provides bacteria with a mechanism of transit from the gut to organs of the reticuloendothelial system and elsewhere.

Mycobacterium tuberculosis, another intracellular pathogen, uses an array of mechanisms to ensure intracellular survival. The *M. tuberculosis* vacuole lacks the usual amounts of the vesicular proton ATPase responsible for mediating acidification and fails to acidify to normal levels.[251] In addition, *M. tuberculosis* blocks fusion of the vacuole with acidic lysosomes, further preventing acidification.[222] Similar to intracellular gram-negative bacterial pathogens, *M. tuberculosis* contains an *mgtC* gene, and mutation of this gene results in impaired virulence in cultured human macrophages and in mouse spleen and lung. Low Mg^{2+} concentration and mildly acidic pH inhibit the growth of the *mgtC* mutant, suggesting that the gene is important for survival in the phagosome, where such conditions may exist.[22]

Another factor that influences *M. tuberculosis* survival within macrophages is isocitrate lyase, an enzyme of the glycolytic shunt

that is essential for metabolism of fatty acids. Expression of isocitrate lyase is up-regulated during infection of activated macrophages and is required for full virulence in a murine model of infection, independent of an effect on bacterial growth.[165] The structure of *M. tuberculosis* isocitrate lyase has been solved and may provide a target for new drug therapies against persistent infection because this enzyme is absent from vertebrates.[227,235]

During interaction with macrophages, *M. tuberculosis* (at a low to moderate multiplicity of infection) is capable of stimulating caspase-1 and inducing macrophage apoptosis. This process may be beneficial to the host, preventing systemic spread of infection; less virulent strains of *M. tuberculosis* are more potent inducers of apoptosis.[133] At the same time, *M. tuberculosis* possesses at least two anti-apoptotic mechanisms that influence the outcome of macrophage encounters further. First, *M. tuberculosis* infection enhances host macrophage production of soluble TNFR2, a protein that binds to tumor necrosis factor–α and interferes with apoptosis.[6] Second, *M. tuberculosis* infection activates production of NF-κB, a transcriptional regulator that activates anti-apoptotic pathways within the host cell.[75] Higher multiplicities of infection with virulent strains of *M. tuberculosis* can induce caspase-independent cell death in macrophages, a mechanism proposed to contribute to the formation of necrotic lesions during tuberculosis disease.[147]

Listeria monocytogenes is an example of an organism that escapes from the phagocytic vacuole in macrophages and epithelial cells and moves into the cytoplasm. This organism causes meningitis and focal brain abscesses in humans and has a predilection for the fetoplacental unit. In pregnant women, listeriosis results in fetal loss in 30 percent of cases. Escape from the vacuole is mediated primarily by listeriolysin O, a hemolysin encoded by the *hly* gene. Listeriolysin O interacts with cholesterol in host cell membranes and forms pores, leading to lysis of the phagosome.[69] Mutants defective in *hly* fail to survive intracellularly and are avirulent in mice,[267] although vacuolar escape of *hly* mutants within human cells may be complemented by other bacterial enzymes. Additional factors that contribute to escape from the phagosome include two phospholipase C molecules, one with broad-range specificity (PC-PLC) and another with phosphatidylinositol specificity (PI-PLC). In human epithelial cells, the contributions of PC-PLC and a metalloproteinase called Mpl are most important for vacuolar escape in the absence of listeriolysin O.[87,159,236]

CELL-TO-CELL SPREAD

Movement from one cell to another may help an organism gain a stronger foothold in host tissues. *L. monocytogenes* is one example of a pathogen capable of cell-to-cell spread. When this organism is free in the cytoplasm, actin begins to polymerize on the bacterial surface. Eventually, the condensed actin forms a polar tail or comet, which propels the organism through the cytoplasm and into adjacent cells. The rate of bacterial movement within a cell correlates with actin tail length.[255] Actin accumulation and condensation is mediated by the *L. monocytogenes* ActA protein, which is tightly anchored to the bacterial surface and is expressed asymmetrically over the length of the organism.[237,254] ActA is the sole *Listeria* factor required for actin polymerization because actin tails form in *Xenopus* cytoplasmic extracts containing ActA-coated beads. In these experiments, motility occurs, however, only when ActA is distributed asymmetrically on the beads.[24] ActA seems to interact directly with actin and with a variety of other host cytoskeletal proteins.[69,256] Cytochalasin D is an inhibitor of actin polymerization and inhibits the cell-to-cell spread of *L. monocytogenes* in epithelial monolayers.[45,174]

On reaching the plasma membrane, bacteria protrude from the cell in filipodium-like structures (called listeriopods), which are engulfed by neighboring cells. This engulfment may be part of a normal host process because madin darby canine kidney (MDCK) cells show low-level endocytosis of adjacent cell membrane fragments even in the absence of bacteria.[217] The formation of listeriopods and the engulfment of these structures by neighboring cells are independent of listeriolysin O, PI-PLC, and PC-PLC.[77] When inside a nascently infected cell, *Listeria* escapes from the double-membrane vacuole via the action of PI-PLC, PC-PLC, and Mpl.[69] On arrival in the cytosol, bacteria can enter another cycle of actin-based motility and cell-to-cell spread, although one or two bacterial generations may be necessary to regain motility.[217]

A second pathogen capable of actin-based motility and cell-to-cell spread is *Shigella flexneri*. In *Shigella*, a single protein called IcsA is sufficient to induce formation of an actin tail, similar to that observed in *L. monocytogenes*. IcsA is an outer membrane protein that is encoded on the *Shigella* virulence plasmid and is distributed on the bacterial surface in a polarized fashion, possibly as a result of specialized machinery for autotransporter protein secretion near the poles of some gram-negative bacteria.[125] Initially, IcsA is distributed over the whole bacterial surface, with a predominance at one pole. Over time, a secreted bacterial protease called IcsP cleaves roughly half of the surface IcsA, mostly at the opposite pole, polarizing distribution further.[56,245] IcsP activity is itself tightly regulated by the virulence regulators VirF and VirB.[280]

Elimination of expression of IcsP leads to increased quantities of IcsA and increased actin-based motility, suggesting that IcsA (rather than host factors) is rate-limiting in the motility process.[232] Similar to ActA, IcsA is necessary and sufficient to induce polymerization of the actin tail, and the tail forms at the end where IcsA concentration is highest.[81] Despite the functional similarities between IcsA and ActA, no significant amino acid sequence homology exists between the two proteins. In contrast to ActA, no direct interaction between IcsA and actin has been shown, and IcsA is found throughout the actin tail, not only at the bacterial pole-actin tail junction.

Rickettsia spp. also are capable of actin-based motility and cell-to-cell spread. Based on examination of *Rickettsia rickettsiae*, *Rickettsia* move through the cytoplasm of infected cells 2.5 to 3 times more slowly than do *L. monocytogenes* and *S. flexneri*. In *Rickettsia conorii*, the actin tails seem to be anchored to the bacterial body in a parallel manner, differing from the actin tails in *Listeria* and *Shigella*, which are composed of much shorter actin filaments organized in a random branching network.[83] Details of the bacterial determinants of *Rickettsia* movement remain poorly defined.

DAMAGE TO THE HOST

Damage to host cells and host tissues represents a fundamental mechanism by which a pathogen is able to survive at a given site and then spread within a host. Generally, damage is induced by microbial toxins. Most toxins are released extracellularly and are capable of inducing damage at very low concentrations (exotoxins). Microbial attachment and invasion facilitate toxin delivery to target cells and target tissues and serve to enhance toxicity.

Historically, microbial toxins have been classified according to a variety of criteria, including cellular target of action (e.g., enterotoxins, leukotoxins, neurotoxins), mechanism of action (e.g., adenosine diphosphate [ADP]–ribosylating toxins, adenylate cyclase toxins, pore-forming toxins, proteolytic toxins), and major biologic effect (e.g., hemolytic toxins, edema-producing toxins). In recent years, the term *toxin* has been applied more broadly to include enzymes that mediate damaging effects via phospholipase or hyaluronidase activity.

WHOOPING COUGH AND *BORDETELLA PERTUSSIS* TOXINS

Whooping cough (*B. pertussis* infection) is a classic example of a toxin-mediated disease and involves an interplay of multiple toxins.[135] The pathogenesis of whooping cough begins with *B. pertussis* colonization of the trachea, which is facilitated by a molecule called *tracheal cytotoxin* (TCT). TCT is a naturally occurring disaccharide-tetrapeptide fragment of peptidoglycan and belongs to the family of muramyl peptides.[82] Many gram-negative organisms produce an analogous fragment during normal turnover of cell wall components, but significant extracellular release apparently occurs only in *Bordetella* spp. and gonococci. In most species, an inner membrane protein called AmpG recycles this fragment back into the bacterial cell.[40] More recent crystal structures of TCT in complex with *Drosophila* pathogen pattern recognition receptors offer insight into the specific recognition of TCT via its unique diaminopimelic acid moiety, in contrast to other muramyl peptides.[27,150] TCT is toxic to tracheal epithelial cells in vitro, stimulating nitric oxide synthase and local production of interleukin-1 and causing inhibition of ciliary motility, inhibition of DNA synthesis, and cell death.[97-99,104] During natural infection, TCT likely paralyzes the mucociliary escalator and interferes with clearance of *B. pertussis* and respiratory mucus.

Beyond TCT, *B. pertussis* elaborates a toxin called *adenylate cyclase toxin* (CyaA), which has pore-forming activity and inhibits adenylate cyclase, resulting in accumulation of cyclic adenosine monophosphate (cAMP). In phagocytic cells, the elevated levels of cAMP inhibit oxidative activity and induce apoptosis, disabling this arm of the immune system.[136,137,203] In respiratory epithelial cells, the elevated levels of cAMP may result in increased fluid and mucus secretion, impairing mucociliary function further. Adenylate cyclase toxin has homology to many other bacterial calcium-dependent, pore-forming toxins known as *RTX toxins* (named because of a repeat found in each toxin), with the prototype being the *E. coli* HlyA hemolysin.[40] These toxins create pores in the host cell plasma membrane, ultimately leading to host cell lysis. Among the family of RTX toxins, the general mechanism of pore formation and the predicted amino acid sequences are conserved, but target cell specificities differ.

Pertussis toxin is thought to be a key determinant of the clinical manifestations of whooping cough. This toxin belongs to a family of bacterial ADP-ribosyltransferase enzymes. The target of pertussis toxin is host cell G proteins, resulting in disruption of normal signaling processes. Many biological effects have been ascribed to pertussis toxin and include induction of lymphocytosis, stimulation of insulin release, sensitization to histamine, and disruption of phagocytic cell function; however, the specific relationship between the effects of pertussis toxin and the symptoms of whooping cough remains unclear.[105] *Bordetella parapertussis* is closely related to *B. pertussis* and produces a similar cough illness but fails to produce pertussis toxin because of mutations in the *ptx* promoter region.[180]

HEMOLYTIC-UREMIC SYNDROME AND SHIGA TOXINS

Numerous intestinal pathogens produce Shiga toxins, including *Shigella dysenteriae*, enterohemorrhagic *E. coli* (including *E. coli* O157:H7), and *Citrobacter freundii*, among others. Shiga toxins are classic A-B toxins, consisting of an A subunit that has toxic activity and five B subunits arranged in a pentameric ringlike structure that promotes binding to host cells and delivery of the A subunit. The B subunits interact with host cell globoseries glycolipids, especially the Pk trisaccharide moiety of globotriaosylceramide (GbO3). The A subunit is endocytosed by the host cell and traverses the cytoplasm in membrane-bound vesicles. Some of these vesicles fuse with lysosomes, resulting in degradation of toxin. Others travel in a retrograde fashion to the Golgi apparatus and the endoplasmic reticulum.[224] Within the endoplasmic reticulum, toxin binds to host 28S ribosomal RNA and cleaves a single adenine residue via N-glycosidase activity. Ultimately, this depurination event results in inhibition of protein elongation and cell death.[223]

In humans, *E. coli* O157:H7 is an important cause of hemorrhagic colitis and sometimes produces hemolytic-uremic syndrome. Infection begins with adherence to epithelial cells via intimin and other proteins encoded by the locus of enterocyte effacement, resulting in formation of attaching and effacing lesions analogous to the lesions observed in EPEC infection.[163] After adherence occurs, the organism releases Shiga toxin, which traverses the intestinal epithelial cell and enters the bloodstream.[2] Toxin circulates to distant organs and mediates damage via toxicity to endothelium. Diarrhea likely results from damage to endothelium in small mesenteric vessels, leading to ischemia and sloughing of the intestinal mucosa. The renal effects observed in human hemolytic-uremic syndrome arise from microvascular and glomerular damage with luminal occlusion by fibrin and platelets.[293] Hemolysis and thrombocytopenia likely develop as a consequence of microangiopathy.

Shiga toxins can be divided into two antigenically distinct groups, Stx1 and Stx2, which share 50 to 60 percent homology. Most isolates of *E. coli* O157:H7 recovered from patients with hemolytic-uremic syndrome express Stx2, and some express Stx1 as well.[145] Wadolkowski and colleagues[269] pretreated mice with antibodies against Stx1, Stx2, or both, and challenged these animals with an *E. coli* strain expressing Stx1 and Stx2. Consistent with the importance of Stx2, mice pretreated with antibodies against Stx2 (with or without antibodies against Stx1) were protected from severe disease, whereas 90 percent of mice pretreated with anti-Stx1 alone or anti-cholera toxin died. Pathologic examination of the kidneys showed acute renal tubular necrosis and not glomerular injury, however, suggesting that this model has deficiencies in mimicking human disease.

Understanding the interaction between Shiga toxins and human glycolipid receptors may lead to important therapeutic interventions to prevent hemolytic-uremic syndrome in children with enterohemorrhagic *E. coli* colitis.[96] One initial effort along these lines was a synthetic GbO3 analogue attached to silica particles (Synsorb Pk). Oral administration of this toxin binder did not reduce the severity of hemolytic-uremic syndrome in clinical trials.[262] A more recent strategy has been to express heterologously in nonpathogenic *E. coli* a modified lipopolysaccharide (LPS) containing a sugar moiety that is a mimic for GbO3.[197,206] Oral administration of such bacteria protects mice from subsequent infection with Shiga toxin–producing *E. coli*. Monoclonal antibodies to Shiga toxins have been designed for systemic administration, offering potential activity against toxin already absorbed from the gut; these agents show promising results in animal models of hemolytic-uremic syndrome.[177,230,231] All of these therapeutic strategies would depend on timely recognition of Shiga toxin–producing *E. coli* diarrhea; consequently, additional efforts are being directed at methods to establish this diagnosis early in the course of diarrheal illness.[155]

TISSUE-DEGRADING TOXINS

Numerous toxins have enzymatic activity and are capable of degrading tissue components. One example is hyaluronidase, which degrades hyaluronic acid, a repeating disaccharide glycosaminoglycan involved in cell motility, adhesion, and proliferation in normal hosts. Hyaluronic acid contains alternating *N*-acetylglucosamine and glucuronic acid moieties, connected by β linkages. It is prominent in extracellular matrix when cell turnover and tissue repair are prominent, such as in embryogenesis,

wound healing, and carcinogenesis.[43] The primary host receptor for hyaluronic acid is CD44, which undergoes post-translational modification that varies according to host cell type. Interactions between hyaluronic acid and CD44 are crucial to T-cell and B-cell stimulation, growth of certain lymphoid malignancies, and propagation of certain inflammatory responses.[171]

In *S. pyogenes*, hyaluronidase is a 96-kd protein that is encoded by the *hylA* gene and is released extracellularly. It is proposed to promote invasion through cell layers and tissue planes and is considered one of several *S. pyogenes* spreading factors.[119] *S. pyogenes* also produces a thick "capsule" of hyaluronic acid that can interact with other host cellular and extracellular matrix proteins to contribute to tissue invasion by the organism. Other pathogens that produce a hyaluronidase include *S. agalactiae* (group B streptococcus), *Treponema pallidum*, *Candida*, *Entamoeba histolytica*, and *Ancylostoma braziliense*.[43]

EVASION OF IMMUNITY

To survive and replicate within the host, a pathogen must evade the host immune system. Initially, the organism must circumvent innate immune mechanisms, including mechanical forces, resident phagocytes, and complement activity. Over time, the organism also must overcome adaptive immunity, including the presence of specific antibodies.

ANTIPHAGOCYTIC FACTORS

As described earlier in this chapter, invasin-mediated entry into M cells plays an important role in the early stages of *Yersinia* infection. At the same time, evasion of phagocytosis is crucial to the pathogenesis of *Yersinia* disease. The ability to avoid phagocytosis depends on the *Yersinia* virulence plasmid, which encodes numerous proteins called *Yops*.[38,248] YopE and YopH interfere with ingestion by macrophages and neutrophils via slightly different mechanisms. YopE shares sequence homology with the *S. typhimurium* SptP protein and down-regulates all three of the Rho GTPases (Rho, Cdc42, and Rac), inhibiting actin rearrangement and blocking formation of membrane ruffles (lamellipodia) and spikes (filopodia).[13] YopH is a protein tyrosine phosphorylase that seems to act on a host cell cytosolic protein called Cas, interfering with recruitment of Rho, Cdc42, and Rac, and preventing formation of actin stress fibers, focal complexes, and focal adhesions.[9,13] YopJ is an acetyltransferase that covalently modifies and inactivates intermediate kinases in the mitogen-activated protein kinase and NF-κB signaling pathways, leading to host cell apoptosis.[178,289] Further elucidation of Yop mechanisms may lead to development of Yop inhibitors that abolish the antiphagocytic properties of this pathogen.

Shigella employs another strategy to induce apoptosis in phagocytic cells. This pathogen produces hemorrhagic enterocolitis and is an important etiology of bloody diarrhea in children. Infection begins with ingestion of organisms, which attach to intestinal M cells and cross the intestinal epithelium.[297] On entry into the subepithelial space, organisms are engulfed by resident macrophages and contained in membrane-bound vacuoles. They quickly escape from macrophage vacuoles, however, and move to the cytosol of the cell, where they induce apoptosis.[296] The mechanism of apoptosis involves a protein called IpaB, which is encoded by the *Shigella* virulence plasmid and is injected into host cell membranes via the *Shigella* type III secretion system.[15] Work by Hilbi and coworkers[106] has established that IpaB binds to cytosolic interleukin-1β converting enzyme (caspase-1), a cysteine protease that cleaves interleukin-1β to its active form. Caspase-1 is homologous to many other enzymes involved in cell death pathways, including ced-3 of *Caenorhabditis elegans*. The *S. typhimurium* SipB protein shares homology with IpaB and induces apoptosis by interacting with caspase-1.[103] Insertion of IpaB into host membranes also may facilitate cell-to-cell spread.

EVASION OF COMPLEMENT ACTIVITY

S. pyogenes expresses at least three factors that interfere with host complement activity. Perhaps best known is M protein, which inhibits activation of the alternative complement pathway. This effect is mediated at least in part by the ability of M protein to bind complement factor H, a regulatory protein that inhibits assembly and accelerates decay of C3bBb. More recent studies indicate that serotype M1 and M57 strains express an extracellular protein called Sic (streptococcal inhibitor of complement-mediated lysis), which associates with human plasma proteins called *clusterin* and *histidine-rich glycoprotein* (HRG) and apparently blocks formation of the membrane attack complex (C5b-C9).[3] Studies of epidemic waves of M1 infection show that Sic undergoes significant variation over time, perhaps in response to the selective pressure associated with specific antibodies.[110,111,166] Nonpolar inactivation of *sic* results in reduced mucosal colonization of mice.[153] In addition, *S. pyogenes* produces a serine protease called *C5a peptidase*, which cleaves and inactivates C5a.[278] C5a is a cleavage product of C5 and serves as a powerful chemoattractant for neutrophils. C5a peptidase serves to attenuate the neutrophil response to streptococcal infection.

N. gonorrhoeae is a common cause of cervicitis, urethritis, and pelvic inflammatory disease and is capable of producing disseminated disease. Fresh clinical isolates of *N. gonorrhoeae* typically are resistant to complement-mediated killing, and resistance to complement likely is important in the pathogenesis of disease. Resistance is due in part to sialylation of lipo-oligosaccharide, which involves addition of host-derived cytidine monophospho-*N*-acetylneuraminic acid (CMP-NANA) by a bacterial sialyltransferase. Given the requirement for CMP-NANA, subcultivation in the absence of human serum or human neutrophils is associated with loss of sialylation and loss of resistance. Sialylated lipo-oligosaccharide binds factor H, resulting in down-regulation of activity of the alternative pathway C3 convertase. In addition, sialylated lipo-oligosaccharide interferes with neutrophil phagocytosis and with the normal oxidative burst in neutrophils.[216,277]

A second determinant of resistance to complement-mediated killing is Por1, an outer membrane porin protein that binds factor H and C4b binding protein (C4b BP).[213] C4b BP binds C4b and serves to inhibit assembly and accelerate decay of C4b2a, the classical pathway C3 convertase. Gonococci express a third factor that influences resistance to complement: an outer membrane protein called AniA (for anaerobically induced protein A), which has been shown to be a copper-containing nitrite reductase.[16,25]

EVASION OF HUMORAL IMMUNITY

Numerous pathogens have evolved mechanisms to vary surface-exposed immunogenic molecules, facilitating evasion of a specific antibody response. *Antigenic variation* represents one such mechanism and is characterized by the emergence of modified molecules with novel antigenic properties. *Phase variation* is a second mechanism and is typified by the reversible loss or gain of a given molecule or structure.

N. gonorrhoeae is capable of producing recurrent infection, reflecting the fact that the antibody response to infection fails to provide lasting immunity. In this context, *N. gonorrhoeae* pili are an important target of serum antibody and undergo frequent antigenic variation. Gonococcal pilin expression is controlled by

the *pilE* locus (the expression locus), which contains an intact pilin gene along with promoter sequences. In addition to *pilE*, the gonococcal chromosome contains numerous copies of variant *pil* sequences, called *pilS* loci.[90] These loci are transcriptionally inactive because they lack a promoter and 5′ coding sequence. They can be introduced into the expression locus by RecA-dependent recombination, however, resulting in an altered structural subunit and antigenically variant pili.[115] Because *N. gonorrhoeae* is naturally transformable, horizontal exchange of species-related DNA possibly also contributes to the generation of new *pil* sequences.

The African trypanosomes (including *Trypanosoma brucei*) cause sleeping sickness in sub-Saharan Africa and account for more than 50,000 deaths per year. These organisms avoid humoral immunity by antigenic variation of a large family of proteins called *variable surface glycoproteins* (VSGs), which coat the entire surface of the trypanosome. VSGs are highly immunogenic and stimulate antibodies that lead to efficient and rapid clearing of parasites from the bloodstream. At any given point in time, the organism is able to express a new VSG, however, allowing some organisms to escape the antibody response against the previous VSG.

Each parasite can express more than 100 different VSGs, with variation in expression occurring spontaneously at a rate of 10^{-2} per cell per generation. Overall, the genome of *T. brucei* contains more than 1000 *vsg* genes, including so-called expression sites located near telomeres on mini-chromosomes and silent loci in non-telomeric sites on large chromosomes.[201,259] Generally, VSG antigenic variation occurs by two different mechanisms. The first is termed *in situ activation* and involves the simultaneous activation of a new expression site and inactivation of the old expression site, occurring independent of DNA rearrangement. The second involves DNA recombination, either between the expressed *vsg* and another telomeric expression site (reciprocal recombination) or between the expressed *vsg* and a silent *vsg* locus (gene conversion).[259]

In the case of *H. influenzae*, LPS likely is a key factor in facilitating colonization and is a major target of the antibody response to infection. *H. influenzae* LPS undergoes phase variation. LPS biosynthesis involves multiple enzymatic steps and numerous genes. Among these genes, *lic1A*, *lic2A*, *lic3A*, *lex-2*, *lgtC*, and an *oafA*-like gene contain long stretches of tandem 4-bp repeats within their 5′ coding region. In studies of the *lic* loci, Weiser and coworkers[273] observed that the number of repeats varies spontaneously, generating translational frame shifts with different ATG start codons falling in or out of frame. Such frame shifts result in synthesis of a protein with a different N-terminus or eliminate protein production altogether (when no in-frame start codon exists).

The mechanism of variation in repeat number is presumed to be slipped-strand mispairing, which occurs during DNA replication and involves a single repeat looping out on either the template or the replicating strand. Changes in *lic2A* and *lic3A* influence glycotransferase activity and alter reactivity with monoclonal antibodies directed against specific LPS oligosaccharide epitopes.[88] The *lic2A* gene product is responsible for the addition of a Gal-α1,4-Galβ moiety, which resembles the globoseries glycolipids and protects *H. influenzae* from antibody-mediated killing, possibly by molecular mimicry.[274] *lgtC* may be involved in formation of a Gal-β1,4-Glu moiety.[112] Variation in the *lic1A* gene affects production of a choline kinase responsible for addition of phosphorylcholine (ChoP) to the LPS molecule, a physical change that enhances binding of C-reactive protein and results in susceptibility to serum bactericidal activity.[154,275,276] Expression of *lex2* results in addition of a tetrasaccharide (Gal-α1,4-Gal-β1,4-Glc-β1,4-Glc) to the proximal heptose in LPS and increases resistance to complement-mediated serum killing.[85] Similarly, expression of the *oafA*-like gene results in LPS O-acetylation, which facilitates resistance to serum killing.[68]

ENCAPSULATION

Expression of an extracellular capsule is a common strategy to evade phagocytosis, complement activity, and humoral immunity among pathogenic bacteria, fungi, and parasites. One example is *H. influenzae*, a common cause of childhood bacteremia and meningitis in underdeveloped countries. Among isolates of *H. influenzae*, six structurally and antigenically distinct capsular types are recognized, designated serotypes a to f. Historically, serotype b isolates have accounted for greater than 95 percent of all *H. influenzae* invasive disease, reflecting the distinct virulence properties of the type b capsule, which is a polymer of ribose and ribitol-5-phosphate (PRP) and is encoded by the *cap*b locus.[175] In animal studies comparing derivatives of *H. influenzae* strain Rd expressing type a, b, c, d, e, or f capsule, the strain expressing the type b capsule was associated with the highest incidence of bacteremia after intranasal inoculation of infant rats. Similarly, this strain was associated with the highest magnitude of bacteremia and incidence of meningitis after intraperitoneal inoculation of experimental rats.[295]

In considering the mechanism by which the type b capsule promotes intravascular survival and invasive disease, in vitro studies using mouse peritoneal macrophages and human peripheral blood monocytes provide some insights. Based on work by Noel and colleagues,[183] the type b capsule has been shown to inhibit bacterial binding to macrophages in the absence of complement and a source of C3. In addition, the type b capsule interferes with ingestion by macrophages when anti-PRP antibody is lacking.[182,183] The type b capsule blocks complement deposition on the bacterial surface and resultant complement-mediated bacteriolysis. In almost all isolates of *H. influenzae* type b, the *cap*b locus is a tandem repeat of 18-kb *cap*b gene sequences.[181] As a consequence of this arrangement, the *cap*b locus serves as a template for further amplification of capsule gene sequences in vivo, resulting in increased capsule production. In a study by Corn and associates,[37] 23 of 66 minimally passaged invasive isolates had three to five copies of the 18-kb repeat. Further analysis showed that amplification of the repeat results in augmented resistance to phagocytosis and complement-mediated bacterial killing.[181]

Given the importance of the type b capsule in the pathogenesis of disease, efforts to develop a vaccine effective against *H. influenzae* type b focused on the type b polysaccharide, initially as a plain polysaccharide vaccine and eventually as a conjugate vaccine with the polysaccharide linked to an immunogenic carrier protein. Since routine immunization with conjugate vaccines has been implemented in developed countries, the incidence of invasive *H. influenzae* type b disease in these countries has plummeted.

VIRAL LATENCY

Among viral pathogens, latency represents an important mechanism for viral persistence in the face of host immunity, especially in the case of viruses belonging to the herpes family. Herpes simplex virus is one example, commonly establishing latency after gingivostomatitis and genital tract infection. After infection of a host cell occurs, herpes simplex virus replication commences. Eventually cell death occurs, resulting in cell lysis and release of viral particles, which can infect adjacent cells. This so-called lytic replication is under control of a few *immediate early* (IE) genes, which must be transcribed in moderate amounts to allow expression of the remainder of the viral genome.

IE gene expression is activated by VP16, a viral protein that binds to a sequence common to IE gene promoters.[211] After lysis of the host cell, new virions enter local nerve termini and travel up the long axon to sensory ganglia, where latency is established within days. In the latent state, viral DNA can be detected in the

neuron, but infectious virions cannot be isolated. During latency, IE genes are repressed, and only one small fragment of viral DNA is actively transcribed, yielding the latency-associated transcript (LAT). No protein product has been attributed to the LAT; instead, more recent work has shown the production of a microRNA, transcribed from exon 1 of LAT, which maintains latency by directly inhibiting transforming growth factor–β signaling and promoting survival of infected cells.[89] LAT-deficient mutants are still able to establish initial latency, however, suggesting that IE gene expression may be under multiple controls.[270] The mechanism by which herpes simplex virus is reactivated seems to involve the viral thymidine kinase (TK) gene because TK^- mutants are defective in lytic replication and ordinarily do not reactivate.[32,124] Although a detailed understanding of reactivation is lacking, other viral genes suspected to support reactivation are being studied.[91,173]

CONCLUSION

With the explosion in the development of molecular techniques in recent years, understanding of the specific microbial and host factors involved in the pathogenesis of a variety of infectious diseases has expanded remarkably. As a consequence of this understanding, numerous new vaccines have been developed, including the *H. influenzae* type b and acellular pertussis vaccines. In the coming years, we likely will benefit from novel approaches for treating and preventing human infections. Possible examples might include inhibitors of type III protein secretion systems, antagonists of periplasmic chaperones, and analogues of important host cell receptors. Given the impressive adaptability of pathogenic organisms, however, as new therapeutic agents become available, we must remain vigilant for new microbial strategies allowing evasion of our interventions.

CHAPTER 2

Normal and Impaired Immunologic Responses to Infection

Michael F. Tosi

This chapter provides an overview of immunologic responses to infection and considers host interactions with different classes of pathogens, normal innate and adaptive immune mechanisms, the developing host responses of neonates, specific primary and secondary immunodeficiencies, and approaches to the evaluation of pediatric patients suspected to have impaired immunity. Human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS) are not considered here because they are addressed fully in Chapter 204A. This chapter is intended to supply sufficient information for the development of a basic understanding of mechanisms involved in normal host responses to infection, an appreciation of the underlying basis and clinical presentation of important immunodeficiencies, and a familiarity with general principles of evaluations and management of patients with suspected or documented disorders of immunity. For greater depth and detail regarding specific topics, readers are referred to many excellent reviews.

HOST-PARASITE INTERACTIONS

GENERAL FEATURES OF HOST-PARASITE INTERACTIONS

Humans constantly are exposed to a daunting number and diversity of microorganisms that can cause infection. Many organisms that usually coexist harmoniously with the human host on the skin or on mucous membranes of the oral cavity, upper airways, or lower gastrointestinal tract may invade and become pathogens if the balance of the commensal relationship is disrupted. Other organisms are more virulent, and they overtly attack the host's normal surface barriers and internal defense mechanisms. The human host has evolved a complex array of protective mechanisms designed to defend itself against these continuous microbial challenges.[626] To understand the pathogenesis, pathology, and natural history of infectious diseases, one must be familiar with the features of infectious agents that confer virulence, which are addressed elsewhere in this book. It is equally important to understand the elements of the host's response that contribute to containment, elimination, and protection against subsequent infection with these agents. It is important further to recognize that host responses to infections also may contribute to the pathophysiology of infectious diseases and may injure the host in other ways.

The characteristic features of specific infectious diseases are determined by the interactions of structural components and released products of microbial pathogens with host tissue, cells, and their products. Virulence tactics commonly employed by organisms include adherence to host cell surfaces, internalization within or invasion of host cells, production of toxins, elaboration of surface barriers such as bacterial polysaccharide capsules, usur-

pation of host synthetic mechanisms, and direct inhibition of specific defense mechanisms within host cells. The successful evolution of host strategies to protect against microbial attack has resulted in defenses designed to interfere with or to counteract many of these modes of microbial virulence.[626] In recent years, some of humanity's oldest microbial adversaries (e.g., smallpox, poliomyelitis, measles) systematically have been, or are being, eradicated. In the meantime, previously unrecognized human pathogens, such as HIV-1 and Ebola virus, have emerged as new challenges. Many of our oldest nemeses (e.g., tuberculosis, malaria) continue to elude our efforts to bring them under control, and they remain serious problems world-wide. Continued research at the interface between microbial pathogenesis and immunologic mechanisms is essential for the development of innovative approaches that can support and augment human immune responses to old and new microbial challenges.

MAIN FEATURES OF HOST RESPONSES TO SPECIFIC CLASSES OF INFECTIOUS AGENTS

Viruses

Viruses are obligate intracellular parasites that consist of genetic material in the form of either DNA or RNA that usually is surrounded by a protein coat and may or may not be bound by a lipid envelope.[395] Diseases caused by viruses are remarkably diverse, ranging from mild and merely inconvenient to rapidly fatal and from acute or brief to chronic or lifelong. Certain features are common to the pathogenesis of most viral infections, however. First, viruses must enter host cells to replicate. Viral entry ordinarily is initiated by attachment of a viral surface protein to a specific receptor molecule on the host cell. The specific viral ligands or their corresponding host cell receptors have been identified for numerous viruses. Rhinovirus has evolved a capsid protein that binds to human intercellular adhesion molecule-1 (ICAM-1) on respiratory epithelium[255]; the envelope glycoproteins of HIV-1 interact with CD4 on T lymphocytes and distinct chemokine receptors on lymphocytes or macrophages[163,327,623]; and internalization of adenoviruses depends on interaction between a specific peptide sequence in the penton base complex of the viral capsid and α_V integrins on host cell surfaces.[618]

After the virus has entered the host cell, the cellular synthetic machinery is redirected to the synthesis of viral components. As with many native proteins made by the host cell, a portion of viral protein is processed into peptides and presented on the infected cell surface by major histocompatibility complex (MHC) class I molecules (see later). The host mechanisms most important in defense against most viral pathogens include the production of specific neutralizing antibodies against viral surface proteins, the development of specific $CD8^+$ cytotoxic T-cell responses that eliminate infected cells, and the production of interferons (IFNs) that disrupt viral replication.[367,369,504]

Other host defenses also may exhibit antiviral activity, although the importance of some of these mechanisms in protection against viral infection in humans has not been established as firmly. It is possible that natural killer (NK) cells mediate the destruction of infected host cells[126,542] and that antibody-dependent cellular cytotoxicity (ADCC) may ensue after IgG antibodies bind to viral antigens on the infected cell, permitting subsequent attachment of NK cells or cytotoxic T cells via IgG Fc receptors.[209] IFNs and other cytokines may enhance NK and ADCC activity, and cytokines such as tumor necrosis factor-α (TNF-α) may exert cytotoxic actions on cells infected with certain viruses.[369] Additionally, opsonic complement components bound to viral surfaces can interfere with cell attachment, and the complement-derived membrane attack complex (MAC) can lyse enveloped viruses.[63]

Bacteria

The human host is colonized with a large variety of bacteria at skin and mucous membrane surfaces.[113,482] The integrity of these mechanical barriers ordinarily prevents systemic invasion of local commensal bacteria.[93] The epithelial cells that constitute these barriers, on recognition of an organism as a pathogen, also can release defensins and other microbicidal molecules.[235] In healthy hosts, circulating polymorphonuclear leukocytes (PMNs) help keep the resident flora in check by leaving the bloodstream at the mucosal sites containing the highest bacterial burdens, such as the oral cavity and the lower intestine.[29] This phenomenon helps account for the increased risk of developing local and systemic infection caused by oral and intestinal organisms in patients with severe neutropenia, including patients who receive prolonged chemotherapy for malignancies, and in patients with phagocytic migratory function disorders, such as leukocyte adhesion deficiency syndromes.[29] Important host defenses against most bacteria that invade the human host systemically include the complement system, specific antibodies that promote the opsonic and the bacteriolytic functions of complement, and phagocytes.[2,29,63,279,310]

Fungi

Host mechanisms crucial for defense against fungi are less well understood than are the defense mechanisms directed at bacteria and viruses, but phagocytes and cell-mediated immunity seem to be most important.[197,225] The relative importance of these factors seems to depend on the specific organisms involved, as is shown by clinical observations in patients with isolated defects of one or the other. Severe mucosal infections caused by *Candida* spp. are common occurrences in patients with acquired or primary cell-mediated immune deficits, such as HIV infection, thymic aplasia (see later), chronic mucocutaneous candidiasis, and some forms of severe combined immunodeficiency (SCID), and in patients with disorders of leukocyte migration.[29,197] Disseminated candidiasis more often is attributed to iatrogenic factors, such as prolonged antimicrobial therapy and indwelling vascular catheters. Patients with malignancies, complicated postsurgical courses, and burns also seem to be at increased risk. Although neutrophils from patients with myeloperoxidase (MPO) deficiency kill *Candida* organisms more slowly than do neutrophils from healthy individuals, these patients usually do not develop *Candida* infections, suggesting that this aspect of neutrophil function is not crucial.[29,197]

In contrast to *Candida*, *Aspergillus* infections are not as great a problem for patients with cell-mediated immune defects as they are for patients with defects in phagocytic host defenses, such as chemotherapy-induced neutropenia, or genetic defects in phagocyte killing, such as chronic granulomatous disease (CGD).[61,622] Fungi such as *Histoplasma* and *Cryptococcus*, similar to *Candida*, tend to cause severe infections in patients with defects in cell-mediated immunity, although phagocytes are required for optimal clearance of these organisms.[305,616] The main role of antibodies and complement in protection from fungi probably is to provide opsonic activity to enhance phagocyte function.[181]

Parasites

Parasites, such as protozoa and helminths, comprise such a widely varying group of pathogenic organisms that generalizing about mechanisms of immunity to these organisms as a group is difficult. The importance of specific host mechanisms in defense against certain parasites may be appreciated, however, by consid-

ering the characteristic host responses mobilized by parasitic infection or infestations and examples of special susceptibilities to certain parasites among patients with impairments of different components of immunity. Many helminths induce production by host cells of chemokines that recruit eosinophils and stimulate their production, suggesting a likely role for these cells in antiparasitic defenses; eosinophils have been shown to be important in protection against helminths such as *Strongyloides* and other parasites in this group that can invade tissues. Among the immunoglobulins, IgE seems to play a special role, often in concert with eosinophils, in antihelminthic defenses. IgG also may be important, based on the susceptibility of individuals with hypogammaglobulinemia to hyperinfection with *Strongyloides*. Patients with hypogammaglobulinema or IgA deficiency also are at risk for developing chronic or severe infestations with the flagellate intestinal parasite, *Giardia lamblia*, suggesting a role for some degree of antibody-mediated protection in normal hosts. Patients with primary or acquired disorders of cell-mediated immunity are prone to development of serious central nervous system and ocular manifestations of infection with the protozoan *Toxoplasma gondii*, an obligate intracellular parasite, and hyperinfection with *Strongyloides*.[318,407,454]

FEATURES OF NORMAL IMMUNE FUNCTION

The organization of the immune system often has been viewed as consisting of several separate arms or compartments, such as complement, phagocytes, cell-mediated immunity, and humoral immunity. A more current approach often considers two broader categories—innate immunity and adaptive immunity. The former encompasses the more rapid and phylogenetically primitive, nonspecific responses to infection, such as surface defenses, cytokine elaboration, complement activation, and phagocytic responses, and the latter involves more slowly developing, persistent, and highly evolved antigen-specific responses, such as cell-mediated immunity and antibody production, which exhibit extraordinarily diverse ranges of specificities. Although the individual components of innate and adaptive immunity are addressed separately, the various arms of the immune system engage in a wide range of interactions that may enhance or regulate functions of other components of immunity and add to the already remarkable complexity of the human immune response, and numerous examples of such interactions are provided.

INNATE IMMUNE RESPONSES

Epithelia, Defensins, and Other Antimicrobial Peptides

The epithelium of skin and mucosal tissue functions as a mechanical barrier to the invasion of microbial pathogens. In the last 2 decades, it has become clear that epithelial cells also are a major source of antimicrobial peptides that play important roles in local host defense.[50,233-235,445] Studies of their structure, sources, expression, and actions also have revealed an unexpected range of immunologic activities for these molecules, the functions of which previously were considered mainly antimicrobial in nature.[3,35]

Epithelial cells of mucous membranes of the airways and intestines and keratinocytes express the human β-defensins, HBD-1, HBD-2, HBD-3, and HBD-4. These small cationic peptides are similar to the α-defensins stored in the azurophilic granules of neutrophils, and they display antimicrobial activity against a broad range of bacteria, fungi, chlamydiae, and enveloped viruses.[50,233,235,445] Their production by epithelial cells may be constitutive, as for HBD-1, or inducible, as for HBD-2, HBD-3, and HBD-4. More recent evidence indicates that epithelial cells of the airway or intestine can produce HBD-2 in response to activation by bacterial products via the Toll-like receptors (TLRs), TLR2 or TLR4 (see later), on the epithelial cells.[275,602,608] Stimulation of epithelium by cytokines, including interleukin-1 (IL-1) or TNF-α, also can induce production of defensins.[50,235]

Defensins have been reported to exert their antimicrobial action either by the creation of membrane pores or by membrane disruption resulting from electrostatic interaction with the polar head groups of membrane lipids, with more evidence now favoring the latter mechanism.[50,288] Some microorganisms have evolved mechanisms for evading the action of defensins. Bacterial polysaccharide capsules may limit access of microbial peptides to the cell membrane,[118] and an exoprotein of *Staphylococcus aureus*, staphylokinase, neutralizes the microbicidal action of neutrophil α-defensins.[304]

Several immunoregulatory properties of defensins and related peptides, distinct from their antimicrobial actions, have been documented.[233] Several of these peptides have been shown to facilitate post-translational processing of IL-1β.[464] Some of the β-defensins have been shown to function as chemoattractants for neutrophils, memory T cells, and immature dendritic cells by binding to the chemokine receptor CCR-6.[287,427,445] Separately, HBD-2 has been shown to activate immature dendritic cells via a mechanism that requires TLR4.[72,625] The activation of immature dendritic cells by these mechanisms also promotes their maturation. The β-defensins also act as a chemoattractant for mast cells by an undefined mechanism, and they can induce mast cell degranulation.[426] HBD-2 and several other antimicrobial peptides can interfere with binding between bacterial lipopolysaccharide (LPS) and LPS-binding protein.[522]

Additional antimicrobial peptides of epithelial cells include lysozyme and cathelicidin. Lysozyme, an antimicrobial peptide also found in neutrophil granules, attacks the peptidoglycan cell walls of bacteria and may be released from cells by mechanisms that involve activation of TLR.[456] Cathelicidin, or LL37, similar to lysozyme, is released from neutrophils and epithelial cells. It exhibits broad antimicrobial activity and can inhibit lentiviral replication.[287,556] Cathelicidin also exhibits chemotactic activity for neutrophils, monocytes, and T lymphocytes. This activity is mediated by a formyl peptide receptor-like molecule, FPRL1, rather than the chemokine receptor CCR6 bound by β-defensins.[624]

The release of defensins in response to activation of TLRs and the many actions of these peptides, including their direct antimicrobial activities, their chemoattractant actions for a wide range of immune cells, and their activation of dendritic cell maturation, already suggest a highly complex and regulatory role in the development of host defense and immunity. More recent genomic evidence for the possible existence of 25 additional human defensins that have not yet been characterized suggests that current knowledge describes only a small sample of the overall contribution of these peptides to immune responses.[50,519]

Toll-Like Receptors

Mononuclear phagocytes, including circulating monocytes and tissue macrophages, other phagocytic cells, and many epithelial cells, express a family of receptors that is highly homologous to the *Drosophila* receptor called *Toll*.[99,275,393,602,608] These receptors mediate a phylogenetically primitive, non-clonal mechanism of pathogen recognition based on binding, not to specific antigens, but to structurally conserved pathogen-associated molecular patterns.[9,442,443,629] At least 10 human TLRs bind a range of microbial ligands, such as gram-negative bacterial LPS, bacterial lipoproteins, lipoteichoic acids of gram-positive bacteria, bacterial cell wall peptidoglycans, cell wall components of yeast and mycobacteria, unmethylated CpG dinucleotide motifs in bacterial DNA, and viral RNA.[9,442,443,629]

Gram-positive cell wall components bind mainly to TLR2, and TLR2 also can bind components of herpes simplex virus.[345,568] Gram-negative LPS activates TLR4 indirectly by first binding to LPS-binding protein, which binds to CD14 at the cell surface. The bound CD14 has no transmembrane domain, but it associates directly with an extracellular domain of TLR4.[443,568] TLR5 has been identified as the receptor for bacterial flagellin, TLR9 recognizes CpG motifs of bacterial DNA, and TLR3 has been shown to bind synthetic and viral double-stranded RNA.[59,265,341,345]

Signaling via TLRs occurs via a well-described pathway in which receptor binding generates a signal via an adapter molecule, MyD88, which leads to intracellular association with IL-1 receptor–associated kinase. This association leads to activation of TNF receptor–associated factor-6, which results in nuclear translocation of nuclear factor-κB.[140] NF-κB is an important transcription factor that activates the promoters of the genes for a broad range of cytokines and other proinflammatory products, such as TNF-α, IL-1, IL-6, and IL-8. This signaling pathway, based on studies with TLR4, is similar to, but not identical to, the signaling pathways activated by other TLRs.[140] The activation of cytokine production by TLRs plays an important role in recruiting other components of innate host defense against bacterial pathogens. With large-scale release of cytokines, the deleterious effects of sepsis or other forms of the systemic inflammatory response syndrome show, however, that these pathways have beneficial and potentially harmful effects for the host.[140] Genetic polymorphisms in TLRs may play a role in determining the balance of these effects in certain individuals responding to the challenge of systemic infection.[140,373,374]

In addition to their "first responder" roles in generating an inflammatory response to invading pathogens, TLRs may network with other components of innate and adaptive immunity. TLR4 function is suppressed by activation of cells via the chemokine receptor CXCR4.[326] Activation of some TLRs also can induce expression of the co-stimulatory molecule B7 on antigen-presenting cells (APCs), which is required for activation of naive T cells.[393]

Cytokines

A heterogeneous group of soluble small polypeptide or glycoprotein mediators, often collectively called *cytokines*, form part of a complex network that helps regulate the immune and inflammatory responses. Included in this group of mediators, molecular weights of which range from approximately 8 kd to approximately 45 kd, are the interleukins (ILs), IFNs, growth factors, and chemokines (see separately subsequently). Most cells of the immune system and many other host cell types release cytokines, respond to cytokines via specific cytokine receptors, or both.

New cytokines are being discovered and characterized regularly, and the range of sources and effects of cytokines and their actions and interrelationships are of such complexity that they cannot be addressed here in detail. A list of cytokines and related molecules that play a role in immune function, with selected characteristics, is provided in Table 2–1.[344,445,468] Excellent general reviews are available.[344,369,446,468] Numerous cytokines are considered in subsequent sections because they play important roles in the functions of various immune cells. Two cytokines, IL-1 and TNF-α, are of such fundamental importance in acute host responses to infection that they warrant specific attention here.

IL-1 and TNF-α are small polypeptides, each with a molecular weight of approximately 17 kd, which exhibit a broad range of effects on immunologic responses, inflammation, metabolism, and hematopoiesis.[69,446] IL-1 originally was described as "endogenous pyrogen," referring to its ability to produce fever in experimental animals, and TNF-α, which produces some of the same effects produced by IL-1, originally was named *cachectin* after the wasting syndrome it produced when injected chronically in mice.[69,446] Many of the physiologic changes associated with gram-negative sepsis can be reproduced by injecting experimental animals with these cytokines in the absence of microorganisms. Depending on the doses injected, these effects may include fever, hypotension, and either neutrophilia or leukopenia.[69,446]

In the production of endotoxic shock secondary to gram-negative sepsis, IL-1 and TNF-α are produced by mononuclear phagocytes in response to activation of TLRs by bacterial LPS. They activate the production of other cytokines and chemokines, lipid mediators such as platelet-activating factor and prostaglandins, and reactive oxygen species. They also induce expression of adhesion molecules of endothelial cells and leukocytes, stimulating recruitment of leukocytes by inducing release of the chemokine IL-8 and activating neutrophils for phagocytosis, degranulation, and oxidative burst activity.[69,140]

These all are important, usually beneficial, host responses to infection. At high levels of activation, pathophysiologic effects of this proinflammatory cascade, including vascular instability, decreased myocardial contractility, capillary leak, tissue hypoperfusion, coagulopathy, and multiple organ failure, may occur.[140] For some systemic actions, notably the production of hemodynamic shock, IL-1 and TNF-α are synergistic. IL-1 and TNF-α also induce production of IL-6, a less potent cytokine that exhibits some of the actions of IL-1 and TNF-α.[446] The human host produces several soluble antagonists of IL-1 and TNF-α, including IL-1 receptor antagonist, soluble TNF-α receptor, and anti-inflammatory cytokines, especially IL-10,[140] that can modulate their effects.

The importance of effects mediated by IL-1 and TNF-α in the pathophysiology of septic shock has prompted much active research aimed at blocking their effects to reduce morbidity and mortality. Monoclonal antibodies against TNF-α and other inhibitors of TNF-α or IL-1 have shown early promise in vitro and in animal models of septic shock.[30,45,140,222,446] They have been far more effective at preventing the effects of cytokines than reversing them, however. More recent attempts to address the issue of the timing of intervention have been directed at the intracellular signaling mechanisms activated through the TNF-α receptor or at mediators that appear later than TNF-α. Lipophilic inhibitors of protein tyrosine kinases, enzymes that propagate the cellular signals via TNF-α receptors, have been found to enhance survival in experimental animals, even when administered 2 hours after systemic injection with endotoxin.[594]

Additionally, monoclonal antibodies against a cytokine-like, non-histone nucleoprotein product of macrophages, high mobility group B1 (which appears much later than TNF-α or IL-1 after LPS stimulation) were found to rescue mice from endotoxin shock, when given 2 hours after an otherwise lethal dose of LPS was administered.[606] More recently, clinical trials with activated protein C, a regulatory protein in the coagulation cascade, have shown beneficial effects in selected patients with septic shock by mechanisms that may involve inhibition of activation of NF-κB.[100,482] To date, despite progress, clinical strategies to interfere with the cytokine-induced cascade that leads to endotoxin shock have continued, overall, to meet with limited success.

Chemokines

A specialized group of small cytokine-like polypeptides, chemokines, all of which share the feature of being ligands for G protein–coupled, seven transmembrane–segment receptors, plays an increasingly appreciated and complex role in the immune response as cellular activators that induce directed cell migration, mainly of immune and inflammatory cells.[46,300,324,386,419,500] The chemokines and their receptors have been classified into four families, based on the motif displayed by the first two cysteine

TABLE 2–1 Features of Selected Human Cytokines and Growth Factors

	Main Cellular Sources	Biologic Effects
IL-1	Mo, TL, BL, NK, PMN, others	Broad range of cellular activation in inflammatory and immune responses
IL-2	TL, BL, NK	TL, BL proliferation and activation; enhances TL and NK cytotoxicity
IL-3	TL	General stimulation of hematopoiesis
IL-4	TL, BL, Mast, Mo	TL, BL proliferation; BL isotype switching; stimulates IgE synthesis; enhances MHC class II expression
IL-5	TL	Stimulation of Eo production
IL-6	TL, BL, Mo	Broad inflammatory activity; stimulates BL differentiation and megakaryocyte production
IL-7	Marrow and thymus stromal cells	TL, BL growth and differentiation
IL-8	Mac, Mo, Endo, Epi, PMN, Eo	Activation and chemotaxis of PMN, Eo
IL-9	TL	Mast growth and differentiation; growth of activated TL
IL-10	TL, BL, Mast, Mac	Broad anti-inflammatory actions; inhibits synthesis of several other cytokines (TNF, IL-2, IL-3, IFN-γ)
IL-11	Marrow stromal cells	General stimulation of hematopoiesis; BL growth and differentiation
IL-12	BL, Mo	Stimulation of TL growth; induction of IFN-γ production; enhancement of TL and NK cytotoxicity
IL-13	TL	BL proliferation and isotype switching; enhances MHC class II expression; inhibits production of cytokines by Mac
IL-14	TL, malignant BL	Induces BL growth
IL-15	Epi, Endo, Mo, Mac, marrow stromal cells	Enhances NK growth, development, function; enhances TL growth/migration
IL-17	TL	Enhances TL growth; induces Mac cytokine release
IL-18	Kupffer cells, Epi, spleen, Mac	Promotes TL, BL, NK cytokine release; promotes TL, BL cytotoxicity
IL-21	TL	Promotes BL, TL proliferation; NK cytoxicity
IL-23	Dendritic cells, Mac	Similar to IL-12
IL-25	TL (T_H2), Mast	TL, Mac T_H2 cytokine secretion
IL-27	Dendritic cells, Mac	TL responsiveness to IL-12
IFN-α	Mo, TL	Interference with viral replication; increases MHC class I expression
IFN-β	Epi, Fibro	Similar to IFN-α
IFN-γ	TL, NK	Similar to IFN-α, IFN-β; stimulates Mac inflammatory functions
TNF-α	Mo, Mac, TL, NK	Broad inflammatory effects; fever; cachexia; stimulates catabolism; activation of leukocytes and Endo
GM-CSF	TL, BL, Mo, PMN, Eo, Fibro, Mast, Endo	Growth of PMN, Eo, Mo, and Mac precursors; enhances leukocyte function
G-CSF	Mo, Epi, Fibro	Enhances production and function of granulocytes
M-CSF	Mo, TL, BL, Endo, Fibro	Promotes Mo production; stimulates Mo and Mac function

BL, B lymphocyte; Endo, endothelial cell; Eo, eosinophil; Epi, epithelial cell; Fibro, fibroblast; GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN, interferon; IL, interleukin; Mac, macrophage; Mast, mast cell; MHC, major histocompatibility complex; Mo, monocyte; NK, natural killer cell; PMN, polymorphonuclear leukocyte; TL, T lymphocyte; TNF, tumor necrosis factor.

residues of the respective chemokine peptide sequence. Each of at least 16 CXC chemokines binds to one or more of the CXCRs, CXCR1 through CXCR6. Examples of CXC chemokines include IL-8 and Gro-α. Similarly, at least 28 CC chemokines, such as MIP-1α, RANTES, and eotaxin-1, eotaxin-2, and eotaxin-3, bind to one or more of the CCRs, CCR1 through CCR10. The sole CX3C chemokine, fractalkine, or neurotaxin, binds to CX3CR1, currently the only receptor in its family. The two XC chemokines, including lymphotaxin, bind to the sole receptor in this family, XCR1.

A new nomenclature has been proposed to designate each of the chemokines as a numbered ligand for its respective receptor family. In this system, Gro-α is CXC ligand (L)-1 (or CXCL-1), and IL-8 now becomes CXCL-8. Similarly, RANTES becomes CCL-5, fractalkine is CX3CL-1, and lymphotactin is XCL-1.[300,500] An update of this nomenclature system has been published, tabulating the members of each family with their respective ligands and receptors and the traditional names in human and murine systems.[300]

Virtually every cell type of the immune system expresses receptors for one or more of the chemokines. The cells of virtually any inflamed tissue can release a variety of chemokines, and tissues infected with different bacteria or viruses release chemokines that recruit characteristic sets of immune cells.[244,324] Rhinoviruses induce the release of chemokines that result mainly in recruitment of neutrophils (early in the course of infection), whereas Epstein-Barr virus induces a set of chemokines that result in recruitment of B cells, NK cells, and $CD4^+$ and $CD8^+$ T cells.[244] Almost mutually exclusive sets of chemokines are induced by cytokines associated with T_H1 (IL-12, IFN-γ) versus T_H2 (IL-4, IL-13) immune responses, indicating a tight interplay between cytokines and chemokines in determining the type of immune response to specific infectious challenges generated under different conditions.[75] The specificity of such cellular responses is influenced strongly by the type of chemokines released by specific tissues, the vascular adhesion molecules expressed in those tissues, the chemokine receptors expressed by different populations of leukocytes, and the specific adhesion molecules expressed by leukocytes.[75,244,324]

Modulation of chemokine function may occur by several mechanisms. Chemokines themselves may be potentiated or inactivated by tissue proteases, including tissue peptidases and matrix metalloproteinases.[392,444] Heparan sulfate–related proteoglycans on endothelial cell surfaces tether chemokines locally, where they can activate circulating leukocytes for adhesion most efficiently (see later). Similar proteoglycans free in the extracellular environment may act to bind and sequester chemokines, however, preventing them from interacting with their cellular receptors.[145,346] Finally, in addition to the well-described use of chemokine receptors as co-receptors for viral entry by HIV-1, other viruses, especially members of the herpesvirus family, encode soluble decoy receptors that compete with native host receptors for chemokine binding, disrupting normal host responses.[145,497]

Natural Killer Cells

NK cells are an important cellular feature of innate immunity. They are lymphoid cells that do not express clonally distributed receptors, such as TCRs or surface immunoglobulin, for specific antigens.[411,412,542] They respond in an antigen-independent manner to help contain viral infections before the development of adaptive immune responses, and they aid in the control of malignant tumors.[542,543] NK cells are found in the peripheral circulation and in the spleen and bone marrow. Similar to many other leukocytes, they can be recruited to sites of inflammation by chemokines and other chemoattractants. They seem to be important for the control of tumors in vivo and serve a crucial function in host defense against viral infections, especially infections caused by members of the herpesvirus family.[126,542] Activated NK cells also are an important source of IFN-γ, which limits tumor angiogenesis and promotes the development of specific protective immune responses.[411,412,542,543]

Regulation of NK cell activity involves a balance between activating and inhibitory signals. Several cytokines can activate NK cell proliferation, cytotoxicity, or IFN-γ production, including IL-12, IL-15, IL-18, IL-21, and IFN-αβ.[542] Activating signals via other receptors on NK cells, such as NKG2D, may lead to cytotoxicity or cytokine production, or both, depending on the receptor's association with distinct intracellular adapter proteins that signal via different kinases.[542,598] Other molecules on NK cells may act as co-stimulatory or adhesion receptors, including CD27, CD28, CD154 (CD40 ligand), and LFA-1 (CD11a/CD18).[53,543] Additionally, FcγRIII (CD16), can contribute to NK cell cytotoxic activity by mechanisms that include ADCC.[209,412]

NK cells are able to distinguish normal cells of self origin via receptors that recognize specific MHC class I molecules. Activation of such receptors provides an inhibitory signal that protects healthy host cells from NK cell–mediated lysis. Virus-infected cells and malignant cells may express MHC class I molecules at reduced levels and may be less able to generate inhibitory NK cell signals, rendering them more susceptible to attack by NK cells.[126,542] NK cell inhibitory receptors, which are not well characterized, seem to contain intracytoplasmic tyrosine-based inhibition motifs and to antagonize NK cell activation pathways via protein tyrosine phosphatases.[480,542] The regulation of the phosphorylation state of specific tyrosine residues by activating kinases and inhibitory phosphatases seems to be a pivotal determinant of NK cell activation.

NK cells kill infected or malignant cells by the release of perforin and granzymes from granular storage compartments and by binding of the death receptors Fas and TRAIL-R on target cells via their respective NK cell ligands.[513,542,543] The mechanisms by which perforin and granzymes mediate target cell death are not fully understood. The best available evidence suggests that perforin and one or more of five human granzymes, released along with perforin from cytotoxic granules of NK cells, associate with the cell membranes of target cells, either by binding via the mannose 6-phosphate receptor or by another mechanism that remains to be defined. One or more of the granzymes seems to activate intracellular pathways leading to target apoptosis via pathways that involve the mitochondria or caspases or both.[319,584] Separately, binding of the death receptors also activates caspases, causing target cell apoptosis.[542] Although some tumor cells do not express Fas, NK cells can induce Fas expression on these targets by releasing IFN-γ, then proceed to kill them by binding to the newly expressed Fas.[523]

NK cells engage in several kinds of interactions with other cells of the immune system, including dendritic cells and other APCs. Dendritic cells can influence the proliferation and activation of NK cells by release of cytokines, including IL-12, and by cell surface interactions, including CD40/CD40 ligand (CD40L), LFA-1/ICAM-1, and CD27/CD70.[173] In return, NK cells can provide signals that result in either dendritic cell maturation or apoptosis.[126,542]

Complement System

The complement system consists of more than 30 different free and membrane-bound activation and regulatory proteins. It has multiple key roles in the clearance of invading microbes, including opsonization, recruitment of inflammatory cells, and lytic destruction of pathogens.[62,178,196,198,217,305,308,309,416] Complement and antibody often act synergistically in host defense against infection. Traditionally, they have been known as the heat-labile (complement) and heat-stable (antibody) factors, which contribute to serum opsonic and bactericidal activity. Activation of the complement response to the initial encounter with an organism usually occurs earlier than that of antibody because some components of complement activation are independent of antibodies and can be initiated before specific antibody can be produced. When specific antibody is available, it serves to activate complement more efficiently and to direct complement binding to locations on the microbial surface that support the optimal execution of its effector functions, such as opsonization and killing.

Approximately 90 percent of complement proteins are synthesized in the liver, but some components can be produced locally at sites of infection by tissue mononuclear phagocytes and fibroblasts.[143,463] In healthy individuals, most complement is found in the circulation; less than 10 percent is in mucosal secretions, and little is detectable in cerebrospinal fluid. Circulating complement levels vary over time, particularly in the presence of inflammation. The inflammatory response may lead to increases in levels of complement components such as C3 that are acute-phase reactants or to decreases in individual components and total complement activity as a result of consumption.

The importance of normal complement component levels and activity in host defense has been well established and is based primarily on the increased susceptibility of patients with specific complement component deficiencies to recurrent and severe infections.[176,178,196,305,308] Although the complement response to infection usually is beneficial to the host, it also may be associated with adverse clinical manifestations, such as septic shock and acute respiratory distress syndrome.[212,610]

COMPLEMENT ACTIVATION

Complement proteins are activated in a specific sequence or "cascade" via one of at least three pathways—the classical pathway, the alternative pathway, and the more recently described mannan-binding lectin (MBL) pathway (Fig. 2–1). These pathways converge at C3, and the complement cascade downstream from C3 proceeds identically, regardless of the pathway by which activation occurs. The C3 convertases, C4b2a for the classical and MBL pathways, and C3bBb for the alternative pathway, cleave the C3 molecule at exactly the same location, producing C3b, which binds to the target surface, and C3a, which is released into the fluid phase. Cleavage and activation of C3 lead to a conformational change in C3b that transiently renders its reactive thioester group capable of forming covalent ester or amide bonds with acceptor molecules on the target surface.[291,353]

If the acceptor molecules are situated on the surface of a microorganism, the bound C3b can act as an opsonin to promote phagocytosis, or it can bind with the classical and alternative pathway C3 convertases to form the C5 convertases, C4b2a3b and C3bBb3b. C5 convertases bind and then cleave C5, with release of the C5a fragment into the fluid phase. The bound C5b fragment can initiate formation of the MAC by the sequential incorporation of the remaining terminal components, C6, C7, C8, and multiple molecules of C9. The MAC can insert into the

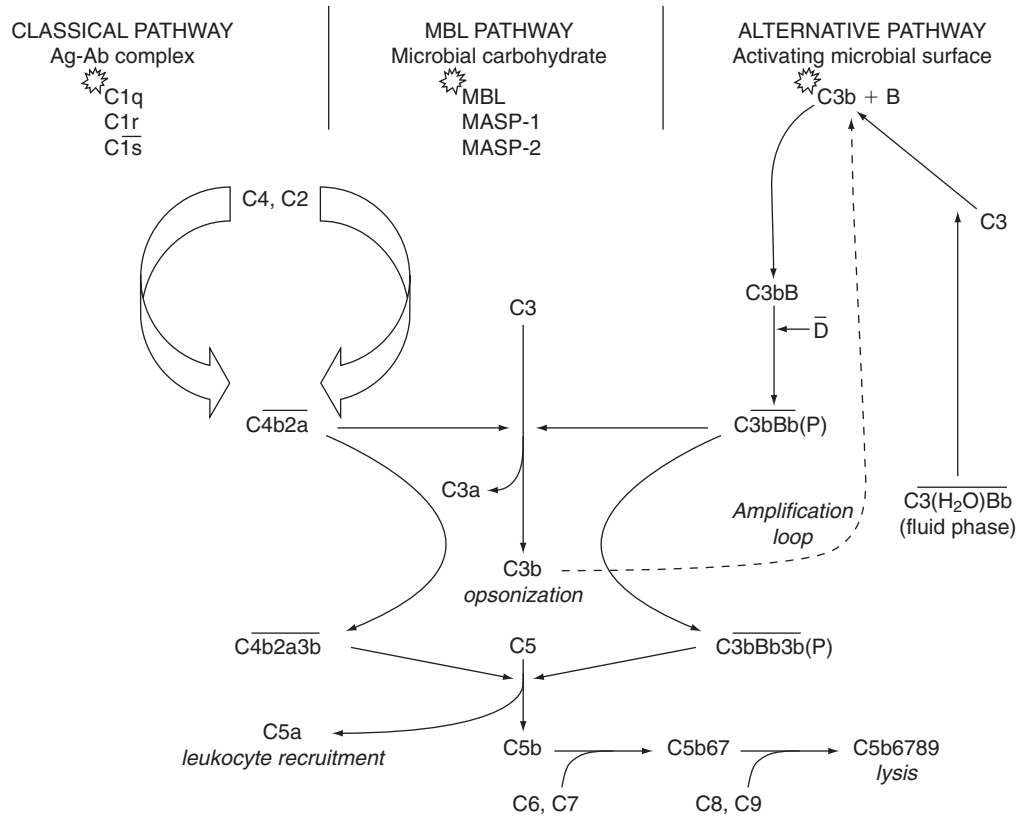

Figure 2–1 The complement cascade. The initial binding events of the classical, mannan-binding lectin (MBL), and alternative pathways are indicated by a *starburst*. These pathways intersect at the conversion of C3 to C3b. This is followed by activation of the terminal components, beginning with the binding and cleavage of C5, releasing C5a and leaving bound C5b to initiate assembly of the remaining components to form the membrane attack complex (C5b, 6, 7, 8, 9). Enzymatically active proteases, or convertases, of the classical and alternative pathways that cleave and activate subsequent components are shown by convention with an *overbar*. The alternative pathway C3 and C5 convertases are shown associated with properdin (P), which increases their stability.

outer membrane of target cells, such as erythrocytes or gram-negative bacteria, and cause cell lysis and death.[309]

Classical Pathway

Ordinarily, the classical pathway is activated by IgM or IgG bound to microbial antigenic targets or by other kinds of antigen-antibody complexes.[178] IgM activates complement more efficiently than does IgG because only one molecule of polymeric IgM is required compared with at least two molecules of IgG.[151] Activation is initiated when C1q binds directly to an immunoglobulin molecule on the surface of an organism or, less often, to a surface molecule of the organism itself. C1r and C1s are activated and bound to C1q sequentially, forming C1qrs. The enzymatic activity of this complex, which resides in the C1s molecule, can cleave multiple molecules of C4 and C2 into two fragments each. The C4a and C2b fragments are released into the environment, whereas C4b and C2a remain bound to each other on the surface of the target to form the classical pathway C3 convertase, C4b2a. C4bC2a can cleave and activate C3 and localize C3b binding to nearby sites on the target surface. As noted previously, some C3b binds with C4b2a to form the classical pathway C5 convertase, C4b2a3b. Activation of the classical pathway ordinarily is not initiated by complexes of antigens with IgG4, IgA, IgD, or IgE.

Alternative Pathway

The classical pathway requires specific antibody and contributes to host defense in immune individuals, whereas the alternative pathway is more important in protection of non-immune hosts, such as premature infants who have low levels of transplacentally acquired antibody and older infants and young children whose maternal antibody has waned, but who have not yet produced their own specific antibodies. The alternative pathway can be initiated by microbial surface macromolecules (e.g., polysaccharide, LPS, teichoic acid), although, as noted earlier, in some circumstances, specific antibody increases alternative pathway efficiency and may direct the location of C3b binding.[309]

A spontaneous low level of hydrolysis of the thioester of C3 in the fluid phase results in an activated form of C3, C3(H_2O). This activated form of C3 can bind factor B, and the latter then is cleaved by factor D to form the fluid-phase C3 convertase C3(H2O)Bb. The constitutive presence of small amounts of this convertase in the fluid phase ensures that a small amount of C3b always is available to bind to microbial surfaces and initiate the alternative pathway.[457] The alternative pathway protein factor B has structural and functional similarities to C2, including the ability to bind to surface-bound C3b. When bound to C3b, factor B undergoes proteolytic cleavage by factor D to release a small soluble fragment, Ba, leaving the larger fragment, Bb, associated with C3b. C3bBb, the alternative pathway C3 convertase, is analogous to the classical pathway C3 convertase, C4b2a. Properdin stabilizes the C3 convertase C3bBb, permitting more efficient activation of C3 to form more C3b, creating the C3 amplification loop (see Fig. 2–1).[211,214] Alternative pathway activation of C3 by this mechanism is several times less efficient than activation via the classical pathway, but it is vital to host defense because it is the principal means by which a non-immune

host can activate C3 until a specific antibody response can be mounted.[175,214]

The most important factor in determining whether or not a specific microbial pathogen would activate the alternative pathway is the biochemical nature of its surface. The surface biochemical features of a microorganism that characterize it as an activator are only partially understood. Microorganisms that bear large amounts of surface sialic acid usually are non-activators, however. The expression of surface sialic acid is one means by which mammalian host cells are protected from complement-mediated lysis in vivo. On surfaces rich in sialic acid, bound C3b is less able to bind factor B because another molecule, factor H, has a strong competitive advantage over factor B under these conditions. When bound by factor H, C3b becomes highly susceptible to further cleavage by factor I (C3b inactivator), resulting in C3bi (or iC3b). Although C3bi can function as an opsonin, it cannot bind factor B. No alternative pathway convertases can be formed, and no amplification loop is established.[62,416]

Organisms whose surfaces do not support activation of the alternative pathway are some of the most successful pathogens in infants and young children, who often lack specific humoral immunity. These organisms include K1 *Escherichia coli*, groups A and B streptococci, *Streptococcus pneumoniae*, *Neisseria meningitidis*, *Haemophilus influenzae* type b, and some salmonellae.[121,309] Development of specific IgG or IgM antibody against these organisms permits some activation of the alternative pathway and efficient activation of the classical pathway of complement at their surfaces and correlates with protection.

Mannan-Binding Lectin Pathway

A third complement activation pathway, the MBL pathway, has been described more recently. It is similar to the classical pathway, but it does not involve antibodies. MBL is a serum protein of the collectin family that has structural and functional similarities to those of C1q. It does not require antigen-antibody complexes to initiate its complement-activating function, however. MBL binds to mannose-containing carbohydrates on microbial surfaces, leading to its association at the microbial surface with activated MBL-associated serine proteases (MASP-1 and MASP-2). These latter proteases seem to have structural and functional similarities to those of C1r and C1s and result in activation of C4, with sequential binding of C4b and C2a and formation of C4b2a, the C3 convertase of the classical pathway. C3 is activated, and the cascade proceeds as described. A more detailed characterization of the MBL pathway and its role in immune responses to infection may be found in an excellent review.[465]

EFFECTOR FUNCTIONS OF COMPLEMENT IN HOST DEFENSE

All complement effector functions in host defense against infection require activation of the complement cascade through at least C3. The cascade needs to be activated through only C3 for effective opsonization, stimulation of leukocytosis, and immune regulation. Activation through C5 is required to produce a normal inflammatory response, including recruitment of phagocytes to sites of inflammation, and activation through C8 is needed for formation of the MAC. Complement may be activated and bound to cell surfaces but may not be able to carry out its effector functions if it is bound at a disadvantageous location.[97,250,290] C3b bound to a pneumococcal cell wall underneath a thick polysaccharide capsule is not accessible to CR1 on phagocytes and does not promote effective opsonophagocytosis. Similarly, complement-mediated killing of some strains of *Salmonella* is prevented when the MAC is bound to long LPS molecules distant from the organism's cell membrane.[309]

Opsonic Activity

Complement opsonic activity is essential for effective removal of organisms from the circulation by macrophages in the liver and spleen and from other sites by neutrophils and tissue macrophages.[82] Opsonins facilitate recognition, binding, ingestion, and killing of microorganisms by phagocytes. Opsonization is particularly important for protection against gram-positive bacteria and fungi because their thick cell walls prevent them from being killed by the MAC.

As noted earlier, activation of C3 leads to a conformational change in C3b that permits its reactive thioester to bind covalently with acceptor molecules on microbial surfaces, where it can serve as an opsonin. C3b also can be cleaved by inactivators such as factor I and CR1 to form iC3b, which may be a more efficient opsonin than C3b.[250,291] Some organisms, including certain serotypes of pneumococci, have surfaces that support degradation of differing amounts of surface-bound C3b to iC3b.[290] Surface-bound C3b and iC3b permit microbes to be recognized by circulating and tissue phagocytes by interacting with the phagocyte surface complement receptors, CR1 (CD35) and CR3 (CD11b/CD18). These interactions lead to binding, ingestion, and intracellular killing of the organisms.[250,291,353]

Antibodies are important opsonins in their own right, but they also facilitate more rapid complement activation and more effective localization of C3b binding to the surface of the organism. In the absence of specific antibody to direct complement binding, complement deposition on the surface of the target would be determined principally by the nature of the surface, and effector functions such as opsonization may not be performed as successfully. As noted earlier, this matter is of particular importance for encapsulated organisms, such as pneumococci, because in the absence of specific anticapsular antibody, C3b would be deposited at the cell wall, where it is inaccessible to phagocyte receptors.[97,290,311]

Inflammation

The cleavage products of several complement proteins contribute to the development of an inflammatory response. C3a stimulates an increase in the number of circulating granulocytes, and C5a serves as a potent stimulus for migration of monocytes, neutrophils, and eosinophils toward the source of C5a gradients being produced at infected tissue sites. C5a also up-regulates phagocytes' expression of CR1 and CR3 and stimulates them to release stored enzymes and other granular contents that also are important mediators of inflammation, aggregation, and production of microbicidal oxidants. C5a-induced neutrophil aggregation and stasis in the pulmonary circulation can be an important feature of the respiratory distress syndrome associated with sepsis.[610]

The anaphylotoxins, C4a, C3a, and especially C5a, induce release of histamine from mast cells and basophils, causing increased vascular dilation and permeability, which permit local influx of other inflammatory mediators.[294] In this way, they help produce the hallmark clinical manifestations of inflammation, swelling, and erythema. When large quantities of anaphylotoxins are released rapidly, they can contribute to septic shock.[212] Carboxypeptidase treatment of C4a, C3a, and C5a destroys their anaphylatoxin activity, but the C5a cleavage product $C5a_{des\ arg}$ maintains some chemoattractant-activating and phagocyte-activating activity.[323]

Microbicidal Activity

Complement can act directly on certain bacteria to kill them. As noted earlier, C5b and the terminal complement proteins C6, C7, C8, and C9 form the MAC, which can kill and lyse target cells such as gram-negative bacteria by penetrating their outer membranes.[309] The C5b-C8 complex serves as a polymerization site for several molecules of C9.[71] Although C9 is not essential

to membrane penetration, its presence as poly-C9 allows it to proceed more efficiently.[569] Electron microscopy of the MAC shows that it is composed of a ringlike structure at the outer surface of the target cell membrane and a perpendicular cylindrical component that penetrates the cell membrane. As has been noted, the MAC cannot penetrate the thick cell walls of gram-positive bacteria and fungi and cannot kill these organisms directly.

The MAC can lyse some virus-infected host cells and some enveloped viruses themselves.[152] Additionally, C1 and C4 can enhance neutralization of virus by antibody.

Immune Regulation

Complement components and fragments can modulate several features of the immune response—directly by binding to CR1, CR2, and CR3 on the surfaces of T cells, B cells, and other cells involved in antigen recognition and indirectly by stimulating the synthesis and release of cytokines.[204] The C3b cleavage product, C3dg, when covalently bound to antigen, brings the antigen close to B cells by binding to B-cell CR2 (CD21).[73,88,119,178,439] Complement decreases the amount of antigen required to induce an immune response and increases the efficiency of the process by facilitating presentation and localization of antigen. C3 influences antigenic localization within germinal centers, and it is involved in anamnestic responses and isotype switching. The importance of complement in the immune response has been shown by the finding that C1-deficient, C2-deficient, C4-deficient, and C3-deficient animals have decreased antibody responses that can be restored by providing the missing protein.[73,88,119,178,439] Deficiency of early complement components, such as C2, in humans also has been associated with antibody deficiencies.[17,119]

Phagocytes

The first recognized cellular mechanism of host defense was the accumulation of phagocytic host cells around a foreign body in starfish observed by Metchnikoff.[397] PMNs, the most abundant circulating phagocytes in the human host, serve as a model here for discussing phagocyte functions. These cells constitute a major line of defense against invading bacteria and fungi. The proliferation of myeloid marrow progenitors and their differentiation into mature progeny are regulated by specific growth factors and cytokines.[47,367,576] The normal half-life of circulating PMNs is approximately 8 to 12 hours.[604] In the absence of active infection, most PMNs leave the circulation via the gingival crevices and the lower gastrointestinal tract, where the resident flora stimulate ongoing local extravasation of PMNs, a process that helps maintain the integrity of these tissues.[30] In response to invasive bacterial infection, circulating PMNs engage in three major functions: (1) migration to the site of infection, (2) recognition and ingestion of invading microorganisms, and (3) killing and digestion of these organisms.

PHAGOCYTE RECRUITMENT TO INFECTED SITES

Activation of endothelial cells that line the microvessels of acutely infected tissue occurs via locally produced cytokines, eicosanoid compounds, and microbial products.[115,534] As a result, the endothelial cells rapidly up-regulate their surface expression of P-selectin and then E-selectin.[70,537] These selectins engage in lectin-like interactions with the fucosylated tetrasaccharide moiety sialyl Lewis X, which is presented on constitutively expressed glycoproteins on PMNs, including L-selectin and P-selectin glycoprotein ligand-1.[350,366,631] These early interactions slow the PMNs in this first adhesive phase of leukocyte recruitment, sometimes described as "slow rolling."[70,115,534]

Within several hours, newly synthesized ICAM-1 is expressed at the endothelial surface.[115,534,536] The slowly rolling PMNs are activated by transient selectin-mediated interactions and locally produced mediators, especially endothelium-derived chemokines, such as IL-8.[365] These chemokines are most effective in activating the PMNs when they are bound by complex proteoglycans at the endothelial cell surface.[346] The activated PMNs produce a conformational activation of their surface β_2 integrins LFA-1 and Mac-1[179,595] and translocate an additional large quantity of Mac-1 from intracellular storage pools to the cell surface.[63,84] The newly translocated Mac-1 also may undergo this activation as the PMN is exposed to increasing concentrations of activating mediators.[179,282]

These activated β_2 integrins interact with the endothelial cell ICAM-1 in this second, firm adhesion phase mediated by integrin-ICAM interactions, which ultimately is necessary for transendothelial migration of the PMNs.[63,115,179,365,525,534,536] Other chemoattractants, such as C5a, N-formyl bacterial oligopeptides, and leukotrienes (e.g., leukotriene B_4), which diffuse from the site of infection, activate PMNs further and provide a chemotactic gradient for migration of PMNs into tissue.[241,419] The receptors for these chemoattractants, similar to the chemokine receptors, are G protein–coupled and have a seven transmembrane–domain structure.[241,419] They constitute important sensory mechanisms of the PMNs for activating adhesion, directional orientation, and the contractile protein-dependent lateral movement of adhesion sites in the PMN membrane necessary for migration.[26,241,419,561]

A scheme for recruitment of PMNs from the microcirculation into infected tissue is presented in Figure 2–2, and a more detailed diagram depicting the surface molecules that mediate PMN-endothelial adhesion is provided in Figure 2–3. Although the specific stimuli and adhesion molecules may vary, this general scheme applies to the local recruitment of virtually all circulating cells of the immune system.[75,244,324]

PHAGOCYTOSIS

After PMNs reach the site of infection, they must recognize and ingest, or phagocytose, the invading bacteria. Opsonization, especially with IgG and fragments of C3, greatly enhances phagocytosis.[290,310] Although non-opsonic phagocytosis may occur, only opsonin-mediated phagocytosis is discussed here. CR1 and CR3, respectively, are the main phagocytic receptors for opsonic C3b and iC3b.[63,213] When PMNs are activated by chemoattractants or other stimuli, CR1 and CR3 are translocated rapidly to the cell surface from intracellular storage compartments, increasing surface expression 10-fold.[63,213] CR3 is identical to the adhesion-mediating integrin Mac-1.[36,63] CR1 and CR3 act synergistically with receptors for the Fc portion of antibodies, especially IgG.[36,310]

Phagocytic cells may express three different types of IgG Fc receptors, or FcγRs, all of which can mediate phagocytosis.[209,587] FcγRI (CD64) is a high-affinity receptor that is expressed mainly on mononuclear phagocytes.[587] The two FcγRs ordinarily expressed on circulating PMNs are FcγRII (CD32) and FcγRIII (CD16).[576,587] FcγRII is conventionally anchored in the cell membrane, exhibits polymorphisms that determine preferences for binding of certain IgG subclasses, and can activate PMN oxidative burst activity directly.[576,587,588] FcγRIII is expressed on PMNs as a glycolipid-anchored protein, although it is anchored conventionally on NK cells and macrophages.[587] Most phagocytes also express IgA receptors. The best-characterized FcαR, CD89, binds monomeric IgA and promotes phagocytosis and killing of IgA-opsonized bacteria.[292,409]

The engagement of phagocyte receptors with microbial opsonins on microbes locally activates cytoskeletal contractile elements, leading to invagination of the phagocyte membrane at

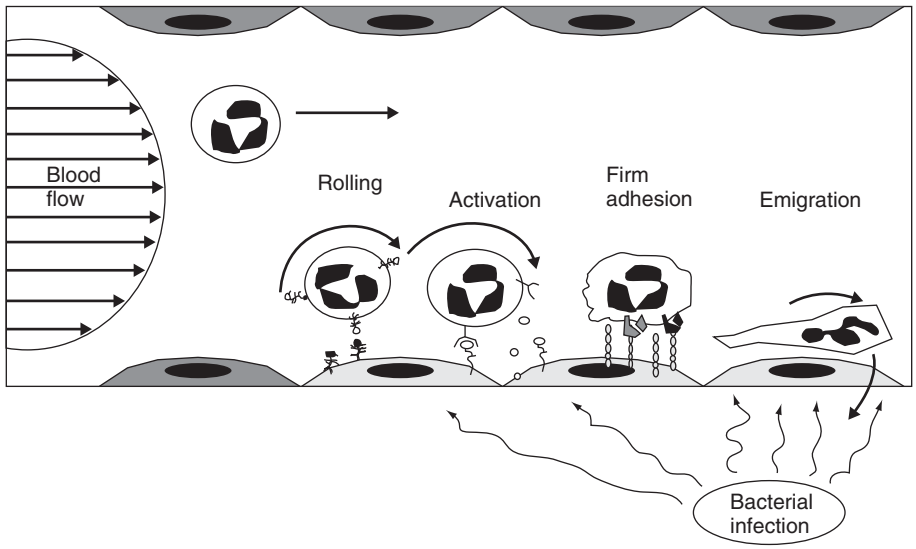

Figure 2–2 Events during polymorphonuclear leukocyte (PMN) recruitment to infected sites. Interactions between microorganisms in infected tissue and host cells and proteins result in elaboration of mediators that diffuse to the local microcirculation and stimulate the endothelial cells. This stimulation induces new surface expression of P-selectin and E-selectin, release of interleukin-8 and other chemokines, and new surface intercellular adhesion molecule 1 (ICAM-1). The endothelial selectins bind to constitutively expressed carbohydrate ligands on circulating PMNs and slow the passage of the PMNs through the microvessels. As the PMNs slow further, they become activated by interaction with chemokines bound to complex glycopeptides on the endothelial surface. This activation of PMNs increases their expression and binding activity of the β_2 (CD11/CD18) integrins, Mac-1 and lymphocyte function-associated antigen 1 (LFA-1). Interactions between these integrins and ICAM-1 (and ICAM-2 in the case of LFA-1) lead to tight adhesion and spreading on the endothelial surface. These latter adhesive interactions also are used for migration between endothelial cells and through the subjacent extracellular matrix in response to the gradient of chemoattractants, such as C5a and bacterial peptides, released at the infected site. Homophilic interactions between platelet–endothelial cell adhesion molecule-1 (PECAM-1) on the PMNs and endothelial cells also seem to contribute to transendothelial migration. *(Drawing courtesy of Dr. Scott Seo.)*

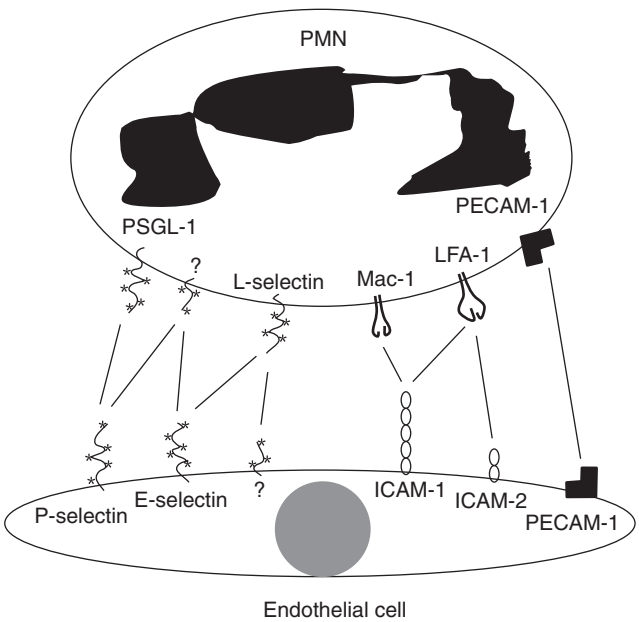

Figure 2–3 Molecular interactions that mediate polymorphonuclear leukocyte (PMN)–endothelial adhesion. The selectins, P-selectin and E-selectin on endothelium and L-selectin on leukocytes, bind to oligosaccharide moieties, including sialyl Lewis X (sLeX), which decorate the selectins and other glycoproteins on the opposite cell, including P-selectin glycoprotein ligand-1 (PSGL-1) on leukocytes. These interactions mediate the early adhesive phase of leukocyte recruitment. The β_2 integrins macrophage antigen 1 (Mac-1) (CD11b/CD18) and lymphocyte function-associated antigen 1 (LFA-1) (CD11a/CD18) on PMNs bind intercellular adhesion molecule 1 (ICAM-1) on endothelial cells. LFA-1 also can bind ICAM-2, which is expressed constitutively on endothelium. Platelet–endothelial cell adhesion molecule-1 (PECAM-1) molecules interact with each other and are expressed on PMNs and endothelial cells.

the site of initial engagement and the extension of pseudopods around the microbe. The ligation of additional opsonin-receptor pairs leads to engulfment of the microbe within a sealed phagosome,[560] as depicted in Figure 2–4. This engulfment is followed by fusion of the phagosome with lysosomal compartments containing the phagocyte's array of microbicidal products.

PHAGOCYTE MICROBICIDAL MECHANISMS

The microbicidal mechanisms of PMNs usually are categorized as either oxygen-dependent or oxygen-independent,[492] and intracellular killing usually occurs after the phagosome fuses with one or more types of lysosomal granules that contain many of the cell's microbicidal weapons. The contents of the three major populations of intracellular granules of PMNs, which contain many of the PMN's microbicidal molecules, either free within the granules or anchored in the granule membrane, are shown in Table 2–2.[84,85,235] Oxygen-dependent microbicidal mechanisms of phagocytes depend on a complex enzyme, nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, which converts molecular oxygen (O_2) into superoxide anion (O_2^-).[42,135] This enzyme is assembled at the activated cell membrane from six or more components that include a cytochrome (*a* and *b* subunits, designated $gp91^{phox}$ and $p22^{phox}$ ["phox" refers to phagocyte oxidase]), a flavoprotein, and a quinone, all of which are associated with the cell membrane, and at least two cytoplasmic proteins, $p47^{phox}$ and $p67^{phox}$, which assemble with the membrane-associated components to form the active enzyme complex.[42,84,135] Each of the main oxidant products derived from these reactions exhibits microbicidal activity, including the earliest products, O_2^- and hydrogen peroxide (H_2O_2), which are less potent than the downstream products hypochlorite (OCl^-) and chloramines (NH_3Cl, RNH_2Cl), chloramines being the most stable.[492] Figure 2–5 shows the sequence of the main oxidative reactions of PMN after the formation of superoxide anion.

TABLE 2–2 Stored Contents of Neutrophil Granules and Vesicles

Primary (Azurophilic) Granules	Secondary (Specific) Granules[a]	Tertiary Granules[b]	Secretory Vesicles[c]
Elastase	Lactoferrin	Gelatinase	Alkaline phosphatase
Cathepsin G	Vitamin B_{12}–binding protein		
Myeloperoxidase	Lysozyme		
Defensins	Gelatinase		
Bactericidal/permeability-increasing protein "p15s"			
Cathelicidin (LL37)			
Lysozyme			

Selected membrane-bound proteins in intracellular granules and vesicles:
f-met-leu-phe receptor[a,b,c]
type 1 complement receptor (CR1)[c]
CD11b/CD18 (CR3, Mac-1)[a,b,c]
cytochrome b_{558}*[a,b,c]*
type III Fcγ receptor (CD16)[?,c]

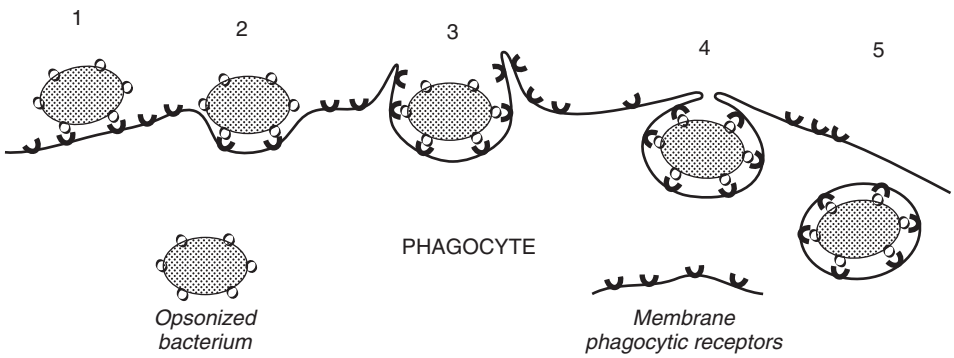

Figure 2–4 Opsonin-receptor-mediated phagocytosis. Phagocytes such as polymorphonuclear leukocytes (PMNs) that reach the site of bacterial infection are activated for enhanced recognition, attachment, and ingestion of bacteria that have been coated with opsonic C3 fragments, IgG, or both via specific receptors on the PMN surface. Binding of opsonized bacteria to opsonin receptors (1) activates contractile elements of the cytoskeleton to produce an invagination at the initial site of attachment (2), with subsequent extension of membrane pseudopods around the organism (3). This process allows engagement of additional opsonin-receptor pairs, as the organism becomes engulfed (4). Finally, the plasma membrane fuses completely around the bacteria to create the phagosome (5), which soon fuses with lysosomal granules, exposing the bacterium to the microbicidal components of the phagocyte.

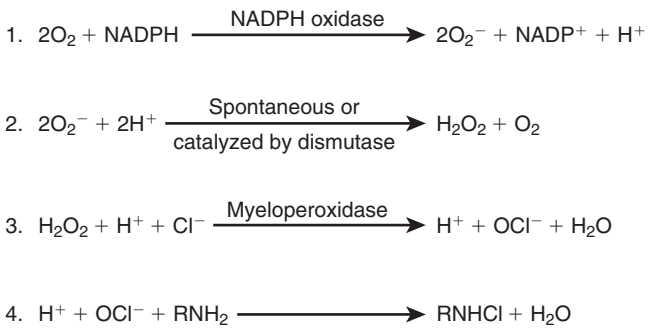

Figure 2–5 Major reactions in the evolution of oxygen-dependent polymorphonuclear leukocyte microbicidal activity. The conversion of molecular oxygen to superoxide anion (O_2^-) by nicotinamide adenine dinucleotide phosphate (NADPH) oxidase is the initial event in the sequence of production of antimicrobial oxidants. Shown in order are the subsequent reactions for production of hydrogen peroxide (H_2O_2), hypochlorite (OCl^-), and chloramines (RNH_2Cl).

Oxygen-independent microbicidal activity of PMNs resides mainly in a group of proteins and peptides stored within primary (azurophilic) granules. Lysozyme is contained in the primary and the secondary (specific) granules of PMN.[551] It cleaves important linkages in the peptidoglycan of bacterial cell walls and is most effective when it can act in concert with the complement MAC.[310] The primary granules contain several cationic proteins with important microbicidal activity. A 59-kd protein, bactericidal/permeability-increasing protein, is active against only gram-negative bacteria.[612] Smaller arginine-rich and cysteine-rich peptides, the α-defensins, similar to the β-defensins of epithelial cells, are active against a range of bacteria, fungi, chlamydiae, and enveloped viruses, and other related molecules include cathelicidin and a group of peptides called p15s.[230,234,235,363] The mechanisms of action of these peptides are not fully understood, although they are addressed in the earlier section on antimicrobial peptides of epithelial cells. Some of these PMN proteins and peptides may interact with each other synergistically to enhance overall antimicrobial activity.[362]

Important Interactions among Innate Immune Mechanisms

A schematic overview of many of the main features of innate immunity discussed previously, along with some of their important interactions, is diagrammed in Figure 2–6. Several levels of interactions are depicted, from initial host-pathogen contact, through a variety of activating signals, to the attack by host effector mechanisms on pathogenic targets.

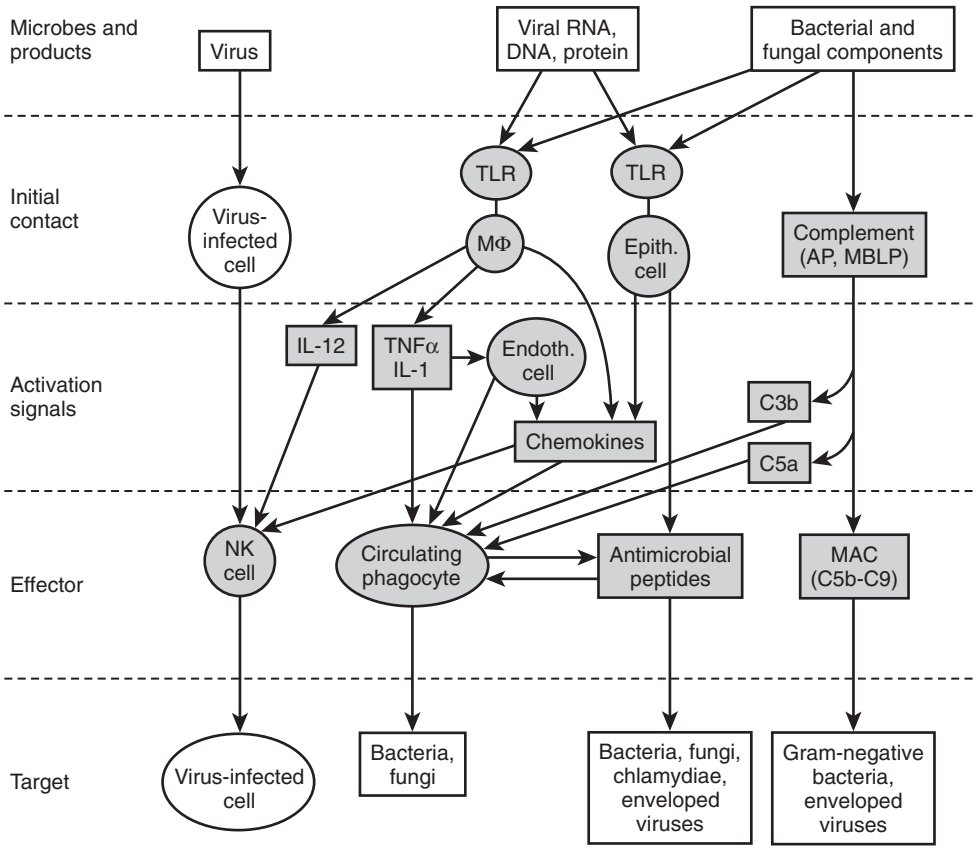

Figure 2–6 Innate immunity: first contact, intermediate signals, and effector mechanisms. Diagrammed are important host responses to infection that are independent of specific cell-mediated immunity or antibodies. Initial contact between the host and microbes or their products may result in viral infection of cells, activation of Toll-like receptors (TLRs) on macrophages (MΦ) and epithelial cells, and activation of the alternative pathway (AP) or mannose-binding lectin pathway (MLBP) of complement. The resulting activation signals, including cytokines (e.g., interleukin-12 [IL-12], tumor necrosis factor–α [TNF-α], IL-1), chemokines, and products of the complement cascade, mobilize cellular (natural killer [NK] cells, phagocytes) and humoral (antimicrobial peptides, membrane attack complex [MAC]) effectors, which attack their respective microbial targets. *(From Tosi, M. F.: Innate immune responses to infection. J. Allergy Clin. Immunol.* 116*:241-249, 2005.)*

ADAPTIVE IMMUNE RESPONSES

Adaptive immunity involves the host's antigen-specific responses to infectious challenges that, once modified, can help clear some infections and can provide specific protection against subsequent challenges. The major steps in the development of adaptive immunity include processing and presentation of specific antigens by APCs, activation of T lymphocytes for specific cytotoxic T-cell activity, T-cell cytokine production, and T-cell help in activating and maturing of antigen-specific B cells for the production of specific antibodies. Innate immune responses often occur in minutes to hours and may activate early cellular responses that are essential for the development of adaptive immunity. The full development of most adaptive immune responses requires days to weeks. When developed, however, adaptive immune responses often can provide durable protection. Figure 2–7 depicts the major events in the adaptive immune response to infection.

Antigen Presentation and Specific Cell-Mediated Immunity

Specific cell-mediated immunity provides T-cell help for production of antibodies by B cells, cytokine production for the stimulation and regulation of a range of immune responses, and cytotoxic T-cell activity against host cells infected with viruses.[184,414,461] The development of cell-mediated immunity requires complex interactions to occur between T cells and APCs via several types of surface molecules on the respective cell surfaces. These interactions include binding of an antigen-specific T-cell receptor (TCR) on the T lymphocyte to a peptide antigen presented on the class I or class II MHC by the APC, with concurrent binding of the class I or class II MHC by CD8 or CD4,[574] as shown in Figure 2–8. Other respective pairs of accessory cell/surface molecules that enhance interactions between T cells and APCs include CD40L/CD40, LFA-1/ICAM-1, and CD28/B7. An additional molecule, cytotoxic T lymphocyte antigen-4, expressed on activated T cells, also can bind to B7 molecules on APCs to generate a suppressive signal that may terminate T-cell activation.[574] The sustained physical interface between T cells and APCs at which these molecular interactions take place has been characterized as the *immunologic synapse*.[96,252]

CLASS I MAJOR HISTOCOMPATIBILITY COMPLEX

Virtually all human cells except neurons express class I MHC.[161] The class I MHC molecule presents antigenic peptides to $CD8^+$ cytotoxic T lymphocytes.[431,565] It consists of a heavy chain that contains the peptide-binding domain and a transmembrane domain and a smaller extracellular subunit, β_2-microglobulin.[77] The three major types of class I MHC heavy chains in humans—HLA-A, HLA-B, and HLA-C—have at least 22, 31, and 12 different alleles, respectively.[630] This polymorphism permits a great diversity in the peptide-binding repertoire in individuals and

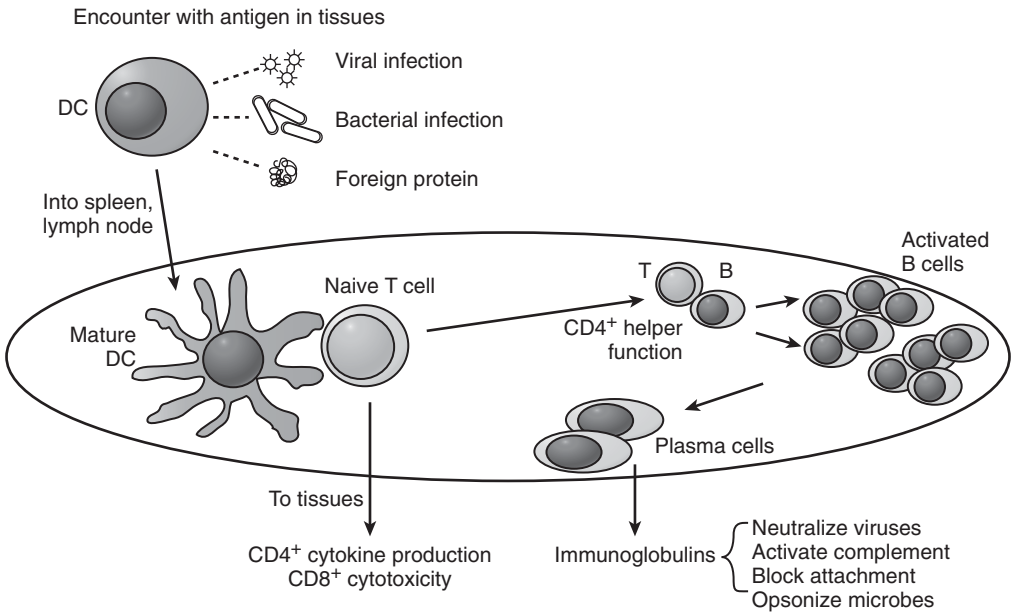

Figure 2–7 A simplified scheme of major events in the development of adaptive immune responses. When antigen-presenting cells, such as dendritic cells (DC), encounter and internalize microbes or their protein antigens in peripheral tissues, they process the microbial proteins and present the resulting antigenic peptides on either class I or class II major histocompatibility complex (MHC) molecules. The activated antigen-presenting cells migrate to lymphoid tissue, where they undergo maturation. When mature DC encounter naive $CD4^+$ or $CD8^+$ T cells expressing T-cell receptors (TCRs) specific for the peptides presented in the appropriate MHC context (CD4/MHC-II; CD8/MHC-I), binding between the cells occurs via TCR/peptide, MHC/$CD4^+$ or MHC/$CD8^+$, and other pairs of accessory molecules, all necessary for stimulating the T cells to become effector cells. Cytotoxic effector $CD8^+$ T cells migrate into the periphery and kill virus-infected cells that present viral peptides via MHC class I. Effector $CD4^+$ cells produce cytokines or provide help for proliferation of antigen-specific B cells in the lymphoid germinal centers and eventual production by plasma cells of specific antibodies that can neutralize viruses, prevent microbial attachment, opsonize microorganisms, or activate complement.

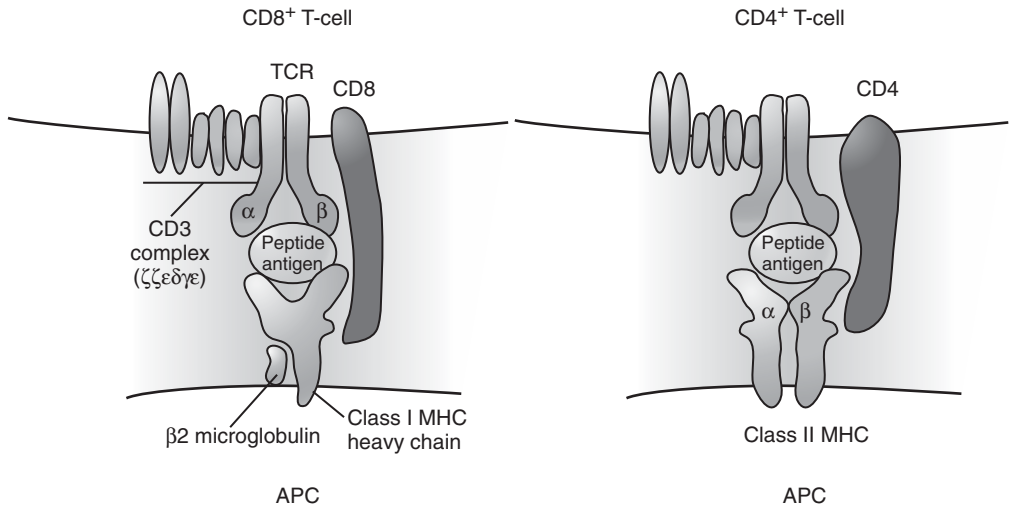

Figure 2–8 Principal cell surface interactions between $CD8^+$ and $CD4^+$ T lymphocytes and peptide antigens complexed with major histocompatibility complex (MHC) class I and class II molecules, respectively. CD3 (composed of six subunits, ζ, ζ, ε, δ, γ, ε) is associated closely with the T-cell receptor (TCR), which recognizes a specific peptide presented on MHC molecules. Class I and class II MHC determinants are recognized by $CD8^+$ and $CD4^+$. Additional or accessory interactions are discussed in the text. APC, antigen-presenting cell. *(Adapted from Lewis, D. B., and Wilson, C. B.: Developmental immunology and role of host defenses in neonatal susceptibility to infection.* In *Remington, J. S., and Klein, J. O. [eds.]: Infectious Diseases of the Fetus and Newborn Infant. 6th ed. Philadelphia, W. B. Saunders, 2006, p. 92.)*

within populations. A restricted degree of MHC genetic polymorphism has been invoked as a possible explanation for the predisposition of certain populations to develop infections.[78]

Class I MHC molecules within the cell ordinarily bind peptides derived from recently synthesized proteins, either of self origin or of infecting viruses.[207,208] A portion of newly synthesized proteins is processed into peptides at a cytoplasmic site termed the *proteasome*.[245] These peptides actively are transported into the endoplasmic reticulum, where they are bound in the peptide-binding cleft of MHC class I. Suitable peptides usually are restricted to 8 to 10 amino acids in length, and they must contain certain amino acids at specific "anchor" positions on the peptide

to bind.[295] Allelic variants of MHC class I may require different amino acids at these anchor positions.[227] The other amino acids of the peptide constitute the antigenic determinant recognized, after trafficking of the MHC-peptide to the cell surface, by a specific TCR on $CD8^+$ cytotoxic T cells, the latter concurrently binding the heavy chain of MHC class I via CD8.[227,295]

CLASS II MAJOR HISTOCOMPATIBILITY COMPLEX

Mononuclear phagocytes, B lymphocytes, and dendritic cells, including specialized tissue-specific dendritic cells such as the Langerhans cells of the skin, all serve the immune system as "professional" APCs.[597] Dendritic cells, the most efficient APCs for primary activation of naive T cells, are macrophage-like cells of a distinct lineage that take up and process antigens in tissues and migrate to local lymph nodes or to the spleen, where they are likely to encounter T cells specific for the presented antigens.[191,263,489,565] A defining feature of these professional APCs is their expression of class II MHC molecules in addition to class I MHC.[161]

Class II MHC molecules are composed of an alpha and a beta chain, which together form a peptide-binding cleft.[98,503] Class II MHC molecules present peptides, 13 to 17 amino acids in length, derived from proteins that are internalized by endocytosis or during phagocytosis of microorganisms.[261,296,503] There are three major types of class II MHC alpha and beta chains—HLA-DR, HLA-DP, and HLA-DQ—each exhibiting a high degree of polymorphism.[383] MHC class II, bound to a separate smaller molecule known as the *invariant chain*, trafficks via the Golgi to endosomal/lysosomal compartments, where it must dissociate from the invariant chain to bind antigenic peptides derived from internalized proteins.[487,572,573] The class II MHC-peptide complexes then move to the cell surface, where the peptides are bound by TCRs of $CD4^+$ T cells, which concurrently bind class II MHC via CD4.[192,372]

Figure 2–9 depicts the essential features of the conventional antigen presentation pathways that involve class I and class II MHC molecules, as described earlier. Alternative mechanisms have been documented by which class I MHC can present peptides derived from internalized exogenous proteins, and class II MHC may present peptides derived from newly synthesized proteins. The importance of these unconventional pathways of antigen presentation in the immune response is not fully understood, but evidence indicates that such "cross-presentation" may be important for generation of $CD8^+$ cytotoxic T-cell response against some viruses or fungi taken up via endocytosis by APCs.[38,313]

CD1 FAMILY OF ANTIGEN-PRESENTING MOLECULES

The CD1 family comprises proteins with significant homology and structural similarity to the MHC class I heavy chain, but

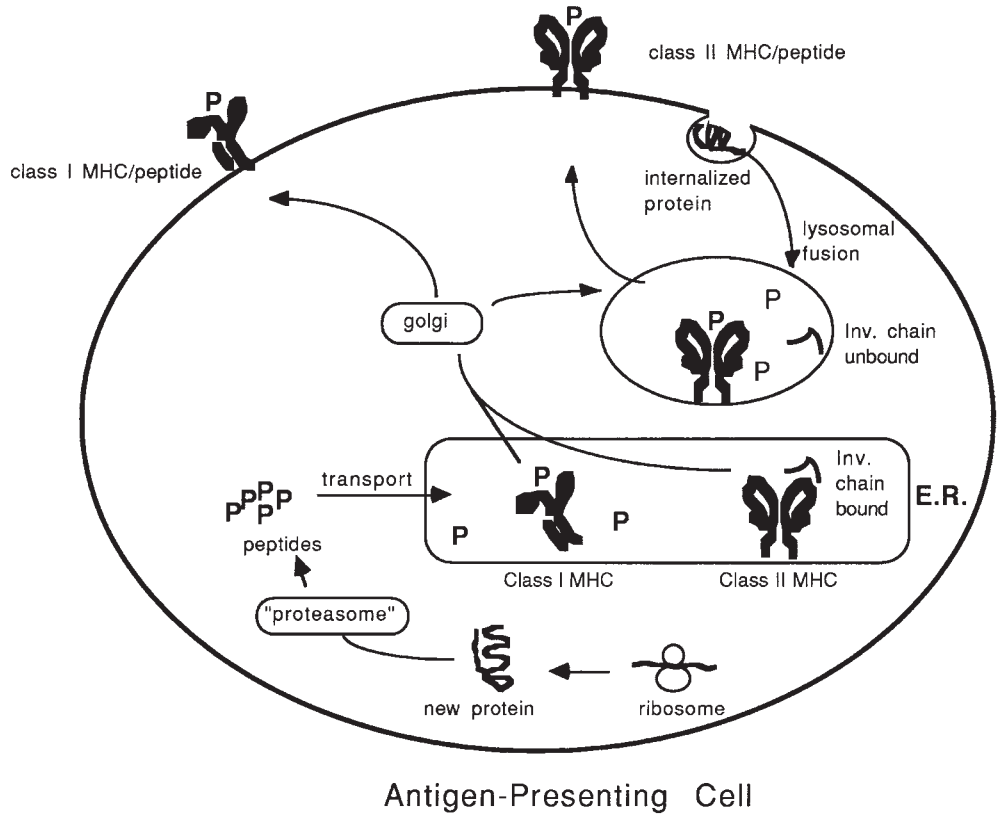

Figure 2–9 Conventional pathways for peptide antigen presentation by class I and class II major histocompatibility complex (MHC) molecules. In the antigen-presenting cell, a proportion of newly synthesized proteins undergoes proteolysis into peptides by enzymes that constitute the "proteasome." The peptides actively are transported into the endoplasmic reticulum (E.R.), where peptides with the appropriate length and sequence bind to MHC class I molecules. MHC class II cannot bind peptides in the E.R. because of interference by the associated "invariant chain." The class I MHC/peptide complex is transported via the Golgi to the cell surface, where it may be recognized by $CD8^+$ lymphocytes. Class II MHC molecules pass via the Golgi to a lysosomal compartment, where conditions favor the release of the invariant chain. This release permits class II MHC to bind peptides derived from internalized proteins that have entered the lysosomal compartment via fusion of endosomes or phagosomes with the lysosome. The lysosome translocates to the cell surface, where the class II MHC/peptide complex may be recognized by $CD4^+$ lymphocytes.

which present lipid and glycolipid antigens. All mammalian species express one or more members of the CD1 family, principally on professional APCs. Four human CD1 proteins—CD1a, CD1b, CD1c, and CD1d—have been identified, each tightly associated with a β_2-microglobulin subunit. Mycolic acid, lipoarabinomannans, and other related components of mycobacteria are the best-documented foreign antigens presented by CD1 molecules, and internalized antigens and antigens synthesized within the APCs by ingested mycobacteria may be presented via distinct trafficking patterns of the CD1-antigen complexes.

Researchers have hypothesized that other antigens, such as the lipoteichoic acids of gram-positive bacteria, the complex capsular polysaccharides of *H. influenzae* and *N. meningitidis*, and the glycosylphosphatidylinositol components of glycosylphosphatidylinositol-linked proteins of malarial parasites and trypanosomes, also could be presented by CD1 molecules. Antigens presented on APC by CD1 molecules are recognized by a specialized subset of CD1-restricted T cells that usually lack CD4 and CD8, known as NK/T cells. These cells share characteristics of NK cells and T cells, exhibiting a limited range of TCR specificity. They represent a sizeable fraction of the T cell compartment, although their function in the immune response is incompletely understood. Greater detail regarding the structure, function, phylogeny, trafficking, expression, and T cell interactions for members of the CD1 family may be found in an extensive review.[470]

T Lymphocytes

The development of T lymphocytes, or T cells, begins when prothymocytes leave the marrow and enter the subcapsular region of the thymus.[190] By mechanisms that are poorly understood, the thymic environment induces the rearrangement of TCR V (variable), D (diversity), and J (joining) gene segments with the eventual expression of mature alpha-beta TCRs complexed with CD3. The T cells, now co-expressing CD4 and CD8, migrate to the thymic cortex, where they undergo screening for TCR specificity to optimize the repertoire for distinguishing self from non-self and to eliminate TCR rearrangements that result in undesirably high self-reactivity. The mechanism by which this screening occurs is the subject of intense investigation and theoretical controversy, and several reviews of the subject are cited here.[249,317,387,396] Thymocytes that do not pass this dual screening procedure receive signals that induce programmed cell death (apoptosis).[396,417,600] Only approximately 5 percent of the original thymocytes pass this screening, after which they express either CD4 or CD8, but not both.[396,417,600]

Mature thymocytes are released into the periphery, where the $CD4^+$ cells serve as the main source of IL-2 and provide help for B-cell antibody production, and the $CD8^+$ cells engage in specific cytotoxic activity. This discussion of T cells and TCRs specifically relates to T cells that express TCRs composed of alpha and beta chains, or alpha-beta T cells. T cells of a distinct type, gamma-delta T cells, are far less numerous in most tissues (intestinal epithelium is a notable exception); exhibit much less TCR diversity than do alpha-beta T cells; may not require an intact thymus for development; and play a role in host responses to certain intracellular bacterial pathogens, including *Listeria* and mycobacteria.[110,264]

Antigen specificity of alpha-beta T cells resides in their TCRs, which are integral membrane proteins that exhibit structural homology with immunoglobulins. TCR diversity results from a rearrangement of V, D, and J segments. There are 100 different V segments, 1 D segment, and 100 different J segments in the complete germline configuration of the TCR genes. Rearrangement of these gene segments into a mature VDJ sequence occurs by the action of a recombinase enzyme complex formed by two proteins, RAG-1 and RAG-2.[440,516] TCR diversity is generated by several factors, including the range of possible combinations of V, D, and J segments; the imprecise action of the recombinase complex; the variability in the number of nucleotides deleted during rearrangement; and the action of another enzyme, *terminal deoxytransferase*, which seems to add nucleotides at random to extend segments during rearrangement.[215,533] The actions of Artemis and DNA ligase IV, two enzymes crucial for the processing and joining of DNA ends, introduce additional sources of variability.[103,200,376] Researchers have estimated that 10^{15} different TCR specificities theoretically could result from the several mechanisms involved in TCR segment rearrangement.[168]

Stimulation of naive $CD4^+$ or $CD8^+$ T cells occurs as they circulate through peripheral lymphoid tissue and encounter dendritic cells and other professional APCs. Localized T-cell migration is highly regulated by specific chemokines and adhesive interactions with local endothelium and involves mechanisms similar to the mechanisms discussed earlier for circulating phagocytes.[194,342] When T cells engage APCs presenting specific peptide antigens on the appropriate MHC molecules, they are activated via their TCR and several costimulatory molecules, especially CD28, to produce IL-2 and to proliferate and differentiate into effector T cells.[134,299] Effector $CD4^+$ T cells may be of the T_H1 or T_H2 type, and this type is influenced by several factors, including the specific cytokines elicited by a particular microbial pathogen. Naive T cells activated in the presence of IL-12 and IFN-γ are likely to develop into T_H1 cells, whereas IL-4 and IL-6 tend to drive development in the direction of T_H2 cells.[413,421] Preferential development of T_H1 effector cells leads mainly to macrophage activation and cell-mediated immunity, whereas T_H2 effector cells, which provide more effective B-cell help, drive the development of humoral immunity.[418]

Activation of naive $CD8^+$ T cells by antigen binding, costimulation by accessory binding molecules on APCs, and exposure to cytokines, including IL-2, leads to clonal proliferation of specific $CD8^+$ cells and their differentiation into cytotoxic effector cells. Effector $CD4^+$ T cells bound in common to an APC may play a role in activating naive $CD8^+$ T cells, either by releasing IL-2 or by activating the APC to provide greater co-stimulation to the $CD8^+$ T cell to make its own IL-2.[33] Antigenically experienced effector $CD8^+$ T cells respond to specific antigen and co-stimulatory molecules on infected host cells by activating cytotoxic mechanisms similar to those described earlier for NK cells, including the release of perforin and granzymes and generation of receptor-mediated signals for target cell apoptosis.[367,504,583]

T-CELL MEMORY

Some proportion of activated $CD4^+$ and $CD8^+$ T cells become endowed with the capacity for long-term antigenic memory and rapidly can become effectors on re-exposure to specific antigen. Whether these cells develop directly from naive T cells or previously have been effector cells, or both, is uncertain, and the mechanisms by which they become memory T cells is poorly understood. Among the features of memory T cells are high levels of expression of CD45RO, the ability to suppress activation of naive T cells of the same specificity, and a homeostatic level of ongoing proliferation in bone marrow and peripheral lymphoid organs.[314,378,509]

T-CELL ACTIVATION BY SUPERANTIGENS

The term *superantigen* describes a class of protein antigens, mainly microbial exotoxins, including most staphylococcal enterotoxins, staphylococcal toxic shock syndrome toxin-1 (TSST-1), and related streptococcal TSST-1-like toxins. These bacterial toxins are potent pyrogens, can induce a potentially lethal toxic shock syndrome, and share binding domains for TCR V regions and MHC class II molecules. Superantigens bypass normal antigen

processing and presentation pathways by binding directly to class II MCH molecules on APCs and to specific variable regions on the beta chain of the T-cell antigen receptor. Through these interactions, superantigens induce a polyclonal activation of T cells at orders of magnitude above levels induced by antigen-specific activation, resulting in massive release of cytokines from T cells and APCs, including TNF-α, TNF-β, IL-1, IL-2, and IFN-γ, which are thought to be responsible for the most severe features of toxic shock syndromes.[16,476]

REGULATORY T CELLS

The existence of T suppressor cells was long a subject of debate among immunologists. Only since the 1990s has solid evidence been developed to support the existence of suppressor T cells, now referred to as *regulatory T cells*. These cells were discovered when thymectomized mice were noted to develop autoimmune disease. Transfer of T cells that expressed CD25, the alpha chain of the IL-2 receptor, from normal adult mice to thymectomized mice prevented autoimmune disease. This population of $CD4^+CD25^+$ regulatory T cells can suppress the activity of other immune cells and has been shown to prevent graft-versus-host disease and allograft rejection. The mechanism of suppression by regulatory T cells is uncertain but may involve direct contact with other cells or secretion of inhibitory cytokines, including IL-10. These inhibitory cytokines can interfere with T-cell proliferation and inhibit the ability of antigen-presenting dendritic cells to promote T-cell activation. The role of regulatory T cells in immunity to infection is only beginning to be studied; some current evidence suggests that the action of regulatory T cells with specificity for microbial antigens may suppress protective immune responses to some infections but also may suppress excessive or injurious host responses.[475]

B Lymphocytes and Immunoglobulins

B LYMPHOCYTES

B lymphocytes (B cells) are the source of humoral immunity in the form of specific immunoglobulin. The earliest recognizable marrow precursors of B cells are pro-B cells, surfaces of which bear the pan-B marker CD19. Further differentiation produces pre-B cells and then mature B cells, the latter expressing cell-surface immunoglobulin by which they recognize and bind antigen. B lymphocytes constitute approximately 20 percent of the lymphocytes in the circulation and peripheral lymphoid tissues, including the lymph nodes, spleen, bone marrow, tonsils, and intestines, and they are identified by the presence of surface immunoglobulin and the pan-B differentiation markers CD19 and CD20.[114,394]

B-cell activation is initiated by recognition and binding of specific antigens to B-cell surface immunoglobulins. Early activation leads to increased expression of receptors that either bind cytokines (e.g., IL-2, IL-4, IL-6) or interact with T cells,[349,459] leading to clonal proliferation and differentiation into memory B cells and plasma cells in the germinal centers of peripheral lymphoid tissue.[321] Some data suggest that B-cell differentiation into memory B cells is favored by exposure to the CD40L on dendritic cells in lymphoid organs, whereas differentiation into plasma cells is favored by exposure to CD23, IL-1a, IL-6, and IL-10.[321,571] The plasma cells, later found in bone marrow and liver and peripheral lymphoid tissue, are responsible for most free production of immunoglobulin.[571]

The B-cell response to protein antigens depends on T-cell help. B cells can process and present antigen to $CD4^+$ T cells they encounter in the lymph nodes and spleen.[320,321,571] B-cell surface immunoglobulin binds to a protein antigen, which is internalized, processed, and presented to the T cell via class II MHC molecules. B cell-mediated activation of T cells during antigen presentation is much more effective for memory T cells, whereas naive T cells are more likely to be turned off or rendered tolerant.[206,229] T-cell help is provided for B-cell proliferation and production of antibody against the specific protein antigen. It is mediated by signaling via CD40L interactions with CD40 on the B cell and by the release of cytokines, which also can induce isotype switching.[429,555] Most B-lymphocyte responses to polysaccharide antigens proceed largely without formal T-cell help, although antibody responses to some such antigens may be enhanced in the presence of T cells.[408]

IMMUNOGLOBULIN

Immunoglobulin molecules may be bound at the surface of B cells or free in the circulation, mucosal secretions, or tissues. Free immunoglobulins function in host defense against infection by binding to microbial surfaces to prevent microbial attachment, activating complement via the classical pathway, neutralizing viruses and toxins, and participating in the formation of immune complexes.[134]

Immunoglobulin molecules are composed of two identical heavy and two identical light chains, as diagrammed in Figure 2–10.[195] The carboxyl terminus of the immunoglobulin molecule is the heavy chain constant, or Fc, region. The amino acid sequence of this region determines the immunoglobulin isotype. The heavy chain is encoded by V, D, J, and constant (C) regions on chromosome 14.[66,605] Each immunoglobulin molecule has a pair of either kappa or lambda light chains, defined by distinct C regions. The variable region of the immunoglobulin molecule contains the antigen binding site. Similar to the TCR, the Fab region consists of two identical heavy and light chain pairs; similarly, broadly diverse antigen specificity results from the variable nature of recombinase-mediated DNA rearrangements of the three hypervariable, or complementarity-determining, regions

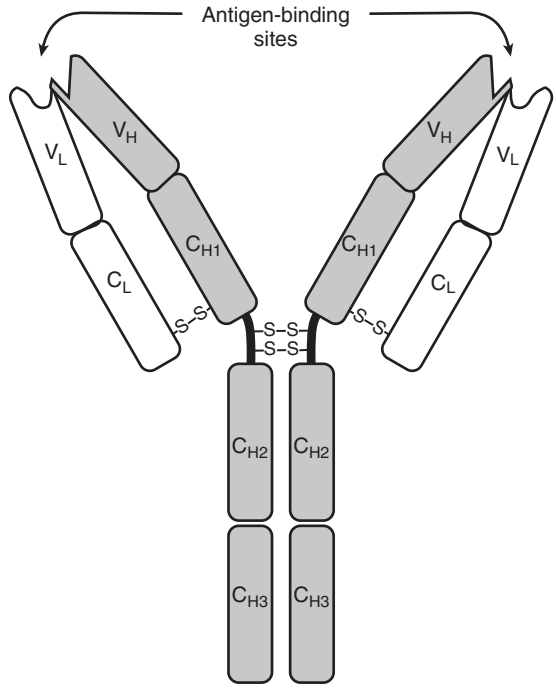

Figure 2–10 Structure of an immunoglobulin molecule. The schematic structure of IgG is shown, depicting the variable (V) and constant (C) regions of the heavy (H) and light (L) chains, the disulfide bonds that link the two heavy chains at the hinge region and the CL region with CH_1, and the antigen-binding sites formed by the complementarity-determining regions of VH and VL.

(CDR1, CDR2, and CDR3) and the four framework regions during development of B cells.[210,381]

The imprecision inherent in this rearrangement, involving mechanisms similar to those described for the TCR, leads to the generation of more than 10^{12} potential antigenic specificities. Somatic hypermutation of variable regions after gene rearrangement occurs adds to the repertoire, and further diversity results from differences in approximation of the three complementarity-determining regions in relation to each other, affecting the three-dimensional structure of the antigen recognition site.[406,458] In contrast to most TCRs, which recognize specific peptide sequences, immunoglobulin molecules can recognize the three-dimensional structures of antigens.[165]

All immunoglobulin is derived from B cells expressing surface IgM. B cells may change immunoglobulin isotype when they differentiate into plasma cells, which produce only one class or subclass of immunoglobulin each. Isotypes other than IgM are the result of isotype switching by replacing a part of the constant region of the immunoglobulin heavy chain with another isotype-specific segment.[555] As already noted, isotype switching primarily depends on specific B-cell interactions with cytokines and T cells. The variable region remains unchanged during isotype switching; no change occurs in antigen specificity. Important features of immunoglobulins, including half-life, localization in tissues, and interactions with cellular IgG receptors, are directly determined by isotype, however.[166]

IMMUNOGLOBULIN ISOTYPES

IgG accounts for approximately 80 percent of circulating immunoglobulin and includes the subclasses IgG1, IgG2, IgG3, and IgG4. The half-life of IgG ordinarily is approximately 21 days (7 days for IgG3).[303] Initial exposure to most microbial protein antigens first induces IgM and then an IgG response consisting of IgG1 and IgG3. IgG2 and IgG4 usually are produced during the secondary immune response. IgG1 usually is made in response to protein antigens.[303] In adults, the main antibody response to polysaccharides is IgG2, whereas in infants, IgG1 predominates.[19] The functions of IgG in host defense include blocking microbial attachment, opsonization, complement activation, toxin and virus neutralization, and promotion of ADCC. IgG1, IgG2, and IgG3, but not IgG4, can trigger complement activation via the classical pathway by binding to C1q.[95]

Free IgM usually exists as an immunoglobulin pentamer that has a molecular weight of approximately 950,000 and is stabilized by a single J chain.[195,336,398,458] Present mainly in the circulation, its half-life is approximately 8 to 10 days. The IgM response is the earliest of the isotype responses, appearing within the first few days of infection, but it is transient. The formation of an IgM response in the absence of an IgG response to infection is not associated with the formation of memory B cells. The main function of IgM in host defense is the activation of complement to promote opsonization and lysis of microorganisms.[166,398]

IgA exists in monomeric circulating and polymeric secretory forms and has a half-life of approximately 7 days.[303] Both forms are produced mainly by plasma cells that have migrated to mucosal sites. Secretory IgA is composed of two or three IgA molecules joined by a stabilizing J segment that is secreted by plasma cells and a secretory component produced by mucosal epithelial cells.[322,336] The secretory component permits delivery of IgA to mucosal surfaces.[430] There are two subclasses, IgA1 and IgA2, which differ in the composition of their heavy chains. Most IgA in the circulation is IgA1, whereas most IgA in secretions is IgA2. IgA1, but not IgA2, may be cleaved at mucosal sites by bacterial proteases.[335] IgA neutralizes viruses at mucosal sites, may block bacterial adhesion, and can act directly as an opsonin to promote phagocytosis and killing of microbes via Fcα receptors.[292,322]

The IgE molecule has a molecular weight of 200,000 and a half-life of only 2.3 days.[303] Most IgE is produced by plasma cells in lymphoid tissue near gastrointestinal and respiratory mucosal surfaces and released into the circulation.[301,564] IgE acts via Fcε receptors to trigger activation of mast cells and basophils, leading to immediate hypersensitivity reactions.[564] Individuals with intestinal metazoan parasites often have elevated serum levels of IgE, and IgE may have a role in protecting against parasitic disease by stimulating mediator release from mast cells, causing intestinal smooth muscle contraction and expulsion of parasites.[564]

IgD has a molecular weight of approximately 180,000 and a half-life of 3 days.[303] It is expressed along with IgM on surfaces of naive B cells but is present in normal adult serum and secretions in very low concentrations. Some antigenic specificity for IgD has been shown, and, although its function in host defense is unclear, it may serve as a secondary antigen receptor on B cells, where it may regulate the development of B-cell antibody responses.[80]

CLINICAL CONDITIONS ASSOCIATED WITH DEFICIENT HOST RESPONSES TO INFECTION

IMMATURE HOST RESPONSES OF THE NEWBORN

A mild febrile respiratory illness in a 10-month-old infant might prompt little more than gentle reassurance over the telephone from the child's pediatrician. If the patient is an infant in the first few weeks of life, however, the physician's response is likely to include an evaluation for systemic bacterial infection and administration of parenteral antibiotics in the hospital until a serious infection can be ruled out. Similarly, in an older infant, the appearance of a few cutaneous perioral vesicles characteristic of herpes simplex virus usually evokes little concern and no specific treatment. The same condition in the first 3 weeks of life is likely to lead to a prolonged hospitalization for antiviral therapy because of the risk of developing serious central nervous system or disseminated infection.[617] It is a well-recognized fact that newborns are much more susceptible to serious disease from many types of organisms than are older children and adults. This predisposition to infection is even more profound in infants born prematurely.[364] The basis for this special vulnerability of neonates is complex and encompasses all arms of the immune system. This vulnerability is of such importance that the clinical approach to possible infections in infants during the first month of life usually is far more aggressive than that in older children.

Cell-Mediated Immunity

Antigen presentation per se, via the mechanisms discussed earlier, seems to be intact in the newborn. Expression of class I and class II MHC molecules has been documented in a broad range of fetal tissues by 12 weeks' gestation,[284,441] and levels of expression are sufficient to mediate normal MHC class II–restricted antigen presentation by neonatal monocytes to maternal or paternal $CD4^+$ T cells and to induce vigorous rejection of allogeneic fetal tissue by $CD8^+$ cytotoxic T cells.[269,283]

By about 20 weeks' gestation, the fetal repertoire of diversity of TCRs has developed fully.[593] At the time of birth, although most basic functions of cell-mediated immunity are present, a high proportion of immature T cells are present in the peripheral circulation and can be identified by their co-expression of CD4 and CD8.[364] This phenotype typifies type II thymocytes, which usually are not found in the periphery in older individuals.

Neonatal T cells seem to be deficient in most of their major functions, including $CD8^+$ T cell–mediated cytotoxicity, delayed hypersensitivity, and T-cell help for B-cell differentiation.

Diminished production of cytokine by neonatal T cells likely accounts for much of this deficiency. The naive status of most neonatal T cells may account for reduced production of cytokine because memory T cells are much more efficient in all of these functions.[364]

B Cells and Antibody

B CELLS

Pre-B cells are found in the fetal liver and omentum by 8 weeks'gestation and in the fetal bone marrow by 13 weeks' gestation.[237,364,545] Pre-B cells with surface IgM have been detected by 10 weeks' gestation. After 30 weeks' gestation and delivery, pre-B cells are seen only in the bone marrow. Mature B cells are present in the circulation by the 11th week of gestation, and have reached adult levels in the bone marrow, blood, and spleen by the 22nd week of gestation.[170,237,545]

Fetal B cells express only IgM, whereas most adult B cells express IgM and IgD. Neonatal B cells may express three immunoglobulin isotypes (e.g., different combinations of IgG, IgA, IgM, and IgD) on their surfaces.[237,260] Data from experiments in mice suggest that exposing B cells with surface IgM, but not IgD, to antigens leads to anergy, or B-cell inactivation. The absence of surface IgD on fetal B cells has been speculated to contribute to the induction of tolerance to self- and, possibly, maternal antigens in utero. In addition, the fetus has a higher proportion of the functionally immature $CD5^+$, or B1, cells than adults do. These cells produce autoantibodies and may play a role in the development of tolerance to self-antigens, maternal antigens, or both.

Although germinal centers are not present in lymphoid tissue at birth, they begin to develop in the first few months of life concomitant with the infant's exposure to antigens.[575] Despite conflicting in vitro data, neonatal T-cell help for B cells probably is comparable to that of adult T cells, as is reflected by the excellent T cell–dependent antibody response of the newborn to immunization with protein antigens such as tetanus toxoid.[174] Neonatal T-cell help is associated with secretion of IgM alone, however, not other isotypes, possibly because neonatal T cells have diminished production of cytokines crucial for promoting isotype switching. Addition of cytokines such as IL-2, IL-4, and IL-6 helps overcome neonatal B-cell dysfunction in vitro.[364] In contrast to adult B cells, neonatal B cells cannot respond to polysaccharides without help from T cells.

ANTIBODY

Maternal IgG accounts for most of the newborn's circulating immunoglobulin because almost none is made by the healthy fetus, and IgG is the only isotype of maternal immunoglobulin that crosses the placenta.[333,384] Maternal transport of IgG can be detected by 8 weeks' gestation, and the newborn's IgG level is directly proportional to gestational age, reaching 100 mg/dL by 17 to 20 weeks' gestation and 50 percent of the maternal level by 30 weeks' gestation (Fig. 2–11).[49,305] By term, the infant has 5 to 10 percent more IgG than the mother does because maternal antibody is transported not only passively but also actively via trophoblast Fc receptors. Trophoblast Fc receptors have higher affinity for IgG1 and IgG3 than for IgG2 and IgG4, and so more of those subclasses are transported from the mother.[199,358] Newborns may have higher proportions of IgG1 and IgG3 than IgG2 and IgG4 compared with adults, and term newborns' IgG1 levels may exceed maternal levels.

By approximately 2 months of chronologic age, the term infant has quantitative IgG that is of approximately half maternal and half infant origin. The physiologic nadir of IgG in all infants is approximately 3 to 4 months of age and ranges from less than 100 mg/dL in very-low-birth-weight preterm infants to about 400 mg/dL in term infants (Table 2–3; see Fig. 2–11).[49,559] Maternal IgG essentially is gone by the time the infant is approximately 12 months old, at which time infant levels are approximately 60

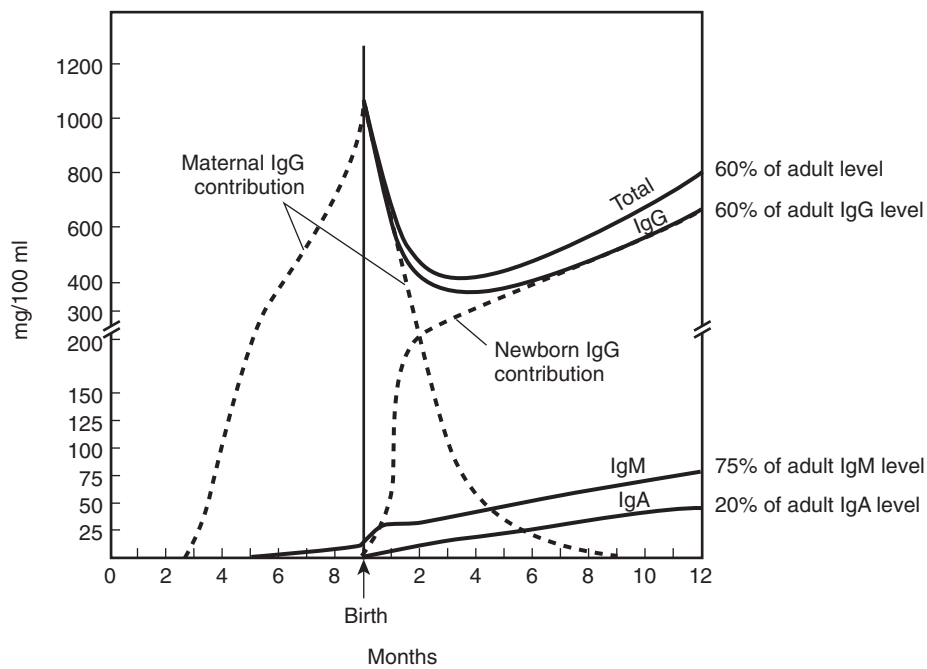

Figure 2–11 Immunoglobulin (IgG, IgM, and IgA) levels in the fetus and infant in the first year of life. The IgG of the fetus and newborn is solely of maternal origin. The maternal IgG disappears by the time the infant is 9 months of age, by which time endogenous synthesis of IgG by the infant is well established. The IgM and IgA of the neonate are synthesized entirely endogenously because maternal IgM and IgA do not cross the placenta. *(After Braun, J., and Stiehm, E. R.: The B-lymphocyte system.* In *Stiehm, E. R. [ed.]: Immunologic Disorders in Infants and Children. 4th ed. Philadelphia, W. B. Saunders, 1996, p. 67.)*

TABLE 2–3 Levels of Immunoglobulins in Sera of Normal Subjects, by Age

Age (mo)	IgG (mg/dL)	IgG (mg/dL)	IgG (mg/dL)	Total Immunoglobulin (mg/dL)
Newborn	1031 ± 200*	11 ± 5	2 ± 3	1044 ± 201
1-3	430 ± 119	30 ± 11	21 ± 13	481 ± 127
4-6	427 ± 186	43 ± 17	28 ± 18	498 ± 204
7-12	661 ± 219	54 ± 23	37 ± 18	752 ± 242
13-14	762 ± 209	58 ± 23	50 ± 24	870 ± 258
25-36	892 ± 183	61 ± 19	71 ± 37	1024 ± 205

**Values were derived from measurements made in 296 children and 30 adults. Levels were determined by the radial diffusion plate method using specific rabbit antisera to human immunoglobulins. Values are ± 1 SD.*

Modified from Stiehm, E. R., and Fudenberg, H. H.: Serum levels of immune globulins in health and disease: A survey. Pediatrics 37:715-727, 1966. Copyright American Academy of Pediatrics, 1966.

percent of adult levels. Production of IgG1 and IgG3 matures more rapidly than that of IgG2 and IgG4, reaching adult levels by the time the child is approximately 8 years old versus 10 and 12 years of age for IgG2 and IgG4.[437]

The fetus normally produces little IgM, IgA, IgE, or IgD, and none is transported from the mother.[285] The presence of IgM levels greater than 20 mg/dL at birth suggests an intrauterine infection. Serum IgA levels at birth in preterm and term infants usually are less than 5 mg/dL and consist of IgA1 and IgA2. Secretory IgA is not detectable until after birth, but it usually is present within the first few weeks of life. IgM and IgA reach approximately 60 percent and 20 percent of adult levels by the time the infant reaches 1 year of age (see Fig. 2–11). Secretory IgA reaches adult levels by the time the child is 6 to 8 years old.[364]

The IgG transferred from the mother to the fetus has been shown to protect the newborn from many infectious agents, including viruses such as varicella, polio, measles, mumps, and rubella, and bacteria such as tetanus, diphtheria, *H. influenzae* type b, and group B streptococcus.[146,147] The infant is not protected by the mother, however, if she does not have specific IgG antibody, even if she is immune to a given organism. The mother may have low or absent levels of circulating IgG antibody but good memory B cells capable of mounting a booster response. In this case, the mother is protected, but she cannot transfer protection to her infant. Similarly, because no IgM is transferred to the fetus, the mother cannot protect her newborn effectively against many gram-negative enteric organisms, even if she is immune.[148,403]

The concept of passive transfer of protective IgG is being used to develop vaccines for maternal immunization before or during pregnancy so that passive transfer of vaccine-induced antibody would result in protection during the neonatal period. Examples of organisms for which such strategies have been investigated include group B streptococcus, *H. influenzae* type b, meningococcus, pneumococcus, rotavirus, and respiratory syncytial virus.[48,203,297]

Researchers have documented that the fetus can respond to antigenic stimulation in the form of maternal immunization with tetanus toxoid vaccine and be primed for a secondary antibody response to repeat immunization after birth.[242,243] Some fetuses near term also can make IgM and IgA antibody to organisms such as toxoplasmosis, rubella, cytomegalovirus, or herpes.[201,422] The amount of fetal antibody produced in response to intrauterine antigenic stimulation is proportional to gestational age.[171,557]

Maternal antibody inhibits the infant's ability to respond to vaccines against certain organisms, such as measles, but it does not prevent the infant from mounting protective immune responses to most normal childhood vaccine antigens, such as tetanus, diphtheria, polio, hepatitis B, and protein-conjugated polysaccharide vaccines.[14] Generally, neonates have protective responses to T cell–dependent antigens, although they may produce less antibody to some antigens than do older infants and adults.[13,164,174,218,540,541]

The newborn's response to T cell–independent type 1 (TI-1) antigens is slightly decreased and to TI-2 antigens is poor.[246] The antibody response to most TI-2 antigens, including the polysaccharide capsules of group B streptococcus, pneumococcus, and *H. influenzae* type b, is not mature until the infant is 18 to 24 months old, although infants 3 months of age can respond to group A meningococcal polysaccharide.[538] In contrast, in the first few weeks of life, infants mount excellent antibody responses to T cell–independent polysaccharide antigens that have been rendered T cell–dependent by covalent conjugation of the polysaccharide to a protein carrier.[7]

A proposal is that immunologic tolerance may be induced in infants by early exposure to some antigens. The subject is controversial, but some data suggest that immunization to pertussis in the newborn period results in lower levels of antibody to subsequent doses of vaccine than does initially immunizing the infant at 1 month of age.[47,52] No evidence indicates, however, that tolerance is induced by administration of tetanus, diphtheria, or oral polio vaccines in the newborn period.[174,518]

The response of premature infants to most routine childhood vaccines, including diphtheria, tetanus, pertussis, and oral and inactivated polio, is comparable to that of 2-month-old term infants.[8,68,122,541] That premature infants do not respond as well to hepatitis B vaccine is well documented; the reasons are unclear.[201,352]

The data are conflicting, but small-for-gestational-age infants may have lower total levels of IgG at birth than those of normal-weight newborns,[199,531,627] possibly because of placental insufficiency. Their response to most routine vaccines is good, but it may be slightly decreased to inactivated polio vaccine.[128]

Complement

Complement proteins do not cross the placenta, but studies of mothers with congenital complement component deficiencies, studies of mother-infant pairs discordant for variants of individual components, and studies of fetal tissues have provided evidence for fetal synthesis of complement beginning as early as 5½ weeks' gestation. Most complement proteins are present by 10 weeks' gestation.[144,333] Levels of complement activity and of individual complement components vary significantly among infants, but generally classical pathway hemolytic activity of term neonates ranges from 50 to 80 percent of maternal values (Table 2–4). Because serum complement levels are elevated during pregnancy, term neonates' levels are approximately 60 to 90 percent of normal adult values.[197,307,628] Alternative pathway hemolytic activity is decreased more consistently than classical pathway activity, and ranges from approximately 50 to 70 percent of normal adult values at term (see Table 2–4).[6,193,434,531] Complement activity usually is lower in premature infants than

TABLE 2–4 Summary of Published Complement Levels in Neonates

	Mean Percentage of Adult Levels	
Complement Component	***Term Neonate***	***Preterm Neonate***

**Number of studies.*

Data from Lewis, D. B., and Wilson, C. B.: Developmental immunology and role of host defenses in neonatal susceptibility to infection. In *Remington, J. S., and Klein, J. O. (eds.): Infectious Diseases of the Fetus and Newborn Infant. 4th ed. Philadelphia, Pa, W. B. Saunders, 1995, p. 65.*

in term infants, with hemolytic activity of both pathways and serum levels of most complement proteins usually corresponding directly with gestational age.[193] Small-for-gestational-age infants have complement levels comparable to levels of infants of the same gestational age who are not small for gestational age.[434,531]

Hemolytic activity of the classical and the alternative pathways increases rapidly and reaches adult levels by the time the infant is 3 to 6 months old (classical pathway) and approximately 6 to 18 months old (alternative pathway). In addition to hemolytic activity, complement-mediated opsonic and bactericidal activity is decreased in newborn sera and generally correlates with C3 and factor B levels.[197] Studies of opsonic and bactericidal activity of newborn sera have been reviewed in detail elsewhere.[197,307,308] Levels of individual complement proteins do not correlate always with their functional activity.[238,291] Zach and Hostetter[628] reported not only that total C3 levels were decreased as measured by enzyme-linked immunosorbent assay, but also that C3 thioester reactivity was decreased, and that it correlated with gestational age. Because the opsonic function of C3 is mediated by its thioester, such a defect may contribute to the newborn's deficiency in functional complement activity. Although complement levels and activity are decreased significantly in most newborns, these abnormalities are mild compared with the abnormalities seen in hereditary complement deficiencies, in which levels of an individual component often are nil. Despite studies in vitro that suggest increased risk of development of infection, the extent to which lower neonatal complement levels predispose the infant to infection in vivo is uncertain.

Phagocytes

The newborn exhibits quantitative and qualitative deficits in phagocytic defenses. Although the number of circulating PMNs usually does not differ greatly from those in older children and adults, under conditions of stress, including systemic infection, the availability of marrow reserves of PMNs is impaired markedly.[131] The ratio of marrow neutrophil reserves to circulating cells in older individuals is nearly 15:1, whereas this ratio in newborns is 2:1 to 3:1.[131,380] Neutropenia is more likely to develop during severe systemic infections in newborns than in older children and adults.[131] The resulting deficiency in PMNs available for delivery to infected sites under conditions of stress is a serious disadvantage for the neonate in containing bacterial and fungal infections. Distinct from this quantitative deficiency in marrow reserves of PMNs are functional impairments of PMNs, which also are important in understanding neonatal phagocytic defenses.

The most important and best-documented functional impairments of neonatal PMNs are related to defective adherence and chemotaxis.[4,5,25-28,339,390,400] Numerous specific structural, functional, and biochemical abnormalities have been documented, any or all of which may contribute to the overall impairment in adhesion and migration of these cells.[280] Impaired adhesion of neonatal PMNs to endothelial cells and other biologic substrates has been linked with deficiencies in the expression or function of the β_2 integrins Mac-1 (CD11b/CD18) and LFA-1 (CD11a/CD18).[4,28,99,312,390] Perhaps the best-documented of these deficiencies is the diminished level of surface expression of Mac-1 on activated neonatal PMNs, although expression on resting PMNs is similar to that of adults.[99,312] The deficiency in stimulated Mac-1 surface expression can be explained sufficiently by the observation that the total cell content of Mac-1 in PMNs from term neonates is only approximately 60 percent of that in adult PMNs.[4] The total PMN content of Mac-1 at the time of birth is related directly to gestational age, and PMNs from very early premature infants (<30 weeks' gestation) may contain less than 20 percent of the Mac-1 content of adult PMNs.[390] The PMN content of LFA-1, which is normal at term, seems to be reduced in infants born before 35 weeks' gestation.[390] In addition to reduced expression of these integrins, reduced adhesive function of the β_2 integrin molecules themselves at the surface of activated PMNs has been documented.[28]

Several other defects of neonatal PMNs that are likely to influence chemotaxis have been documented. They include defective redistribution of surface adhesion sites,[26] impaired uropod formation during stimulated shape change,[27] reduced cell deformability,[310] impaired microtubule assembly,[27] deficient F-actin polymerization,[262,506] reduced lactoferrin content and release,[25] reduced ability to effect membrane depolarization and intracellular calcium ion transients,[507] and impaired uptake of glucose during stimulation by chemoattractants.[5] The importance of each of these individual impairments to the overall deficiency in chemotaxis by neonatal PMNs has not been determined.

Evidence suggests that the number and binding efficiencies of receptors for chemoattractants, including C5a and synthetic bacterial peptides such as the formyl peptide N-f-met-leu-phe, are normal.[26,507,562] Phagocytosis and microbicidal activity of neonatal PMNs have been found in several studies to be similar to that of adult PMNs.[399,400] In some studies in which the assay conditions are designed to expose a potential defect in these functions (e.g., limiting concentrations of opsonins and high bacterial inocula), defects in phagocytosis and killing have been documented, however.[399,400] Whether these potential deficiencies play a role in impaired neonatal phagocyte defenses in vivo is unclear.

PRIMARY OR HERITABLE IMMUNOLOGIC DEFICIENCIES

Physicians who care for children often are faced with the problem of a child who has a predilection for recurrent infections. Most of these children are normal infants or toddlers who have been exposed to a succession of common respiratory infections when they entered daycare or a similar setting for the first time.[117] For most of these children, repeated exposure elicits relative immunity to many or most of the infectious agents. It is an important challenge for the physician to identify infants and children who do not fit into the normal pattern, but who are unusually susceptible to development of infection with respect to frequency, severity, type of causative agent, and response to appropriate

treatment. This challenge usually falls to the pediatrician or family physician because, with few exceptions, the primary immunodeficiencies manifest during infancy and early childhood.[149]

As suggested earlier, an infant or toddler who experiences six to eight presumed viral upper respiratory infections during the course of a winter season, without other complications, ordinarily would not be considered likely to have an immunodeficiency. In contrast, a child who has experienced five episodes of acute otitis media in the previous 4 months, several episodes accompanied by sinusitis or pneumonia, has displayed reasonable cause to suspect a humoral immunodeficiency.[149] For certain organisms, infection in the healthy host is so rare that even a single episode should prompt a high suspicion of impaired host defenses. *Pneumocystis jiroveci* pneumonia strongly suggests a severe defect of T-cell number or function.[149] Similarly, lymphadenitis or osteomyelitis caused by gram-negative enteric bacilli suggests a defect of phagocytic killing, such as CGD.[306,474] The following discussion of specific immunologic defects, their genetic basis, if known, and their infectious consequences focuses on well-characterized prototypic disorders within each class of defects, but addresses other related disorders.

Antibody Deficiencies

Humoral immunity is provided by antibody and plays an important role in host defense against most pathogens, as illustrated by the finding that patients with significant antibody deficiencies develop recurrent and sometimes life-threatening infections.[148,156,439] These patients particularly are prone to otitis media, sinusitis, bronchitis, pneumonia, sepsis, and meningitis. Antibodies participate in complement-dependent and complement-independent opsonization, bactericidal activity, virus and toxin neutralization, and the formation of immune complexes that can be cleared by the reticuloendothelial system.[134,270] The role of immunoglobulins globally and of distinct isotypes and subclasses in humoral immunity is elucidated by the nature of infections found in patients with the specific deficiencies addressed subsequently.

X-LINKED AGAMMAGLOBULINEMIA

X-linked agammaglobulinemia (XLA), first described by Bruton, is a primary immunodeficiency disorder of the B-cell lineage and is the most serious disorder of humoral immunity.[102,357,439,494] XLA is characterized by absent or severely decreased numbers of circulating B lymphocytes and absent or extremely low levels of all classes of circulating immunoglobulins. It is caused by several different mutations in the gene encoding for a B cell–specific tyrosine kinase, *Btk*, which maps to the long arm of the X chromosome at Xq22.[585,596] This abnormality in kinase activity results in an arrest in the development of B cells, usually at the pre-B cell stage, and few B cells or their progeny (e.g., plasma cells) are in the circulation or lymphoid tissues.[248]

Most individuals with XLA develop chronic or recurrent pyogenic bacterial sinopulmonary or gastrointestinal infections, and they may have recurrent skin infections.[102,357,439] Systemic disease, such as sepsis, and serious focal infections resulting from bacteremia, such as meningitis, osteomyelitis, and septic arthritis, do not occur as frequently as do respiratory and gastrointestinal infections, but they occur more commonly and are more severe than in normal hosts. The causative agents of most of these infections are *S. pneumoniae* and *H. influenzae*, but *S. aureus* and *Pseudomonas aeruginosa* and other gram-negative organisms may be implicated. The most troublesome gastrointestinal infections in XLA are caused by *Salmonella*, *Campylobacter*, and chronic infestation with *Giardia lamblia*. Although they have no increased susceptibility to most viruses, these patients have been found to have unusually severe or chronic enterovirus infections, which can be manifested by chronic meningoencephalitis, dermatomyositis, hepatitis, or a combination thereof, and several patients with XLA have developed vaccine-related paralytic poliomyelitis after receiving the live oral polio vaccine.[357]

The only abnormality on physical examination that is not related directly to infections is a paucity of normal B cell–containing lymphoid tissues, such as tonsils, adenoids, and peripheral lymph nodes.[439] Patients who are diagnosed and treated early in life have normal physical examination, growth, and development.

Older individuals with XLA have very low serum levels of IgG, IgM, IgA, and IgE. The diagnosis can be confirmed by studying lymphocyte markers.[439] These patients have a lack of circulating cells that stain for surface immunoglobulin or of B cell–specific monoclonal antibodies against CD19, CD20, or both. The number and function of T lymphocytes are normal in XLA. Establishing the diagnosis in the newborn period may be difficult because maternally derived immunoglobulin bestows normal IgG levels. If there are other reasons to suspect this diagnosis, such as a newborn boy with a documented family history, the diagnosis can be established by documenting a paucity of circulating B cells.

Advances in genetic techniques have enabled maternal carrier detection.[148] In contrast to carriers of some other X-linked genetic diseases, X chromosome inactivation is not random in carriers of XLA. Instead of the two populations of B cells in normal individuals, B lymphocytes of XLA carriers express only one population of B cells—those with the normal allele on the X chromosome—suggesting that B cells with the mutant allele are at a selective disadvantage and do not develop. Prenatal diagnosis is made by genetic studies of amniotic fluid cells or quantitation of fetal circulating B cells.

The prognosis for patients with XLA has improved markedly with earlier diagnosis, high-dose intravenous immunoglobulin (IVIG) therapy, and aggressive use of antibiotics.[439] Before the availability of IVIG, most patients who survived to the third decade of life had chronic lung disease from pulmonary infections and hearing loss from recurrent otitis media.[357]

IgG SUBCLASS DEFICIENCY

Individuals with IgG subclass deficiencies have levels of one or more IgG subclasses that are more than two standard deviations below normal for age, normal to slightly decreased total IgG, normal levels of other immunoglobulin isotypes, and, often, a poor antibody response to certain antigens.* Patients with IgG subclass deficiency who also have IgM and IgA deficiency may have another immunodeficiency disorder, such as common variable immunodeficiency (CVID).

Patients with individual or combined deficiencies of IgG1, IgG2, and IgG3 may be at increased risk for development of infection, particularly if the deficiency is associated with an abnormal antibody response to antigenic stimulation. The most common kinds of infections in patients with IgG subclass deficiency involve the upper respiratory tract. Ordinarily, these patients do not have life-threatening systemic infections.

Because this subclass accounts for approximately 60 percent of total IgG, deficiency of IgG1 is most likely to be associated with subnormal levels of total IgG, and it usually is associated with other subclass deficiencies.[18,19,521,527-529] IgG1-deficient individuals may have recurrent pulmonary infections that can lead to chronic lung disease. IgG2 deficiency usually is associated with normal total serum IgG levels and is more likely to be clinically significant if accompanied by IgG4 or IgA deficiency. Patients with IgG2 deficiency have poor antibody responses to polysac-

charide antigens but normal responses to protein antigens. Their infections are localized primarily to the respiratory tract, but some patients have had recurrent meningococcal meningitis or disseminated pneumococcal disease. IgG3 deficiency has been associated with low total levels of serum IgG and recurrent respiratory infections, which also may lead to chronic pulmonary disease.[437] IgG4 deficiency is difficult to diagnose because many normal individuals have low serum levels of IgG4, and most normal infants have no detectable IgG4.[437] IgG4 deficiency seems to be of clinical significance if it is associated with IgG2 and IgA deficiency.

The treatment for children with IgG subclass deficiency usually is individualized according to the frequency and severity of symptoms. Noninvasive infections usually can be treated successfully with appropriate antibiotics. Patients with more severe presentations may benefit from IVIG therapy, but patients who also are IgA-deficient should be followed closely for the formation of anti-IgA antibodies and treated only with IgA-depleted IVIG preparations.

HYPER-IgM SYNDROME

Immunoglobulin deficiency with increased IgM is characterized by low levels of IgG, IgA, and IgE but normal to increased levels of IgM in the circulation and normal numbers of circulating B cells.[433,437] The disorder is caused by an intrinsic T-cell abnormality that alters switching from IgM to other isotypes. The basis for the various genetic forms of this defect is in one of several possible defects that involve interactions between CD40 on B cells and CD40L on T cells. In normal individuals, CD40 on the surface of B cells interacts with CD40L on activated T cells to cause B-cell differentiation into memory B cells and switching from IgM to other isotypes. B cells from patients with hyper-IgM syndrome make only IgM antibody, and their B cells express only surface IgM and IgD. The originally described and most common form of the defect is X-linked recessive and results from a mutation in the gene encoding CD40L, a protein expressed transiently on activated T cells.[14,39] More recently described autosomal recessive forms of this disorder involve mutations either in CD40 itself[216] or in a CD40-activated RNA editing enzyme, activation-induced cytidine deaminase.[481] Other cells have surface CD40, and immunologic abnormalities such as the neutropenia and the increased incidence of infections caused by *Pneumocystis* and of malignancies in patients with the hyper-IgM syndrome also may be the result of impaired cell interactions via CD40.

Clinically, hyper-IgM syndrome is manifested by recurrent bacterial infections, especially of the respiratory tract, beginning after maternal immunoglobulin levels subside during the first few months of life.[433,437] Such individuals are susceptible to the same kinds of recurrent pyogenic infections that are associated with other immunoglobulin deficiencies and to infections with organisms more commonly encountered in patients with T-cell defects (e.g., *P. jiroveci*).[51] Some patients with this syndrome have recurrent diarrhea caused by *G. lamblia* and *Cryptosporidium* that is severe enough to require parenteral nutrition. Life-threatening peritonsillar and peritracheal soft tissue infections also have been observed. Approximately half of patients also have persistent or recurrent neutropenia. Patients with autoantibodies may have thrombocytopenia, hemolytic anemia, nephritis, hypothyroidism, or arthritis, as noted earlier.

Physical examination usually is normal except for the sequelae of infections and lymphoid hyperplasia, which probably is caused by constant antigenic stimulation. Arthritis and arthralgia may be the result of chronic infection or the production of autoantibodies. The diagnosis of X-linked hyper-IgM syndrome may be established by using immunofluoresence to document absent expression of CD40L on activated T cells or absent CD40 expression on B cells, or by showing a mutation in one of the genes encoding CD40, CD40L, or the enzyme activation-induced cytidine deaminase.

IVIG treatment of patients with hyper-IgM syndrome usually results in marked clinical improvement.[51] Patients who have neutropenia with granulocyte colony-stimulating factor (G-CSF) and patients with arthritis or other autoimmune symptoms may need to be treated with steroids. Patients with hyper-IgM syndrome usually do not do as well as patients with XLA because, in addition to their immunoglobulin deficiency, they have an increased incidence of neutropenia, autoimmune disease, and malignancy.

IgA DEFICIENCY

IgA deficiency is the most common immunodeficiency, occurring with a frequency of 1:400. Most of the functions of serum IgA can be performed by IgG and IgM.[156,437] Although deficiencies of secretory IgA may lead to recurrent respiratory or gastrointestinal tract infections, deficiency of serum IgA usually is not associated with increased susceptibility to systemic infections.[24] IgA deficiency has been associated with many other conditions, including recurrent infections, IgG2 deficiency, a family history of immunodeficiency (e.g., relatives with CVID), autoimmune disorders, and malignancy.[23] Recurrent infections are most likely to occur in the subset of IgA-deficient patients who also have IgG2 deficiency.[156,450]

Infections usually are mild and involve the upper respiratory and gastrointestinal tracts. Chronic gastrointestinal disease can be caused by *G. lamblia* infections, nodular lymphoid hyperplasia, lactose intolerance, malabsorption, ulcerative colitis, regional enteritis, or autoimmune disorders (e.g., chronic hepatitis, cirrhosis, pernicious anemia). Approximately 20 percent of IgA-deficient patients have allergies, and many have elevated levels of IgE.[156] Food allergy is a common finding and may be the result of abnormal processing of antigen at mucosal surfaces. Other autoimmune diseases that are associated with IgA deficiency include rheumatoid arthritis, systemic lupus erythematosus, thyroiditis, transfusion reactions, pulmonary hemosiderosis, myasthenia gravis, and vitiligo.[156] IgA deficiency seems to occur sporadically, but familial cases have been described.[24,156]

Serum IgA levels less than 5 mg/dL can be clinically significant because patients with levels this low who receive transfusions may make antibody against donor IgA and have severe reactions when transfused again.[517] Reactions to IVIG also may occur because IVIG preparations contain varying amounts of IgA. IgA-depleted preparations are available and usually are well tolerated.

IgE DEFICIENCY

The clinical significance of selective IgE deficiency is unclear because it has been described in healthy individuals. Some patients with profound antibody and cellular immunodeficiencies lack serum IgE, but several partial cellular immunodeficiency syndromes are characterized by elevated levels of IgE (e.g., DiGeorge syndrome, Wiskott-Aldrich syndrome, Hodgkin disease).[437] The absence of IgE does not correlate with an enhanced susceptibility to infection in developed countries, but it has not been investigated in the developing world, where its role in immunity to parasites may be more important.

TRANSIENT HYPOGAMMAGLOBULINEMIA OF INFANCY

Hypogammaglobulinemia is a normal physiologic phenomenon occurring in all infants beginning about 3 to 4 months of age, when maternal antibody wanes and infant synthesis of immunoglobulin has not compensated yet.[437] The syndrome of transient hypogammaglobulinemia of infancy can be differentiated from physiologic hypogammaglobulinemia by the fact that immuno-

globulin levels of normal infants begin to increase by the time they are approximately 6 months old, whereas the immunoglobulin levels of infants with transient hypogammaglobulinemia of infancy do not begin to increase until they are 18 to 36 months old.[437] Infants suspected to have this syndrome should be evaluated for XLA and CVID (see later) and followed closely until their immunoglobulin levels normalize for age.

ANTIBODY DEFICIENCY WITH NORMAL OR ELEVATED LEVELS OF IMMUNOGLOBULINS

Some individuals with normal levels of all circulating immunoglobulin isotypes are at increased risk of acquiring infection.[18,20,437] The cause of this disorder remains poorly defined, but it may be related to an inability to respond to specific antigens or the induction of tolerance by exposure to certain antigens very early in development. The most common infections in these patients are recurrent sinopulmonary infections, although a few patients have developed pneumococcal sepsis.[20]

Such individuals can be identified by their inability to make antibody in response to stimulation with specific antigens. They do not have abnormal total serum immunoglobulin classes or subclasses or B-cell or T-cell quantity or function. They can respond to some, but not all, antigenic stimulation. It is important to test these individuals with a variety of stimuli. A good way to test for this syndrome is to immunize with protein antigens, such as tetanus and diphtheria toxoids, and with polysaccharide antigens, such as pneumococcal and *H. influenzae* type b capsular polysaccharide vaccines. Patients who can respond to protein but not to polysaccharide antigens usually respond to protein-polysaccharide conjugates. Treatment with IVIG may help prevent recurrent infections in these patients, although their normal overall levels of immunoglobulin could pose difficulties in determining the appropriate doses of IVIG and intervals between infusions.

Defects of Cell-Mediated Immunity: DiGeorge Syndrome

The prototypic pure T-cell defect, DiGeorge syndrome, is characterized clinically by congenital heart disease (usually involving the aortic arch), hypocalcemic tetany, unusual facial features, and recurrent infections.[182] In the classic or complete form of this disorder, there is absence or hypoplasia of the thymus and parathyroid glands, cardiac or aortic arch deformities, and a stereotypic constellation of abnormal facial features.[182,340,567] Although the condition usually is considered to be associated with immunodeficiency because of the thymic hypoplasia, only approximately 25 percent of patients actually exhibit an immunologic defect.[58] Although currently out of favor, the term *partial DiGeorge syndrome* has been used to describe patients with the typical anatomic findings, but without immunodeficiency, or with mild immunologic impairment.[286]

Some sources designate this disorder as an "anomaly" or "sequence," rather than a syndrome, because of confusion about its relationship to 22q11 deletion syndrome (del22q11) or to the more recently defined microdeletion, del22p11.2, a deletion also associated with velocardiofacial syndrome. Robin and Shprintzen[486] hold that the findings that comprise the DiGeorge "sequence," although often associated with del22q11.2, are etiologically heterogeneous and have been associated with other chromosomal deletions, such as del10p and del17p, or del10q13. Numerous individuals with del22p11.2 exhibit abnormalities distinct from those of the DiGeorge sequence.[253,254,286,348,462,486] This genetic and phenotypic heterogeneity should be considered when evaluating patients with the classic facial and cardiac findings that so often have been associated with a serious T-cell defect.

DiGeorge syndrome usually is recognized in the newborn period by the presence of unusual but characteristic facial features, hypocalcemic tetany in the first 2 days of life, or the presence of serious cardiovascular manifestations, most commonly associated with an interrupted aortic arch or truncus arteriosus.[286,371] Because of the serious nature of the cardiovascular defect, many patients with DiGeorge syndrome have not survived long enough for the immune defect to become a clinical problem.[286] However, with improvements in aggressive surgical treatment of the heart defects, more of these infants are surviving long enough to display manifestations of the immunodeficiency that results in an increased frequency and severity of viral and fungal infections and *Pneumocystis* pneumonia. In such patients, management often has included prophylaxis against *Pneumocystis*, periodic immunoglobulin infusions, and avoidance of live virus vaccines.[286] Transplantation of fetal or postnatal thymic tissue has corrected the immunologic problem for the long-term in approximately a third of such attempts.[247,286] More recently, HLA-matched bone marrow transplantation has been successful in some cases.[87,247,286]

Combined Defects of Cellular and Humoral Immunity

SEVERE COMBINED IMMUNODEFICIENCY DISEASE

SCID describes a heterogeneous group of heritable immunodeficiencies that involve serious impairments of cellular and humoral immunity with recurrent severe infections by a wide range of viral, bacterial, and fungal organisms. SCID has many different forms, which have been reviewed in greater detail elsewhere.[104,107,501] At this writing, there are at least 10 genes, abnormalities of which are known to result in SCID. X-linked SCID, the most common form of SCID, is caused by a mutation in the common gamma chain of the receptor for IL-2 and several other cytokines (γ_c).[104,361] The other known forms of SCID are either known or presumed to be autosomal recessive. They include a deficiency of adenosine deaminase (a purine salvage pathway enzyme), a deficiency in Janus kinase 3 (a cytokine receptor signaling molecule), and a defect in the alpha chain of the IL-7 receptor.[104,315] Mutation of one of at least six different genes whose products play a role in TCR or immunoglobulin gene recombination or TCR signaling, including RAG1, RAG2, Artemis, DNA ligase IV, CD3-delta, and CD3-epsilon, also results in SCID.[104,200,315,377] Additionally, SCID is caused by a mutation in CD45, a phosphatase that regulates signaling thresholds in immune cells.[315]

Long-term management of patients with SCID involves modalities employed in T-cell and B-cell disorders, including prophylaxis against pneumocystis pneumonia, avoidance of live viral vaccines, and immunoglobulin replacement therapy.[104] Bone marrow transplantation from HLA-matched siblings has corrected the defect in many cases and is considered the current treatment of choice.[106] Considerable effort has been expended toward development of gene therapy to treat SCID.[361] Adenosine deaminase deficiency is of historical interest in that it is the first heritable disorder for which gene therapy was attempted, although early success was limited.[79,106] More recent advances in retroviral gene therapy for X-linked SCID initially appeared to be successful. However, at least three patients have developed lymphoproliferative disorders similar to lymphocytic leukemia, with malignant cells showing insertion of the vector into the promoter or first intron of a proto-oncogene, LMO2.[83,107,124,220,472]

COMMON VARIABLE IMMUNODEFICIENCY

CVID is a heterogeneous group of combined immunodeficiencies that differ from most other primary immunodeficiencies in that they usually manifest in the second or third decade of life,

although they may manifest at any age.[155,157] Some sources indicate that CVID may be the most common symptomatic primary immunodeficiency. Patients with CVID have normal or only slightly decreased numbers of circulating B cells; low, but not absent, levels of IgG, IgM, and IgA; poor responsiveness to antigens; and abnormal T-lymphocyte function.[159]

Although T-cell and B-cell abnormalities often can be shown, the clinical presentation usually is comparable to that in patients with humoral or B-cell defects (i.e., recurrent bacterial otitis media and sinopulmonary infections).[155,271,494] Occasionally, in addition to having the organisms causing infections in patients with XLA, these patients also have infections with organisms found more commonly in individuals with T-lymphocyte abnormalities, such as *P. jiroveci*, *Mycoplasma pneumoniae*, recurrent herpes simplex virus, and herpes zoster virus infections. Chronic gastrointestinal problems may be caused by *G. lamblia* or other intestinal pathogens. Patients with CVID are prone to development of nodular lymphoid hyperplasia, autoimmune diseases, and malignancies. CVID occasionally has been reported to be familial, and it has been described in families with IgA deficiency. Several gene mutations that have been found more recently in patients with CVID include the genes encoding for CD19, TACI (transmembrane activator and CAML interactor), BAFF-R (receptor for B-cell activating factor of the TNF receptor family), and ICOS (inducible co-stimulatory molecule).[120,514,592]

Patients with CVID usually can benefit from therapy with IVIG, which reduces the incidence of acute infections. Most patients with CVID, even some who undergo long-term treatment with IVIG, develop chronic sinopulmonary disease.[157,449]

Defects of the Interferon-γ and Interleukin-12 Pathways

Macrophages infected by intracellular pathogens, especially mycobacteria or salmonellae, are stimulated via a TLR4-dependent mechanism to release IL-12, along with IL-18, IL-23, and IL-27. These cytokines stimulate T cells and NK cells to produce IFN-γ, via interactions with cellular receptors for the aforementioned cytokines. The released IFN stimulates the macrophage further to release more IL-12 and to activate killing. The mechanism by which this intracellular killing occurs is unknown. This cycle of mutual activation is essential for normal defense against mycobacterial pathogens, and numerous genetic defects of these cytokines, their cellular receptors, or related molecules crucial for receptor-mediated signaling have been associated with increased susceptibility to mycobacterial infections. Deficiencies in this system have resulted from mutations in either of the two receptors for IFN-γ, IFN-γR1 and IFN-γR2, and mutations in STAT1, a molecule crucial for transducing signals from both IFN-γ receptors. Mutations also have been described in the 40-kd subunit of IL-12, IL-12p40, and in the IL-12 receptor, IL-12Rb1. These disorders are uncommon, all involving fewer than 100 known patients.[498]

Mutation of either of the IFN-γ receptors is associated with increased risk of developing mycobacterial infections. Deficiencies of IFN-γR1 may be autosomal recessive or dominant and complete or partial. Most recessive defects are complete and result in absent IFN-γ responsiveness. Dominant IFN-γR1 deficiency is associated with mutations that result in heterozygous truncations of the cytoplasmic domain of the receptor with excessive accumulation of nonfunctional receptor at the cell surface, leading to reduced, but not absent, responsiveness to IFN-γ. Patients with the recessive complete form of this deficiency have a much more severe clinical phenotype than that of patients with the dominant partial form, although the latter have a fivefold greater frequency of nontuberculous mycobacterial osteomyelitis. Defects in IFN-γR2, much less common, also may be recessive or dominant in inheritance and complete or partial. Rare deficiencies in the receptor signaling molecule STAT1 have led to an increased number of mycobacterial infections in a partial deficiency or, in two patients with a recessive complete form, to post-vaccination disseminated bacille Calmette-Guérin disease followed later by death from severe viral infections. The latter probably relates to the additional role of STAT1 in development of IFN-α/β-mediated antiviral activity.[498]

Deficiencies of IL-12p40 or its receptor IL-12Rβ1 are associated with disseminated nontuberculous mycobacterial infections, tuberculosis, and *Salmonella* infections. The receptor deficiency results in unresponsiveness to IL-12. This defect apparently is autosomal recessive with variable clinical penetrance. Deficiency of IL-12p40 also varies in its clinical phenotype and has resulted in deaths caused by severe mycobacterial infections.[452,498,554]

Diagnosis of defects of the IFN-γ pathway usually first involves immunofluorescence flow cytometry to examine cells for deficient or abnormally excessive expression of IFN-γR1. If these studies are normal, studies of STAT1 phosphorylation in response to IFN-γ stimulation may reveal a defect in IFN-γR2 function or expression. For evaluation of the IL-12 pathway, IL-12p40 can be measured in cell supernatants with an enzyme immunoassay, and IL-12Rb1 expression function can be assessed with flow cytometry and, if necessary, by measuring STAT4 phosphorylation after stimulation with IL-12. These studies ordinarily should be done only in a highly specialized reference laboratory.[498]

Complement Deficiencies

Approximately 0.03 percent of the general population have complement deficiencies resulting from acquired or congenital abnormalities of single or multiple complement components or regulatory proteins. Excellent reviews of complement deficiencies are available elsewhere.[175,176,178,185,277,308,499,614]

The most common complement deficiencies are acquired and are transient. They include the relative complement deficiencies in infants (see earlier) and complement deficiencies that result from complement consumption in various inflammatory states, such as connective tissue disorders and acute or chronic infections.[175,176,178,308] Acquired complement deficiencies usually are associated with low levels of more than one complement component.[176] These deficiencies generally are incomplete and are of doubtful clinical significance in host defense against infection.

In contrast, congenital or hereditary deficiencies more often are manifested by abnormality or complete absence of a single complement protein. Deficiencies of individual components may have profound clinical implications because they have been well documented to predispose to acquiring life-threatening infections. Most primary complement abnormalities (C1q dysfunction and C1rs, C4, C2, C3, C5, C6, C7, C8, and C9 deficiencies) are inherited as autosomal co-dominant traits.[176]

Patients with homozygous or heterozygous deficiency of the early classical pathway proteins—C1, C2, and C4—are more prone to develop collagen vascular disease than infections, for reasons that are not fully understood. Approximately 20 percent of patients with homozygous deficiency of early components have problems, however, with recurrent or severe infections that are similar to those seen in C3 deficiency.[176,217,499] Ordinarily, these patients do not have as serious or as frequent problems with infections as do patients with alternative pathway deficiencies because they always can protect themselves via the alternative pathway whether or not they have specific antibody to the infecting organism. Their predilection to development of collagen vascular disease probably is due partly to abnormal solubilization and removal of immune complexes. Although cases of deficiency of one of the isotypes of C4 (C4B) have been reported to be

associated with increased susceptibility to infection caused by encapsulated organisms, subsequent studies have not confirmed this finding.[74,121] C2 deficiency has been associated with antibody deficiencies in individuals with recurrent infections.[17,119]

Deficiencies of alternative pathway proteins predispose to development of serious, often fatal, infections because of the lack of ability to respond promptly to organisms not previously encountered.[176] Although the classical pathway is intact, patients with alternative pathway deficiencies often die before they have the opportunity to make the specific antibody required for its activation. No homozygous factor B–deficient patients have been reported. Properdin deficiency, the only X-linked complement deficiency, has been associated with fulminant, usually fatal, meningococcal infection.[177] Factor D deficiency is rare and seems to predispose to recurrent neisserial infection.[330]

More recently, mutations or variants in the gene for MBL, the initiator of the MBL pathway (see earlier), have been associated with an increased risk of having recurrent infections.[185,277,563] In particular, homozygosity for such mutations or variants was found to be associated with an increased risk for developing systemic meningococcal disease.[223]

Because all three complement activation pathways converge at the activation of C3, patients who are deficient in C3 are unable to mobilize any of the three main effector functions of complement in host defense—opsonization, phagocyte recruitment, or bacteriolysis. One is not surprised that the most serious complement deficiency state is the total absence of C3.[176] Congenital C3 deficiency is rare and results from decreased production of C3.[217,499] Patients with deficiencies of factors H and I have low, but detectable, levels of C3 because absence of either of these regulatory factors allows continuous activation of the alternative pathway and uncontrolled C3 consumption. Patients with C3 deficiency caused by any of these mechanisms have increased susceptibility to infections caused by encapsulated bacteria, such as pneumococci, meningococci, and *H. influenzae* type b. Many of these infections involve the respiratory tract (otitis, sinusitis, bronchitis, and pneumonia), but C3-deficient patients also are predisposed to development of sepsis and meningitis.[176,217,499] In addition, some C3-deficient patients develop one of several different autoimmune diseases.[176,217,499]

Deficiencies of terminal complement proteins C5, C6, C7, and C8 greatly increase the risk of developing systemic infections caused by *N. meningitidis* or *Neisseria gonorrhoeae*.[76] Because C9 is not absolutely required for bacteriolysis—although it renders this process more efficient—C9 deficiency increases the risk of infection to a lesser degree than deficiencies of other terminal components. C9 deficiency was found to be present in approximately 0.1 percent of the population in Japan, and the risk of acquiring meningococcal disease was increased 5000-fold in C7-deficient patients and 700-fold in C9-deficient patients.[420]

The risk of developing infection is higher in patients with C5 deficiency than in patients with deficiencies of other terminal proteins because, in addition to the role of C5 in initiating assembly of the MAC, the free C5 fragment, C5a, is an important chemoattractant and is crucial for leukocyte recruitment to sites of microbial invasion and for bactericidal activity.[175] Although a rare patient with C5 deficiency had recurrent subcutaneous skin infections, as might characterize a disorder of chemotaxis, most patients with this disorder are at increased risk for acquiring meningococcal and disseminated gonococcal infections.

At least one episode of meningococcal disease occurs in approximately 60 percent of individuals who have been identified as having C5, C6, C7, C8, or properdin deficiency, and 75 to 85 percent of documented bacterial infections in complement-deficient patients are meningococcal.[176,217,499] Conversely, approximately 14 percent of patients presenting with sporadic meningococcal diseases may be expected to have a defect in one of the late complement components, and this percentage increases to approximately one third among individuals with two or more meningococcal infections.

Differences in the features of meningococcal disease between individuals with complement component deficiencies and normal hosts have been noted. First, meningococcal disease occurs in older individuals (mean age 17 years versus 3 years), and a higher proportion of disease is caused by groups Y, W135, and X in complement-deficient individuals than in normal individuals.[176] Additionally, the mortality rate in meningococcal infection is much lower than in normal individuals, probably because many patients with one of these deficiencies have developed antibodies to meningococci that can activate the classical pathway leading to normal opsonization and phagocyte activation, functions upstream in the cascade from the MAC. In contrast, individuals with normal complement levels who develop meningococcal infection usually do so because they do not have specific antibodies with which to activate the classical pathway, and meningococci are poor activators of the alternative pathway.

Currently, no specific treatment exists for patients with hereditary complement deficiencies. Replacement of missing complement proteins has been attempted with fresh-frozen plasma, but it is not practical because of the short half-life of most of the components.[55,351,502] Immunization of complement-deficient patients and their close household contacts against encapsulated organisms may reduce the risk of acquiring infections caused by these organisms.

Disorders of Phagocyte Function

GENERAL FEATURES OF PHAGOCYTE DISORDERS

The most frequent reminder of the importance of having an adequate supply of well-functioning phagocytes comes from patients who develop neutropenia after undergoing chemotherapy for malignancies. The high risk of developing bacterial and fungal infections in these patients mainly is the result of a lack of circulating neutrophils available for delivery to infected tissue.[467] The qualitative disorders of phagocyte function discussed in this section result in similar susceptibilities to these infections, either because the circulating cells are unable to migrate to an infected site or because, even having migrated to the infected tissue, they are unable to effect normal microbicidal activity. Some overlap exists among the types of infectious complications associated with disorders of migration versus killing. As a rule, defects of neutrophil migration tend to be associated with infections at skin and mucous membrane sites. In contrast, killing defects are more likely to result in infections of soft tissues and internal organs, although skin infections are common findings.

INTRINSIC DISORDERS OF CELL MIGRATION

Type 1 Leukocyte Adhesion Deficiency

In the late 1970s and the first half of the 1980s, several reports described patients with recurrent bacterial infections, diminished neutrophil motility, and delayed separation of the umbilical cord.[2,29-31,37,89,154,221,268] The neutrophils of these patients were discovered to be markedly deficient in adherence to natural and artificial surfaces, in response to complement-opsonized particles, and in expression of surface glycoproteins in the molecular weight range of 150 to 180 kd. The deficient glycoproteins were found to be members of a family of heterodimeric glycoproteins, LFA-1, Mac-1, and pl50,95, each defined by its own unique alpha subunit, CD11a, CD11b, and CD11c, respectively, but sharing a common 95-kd beta subunit designated CD18.[30,31,36,37,552] A fourth alpha subunit, CD11d, the importance of which remains poorly understood, has been described more recently.

These proteins, also called the β_2 leukocyte integrins, were identified as crucial determinants of adhesion-dependent func-

tions on neutrophils and other phagocytic cells, and their absence seemed to be directly responsible for the striking adherence-dependent defects that characterized the function of leukocytes from patients with this disorder.[29-31,36,37,552] Variously called Mac-1 deficiency, MO1 deficiency, LFA-1 deficiency, CD11/CD18 deficiency, or CR3 deficiency, this disorder, now usually termed *type 1 leukocyte adhesion deficiency* (LAD-1), is an autosomal recessive disorder with one of numerous mutations in the β_2 integrin subunit, CD18, localized to chromosome 21.[31,36,552,553] It has been identified in more than 150 individuals worldwide and has a broad ethnic diversity.[31,36] Patients may exhibit a moderate or severe phenotype, depending on the extent of the defect in protein expression.[30,31] The documented mutations of CD18 that result in LAD-1 have been diverse, leading to abnormalities ranging from complete absence of the protein to extensions of the molecule, truncations of the extracellular portion or of the cytoplasmic domain of the molecule, small deletions, and point mutations.[33,36,282]

Patients with LAD-1 develop recurrent necrotic skin and soft tissue infections with poor or absent formation of pus, and they exhibit poor wound healing.[30,31] They develop a severe generalized form of gingivitis or periodontitis, often losing most or all of their primary and secondary dentition along with some of their alveolar bone.[30,31] They also may develop enterocolitis similar to that seen in neutropenic patients.[30,31] Delayed separation of the umbilical cord, presumably caused by an impaired inflammatory response, is a common feature of the more severe phenotype of this disorder,[30,31] but this finding alone in infants without infectious complications or other characteristic features is of doubtful significance.[619] Pronounced leukocytosis is a common feature of LAD-1, even in the absence of active infection.[30,31] The reason for this feature is not completely understood. The fact that LAD-1 neutrophils are incapable of normal egress from the circulation via the oral cavity or lower intestinal tract was long thought to provide the principal explanation for the high circulating neutrophil counts. More recent studies in CD18-null LAD-1 mice reveal abnormally high circulating G-CSF levels, however, and suggest that a more likely explanation involves the absence of a negative feedback mechanism on production of G-CSF that occurs during normal transendothelial migration of leukocytes and involves IL-17. Absent ongoing transendothelial migration results in failure of this putative feedback mechanism, resulting in elevated G-CSF levels and higher circulating granulocyte counts.[225]

Functional studies of neutrophils from patients with LAD-1 reveal a marked impairment of adherence-dependent functions that require the β_2 integrins, including attachment to various surfaces, orientation in a chemotactic gradient, chemotaxis through nitrocellulose filters or under agarose gels, aggregation, phagocytosis of iC3b-opsonized particles, degranulation or activation of the oxidative metabolic burst in response to such particles, and recruitment of PMNs in vivo to Rebuck skin windows or dermal suction blisters.[29-31,111,232] In contrast, neutrophil functions that are independent of CD11/CD18-mediated interactions, including degranulation or oxidative burst activation in response to soluble stimuli or polarized shape change in suspension in response to chemoattractants, are normal.[29-31] PMNs and NK cells from patients with LAD-1 exhibit impaired ADCC for virus-infected target cells, suggesting that CD11/CD18-mediated cell-cell adhesion is essential for normal killing of virus-infected cells by this mechanism[331] and that the increased severity of viral infections in a few of the most severely affected patients could be related to defective ADCC. Currently, the specific diagnosis of LAD usually is made by showing absent or markedly deficient expression of the CD11/CD18 family of glycoproteins on circulating leukocytes by immunofluorescence flow cytometry, although various other methods have been used.[29-31,37]

Careful attention given to skin and oral hygiene, aggressive management of infections, and meticulous local care of wound sites are important in the care of patients with LAD-1 or any serious disorder of neutrophil migration. Prophylactic antibiotics, usually trimethoprim-sulfamethoxazole, have been used in many of these patients, but their efficacy has not been well established. Granulocyte transfusions have been used with some success to treat severe infections in a few patients with LAD-1.[31,89] Bone marrow transplantation with HLA-matched allogeneic marrow has led to missed results, ranging from complete correction of the phagocytic defect to death from graft-versus-host disease 9 months after transplantation.[31,221] The human CD18 gene has been cloned and sequenced, and human LAD-1 cells have been corrected successfully in vitro with the normal CD18 complementary DNA carried by retrovirus vectors, hinting at the future promise of gene therapy for patients with LAD-1.[31,32] The development of genetic knockout mice deficient in CD18 may provide a useful model for studying gene therapy in vivo and for helping to elucidate features of the underlying deficiency itself.[31,338]

Type 2 Leukocyte Adhesion Deficiency

In 1992, two unrelated patients were reported, both products of consanguineous matings, who exhibited clinical characteristics virtually identical to those described for LAD-1.[228] Expression of the β_2 (CD18) integrins on leukocytes was normal, however. In addition to defects in neutrophil motility, these children exhibited short stature, psychomotor retardation, and the Bombay (hh) erythrocyte phenotype (homozygous for absence of the H antigen). Phagocytosis by PMNs was normal.

This defect has been documented to be caused by one or more mutations of a specific guanosine diphosphate–fucose transporter,[375] resulting in the absence of fucosyl residues on sialyl Lewis X, the tetrasaccharide moiety that serves as an important ligand for members of the selectin family of adhesion molecules.[228,350,600] In vivo and in vitro studies comparing the adhesive functions of PMNs from LAD-1 and this new disorder, now called LAD-2, have provided elegant validation of the distinct roles of selectins and integrins in the recruitment of leukocytes in vivo, with the initial selectin-mediated "rolling" stage (deficient in LAD-2) required first for the second integrin-mediated "firm adhesion and extravasation" stage (deficient in LAD-1) to occur.[600] A deficiency in either mechanism results in defective delivery of PMNs to infected sites and is manifested clinically as a form of LAD. The other somatic and neurologic features of LAD-2 may be related to more widespread consequences of the generalized defect in fucosylation of glycoproteins.[375] Because of the generalized nature of this deficiency, a proposal has been made to designate this disorder *type IIc congenital disorder of glycosylation*.[375]

Type 3 Leukocyte Adhesion Deficiency (Integrin Activation Defect)

In recent years, at least four patients have been reported who have clinical phenotypes that include features of type 1 LAD and Glanzmann thrombasthenia, a bleeding disorder associated with mutations in the $\alpha IIb\beta 3$ integrin on platelets. Laboratory studies of these patients revealed markedly deficient integrin-mediated adhesive functions of leukocytes and platelets despite normal surface expression of leukocyte and platelet integrins. Further studies led to the conclusion that this defect in integrin function was the result of defective "inside-out" signaling pathways that normally lead to integrin activation.[205,325,389] Although the precise molecular defect in this disorder remains uncharacterized, cells from one patient with this disorder have been reported to exhibit deficient activation of a small guanosine triphosphatase, Rap1, an important regulator of inside-out integrin activation.[325] A growing consensus is that this defect of integrin activation be termed *type 3 leukocyte adhesion deficiency* (LAD-3), although this nomencla-

ture does not include reference to the defect in platelet function.[205,325]

Specific Granule Deficiency

Rare patients with hereditary specific granule deficiency have been reported, beginning with the original description by Spitznagel and colleagues in 1972.[90,231,550] These patients exhibited recurrent and severe infections, primarily of the skin and mucous membranes, sometimes involving the lung and, in one patient, the mastoid. Normal human neutrophils contain azurophilic (primary) granules and specific (secondary) granules, the contents of which have been summarized previously. Neutrophils from patients with this disorder exhibit bilobed nuclei and absent specific granules on Wright-stained blood smears. Lactoferrin released from specific granules reduces the negative surface charge of the plasma membrane, contributing to nonspecific adhesiveness of the cell.[231]

The specific granule membrane also contains some of the intracellular store of the important adhesion molecule Mac-1 (CD11b/CD18) that is mobilized to the plasma membrane on stimulation by chemoattractants or other stimuli that induce granule secretion.[63,85] Specific granule deficiency results in marked impairment of adhesion and migration of neutrophils, probably on the basis of diminished intracellular pools of adhesive proteins and the inability to effect the change in surface charge caused by lactoferrin. This impairment leads to the recurrent skin and mucous membrane infections caused by *S. aureus*, gram-negative bacilli, and *Candida* that characterize the natural history of patients with this disorder.[90,231,550] Neutrophils in this disorder also exhibit diminished microbicidal activity, presumably because of diminished amounts of the cytochrome b_{558} component of NADPH oxidase that are stored in the membrane of specific granules.

Although the disorder is probably too rare to make such generalizations, specific granule deficiency likely is autosomal recessive in its mode of inheritance because males and females are represented equally. The documentation of a specific granule deficiency phenotype in mice rendered genetically null for an important myeloid cell transcription factor known as *CCAAT/enhancer binding protein epsilon* (C/EBPε) has led to studies in a few patients with specific granule deficiency that confirmed a deletion in the C/EBPε gene, with absent expression of this transcription factor, although not all patients with this disorder have a mutation of this gene.[183,360] Specific granule deficiency may be diagnosed in a patient with recurrent skin and mucous membrane infections whose neutrophils exhibit the characteristic absence of specific granules on Wright stain and a marked impairment of chemotaxis in vivo and in vitro.

Chédiak-Higashi Syndrome

Chédiak-Higashi syndrome is a complex, rare autosomal recessive disorder characterized by partial oculocutaneous albinism, recurrent pyogenic infections, peripheral neuropathy, and neutropenia.[81] The illness also may involve an accelerated lymphoproliferative phase.[81] Granular cells, including neutrophils, contain giant lysosomal granules that are the apparent result of spontaneous intracellular fusion of azurophilic granules and, to a lesser extent, specific granules.[81] Corresponding disorders of intracellular pigment granules and vesicle trafficking in axons account for the albinism and other manifestations of this disease.[81] Similar disorders have been described in Aleutian mink, beige mice, albino Hereford cattle, and albino whales.[81] The genetic basis of the defect now is known to involve either a nonsense or a frameshift mutation in the gene encoding a large protein called the *lysosomal trafficking regulator*; homologous to the "beige" gene in mice, with all mutations studied so far resulting in a truncated protein.[54,125]

Patients with Chédiak-Higashi syndrome develop recurrent skin and mucosal infections, most often caused by *S. aureus*, which are characteristic of those observed in defects of phagocyte migration.[31,81] They have a consistent defect in cell migration that seems to be related to abnormal regulation of microtubule polymerization on stimulation by chemoattractant agents.[81] The possible role of intracellular levels of cyclic adenosine monophosphate (cAMP) and guanylic acid in this microtubule abnormality has been suggested,[93] but the relationship between cyclic nucleotides and the microtubule dysfunction in Chédiak-Higashi syndrome has not been established. Ascorbic acid has been shown in at least one study to normalize the elevated levels of cAMP and the number of microtubules present within the cell.[93] Studies of two brothers with Chédiak-Higashi syndrome showed abnormally increased tyrosinylation of the alpha subunit of tubulin.[81,423] Phagocytosis is normal, but killing of ingested bacteria is defective or delayed. The reason for this deficient or delayed killing is uncertain but may involve defective phagolysosomal fusion or abnormalities in levels of microbicidal defensins, which also are stored in primary granules.[235]

The diagnosis of Chédiak-Higashi syndrome usually is suspected clinically on the basis of partial oculocutaneous albinism and recurrent pyogenic infections. A Wright stain showing giant lysosomal granules and laboratory studies showing defective cell migration are confirmatory.

Neutrophil Actin Dysfunction

Filamentous actin constitutes the main contractile mechanism of neutrophils for migration and phagocytosis.[560] An extremely rare and apparently heterogeneous disorder, neutrophil actin dysfunction, has been characterized by recurrent skin infections caused by *S. aureus* and *Candida albicans*. Biopsy samples of infected skin lesions in one child showed necrotic tissue with a notable absence of neutrophils. In vivo and in vitro studies revealed severely impaired neutrophil chemotaxis and phagocytosis.[91] The capacity for polymerization of actin from cell extracts also was diminished markedly. PMNs from family members of this patient also were found to be variably deficient in the CD11/CD18 family of glycoproteins that are the basis of LAD-1.[547,548] The nature and significance of this association is uncertain.

Another infant reported to have recurrent skin and mucosal infections and defective neutrophil chemotaxis was found to have abnormally high levels of a 47-kd protein, now identified as *lymphocyte-specific protein–1*, which exhibits actin-binding activity.[138] More recently, a 12-year-old patient with recurrent infections, mental retardation, and abnormal neutrophil chemotaxis was reported to be heterozygous for a substitution of lysine for glutamic acid-364 in non-muscle β-actin.[435] This substitution lies in a region important for binding to profilin and other actin-regulatory molecules. This patient's neutrophils also exhibited reduced production of superoxide, suggesting a possible role for normal actin function in the assembly of the NADPH oxidase complex.

Glycogen Storage Disease Type 1B

Beaudet and colleagues[60] first reported the association of recurrent infection, neutropenia, and impaired neutrophil migration with glycogen storage disease (GSD) type 1B, a metabolic disorder characterized by defective microsomal transport of glucose-6-phosphate. In 1985, Ambruso and coworkers[21] reviewed the features of 21 patients with GSD type 1B, 15 of whom had frequent infections, especially of the skin and subcutaneous tissues. Osteomyelitis, pneumonitis, sinusitis, and septicemia also were reported. Seventeen of these 21 patients were found to have serum inhibitors of myeloid stem cell proliferation, which were presumed to account for their chronic neutropenia. Impaired neutrophil motility was found in 8 of 11 patients in whom this condition was evaluated. Assays of neutrophil microbicidal capacity generally were normal. A specific relationship between the

underlying metabolic defect in GSD type 1B and the mechanism of impaired cell motility has not been established. However, exogenous glucose is an important energy source for chemotaxis,[611] and the uptake of glucose by PMNs in response to chemoattractant stimulation is impaired in patients with GSD type 1B and in neonates, both examples of patients with impaired PMN migration.[5,56]

EXTRINSIC OR SECONDARY DEFECTS OF POLYMORPHONUCLEAR LEUKOCYTE MIGRATION

Defective Neutrophil Chemotaxis Associated with Serum Inhibitors of Cell Function

Many investigators have reported the presence of inhibitors of PMN chemotaxis in the serum of patients with recurrent infection.[337,415,535,546,590,609] In most cases, the pathophysiologic mechanisms of these inhibitors are unknown. In many of the patients described, other associated immunologic disorders could account for at least part of the increased susceptibility to infection. In each case, the patient's neutrophils exhibited diminished chemotaxis in the presence of autologous serum or plasma, whereas identical assays in the presence of control serum or plasma resulted in a normal chemotactic response. Most such inhibitors seem to be immunoglobulins or immunoglobulin-like molecules.

Hyper-IgE Syndrome

In 1966, Davis and colleagues[169] described two young girls with coarse facial features, reddish hair, fair skin, severe eczema, dystrophic nails, staphylococcal skin abscesses, and recurrent sinopulmonary infections. The absence of classic signs of inflammation accompanying the staphylococcal abscesses led to their being characterized as cold abscesses. The term *Job syndrome* was suggested, referring to the similar biblical affliction. Additional patients, including a patient who exhibited a defect in neutrophil chemotaxis reported in 1973 by Clark and associates,[137] were described with a similar disorder, first associated by Buckley and colleagues[109] with very high serum IgE levels.

Subsequent reports of similar patients have shown that certain features are common to all patients with the disease, now called *hyper-IgE syndrome*. These consistent features include a history of staphylococcal infections of the skin and sinopulmonary tract beginning in infancy or early childhood and serum levels of IgE that are greater that 2000 IU/mL.[105,109,188] Other characteristic, but variable, features of this disorder include coarse facies, cold abscesses of the skin and subcutaneous tissues, a chronic eczematoid rash, eosinophilia, and mucocutaneous candidiasis.[105,188] Comprehensive reviews have provided detailed characterizations of the abnormalities of patients with this poorly understood disorder.[105,188] Consistent abnormalities of cell-mediated immune functions in patients with hyper-IgE syndrome suggest that the pathogenic basis involves a defect of T-cell regulation.[239] Documented abnormalities include diminished reactivity to *Candida* and tetanus toxoid in delayed hypersensitivity skin testing, decreased in vitro lymphocyte proliferative responses to these antigens, and reduced numbers of T cells with the CD45RO memory T-cell phenotype.[108,132,188]

A more recent extensive study of 30 patients with hyper-IgE syndrome and 70 of their relatives concluded that this disorder is inherited as a single-locus autosomal dominant trait with variable expressivity.[256] Although the specific gene defect or defects responsible for this disorder remain unknown, a study of 19 kindreds has revealed a genetic locus for hyper-IgE syndrome on chromosome 4, in the proximal 4q region.[257,258] More recently, a novel autosomal recessive form of hyper-IgE syndrome has been described that includes some patients who have developed severe viral infections or a form of autoimmune vasculitis involving the central nervous system.[83,257]

Although hyper-IgE syndrome more properly may belong in discussions of defective T-cell regulation, some patients with hyper-IgE syndrome may have a defect in neutrophil chemotaxis.[188] The defect, if observed at all, usually is intermittent. In several cases, the presence of a serum inhibitor of chemotaxis has been recognized.[188] Donabedian and Gallin[187] showed an inhibitor of granulocyte chemotaxis in supernatants from cultured peripheral blood monocytes from patients with hyper-IgE syndrome. The persistence of infectious complications in this disorder, at times when chemotaxis has been found to be normal and the presence of large purulent collections within cold abscesses, raises questions about the significance of a chemotactic disorder in explaining the markedly increased susceptibility of these patients to recurrent infections.

Impaired Generation of Serum-Derived Chemotaxins

A deficiency in the host's ability to produce chemotaxins derived from serum components may have profound consequences for the recruitment of PMNs to an infected site. The most important serum-derived chemotaxin is the fragment of the fifth component of complement, C5a, and its des-arg form. Several kindreds have been described with either absent or defective C5.[495] The chemoattractant activity measured in activated normal serum virtually is absent in C5-deficient serum.[496] The risk of developing systemic *Neisseria* infections owing to deficient activation of the lytic terminal complement sequence seems far more significant than any phagocytic recruitment defect caused by impaired production of chemotaxins.[62,217] Patients with C3 deficiency also have impaired chemotaxigenesis because C5 cannot be activated. Host impairment usually is more severe because of the importance of C3 in opsonization and its role in the activation of the remainder of the complement cascade.[499]

OTHER SECONDARY OR POORLY DEFINED DISORDERS OF POLYMORPHONUCLEAR LEUKOCYTE MIGRATION

Patients with protein-calorie malnutrition have defective PMN chemotaxis that seems to be based on systemic pre-activation of circulating cells owing to chronic low-level endotoxemia that results from impaired intestinal mucosal integrity.[128,512] Shwachman-Diamond syndrome, is associated with defective PMN migration in addition to pancreatic insufficiency, neutropenia, and growth retardation.[11] Two kindreds with congenital ichthyosis and an associated defect of PMN migration have been described.[402] Patients with severe thermal injuries develop an acquired form of specific granule deficiency with impaired PMN migration beginning approximately 14 days after injury.[231] Children with juvenile periodontitis of various types may exhibit reduced PMN chemotaxis.[437] In some of these patients, this condition has been associated with gingival infections caused by *Capnocytophaga*, an anaerobic gram-negative organism that can elaborate factors that markedly impair PMN migration in vitro.[532] In one such patient, the ultimate diagnosis was LAD-1, a finding that raises some uncertainty about the role of *Capnocytophaga* in such disorders.[282] Several reports have been published of a poorly defined disorder of neutrophil migration termed *lazy leukocyte syndrome*,[10,401] which is characterized by recurrent staphylococcal skin infections, rhinitis, gingivitis, stomatitis, neutropenia despite adequate marrow precursors, and diminished in vivo and in vitro migration of neutrophils.

DEFECTS IN PHAGOCYTE MICROBICIDAL ACTIVITY

As described earlier, the broad array of available phagocyte microbicidal mechanisms may be divided into oxygen-dependent and oxygen-independent mechanisms. To date, no isolated deficiency of a specific oxygen-independent microbicidal mechanism has been described. This section is concerned mainly with the

known deficiencies of oxygen-dependent microbicidal mechanisms of phagocytes, especially CGD, the prototypic defect in this group. PMN migration usually is normal in these killing defects. Monocytes and the fixed phagocytes of the reticuloendothelial system generally share in the deficient microbicidal activity.

Chronic Granulomatous Disease

CGD was one of the earliest syndromes of phagocyte dysfunction to be characterized[474] and probably is the most extensively studied among individual phagocyte defects. It is recognized now to be a family of biochemically and genetically heterogeneous disorders of distinct components of the phagocyte NADPH oxidase complex.[87,128,183] CGD results in the inability of phagocytes to generate superoxide anion and other reactive oxygen species.[183] Organisms that produce catalase pose a special problem for patients with CGD[183,189,306,355] and encompass a broad range of pathogens that includes staphylococci, gram-negative enteric bacteria, *Pseudomonas* spp., yeast, fungi, *Nocardia* spp., and numerous other pathogenic species.[189,306,355,622]

Most microorganisms produce H_2O_2, which might be used, even by the CGD phagocyte, as an effective microbicidal weapon because it feeds into the sequence of oxidant reactions downstream from the defective oxidase enzyme (see Fig. 2–5).[492] Organisms that produce catalase are able to survive within these deficient cells because catalase is an enzyme that degrades H_2O_2 to oxygen and water.[306,492] Infections with catalase-negative bacteria, such as *S. pneumoniae*, *H. influenzae*, and *N. meningitidis*, do not occur with increased frequency in patients with CGD,[622] and these organisms are killed normally in vitro by CGD phagocytes. Phagocyte functions not related directly to oxidative mechanisms of intracellular killing, including adherence, chemotaxis, phagocytosis, and degranulation, usually are normal in patients with CGD.[44,405,474,544]

The genetic defect in CGD may be inherited by X-linked recessive or autosomal recessive mechanisms.[87,160] In the female obligate carriers of X-linked CGD, the proportion of cells that express the defect usually is 35 to 65 percent, depending on the proportion of cells in which random inactivation of the normal versus the affected X chromosome occurs.[376,622] In most of the autosomal recessive forms of CGD, the quantity of the cytochrome in cells is normal, but there is a deficiency in one of two cytosolic proteins, $p47^{phox}$ and $p67^{phox}$, each of which is a crucial component of the fully assembled NADPH oxidase complex.[42,87,136] In the report of a recently created registry of 368 patients with CGD in the United States,[622] greater than two thirds of the patients had the X-linked recessive form with absent $gp91^{phox}$, the larger subunit of the cytochrome b_{558}; approximately 12 percent had an autosomal recessive form with absent $p47^{phox}$; and fewer than 5 percent each had autosomal recessive disease with absence of the $p67^{phox}$ or absence of $p22^{phox}$, the smaller subunit of the cytochrome b_{558}. Approximately 12 percent had an unknown genetic form of the disease.

A more recent review[276] indicates that approximately 5 percent of patients with CGD have normal levels of an abnormal protein that is inactive and that at least 410 different mutations have been reported to result in CGD. These genetically diverse defects all result in defective function of the oxidase and the characteristic CGD phenotype. Included in the above-mentioned registry were two rare adult women whose sons had X-linked disease and who exhibited clinical signs of the CGD phenotype because of dramatically skewed X-chromosome inactivation with 5 percent or less of their phagocytes showing oxidase activity. Overall, patients with X-linked disease have more severe courses and experience higher yearly death rates than do patients with autosomal recessive forms of the disease.[622]

Patients with CGD experience recurrent serious bacterial and fungal infections, usually beginning in the first few months of life. *S. aureus* and gram-negative bacilli, especially *Serratia* and *Burkholderia cepacia*, are the most common causes of infection in patients with CGD, but fungi, especially *Aspergillus* spp., also are prominent etiologic agents.[355,479,622] Infections caused by *Aspergillus* are the most common cause of death in patients with CGD.[622] Lymphadenopathy associated with lymphadenitis and chronic suppuration with poor healing is a common presenting feature of CGD. Granuloma formation at infected sites is a histologic hallmark of this disorder.[306,479] Pulmonary infections and their complications have been the reported cause of death in 50 percent of patients with CGD in some series, and *Aspergillus* predominates.[622]

These infections often are protracted and respond slowly to appropriate antibiotic therapy.[306,479] Progression to lung abscess, empyema, or both occurs in approximately 20 percent of patients with CGD and pneumonia.[306] Liver abscesses occur in approximately half of patients with CGD and may be recurrent.[62,133] The hepatosplenomegaly common in patients with CGD may result from these infections but probably is more likely to result from chronic infections at various sites with systemic lymphoid hyperplasia.[47,306] Osteomyelitis occurs in approximately one third of patients with CGD.[306,479,622] In contrast to normal children, in whom this infection usually involves the metaphyseal area of long bones, patients with CGD more often develop infections of the small bones of the hands and feet. In normal children, *S. aureus* is the most common etiologic agent, and this agent does cause a significant proportion of cases in CGD. However, gram-negative bacilli and *Aspergillus* seem to be the predominant etiologies, and other agents, including *Nocardia*, also may be important etiologic agents in CGD.[462,566,622] Skin infections in patients with CGD may include pyoderma, purulent dermatitis, and cutaneous or subcutaneous abscesses and often are preceded by a chronic eczematoid skin rash[479] but are less of a problem than in patients with leukocyte migration defects.

Although localized infections are the rule in patients with CGD, these patients also may develop septicemia.[306,479,622] The most common cause of septicemia in most series has been *Salmonella*, but other gram-negative enteric bacilli also have been prominent.[306,355] *S. aureus*, the most common etiologic agent of localized infections in CGD, is a proportionally less common cause of septicemia in these patients.[479,622] Other infections sometimes seen in patients with CGD include recurrent urinary tract infections in approximately 6 to 8 percent of patients; ocular infections with conjunctivitis, blepharitis, or both in approximately 20 percent of patients; and, rarely, chorioretinitis.[385,479]

Granuloma formation adjacent to hollow viscera in patients with CGD has been found to produce clinically significant obstruction. Reported examples of this problem include obstruction of the gastric outlet, esophagus, small intestine, and ureters.[22,129,189] This complication usually responds to treatment with corticosteroids.[129]

CGD should be suspected in patients with a history of recurrent indolent infections caused by catalase-positive organisms such as those described earlier, especially if granulomas are found in biopsy specimens of lymph nodes or other tissues. Confirmation of the diagnosis usually rests on the demonstration of an absent or nearly absent oxidative metabolic burst in the patient's phagocytes. This burst can be detected by the slide nitroblue tetrazolium test (Fig. 2–12) or by other measurements of oxidative burst activity, such as cytochrome reduction, lucigenin-enhanced or luminol-enhanced chemiluminescence, oxygen consumption, H_2O_2 production, and flow cytometry of cells loaded with oxidant-sensitive fluorescent dyes.[15,42,57,391,491,579] Prenatal diagnosis has been achieved by the use of the slide nitroblue tetrazolium test with blood from placental vessels obtained at fetoscopy.[425]

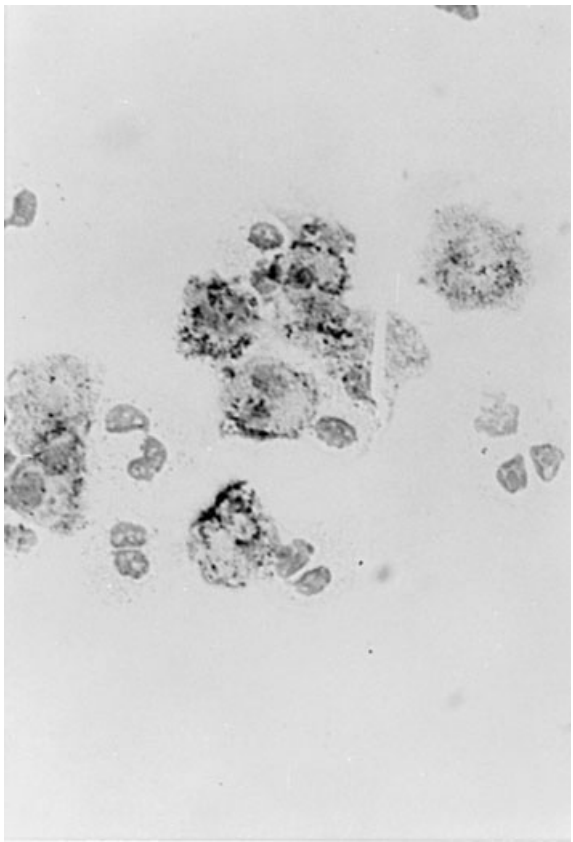

Figure 2–12 Photomicrograph of a slide nitroblue tetrazolium (NBT) test of polymorphonuclear leukocytes (PMNs) isolated from the blood of a maternal carrier of X-linked recessive chronic granulomatous disease. Because of random inactivation of either the normal or the affected X chromosome in maternal carriers of this disorder, approximately half of the PMNs exhibit the granular blue-black staining characteristic of the oxidative reduction of NBT by normal PMNs. In contrast, the remaining PMNs, which express the reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase defect of chronic granulomatous disease, are visible only by their nuclear counterstain.

The management of patients with CGD traditionally has relied on antibiotic prophylaxis, usually with trimethoprim-sulfamethoxazole or an oral antistaphylococcal penicillin, and an aggressive approach to the specific diagnosis and treatment of acute infections.[479] The use of antifungal prophylaxis with itraconazole or newer azole derivatives that also have activity against *Apergillus* has become standard in most centers. Granulocyte transfusions have been reported to be at least partially beneficial in a few cases.[112,142] Bone marrow transplantation met with limited success in the late 1970s and early 1980s, with only one successful long-term engraftment reported among four separate attempts in different patients.[251,316,477,615] Allogeneic peripheral blood stem cell transplantation from HLA-identical sibling donors, with prior myeloablative conditioning, has been considerably more promising, as suggested by the European experience from 1985 to 2000—22 of 23 patients "cured," with median follow-up of 12 years.[524] Longer term follow-up is necessary, however, to confirm the promise of this approach to treatment.

One of the most important developments in the treatment of patients with CGD is the administration of IFN-γ. A multicenter study initially showed that daily subcutaneous injections of this agent reduced the requirement for hospitalization of patients with CGD for serious infections by approximately two thirds.[298] IFN-γ does not increase oxidase activity in neutrophils, and the mechanism by which IFN-γ exerts its beneficial effect in CGD has not been determined. Long-term follow-up of patients being treated with IFN-γ has indicated that it continues to reduce the rate of serious infections over the course of many years and generally is well tolerated.[382] This treatment carries some mild systemic side effects, such as fever, fatigue, and myalgia,[298] but it has become part of the standard regimen for managing most patients with CGD.

The definition of the molecular basis for CGD and the cloning of the genes responsible for the various forms of this defect have led to correction of some forms of the defect in cultured cells and the development of animal models of CGD in mice,[183,301,469,599] both of which are crucial steps in developing gene therapy for patients with this disorder in the future. Preclinical studies of gene therapy in mice with CGD have shown promise when bone marrow cells are transduced using retroviral vectors ex vivo and transplanted into irradiated syngeneic recipients.[183] Fifty to eighty percent of circulating neutrophils were oxidase-positive 12 to 14 weeks post-transplantation, and protection from respiratory challenge with *Aspergillus* was achieved.[183] Early human phase I trials with autosomal recessive ($p47^{phox}$) and X-linked CGD, using autologous peripheral blood stem cells retrovirally transduced ex vivo and then re-infused without prior marrow conditioning, have yielded a maximum of 0.2 percent oxidase-corrected neutrophils in the circulation.[379] This accomplishment is still far short of what probably must be achieved to produce a clinically meaningful correction.[183]

Deficiencies of Glucose-6-Phosphate Dehydrogenase and Glutathione Peroxidase

The normal activity of the NADPH oxidase enzyme complex depends on the continued availability of NADPH to reduce molecular oxygen to form superoxide anion.[40,135,491] The primary source of NADPH for this enzyme is the hexose monophosphate shunt. It is provided with the hexose substrate, 6-phosphoglucose, by the enzyme glucose-6-phosphate dehydrogenase, which also generates NADPH in a coupled reaction.[492] The reactions of the hexose monophosphate shunt itself are coupled to two other enzymes, glutathione reductase and glutathione peroxidase, which recycle oxidized and reduced glutathione.[492]

The absence of any of these three enzymes results in a lack of available NADPH to drive the NADPH oxidase. Deficiencies in any of these other three enzymes may result in a phagocyte killing defect similar to that of CGD. Patients with deficiencies of glucose-6-phosphate dehydrogenase or glutathione peroxidase have been described with functional oxidative metabolic defects and presentations that are clinically indistinguishable from CGD caused by defects in the NADPH oxidase itself.[43,505] Glucose-6-phosphate dehydrogenase deficiency usually involves erythrocytes and is associated with hemolytic anemia, especially in conjunction with the administration of sulfonamides.[150] Only when the defect also involves myeloid cells and is severe or complete (<5 percent of normal enzyme levels) is the CGD-like disorder manifested.[43,505] A partial deficiency of glutathione reductase has been reported, with hemolytic anemia and early cataracts, but no increased incidence of infection was noted.[490]

Glutathione Synthetase Deficiency

Glutathione, along with glutathione peroxidase and glutathione reductase, the two enzymes involved in its recycling between oxidized and reduced forms, constitutes a protective mechanism in PMNs against membrane damage mediated by reactive oxygen intermediates formed during PMN activation.[490] The synthesis of an adequate supply of glutathione is crucial to these cells. Two brothers with glutathione synthetase deficiency who presented with neutropenia, hemolytic anemia, acidosis, 5-oxoprolinuria, and recurrent infection were reported by Spielberg and colleagues.[92,549] The PMNs from these patients exhibited elevated

cytosolic H_2O_2 levels, diminished oxidative microbicidal activity, and impaired microtubule assembly. Antioxidant therapy with vitamin E normalized the in vitro abnormalities of the patients' PMNs, and these patients had no further difficulty with recurrent infections.[92] This result suggested that vitamin E protected the cell membranes by scavenging excess H_2O_2 produced during PMN activation and prevented or minimized oxidant-induced membrane damage.

Myeloperoxidase Deficiency

Congenital deficiency of neutrophil MPO, previously thought to be a rare disorder, has come to be recognized as the most common heritable disorder of neutrophil function. Its clinical significance remains in doubt, however. Population surveys made possible with the advent of automated flow cytochemical techniques have indicated an incidence of MPO deficiency of approximately 1 in 2000 individuals.[424,460] Approximately half of these patients have complete absence of this neutrophil enzyme, and the remainder have a partial deficiency. The precise mode of inheritance of this defect has not been established, but MPO is known to be a product of a single gene on chromosome 17.[591] The reaction of MPO with H_2O_2 and chloride, causing the formation of hypochlorite, is one of the most effective microbicidal mechanisms of neutrophils, and cells from some patients with MPO deficiency have been found to exhibit delayed killing of *C. albicans* and *S. aureus*. MPO deficiency rarely has been associated with unusual infectious complications, however.

IMPORTANT EXAMPLES OF SECONDARY IMMUNODEFICIENCY (NOT INCLUDING HUMAN IMMUNODEFICIENCY VIRUS INFECTION)

Asplenia

Fulminant infections can occur in patients who have anatomic or functional asplenia.[512] The mortality rate from these infections in asplenic patients ranges from 40 to 80 percent.[621] The most common pathogens are encapsulated bacteria, including *S. pneumoniae* (50 to 70%), *H. influenzae*, and *N. meningitidis*.[621] Other streptococci, *S. aureus*, *Salmonella*, and other gram-negative bacilli are important but less common pathogens. All can cause fulminant, often fatal, disease characterized by rapid onset of shock. Malaria and babesiosis also are more severe in asplenic individuals. Infections can occur at any time but are most common within the first 2 years after patients undergo splenectomy.

The liver and the spleen are important in phagocytic clearance of bacteria from the circulation, and the spleen is an important site for antibody production. The spleen is more important than the liver in processing antigen in the naive host. The younger the individual is when splenic function is lost, the higher is the risk for developing serious infection. Young children who become asplenic are much more susceptible to fulminant infection than are adults because adults are more likely than are children to have encountered antigens before undergoing splenectomy. Individuals whose indication for splenectomy is thalassemia or Hodgkin disease are at higher risk of dying of overwhelming infection than are individuals who have functional asplenia from sickle-cell disease. Patients who undergo removal of their spleens for spherocytosis or idiopathic thrombocytopenia have a lower risk of developing infection. The lowest risk group consists of adults whose spleens are removed surgically after trauma, who are at little or no increased risk of developing infection.[147]

Congenital asplenia usually is associated with complex congenital cardiac disease and occasionally with structural abnormalities of the gastrointestinal or genitourinary tracts. Asplenia should be suspected in any patient with congenital heart disease and sepsis caused by encapsulated organisms. Anatomic or functional asplenia also should be suspected in patients with erythrocytes that contain Howell-Jolly bodies because these bodies are normally removed from the circulation by the normally functioning spleen. A radionuclide liver spleen scan or other modes of abdominal imaging usually can confirm asplenia or significant hyposplenia.[512]

Elective splenectomy for conditions such as hereditary spherocytosis should be delayed as long as possible, and splenic repair or subtotal splenectomy should be performed whenever possible after trauma. Asplenic patients are managed using prophylactic antibiotics, usually penicillin V or amoxicillin until at least 5 years of age.[147] They also should be immunized against encapsulated organisms at the appropriate ages (e.g., *H. influenzae* type b and pneumococcal conjugate vaccines beginning at 2 months and meningococcal polysaccharide vaccines at 2 years).[147] Patients should be warned about their increased risk of acquiring serious infections caused by malaria and babesiosis.

Sickle-Cell Disease

Immunodeficiency in patients with sickle-cell disease is due largely to their functional asplenia.[512] Part of the risk of developing infection stems from local infarction and tissue necrosis caused by sickling, which causes sludging and resultant tissue hypoxia. The reticuloendothelial system also may be obstructed by having to deal with chronic hemolysis. Patients with sickle-cell disease are protected partially from *Plasmodium falciparum* malaria but have a high incidence of fulminant sepsis and meningitis caused by encapsulated organisms (e.g., *S. pneumoniae*, *H. influenzae* type b, *N. meningitidis*) and *Salmonella*.[224] The relative risk of pneumococcal meningitis developing in children with sickle-cell disease is approximately 500 times that of normal children. *Salmonella* infections often are associated with osteomyelitis or meningitis.[202]

Patients with sickle-cell disease seem to have normal antibody response to most antigens, including age-appropriate responses to vaccines. A deficiency in heat-labile opsonic activity has been reported and may be due to a defect in the alternative pathway of complement. Rare cases of patients with sickle-cell disease who have deficiencies of factor B have been reported, but patients with sickle-cell disease have normal CH_{50} and normal levels of properdin, C3, and factor I.[308] Patients with sickle-cell disease should be managed with prophylactic antibiotics until they are at least 5 years old and should be immunized against *H. influenzae* type b, pneumococci, and meningococci at the appropriate ages.[147]

Cystic Fibrosis

Cystic fibrosis (CF) is an autosomal recessive disorder caused by mutations in both alleles of the gene encoding the protein called *cystic fibrosis transmembrane conductance regulator* (CFTR), a cAMP-regulated chloride channel expressed at the luminal surface of airway epithelial cells.[613] Most patients with CF develop chronic endobronchial infection with *P. aeruginosa* of the mucoid phenotype. This infection is accompanied by an intense chronic airway inflammation with an exuberant influx of neutrophils that leads to bronchiectasis and destruction and fibrosis of lung and airway tissue and early death.[130,334] No systemic disorder of immunity has been documented in CF, but local factors in the airway inflammatory milieu, including neutrophil-derived proteases such as elastase, contribute to secondary impairments in opsonic and phagocytic host defenses by cleaving opsonic antibody and complement fragments and important phagocytic receptors for these opsonins.[581]

Mucociliary clearance of bacteria from the CF airway is impaired because of viscous, dehydrated epithelial lining fluid, although the early pathogenesis of the unique chronic endobron-

chial infection in CF and its relationship to the underlying genetic defect have remained obscure. Several possible explanations have been offered. Researchers have suggested that CFTR on airway epithelial cells may function as a receptor for *Pseudomonas* that the cells normally use to internalize the organisms before being sloughed and cleared by mucociliary action and that this internalization may be deficient in CF epithelial cells.[466] Other evidence suggests that microbicidal peptides of or related to the defensin family, released from airway epithelial cells as a local defense mechanism, may be inactivated by abnormal salt concentrations at the airway epithelial surface, thwarting an important first line of local antibacterial defense.[539]

None of the aforementioned explanations has proved satisfactory. A reduction in cell surface sialic acid on CF epithelial cells unmasks the glycoprotein asialo-GM-1, which seems to function as an epithelial receptor for adhesion by *P. aeruginosa* and may promote early airway colonization.[508] More recently, investigators have proposed that reduced expression of inducible nitric oxide synthase by CF airway epithelial cells may impair airway host defenses against early small inocula of bacteria, but the unresolved question of the relationship between the CF genetic defect and *Pseudomonas* chronic lung infection continues to stimulate active research.[130]

EVALUATION FOR IMMUNODEFICIENCY IN A CHILD WITH RECURRENT OR SEVERE INFECTIONS

Most immunodeficiency disorders can be diagnosed readily by employing a methodical process that begins with careful analysis of the child's presenting history and physical examination.[149,156,178,285,439,512,515] This information serves as the foundation for a rational laboratory evaluation. It is important to bear in mind that it is normal for children to have several infections every year. Normal children who are exposed to other children, particularly older school-aged siblings or classmates, develop approximately one infection per month. Most infections in immunocompetent children are characterized by being mild and localized to the gastrointestinal or upper respiratory tracts, and they either are self-limited or respond rapidly to conventional therapy. Immunocompromised hosts tend to have more frequent, severe, and unusual infections that may not respond readily to appropriate therapy.

HISTORY

A detailed history alone is sufficient to determine whether or not an immunologic evaluation should be pursued in many children who have recurrent or severe infections. If tests for immunity are indicated, the history also serves as a guide to the types of studies that should be performed initially. Table 2–5 provides a list of historical information that is valuable in assessing the likelihood the patient has an immunodeficiency. Whenever possible, the child's complete medical records (including growth charts) should be obtained, particularly if several physicians have provided care, because the history often is complicated, and incomplete or inaccurate information may be misleading.

The age of onset of suspicious infections usually helps define the underlying problem. Children with isolated immunoglobulin deficiencies tend to do well during the first few months of life because they are protected by maternal antibody. They usually start developing serious infections later in the first year of life. Children with cell-mediated or phagocytic disorders may begin developing infections in the newborn period (see earlier). In contrast, healthy children who have been cared for at home by their mothers and who have no siblings often have few infections in the first few years of life but may present for immunologic evaluation when they develop recurrent respiratory infections beginning the first few weeks after entering daycare, preschool, or kindergarten, owing to new exposure to various respiratory viral pathogens.

TABLE 2–5 History in the Evaluation of a Child with Recurrent or Severe Infections

Age at onset of infections
Number, frequency, and periodicity of infections
Nature of infections
Location on body
Organism(s)
Severity
Duration
Nature and duration of therapy
Response to therapy
Hospitalizations
Surgery
Growth pattern
Periodontal disease
Allergies
Immunizations
Exposure history
Contagious diseases in family, school, or community
Number and ages of siblings
Parents' occupations
Babysitting or daycare arrangements
Foreign travel
Parental smoking
Wood furnaces
Family history (especially in males)
Immunodeficiency
Recurrent, severe, or unusual infections
Cause of early deaths
Autoimmune disease
Allergy
Consanguinity
Days of school missed (and why)

The number, nature, and severity of infections help in determining how aggressively to pursue an immunologic evaluation. Certain clinical presentations of disease and causative organisms are associated with a high likelihood of an immunodeficiency. Antibody or complement deficiencies, or functional asplenia, should be suspected in children with recurrent or life-threatening infections, such as sepsis and meningitis caused by encapsulated organisms (e.g., *S. pneumoniae*, *H. influenzae* type b).[102,178,308,357,439,493] Complement deficiencies should be considered in individuals with recurrent or severe neisserial disease.[175] CGD should be suspected in the presence of recurrent or unusual deep tissue infections, such as liver abscess, lymphadenopathy, pneumonia, or osteomyelitis, especially when caused by unusual gram-negative bacteria, such as *Serratia marcescens*, or by *Aspergillus* spp.[622] Pneumonia caused by *Pneumocystis* suggests a T-cell deficiency, either hereditary or due to HIV infection.

Recurrent or even severe infections with group A streptococci have not been associated with immunodeficiency. Recurrent urinary tract infections usually are associated with anatomic abnormalities of the urinary tract and not immunodeficiency.

An essential part of the history is documentation of the child's growth pattern. Children who are thriving, particularly those older than 2 years of age, are much less likely to have serious immune disorders than children with failure to thrive.

The immunization history should be documented carefully because it may prove to be useful in evaluating the child's ability to mount an antibody response to specific vaccine antigens. The

history of recent live viral immunization should be obtained in children who have clinical presentations compatible with polio or measles because infection caused by vaccine strains of these viruses is the first indication of immunodeficiency in some children.

Exposures to contagious diseases may lead to recurrent and occasionally even severe infections in individuals with normal host defenses. Children who never leave the house may have recurrent infections from organisms brought home by older siblings, other relatives, or neighbors. One must assume that children who attend daycare facilities or schools constantly are being exposed to common infections. Familiarity with community patterns of disease, such as prevalent clinical manifestations of enterovirus infection or the beginning of croup, respiratory syncytial virus, influenza, or rotavirus seasons, can be used to reassure families of normal children with frequent mild infections. Environmental pollutants, such as cigarette smoke and wood-burning stoves, also have been associated with an increased risk of acute lower respiratory illnesses developing in children.[485]

Because many immunodeficiencies are hereditary, a detailed family history should be obtained that includes questions about the presence of immunodeficiency, recurrent or severe infections, contributing factors to any early deaths, the gender of affected individuals, and consanguinity. A history of recurrent or severe infections in more than one male relative is highly suspicious of a familial immunodeficiency disorder. Autoimmune diseases may suggest a familial disorder of complement or cell-mediated immunity.[175]

A thorough history of school absenteeism and the reasons the child stays home may be helpful in differentiating medical from psychosocial problems in older children who present for evaluation for recurrent infections, particularly when symptoms are unusual or inconsistent with physical findings. Prolonged absences for vague problems with no physical findings, particularly in the presence of normal growth, are less likely to be caused by infections than are those characterized by well-defined physical or laboratory findings and poor growth. Generally, recurrent severe infections beginning before the child reaches age 1 year, failure to thrive, invasive disease caused by encapsulated or unusual organisms, or family histories of such infections should prompt consideration of an immunologic evaluation.

PHYSICAL EXAMINATION

Physical examination may provide valuable clues as to the nature of the immune disorder. In certain cases, such as some patients with hyper-IgE syndrome[105,281] and DiGeorge syndrome[182] who exhibit the characteristic facies, it may be diagnostic. As noted earlier, one of the most obvious signs that a child may have a serious underlying medical problem is failure to thrive. Every immunologic evaluation *must* include documentation of current growth parameters and a comparison with past growth.

Many immunodeficiency disorders have dermatologic manifestations. Eczematoid rashes are seen in patients with the hyper-IgE syndrome and CGD.[105,281] CGD also is characterized by slow wound healing and the development of hypertrophic scars.[622] Patients with Chédiak-Higashi syndrome have partial albinism.[81] Severe gingival disease and early loss of teeth are prominent clinical features in disorders of neutrophil migration, such as LAD.[30,31]

The chest should be evaluated for physical signs of active disease, such as rales and rhonchi, and evidence of chronic infection, such as an increased anterior-posterior diameter. Pneumonia, bronchitis, bronchiectasis, and scarring can occur with most immunodeficiencies but are associated most frequently with immunoglobulin deficiencies.[102,271,439] Cardiac abnormalities may be associated with primary asplenia or immunodeficiency disorders such as DiGeorge syndrome,[182] and situs inversus should alert the clinician to the possibility of ciliary dyskinesia.[149] Although hepatosplenomegaly may be found in many types of primary immunodeficiency disease, it occurs more frequently in patients with disorders of phagocyte function, especially CGD.[622]

LABORATORY STUDIES

The laboratory evaluation should be guided by the history and physical findings. Simple, inexpensive screening tests often can help narrow the differential diagnosis and streamline the evaluation. One of the first tests that should be performed is a complete blood count with differential and evaluation of the blood smear. This simple test can detect several immunologic abnormalities, including neutropenia, lymphopenia associated with HIV-1 or forms of SCID, the abnormal neutrophil granules associated with the Chédiak-Higashi syndrome, Howell-Jolly bodies found with asplenia, and some malignancies. Chest radiographs should be examined for thymic tissue, mediastinal lymphadenopathy, pneumonia, bronchiectasis, and other evidence of pulmonary infections. Consideration also should be given to evaluating patients with chronic pulmonary disease for CF with a sweat chloride test.

Quantitative immunoglobulin levels provide a useful screening test for evaluating patients with suspected humoral immunodeficiency. IgG2 deficiency often is not reflected in the IgG level, however, because it makes up such a relatively small proportion of total IgG. Patients with suspected humoral immunodeficiency usually should be tested for IgG subclasses and quantitative IgG, IgA, and IgM. Enumeration of B cells and marker studies by immunofluorescence flow cytometry should be considered if more severe forms of humoral deficiency, such as XLA or some forms of CVID, are suspected. Very high IgE levels may be helpful in establishing the diagnosis of hyper-IgE syndrome, although an elevated IgE level is much more common in patients with allergies than immunologic abnormalities. Immunoglobulin levels may be extremely elevated in children with HIV-1 infection.

Children who have normal quantitative immunoglobulin and IgG subclass levels but who continue to have frequent sinopulmonary infections that do not respond well to appropriate medical and surgical management (e.g., ventilation tubes) also can be evaluated by measuring antibody responses to specific antigens, such as tetanus and diphtheria toxoids and *H. influenzae* type b and meningococcal and pneumococcal capsular polysaccharides. Antibody levels can be measured before immunization and approximately 1 to 2 months after immunization is administered to evaluate the child's ability to respond to different kinds of antigens, including T cell–dependent antigens such as diphtheria and tetanus toxoid or T cell–independent antigens such as unconjugated pneumococcal capsular polysaccharide vaccine.

The complement system should be evaluated in individuals with recurrent or life-threatening neisserial disease, including systemic gonococcal infections and sporadic meningococcal disease. The best screening test for hemolytic complement is the CH_{50}. A normal CH_{50} reflects a normal quantity and function of classical pathway proteins (C1, C4, C2), C3, and terminal components through C8, as noted earlier.[143] The alternative pathway proteins can be measured in a similar assay employing rabbit erythrocytes instead of antibody-coated sheep cells. Alternative pathway deficiencies are extremely rare; demonstration of a normal CH_{50} generally is a sufficient indicator of normal complement activity. An abnormal CH_{50} should be repeated immediately, taking care that the specimen is handled correctly. Complement abnormalities may be quantitative or qualitative. If a very low CH_{50} is confirmed, determining the serum levels of

individual complement proteins and their functional activity in consultation with a reference laboratory is important.

Delayed hypersensitivity skin testing with antigens such as *Candida* or mumps antigens may be useful to assess cell-mediated immunity, but results are not always reliable. T-lymphocyte subset quantitation may be helpful in diagnosing such conditions as SCID and HIV, but more sophisticated testing of lymphocyte function, such as mitogen and antigen stimulation, should be done in patients with recurrent or severe fungal infection. These studies ideally should be directed by a clinical immunologist.

Similarly, suspected phagocyte function disorders should be evaluated in consultation with experts in phagocyte function because lack of proper standardization and expertise often leads to misleading results from commercial laboratories. Phagocyte function studies should be directed toward adherence and migration in patients with recurrent skin and mucosal infections, poor or absent formation of pus, and persistent leukocytosis suggestive of a leukocyte adhesion defect. Tests of oxidative metabolic activity and killing should be performed in patients with recurrent staphylococcal or unusual gram-negative or fungal tissue infections suggestive of CGD.

Whenever clinical suspicion of an inherited immunodeficiency is confirmed by appropriate functional laboratory studies, arranging for specific genetic testing to determine the precise nature of a patient's genetic mutation or variation, when such testing is available, may be desirable. This testing may assist greatly in subsequent genetic counseling and would add important information to the clinical database on patients with the specific disorder.

MANAGEMENT OF IMMUNODEFICIENCY DISORDERS

Proper management of immunodeficiency disorders (as described earlier) can enhance markedly the quality of life and life expectancy. Although some children with immunodeficiency disorders have serious problems with autoimmune disease, malignancy, or both, most morbidity and mortalities result from infections. This discussion is limited to the general principles of managing infectious complications of immunodeficiency.

EDUCATION

After the immunologic abnormality has been thoroughly characterized, the first step in management is to educate the family and, when he or she is old enough, the patient regarding environmental risks, how to take medications, and precisely when and where to seek medical care. Families of patients with inherited disorders should receive genetic counseling and be offered the option of prenatal screening if it is available for the disease in question.

EVALUATION FOR INFECTION

Patients with known immunodeficiency disorders should be evaluated promptly and thoroughly for unexplained fevers or any other indication of infection. Immunodeficient individuals are susceptible to a wide variety of pathogens, their responses to appropriate therapy may be slow, and they often require prolonged treatment. Every effort should be made to identify the infecting organism so that treatment can be specific. Unless the pathogen is known, extended courses of empiric broad-spectrum coverage may be required, which may lead to superinfection caused by multidrug-resistant pathogens.

TREATMENT OF INFECTIONS

Many aspects of disease-specific therapy already have been discussed. Generally, patients with immunodeficiency who are susceptible to bacterial infections should be treated empirically and aggressively with antibiotics at the first indication of infection. Antifungal therapy should be added empirically in patients with increased risk of developing fungal infection (e.g., patients with cell-mediated immune and neutrophil disorders) if a prompt response to antibacterial therapy does not occur. When a definitive etiology has been established, treatment should be tailored to the pathogen. The duration of therapy must be individualized, but generally patients with abnormal immune systems should be treated longer than normal hosts who have similar infections.

PREVENTION OF INFECTION

Patients and household members should be immunized with appropriate vaccines as soon as possible after a diagnosis of immunodeficiency has been established.[147] Although many immunodeficient patients, such as those with XLA, cannot respond to immunizations, immunization of household members and other close contacts with vaccines may reduce the patients' likelihood of developing infection. Patients with complement deficiencies, asplenia, and sickle-cell disease should be immunized with vaccines directed against encapsulated organisms, such as meningococci, pneumococci, and *H. influenzae* type b. These patients may not have normal responses to immunization, however, and, if possible, their antibody responses to these vaccines should be measured; if they are low, these patients should receive extra doses of the vaccines. Live viral vaccines should not be administered to patients with primary defects in cell-mediated immunity.

Patients with disorders characterized by recurrent or severe bacterial or fungal infections may require prophylactic antibacterial or antifungal therapy. The benefits of long-term antimicrobial therapy must be weighed carefully against the risks of rapid emergence of multidrug-resistant organisms.

PROSPECTS FOR CORRECTION OF SERIOUS PRIMARY IMMUNODEFICIENCIES

Bone marrow or stem cell transplants have been successful in a few patients with specific immunologic disorders, including SCID,[104,124] Wiskott-Aldrich syndrome,[453] LAD, and CGD.[31,221,615] Gene therapy has raised new possibilities for correcting certain immunologic defects, having shown early promise for some forms of SCID and early success in animal models of CGD.[183,472] The development of malignancies associated with retroviral gene therapy in some cases raises serious concerns about the ultimate feasibility of this approach,[107,472] but the means of overcoming these and other potential obstacles to gene therapy will continue to be sought.

CHAPTER 3

Metabolic Response of the Host to Infections

Alina Olteanu ✪ Ralph D. Feigin ✪ William R. Beisel

Although infectious microorganisms constitute a continuing threat at all ages of life, they are particularly dangerous in neonates, infants, and young children. Despite the availability of modern sanitation, public health measures, vaccines, and antibiotics, most children have many discrete episodes of acute infection before reaching adulthood. Depending on their severity and duration, infectious illnesses can interrupt normal growth patterns. More importantly, if closely spaced in time, a series of infections can initiate a downhill health spiral, leading to malnutrition, chronic debilitation, immune system dysfunction, and death.[12,14,86,87,129] This possibility is of greatest concern in newborns and weaning children, especially in Third World areas.

The human host normally protects itself against invading microorganisms by maintaining a broad array of general defensive mechanisms and immunologic responses. This array includes the initiation of acute-phase reactions triggered by the release of proinflammatory cytokines from macrophages, monocytes, and other cells.[7,12,14,42] The resulting nonspecific defensive measures typically include fever and anorexia, slow-wave sleep, accelerated production of phagocytic cells, hormonal responses, and participation of many biochemical pathways and molecular mechanisms within body cells.[7,8,10-12,14,170] The acute-phase reaction produces stereotyped patterns of transient metabolic sequelae (diagrammed in Fig. 3–1), which accompany and follow most acute, generalized infectious illnesses and some localized ones.[60] A pediatrician should anticipate these metabolic changes so as to recognize dangerous complications, such as hypoglycemia and electrolyte imbalance, that may occur during an acute infection.

The array of metabolic changes depicted in Figure 3–1 typically is shared as a group of common responses during all generalized acute infectious diseases.[6-9,12,13,141] Similar changes are seen during other types of disease or trauma when they are accompanied by fever or inflammatory reactions.[75] These common acute-phase responses are composed of a hypermetabolic admixture of anabolic and catabolic components. Each 1° C of fever causes basal cellular oxygen consumption to increase approximately 13 percent.[8] The resultant increase in cellular energy expenditure comes at a time when food intake and intestinal absorption are diminished by anorexia and sometimes by vomiting and diarrhea. In the absence of an adequate intake of nutrients, body energy needs are met mostly by the oxidation of metabolic substrates that are derived from nutrient stores already contained within body tissues. The hypermetabolic effects of acute fever are fueled primarily by carbohydrates (some of which are derived from the metabolism of amino acids),[8] but if infectious illnesses become subacute or chronic, body fats become the important sustaining fuel.

Generalized acute-phase metabolic responses may be modified by numerous factors, such as the severity of an infectious process, its duration, and its possible progression to a subacute or chronic disease.[7-12,14] The age and sex of the patient, the presence of genetic resistance (or susceptibility) factors or partial immunity, the adequacy of nonspecific defensive mechanisms and de novo immune responsiveness, the preexisting nutritional status, and the presence or absence of other diseases all combine to modify host metabolic responses through their diverse influences on the infectious process per se.

Superimposed on this general array of common host metabolic responses are additional metabolic changes that occur when an infectious process becomes localized within certain anatomic sites or organ systems. Diarrhea that develops during gastrointestinal infections can lead to depletion of fluids and electrolytes, hepatic infections can lead to derangements of carbohydrate and amino acid metabolism, and infections of the central nervous system that cause neuronal destruction are accompanied by muscle paralysis and atrophy. Other infections localized within the cranial vault often produce an inappropriate secretion of antidiuretic hormone, leading to development of dangerous overhydration in children.[14] The development of shock syndromes during infectious diseases imposes additional metabolic derangements because of progressive stagnant hypoxia.[10,135]

In recent years, the role of genetic variations in host genes important in the immune response to infections has been studied. Wide variations in individual response to several microorganisms, such as *Chlamydia trachomatis*[38] and *Candida albicans*, have been documented.[148]

The total number of discrete metabolic responses known to occur during acute and chronic infectious illnesses continues to expand.[10] The most widely recognized of these multiple responses are grouped for discussion into major categories, including changes in nitrogen, amino acid, carbohydrate, lipid, electrolyte, vitamin, and trace element metabolism. Another important mechanism involved in the host response to infection is oxidative stress, which plays a major role in the systemic inflammatory response in bacterial[153] and viral infections.[147] The important initiating and control mechanisms provided by cytokines, antioxidants, and the endocrine system also are discussed.

Importantly, each of the many individual metabolic changes that occur during the course of an infection must be interpreted in a manner that reflects its longitudinal development and progression over time and its relationship to the evolving phases of the infectious process.[7] Some metabolic changes may be detected during the incubation period, many other responses occur at the onset of fever, and still other phenomena develop during the recovery phase of illness or later during convalescence.

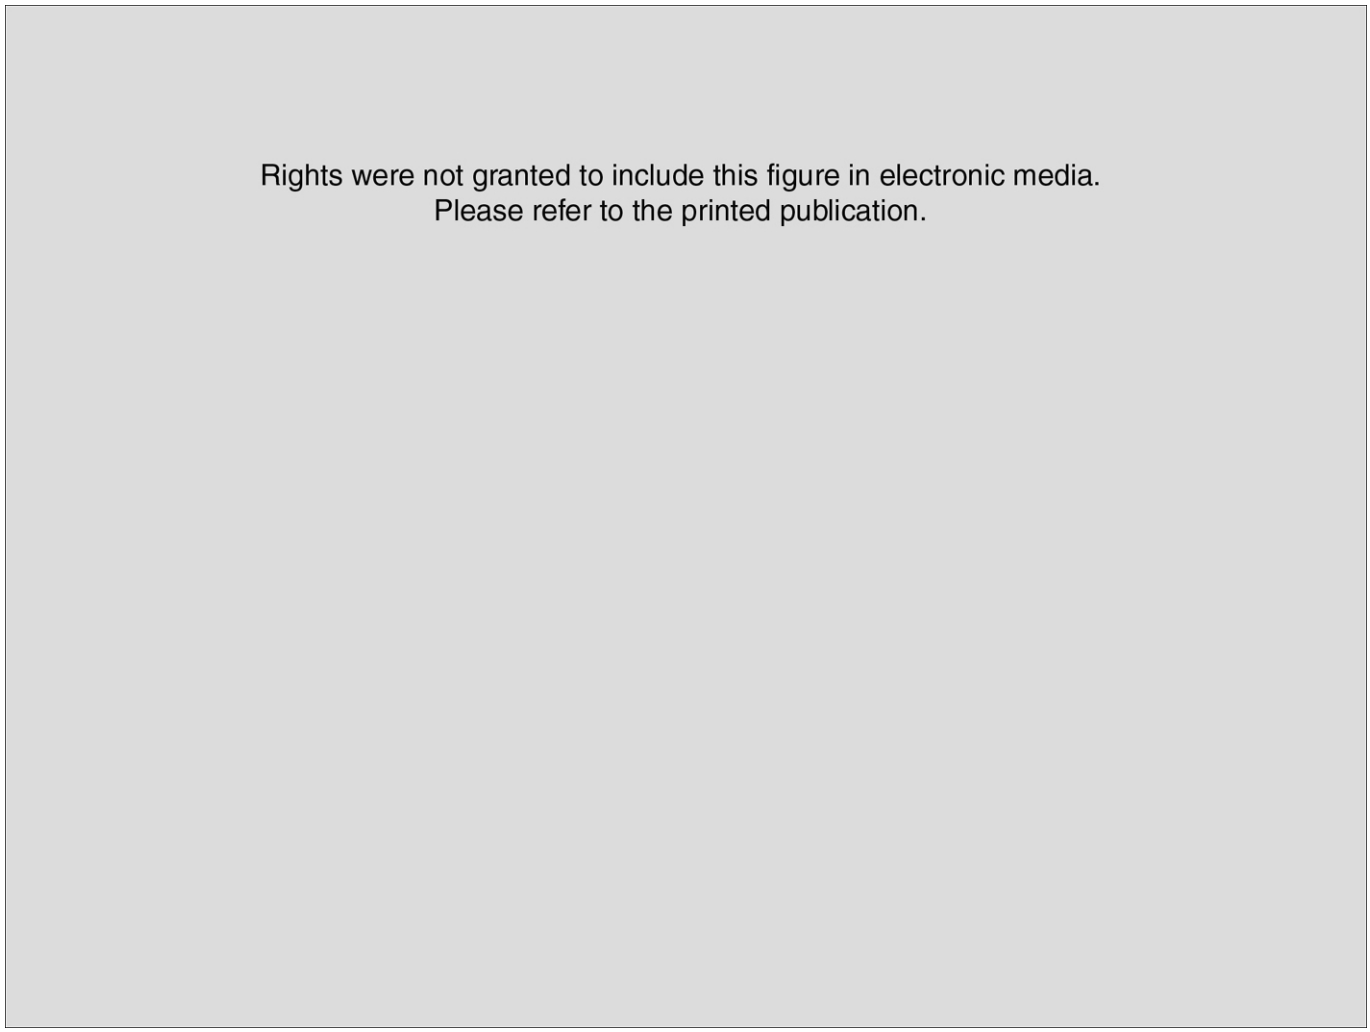

Figure 3–1 Onset time of various host metabolic responses in relation to the sequential phases of a "model" acute, self-limited, generalized infectious illness. *(From McKigney, J. I., and Munro, H. N. [eds.]: Nutrient Requirements in Adolescence. Cambridge, MA, MIT Press, 1976, p. 250.)*

NITROGEN METABOLISM

Fever and its accompanying hypermetabolic state, as induced by acute-phase responses during infectious illnesses, trigger a complex assortment of changes in protein, amino acid, and nitrogen metabolism.[9] Although the catabolic destruction of skeletal muscle protein is most obvious clinically, important anabolic events occur simultaneously. These events involve the synthesis of new proteins and cells that are important in host defense mechanisms. Increases in whole-body protein turnover involve catabolic and anabolic events in chronic infections also, as shown by leucine kinetic studies in patients with human immunodeficiency virus (HIV) infections.[82] Using amino acids isotope tracing techniques to measure muscle protein synthesis, researchers also showed that high plasma HIV RNA interferes with muscle amino acid synthesis and muscle proteolysis.[174]

NITROGEN BALANCE STUDIES

Because the ability of body cells to synthesize new proteins is a fundamental necessity for maintaining all known host defensive mechanisms, including the immunologic ones, understanding the changes that occur in the nitrogen metabolism of an infected individual is important.[110] When the availability of free amino acids within body pools is restricted by diet or disease, the catabolism of certain existing body proteins (chiefly the contractile proteins of skeletal muscle) generates the free amino acids required to synthesize new body proteins with higher priorities in terms of the many new proteins needed for defensive purposes. Information about these metabolic responses has been gained through quantitative analyses of proteins and other nitrogen-containing compounds in tissues, body fluids, and excretions, and through kinetic studies with tagged molecules.[82,99,107,122,158]

One useful approach has been the measurement of nitrogen balance throughout the sequential course of an infectious process.[9,10,110] Daily measurements of nitrogen intake and all nitrogen losses that occur via different routes are obtained to determine whether the body is losing or retaining nitrogen. Other investigative techniques are needed to provide specific information about the molecular mechanisms involved in producing any observed changes in nitrogen balance. Nonetheless, the use of balance techniques has provided information concerning the typical losses of body nitrogen and muscle mass during acute generalized infections (Fig. 3–2). Quantitation of these catabolic losses provides an important framework of reference for more detailed studies of changes in nitrogen metabolism.

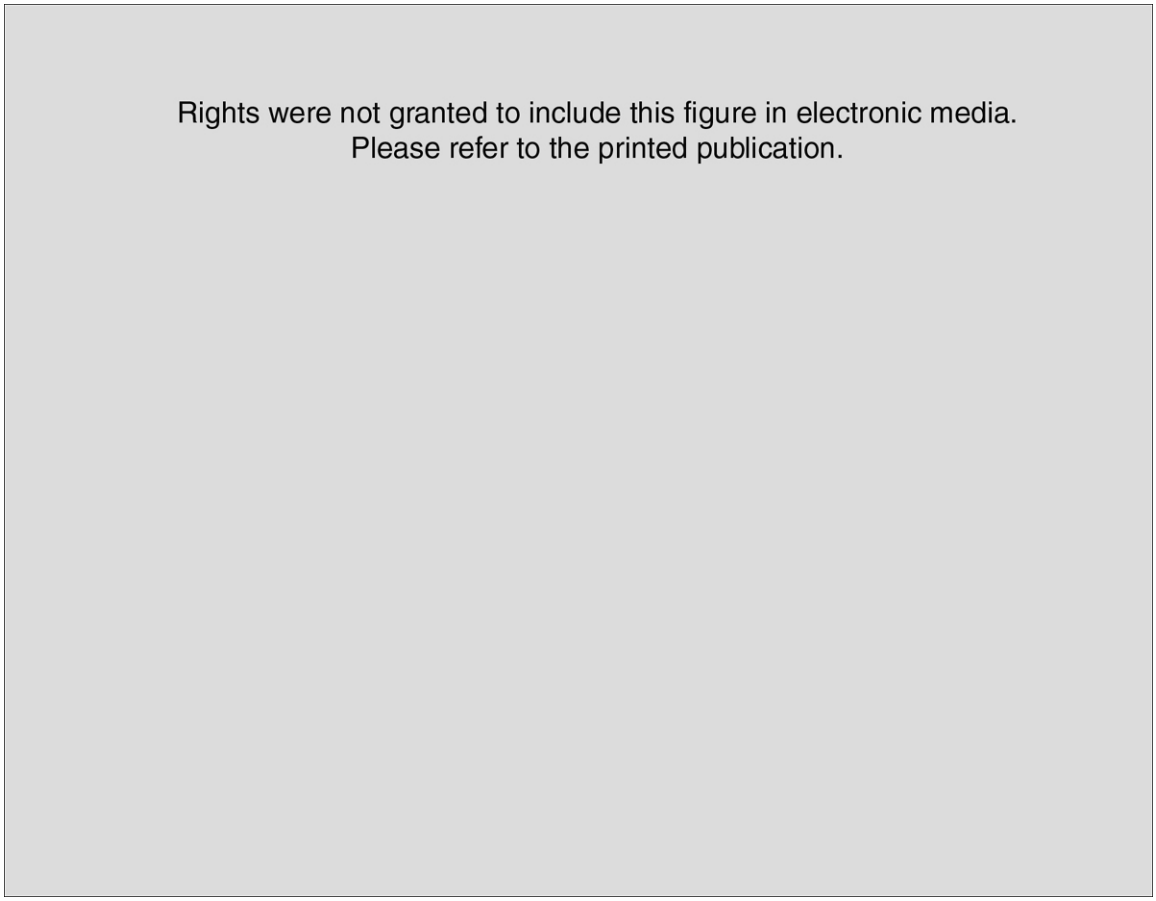

Figure 3–2 Comparisons between the occurrence of fever (top) and changes in daily nitrogen balance (middle) and cumulative nitrogen (bottom) in patients with viral, bacterial, and generalized parasitic infections. Cumulative balance values for pair-fed healthy control subjects show the amounts of body nitrogen loss that can be ascribed to diminished food intake during infection. *(From McKigney, J. I., and Munro, H. N. [eds.]: Nutrient Requirements in Adolescence. Cambridge, MA, MIT Press, 1976, p. 261.)*

A comprehensive series of nitrogen balance studies was obtained in young adult male volunteers subjected to different kinds of experimentally induced infections during the course of studies to test vaccine efficacy.[9] Extensive normal baseline data were obtained on each volunteer before the time of his or her inoculation with or exposure to infectious bacteria, viruses, or rickettsiae. Longitudinal serial measurements made throughout the course of the infectious process allowed for a comprehensive, prospective evaluation of metabolic balance changes in nitrogen and other elements to be obtained.[9]

Nitrogen balances did not change from baseline values during the incubation periods of the infectious diseases studied (see Fig. 3–2). The body began to lose nitrogen only after symptoms and fever had begun. These losses persisted for a period encompassing the acute illness. In convalescence, the subjects began to retain nitrogen so that gradually, over the course of several weeks, body nitrogen losses were regained. Similar nitrogen balance studies were conducted in healthy control volunteers who were not infected.[9,13,15] Instead, these controls were subjected to (1) partial food deprivation to mimic the anorexia-induced reduction in dietary intake measured in the patients with infection, (2) a 24-hour exposure to artificially induced high environmental temperatures to produce an increase in body temperature comparable to that seen in patients with infection, (3) treatment with antibiotic therapy in courses identical to those given to patients with infections, or (4) treatment with oral hydrocortisone using sequentially changing daily doses to mimic the measured adrenal responses of infected subjects.

These balance studies showed that the major losses in body nitrogen resulted from the combined effects of a reduced intake of food plus a continued (or increased) loss of nitrogen via the urine.[9] In contrast, simple starvation produced a prompt decrease in the daily losses of nitrogen via the urine. A patient with an acute infectious illness differed markedly from someone subjected to only simple dietary deprivation. Urinary nitrogen losses did not decline appreciably, or they increased in the presence of fever, whether the fever was caused by an active infection or an artificial increase in environmental temperatures.[15] The control studies also showed that the negative nitrogen balances that occurred during infection were not caused by adrenal glucocorticoid hormones or the antibiotics used in therapy.[7,13] Rather, by terminating infection quickly, antibiotics helped to reverse the loss of body nitrogen, allowing a more rapid restoration of nitrogen stores.

Because the loss of sizable quantities of nitrogen has important nutritional consequences, the same balance data were used to determine patterns of cumulative loss of body nitrogen.[7,9,10] As shown in Figure 3–2, total losses of body nitrogen grew progressively larger as the acute febrile phase of illness continued; the cumulative total loss of body nitrogen persisted throughout early convalescence. When nitrogen balances finally became positive, nitrogen was recovered over the course of weeks as body stores were accumulated slowly.

Studies performed in adult patients with infections such as tuberculosis and malaria suggested that the depletion of body stores of protein nitrogen did not continue unabated during sub-

acute or chronic infection.[67] Rather, a new state of relative nitrogen equilibrium became established as chronically ill patients lapsed into a cachectic state. Total body nitrogen in such chronically ill patients was neither gained nor lost. Vital body processes continued to function for extended periods, despite the presence of cachexia and markedly depleted body nitrogen stores.[8] This state was hazardous at best and was comparable to the threat faced by infants and children with severe protein-energy malnutrition, who constantly face the additional threat of developing dangerous new or superimposed infectious diseases.[86,87,104,129]

Only limited nitrogen balance data have been collected in children with acute febrile infections. These data tend to reflect closely the patterns of change described in adults, with one major exception. Adults normally are in a state of nitrogen equilibrium, with neither a net gain nor a net loss over time, whereas healthy infants and children are consistently in positive balance because they must retain nitrogen to meet their needs for normal growth.

Few prospective measurements are available to document the changes in nitrogen balance throughout an entire infectious process in children. In 1926, Beck[6] in Germany reported a series of metabolic balance studies conducted in healthy infants inoculated with vaccinia virus. One study was begun in a child exposed to varicella 15 days before the onset of pustules; another study was begun in an infant exposed to measles virus 14 days before the onset of clinical illness. The grouped nitrogen balance data from the vaccinated infants are shown in Figure 3–3. Despite the development of a short-lived fever in this mild infection, the infants maintained their usual food intake. The vaccinated infants did not go into negative nitrogen balance, and their rate of growth barely was slowed.[6] In measles or varicella, illness was of greater severity, and a transient period of negative nitrogen balance was recorded.

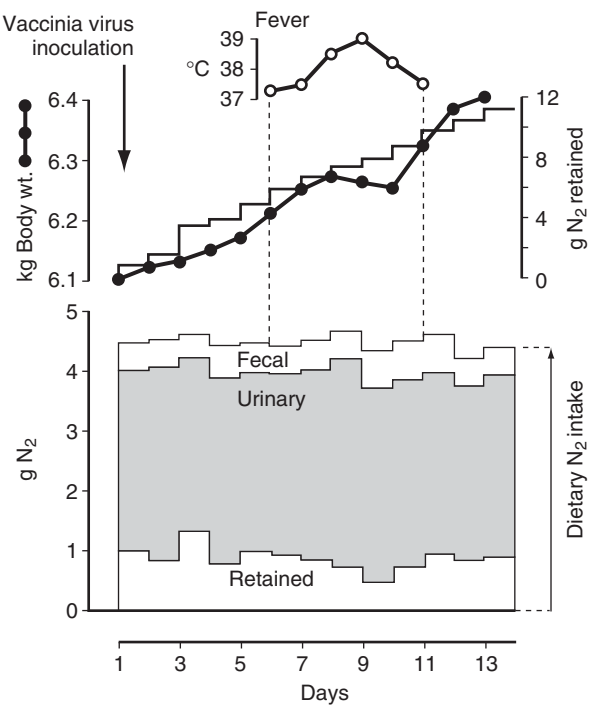

Figure 3–3 Sequential measurements of body weight and cumulative nitrogen balance (top) and daily nitrogen balance (bottom) in a group of five healthy infants inoculated with vaccinia virus. Nitrogen intake values (plotted upward from baseline) and fecal and urinary losses (plotted downward from intake) reveal that the growing infants continued to retain nitrogen despite having brief periods of fever. *(Drawn from numerical data published by Beck.[6])*

Similarly, Viteri and Behar[156] measured nitrogen balance during childhood infections or after administration of live vaccines. Nitrogen loss varied with the severity of the illness. Wilson and colleagues[172] reported changes in nitrogen balances in hospitalized children who were convalescing from kwashiorkor when they developed varicella. A reduction in nitrogen retention occurred, and some children developed negative balances. Despite efforts to maintain a constant dietary intake, the children consumed less food during the course of the infection.

Acute nondiarrheal infections typically do not cause an increased loss of fecal nitrogen; however, if diarrhea is present during an illness, fecal losses of nitrogen and other nutrients can occur.[104,126] Nitrogen losses also can occur through sweat, exudates, blood loss (from illness or from laboratory tests), sputum, gaseous exchanges, or sites of surgical drainage.[9,15]

The absolute loss of body nitrogen, as measured by metabolic balance techniques during infection, also can be used as a guide for estimating the absolute losses from the body of other intracellular elements, such as potassium, magnesium, phosphate, and, to a lesser degree, sulfur and zinc.[9,10] By using the ratios present in normal skeletal muscle of nitrogen to potassium and of nitrogen to magnesium, one can use measured losses of body nitrogen during infection to estimate concomitant losses of potassium and magnesium from the body. Similarly, a ratio of nitrogen to phosphorus in skeletal muscle can be used to estimate inorganic phosphate losses that occur during infection, provided that corrections are made first to account for any phosphate losses originating from demineralized bone. Calculations such as these suggest that the absolute losses of body nitrogen during infection are derived primarily from intracellular sources because they correlate in timing and magnitude with losses of the other principal intracellular elements.[9]

In contrast to infection-induced losses of intracellular elements, the losses of extracellular ions, sodium and chloride, follow an independent course during infection. Calcium losses are minimal in acute infection in the absence of long-term bed rest or paralysis with body immobilization.[9,168]

A newer method to measure total protein metabolism involves the use of a single oral dose of [^{15}N] glycine. This method was used to study children with septic shock as a result of meningococcemia and showed that the protein metabolism of these patients is increased significantly compared with healthy children.[41] A similar method was used previously in children with malaria, HIV, and measles.[41]

URINARY EXCRETION OF NITROGEN-CONTAINING COMPOUNDS

The onset of fever typically is accompanied by an increased urinary loss of creatinine. This loss usually is followed within 1 day by increased losses of urea and ammonia.[9] Although alpha-amino nitrogen losses may increase transiently at the onset of fever in some infections, this excretion tends to be lower than baseline measurements during the remainder of the illness and throughout convalescence. When measured prospectively, excretion of urinary alpha-amino nitrogen or most individual free amino acids did not change appreciably during sandfly fever, a mild virus infection.[159] In contrast, urinary losses of 3-methylhistidine and phenylalanine increased. The increased loss of phenylalanine seemed to reflect its increased concentrations in plasma.[160] Studies using radioactive compounds in rats suggested that most of the excess urea excreted during an acute infection was generated by the deamination of endogenous amino acids derived principally from skeletal muscle.[10]

Increased excretion of one of the amino acids, 3-methylhistidine, serves to indicate the extent of skeletal muscle catabolism.

This amino acid cannot be reused after its release from contractile proteins.[80,178]

Uric acid excretion may increase during febrile periods, but the greatest changes have been reported during infectious mononucleosis.[102] Uric acid losses are ascribed to an accelerated turnover of nucleic acids and enhanced purine degradation.

An increased excretion of urinary diazo reactants commonly occurs during most acute infectious illnesses, especially typhoid fever. These reactants include metabolites, such as kynurenine, 3-hydroxykynurenine, *o*-aminohippuric acid, xanthurenic acid, and anthranilic acid, which are created during the accelerated hepatic metabolism of tryptophan via the kynurenine pathway.[118]

A sudden, dramatic increase in urinary nitrate excretion occurs during acute infections. This increase is a reflection of the cytokine-stimulated production of nitric oxide as a host defensive measure.[44,139,144,157]

METABOLISM OF FREE AMINO ACIDS

The distribution, use, and metabolism of free amino acids undergo profound alterations during the course of acute infectious illness. Measurements in patients show patterns of change that can be explained by studies performed in experimental laboratory animals.[46,110,113,161] As some proteins are produced, others are degraded, and many of the released amino acids are redistributed throughout the body before they are reused.

A diminution in the concentration of most free individual amino acids in plasma may begin before the onset of symptoms. Hypoaminoacidemia generally persists throughout the febrile period of an illness, the largest decreases occurring in the branched-chain amino acids, leucine, isoleucine, and valine.[99] The decline in branched-chain amino acids is caused primarily by an accelerated uptake of free amino acids by the liver. This increased flux from plasma to liver has been shown to occur in several species of animals during a variety of infections.[99] The amino acids that enter the liver are used for a variety of purposes. Amino acids may be metabolized to other compounds, oxidized, or reused for the synthesis of new proteins. Interleukin-6 (IL-6) seems to trigger many of the alterations in hepatic protein and amino acid metabolism that occur during an acute infection.[12,133]

Amino acids become important sources of energy during the hypermetabolic phase of acute infections. Some amino acids are oxidized directly in muscle, whereas others are transformed progressively into glucose and glucagon. Gluconeogenic amino acids, such as alanine, are deaminated; their carbon skeletons are used as the principal substrate for producing glucose; and their nitrogen is used to create urea for excretion.

Serum and the total body pool of certain amino acids are depleted in various infections, presumably to diminish the substrate that some microorganism may use to replicate. Interferon-γ secretion causes a depletion of the body pool of tryptophan to retard the progression of *Chlamydia* infection.[116] A complete spectrum of amino acids is required for the synthesis of new body proteins generated during infection, including hepatic enzymes,[119] such as tryptophan oxygenase and tyrosine transaminase, and the lipoproteins and glycoproteins released into the plasma.[10,110,111] This group of glycoproteins constitutes the "acute-phase reactants," which include alpha$_1$-antitrypsin, amyloid, alpha$_1$-acid glycoprotein, haptoglobin, C-reactive protein, fibrinogen (the third component of complement), and ceruloplasmin.

These acute-phase reactant proteins are produced in excess during infections, even in protein-deficient children who exhibit acute kwashiorkor.[108] Some of the potentially beneficial functions attributed to acute-phase reactants include an amplification of humoral and cell-mediated immunity, antiproteinase effects that could limit or contain harmful enzymes liberated during inflammatory reactions, oxidase activities, and the detoxification of free hemoglobin.[110]

In addition to the accelerated synthesis of proteins within the liver, infection increases the production of phagocytic and lymphoid cells. A need to produce increased quantities of such diverse proteins as the cytokines, complement and kinin components, fibronectin, and the several classes of immunoglobulins also exists. All of these requirements involve the need for free amino acids.

Proinflammatory cytokines and interferon-γ stimulate the production of nitric oxide from arginine, its sole precursor.[44,157] Among the many important biologic effects of nitric oxide are the effects resulting from its being a highly potent microbicidal, parasiticidal, and tumoricidal agent,[139] and from having major immunomodulatory functions.[84] Research also has shown that nitric oxide may act as an antiviral agent against adenoviruses and other similar viruses.[25]

The importance of nitric oxide in these roles may rival those of free oxygen radicals in potency and effectiveness.[144] This newly recognized host defense agent is generated when cytokine-induced nitric oxide synthase initiates the oxygenation of one of arginine's guanido nitrogen groups to produce citrulline and nitric oxide.[139] During sepsis, arginine balance becomes negative, as consumption of arginine exceeds the rate of synthesis. Because arginine is the sole source of nitric oxide, it becomes an essential amino acid in critically ill children.[4] Arginine also plays an important role in wound healing. In patients with infected chronic wounds, total plasma arginine is decreased, and wound healing is impaired secondary to defective usage of arginine.[36]

AMINO ACID AVAILABILITY

In the presence of anorexia and a diminished intake of food nutrients, the body in large measure must use endogenous sources to supply its increased amino acid needs. The principal sources of potentially available endogenous amino acids are the proteins of somatic tissues, including skeletal muscle and skin. The free amino acid pool contains the equivalent of approximately 12.5 g of protein in a normal man, an amount that represents only 0.1 percent of total body protein.[158] Because the normal turnover of protein in a healthy adult is approximately 200 to 250 g each day, the free amino acid pool must be resupplied continually from endogenous and exogenous sources. During infections, the absorption of individual amino acids from the intestine may be depressed and delayed[93] or increased,[33] depending on the infection.

Protein synthesis is not stopped entirely within body somatic tissues during an infection, but it is slowed markedly. At the same time, the rates of degradation of somatic proteins are accelerated so that a net loss of muscle, skin, and other somatic proteins occurs through catabolic wasting. Catabolic degradation of skeletal muscle protein can be initiated by IL-1,[5,8,31,42] which triggers muscular proteases via the intracellular production of prostaglandin E_2. The body apparently sacrifices contractile proteins of skeletal muscle to obtain the free amino acids needed for higher priority requirements.

Some of the amino acids liberated during muscle protein catabolism are lost directly to the plasma. Others, such as the branched-chain group, are used in situ as sources of energy for muscle fibers; after oxidation, their amino groups are used to manufacture new glutamine and alanine, which can be used elsewhere for gluconeogenesis.[80] Because the branched-chain amino acids can be oxidized within skeletal muscle, their rate of release from muscle is decreased, which exaggerates the decline in their concentrations in plasma.[10,99,158] Branched-chain amino acids also play a major role in protein synthesis for lymphocytes and in

immunity.[23] Some of the free amino acids liberated within muscle are retained within contractile cells and reused for the slowed but continuing process of muscle protein anabolism.

This catabolic breakdown of somatic protein to supply amino acids for use in other parts of the body is a highly visible clinical phenomenon. In this regard, the proteins of skin, skeletal muscle, and other somatic structures seem to constitute the principal body pool of "labile" nitrogen, which is called on to maintain protein homeostasis and the physiologic functions of visceral tissues during periods of infectious illness or other stresses. Because infants and small children have very little muscle protein (and a very small "bank" of readily available amino acids), the infection-induced need for free amino acids puts them at a special disadvantage.

To study the complex interrelationships involved in amino acid metabolism, workers have used isotopes to measure the simultaneous rates of anabolism and catabolism in the protein of skeletal muscle and other tissues of experimental animals during the course of infection.[122] In addition, clinically useful estimates of skeletal muscle degradation can be obtained in patients through the quantitative daily measurements of 3-methylhistidine excretion into urine. More than 90 percent of the total body content of 3-methylhistidine is associated with the peptide chains of actin in all muscle and of myosin in white muscle fibers.[178] This unique amino acid is formed in situ through the transmethylation of histidine, but only after the histidine first has been incorporated into the amino acid structure of myofibrillar proteins. When released, 3-methylhistidine cannot be reused by the body and instead is lost via the urine.

The increase in excretion of 3-methylhistidine during acute infections is in keeping with other estimates of skeletal muscle wasting. The extent to which proteolysis occurs during periods of severe surgical sepsis also has been quantified by measuring the differences among concentrations of glucose, lactate, free fatty acids, ketones, and alanine in femoral arterial and venous blood.[106] Neither free fatty acid nor ketone use was increased during occurrences of acute fevers, but an increased oxidation of glucose and of amino acids derived from protein was used to fuel cellular hypermetabolism. Although infection stimulates a sizable increase in the rates of body protein synthesis, the acceleration of protein catabolism is increased even further, and the body experiences a net loss of somatic proteins and even some visceral ones.[158]

Phenylalanine is one of the amino acids released by the accelerated catabolism of somatic proteins. Only limited amounts of phenylalanine can be used, however, for the synthesis of new proteins or for its conversion into tyrosine.[158,160] Phenylalanine concentrations in the circulating free amino acid pool tend to increase rather than decrease during periods of fever. These increases occur coincidentally with the typical declines in plasma values for tyrosine and most other free amino acids. The exaggerated phenylalanine-to-tyrosine ratio can be useful for evaluating these opposing changes during febrile illnesses. An increase in this ratio is a useful clinical index of the severity of infection-induced alterations in amino acid metabolism.[158] During occurrences of infections of great severity and infections with hepatocellular dysfunction, hypoaminoacidemia may be replaced by an excessive accumulation of many other free amino acids in plasma.[10,135,170]

Free tryptophan, also liberated from degrading protein, undergoes an accelerated metabolism via several different metabolic pathways in the liver.[10,96,97,112] In response to the increased hepatic availability of tryptophan or the increased synthesis of tryptophan oxygenase, or both, excess tryptophan enters the kynurenine pathways, where it is converted into different diazoreactant compounds and pyrimidine nucleotides.[112] At the same time, tryptophan enters other pathways, leading possibly to increased synthesis of serotonin or indoleacetic acid.[118]

CARBOHYDRATE METABOLISM

During the febrile phase of infectious illnesses, carbohydrate metabolism provides much of the additional energy needed by body cells. An increased demand for metabolizable energy is met by a resetting of the endocrine control mechanisms to permit a marked acceleration of the synthesis and release of glucose from the liver.[35,54,171] Although some glucose is derived from hepatocellular glycogen, most additional requirements for glucose during acute infections are met by accelerated hepatic gluconeogenic mechanisms. Recycled lactate and amino acids, especially amino acids with gluconeogenic potential, such as alanine, are the principal substrates used by the liver to increase its output of newly synthesized glucose; glycerol (derived from the metabolism of triglyceride lipids) and pyruvate also are used.[80]

Early in acute infectious illnesses, basal blood glucose concentrations tend to become elevated. Diabetic patients who require insulin often develop glycosuria at the onset of febrile infections, and more insulin must be given to maintain their control. The tendency for acute infections to be accompanied by an early modest hyperglycemia also is seen in laboratory animals. Modest hyperglycemia often is noted in animals after they have been injected with bacterial endotoxin.[21,89]

Although an early hyperglycemic response seems to be the initial change in carbohydrate metabolism, the ability of the body to sustain an accelerated production of glucose may be lost. Hypoglycemia may emerge as an important clinical problem. Hypoglycemia generally results from one of two major pathogenic mechanisms: a diminished availability of substrate molecules required for gluconeogenesis or a failure of the metabolic mechanisms needed to produce hepatic glucose. Carbohydrate pathway defects at the molecular level have not been found in overwhelming bacterial infections in laboratory animals.[61,103] Carbohydrate depletion during overwhelming or terminal infections can be ascribed to nonavailability of substrate. If hepatic cells are injured during an infectious disease, such as viral hepatitis, hypoglycemia can result from a failure of gluconeogenic processes.[10,47,126]

The depletion of substrate for adequate gluconeogenesis occurs primarily as a dangerous clinical complication of neonatal sepsis. Infants are born with only minimal amounts of skeletal muscle protein. Because muscle contains the principal "labile nitrogen" pool for supplying amino acids that can be converted into glucose, neonatal infants lack a sufficient quantity of potential substrate molecules for sustaining long-term gluconeogenesis. Newborns especially are prone to develop severe hypoglycemia whenever a septic process becomes established.[176] Hypoglycemia that results from a breakdown of hepatic gluconeogenic mechanisms occurs primarily when liver cells are damaged by an infectious or toxemic process. Hypoglycemia can become an important complicating factor in severe viral hepatitis, yellow fever, or endotoxemia during gram-negative sepsis.[47,89] These conditions can cause hepatocellular damage and a breakdown of enzyme-synthesizing mechanisms within the liver.[89]

A change in glucose tolerance can be detected within hours after the onset of a febrile infection.[121,132] Baseline blood glucose values may be elevated, and disappearance of glucose is slowed moderately as a component aspect of a febrile illness. Under these circumstances, the pancreatic islets produce insulin in excess quantities. Despite an increase in plasma insulin concentrations, glucose disappearance rates are slowed; these combined metabolic changes resemble the changes caused by mild insulin resistance. In low-birth-weight neonates, hyperglycemia could be an ominous sign and suggests the presence of systemic fungal infections.[85]

Bacterial and viral infections also cause increased secretion of pancreatic glucagon,[121,124] which, together with release of catecholamines accompanying infection,[58,60,171] provides hormonal

stimuli for accelerating gluconeogenesis within the liver. These hormonal stimuli initiate their hepatic effects during infection by activating adenylate cyclase.[35] The unusual simultaneous increase in basal concentrations of insulin and glucagon in plasma results from direct cytokine stimulation of pancreatic islet cells.[8,53,175] Because of these hormonal changes and high plasma glucocorticoid values in patients with severe bacterial sepsis, infusions of glucose may fail to suppress hepatic gluconeogenesis.[80,81] The resultant increase in glucose pool size helps to explain the apparent slowing of glucose disappearance and the hyperinsulinemia that occur during infections.

Certain viral infections in children seem prone to initiate acute juvenile-type, insulin-requiring diabetes mellitus. Although the evidence for a viral cause of diabetes has not been established fully in humans, epidemiologic findings indicate that juvenile diabetes may develop several months after onset of certain viral illnesses, especially mumps, coxsackievirus B (type 4) infection, rubella, or cytomegalovirus infection.[101] Additional epidemiologic evidence is based on a tendency for new cases of juvenile-type diabetes to appear in clusters.

Susceptibility to juvenile diabetes also may be influenced by genetic make-up. A high incidence of human leukocyte antigen types B8 and Bw15 has been detected in juvenile diabetics.[127] Studies in laboratory animals suggest that genetically susceptible species may have virus receptor sites on their insulin-producing beta cells. These receptors in species with high-risk haplotypes allow viruses to be absorbed by the pancreatic beta cells, with subsequent destruction of insulin-producing cells.

The cytokine granulocyte colony-stimulating factor influences the uptake of glucose by phagocytic cells and their mobilization during inflammatory reactions.[77] Availability of glucose contributes directly to the respiratory burst that accompanies phagocytosis and to the production of the myeloperoxidase enzymes needed to kill engulfed organisms.

TABLE 3–1 Basic Mechanisms Leading to Observed Effects of Infection on Lipid Metabolism of the Host

Effects Associated with the Presence of Invading Microorganisms
1. Direct effects
   a. Microorganism use of host lipids for replication
   b. Disruption of host cell metabolism by intracellular microorganisms
   c. Localized destruction of fat cells by infectious process
2. Indirect effects
   a. Alterations in host metabolism caused by bacterial exotoxins, endotoxins, or bacterial enzymes
   b. Activation of lipases and other lipid-affecting enzymes within host phagocytes

Effects Secondary to Development of Generalized Illness Due to Infection
1. Decreased dietary fat intake
2. Interference with intestinal digestion and absorption of lipids
3. Alterations in lipid transport
   a. Changing concentrations of lipid transport proteins
   b. Decreased lipoprotein lipase activity (caused by tumor necrosis factor), which allows triglycerides to accumulate in plasma
4. Altered lipid metabolism within host cells caused by proinflammatory cytokines
   a. Activation of cell wall phospholipases by proinflammatory cytokines
   b. Creation, from cell wall polyunsaturated fatty acids, of intracellular arachidonic or eicosapentanoic acids or both
   c. Transformation of arachidonic and eicosapentanoic acids into various eicosanoids (prostaglandins, prostacyclin, thromboxanes, and lipoxins)
5. Other alterations of lipid metabolism within host cells
   a. Altered rates of hormone-mediated lipolysis within fat depots
   b. Accelerated fatty acid synthesis within the liver
   c. Depressed hepatic ketogenesis
   d. Altered rates of lipid uptake and use by peripheral tissues
6. Participation of newly formed eicosanoids in inflammatory and immunologic responses, and coagulation mechanisms
7. Effects related to prior nutritional status of the patient
8. Terminal pathologic hyperlipidemic effects associated with gram-negative sepsis and hypotensive shock

LIPID METABOLISM

As Table 3–1 shows, numerous changes in lipid metabolism have been documented during infection. In contrast to the stereotyped patterns of change in nitrogen and amino acid metabolism and in the accelerated production of glucose, responses involving body lipids vary more from infection to infection. Plasma lipid changes also may be biphasic during the course of a single infection. This complexity results partly from the multiple factors that control the metabolism of lipids during infectious illnesses,[10,135] including the need for hepatic synthesis of serum lipoproteins, variations in the production and use of free fatty acids and ketones as sources of cellular energy, and variable changes in rates of uptake or release of lipids from body fat depots.[10,135]

Lipids have another function that is crucial during acute-phase reactions. This function involves the cytokine-stimulated use of polyunsaturated fatty acids localized within cell walls to serve as precursor molecules for various families of eicosanoids (prostaglandins, prostacyclins, thromboxanes, and lipoxins). These eicosanoid lipids trigger many of the diverse cellular responses seen during infection, inflammation, and immune responses.[73,123]

PLASMA LIPIDS AND LIPOPROTEINS

Because the concentrations of individual lipid moieties in plasma depend on the algebraic summation of input and removal rates, the mechanisms that control the release or uptake of individual lipids must be studied throughout the course of various kinds of infectious illnesses. Concentrations of cholesterol have been reported to increase, to decrease, or to remain unchanged.[10] In severe meningococcal sepsis, high-density lipoprotein and low-density lipoprotein levels are low, and the severity of total hypocholesterolemia correlates with the severity of disease.[152] Other studies have shown that hypocholesterolemia in sepsis may have prognostic value. Decrease of cholesterol parallels increase of C-reactive protein, fibrinogen, and white blood cells in septic patients.[28]

Mild viral infections often are associated with a transient decline in serum cholesterol values. When longitudinal studies were conducted during the course of experimentally induced sandfly fever in young adult male volunteers, plasma values for total and esterified cholesterol, phospholipids, and free fatty acids all declined in conjunction with, or immediately before, the onset of fever.[78] This decline in concentration included the cholesterol and the protein components of the low-density beta-lipoproteins. In contrast, the plasma triglyceride values showed a biphasic pattern of change: An initial decline was followed by an increase above baseline control concentrations during the early convalescent period. Depressions of total serum cholesterol values also have been reported to occur during pneumococcal pneumonia, cholera, tuberculosis, and malaria.

When studied in rhesus monkeys experimentally infected with *Streptococcus pneumoniae* or *Salmonella typhimurium*, rates of [^{3}H] mevalonic acid incorporation into free cholesterol were accelerated,[48] and no evidence of an inhibition of squalene synthesis or its conversion to cholesterol was found. In contrast, the synthesis

of cholesterol was blocked partially when monkeys with diet-induced hypercholesterolemia were subjected to a pneumococcal infection.[48]

Marked increases in the concentrations of total serum lipids and triglycerides are found consistently in patients with infections caused by gram-negative bacilli,[10,69,135] but this response is minimized or fails to occur in patients with viral or gram-positive coccal infections. A similar difference has been noted in monkeys with either *S. pneumoniae* or *S. typhimurium* infection.[70] Tumor necrosis factor, a proinflammatory cytokine with a unique additional function that inhibits the enzyme lipoprotein lipase, seems to be of central importance in accounting for these differences.[69]

Although a release of tumor necrosis factor from activated macrophages may occur in many infections, its release is stimulated markedly by bacterial endotoxins released during gram-negative infections.[10,92] Hypertriglyceridemia occurring during periods of *S. typhimurium* infection in monkeys was generated by tumor necrosis factor–induced mechanisms that reduced the clearance of lipids from plasma and the activity of heparin-sensitive plasma lipoprotein lipase. Hypertriglyceridemia that accompanied pneumococcal infections was far less severe than that observed with gram-negative infections. After endotoxin was administered,[69] hypertriglyceridemia developed chiefly as the result of an impaired lipid disposal mechanism, secondary to release of tumor necrosis factor from macrophages.[8] An acceleration in the rate of hepatic production of triglycerides from free fatty acid precursors also occurred.

LIPIDS AND ENERGY METABOLISM DURING INFECTION

Requirements for cellular energy during periods of chronic infections in laboratory animals seem to be met largely through the catabolism of stored body fat.[82] In contrast, fat wasting does not seem to be as prominent during rapidly lethal bacterial infections. Ketogenesis also seems to be blunted during periods of acute infections.[103] Concentrations of free fatty acid in plasma normally are increased by the actions of catecholamines, growth hormone, and glucagon, which are increased during the course of infection.[10] Concomitantly high concentrations of plasma insulin apparently serve to inhibit lipolysis and ketogenesis.[10,103] The contribution of free fatty acids to energy production during an infection is influenced by the interplay of these hormones, the availability of glucose, and the functional capacity of the liver to take up fatty acids and convert them to triglycerides.[48,49,53,54]

Finally, brown fat is thought to contribute importantly to heat production in newborns via sympathetic nerve activation of this tissue. Because numerous viruses are known to proliferate in brown fat,[136] fever that occurs with neonatal viral infections may involve brown fat thermogenesis.

Acute infectious illnesses produce few effects on the intestinal absorption of fat, although it may be reduced with intestinal infections and parasitemic or enterotoxemic illnesses.[109,126] Lipid precursors needed for the replication of microorganisms within host tissues must be supplied from metabolic pools within the host. Malarial parasites obtain their structural lipids from red blood cell precursors; lipid-containing viruses apparently obtain the lipid components needed for their assembly from lipid-rich membranes already present within host cells.

LIPID METABOLISM AND HOST DEFENSIVE MEASURES

Rapid metabolic responses by cell wall lipids play a major role in initiating a panoply of intracellular events during acute-phase reactions. The attachment of proinflammatory cytokines to cell wall receptors triggers the conversion of polyunsaturated fatty acid in cell wall membranes to a variety of biologically active eicosanoids. Lipids of various eicosanoid families become the messenger molecules that are responsible for many of the acute-phase metabolic and cellular responses[8,42] that occur with infection. These short-lived eicosanoids are biopotent at nanomolar to picomolar concentrations.

In addition to their importance within lymphocytes of the immune system, eicosanoid lipids transmit stimulatory or inhibitory signals between other cells and tissues in health and disease.[73,123] Although they do not initiate disease processes, various eicosanoid lipids (i.e., prostaglandins, leukotrienes, prostacyclin, lipoxins, and thromboxanes) are important components of the pathogenic progression of infectious diseases.[73,123]

Eicosanoids also have important effects on other white blood cells and platelets and on such diverse organs as the brain, lungs, stomach, and kidneys. These eicosanoids seem to be components of complex, often overlapping, regulatory mechanisms that interconnect the immune system, the central nervous system, the endocrine glands, and the functions of many other organs and tissues. These homeostatic (and at times pathogenic) mechanisms are characterized by numerous duplications, amplifications, checks and balances, and feedback control loops.

Biochemical details now are well established concerning the intracellular synthesis of individual eicosanoids from *n*-3 and *n*-6 polyunsaturated fatty acid precursors.[73,123] After cytokines interact with cell wall receptors, they activate cell membrane phospholipase enzymes. These enzymes initiate the release (into the cell interior) of arachidonic acid from cell wall (*n*-6) polyunsaturated fatty acid or eicosapentanoic acid from (*n*-3) polyunsaturated fatty acid. These first steps of eicosanoid synthesis can be blocked by adrenocorticoid hormones. In target cells having cyclooxygenase enzymes, arachidonic acid is oxygenated into 4-series leukotrienes, 2-series prostaglandins, or thromboxanes and prostacyclin. If a cell possesses lipooxygenase enzymes, arachidonic acid is oxygenated into the sometimes less potent 5-series leukotrienes, 3-series prostaglandins, or lipoxins.[123] The highly active eicosanoid molecules are degraded rapidly. Importantly, synthesis of prostaglandins of the 2-series and the 4-series can be blocked by certain nonsteroidal anti-inflammatory drugs, such as aspirin, indomethacin, and ibuprofen.[73,123]

Other fatty acids may participate in defense mechanisms of the host and occasionally even may be involved in pathogenic events of a harmful nature. An increase in the fat content of vital organs is a common occurrence in patients dying of severe bacterial infections; fatty metamorphosis especially is prominent in the liver, kidney, and heart.[66] Hyperlipemia in gram-negative septicemia may be accompanied by fat embolization to the lungs. Other deleterious actions of body lipids involve the liberation of phospholipids from platelets and their subsequent participation in the activation of the blood-clotting cascade leading to disseminated intravascular coagulation. Chronic *Chlamydia* pneumonia infection leads to oxidation of low-density lipoprotein, which promotes atherogenesis.[43]

ELECTROLYTE AND ACID-BASE METABOLISM

Many life-threatening medical emergencies faced by infants and children with acute infectious diseases involve problems in the areas of salt and water or acid-base balance. Some infections cause severe overhydration, and others produce dehydration with hypovolemic shock. Pathogenic mechanisms that come into play during various infections can lead to metabolic alkalosis or acidosis, to respiratory alkalosis or acidosis, or to complex admixtures of these pathophysiologic perturbations.[8,18]

The onset of fever typically is accompanied by tachypnea and accelerated respiratory gas exchange, which leads to an exaggerated loss of dissolved carbon dioxide from blood and a state of

uncompensated respiratory alkalosis.[10] Alkalosis may persist as long as febrile tachypnea lasts, and gas exchange within the alveoli remains unimpeded.

Conversely, infections that produce extensive pulmonary consolidation can impair carbon dioxide exchange and cause respiratory acidosis. Respiratory acidosis also is a complication in patients whose pulmonary musculature no longer can function effectively, such as patients with poliomyelitis, tetanus, botulism, or respiratory distress syndrome.

Metabolic acidosis generally develops whenever an infectious disease process becomes severe. With the hypotension, vascular stasis, and cellular anoxia seen during gram-negative sepsis, the generation of excessive lactic acid and other acidic metabolic products exceeds the capacity of the body's buffering systems.[10,135]

Diarrheal diseases can be accompanied by two other forms of metabolic acid-base derangement.[18,126,163] Toxigenic diarrhea characterized by high-volume stool loss, such as that seen in Asiatic cholera or *Escherichia coli* enterotoxemia, causes an excessive loss of fecal bicarbonate and an alkaline stool, with a resultant decline in blood pH. Bicarbonate is secreted actively in the lower ileum and cannot be reabsorbed completely by the colonic mucosa if high-volume losses of watery stool occur.[18]

In contrast, diarrhea accompanied by only low-volume stool losses, as in rotavirus infections,[126] tends to be associated with an acid stool associated with an exaggerated loss of fecal potassium rather than bicarbonate. If fecal potassium losses persist chronically for a long time or occur rapidly as part of the massive fluid loss of acute secretory diarrhea, such as in pediatric cholera, body potassium can be depleted severely. The loss of cellular potassium can produce metabolic alkalosis, cardiac arrhythmia, paralytic ileus, and weakness in children and the occurrence of hypokalemic vacuolization in cells of the myocardium and renal tubular epithelium. Even if the balance of fluid is restored promptly in these patients, a prolonged state of metabolic alkalosis can persist until body potassium stores are replenished.

The importance of diarrheal diseases in infants and small children is great, with an estimated 2 to 3 million deaths occurring worldwide each year.[104] Life-threatening dehydration can result from the loss of body water and electrolytes during an episode of high-volume diarrhea. Because massive diarrhea produces an iso-osmotic loss of body water and electrolytes, the fluid losses come from the extracellular rather than the intracellular space.[163] The circulating blood becomes thick and viscous because of a relative increase in hematocrit values and a progressive concentration of serum proteins, which can increase to more than twice their normal values. Despite serious dehydration, concentrations of plasma sodium remain normal, when expressed in terms of plasma water.[163] This type of acute, massive diarrhea can lead to the rapid onset of hypovolemic shock, renal failure, and death.

Dehydration usually does not become a problem in infectious diseases that lack protracted vomiting, diarrhea, or prominent sweat loss. Instead, severe generalized infections in children may be accompanied by some retention of body water and salt. Soon after the onset of a febrile illness, the adrenal secretion of aldosterone increases,[9,17] and this mineralocorticoid stimulates the renal retention of sodium and chloride. These electrolytes virtually may disappear from the urine during a severe febrile illness. Retention of salt tends to be accompanied by a retention of body water throughout the illness.[10] Generalized edema is an infection-induced manifestation of kwashiorkor and can be seen during severe infections in well-nourished children. Accumulations of excess water and salt typically are excreted after the acute phase of illness by a transient period of diuresis during the early convalescent period.

Some infections, particularly infections that become localized within the central nervous system, also are complicated by an inappropriate secretion of antidiuretic hormone from the posterior pituitary.[45,169] The ensuing retention of body water may dilute the sodium and chloride in plasma. Redistribution of sodium also may contribute to the development of hyponatremia during infections. Sodium may begin to accumulate within body cells, apparently because the sodium-pumping mechanisms in extracellular membranes may fail to maintain internal electrolyte homeostasis.[10] This form of sodium sequestration is evidence of severe illness. It is not reversed easily and may be a major complication in patients with severe infections, such as meningococcemia or Rocky Mountain spotted fever.

VITAMIN METABOLISM

Although few measurement data are available concerning infection-induced changes in vitamin metabolism, the consensus is that the use or metabolism of most vitamins is accelerated.[16,155] Scattered reports suggest that infectious diseases in humans may be followed by classic scurvy, beriberi, pellagra, or xerophthalmia.[129]

More recent attention has focused on vitamin A, which previously was termed the anti-infection vitamin. Declining concentrations of plasma vitamin A during episodes of childhood infections are accompanied or perhaps caused by a marked urinary loss of this vitamin.[1,142] Not only does the heightened vitamin A deficiency induced by infection contribute to the subsequent development of ocular and conjunctival pathologies, but also subclinical deficiencies of vitamin A and their associated immunologic dysfunctions can heighten the mortality associated with childhood infections,[130] as shown most dramatically in measles.[138] Depressed plasma concentrations of several other vitamins have been reported.[10] In addition to the urinary losses of vitamin A,[1,142] increased excretion of urinary riboflavin and vitamin C may occur in conjunction with negative nitrogen balance.[16]

Vitamins are known to participate in metabolic processes activated during host defensive mechanisms.[8] The rapid synthesis of steroid hormones by the adrenal cortex is accompanied by a decline in the adrenal content of vitamin C. The B group vitamins, vitamin C, and folate all participate in the metabolism of activated phagocytic cells.

Controversy continues to exist over whether massive daily doses of vitamin C can suppress or prevent the common cold and other viral respiratory infections. More than 2 decades ago, the American Academy of Pediatrics Committee on Drugs[2] failed to find sufficient scientific evidence to support Pauling's claim, but new data subsequently were introduced.[63] Concentrations of vitamin C in neutrophils decline during infectious diseases. Vitamin C is recognized for its importance in the locomotive activity of phagocytic cells and its contributions to the immune system.[3]

Intestinal parasites, such as tapeworms, may take up sufficient vitamin B_{12} from the succus entericus to diminish vitamin B_{12} absorption and lead to the development of megaloblastic anemia. The intestinal absorption of fat-soluble vitamins and folate also may be impaired for a time in children with enteric infections or parasitic diseases.[83]

The antioxidant role of several vitamins (A, C, and E) has been recognized more recently. Antioxidants act to reduce oxidative stress within the body by serving as scavengers of singlet oxygen radicals. The antioxidant functions of several other provitamin-A carotenoids are of still greater importance. They include beta carotene, lycopene (the red pigment found in tomatoes and other brightly colored fruits), lutein (from spinach), and zeoxanthin (from kale and other dark green collard greens). Lycopene is more abundant in plasma than is beta carotene and twice as powerful in quenching free oxygen radicals. Lutein and zeoxanthin are retinal pigments, with lutein being found throughout the

retina and zeoxanthin being concentrated in the macula. Antioxidants are thought to protect cell membranes, DNA, and arteries to augment the immune system and the function of natural killer cells and to help prevent heart attacks, macular degeneration, and various cancers, especially prostate cancer. Little is known about the probable role of antioxidants during episodes of infectious diseases of children.

More recent studies on a small sample of adults have suggested that vitamin D is decreased in patients with HIV infection, and that vitamin D levels correlate directly with the CD4 count and inversely with mortality in HIV-infected patients.[154] Vitamin C seems to be decreased in patients with HIV infection, whereas vitamin E concentrations are similar to those in healthy subjects.[143] Oxidative damage is known to play an important role in inflammation, but the exact mechanism by which vitamin C is involved in the antioxidant host defense is unclear. One study that looked at *Klebsiella pneumoniae* infection showed that vitamin C does not prevent lipid and protein oxidation. Another study suggests that vitamin C is protective against oxidative stress, at least partly by decreasing lipid peroxidation.[72] Vitamin C seems to protect against infections in mouse models.[52]

TRACE ELEMENT METABOLISM

As Table 3–2 shows, infectious illnesses often are accompanied by changes in the concentration of several of the trace elements in plasma. The most consistent responses include a decrease in the concentrations of plasma iron and zinc and an increase in plasma copper.[10] This triad of trace-element changes has been reported in bacterial, viral, rickettsial, and parasitic infections. In acute viral hepatitis, serum iron values tend to increase, however, in the second and third weeks of illness. Hepatitis also is associated with an unusual change in the binding of zinc to various ligands.[65] Soon after the acute onset of jaundice, plasma zinc is found to be bound almost entirely as microligands to small molecules, such as the amino acids. This phenomenon contrasts with the normal propensity for approximately 95 percent of plasma zinc to bind predominantly as a macroligand with either albumin or alpha$_2$-macroglobulin. In any event, plasma zinc is sequestered rapidly in the liver, where it becomes tightly bound during acute infections to newly synthesized metallothioneins.[137]

CHANGES IN IRON METABOLISM

An abrupt depression in serum iron concentrations has been observed in virtually all infections in which iron values have been measured except acute viral hepatitis, with pyogenic infections causing the greatest effects. This hypoferremia has been ascribed primarily to an accelerated flux of iron from plasma into the liver, where it becomes localized in reticuloendothelial cells and hepatocytes. There the iron becomes sequestered as intracellular hemosiderin molecules or as a complex with ferritin.[8] Tumor necrosis factor and IL-1 seem to trigger this sequestration of iron by inducing the formation of ferritin,[24] some of which may be found in plasma. Plasma ferritin values provide a valuable clue concerning the quantities of body iron available in storage depots. When iron has become sequestered, it is not released readily until the infection is terminated.

Hepcidin is a peptide involved in major iron metabolic pathways. Hepcidin's secretion in the liver is induced during infections, likely by cytokines such as IL-6. Increased production of hepcidin leads to decreased plasma iron, which can be detrimental to the host but nonetheless acts as a host defense mechanism by reducing the iron available to different microorganisms.[51] Despite a low pool of plasma iron, some microorganisms, such as mycobacteria, have developed survival mechanisms by using the iron stored intracellularly in macrophages.[128]

During acute and chronic infections, the normal mechanisms that allow for the continuing release from tissue stores of the iron needed for use in erythropoiesis seem to be inhibited. If an infection persists for a prolonged period, anemia may develop. Although the "anemia of infection" resembles iron-deficiency anemia in its peripheral manifestations, it develops in the presence of adequate quantities of iron in storage sites and cannot be reversed by the therapeutic administration of iron.[8]

Other factors that influence iron metabolism during episodes of infection include an accelerated destruction of red blood cells and their direct loss in diseases in which hemolysis or bleeding

TABLE 3–2 Infection-Related Changes in Trace Elements

Trace Element	Observed Change during Infection	Suggested Pathophysiologic Mechanisms
Iron	Hyposideremia (common)	Flux of iron into liver and reticuloendothelial system cells
		Increased synthesis of ferritin
		Sequestration of iron in tissue stores
		Diminished iron absorption
	Anemia	Accelerated red blood cell destruction
		Direct blood loss
		Inhibition of erythropoiesis
	Reduced serum iron-binding capacity	Reduced synthesis of transferrin
	Hypersideremia (selective)	Hepatocyte damage during hepatitis
Zinc	Hypozincemia	Accelerated flux of zinc into liver
		Hepatic synthesis of additional metallothioneins
		Negative body balance of zinc
	Hyperzincuria	Hepatitis-induced inhibition of zinc binding to plasma proteins
Copper	Hypercupremia	Accelerated hepatic synthesis and release of ceruloplasmin
Chromium	Hypochromia	Unknown
Manganese	Hypermanganemia	Hepatocyte damage during hepatitis
Cobalt	Hypercobaltemia	Hepatocyte damage during hepatitis
	Macrocytic anemia	Intestinal parasitic competition for available vitamin B_{12}
Gallium	Hypergallemia	Hepatocyte damage during hepatitis
	Accumulation in sites of localized infection	Unknown
Iodine	Accelerated deiodination of thyroid hormones	Increased cellular metabolic rates
		Increased iodine availability for cellular bactericidal functions

is a factor. Excessive laboratory testing of blood samples can occur. In malaria, serum iron values tend to decline, despite the unusually large amounts of hemoglobin released from parasitized red blood cells. The released hemoglobin rapidly complexes with haptoglobin and is taken up by reticuloendothelial cells.[42] As in other forms of hemolytic anemia, a depression of serum haptoglobin values in malaria can serve as an index of the severity of red blood cell destruction.

An inhibition of iron absorption in the intestinal tract also can contribute to an infection-induced depression of serum iron values.[166] Studies using radioactive iron showed that a febrile illness or the febrile response of infants or young children to immunization could depress intestinal iron absorption for several days.[20]

The abrupt decrease in serum iron concentration, which can reach virtually undetectable values, occurs without any appreciable change in total serum iron-binding capacity. Although concentrations of serum transferrin decline along with concentrations of albumin during states of severe protein deficiency, they decline only slowly, if at all, during occurrences of acute infections. The combination of a normal iron-binding capacity and a markedly depressed concentration of serum iron in previously well-nourished children results in an increase in the concentration of serum unsaturated transferrin.[8] Unsaturated transferrin may play an important host defensive role by competing with siderophores of bacteria, which need to acquire iron for their growth and replication.[165] Because of its high affinity constant for iron, unsaturated transferrin is an important potential mechanism for inhibiting bacterial replication.

Increased concentrations of serum iron have been reported during bacillary dysentery, typhoidal infections, and, most commonly, acute viral hepatitis. The increase in concentrations of serum iron is delayed in hepatitis until several weeks after the initial appearance of jaundice; this increase may be large enough virtually to saturate the iron-binding capacity of serum. An impairment of mechanisms accounting for the normal daily hepatic removal of iron from serum has been thought to explain the hyperferremia noted during infections associated with liver cell dysfunction. An alternative hypothesis suggests that hepatitis-induced hyperferremia is caused by an escape of iron from the damaged hepatocytes. The latter explanation also is used to explain the reported increase in concentrations of serum manganese, gallium, and cobalt during acute hepatitis.[10]

CHANGES IN ZINC METABOLISM

Concentrations of zinc decline during episodes of various infectious diseases, as they do with a large variety of other diseases characterized by the presence of an inflammatory process.[10,111] Zinc values rarely decrease, however, as much as iron values do. This difference apparently is because of the large amount of plasma zinc that is bound tightly to alpha$_2$-macroglobulin. This plasma protein remains constant during periods of infection.[10]

Similar to iron, zinc seems to move into the liver at an accelerated rate during episodes of acute infections. This increased flux of zinc from serum to liver apparently is triggered by the action of proinflammatory cytokines released from activated monocytes and macrophages.[8,10] The hepatic uptake and sequestration of zinc are associated with an increased synthesis of zinc-binding metallothioneins within the hepatic cells.[137] The reason for this flux of zinc from serum to liver has not been explained in terms of host defense.

Body balances of zinc are thought to become negative during episodes of infectious diseases because of a combination of factors, including a reduction in dietary zinc intake, a diminished absorption from the intestinal tract, and a concomitant continuation (or increase) of zinc losses via the urine and possibly via the feces and sweat. During periods of acute infectious hepatitis, a marked increase in the urinary loss of zinc occurs. This loss is caused by enhanced glomerular filtration and excretion of zinc microligands.[65] The increased formation of zinc microligands with amino acids, such as histidine and cysteine, permits plasma zinc to be excreted from the body via the urine. Whether an increased binding of zinc to amino acid microligands occurs with infections other than acute hepatitis is unknown; this phenomenon was not detected with sandfly fever. Zinc deficiency is important particularly in developing countries, where zinc deficiency is widespread and plays a significant role in diarrhea, pneumonia, tuberculosis, and malaria.[34]

CHANGES IN COPPER METABOLISM

Concentrations of plasma copper increase in virtually all infections. This increase apparently accompanies the accelerated synthesis and release from the liver of ceruloplasmin, the copper-binding protein of plasma. The increase in plasma ceruloplasmin resembles that of other acute-phase reactant proteins produced by the liver during inflammatory states when triggered by IL-6 and other proinflammatory cytokines.[8] Increases in ceruloplasmin and copper occur later than do the abrupt depressions in serum iron and zinc. The increase in copper values tends to persist longer than the changes in zinc and iron do, apparently as a result of the long in vivo half-disappearance time of ceruloplasmin from plasma. Body balances of copper have not been studied during an episode of an infectious illness.

PROINFLAMMATORY CYTOKINES

The generalized metabolic and physiologic responses to febrile infections are initiated and sustained by a unique control mechanism. This mechanism involves the secretion by various body cells of hormone-like cytokines (mainly monokines and lymphokines).[42] The cytokines include ILs, interferons, colony-stimulating factors, and tumor necrosis factor. Cytokines also function during localized infections.[117]

Complex interactions of cytokines that occur during illness only now are being unraveled.[8,42] Cytokines are not classified as hormones because they are produced by a variety of different cells located throughout the body, rather than by anatomically distinct glands; because cytokines are effective at far lower concentrations than are hormones; and because their interacting array of checks and balances is far more complex than that of hormones. Although cytokines are not components of either the central nervous or the endocrine systems, they interact with and trigger responses by both of these major regulatory control systems.[8,111]

Proinflammatory cytokines (which include IL-1, IL-6, and IL-8, and tumor necrosis factor) initiate and orchestrate the highly complex but stereotyped admixture of concomitant anabolic and catabolic events that make up the generalized host response to febrile infections. Individual components of this generalized response form distinct patterns. Some metabolic responses begin during the incubation period; some, at the onset of fever; some, late in the course of fever; and some, during convalescence.[8,10-12,14,21] No matter which type of microorganism causes an acute, generalized, febrile infection, the onset of most metabolic, biochemical, or physiologic responses seems to occur at consistent, predictable times. These many responses can be categorized temporally by their relationships to the time of onset of clinical symptoms and fever.[8] Virtually every metabolic or biochemical process is influenced in some manner by the body's response to an acute infection. The duration and magnitude of individual components of the generalized response show some

variability from infection to infection. More must be learned about how the cytokines influence this variability in host metabolic responses.

In today's terminology, this overall response is termed an *acute-phase response*, an *acute-phase reaction*, or the *systemic inflammatory response syndrome*. This acute-phase response may accompany other severe medical and surgical problems, in addition to infection.[75] This complex response, which also activates complement and stimulates the immune system, seems to help defend the body.[8,75] On the negative side, acute-phase responses generate important nutritional costs,[8,10,125] costs that can produce severe, life-threatening malnutrition. In addition, acute-phase responses that become excessive or overly prolonged can lead to hypotensive shock, multiorgan dysfunction, and death.[42,79,106,125]

Acute-phase responses are initiated and controlled by the proinflammatory cytokines.[42,62,64,71,79,134,140,167] The cytokine interferon-α also can contribute to the wasting syndrome of acute infections.[32] The acute-phase reaction may be modified by bacterial endotoxins, which uniquely stimulate an exaggerated release of tumor necrosis factor, a cytokine that inhibits lipoprotein lipase enzymes, to account for the high concentrations of plasma triglycerides that develop during gram-negative sepsis.[8,69]

The primary control mechanisms that initiate acute-phase responses normally exist in a standby mode but can be turned on whenever necessary by the activation of macrophages, blood monocytes, or other body cells, and by the subsequent rapid release of proinflammatory cytokines.[8,42,92] The many diverse types of stimuli that can activate these cells include the phagocytosis of microorganisms, tissue debris, or other particulate matter; the effects of polynucleotides, certain drugs and chemicals, antigen-antibody complexes, and bacterial toxins; and the actions of other cytokines. During infectious illnesses, proinflammatory cytokines can be detected in body fluids, body secretions, urine, and stools.[55,88,117,120]

After their release from producing cells, proinflammatory cytokines circulate via the plasma or diffuse through tissue fluids to stimulate cell populations in many locations throughout the body. These cytokines have multiple, often overlapping, actions, and they stimulate the release of companion cytokines. IL-1 previously was termed *endogenous pyrogen*, *leukocytic endogenous mediator*, and *lymphocyte-activating factor*;[42] and tumor necrosis factor previously was termed *cachectin*. Proinflammatory cytokines stimulate the hypothalamic temperature-regulating center to initiate fever,[8,42] endocrine glands to secrete hormones, the liver to take up amino acids and trace elements and to synthesize many different proteins,[8,111,134] the pancreatic islets to release insulin and glucagon,[53,175] and the muscle cells to catabolize contractile proteins.[3,31] These cytokines also stimulate the bone marrow to produce and release neutrophils[111] and synovial cells and fibroblasts to activate collagenase.[42] Proinflammatory cytokines also may affect growth during certain viral infections by exerting a direct effect on bone remodeling.[141] Marrow stimulation involves the effect of IL-1 on progenitor cells[98] and its ability to trigger the release of various colony-stimulating cytokines.[8,59,98] In this regard, IL-1 has been found to be identical with hematopoietin.[98] The proinflammatory cytokines also activate the immune system and cause certain subsets of T lymphocytes to secrete IL-2, IL-3, IL-4, and IL-5.[8,42]

Proinflammatory cytokines are thought to function, after attachment to their specific cell wall receptors, by activating phospholipase A_2 within the cell walls, leading to the intracellular release of arachidonic acid or eicosapentanoic acid, or both, from cell wall polyunsaturated fatty acid phospholipids.[42] Subsequent responses by the cytokine-stimulated cell are determined by the intracellular enzymes that can metabolize these acids to one of many possible eicosanoids.

CONTROL MECHANISMS FOR PROINFLAMMATORY CYTOKINE ACTIONS

Similar to the action of hormones, proinflammatory cytokine actions are regulated by numerous checks and balances. To act on a cell, a cytokine first must attach itself to a protein receptor on an exterior cell wall. Cells produce other similar receptor proteins, however, which are released to float free in plasma.[76,107] Freely circulating receptors can intercept and inactivate their matching cytokine.[50,56] Other unique plasma protein molecules, receptor antagonists, also are produced.[149] They can attach to and block the cellular receptors for specific cytokines.[76,107] Cytokine inhibitor proteins have been identified.[27,150] Other cytokines, such as IL-4 and IL-10, can suppress the cellular production of proinflammatory cytokines.[39,57,76,115,145] Cytokine stimulation of release of cortisol has complex feedback effects because cortisol can block the intracellular formation of eicosanoids stimulated by the cytokines. Cortisol and epinephrine also can stimulate the production of cytokines.[79]

CYTOKINE DETECTION IN BIOLOGIC FLUIDS

Individual components of this complex cytokine system of checks and balances now can be measured in body fluids, and their relationships can be studied throughout the course of an acute-phase reaction.[22,26,42,71,76,140,150] These cytokines and their free receptors can be found in mucosal fluids and in plasma.[105,114,120] Cytokine measurements may have diagnostic and prognostic value.[26,134] Identification of IL-8 in amniotic cord sera was reported to be a specific marker for preterm chorioamnionitis.[134] Raqib and colleagues[120] described longitudinal measurements of cytokines and receptor antagonists in the plasma and stools of patients with acute shigellosis. Concentrations of tumor necrosis factor–α; IL-1β, IL-6, and IL-8; and IL-1 receptor antagonist in stools were quite high when patients with shigellosis first were seen and gradually returned to normal values during the next 2 weeks.[134] IL-6 and IL-8 can be used as markers for neonatal sepsis with coagulase-negative staphylococci and to differentiate between bacterial and enteroviral infections.[151] Proinflammatory cytokines also are responsible for the cachexia associated with acute or chronic inflammatory diseases.[37] The pathogenic or physiologic effects of these interacting molecules in either systemic or localized diseases still are not fully understood.

HORMONAL RESPONSES

Infectious illnesses are accompanied by a variety of endocrine responses, which especially include increased secretion of the hormones that regulate carbohydrate and energy metabolism and the hormones that influence salt and water retention. These hormonal responses are secondary to and often are initiated by the primary release of proinflammatory cytokines from activated cells.

In addition to their participation in physiologic responses, endocrine functions also may be affected by pathologic complications of an infectious process that results in the direct destruction or dysfunction of hormone-producing cells. The adrenal glands may be destroyed if tubercle bacilli localize in these glands or if hemorrhagic necrosis becomes a complication of such infections as acute meningococcemia. Pancreatic islet cells may be destroyed during episodes of viral infections of experimental animals, and the same pathogenic possibility may initiate insulin-requiring diabetes in children. Thyroid function may be impaired after occurrence of a viral infection that triggers an autoimmune thy-

roiditis, and gonadal tissues may be the site of localization and destruction by the mumps virus.

PITUITARY GLAND FUNCTIONS

Secretion of certain of the trophic hormones produced by the anterior pituitary is increased during infection. An increase in adrenocorticotropic hormone production (stimulated by proinflammatory cytokines) triggers an increased secretion of several adrenocorticoids. Concentrations of plasma growth hormone generally are increased in acute infections in which this hormone has been measured,[19,121] but the increases do not seem to correlate directly in timing or magnitude with the presence or severity of fever.[7,10] This increase in plasma growth hormone may be due partly to its production by mononuclear leukocytes.[164] Concentrations of plasma growth hormone increase rapidly in a paradoxical manner if an intravenous infusion of glucose is given to a patient or a laboratory animal with an acute infection.[121] Thyroid-stimulating hormone does not respond during the early phases of an acute febrile illness but may increase during the convalescent period. No increases in the gonadotropic hormones have been documented during an episode of an infection. A release of several anterior pituitary hormones can be stimulated by fever-producing doses of bacterial endotoxin. Such responses have been used in the clinical testing of anterior pituitary function.[74,95]

As described in the earlier discussion of salt and water imbalances, inappropriate secretion of antidiuretic hormone may occur in patients with severe infectious diseases.[45] This phenomenon also seems to be a characteristic response in patients whose infectious process becomes localized within the cranial vault.

ADRENAL FUNCTIONS

Although the adrenocortical hormones are known to influence the ability of a patient to respond to stressful situations, few data define the duration and magnitude of the adrenal response or characterize the spectrum of specific steroid hormones produced in excess.[17,94] Available data suggest that acute generalized infections typically are accompanied by a transient increase in the adrenal output of glucocorticoid hormones that is of short duration. Although these responses generally are limited in magnitude, they serve to maintain a constant concentration of cortisol in plasma throughout the early periods of fever.[17]

The usual diurnal decline in plasma 17-hydroxycorticosteroid values fails to occur during the afternoon and evening hours if fever is present. Cortisol-binding proteins have not been observed to change in plasma during periods of acute infection.[10] The plasma concentrations of unbound, physiologically active cortisol are maintained at or higher than the normal peak early morning values throughout the initial period of a febrile illness.[10,17] The total increase in glucocorticoid secretion rates during early illness ranges from two to five times normal values in infections that have been studied. Lesser degrees of increase have been noted in the adrenocortical output of pregnanetriol and the weak ketosteroid androgens.[17] If an infectious illness becomes chronic, adrenal output generally returns to or even falls below baseline values, and diminished adrenal responsiveness to adrenocorticotropic hormone may occur.

Extremely high concentrations of plasma 17-hydroxycorticosteroids may develop during gram-negative septicemia or before death in patients with other severe acute infections.[91,94] These high terminal values may be ascribed to failures in the hepatic clearance of cortisol from plasma and the metabolic pathways for converting cortisol to water-soluble metabolites; high plasma values are not the result of an extraordinary increase in adrenal secretion rates.[91] In a detailed study of adrenal function in children with meningitis, Migeon and coworkers[94] reported a maximum average increase in cortisol secretion rate of approximately threefold during uncomplicated aseptic or bacterial meningitis. This increase was accompanied by a threefold increase in the excretion of urinary 17-hydroxycorticosteroids during the first few days of illness. On admission to the hospital, these children had concentrations of plasma cortisol that ranged from high normal to twice normal values. Severely ill patients who were dying of adrenal hemorrhage generally had values that were depressed or absent.

Mechanisms by which small increases in adrenal glucocorticoid secretion might protect the host have not been defined. The ability of the liver to produce some of its proteins during periods of infection is known, however, to depend on the permissive presence of glucocorticoid hormones.[17]

The increase in production of aldosterone seems to lag behind the increase in production of cortisol during periods of acute infections and then persists longer. Increases in aldosterone stimulate the intense retention of sodium and chloride by the kidney during episodes of acute infections.[13]

The adrenomedullary secretion of catecholamines may increase in severe infectious diseases.[60,171] High plasma epinephrine and norepinephrine values develop in patients with gram-negative sepsis and bacterial meningitis. The catecholamine response contributes significantly to the acceleration of gluconeogenesis during periods of infection.

CARBOHYDRATE-REGULATING HORMONES

Hormones that serve in the normal regulation of carbohydrate metabolism also participate in the host response to infection. In addition to the heightened secretion of the glucocorticoids, catecholamines, and growth hormone, the major pancreatic hormones insulin and glucagon circulate in increased concentrations in the plasma of patients with acute infectious diseases.[171] The combined effect of these hormonal actions is to accelerate the production of glucose within the liver and to stimulate the release of glucose from stored glycogen. These actions cause the glucose pool size to increase twofold or threefold to provide an important source of metabolizable energy during the early febrile periods of acute infections.

Intravenous glucose tolerance tests performed early in the course of febrile infections in young adult subjects[121,132] led to an exaggerated increase of concentrations of plasma insulin in magnitude and duration, to an appropriate decline in elevated fasting concentrations of plasma glucagon, and to a paradoxical stimulation of release of growth hormone. Extreme hyperinsulinism also was observed after glucose infusions were given to dogs with endotoxic shock.[21]

The modest increase in concentrations of fasting plasma insulin that occurs during periods of infection seems to account for an inhibition of ketogenesis and fat depot lipolysis, two responses that would be expected to occur because of concomitant starvation or semistarvation. The simultaneous combination of high fasting plasma glucagon and insulin values and their effects on the liver and peripheral fat depots and somatic tissues helps to explain the observed differences between the anorexia-induced semistarvation associated with infectious illnesses and the starvation caused by food deprivation.

THYROID HORMONES

Thyroid hormones do not seem to initiate or sustain the hypermetabolic response to fever. Nonetheless, thyroxine (T_4) and triiodothyronine (T_3) are deiodinated at accelerated rates within the body tissues, especially in the liver, during the early phases

of infections studied in humans and experimental animals.[40,162,173] This acceleration in the metabolism of peripheral thyroid hormones accounts for an early decline in serum protein-bound iodine values.[131] Only after an infectious illness has progressed for several days does the thyroid gland hormone output seem to increase. This increase in thyroid secretion persists into early convalescence so that for a time the production of thyroid hormones exceeds apparent body requirements. As a result, protein-bound iodine values in serum are increased in the convalescent period. This sequence of events produces a biphasic response pattern with an initial decrease and a late increase in concentrations of thyroid hormones. Serum concentrations of "reverse T_3" increase during febrile illnesses.[29] Because reverse T_3 has an apparent role in regulating the peripheral cellular actions of T_4 and T_3, its function during acute infectious illness remains to be elucidated.

In studies of patients with falciparum malaria infection, serum T_3 values declined abruptly, whereas serum T_4 values were stable or increased slightly.[162] The decline in serum T_3 concentrations was accompanied by reciprocal increases in reverse T_3. The slowing of T_4 turnover during periods of malaria may be caused by an impaired ability of hepatocytes to metabolize or deiodinate T_4. Hypothalamic suppression in early stages of malaria seems to result in a decreased release of thyroid-stimulating hormone from the anterior pituitary and a secondary decrease in T_4 and T_3 secretion from the thyroid gland. In patients with sepsis and septic shock, thyroid hormones (total and free T_3, T_4, and thyroid-stimulating hormone) are decreased and are associated with poor prognosis.[177]

PROCALCITONIN

Procalcitonin, discovered in the early 1960s, is a prohormone, the precursor of the hormone calcitonin. Multiple studies have shown that procalcitonin is involved in the pathogenesis of infections, and that it can be a useful diagnostic marker for infections such as bacterial pneumonia,[68] bacterial sepsis and septic shock, meningitis, infectious endocarditis, pancreatitis, and urinary tract infections.[30,100,146]

The role of calcitonin is unclear; most likely, it had an evolutionary role, and it currently is nonessential in humans.[30] Serum concentrations of procalcitonin and other precursors of mature calcitonin are elevated significantly during episodes of sepsis and other infectious and noninfectious causes of inflammation. Serum concentration of procalcitonin also is elevated in patients with malaria. The serum concentration of procalcitonin usually correlates with the severity of infection and with mortality.[30]

Secretion of procalcitonin is stimulated by IL-1β and tumor necrosis factor–α in patients with bacterial infections and by interferon-γ in patients with viral infections. The target tissues are lung, liver, kidney, adipose tissue, and muscle.

Several studies have suggested procalcitonin could be used as a marker for bacterial sepsis and could be used to differentiate infectious from noninfectious causes of inflammation. Although procalcitonin has been shown possibly to have greater specificity and sensitivity compared with C-reactive protein as a marker for bacterial infections, it should not be used without evaluation of other clinical and laboratory data in making therapeutic decisions because serum procalcitonin concentration may be normal in patients with sepsis or increased in some individuals with no clinical symptoms.[30]

CHAPTER 4

Interaction of Infection and Nutrition

Ralph D. Feigin ✪ Kathrin M. Bernt

The introduction to the World Health Organization (WHO) report on nutrition and infection, published in 1965, stated the following[343]:

> The concept that malnutrition could make man more susceptible to infectious disease and also alter the course and outcome of the resulting illness has long been current in the history of medicine and public health. Circumstantial evidence is plentiful, principally based on clinical experience. Well controlled observations have been few, and hence clear proof in support of the concept has been slow to accumulate. It has been much easier to demonstrate that infection is often directly responsible for lowering the state of nutrition.

The 2005 WHO report estimated that 1 million children would die before reaching 5 years of age. Infections, including acute respiratory infections (19%), diarrheal diseases (17%), neonatal infections (including neonatal tetanus) (14%), malaria (8%), measles (4%), and human immunodeficiency virus (HIV) (3%),[347] account for most of these deaths. More than half of these deaths are associated with malnutrition.[46] This problem has been called "silent genocide" by WHO officials and is one of the most underreported health problems facing humans.

The association of malnutrition with infection has been documented repeatedly. The devastating effects of long-term semistarvation in infants and small children were described by physicians trapped in the Jewish ghetto of Warsaw by the prolonged Nazi siege.[41,341] They observed gross and microscopic evidence of lymphoid tissue atrophy and the disappearance of delayed hypersensitivity reactions and acute inflammation, as well as the disappearance of clinical allergies, blood eosinophils, and gastric acid in severely malnourished children. More recent data also support the concept that malnutrition renders individuals more susceptible to acquisition of infection. Metabolic, biochemical, and clinical evidence has accumulated that strongly supports the concept that nutrition affects profoundly the progress of infection within the host. The normal host response to infection is described in detail in Chapter 3. Virtually every normal metabolic or endocrine function is altered in some manner by the presence of an infectious illness.

Traditionally, clinical inquiries into the interaction of nutrition and infection have focused on patients with protein-calorie malnutrition. Nutrition is a crucial determinant of immunocompetence and risk for development of illness. Young children with protein-calorie malnutrition exhibit increased morbidity and mortality rates largely secondary to infectious diseases.[59] These children often have isolated deficiencies of single nutrients, and single-nutrient deficiencies and protein-calorie malnutrition are associated with impaired immune responses.

In light of the well-recognized biologic synergism that exists between malnutrition and infection, it is noteworthy that malnutrition has not received comparable attention in child health and survival strategies. This oversight may occur partly because data on mortality gathered from health facilities in developing countries report only the proximate cause of death (usually infectious diseases), such that only the severe cases of nutritional deficiency are recorded as nutritional causes of death.[237]

PROTEIN-CALORIE MALNUTRITION

Protein-calorie malnutrition describes a wide range of clinical conditions resulting from mild to severe undernutrition. The

WHO estimated in 1996[345] that 174 million children younger than 5 years of age in the developing world were malnourished, as indicated by low weight for age, and that 230 million were stunted. Mild protein-calorie malnutrition may be detected primarily by poor growth because when energy consumption is low, amino acids from dietary protein are used for energy, rather than for protein synthesis and growth.

The conditions of kwashiorkor and marasmus represent manifestations of severe protein-calorie malnutrition. Both conditions result from consumption of a diet deficient in protein and calories, but infections also play an important role. Frequently, an acute infection is incriminated as the event precipitating kwashiorkor.[13,117,134,306] Marasmus is characterized by severe wasting, whereas kwashiorkor is manifested by the presence of edema. In marasmus, the prognosis on refeeding is good, whereas treatment of kwashiorkor is more difficult, and the prognosis often is poor.[122] African studies have estimated the mortality rate in kwashiorkor to be 25 to 31 percent.[112,188] In these children, infection was second only to electrolyte abnormalities as a leading cause of death. Inadequate diet, including insufficient intake of energy, protein, and micronutrients (e.g., iron, vitamins, and minerals), leads to weight loss, retarded growth rate, diminished immunity, and mucosal damage. These factors exacerbate the incidence, severity, and duration of infectious diseases, which lead to the loss of nutrients, malabsorption, altered metabolism, and loss of appetite that lead to further inadequate dietary intake.[35]

That various infectious diseases interfere with or influence the responses of host defense is well known. Metabolic responses of the host to infection include increased use of proteins, carbohydrates, lipids, minerals, electrolytes, trace elements, vitamins, and hormones. The normal host responds to infection by initiating an immediate and marked stimulus for protein anabolism. The chemical changes in protein-calorie malnutrition include low serum albumin, low concentrations of essential amino acids in serum, generalized aminoaciduria, lower glycosylated hemoglobin levels, and decreased activity of many enzymes. Reduction in the activity of diphosphopyridine nucleotide, cytochrome *c* reductase, plasma esterase, and leukocyte pyruvate kinase has been documented.

A patient with kwashiorkor, depleted of amino acids and protein, cannot initiate the necessary anabolic response when challenged by infection, which seems to alter the capacity of the host to resist the debilitating effects of infection. Decreased activity of the various enzymes that help to resist infection and the inability to synthesize new enzymes necessary for energy-producing reactions in the body impose an additional burden on an individual with protein-calorie malnutrition. If the diet does not replace calories and protein sufficiently, the individual becomes progressively depleted with each episode of infection. Repeated episodes of infection may be a major factor in precipitating frank kwashiorkor in children on a borderline diet with regard to protein and calories. In many instances, whether the malnutrition or the infection was the event that initiated the ultimate deterioration of the patient cannot be determined.

Postmortem studies have confirmed that acute bacterial infections are the major cause of death in patients with severe protein-calorie malnutrition. Septicemia is the most dreaded infectious complication of protein-calorie malnutrition and has been reported in 31 percent of hospitalized patients. Gram-negative enteric bacilli are the most common cause; less frequent agents include *Haemophilus influenzae*, *Shigella flexneri*, *Pseudomonas aeruginosa*, *Corynebacterium diphtheriae*, *Streptococcus* spp., *Staphylococcus aureus*, and *Neisseria* spp. Tuberculosis occurs more frequently, is more virulent, spreads faster, and reinfects more readily individuals with protein-calorie malnutrition. The rate of urinary tract infections in malnourished children is increased significantly, with gram-negative enteric bacilli encountered most frequently. Diarrhea is a common occurrence in malnourished children, the most common infectious cause being enteric pathogens, such as *Salmonella enteritidis*, enteropathogenic *Escherichia coli*, and nontyphi *Salmonella* spp.[286] The occurrence of *Pneumocystis carinii* infection in malnourished individuals also has been highlighted.[134] Additionally, viral diseases, such as measles, varicella, hepatitis, and herpes simplex, are prevalent in patients with protein-calorie malnutrition.[13,117,306]

Almost all cases of severe protein-calorie malnutrition exhibit biochemical or clinical evidence of micronutrient deficiencies, such as vitamin A deficiency or iron-deficiency anemia. Little evidence exists, however, that any one micronutrient deficiency is the main cause of protein-calorie malnutrition or by itself is responsible for the edema of kwashiorkor.

Although protein is an essential and important nutrient, protein-calorie malnutrition is associated more often with deficient food intake than with protein intake. When commonly consumed cereal-based diets meet caloric needs, they *usually* meet protein needs, especially if the diet also provides modest amounts of legumes and vegetables. Control and prevention of protein-calorie malnutrition should focus on improvements in the quantity and quality of food consumed, immunization, provision of oral rehydration therapy for diarrhea, early treatment of common diseases, regular deworming, and attention given to the underlying causes of protein-calorie malnutrition, such as poverty and inequity.[173]

IN UTERO EFFECTS OF MALNUTRITION

The medical literature reports widespread occurrence of infant low birth weight throughout the nations of the world in which malnutrition is prevalent. Hytten,[137] discussing the relationship of maternal diet to the size of the infant's body, called attention to the fact that dietary status in pregnancy is only part of the broad environmental picture. He emphasized that the mother's nutrition throughout life may be as important as nutrition during pregnancy in ensuring the birth of an infant of normal size. A well-fed mother deprived of food during pregnancy may have been able to lay down a sufficient energy reserve to protect the fetus during intrauterine life despite deficiencies in day-to-day intake. Short maternal stature, which is influenced by biosocial factors, large family size, malnutrition, and chronic disease, frequently becomes intergenerational. Women who were growth retarded as newborns tend to give birth to infants who also are growth retarded, which may be a reflection of poor maternal nutritional status during childhood and adolescence.[183]

Severe nutritional deprivation during pregnancy may affect the size and vitality of the fetus. Abrams and Laros[1] showed that underweight women and women with poor weight gain during pregnancy had an increased risk for delivering an infant weighing less than 2500 g.

Maternal malnutrition results in impaired placental function and chronic vascular insufficiency, which leads to symmetric growth retardation. As nutritional deprivation becomes more severe, first weight, then length, and finally brain mass are affected. Acute placental insufficiency results in asymmetric growth retardation. When the nutritional insult occurs late in pregnancy, when length velocity is declining and weight velocity is increasing, the amount of muscle, fat, and hepatic glycogen is affected adversely. This type of growth retardation is seen in postmature infants; in these infants, placental function no longer is adequate to meet fetal needs, and the fetus must mobilize its own fat and carbohydrate stores.[183]

Maternal malnutrition before or during pregnancy and maternal infection during pregnancy may act alone or in concert to influence the size, gestational age at birth, and vitality of the fetus. Infection during pregnancy occurs commonly in the areas of the world where malnutrition is prevalent. In a prospective study in four Guatemalan villages, 12 percent of village women who were tested serologically throughout pregnancy for cytomegalovirus, herpes simplex, rubella, syphilis, and *Toxoplasma* spp. infection showed seroconversion during pregnancy to one of these agents.[144] The aforementioned infections, varicella, HIV, malaria, and trypanosomiasis are associated with intrauterine growth retardation.[32]

Infant size at birth correlates to a great extent with neonatal survival. Village infants who are small for gestational age at birth have a greater risk for developing subsequent malnutrition and infection than do term infants with an adequate birth weight. Infants with low birth weight (predominantly small for gestational age) have higher rates of infection with *Shigella* spp., *Entamoeba histolytica*, and *Giardia* spp. in the first month of life and exhibit higher occurrences of diarrhea and oral candidiasis in the first 6 months than do term infants.

A case-control study in rural Africa suggests this susceptibility to infectious disease extends far beyond the first 6 months of life.[212] As late as adolescence, increased infectious mortality rates were seen in individuals who had been born during the "hungry season" compared with those born during the "harvest season." These findings suggest that nutritionally mediated growth retardation may impair development of immune function permanently. Animal models highlight these long-term effects of intrauterine malnutrition by showing impaired T-cell–dependent immune responses in the first-generation and second-generation offspring of animals subjected to prenatal nutritional deprivation.[54]

Even if caloric requirements are met during pregnancy, micronutrient deficiencies have been linked to adverse pregnancy outcomes, and the worldwide prevalence of these deficiencies varies greatly.[280] In particular, iodine and folic acid are two micronutrients with proven roles in embryonic/fetal development. Deficiencies are endemic in certain parts of the world and may have devastating consequences for affected infants. More recently, zinc deficiency during pregnancy has been implicated in postnatal immune dysfunction and increased risk for development of infections.[338]

Even in industrialized countries, the consequences of low birth weight can be extensive. Providing enteral nourishment to very-low-birth-weight infants can be difficult because of systemic illnesses, such as respiratory distress syndrome and gastrointestinal tract immaturity. Many of these infants ultimately develop clinical and biochemical signs of malnutrition during the early postnatal period. This malnutrition may compromise an already inadequate immune system and alter host susceptibility to infection. Reductions in spleen, thymus, and body weights were noted in rats after experiencing intrauterine protein-calorie deprivation. After nutritional restoration was achieved in these animals, thymic tissue remained depleted of lymphocytes and significantly reduced in weight.

Newborn infants may develop similar long-term immunologic defects after in utero or early postnatal malnutrition. Low-birth-weight infants born to malnourished mothers have decreased thymus and spleen size and diminished cell-mediated immune responses, reduced transfer of maternal-fetal IgG, and decreased number of T lymphocytes. Infants with fetal growth retardation have shown diminished neutrophil chemotaxis, abnormal nitroblue tetrazolium oxidative reduction, and deficient microbicidal activity.[55,121] After birth, nutritional deprivation may create the environment for frequent episodes of infection. Mechanisms responsible for the increased number and severity of infections in the malnourished host are detailed subsequently.

BREAST-FEEDING

The nutritional, immunologic, psychosocial, and child-spacing benefits of breast-feeding are recognized universally. According to numerous reports, breast-fed infants seem to be less susceptible than are bottle-fed infants to certain infections. The protective effect is most evident for upper respiratory infections, otitis media, and gastroenteritis and has been studied most extensively in developing countries; the impact of breast-feeding on other infections and in more developed countries also is under investigation. Many studies are investigating the specific agents present in human milk that may be important in imparting protection to the infant. In addition to its anti-infective properties, breast milk has been shown to exhibit other advantages over infant formula; however, despite its many benefits, in certain situations, breast-feeding is contraindicated.

The antimicrobial system in human milk constitutes a complex group of biochemical agents that differ widely in structure but have a common effect at the mucosa. These agents include lysozyme, lactoperoxidase, lactoferrin, interferon, complement components, immunoglobulins, leukocytes, lipids, and retinol. These anti-infective factors transmitted by breast milk protect primarily by noninflammatory mechanisms and act to reduce the risk for development of mucosal infection in the gut. Proteins present in breast milk are thought to escape digestion in young infants as a result of low acid, reduced protease activity in gastric and pancreatic secretions, and the presence of protease inhibitors in breast milk.

The component most important to the newborn may be secretory IgA, which is found in high concentrations in colostrum and early milk. Secretory IgA constitutes more than 90 percent of the immunoglobulins in human milk and is formed by intricate processes that may be regulated by cytokines and hormones produced late in pregnancy or during lactation. During this process, B cells producing IgA against respiratory and gastrointestinal infectious agents migrate to the mammary gland in a higher proportion than their percentage of the total IgA-secreting B-cell pool. IgA possesses virus-neutralizing and antibacterial properties and is capable of activating the alternate complement pathway, providing local protection in the gastrointestinal tract.

Lactoferrin is an iron-binding glycoprotein that competes with siderophilic bacteria for ferric iron and interferes with the multiplication of organisms. Lactoferrin also may have a positive influence on cell growth and a negative effect on inflammation. Lysozyme is found in high concentrations in external secretions, including human milk, and lysis-susceptible bacteria by hydrolyzing β-1,4 linkages between *N*-acetylmuramic acid and 2-acetylamino-2-deoxy-D-glucose residues in cell walls. Lysozyme is resistant to digestion by trypsin and denaturation caused by acid. Fibronectin is a high-molecular-weight protein found in breast milk that facilitates the uptake of particulates by phagocytic cells.

Human milk also is rich in carbohydrate moieties that act as receptor homologues and inhibit attachment of pathogenic bacteria, such as *Vibrio cholerae*, *Streptococcus pneumoniae*, *H. influenzae*, and *E. coli*, onto epithelial cells.[72] Certain oligosaccharides in human milk promote the growth of *Bifidobacterium* spp. and lactobacilli in the lower intestinal tract, which produce acetic acid and inhibit the multiplication of bacterial pathogens such as *E. coli* and *Salmonella* and *Shigella* spp. Additionally, lactadherin, a component of human milk, has been found to bind specifically to rotavirus and inhibit its replication in vitro.[222] A study of rotavirus infection in Nicaraguan children supports this finding by showing an association between a longer duration of breast-feeding and decreased symptoms with rotavirus infection.[92]

A plethora of cytokines have been isolated from human milk, many in concentrations exceeding maternal serum, which sug-

gests an active transport mechanism. Viable leukocytes are found in human milk and have been proposed to play a role in protection against infections and immune modulation.[33]

Epidemiologic studies of the association between infections and breast-feeding have come under great scrutiny. Strong evidence has shown that in developing countries, infant morbidity is reduced by breast-feeding. A pooled analysis[348] of studies performed in the Philippines, Brazil, and Pakistan indicates that breast-feeding offers protection against the risks of diarrhea and of mortality from acute respiratory infection. The greatest protection is offered early in infancy and then steadily declines. Multiple small studies from Mexico,[181,330] India,[335] Belarus (diarrhea only; no protective effect against respiratory infections),[163] Haiti,[157] and Nicaragua[92] confirm these results. In a study from Nicaragua, protection against *Giardia* infections depended on the maternal antibody status: breast-fed infants of nonimmune mothers had a higher risk of developing giardiasis and experienced more severe symptoms compared with breast-fed infants of immune mothers.[310]

Many researchers consider that infants in more developed countries have similar benefits.[56,69,233,333,349] In a longitudinal analysis of infants in the United States, the risk for developing otitis media or diarrhea increased as the amount of breast milk received decreased.[265] The effect against otitis media may be the result of transmission of humoral or cellular immune components to the infant or the result of positioning during bottle feeding, which may predispose the infant to otitis media. Data showing general protection against infection are supplemented by studies that investigate the effects of breast milk on specific pathologic organisms. Formula-fed infants are more likely than are breast-fed infants to have colonization[130] or invasive disease[287] caused by *H. influenzae* and a higher risk for acquiring invasive pneumococcal disease.[176] Other studies have shown decreased risk for developing respiratory illnesses,[38,223] meningococcal disease,[210] urinary tract infections,[189] salmonellosis,[255] and human herpesvirus-7[172] infection with breast-feeding.

Despite studies such as these, the evidence in highly developed countries remains controversial. Bauchner and associates[21] presented a meta-analysis of the association between breast-feeding and infections in industrialized countries. Of 20 studies in the meta-analysis, only 6 met strict methodologic standards. These investigators concluded that the evidence supports only a minimally protective effect of breast-feeding. In 1990, a group from Denmark reported their results after following 500 infants prospectively for the first year of life.[258] They were unable to document a protective effect of breast-feeding against infectious illness. A case-control study of 13,224 mother-infant pairs, the largest study published to date, found no measurable association between breast-feeding and risk of neonatal respiratory infections in boys and only a small protective effect in girls.[290] These differences highlight the importance of environmental factors, such as socioeconomic status, parental education, exposure in daycare centers, and parental smoking, to the incidence of infectious disease in infants. Nonetheless, a report of the Department of Health and Human Services Office on Women's Health[83] recommends exclusive breast-feeding except in special situations in which contraindications to breast-feeding exist.

Breast-feeding has distinct advantages over bottle feeding in situations in which infection is not an important factor. Numerous studies in various parts of the world have investigated the possible prevention of atopic or allergic diseases by breast-feeding. Three more recent meta-analyses concluded that there was a lower incidence of asthma[111] and allergic rhinitis[205] in breast-fed infants and a lower incidence of eczema in breast-fed versus formula-fed infants with a family history of atopy.[110] A study analyzing cytokine profiles in formula-fed or breast-fed infants with respiratory syncytial virus (RSV) bronchiolitis suggested that the protective effect of breast milk against infections together with its potential immune-modulatory properties act together to protect infants from more severe RSV disease.[252]

The effect of breast-feeding on the prevention of atopic diseases has not been unchallenged—a cohort study from Brazil found an increased risk for development of asthma associated with being breast-fed for 9 months or longer.[71] The data currently available point toward a protective effect of breast-feeding, however, during the first 6 months of life on allergic or atopic diseases. Although evidence is inconclusive, some studies have implied that breast-feeding provides protection against sudden infant death syndrome, obesity, type 1 and type 2 diabetes, hypercholesterolemia, arteriosclerosis, celiac disease, and other metabolic disorders, and enhances neurodevelopment.[8,149]

Colostrum and early milk contain hormones and growth factors, such as epidermal growth factor, prostaglandins, insulin, and thyroid hormones, that may benefit children whose gut integrity has been compromised by malnutrition and gastrointestinal disease.[242] Whether these components are present in amounts sufficient to have any physiologic effect after the first few months of lactation is unclear, however. Breast milk also contains the digestive enzymes amylase, bile salt–stimulated lipase, and bile salt–stimulated esterase in measurable quantities after 6 months of lactation. Children whose digestive functions are compromised by malnutrition or small bowel overgrowth may benefit from the addition of breast milk enzymes. The combined effects of protection against infections, immune modulation, and maintenance of the integrity and promotion of growth of the intestinal mucosa may work together to explain a much decreased incidence of sepsis and necrotizing enterocolitis in a cohort study of Norwegian extremely-low-birth-weight infants in whom early enteral feeding with human milk was established.[253]

In certain circumstances, breast-feeding is contraindicated. The most common of these situations is maternal infection with HIV, a topic that has been the focus of much recent research. More recent studies estimate that one third to one half of mother-to-child transmissions of HIV occur through breast milk.[164,314] A randomized clinical trial of 401 mother-infant pairs in Kenya[218] showed that the risk for transmission in breast milk was 16.2 percent and that the use of formula feeding prevented 44 percent of infant infections. Risk for transmission is approximately 14 percent in chronic maternal HIV infection and increases to 29 percent in acute infection.

Other factors that may increase transmission of HIV through breast milk include longer duration of breast-feeding, mastitis in the mother, lower maternal CD4 counts, and mixed feedings (i.e., infants fed breast milk and formula).[314] The mechanism by which mixed feedings increase transmission is currently under debate. Some researchers theorize that a subclinical mastitis caused by milk stasis is responsible, whereas others hypothesize that an inflammatory or immunologic response in the infant gut may play a role. Currently, breast-feeding by HIV-infected women is contraindicated in areas where safe alternative sources of infant nutrition exist. Some researchers argue that in areas where environmental contamination precludes the safe use of other infant feeding regimens, exclusive breast-feeding should be promoted. A more recent study conducted in Kenya showed, however, that with access to clean water, formula feeding can decrease HIV transmission rates significantly without substantially increasing morbidity and mortality rates from diarrhea and pneumonia even in resource-poor settings.[194]

Breast-feeding also is contraindicated in mothers who are sputum-positive for *Mycobacterium tuberculosis* or who are carriers of hepatitis B virus. Breast milk has been implicated in the transmission of rubella, cholera, Q fever, human T-cell lymphotropic virus 1, and cytomegalovirus in selected individuals. Human milk also can transmit environmental toxins, such as polychlorinated biphenyl compounds and dichlorodiphenyltrichloroethane. Toxic side effects can occur in nursing infants secondary to passive

excretion of medicines taken by the mother.[88,149] On balance, breast milk is preferable except in unusual circumstances and helps diminish the role of infection during infancy.

IMMUNE SYSTEM AND MALNOURISHED HOST

MUCOSAL IMMUNITY

The first barrier to potential pathogens is the physical integrity of the skin and mucous membranes. This barrier involves single or multiple layers of cells, mechanical clearance mechanisms such as the cilia of the respiratory epithelium, complex carbohydrate structures in the intestinal epithelium, lubricants such as sebum or mucus, and soluble factors such as antibodies and lysozyme.

A "mucosal immune system" has been described in the gut, where tissue resident cells of the monocyte/macrophage lineage and specialized enterocytes act as antigen-presenting cells to lymphocytes. Primed lymphocytes migrate to the Peyer patches, where they proliferate and differentiate. A subset also enters the circulation to reach central immune organs, such as the spleen, bone marrow, and possibly thymus, where the lymphocytes undergo further clonal expansion. Eventually, they become IgA-producing cells that re-enter the circulation and by a selective homing process migrate to the mucosa of the gut and to salivary, lacrimal, bronchial, and lactating mammary glands.[243]

The physical integrity of the cell layers of skin or mucous membranes is affected in numerous nutritional deficiencies. Examples include the metaplastic hyperkeratosis caused by avitaminosis A; the dermatitis, cheilitis, and angular stomatitis from iron, riboflavin, and pyridoxine deficiencies; the mucosal atrophy and dermatosis of pellagra; the acrodermatitis enteropathica associated with zinc deficiency; the spongy gums and subcutaneous hemorrhages of scurvy; and the atrophy of skin and gastrointestinal mucosa of severe protein deficiency.

The carbohydrate composition of intestinal epithelium has been shown to vary according to dietary influences, and a decreased risk for gastrointestinal infections in breast-fed infants is thought to be due partly to decreased carbohydrate receptor sites for intestinal pathogens. Severe protein malnutrition and xerophthalmia have been shown to suppress significantly the secretion of lysozyme in the tears of children.[344] Diminished secretory IgA has been noted in malnutrition, which may increase host susceptibility to infection by permitting increased penetration of infectious agents into the circulation.[292,301] Malnutrition also affects other parts of the "mucosal immune system": Malnourished children have a reduced number of lymphocytes and plasma cells in the interstitial space, and the migration of lymphoblasts from the mesentery is decreased.[63]

HUMORAL IMMUNITY

Numerous studies of B-cell function have been done in patients with protein-calorie malnutrition, albeit with conflicting results. The total number of circulating B cells has been reported to be normal or increased,[312] or diminished.[217,248] Serum immunoglobulin concentrations may be normal or elevated.[293] Cohen and Hansen[65] showed that children with protein-calorie malnutrition and infection synthesized gamma-globulin at three times the rate of uninfected malnourished individuals, documenting the fact that synthesis of gamma-globulin was not rate-limited in malnutrition at the expense of other protein synthesis, such as that of albumin. In protein-calorie malnutrition, antibody affinity is decreased, which may explain the higher frequency of antigen-antibody complexes found in malnourished patients.

In protein-calorie malnutrition, the most dramatic change in humoral immunity concerns IgE. Serum IgE concentrations in healthy, well-nourished children are extremely low. Significant elevations of serum IgE in malnourished children have been reported in the absence of allergy or parasitic infections, possibly caused by an imbalance in T-lymphocyte regulation of IgE-producing B-cell function. The defect in cell-mediated immunity in patients with protein-calorie malnutrition could initiate an exaggerated IgE response during infections with respiratory pathogens, such as RSV or parainfluenza virus, and increase the risk for developing severe bronchiolitis.[153]

Antibody production after immunization with antigen is the best functional measure of humoral immunity. Much of the data on specific serum antibody responses in human malnutrition are conflicting. The serum antibody response to many protein antigens, such as tetanus or diphtheria toxoid, is well preserved. The responses to immunization with viral antigens vary. Responses to yellow fever vaccine, hepatitis, and killed influenza A have been reported to be impaired in protein-calorie malnutrition. Chronic malnutrition also is associated with a poor response to measles vaccine.[331] A diminished antibody response to polysaccharide antigens, such as killed typhoid vaccine (polysaccharide typhoid O antigen), is seen in severe protein-calorie malnutrition. The degree of malnutrition may play a role; mild protein-calorie malnutrition had no impact on the response to a meningococcal group C polysaccharide vaccine.[120]

A diminished antibody response to polysaccharide antigens may be caused by a selective impact on the IgG subclasses that contain antibody to polysaccharide antigens, IgG2 and IgG4.[153] Studies in rats deficient in vitamin A support this hypothesis[156]; however, total serum levels and IgG subclasses in 109 malnourished children from Ghana were found to be normal.[248] Further studies investigating the relationship between IgG subclasses and protein-calorie malnutrition are needed.

CELLULAR IMMUNITY

In patients with malnutrition, the cellular immune system (T-cell system) seems to be the component of the immune system affected most significantly. Impairments have been shown at nearly all levels of T-cell development and function. Histological studies of lymphoid tissues show severe depletion of T-cell areas in malnourished hosts.[197] The total number of circulating T cells, particularly the helper CD4 subset, is decreased.[217] Little change occurs in the number of suppressor T cells; the helper-to-suppressor ratio is decreased significantly.[62,234] The levels of circulating immature ($CD1a^+$, or $CD4^-CD8^-$ "null cell") T cells have been found to be increased in several studies, pointing toward a defect in maturation.[234] Indirect evidence, such as decreased deoxynucleotide transferase activity and increased adenosine deaminase in the serum of malnourished children, also suggests a defect in T-cell maturation.[206]

T-cell function in malnourished hosts seems to be impaired as well. Several studies have shown decreased responses to mitogenic stimuli and decreased production of cytokine, particularly type 1 cytokines (interleukin-2 [IL-2], interferon-γ).[89,251,266] Finally, the level of circulating memory T cells ($CD45RO^+$) has been found to be decreased in malnourished children.[216]

The observed abnormalities in T-cell numbers and function are clinically reflected in decreased responses to skin testing for antigens that normally induce delayed hypersensitivity responses. Chandra[60] reported that malnourished children had a decreased ability to respond to tuberculin antigen after receiving bacille Calmette-Guérin (BCG) immunization, and, in most cases, they could not be sensitized to dinitrochlorobenzene. Smythe and associates[293] reported similar findings in malnourished children and noted lymphocyte depletion in the thymus glands of 118 children with kwashiorkor or marasmus at necropsy. Bhaskaram and coworkers[36] showed that malnutrition did not influence the

ability of BCG-vaccinated children to localize tuberculosis infection; however, malnourished children who did not receive the vaccine had a significantly greater incidence of systemic tuberculosis infection than did BCG-vaccinated malnourished children. Another study of 69 children with protein-calorie malnutrition and 20 healthy controls showed an association between all levels of protein-calorie malnutrition and decreased absolute lymphocyte count, but a decreased response to tuberculin antigen was found only in children with moderate or severe malnutrition.[206]

A few contradicting studies regarding the influence of malnutrition on cellular immunity have been published. McFarlane[195] reported that skin transplants in malnourished rats were rejected, suggesting that all aspects of cell-mediated immunity may not be impaired simultaneously or to the same extent. Good and colleagues[115] have evaluated many aspects of the effect of nutritional status (including chronic protein deficiency) on cellular immune functions, including tumor immunity in animal models. Their results suggest an enhancement of cell-mediated immunity in chronic protein deficiency in the absence of infection. The mechanism for this enhancement and the implications of these findings in humans are unclear.

Most significant is the clinical and epidemiologic evidence for impaired cellular immunity in malnutrition. Numerous studies show that malnourished children are much more susceptible to tuberculosis, measles, disseminated herpes simplex, hepatitis, *P. carinii*, and many other diseases for which prevention requires optimal function of the cellular immune system.

THYMUS

Dourov[85] reviewed the morphologic response of the thymus in malnutrition. In 1845, Simon recognized that the thymus was an "early critical barometer of nutrition." In protein-calorie malnutrition, the severe nutritional defect leads to thymic atrophy and fibrotic changes, with the cortex affected sooner than is the medulla. In contrast to atrophy of liver, kidney, or cardiac muscle, thymic atrophy is characterized more by a loss of cells than by a decrease in cell size. Histologically, corticomedullary differentiation is lost, and fewer lymphoid cells are present. Hassall bodies are enlarged, degenerated, and occasionally calcified. These changes are noted after 5 days of starvation and can be reversed after 6 days of refeeding. In contrast to other organs, thymic tissue does not regain normal size after refeeding. Histopathologic studies on the thymuses of 19 malnourished children at necropsy showed that the degree of lymphocyte depletion correlates with an increase in the extracellular matrix.[186]

In addition to substrate deficiency, stress-related factors may play a role in thymic atrophy. Generally, stress-induced immunosuppression seems to be adrenal-mediated. The stress of malnutrition has been associated with an increase of serum glucocorticoids, a lower binding capacity for steroids, and an increase in their metabolically active forms. Schlesinger and associates[267] found elevated levels of norepinephrine in the thymuses of rats with protein-calorie malnutrition that correlated with decreased immune response.

Functional changes resulting from thymic atrophy also are under investigation. Thymic factors, such as thymosin and thymopoietin, have been incubated with isolated T cells from malnourished children, resulting in a normalization of the maturational characteristics of the lymphocytes.[138,227,234] These observations were confirmed when the results were controlled for infection and zinc content.[140]

The nutritional influence on early thymic development may have lifelong consequences. In rural Gambia, being born during the "hungry" season (July through December) predicts increased infection-related adult mortality. Serial sonographic measurements of thymic indices in children born during the "hungry" season were lower than the measurements in children born during the harvest season, and measurements in all children regardless of birth month were lower when assessed during "hungry" versus "harvest" months. This difference persisted even when adjusted for current weight and infectious markers, pointing toward severe long-term effects of starvation on thymic development and function.[67]

MEDIATORS (CYTOKINES, CHEMOKINES, AND COMPLEMENT SYSTEM)

Data are conflicting with regard to circulating cytokine levels and malnutrition. Normal, decreased, and increased tumor necrosis factor–α (TNF-α) production all have been reported in malnourished children.[17,89] In several studies, a T-helper cell type 1 (T_H1) to T_H2 type shift in cytokine profiles has been reported, with increased levels of IL-4 and IL-10 and decreased levels of IL-2 and interferon-γ.[89,251] These results suggest a diminished ability of malnourished children to mount a T_H1 response important for the elimination of pathogens. The observed skewing of the serum cytokine profile and the reported increased IgE production and increased severity of RSV bronchiolitis in malnourished children also point toward inappropriately hyperactive T_H2 responses and, consequently, more severe tissue damage than in children with intact nutritional status. The available data on cytokine profiles in malnourished children should be interpreted with caution because many confounders, such as chronic infections and living in extremely stressful environments, are likely to coexist in this population and have been shown to influence cytokine profiles.

The proteins of the complement system seem to be sensitive to nutritional stress.[62] Seth and Chandra[278] noted low serum complement in patients with protein-calorie malnutrition. Sirisinha and associates[291] also reported low serum concentrations of all complement components except C4 in malnourished children. Children with kwashiorkor had levels lower than those of children with marasmus. These data are consistent with more recent animal studies that show significantly decreased levels of C1, C2, C3, and C4 in malnourished rats compared with controls.[260]

The cause of the hypocomplementemia is unclear. Electrophoretically distinct C3 breakdown products have been detected in one study, as have increased titers of immunocoagglutinin, an antibody directed to the C423b complex of activated complement. Alternatively, activation of the complement pathway may be a consequence of infection. Complement serum concentrations also may decrease in the malnourished individual as a result of a consumption complementopathy, or a decreased ability to synthesize complement de novo. Complement-derived chemotactic factors and opsonic factors also are depressed. These functional deficits may contribute to an enhanced susceptibility to infection.

Despite these changes, complement may be less susceptible to nutritional stress than other aspects of the immune system. Complement activity seems to be preserved better in patients with severe protein-calorie malnutrition than cell-mediated immunity and it recovers more rapidly after refeeding.[259,261]

PHAGOCYTOSIS

Phagocyte function can be divided into three main phases: (1) adherence and chemotaxis; (2) recognition, opsonization, and engulfment; and (3) postphagocytic events, which include formation of phagocytic vacuoles or phagosomes followed by fusion of lysosomes with phagosomes and degranulation of lysosomal enzymes, microbicidal activity, and associated metabolic changes.[122] Phagocytosis and intracellular microbicidal activity of neutrophils and macrophages depend on various components of the comple-

ment system, antibodies against surface microbial antigens, and possibly acute-phase reactants, such as C-reactive protein. Appropriate phagocytic function also requires adequate pool sizes of neutrophils and mononuclear phagocytes at inflammatory sites and adequate capacity of the bone marrow to produce and mobilize these cells. More recent research suggests that an association exists between low neutrophil count and decreased weight-for-height measurements in children.[321] Protein deprivation in mice results in a marked decrease in phagocyte precursor cell pool sizes as measured colony-forming units in the spleen.[122]

In malnourished individuals, defects in phagocytosis and killing have been identified, but these deficits are subtle. Research has shown that neutrophils from malnourished children have enhanced baseline adhesion; however, after being stimulated with chemotactic factors, the adherence response is decreased, and neutrophil chemotaxis is diminished. These abnormalities reverse with nutritional recovery.[10,122] Schopfer and Douglas[269] investigated the neutrophil function of 46 children with kwashiorkor. Chemotactic response was reduced at early intervals (30, 60, and 120 minutes) and reached values achieved by controls only after 180 minutes, which suggests an early migration defect.

Studies of opsonization and phagocytosis of cells in malnourished animals and humans indicate that neutrophil membrane receptors for Fc-IgG and complement (C3b) are intact. Serum from malnourished patients is deficient in opsonic activity, however, and kinetic studies in malnourished children suggest that the defect in opsonization is related to complement deficiencies.[121] An indirect measure of opsonic activity is fibronectin, and reduced levels of fibronectin have been reported in starvation in rats and in protein-calorie malnutrition in infants. The levels of fibronectin increase to greater than normal values after nutritional rehabilitation.[121]

No evidence has been found for any abnormalities in lysosomal fusion or degranulation in leukocytes of malnourished hosts. Nonetheless, intracellular killing seems to be impaired in malnourished states. Schopfer and Douglas[269] noted that neutrophils from children with kwashiorkor did not kill *Candida albicans* intracellularly as well as did control cells. Seth and Chandra[278] reported impaired intracellular bactericidal killing in patients with kwashiorkor. De la Fuente and Munoz[77] showed a decrease in nitroblue tetrazolium reduction in stimulated and nonstimulated macrophages from mice with protein-calorie malnutrition. Because the nitroblue tetrazolium dye reduction test in nonstimulated phagocytes indirectly measures intracellular hexose monophosphate shunt activity, protein-calorie malnutrition may interfere with this metabolic pathway. Studies from children with kwashiorkor show diminished neutrophil iodination during phagocytosis,[121] suggesting an abnormality in the myeloperoxidase-halide–mediated system.

SINGLE NUTRIENTS

Many barriers exist to analyzing the clinical significance of single nutrients in maintaining normal immune function. First, nourishment is a combination event, and nutrient-nutrient interaction can be of major consequence. Competition for transport may affect absorption or excretion in intracellular and extracellular environments. Second, a hierarchy exists for some nutrient requirements. If an element subserves several functions, as does iron, the prerequisite amount may vary with the function. Third, experimental animal models do not always allow for extrapolation to human medicine. Most species, with the notable exception of the guinea pig, make indigenous vitamin C, and no animal model exists for studying cobalamin deficiency. Finally, infection can affect body stores of essential nutrients. Chandra[58] suggested a framework for evaluation of micronutrients. Alterations in immune responses occur early in the course of reduced intake, and these alterations may predict the risk for developing infection and mortality.[324] In the case of many nutrients, excessive intake also is associated with immune abnormalities.

IRON

Iron deficiency is the most common nutritional deficiency in the world and results in systemic disease involving all cell systems. The role of iron in chronic and acute infection is complex. Experimental and clinical studies have been published that support an impaired immune function in iron deficiency on one hand and a protective role of low iron states against certain infections on the other.[228]

Experimental data suggesting impaired immune function in iron deficiency exist for almost any part of the immune system. Severely iron-deficient rats have an increased number of phagocytes in whole blood, but granulocytic activity as measured by nitroblue tetrazolium dye reduction is decreased significantly.[284] The rate at which granulocytes killed staphylococci was decreased in 819 iron-deficient patients studied by Joynson and coworkers.[147] Retention of iron in the reticuloendothelial system may enable macrophages to detoxify bacterial toxins. Iron in monocytes may enhance antibacterial activity of these cells.[144] Iron also may activate lysosomal hydrolases.[141] Cellular development of lymphoid tissues has been shown to be diminished in iron deficiency; lymphoid tissue from iron-deficient rats shows reduced cellularity, decreased lymphopoiesis, and deranged histology.[284]

In humans with iron deficiency, reduced numbers of circulating T cells and decreased in vitro lymphocyte response to mitogens have been reported.[81] The bactericidal capacity of leukocytes also is reduced, which may be caused by deficient function of iron-dependent myeloperoxidase and cytochrome enzymes.[60] Natural killer cell activity is impaired significantly in moderate and severe iron deficiency compared with controls. In iron-deficient patients studied by Macdougall and coworkers,[184] impaired leukocyte responsiveness, decreased bactericidal capacity, increased IgA, and increased C3 concentrations were observed. Restoration of normal bactericidal function occured before any increase in hemoglobin concentrations was noted, suggesting that tissue iron depletion rather than anemia was an etiologic factor in depressing bactericidal function. Clinically, impairment of delayed cutaneous hypersensitivity responses are found in humans with iron deficiency.[81]

Humoral immunity also may be affected by iron deficiency. In studies in iron-deficient rats, baseline plasma IgG levels were normal, and IgM was low only in severe iron deficiency, but rates of de novo synthesis of IgM and IgG after stimulation were found to be decreased significantly. Although circulating plasma immunoglobulin may be normal in iron-deficiency anemia, iron deficiency may result in diminished antibody production. Cytokine and chemokine production is impaired in individuals with iron deficiency, as has been shown for IL-1 and migration inhibitory factor.[147,269]

Taken together, these studies imply that appropriate iron stores and availability of iron within cells, particularly in selected tissue, is beneficial to the host. Numerous studies suggest, however, that free iron may be detrimental to the host during bacterial infection. Iron may stimulate the growth of the pathogen with which the host is infected, may inhibit bactericidal proteins, and may enhance bacterial metabolism.[337] The percentage of saturation of transferrin with iron in plasma correlates directly with the ability of the sera to support the growth of various microorganisms. Iron in fluids such as plasma, milk, nasal secretions, and saliva is to a greater or lesser extent unavailable to many bacteria and fungi because of the presence of the iron-binding proteins transferrin and lactoferrin.[174,191] Microorganisms produce iron chelators termed *siderophores*. If the supply of

iron in the host is so high that the physiologic processes to withhold it are exceeded, the invading microbes can obtain iron for growth.[284]

The administration of iron to animals by the intravenous, intramuscular, or intraperitoneal route reduces the LD_{50} for *P. aeruginosa*, *Salmonella typhosa*, streptococci, *Klebsiella pneumoniae*, *Salmonella typhimurium*, and *Listeria monocytogenes*.[337] Similarly, the administration of iron intramuscularly to children with kwashiorkor has resulted in overwhelming infection and death. Clinicians in these cases concluded that iron therapy should be deferred until transferrin synthesis was restored by protein nutrition. No evidence exists, however, that gradual oral replenishment of iron predisposes children to more severe infection.

Secondary bacterial infection occurs commonly in patients with bartonellosis and malaria,[175] and bacterial infection, particularly that caused by *S. pneumoniae* and *Salmonella* spp., occurs more frequently in individuals with sickle cell anemia.[19,175] This evidence has been cited by some investigators to support the concept that iron is detrimental to the host during infection. This theory is not justified because patients with these diseases are known to have other deficits that intrinsically increase propensity for infection. The increased incidence of bacterial infection in these individuals cannot be attributed specifically to an increase in free iron.

Malaria frequently is cited as a situation in which iron-deficient states are protective to the host. Field researchers in malaria-endemic countries noted that treatment of iron deficiency, especially with parenteral iron, often was associated with an increase in the incidence of smear-positive malaria. Other studies have manipulated iron availability by using desferrioxamine, which is an iron chelator. In vitro and in vivo, desferrioxamine inhibits the growth of malaria parasites. The effect of desferrioxamine seems to be directly on parasitized erythrocytes, which behave as if they contain a chelation-labile iron pool.[152] In a study of Indian children, no statistical difference was found, however, in the incidence or prevalence of malaria or in the severity of *Plasmodium falciparum* parasitemia at different hemoglobin or nutritional levels.[98]

Several studies[9,185] of iron supplementation have reported fewer episodes of respiratory and gastrointestinal illnesses in iron-supplemented infants, but because of difficulties defining and statistically evaluating infectious episodes, the significance of these findings is not compelling. In a study in Colombia[11] in which iron deficiency was severe, nutritional supplementation and medical care had no impact on the mortality caused by infectious diseases, but supplemented groups experienced an impressive reduction in enteric infections. The relative contributions of iron and other supplements in decreasing morbidity could not be ascertained. Significantly improved iron status and reduced morbidity from upper respiratory tract infections were found in a placebo-controlled trial of iron supplementation in a study on 363 low-income children from Sri Lanka.[78]

Taken together, the depletion of tissue levels of iron as noted in iron deficiency are likely to be detrimental to optimal performance of the inflammatory and immune systems. To date, no studies have identified the point at which iron deprivation interferes with immunologic states. The diverse role of iron in multiple enzyme systems, mammalian and bacterial, may be understood best in a hierarchy of functions in which optimal activity of the different systems may be at different elemental concentrations. The suggestion that iron deficiency protects humans against infection cannot be supported, although caution against rapid parenteral iron repletion in states of acute infection may be advised. Recognizing the importance of maintaining appropriate iron stores, the WHO recommended iron and folic acid supplementation of flour in developing countries as a strategy for breaking the vicious cycle of malnutrition and infection.[327]

SELENIUM

Selenium has three major functions in the tissues and cells of the immune system: reduction of organic and inorganic peroxides, metabolism of hydroperoxides, and modulation of the respiratory burst. Glutathione peroxidase and phospholipid hydroperoxide glutathione peroxidase are selenium-containing enzymes that catalyze the reduction of peroxides formed from general metabolism, drugs, and other initiators of free radical chain reactions. Both of these enzymes also are involved in steps in the synthesis of thromboxane A_2, prostaglandins, leukotrienes, and lipoxins.

Research has shown reduction of eicosanoid biosynthesis in the absence of selenium and glutathione peroxidase. Selenium and the glutathione peroxidases also modulate the production of the oxidizing products of the respiratory burst: O^+_2, H_2O_2, CLO^+, and chloramines, which are used in the phagolysosome to lyse and destroy phagocytized cells. As predicted from these roles, selenium supplementation prevents oxidative stress–induced damage to immune cells. Selenium deficiency in experimental animals is associated with decreased glutathione peroxidase activity in phagocytic cells, release of increased amounts of H_2O_2 by macrophages and peritoneal granulocytes, and increased superoxide formation in macrophages.[58,196,297]

Selenium also apparently boosts cellular immunity by upregulating the expression of the T-cell high-affinity IL-2 receptor, enhancing T-cell response. Splenic leukocytes from selenium-deficient rats proliferated less after mitogenic stimulation than did leukocytes from control rats.[241] Controversy still surrounds the role of selenium in the prevention of infections in humans. Deficiency has been associated with generalized immunosuppression affecting neutrophil function, antibody production, and lymphocyte proliferation. A more recent study investigating selenium levels in 134 patients in intensive care units (ICUs) found that the mean plasma selenium concentration of these patients was 2 standard deviations below that of the general population.[106] This study also showed an inverse correlation between plasma selenium and severity of sepsis in these patients. The treatment of patients in ICUs with supplemental selenium has not been investigated.

In Keshan, China, selenium deficiency has been implicated in the pathogenesis of a dilated cardiomyopathy known as Keshan disease. The seasonal and annual incidences of Keshan disease were characteristic of an infectious disease, and screening of tissues from patients revealed the presence of numerous viruses, including coxsackieviruses. These findings are significant in light of Beck and Levander's[26] studies showing increased virulence of certain coxsackieviruses in selenium-deficient animals.

ZINC

Zinc is a cofactor for more than 300 cellular enzymes, with functions ranging from signal transduction to transcription to replication. Zinc deficiency in humans has been associated with poor growth and development, impaired wound healing, and impaired sensory perception. The low levels of zinc in acrodermatitis enteropathica may be related to the thymic atrophy and high frequency of serious bacterial, viral, and fungal infections seen in these patients because pharmacologic zinc supplementation can reverse all of these symptoms.[219]

Multiple animal models show the association of zinc deficiency with altered nonspecific and specific immune responses.[271,338] Lower zinc levels have been found in serum and hair of otherwise well-nourished children with pneumonia compared with healthy controls in Bangladesh.[281] Patients maintained on parenteral nutrition lacking in zinc showed reduced T-lymphocyte proliferation in response to mitogenic stimulation, which markedly increased after repletion of zinc.[285] A trial in Indian children

showed increased CD3 and CD4 cell counts and an increased CD4/CD8 ratio in children given zinc supplementation compared with controls.[264] Deficiencies in zinc also are associated with reduction in thymulin activity and slower neutrophil chemotaxis; these changes are reversed with the zinc supplementation.[58] Zinc deficiency impairs the function of antigen-presenting cells.[270] Conversely, excessive supplementation with zinc has been shown to cause reduced chemotactic and phagocytic activities and a suppressive effect on lymphocyte proliferation.[70] The inhibition of T-cell proliferation seems to be caused by inhibition of an IL-1 receptor–associated protein kinase by zinc ions at higher concentrations.[339]

Several randomized, double-blind, placebo-controlled trials of zinc supplementation have been done with children in developing countries, most of whom exhibit some manifestations of malnutrition.[231,256,257,263,322] These studies showed the association of zinc supplementation with decreased incidence of and morbidity from respiratory infections and reduced morbidity from diarrhea. Micronutrient deficiencies may be of particular clinical significance in malnourished children with chronic diarrhea or intestinal parasitic infections. Treatment of the infection has been shown to increase serum zinc levels without nutritional intervention, suggesting a vicious cycle comprising malabsorption, immune dysfunction, and inability to clear the infection.[226]

The immunologic consequences of zinc deficiency during pregnancy have received increased attention more recently. Animal studies have shown reduced thymic and spleen size and decreased active and passive immunity in the offspring, which was not fully reversible by postnatal zinc supplementation and partially persisted into the next generation.[338]

OTHER TRACE ELEMENTS

Copper facilitates absorption of iron from the gastrointestinal tract and is essential for the production of red blood cells. It also is crucial for several oxidative enzyme systems. Copper deficiency has been shown to cause anemia of varying degrees and gross ataxia in neonates of many species and defects in formation of connective tissue. Neutropenia has been documented in children with a copper-deficient diet. Copper deficiency is associated with depressed function of the reticuloendothelial system, reduced microbicidal activity of granulocytes, decreased response of splenic lymphocytes to T-cell and B-cell mitogens, and impaired natural killer cell cytotoxicity in animal models. The reduced microbicidal activity of granulocytes is attributed to the role of copper in superoxide dismutase and cytochrome-*c* oxidase enzyme systems.[285] Copper-deficient patients are more susceptible to contracting bronchopneumonia and bacterial sepsis, especially with *E. coli*. Copper-deficient animals show increased mortality rates when exposed to *S. typhimurium*, *L. monocytogenes*, and coxsackievirus B.

The role of chromium in disease control is undefined. Excess amounts adversely affect macrophage and lymphocyte cultures.[109,332] Chromium acts as a cofactor for the potentiation of insulin at the cellular level, and deficiency is characterized by impaired glucose use.[198,236] The role of chromium in impaired glucose homeostasis in kwashiorkor has been documented.[51]

Manganese is another essential trace element necessary for optimal growth. It affects the primary sites of chondroitin sulfate synthesis. In humans, manganese deficiency is characterized by weight loss, transient dermatitis, occasional nausea and vomiting, changes in hair color, hypocholesterolemia, and teratogenicity.

Lymphocyte and neutrophil functions in iodine deficiency are diminished. Iodide interacts with neutrophil peroxidases to form the halide-superoxide system, which is modulated by the amount of thyroid hormone, which supplies the iodide molecule. In hypothyroid patients, the bactericidal activity is decreased and restored after treatment with thyroid hormone.[58]

VITAMIN A

Three of the fat-soluble vitamins—A, D, and E—have recognized effects on immune system function. Before the discovery of antibiotics, researchers noted that urinary tract infections in children responded to vitamin A therapy. In the modern era, vitamin A deficiency is well documented to be a major risk factor for infections in Third World countries. Vitamin A levels in the serum have been used as markers of malnutrition; the independent effects of vitamin A deficiency are significant. Researchers have suggested that improving the vitamin A status of all children who are deficient would prevent approximately 1 to 3 million deaths each year, curtailing the incidence and severity of infectious episodes, especially respiratory and diarrheal infections.[135]

Vitamin A plays an important role in maintaining the integrity of epithelial surfaces. In animals and humans, vitamin A deficiency is associated with keratinizing metaplasia of mucus-secreting epithelial surfaces, particularly of the respiratory, gastrointestinal, and genitourinary tracts, and corneal tissues. This histopathologic alteration is conducive to an overgrowth of bacteria and secondary infections of loculated areas obstructed by keratinized debris. A classic example of this type of alteration is a Bitot spot, a triangular patch of xerotic conjunctiva characteristic of xerophthalmia, which is composed largely of keratin debris and a heavy growth of *Xerosis bacillus*, a saprophytic diphtheroid.

Immune changes in patients with vitamin A deficiency are characterized by disruption of the skin and epithelial barriers, increased bacterial binding to epithelial cells, reduced thymic weight, decreased lymphocyte proliferation, reduced immunoglobulin production, decreased T-helper cell activity, and decreased cytokine production. Vitamin A deficiency also is characterized by reduced phagocytosis, diminished nitroblue tetrazolium dye reduction by neutrophils, and reduced macrophage function.[60,113,275] Lysozyme is a vitamin A–dependent glycoprotein; the activity of this protein is decreased markedly in vitamin A deficiency.[340]

Vitamin A deficiency in children seems to increase their susceptibility to various types of infections. In a malnutrition ward in Bangladesh, 78 percent of children with xerophthalmia had bacteriuria determined by urine culture obtained by bladder tap compared with 17 percent of malnourished peers without xerophthalmia.[44] Studies from South Africa[86] and Israel[66] showed a strong association between poor vitamin A status and increased incidence and severity of acute respiratory infections.

Vitamin A supplementation may reverse some of these susceptibilities. A double-blind, placebo-controlled trial in a malaria-endemic area of Papua New Guinea showed that children supplemented with vitamin A had fewer febrile episodes and decreased parasite counts compared with unsupplemented controls.[282] In contrast, a study from Nigeria failed to establish a relationship between the use of red palm oil, a local oil rich in vitamin A, and decreased disease severity from malaria, whereas such a relationship existed for the overall nutritional status.[68] Finally, a meta-analysis of randomized trials of vitamin A supplementation in developing countries indicated a significant decrease in rates of respiratory and diarrheal disease mortality with vitamin A supplementation compared with placebo in children with no overt deficiency.[113] Vitamin A supplementation may be of particular importance in states of baseline increased susceptibility to infections, such as in children with HIV.[87,100]

Children in Third World countries frequently are caught in a vicious cycle in which infection leads to vitamin A deficiency,

which increases the risk for subsequent development of infection. The impact that vitamin A supplementation would have on childhood morbidity and mortality depends on several factors, including the prevalence and severity of deficiency, aggravating conditions (e.g., protein-calorie malnutrition), associated nutrient defects, virulence of the infectious agents to which they are exposed, and adequacy of supplementation.[296]

The effects of retinoids on the maintenance of the integrity and differentiation of epithelial surfaces on one hand, and their various immunologic effects on the other, raise the interesting question whether retinoid supplementation might help to prevent human papillomavirus–associated cervical dysplasia. In a more recent study, *trans*-leukopene and *cis*-leukopene (but not retinol, tocopherols, vitamin B_{12}, and folic acid) levels correlated with higher rates of clearing of an established infection with oncogenic strains of human papillomavirus.[273]

VITAMIN D

Vitamin D serves as an immunoregulatory hormone and as a lymphocyte-differentiating hormone in addition to its classic role of mineral homeostasis. 1,25-Dihydroxyvitamin D_3 functions in the manner of a steroid hormone in many different cell types. Receptors for 1,25-dihydroxyvitamin D_3 have been identified on the surface of T lymphocytes, monocytes, and macrophages,[326] and an extensive number of RNA polymerase II–transcribed genes that govern lymphokine expression are regulated by this vitamin-hormone.[27] Although vitamin D must be present at a certain concentration for proper immune function, high-dose supplementation also may have detrimental effects. One study has shown suppression of the delayed hypersensitivity response in patients with vitamin D deficiency and in individuals receiving high doses of vitamin D.[145] Activated vitamin D may inhibit T-lymphocyte proliferation and natural killer cell cytotoxicity and decrease concentrations of interferon-γ, IL-2, and IL-12.[180] Additionally, the differentiation of immature dendritic cells into antigen-presenting cells is inhibited in culture by activated vitamin D.[239]

A more recent case-control study from India found subclinical vitamin D deficiency to be a risk factor for pneumonia in children younger than 5 years old.[335] A case-control study from Jordan reported longer hospital stays in children with rickets and pneumonia compared with the nonrachitic controls.[215]

VITAMIN E

Vitamin E enhances immune responses and phagocytosis by acting as an antioxidant to prevent lipid peroxidation of cell membranes. Rapidly proliferating cells of the specific immune and phagocytic systems are prone to peroxidative damage by free radicals, peroxides, and superoxides. In vitro studies of rat alveolar macrophages show that high levels of vitamin E suppress the release of reactive oxygen species after stimulation.[235] These findings suggest that vitamin E may reduce self-inflicted damage to macrophages and surrounding tissue during infection. The antioxidant effect of vitamin E also modulates the biosynthesis and activity of prostaglandins, thromboxane, and leukotrienes.[311]

Several studies have shown that vitamin E deficiency impairs cell-mediated and humoral immunity in different animal models. Some studies suggest that vitamin E deficiency may contribute to the decreased immune function of neonates, especially premature infants.[199] In humans, vitamin E deficiency impairs T-cell–mediated function, which is reversible by vitamin E supplementation. Supplementation in an amount 2 to 10 times greater than the present recommended dose significantly increased humoral and cell-mediated immune responses and phagocytic functions in laboratory animals and humans.[311] Vitamin E seems to interact with other micronutrients in immune modulation. The heightened humoral response noted with vitamin E is synergistic with selenium[124] and copper.[311] In addition, zinc deficiency, even when marginal, can decrease markedly vitamin E serum concentrations.[249]

WATER-SOLUBLE VITAMINS

Among the water-soluble vitamins, B_1, B_6, B_{12}, and C have been implicated in immune function. Vitamin B_6 deficiency impairs immunity by slowing the rate of production of one-carbon units necessary for nucleic acid synthesis in these rapidly proliferating cells. Animal models deficient in vitamin B_6 exhibit impaired antibody production, a delay in IgM-to-IgG class switching, and altered cell-mediated immunity with reduced delayed-type hypersensitivity responses.[315] Humans consuming a diet low in vitamin B_6 or being treated with deoxypyridoxine (vitamin B_6 antagonist) have a decreased number of circulating lymphocytes and reduced antibody production and a mild decrease in the percentage of helper T cells.[200] The thymus is smaller, and thymic hormone activity is decreased in patients with vitamin B_6 deficiency.

Vitamin B_{12} also seems to affect immunity. Patients with vitamin B_{12} deficiency were found to have decreased numbers of lymphocytes, decreased CD8 cells, an altered CD8/CD4 ratio, and suppressed natural killer cell cytotoxicity.[308] All of these parameters improved with supplementation of vitamin B_{12}. Osawa[230] first suggested that thiamine deficiency may predispose to the occurrence of tropical pyomyositis, a hematogenous pyogenic infection characterized by abscess formation in various muscle tissues. Muscle tissue generally is resistant to infection, but lack of thiamine may change the biochemical milieu of the muscle, rendering it more susceptible to infection.

Physiologic quantities of ascorbic acid are necessary for normal metabolism of lipids and iron. One of the major functions of vitamin C is as an antioxidant that protects the $alpha_1$ proteinase inhibitor from inactivation by free radical products of the respiratory burst. $Alpha_1$ proteinase inhibitor is present in plasma, where it reacts with elastase, protecting the extracellular space from escaped proteases from damaged cells. The concentration of intracellular vitamin C is approximately 50 times that found in plasma, which suggests that vitamin C may protect intracellular regions from oxidants that leak into the cytoplasm.

Host susceptibility to infection is increased in scurvy. Vitamin C deficiency is associated with impaired phagocytic activity. Microtubule organization is responsible for phagocytosis and locomotion and depends on the redox state of the cell; vitamin C may modulate it by an antioxidant effect on tubulin tyrosinolation.[126] Macrophages from mice supplemented with vitamin C, vitamin E, or both showed increased random migration, chemotaxis, ingestion, and superoxide anion production compared with controls.[80] Because vitamin C is associated with chemotactic activation of phagocytes, its use has been suggested in patients with disorders of phagocyte function, such as Chédiak-Higashi syndrome.[268]

The possibility that vitamin C may be important in preventing upper respiratory infections has received widespread publicity in the medical and lay presses. Chalmers[53] reported, however, after reviewing 14 clinical trials of ascorbic acid in the prevention and treatment of the common cold, that differences between supplemented and nonsupplemented subjects were minor and insignificant. Nonetheless, in most studies, the severity of symptoms was worse in patients who received placebo. Miller and colleagues[201] performed a double-blind, co-twin controlled study on 44 monozygotic twins of school age. During the 5-month study period, no statistically significant difference in the number or severity of

illness episodes was noted between the recipients of vitamin C and a placebo control group. Several studies have shown a consistent decrease in the duration of the common cold episodes; although most of the results are not statistically significant, all of them point consistently in the same direction.[126] Administration of ascorbic acid is not a panacea for upper respiratory infections. Also, although lack of vitamin C is detrimental, excess intake is of no proven value.

Vitamin deficiencies interfere with host defenses. Infections also may cause or exacerbate certain vitamin deficiencies. Concentrations of vitamins A, B_6, and C have been reported to be lower than normal during acute bacterial and viral infections, and reduced concentrations of folic acid in blood and serum have been found in infants with diarrhea or acute bacterial infection[193] and in adults with tuberculosis or malaria.[250] Severe xerophthalmia in Indian children often is preceded by diarrhea, measles, or a respiratory infection and may have been precipitated by a decline in serum vitamin A and retinol-binding protein concentrations during the course of the infection. A study in children with shigellosis showed increased urinary excretion of vitamin A during infection, which was attributed to impaired renal tubular absorption of low-molecular-weight proteins, such as retinol-binding protein bound to retinol.[207] Infections may alter plasma retinol levels because activation of the acute-phase response may decrease the synthesis of the circulating proteins that transport retinol.[313]

Altered concentrations of circulating vitamins during infection also may be caused by several other mechanisms, including impaired absorption from the gastrointestinal tract, liver cell damage, and altered rates of vitamin excretion. Transient malabsorption of folic acid and vitamin B_{12} has been noted during and after recovery from acute intestinal infections, including cholera and salmonellosis.[178] The urinary excretion of the group B vitamins and vitamin C also has been observed to change during hepatitis and tuberculosis.[125,146]

Taken together, in vitro studies show alterations in immune cell function; animal models and clinical studies show an enhanced susceptibility to infection with deficiencies of macronutrients and micronutrients. More studies are needed, however, to assess particularly mild micronutrient deficiencies, possible synergistic effects, and optimal substitution regimens.

CONSIDERATIONS OF NUTRITION AND INFECTION IN SPECIAL POPULATIONS

Overall, the prevalence of malnutrition in industrialized nations is considerably less than that in developing countries; however, in industrialized nations, certain populations are at increased risk for developing malnutrition. Malnutrition is a common complication in HIV-positive individuals, regardless of their geographic location or economic situation. Critically ill patients have an increased risk for development of malnutrition and infection. Finally, burn patients, premature neonates, cancer patients, and children with cystic fibrosis have special nutritional requirements and metabolic changes that highlight the interactions of infection and nutrition.

HUMAN IMMUNODEFICIENCY VIRUS AND NUTRITION

Acquired immunodeficiency syndrome (AIDS) has become one of the most pressing public health problems, with more than 40 million HIV-infected individuals worldwide (WHO estimate 2005[346]) and more than 1 million in the United States. Infection with HIV has a devastating effect on nutritional status. Malnutrition was one of the earliest recognized complications of AIDS, and unexplained weight loss remains one of the most common initial AIDS-defining diagnoses reported to public health authorities. Patients may lose 30 to 50 percent of their body mass before dying of AIDS. The onset of depletion of body cell mass occurs early in HIV infection and may predate any significant immunodeficiency, suggesting that the virus itself may be responsible.[161]

Most commonly, the malnutrition associated with HIV is multifactorial. Decreased caloric intake, malabsorption of nutrients, and elevated energy expenditure, especially during systemic opportunistic infections, all contribute to malnutrition in these patients. Protein-calorie malnutrition is encountered frequently, as are individual or combined micronutrient deficiencies. All contribute to the growth failure seen in children with HIV, emphasizing the need for early and intensive nutritional intervention and treatment in these patients.

Two major paradigms of weight loss that contribute in patients with HIV infection are starvation and cachexia.[18] Starvation refers to a voluntary or involuntary deprivation of food that leads to increased losses of body fat and extracellular water, with relative sparing of lean body mass. In contrast, cachexia is characterized by a disproportionate loss of lean body mass resulting from specific alterations in metabolism. These alterations during cachexia are caused by shifts in cytokine levels and may include changes in protein metabolism or energy expenditure, appetite changes, or derangement of the sleep-wake cycle.

Investigation of energy metabolism in HIV-infected individuals has produced conflicting results. Some studies report increased resting energy expenditure, and others report that energy expenditure was decreased. A study of 36 HIV-infected children between infancy and 10 years of age showed that cardiac muscle mass and heart rate were correlated inversely with weight and skeletal muscle mass.[204] This finding is inconsistent with the decreased energy expenditure of hypometabolic compensation that occurs in starvation; instead, it suggests that these children have cachexia and intrinsic metabolic changes.

Animal and human studies have found correlations between cytokine levels and anorexia, cachexia, and altered lipid metabolism. Serum levels of interferon-α are increased in some patients with AIDS and are correlated significantly with elevated serum triglyceride levels. Adult patients with AIDS and with wasting were found to have higher plasma concentrations of TNF-α and cholecystokinin octapeptide sulfate, an appetite neuropeptide, and lower levels of β-endorphins compared with well-nourished patients with AIDS and healthy controls.[12] These changes may inhibit appetite pathologically and contribute to weight loss.

Very different metabolic changes have been observed more recently in patients with HIV who are receiving antiretroviral therapy. Lipodystrophy, or fat redistribution syndrome, seems to be associated more strongly with the administration of protease inhibitors than are other antiretroviral agents. Patients with this condition develop a dorsocervical fat pad; abdominal adiposity; and facial, extremity, and buttocks wasting. Increased breast size also is seen in female patients. Other changes include hyperlipidemia with increased levels of total cholesterol and low-density lipoprotein and decreased levels of high-density lipoprotein. These patients also may develop insulin resistance. The mechanism of this syndrome and its long-term consequences are unclear. A study examining the effect of protease inhibitors on growth of children found that despite the protease inhibitor–induced metabolic abnormalities, protease inhibitor therapy had a positive effect on growth parameters, including height, weight, and muscle mass, likely through reducing viral load and improving disease control.[203]

Involvement of the gastrointestinal tract in patients with HIV infections also undoubtedly plays a role in weight loss. Chronic weight loss often is related to gastrointestinal disease and malabsorption. The pathogenesis of malabsorption involves a combination of factors, including primary enterocyte injury with partial

villous atrophy and crypt hyperplasia, ileal dysfunction with bile salt wasting and fat malabsorption, and exudative enteropathy.[162] Small intestine pathology or pancreatic insufficiency may lead to malabsorption of fat, weight loss, and depletion of fat-soluble vitamins.[171] Hypochlorhydria has been found in almost 75 percent of patients with AIDS and can allow for enteric infections and reduced absorption of micronutrients, such as folate and iron. Malabsorption of lactose is a common finding and is more severe in symptomatic than asymptomatic HIV-infected children.[353] Subclinical malabsorption may play a role in early HIV disease, whereas overt malabsorption is found more frequently in advanced HIV infection.

Along with the direct effects of HIV, immunosuppression leads to an increased frequency of gastrointestinal infections, which exacerbate weight loss caused by diarrhea and malabsorption. Protozoal infections can disrupt mucosal architecture in the small intestine, resulting in severe malnutrition. Studies indicate that HIV-infected patients with diarrhea caused by enteric infections experience greater weight loss than do HIV-infected patients with diarrhea for which no pathogen can be identified.[50]

Protein-calorie malnutrition is a common occurrence in patients with AIDS and is considered a predominant cause of morbidity in AIDS. In the United States, 30 to 50 percent of children followed in HIV programs have evidence of protein-calorie malnutrition.[202] The immune effects of protein-calorie malnutrition and HIV infection are similar: Decreased CD4 cells, reversal of the helper-to-suppressor T-cell ratio, impairment of delayed hypersensitivity reactions, and abnormal humoral responses occur in both conditions. A child with protein-calorie malnutrition and HIV infection is likely to have an outcome worse than that of a child with either condition alone.

Low levels of vitamins A, E, B_6, B_{12}, and C and of carotenoids, selenium, and zinc are common findings in many HIV-infected populations. These deficiencies may be caused by decreased dietary intake, diarrhea, malabsorption, impaired storage, or altered metabolism of micronutrients.[277] Some researchers attribute the low levels of zinc in HIV-infected patients to direct use of zinc by the virus for gene expression, multimerization, and integration into the host genome.[23]

More recently, the prognostic significance of the status of selenium has received much attention. Several studies[22,24,49] have shown that selenium deficiency is associated more strongly than other micronutrient deficiencies with mortality in HIV-infected patients. Selenium-deficient, HIV-infected patients had a 10-fold to 20-fold increase in mortality rates compared with HIV-infected patients with adequate selenium levels. Among HIV-infected children who died, children with low selenium levels died at a younger age (mean age at death of 4.3 years versus 8 years), suggesting a more rapid progression of disease in patients with selenium deficiency.[49] The relationship between selenium deficiency and early death in HIV may be associated with the role of selenium in preventing oxidative stress, which may be involved in maintaining viral latency in an infected cell. An in vitro study of HIV-infected monocytes and T lymphocytes emphasized this role by showing that selenium supplementation partially suppresses the TNF-α–mediated replication of the virus.[131]

Controversy currently surrounds the role of maternal micronutrient status, particularly vitamin A, in the perinatal transmission of HIV. Several studies[119,275] show an increased risk for perinatal HIV transmission with maternal vitamin A deficiency; one study[275] showed that the risk for perinatal transmission was correlated inversely with concentration of maternal serum retinol. Other studies showed no association, however, between maternal vitamin A level and risk for transmission of HIV to the infant.[47,48,98,99,303] Further research is required before any conclusions can be drawn. In contrast, administration of vitamin A supplementation in children starting at 6 months of age has been shown to be beneficial in reducing mortality rates and morbidity among HIV-infected children.[100]

In children with HIV, the combination of diarrhea, malabsorption, protein-calorie malnutrition, and micronutrient deficiencies can have devastating effects on growth. HIV-infected infants may exhibit growth failure, failure to thrive, developmental delay, or frank malnutrition by 4 months of age.[101] A retrospective, cross-sectional analysis of 54 children with perinatally acquired HIV showed an early decline in the rate of linear growth (growth failure) with relative preservation of weight for age.[240] A prospective study of HIV-infected infants in Uganda[30] showed an association between mortality and the severity of growth failure. The exact nature of the relationship between growth failure and mortality in HIV infection is unclear. Poor nutritional parameters may represent frequent opportunistic infections and debilitation in infants with already advanced disease; conversely, poor nutritional status may accelerate the progression from asymptomatic HIV infection to symptomatic AIDS.

Nutritional intervention is important for all HIV-infected patients, but it is particularly crucial in the management of infants and children. In 2000, the American Dietetic Association and Dieticians of Canada recommended that children should be referred for a full nutrition evaluation as soon as possible after receiving the diagnosis of HIV infection.[101] Nutrition intervention should begin early in the course of HIV infection in the hopes of stabilizing weight loss and preventing growth failure. Evaluation should address stages of growth and development, anthropometrics, dietary intake assessment, medical data, and any psychosocial or economic issues that may be barriers to establishing adequate nutrition.

Specific dietary interventions include maximizing intake of high-calorie, nutrient-dense foods and vitamin and mineral supplements, especially vitamins A, B_6, B_{12}, E, and C, and riboflavin, zinc, and selenium. In addition, dietary counseling should emphasize the importance of daily ingestion of a full complement of amino acids. If adequate nutritional status cannot be maintained orally, enteral supplementation should be used. To maximize absorption and minimize diarrhea, formulas that have low residue or low lactose and that contain peptides and medium-chain triglycerides should be used. If the patient has intractable diarrhea or impaired function of the gastrointestinal tract, or if nutrient needs are not met by enteral nutrition, home total parenteral nutrition (TPN) may be considered for long-term use; however, TPN therapy may be complicated by metabolic abnormalities (hypertriglyceridemia, hyperglycemia, fluid and electrolyte imbalance) and problems related to catheters, such as infection, hemorrhage, and pneumothorax. Standard nutritional recommendations for patients with AIDS have not been established because of the heterogeneous nature of the complications of this disease.

ROUTE AND COMPOSITION OF NUTRITION IN CRITICALLY ILL PATIENTS

The effects of quality and quantity of nutrients on the immune system have been shown, but the route of administration of nutrition also has been shown to affect host susceptibility to infection. The first experimental evidence that the route of nutrition plays a role in host defense came from Kudsk and associates[166] in the early 1980s. Well-nourished rats were fed the same solution through either gastrostomy or central catheter for 12 days, after which hemoglobin–*E. coli* peritonitis was induced. The 48-hour survival was 60 percent in the enterally fed group compared with 20 percent in the parenterally fed group. Improved survival also was observed in malnourished rats under similar experimental conditions.[165]

Analyses of infection rates in hospitalized patients seem to confirm an association between TPN and susceptibility to infection. In a meta-analysis of data from eight prospective, randomized trials of early enteral versus parenteral feeding of high-risk surgical patients, Moore and colleagues[211] found a 35 percent risk for development of septic complications in patients receiving TPN compared with an 18 percent risk in patients fed enterally. Similar increases in infection rates have been observed in children. Several prospective cohort studies of patients in neonatal and pediatric ICUs have shown that TPN is the most significant risk factor for acquiring a nosocomial infection.[42,114,289]

Numerous hypotheses have been proposed to explain the increased risk for development of infection in parenterally fed patients. Intravenous nutrition may induce immunosuppression directly. In vitro studies of whole blood from infants receiving long-term TPN showed impaired phagocytosis and intracellular killing in response to challenge with coagulase-negative staphylococci, a model for bacteremia.[224,225] The intracellular killing was correlated negatively with duration, but not amount, of parenteral feeding and was found to normalize after the addition of small enteral feeding.[225] Correction of this immune defect with enteral feeding implies the involvement of the gastrointestinal tract in the increased infection risk with parenteral feeding.

Enteral feeding helps to maintain barrier function of the gut through increased gastric acidity, mucus production, and intact peristalsis.[7] Gastrointestinal tract "starvation" in animal models produces mucosal atrophy, bacterial overgrowth, decreased secretory IgA, increased intestinal permeability and translocation of bacteria or toxins, and atrophy of gut-associated lymphoid tissue.[155,177,225] The preliminary evidence suggests that enteral feeding may maintain immunologic integrity in the gut and result in increased resistance to infection.

The composition of enteral diets has been another area of more recent investigation. Certain key nutrients are being recognized for their ability to modulate a variety of inflammatory, metabolic, and immune processes when ingested in increased amounts. Nutritional components such as dietary nucleotides, omega-3 fatty acids, glutamine, and arginine are being called "immune-enhancing agents" because of their potential roles in bolstering and maintaining host defenses against infection.

Nucleotides are thought to have immune-modulating properties because of their role as structural units for DNA, RNA, adenosine triphosphate, and cyclic adenosine monophosphate. The unaltered human gastrointestinal tract contains bacteria, the continuous turnover of which provides an adequate supply of nucleotides, but this flora may be altered in critically ill patients.[20] Periods of rapid growth or certain disease states also may create increased demands for nucleotides. Under these conditions, supplemental dietary nucleotides may spare the energy of de novo synthesis and optimize the function of rapidly proliferating cells of the immune system.[52] Numerous studies have shown the immune-modulating effects of nucleotides in vitro and in animal models.[148,167] More recent studies in children also show these effects. Studies in infants showed that infants receiving nucleotide-supplemented formula had increased natural killer cell cytotoxicity, increased IL-2 production by stimulated mononuclear cells, and higher serum concentrations of IgM and IgA compared with infants fed standard formulas, and they were less likely to experience diarrhea.[52,190,350]

Omega-3 fatty acids may regulate immune function by modulating formation of prostaglandins and regional blood flow. Some inflammatory mediators of shock and sepsis, including prostaglandins, leukotrienes, and platelet-activating factor, are metabolites of omega-6 fatty acids, the primary fat source in many nutritional formulations. Substitution of omega-3 fatty acids for omega-6 fatty acids has been shown to have anti-inflammatory effects.[20] Parenterally fed rats receiving supplemental omega-3 fatty acids had increased splanchnic blood flow in response to endotoxin challenge compared with parenterally fed rats without supplementation.[245] They also had decreased viable bacteria in mesenteric lymph nodes and liver, which may represent decreased bacterial translocation from the gastrointestinal tract or improved bactericidal activity.

Glutamine is the most abundant amino acid in human muscle and plasma and is used as a fuel source for lymphocytes, macrophages, and enterocytes. It also is a precursor of glutathione and nucleotide synthesis. Glutamine is a nonessential amino acid; however, during catabolic illness, glutamine uptake by small intestinal and immune cells may exceed synthesis and release from skeletal muscle, rendering it conditionally essential.[20] Studies of glutamine supplementation to enteral feeding solutions in adult trauma patients have shown significantly less pneumonia, bacteremia, and sepsis in supplemented groups compared with controls.[132] Small individual trials have suggested a beneficial effect of glutamine supplementation in preterm infants.[220] A Cochrane review examining the effect of enteral and parenteral glutamine supplementation on mortality, sepsis, necrotizing enterocolitis, duration of hospitalization, and neurodevelopmental outcome found no clinically significant benefit, however.[317]

Arginine, a nonessential amino acid, has received considerable attention for its immune-enhancing properties. Arginine is a precursor for nitric oxide in vascular endothelial cells, macrophages, and neutrophils, and infusion of arginine stimulates release of growth hormone, glucagon, somatostatin, prolactin, and insulin.[20] A meta-analysis of 15 randomized, controlled trials comparing standard enteral nutrition with commercially available immune-enhancing enteral formulations containing arginine, with or without glutamine, nucleotides, and omega-3 fatty acids, found no effect on mortality, but patients receiving the immune-enhancing formulations showed a decreased risk for developing infection and had shorter hospital stays.[25]

Finally, probiotics such as lactobacillus have received increasing attention as potentially promising supplements for critically ill patients, given their beneficial effects on the gastrointestinal flora in patients with infectious diarrhea or inflammatory bowel disease.[29] Most clinical trials available to date that investigated lactobacillus supplementation in critically ill neonates and adults established safety but were unable to measure any clinical benefit.[74,139]

NUTRITION IN PRETERM INFANTS

Critically ill preterm infants represent a particular nutritional challenge. In addition to all the immunologic abnormalities seen in patients in the ICU, the preterm infant's immune system is immature. Immaturity of the gastrointestinal system renders enteral nutrition particularly difficult and is associated with potentially lethal conditions such as necrotizing enterocolitis, which is not seen in adults. The nutritional requirements of preterm infants exceed the requirements of older patients several-fold in terms of total calories and specific nutrients, calcium, phosphorus, iron, and vitamins. Nutritional management of the critically ill preterm infant is particularly difficult and, at the same time, of utmost importance.

Specialized preterm formulas or human milk fortifiers try to meet the preterm infant's nutritional needs. These formulas are optimized in their caloric content, composition of carbohydrates, type of protein, type of fat, electrolyte and mineral composition, iron content, vitamins, and trace elements. Introduction of enteral feeding often is delayed, however, because of intolerance, immaturity, or an intercurrent episode of infection, hemodynamic decompensation, or necrotizing enterocolitis. Most very-low-birth-weight infants at some point during hospitalization have nutritional deficiencies of vitamin A, vitamin E, or iron, from decreased bone mineralization and growth retardation.

An important strategy in the nutrition of preterm infants is the concept of "trophic feeds." Very small amounts of enteral nutrition, which contribute only minimally to the overall caloric intake, have been shown to avoid many of the devastating consequences of TPN, such as gut atrophy and short gut syndrome. The role of the gut-associated immune system in the overall acquisition of immunocompetence is likely of great importance, and (even trophic) enteral feeds are thought to enhance the development and improve the function of this important part of the immune system. Studies suggest beneficial immunologic effects of early enteral feeds manifesting in decreased incidence of sepsis.[103,250,304] Despite a plethora of studies, the minimal amount at which a clinically significant effect of trophic feeds can be expected is controversial.

BURNS, INFECTION, AND NUTRITION

In the United States, approximately 2.5 million people seek medical care for burns each year. More than 100,000 individuals are hospitalized with burns each year, and 12,000 die. During the past 50 years, great strides have been made in the treatment and management of patients who have sustained thermal injuries. A marked decrease in burn mortality rates, particularly in patients younger than age 35 years, has occurred.[214]

Infection always has been the predominant determinant of wound healing and outcome of burn patients. The incidence of infectious complications in burn patients increases in proportion to the fraction of the body surface injured. The direct effects of heat on skin and underlying tissue render the burn wound particularly susceptible to infection; the denatured protein in burn-injured tissue serves as a rich medium for microbial growth. The thermal thrombosis that renders the eschar avascular precludes delivery of the cellular components of the host defense system and limits delivery of blood-borne antibiotics to the infected wound site. Further microbial proliferation occurs at the interface between viable tissue and the eschar, termed the *subeschar space*. If host defenses are adequate, the eschar is sloughed; however, microbial invasion of the viable tissue occurs if host defenses are deficient.

Pneumonia is the most frequent infection occurring in burn patients. Other infectious complications, such as suppurative thrombophlebitis and septicemia, have been decreasing in incidence as a result of improvements in patient management, wound care, and infection control.[244]

A larger role in the development of sepsis has been attributed more recently to the gastrointestinal tract. The gastrointestinal barrier normally is highly effective in containing its flora. Critically ill patients often experience a breakdown of the barrier, followed by translocation of inert particles and microorganisms across the intestinal wall. This event may play a role in the colonization of burn wounds by gram-negative organisms. Alteration of the indigenous microbial flora, which may be caused by the stress of injury, antibiotics, or composition of enteral feedings, has been shown to influence translocation markedly.

Translocation of bacteria and their toxins from ischemic bowel causes a massive release of cytokines and inflammatory mediators.[79] This "cytokine storm" is associated with depressed cytotoxic activity of T cells, decreased ratio of helper-to-suppressor T lymphocytes, depressed phagocytic activity, reduced intracellular killing, increased superoxide formation, decreased serum concentrations of immunoglobulins, and activation of complement with release of anaphylatoxins.[123]

Major thermal injury is associated with extreme hypermetabolism and catabolism, which occur shortly after successful resuscitation from the shock phase of the burn injury. This hypermetabolic state is characterized by elevated cardiac output, increased energy expenditure, erosion of lean body mass, negative nitrogen balance, and disturbances in glucose metabolism.[316]

The role of nutrition in maintaining immunocompetence and modulating hypermetabolism in burned patients has become increasingly important. The use of early enteral nutrition combined with early excision of nonviable tissue has resulted in reduced energy requirements in burned children.[127] Providing proper nutrition by the enteral route when possible may satisfy caloric needs, regulate microflora, and maintain the integrity of the mucosa of the gut, but it also may blunt the hypermetabolic response after thermal injury.[143]

CANCER AND NUTRITION

Cancer predisposes patients to malnutrition through several mechanisms. Often, patients with cancer have experienced a period of weight loss before being diagnosed with a malignancy. This loss varies for different forms of cancer. Acute lymphoblastic leukemia typically is of rapid onset, and only 6 percent of children have lost a substantial amount of weight at diagnosis. In contrast, 50 percent of patients with stage IV neuroblastoma present with at least some degree of malnutrition.[6]

Malnutrition in patients with cancer originates from a combination of anorexia (i.e., decreased intake) and cachexia (i.e., increased metabolic demand). The latter is particularly evident in children with a very high tumor burden.[238] Anorexia in patients with cancer is due to the malignancy itself and is a common side effect of various cancer treatments. Chemotherapy and radiation often induce substantial nausea, altered smell or taste, vomiting, mucositis, gastric ulcers, or colitis. Certain chemotherapeutic agents, such as vinca alkaloids, can cause severe constipation, as do narcotics, which often are needed to control pain. Pain, malaise, and infections decrease oral intake and are frequent occurrences as a manifestation of the malignancy (bone marrow infiltration leading to immune dysfunction) and as a side effect of therapy. Antibiotics and antifungal agents can cause gastric irritation and diarrhea. Some agents, such as amphotericin B, also may lead to a tubulopathy with urinary losses of electrolytes, amino acids, and trace elements.

Supporting enteral nutrition with nasogastric or gastrostomy tube feeds in patients with cancer is complex. Mucositis and nausea decrease the tolerance for, and compliance with, nasogastric feeds, whereas poor healing and infectious complications affect gastrostomy feedings. Despite these drawbacks, enteral nutrition is much preferred over TPN for its beneficial effect on the gastrointestinal flora and on the structural and functional integrity of the gastrointestinal tract, which helps to prevent translocation of bacteria from the gut into the bloodstream with the associated risk of gram-negative septicemia. In contrast, TPN is associated with a high complication rate, such as central line infections and sepsis, and TPN cholestasis. Nonetheless, both types of nutritional support are used currently in children with cancer.

A variety of clinical studies have highlighted the importance of maintaining adequate nutrition in children with cancer. Malnourished children undergoing cancer chemotherapy have more infectious complications and experience more therapy-related toxicity than do children undergoing therapy with normal nutritional status.[82,151,169,307] In addition to the risks for adverse outcomes from the complications themselves, infections and delayed recovery between cycles of chemotherapy may lead to delays and dose reductions in subsequent cycles. In Brazil, malnutrition has been linked to an increased risk for relapse after treatment for acute lymphoblastic leukemia.[328] Particularly mild nutritional deficits have not been linked conclusively to a decreased rate of overall or event-free survival, however.[232,323] Currently, no national or international standards have been established regarding the nutritional management of children with cancer, and

nutritional support practices vary widely even among centers of the Children's Oncology Group. An urgent need exists for more conclusive studies to be performed on the impact of nutrition on toxicity, infectious complications, and, particularly, survival and on the different types of nutritional support for children undergoing cancer treatment.[168]

CYSTIC FIBROSIS

Malnutrition and growth failure are two common presenting signs of cystic fibrosis with pancreatic insufficiency. The failure to thrive seen in these patients is mostly a consequence of malabsorption; however, chronic infections with repeated exacerbations likely also play a role. Particularly crucial is the absorption of fat-soluble vitamins. The importance of vitamins A, D, and E for the development of the immune system and host defenses against infections has been reviewed earlier in this chapter. Later in life, many children with cystic fibrosis also develop insulin-dependent diabetes mellitus, which decreases further their ability to fight off infections.

Based on the multiple levels of interplay among growth, nutrition, development of the immune system, maintenance of immunologic functions, infections, and pulmonary damage, newborn screening for cystic fibrosis has been proposed. Nutritional deficits have been identified through screening in asymptomatic infants 2 months of age.[247] Early recognition and nutritional intervention not only may prevent failure to thrive but also strengthen host defenses and decrease or delay the severity of pulmonary colonization and infections, and ultimately improve overall survival.

Many studies have addressed this hypothesis and have found conflicting results. Data from the Cystic Fibrosis Foundation Registry suggest that early diagnosis is associated with a survival advantage.[170] Almost all studies confirm that early nutritional optimization through early diagnosis helps to avoid malnutrition and stunting, with benefits measurable in adolescence. Although some studies suggest fewer infectious complications, decreased colonization rate with *P. aeruginosa*, and improved pulmonary function tests in 20-year-old patients who were diagnosed through newborn screens,[2,288,302] other studies have been unable to confirm improved pulmonary function or improved survival through early intervention.[96,288] Malnourished *CFTR* knockout mice showed similar levels of cytokine production, inflammatory cells in bronchoalveolar lavage, and survival after challenge with *P. aeruginosa* as wild-type and nonmalnourished *CFTR* knockout mice.[324]

One also must bear in mind that early intervention is likely to lead to not only early and more targeted nutritional intervention, but also to more aggressive monitoring of pulmonary function tests and colonization with pathogens, with earlier and more aggressive antibiotic intervention. Although most data on newborn screening for cystic fibrosis point toward a beneficial effect of early diagnosis, the exact role of nutritional optimization in preventing colonization and infections needs to be studied in more detail.

OBESITY AND INFECTIONS

In industrialized countries, the burden of morbidity and mortality continues to shift toward chronic diseases. Research has focused on the effects of surfeit nutrition, especially obesity.

Numerous animal studies suggest that obesity increases the susceptibility for, and interferes with the ability to respond appropriately to, infection. When dogs were fed a high-calorie diet, a greater susceptibility to distemper virus and a shorter survival time were noted than in control animals fed a normal diet.[221] Chickens on a high-protein diet experienced greater mortality and morbidity from Newcastle disease agent than did controls that were fed normally.[40] Swiss mice made obese by high-fat diets were less resistant to infection by *S. typhimurium* and *K. pneumoniae* compared with mice fed a standard laboratory diet.[300] High-fat diets result in consistently depressed host resistance to tuberculosis and malaria in rats and to pneumococcal infections in chickens.[187] Erickson and associates[90,91] discovered that high levels of dietary fat, particularly polyunsaturated fat, suppressed the response of lymphocytes to T-cell mitogens. Animal models also have shown the adverse effects of excess cholesterol. Fiser and coworkers[102] found that hypercholesterolemic monkeys developed altered humoral and cellular immune function. Hypercholesterolemia also has been found to increase mortality rates in mice infected with group B coxsackieviruses.[182]

Epidemiologic and clinical data in patients support the concept of obesity-related disturbances in immune function. A cross-sectional study of 1129 preadolescent children suggests that obesity in children may be a predisposing factor to acute respiratory disease.[142] The study showed that children with a body mass index greater than or equal to 20 had twice as high a risk for acquiring acute respiratory infections compared with children with a lower body mass index. Chandra[57] examined the immunocompetence of obese children, adolescents, and adults. Approximately one third of the obese group showed a variable impairment of cell-mediated immune responses and a reduction of intracellular bacterial killing by neutrophils. The obese group had moderately low concentrations of serum zinc and iron, and therapy with these micronutrients for 4 weeks resulted in improvement in immunologic responses.

Obese adolescents and adults experience a greater risk for developing sepsis and wound infections after surgery than do lean control subjects.[97,300] Obese individuals exhibit a slight impairment of delayed cutaneous hypersensitivity responses, reduced helper T-cell populations, decreased lymphocyte response to mitogens, and reduced bactericidal capacity of neutrophils. Humoral immunity also may be affected by obesity. A randomized clinical trial of immunogenicity of hepatitis B vaccine found obesity to be a risk factor for nonresponse to the vaccine.[16] Obese subjects were 2.1 times more likely to be nonresponders than were lean subjects.

Obesity also is implicated in altering cytokine responses. Animal studies have shown that elevated levels of TNF are associated with insulin resistance; Boeck and associates[39] reported that obese patients with significant insulin resistance had little or no detectable plasma TNF compared with control subjects. Genetically obese rodents have attenuated production of TNF and IL-6 in response to lipopolysaccharide compared with their lean littermates.[179] These findings may reflect a refractive state in obesity in which production of TNF is down-regulated. Kolterman and colleagues[158] reported reduced release of migration inhibitory factor by stimulated lymphocytes from moderately obese, nonhyperglycemic subjects to 36 percent of the level of normal-weight controls.

A variety of cell-mediated immune responses have been evaluated in genetically obese animals. Reduced numbers of T lymphocytes in peripheral blood, spleen, and thymus were described in obese rats compared with nonobese littermates. The proliferative response of splenocytes to mitogens and natural killer cell activity also was significantly lower in the obese rats.[309] When obese mice were immunized with lymphoma cells, the cytotoxic response of spleen cells was markedly lower than that of lean controls.[60] When lymphocytes from obese and lean mice were sensitized in vitro rather than in vivo, however, they performed similarly. This observation suggests that the microenvironment of obese animals, which includes hyperlipidemia, hyperglycemia, and altered levels of insulin, glucagon, cortisol, and adrenocorticotropic hormone, may be responsible for impaired cellular responses.

Studies indicate that leptin, a protein known to regulate appetite and energy expenditure, may play a role in the altered immune responses associated with obesity. The molecular structure of leptin is similar to that of IL-6, whereas its receptor is a member of the class I cytokine receptor superfamily. Studies of rodents with genetic abnormalities of leptin or leptin receptor revealed deficits in cell-mediated and humoral specific immunity[192] and in macrophage proliferation and phagocytosis.[108,179]

In humans, genetic leptin deficiency is associated with increased susceptibility to infections. Administration of recombinant leptin to two children with congenital leptin deficiency restored mitogenic responses and cytokine responses of T lymphocytes. This result raises the question as to whether, and if so to what extent, low leptin levels contribute to the immune dysfunction seen in malnutrition. Animal data suggest that malnutrition-induced immunosuppression is reversed, at least partially, through administration of leptin. Weight gain in malnourished children has been shown to lead to an increase in leptin serum concentrations and cytokine production and proliferative responses in T cells. A study conducted in mildly undernourished children in Gambia found that, although leptin serum concentrations were low and correlated well with nutritional status, an association between low leptin levels and depressed immune function as measured by vaccine and delayed hypersensitivity responses could not be established in this population.[213]

The role of leptin in the clinically observed increased susceptibility to infections in obese patients is even less clear. Some researchers have hypothesized that increased serum concentrations of leptin in obesity lead to down-regulation of the leptin receptor and leptin resistance in the target cell. The net effect on a cellular level may be that of decreased leptin signaling in obesity and starvation.[192] Characterizing intracellular signaling pathways through leptin in malnutrition and obesity may help to understand better the influence of different nutritional states on leptin's effect on immune responses. It is hoped that animal and clinical studies will help to define the interrelationship among leptin, infections, and obesity or malnutrition and may aid the discovery of new targets for therapeutic interventions.

EFFECT OF NUTRITION ON RESISTANCE TO SPECIFIC INFECTIONS

When malnutrition diminishes resistance to infection or when infection aggravates malnutrition, the relationship between the two can be described as synergistic. In other situations, malnutrition impedes the multiplication of the agent more than it diminishes resistance of the host. In this case, the interaction between infection and malnutrition can be considered antagonistic. Vitamin A deficient patients have been reported to have a higher incidence of tuberculosis, bronchitis, otitis media, urinary tract infections, and bronchopneumonia. Protein deficiency leaves patients more susceptible to typhus, hepatitis, amebic dysentery, diarrheal disease, and tuberculosis. A reasonable assumption is that most deficiency states decrease host resistance to infection.

EXPERIMENTAL VIRAL INFECTION

The effects of malnutrition on experimental viral infection have been studied, but results have not been uniform. Most studies published before 1965 suggested that starved, fasted, or underfed animals are more resistant to viral infections than are normal animals and that the severity of viral infection is decreased.[28,76,246,298,299,336] Despite some contradicting reports, the concept that healthy animals are more susceptible than are their malnourished counterparts to experimental viral infection gained broad acceptance.[272] This antagonistic effect of malnutrition on viral infection was attributed by some investigators to starvation of the virus at the cellular level, with restriction of viral replication.[34,107]

The first studies to cast doubt on this prevailing concept were done by Woodruff and Kilbourne.[342] Their studies convincingly showed an increased severity of infection with coxsackievirus B3 in male albino mice that were subjected to sustained postweaning undernutrition. Severity of infection was proportional to the magnitude of malnutrition. Virus persisted in the heart, spleen, pancreas, and liver of severely malnourished animals, and mortality rates were highest in these groups. If a quantitatively optimal diet was fed to previously malnourished mice at the time of infection, they were protected from further viremia and death.

Further studies of coxsackievirus B in mice with specific nutrient deficiencies were done by Beck and Levander.[26] In these studies, a normally benign strain of coxsackievirus B behaved more virulently and induced cardiomyopathy in selenium-deficient and vitamin E–deficient mice. The increased virulence was caused by genotypic changes in the virus so that the sequence of the normally benign virus now resembles that of more virulent strains. These viral genotypic changes may be secondary to a decreased immune response in the host, leading to increased viral replication and risk for mutation. Alternatively, the increased oxidative stress in a selenium-deficient or vitamin E–deficient host may result in an increase in free radicals that could damage viral RNA directly and result in mutations. This study is the first example of a host diet having a direct effect on the genetic composition of a pathogen.

Overall, the broad consensus is that malnutrition leads to increased susceptibility, morbidity, and mortality from almost all viral infections. Dengue fever seems to constitute an exception, however: Malnourished children apparently have a lower risk of contracting dengue fever than do children with normal nutritional status.[150] The mechanism underlying this observation is unclear.

MEASLES

Measles may be the most extreme example of a childhood disease that is benign in industrialized populations but associated with high mortality rates in developing nations. This difference can be attributed to many factors, including vaccination patterns, concurrent disease, and available medical care. One of the most important causes of this differential mortality is varying nutritional status. Measles influences the nutritional and immune status by several mechanisms. Similar to any other febrile illness, measles contributes to severe reduction in food intake, vomiting, and increased metabolic losses. Measles also can produce a viral enteritis that results in a protein-losing enteropathy. Measles induces prolonged immunosuppression characterized by a decrease in the number of circulating T cells and impaired proliferation of T lymphocytes that has been shown to last for nearly 6 months.

A study in India revealed a close association between protein-calorie malnutrition and measles, with nearly 25 percent of children hospitalized for severe protein-calorie malnutrition reporting an episode of measles in the preceding 3 to 6 months.[36] In a prospective study done in the urban slums of Hyderabad, measles was associated with a weight loss of 2 to 12 percent of initial body weight. These children also were shown to have retarded growth 6 months after the initial infection, and 4 percent developed clinical signs of kwashiorkor or marasmus. All children with severe protein-calorie malnutrition in the post-measles period were undernourished before contracting the infection, which highlights the importance of nutritional status as a major determinant of the severity of nutritional deficiencies and growth failure that occur in the post-measles period.[36]

In the malnourished host, the epithelial surfaces are affected severely by measles, with eye and mouth involvement, laryngitis,

bronchopneumonia, and gastroenteritis. These children carry and transmit the virus three times longer than do children with normal nutritional status, and they are more susceptible to viral and bacterial superinfection. A study in Nigeria found a mortality rate of 26 percent, with respiratory complications accounting for more than 90 percent of deaths.[94]

Vitamin A deficiency may cause some of the severe manifestations of measles that occur in malnourished hosts. As mentioned previously, vitamin A is essential for maintenance of epithelial surfaces and for the synthesis of the ground substance of the corneal stroma. The striking occurrence of post-measles blindness in approximately 1 percent of all children with measles in developing countries demonstrates the crucial role of vitamin A metabolism in the malnourished host. Vitamin A supplementation in patients with measles in developing countries is associated with significantly decreased morbidity and mortality rates.[113,136] Patients given vitamin A supplementation showed increased serum concentrations of IgG and faster resolution of virus-induced lymphopenia compared with controls, suggesting an increased immunoresponsiveness to the disease. Hyporetinemia is associated with increased severity of measles,[113] but the relationship between cause and effect is unclear. In the case of malnutrition, exhaustion of hepatic stores accounts for decreased retinol and may predispose the patient to severe measles. Alternatively, hepatic stores of retinol may be mobilized inadequately during severe measles.

Vaccination is an extremely important tool in preventing measles and its associated infections. Often, tuberculosis and malnutrition are considered contraindications for administering measles vaccination. In contrast to the natural measles infection, the attenuated virus has no immunosuppressive effect and is unlikely to activate latent tuberculosis.[36] Several studies in undernourished children have shown high rates of seroconversion to the measles vaccine except in cases of severe protein-calorie malnutrition, indicating the efficacy of immunization against measles in undernourished children.[37,75]

BACTERIAL INFECTION

Bacteremia, the most dreaded infective complication of severe malnutrition, varies in incidence among different studies from 2 to 31 percent. Most commonly, bacteremia is caused by gram-negative enteric bacilli, especially *Salmonella* spp. and *E. coli*, and the common organisms that infect normal hosts. Malnourished patients with bacteremia have an increased risk for organ failure and mortality compared with patients with adequate nutrition. Malnutrition also may modify the response of the immune system to bacterial infections and increase the risk for development of long-term sequelae. In a study of Bangladeshi children with antecedent group A beta-hemolytic streptococcal throat infections, poor nutritional status was associated with an increased risk for developing rheumatic fever.[351] This finding is consistent with the steady decline of the incidence of rheumatic fever in the industrialized countries in the first half of the 20th century, before the advent of penicillin, which was due largely to better socioeconomic conditions and consequently better nutrition of large parts of the population.

More recent research has examined the association between nutrition and *Helicobacter pylori* infection. *H. pylori* infection often is acquired in early childhood. The prevalence of *H. pylori* infection has been reported to be higher in breast-fed compared with formula-fed children, and infection rates seemed to correlate with the duration of breast-feeding.[254] A study in Colombian children found an increased incidence of *H. pylori* infection in children with lower consumption of fruits and vegetables, vitamin C, and beta carotene.[116] Because *H. pylori* is associated with depressed gastric acid secretion and loss of the gastric acid barrier, it predisposes hosts to enteric infections and may exacerbate malnutrition. A study in Gambian children reported decreased weight for age in infants with sustained *H. pylori* infections compared with uninfected controls.[73] In contrast, an association between *H. pylori* and decreased adult height could not be shown conclusively in an industrialized setting and may not exist without established baseline malnutrition.[208]

Urinary tract infections usually are caused by bacteria that are physiologically present in the stool. Researchers hypothesized that certain foods, by means of altering the composition of the gastrointestinal flora, may affect the incidence of urinary tract infections. In addition, certain foods may alter the urinary pH and render the bladder milieu more or less conducive to bacterial growth. Based on these theories, dietary modifications have been proposed as preventive and therapeutic interventions. Consumption of berry juices or food items containing probiotic bacteria seems to decrease the incidence of urinary tract infections. Some studies showed a therapeutic effect of cranberries or blueberry products on established urinary tract infections, but a therapeutic effect of probiotic bacteria could not be established.[159] Breast-feeding has been shown to decrease the incidence of urinary tract infections in neonates.[189] Whether this effect is due to transferred immunity, alteration of the infant's immune system, local effects on the bladder milieu, or the bacterial composition of the stool is unclear.

PARASITIC INFECTION

Parasitic disease in humans has been estimated to affect more than 1 billion people, particularly children who are living in developing countries in Africa, Asia, and Latin America, where protein-calorie malnutrition is endemic. The same conditions of poverty, overcrowding, and inadequate sanitation that are associated with parasitic infections also are associated with individuals who are at the highest risk for having malnutrition. A particularly vulnerable time for children seems to be from the time they are 4 months old until they are approximately 5 years old. During this period, the transition from breast-feeding to a home diet occurs, and the exposure to disease in the environment increases. Parasitic diseases may reduce intake, interfere with absorption from the intestine, or cause increased losses of nutrients through gastrointestinal, urinary, or blood loss. Evidence suggests that parasitic infections in humans may reduce voluntary food intake by immunologic mechanisms that cause anorexia. Zwingenberger and associates[354] found elevated levels of TNF and cachectin in humans infected with *Schistosoma mansoni*, which normalized after treatment.

Schistosoma haematobium causes urinary schistosomiasis and is endemic in 52 African and eastern Mediterranean countries. *S. mansoni* and *Schistosoma japonicum* cause intestinal schistosomiasis. *S. mansoni* is endemic in Africa, the Middle East, and a few countries in South America and the Caribbean. Schistosomiasis has been implicated as a major contributor to the two most important forms of malnutrition in the Third World—protein-calorie malnutrition and iron-deficiency anemia. The larval and the adult stages of the infection can alter nutritional status by reducing food and nutrient intake, increasing nutrient excretion (mainly through blood loss, vomiting, and diarrhea), or altering nutrient metabolism within the body.[354]

S. haematobium infection is characterized by hematuria and proteinuria. Infected subjects had mean hemoglobin levels 0.9 to 1.3 g/dL lower than the levels of uninfected controls from their areas. The daily urinary protein losses in urinary schistosomiasis are an average of 1 g/day. *S. haematobium* infection may cause splenomegaly and hepatomegaly. Splenomegaly may be related to increased destruction of erythrocytes and can predispose to anemia, whereas hepatomegaly may alter nutrient metabolism.

Hepatomegaly and splenomegaly are reversible with adequate treatment.[354]

S. mansoni infection is associated with blood loss in the stool. Farid and associates[95] estimated the daily fecal blood loss in seven chronically infected Egyptian patients to be equivalent to 3.3 mg/day of iron. These iron losses are sufficient to produce anemia if persistent and if the daily intake of iron is inadequate. Severe infection with *S. mansoni* has been reported to result in significantly lower height for age and skin-fold thickness than milder or no infection. In particular, hepatosplenic involvement has been associated with lower insulin-like growth factor–I, lower insulin-like growth factor binding protein 3, and lower body mass index in affected children.[229] Increasing evidence indicates that mild and moderate infections also have deleterious effects on childhood nutrition. A double-blind, placebo-controlled trial in Brazilian schoolchildren showed that treatment of mild to moderate intensity *S. mansoni* infections was associated with improvement in height, weight, and body mass index in boys.[15]

The effects of *S. japonicum* are similar to those of *S. mansoni*; however, they tend to be more severe because *S. japonicum* produces 10 times as many eggs per worm pair as does *S. mansoni*. Studies from China report that the presence and intensity of *S. japonicum* infection are related directly to reduced arm circumference, skin-fold thickness, height, weight, and weight-for-height ratios.[352]

Hookworms and *Trichuris* spp. are associated with significant intestinal blood losses. Foo[105] showed that children with hookworm infection were on average 1 kg lighter and 2.4 cm shorter and had hemoglobin levels 1.1 g/dL lower. *Ascaris lumbricoides* infection has been shown to interfere with the absorption of fat and is associated with reduced weight and height and reduced serum concentrations of albumin and vitamin A and C.[128] In addition to reducing fat absorption, *Giardia intestinalis* and *A. lumbricoides* reduce intestinal lactase activity, resulting in lactose intolerance. *Strongyloides stercoralis* infection is associated with a protein-losing enteropathy resulting in significant hypoalbuminemia. To a lesser degree, *Giardia lamblia* has been associated with a protein-losing enteropathy without hypoalbuminemia.[305] Several more recent studies[64,209] have shown an association between infection with *Cryptosporidium parvum* and poor linear growth in children, with more marked and lasting effects seen with younger age at infection.

Malnutrition also may affect reinfection rates after successful eradication of enteral parasites. Follow-up of 585 Brazilian children from a poor neighborhood of São Paulo showed higher reinfection rates in malnourished children; the results maintained borderline statistical significance when corrected for confounding variables, such as income or literacy.[262]

Many parasitic infections are caused by crowded living conditions and poor sanitation. At the same time, parasitic infections place an enormous economical and social burden on societies in which they are widespread. In this context, two more recent studies reported parasitic infections as an independent risk factor for poor cognitive function, even when controlled for socioeconomic or nutritional status.[31,93]

DIARRHEAL DISEASE

Disease of the intestinal tract is the most obvious link between the mutually aggravating conditions of infection and malnutrition.[43] Historically, diarrhea has been a primary cause of childhood morbidity and mortality in developing countries. Poor nutrition increases susceptibility to diarrhea, and diarrhea contributes to deteriorating nutrition. Overcrowding and poor sanitation, conditions that coexist with poverty, also act synergistically with malnutrition to enhance the risk for and morbidity of diarrhea. Steps to improve nutrition and to provide oral rehydration therapy in acute situations can contribute to decreasing diarrheal disease and its effects.

The risk for developing diarrheal disease seems to increase proportionately with the degree of malnutrition. A study of children in the Sudan[160] showed that mild to moderate wasting was associated with a 9 percent increased risk for developing diarrhea, severe wasting was associated with a 34 percent increased risk, and very severe wasting was associated with a 50 percent increased risk compared with normally nourished controls. Gracey[118] has suggested that protein-calorie malnutrition predisposes an individual to having chronic diarrhea by causing changes in the intestinal mucosa. The changes include thinning of the gut wall, flattening of the intestinal villi, inflammatory infiltration of the lamina propria, and alteration of the enterocytes from columnar to cuboidal or squamous.

The gastric mucosa also is abnormal in malnourished states. Chronic gastritis has been noted in Indonesian children in association with a reduction of secretion of gastric acid. This condition may lead to heavy bacterial infestation of the upper gut. The changes seen in the gastrointestinal tracts of children with malnutrition may account for their altered susceptibility to various pathogenic organisms. A cohort study of children in Bangladesh revealed that shigellosis and cholera were common causes of diarrhea in severely malnourished children, whereas rotavirus was seen more often in well-nourished children with diarrhea.[84] Exposure to different pathogens depending on the socioeconomic status also is likely to play a role in this epidemiology.

The mechanisms of nutrient loss in diarrhea that lead to malnutrition include maldigestion resulting in insufficient breakdown of substrates, malabsorption characterized by inefficient uptake, and excessive wastage of nutrients from the body. Bile salt pool depletion and impaired micelle formation in malnutrition cause steatorrhea. Carbohydrate intolerance and malabsorption occur partly because of enterocyte damage and loss of brush border enzymes and partly because of bacterial overgrowth. All of these mechanisms act synergistically with the enteric pathogen to exacerbate the ill effects of malnutrition on the individual.[129,295]

In addition, nonenteral infections commonly coexist and worsen the prognosis. Nutritional restitution is vital and a key factor in survival. It may be initiated through oral feedings or by a modified parenteral route in children who are unable to tolerate oral feedings. Ahmed and coworkers[5] tested a protocol for treating severely malnourished patients with diarrhea that emphasized oral rehydration, immediate refeeding, routine micronutrient supplementation, and broad-spectrum antibiotics. A 47 percent reduction in mortality rates was observed compared with treatment with the conventional protocol, which focused on immediate parenteral rehydration and delayed feeding without routine micronutrient supplementation. Specialized formulas, such as lactose-free formulas or probiotics, may assist further in the treatment of diarrhea, malabsorption, and dehydration, although this approach may be difficult to implement in situations where meeting the most basic needs, such as clean water, is a challenge.[14,294]

Several studies have suggested that breast-feeding and immunization against major pathogens (e.g., measles, rotavirus, cholera) play a protective role in reducing the incidence of morbidity and mortality from diarrhea.[45,133,329] Steps such as improving water quality and availability, ensuring proper food and personal hygiene, controlling zoonotic reservoirs, and improving waste disposal and sanitation would minimize transmission of pathogens to individuals at risk.[129]

RESPIRATORY INFECTION

In the underdeveloped world, acute respiratory infections rank with diarrheal disease as a leading cause of morbidity and mortal-

ity. In developing countries, acute respiratory infections account for approximately 28 percent of childhood deaths and are even more frequent than diarrheal episodes. The annual incidence of pneumonia for children younger than 5 years of age in industrialized countries is 3 to 4 percent compared with 10 to 20 percent in most developing countries. This increased incidence of lower respiratory infection likely relates to the increased incidence of malnutrition in these areas.[283]

Malnourished infants are 10 to 20 times as likely to contract pneumonia as are children of normal weight for age.[66] Severe complications, such as empyema and bronchiectasis, also are more likely to occur in the face of nutritional deficiencies. A community-based study in the Philippines showed that malnutrition was the most important determinant of mortality associated with respiratory disease.[320] Such evidence supports WHO recommendations that in areas of prevalent malnutrition the use of antibiotic therapy be determined on the basis of clinical signs that can be recognized by minimally trained health care workers.[344] The presentation of a child with cough, chest indrawing, inability to drink, or a respiratory rate of more than 50 breaths per minute meets the requirement for antimicrobial therapy.

The World Bank Health Sector Review on Acute Respiratory Infections suggested that the most cost-effective interventions to reduce mortality from respiratory infections are case management, promotion of breast-feeding, vaccination against childhood communicable diseases, reduction of malnutrition, and pneumococcal vaccination. Pneumococcal vaccines such as PCV-7 may not be as efficient in preventing severe infections in Third World countries because the spectrum of the most prevalent strains differs in different parts of the world, and antigens of regionally common strains may not be present in vaccines that are directed toward marketing in industrialized countries. Reduction in malnutrition probably is the most important preventive intervention because mortality correlates directly with nutritional status. Other studies also have stressed the importance of vitamin A supplementation in malnourished children, improved access to health care services, adequate housing, and proper waste management in reducing the transmission and development of acute respiratory diseases in children.[133,318,319,325]

PROPHYLAXIS AND IMMUNIZATION

The link between malnutrition and infection must be considered from biologic and social viewpoints. Strategies for improving the control of disease in the developing world have been reviewed by Keusch and Scrimshaw.[154] Immediate interventions include immunizations, oral rehydration programs, promotion of breast-feeding, adequate weaning foods with increased protein, continued feeding during infection, nutrient fortification, and growth monitoring. Complex measures, such as improved sanitation and general education, are important long-term goals.

The effect of malnutrition on the ability of a child to establish immunity after vaccination varies for different types of vaccines and for different degrees and types of malnutrition. Several investigators have concluded that the immune response to immunization remains unimpaired in balanced mild to moderate malnutrition; however, severe forms of protein-calorie malnutrition, especially when maintained for long periods, may affect negatively the ability to seroconvert after immunization.[3,4,75,276] Response rates to tetanus and diphtheria toxoid are well preserved even in children with severe malnutrition. In contrast, impaired responses to measles, yellow fever vaccine, hepatitis, killed influenza A, and killed typhoid vaccine all have been described in moderate to severe protein-calorie malnutrition. Cell-mediated immune responses after BCG immunization in Indian schoolchildren correlated positively with adequate nutrition and waned more rapidly in malnourished than in normal individuals.[279]

Despite these concerns, most data on vaccine campaigns indicate that virtually every immunization program among populations with malnourished children has been at least partially successful.[312] Adequate studies to define the extent of immunization failure in malnourished populations have not been done. The route of vaccination also may play a role. Flo and associates[104] showed that malnourished rats, after receiving oral immunization with cholera toxin, had diminished levels of total IgA in intestinal fluid and an impaired ability to neutralize cholera toxin in vitro compared with well-nourished controls. This finding suggests that oral immunizations have a diminished capacity to evoke an immune response compared with systemic immunizations in severe malnutrition.

Further research may help to improve the immune response after vaccinations in children with severe protein-calorie malnutrition. Of greater importance, no data are available to answer important questions regarding the possible harmful effects of live viral vaccines in malnourished children.

CONCLUSION

Attempts to reduce the mortality and morbidity referable to infection in a malnourished individual must be predicated on a more comprehensive understanding of this process than that presently available; the need for further research is clear. In the interim, every effort must be expended to control infection and improve nutrition and living conditions throughout the world. Meeting these goals requires education, improvement in sanitation, improvement in prenatal care to reduce the incidence of prematurity, and either greater access to appropriate food supplies or education directed toward improving the use of food of appropriate nutritional quality when it already is available.

Mounting evidence indicates that fine-tuning nutritional interventions in premature neonates, critically ill patients, and children with chronic diseases helps to prevent or decrease the development of infectious complications of these various conditions. It is hoped that further reductions in morbidity and mortality rates can be achieved in these patients as more is learned about the various levels of interplay between nutrition and immune function.

The possible link between cardiovascular disease and the immunologic consequences of obesity, such as increased susceptibility to infections and a chronic inflammatory state, constitutes an interesting platform for new therapeutic intervention in the fight against the number one killer in industrialized countries. It also underscores the importance of fighting obesity early in life. Pediatricians will be asked to play an ever more important role in educating their patients to prevent overweight; helping obese children to stabilize or lose weight; advocating for healthier school lunches and sports; and treating the increasingly more prevalent consequences of obesity, such as hypertension, type 2 diabetes, and obstructive sleep apnea, which were previously rare findings in pediatric patients.

CHAPTER 5

Fever: Pathogenesis and Treatment

Mark A. Ward ❂ Carolyn Lentzsch Parcells

Fever is defined as a thermoregulated increase in body temperature above normal as the result of a coordinated response to a pathologic insult. Fever has two essential features: abnormal elevation in body temperature and being the end-product of a coordinated physiologic response. The first feature differentiates fever from normal regulated elevations in body temperature (e.g., elevations associated with the circadian rhythm), whereas the latter distinguishes it from conditions in which the regulatory mechanisms are overwhelmed or dysfunctional (e.g., heat stroke). In children, the pathologic insult most likely to result in fever is infection. A variety of other conditions, including malignancies and autoimmune diseases, also may result in this phenomenon, however.

NORMAL BODY TEMPERATURE

Although the general public and physicians alike often refer to "*the*" body temperature, the implication that a single number can represent the thermal state of the entire body is inaccurate. Depending on the site of measurement, body temperature may vary by 1° C or more.[34] These regional variations in temperature do not have a fixed relationship to each other. Although axillary temperatures are consistently lower than rectal temperatures, the absolute difference between the two varies greatly.[4] In addition, even in the healthy state, body temperature is not constant; it varies depending on numerous factors, such as time of day, level of activity, and phase of the menstrual cycle. Generally, clinicians have been most interested in the core body temperature, defined as the temperature of the internal organs of the trunk and head. Under normal circumstances, core temperature is higher than the temperature of more superficial tissues such as skin. Even within these two anatomic regions, temperature gradients exist, however.

The most widely accepted definition of normal body temperature is 37° C (98.6° F).[45] This number is derived from studies performed in the 19th century by Wunderlich.[82] He reportedly arrived at this figure based on the result of several million

measurements conducted in approximately 25,000 individuals. Other, more recent studies have found slightly lower mean temperatures in healthy individuals, despite the fact that these more recent studies are based on oral or rectal temperatures, whereas Wunderlich's studies relied on axillary temperatures.[28] Mackowiak and colleagues[46] determined the mean oral temperature in adults to be 36.8° C (98.2° F), with the upper limit of normal ranging from 37.2° C (98.9° F) at 6:00 A.M. to 37.7° C (99.9° F) at 4:00 P.M. Given the limitations imposed by the technology available at the time, however, perhaps the most surprising aspect of the value reported by Wunderlich is how closely it approximates these more recent determinations.

As noted previously, body temperature fluctuates depending on numerous normal physiologic factors. Core temperature shows a diurnal variation of 1° C, the nadir occurring in the early morning hours and the peak in the late afternoon.[36,46] After exercise and in the postprandial state, body temperature increases.[51,65] In addition, variations in the normal body temperature of women associated with the menstrual cycle are well described, with increases in baseline temperature occurring after ovulation.[15]

THERMOREGULATION

Humans, similar to other mammals, are homeothermic, indicating that they regulate body temperature within a narrow range despite wide variations in the ambient temperature. Regulation of temperature is mediated by a variety of physiologic (e.g., vasoconstriction, sweating) and behavioral (e.g., moving to a warmer environment, putting on additional clothing) responses.

The principal thermoregulatory area is located within the brain in the preoptic area and anterior hypothalamus. Although it frequently is conceptualized as a single center, no single neuronal structure seems to control all aspects of temperature regulation.[10] Rather, a complex interplay occurs among a variety of neural pathways, with the final result being the maintenance of the body's temperature within a narrow range. Regardless of the precise nature of central regulation, body temperature ultimately is a function of the balance between heat gain and heat loss.

Heat energy is a by-product of the inefficiency of the body's normal metabolic processes. It is this "waste" heat that renders the homeothermic state possible. During exercise, the increased metabolic activity in muscle tissue results in increased production of heat, leading to an increase in the body's temperature.[63] Shivering, an involuntary form of muscle activity, is the primary means by which the body generates additional heat under conditions of cold stress. Heat also may be generated by a process known as *non-shivering thermogenesis*. Originally described in rats, non-shivering thermogenesis has been found to occur in a variety of mammals, including humans. It seems to be of greater importance in newborns than in adults. Although this process has been shown to occur in a variety of tissues, brown adipose tissue seems to be the most important site for this phenomenon. Under the control of the adrenergic system, production of free fatty acid is increased, resulting in an uncoupling of oxidative phosphorylation and the production of large amounts of heat.[9,27]

Four mechanisms are responsible for heat transfer: radiation, conduction, convection, and evaporation. Heat loss owing to radiation occurs when heat is transferred directly between two objects not in direct contact. Conduction involves the transfer of heat energy between two objects in contact with each other. Convection is the result of the movement of a fluid or gas across the surface of the body (e.g., as the result of fanning). Evaporative heat loss occurs in association with the energy required to convert liquid to gas form.

Under normal conditions, radiation accounts for most of the body's heat loss. By contrast, conductive losses are smaller under normal circumstances. Conductive losses may become substantial, however, under conditions in which a substantial portion of the individual's body surface is in direct contact with a cooler object (e.g., an unclothed infant in an unheated bassinet). Convective losses are proportional to the amount of air moving over the body surface; these losses are greatest in windy conditions. Conductive and convective heat losses are particularly important in infants and children because of their relatively greater body surface area compared with that of adults. Evaporative losses occur when fluids such as sweat evaporate from the skin's surface. In addition, substantial evaporative losses are associated with respiration.

PATHOGENESIS OF FEVER

In the classic model of fever pathogenesis, exogenous pyrogens stimulate the release of circulating endogenous pyrogens, which act via prostaglandins to increase the set-point of the hypothalamic thermoregulatory center.[17] In this model, exogenous pyrogens are substances extrinsic to the body, primarily various bacterial microorganisms or the products of those microorganisms. Conversely, endogenous pyrogens are a varied group of proteins produced within the human body that share the intrinsic ability to induce fever. The first endogenous pyrogen was described originally more than 60 years ago and was derived from leukocytes, primarily granulocytes, and now is known as interleukin-1.[18] Numerous other cytokines that qualify as endogenous pyrogens, including tumor necrosis factor, interferon-α, interferon-γ, and interleukin-6, have been identified.[44,83]

A variety of alternative and complementary theories of fever pathogenesis have been proposed.[52] The actual mechanisms involved likely are more varied and complex than just described. A variety of intrinsically produced substances (e.g., antigen-antibody complexes) may act as "exogenous" pyrogens.[61] The classic model provides a reasonable framework, however, for understanding most of the observed phenomena associated with the febrile response.

Regardless of the precise pathogenesis, the height of fever seems to be a limit. Retrospective studies of hyperpyrexia in children have found that it is unusual for the body temperature to rise above 41.1° C (106° F), and it rarely rises above 41.7° C (107° F).[56,75] Children with temperatures exceeding this range almost always have an element of heat illness.

EFFECTS OF FEVER

Attempts to treat fever often are predicated on the assumption that fever has harmful effects and that reduction in temperature would abrogate such harm. The evidence with regard to these premises is mixed, however.

ADVERSE EFFECTS

Some animal studies have found that high fever may impair certain immunologic responses, including phagocytosis of staphylococci by polymorphonuclear leukocytes[5,21,22] and lymphocyte transformation in response to mitogens.[60] Whether these isolated in vitro phenomena observed in animal models are relevant to human infection is unknown.

Fever may cause seizures, a phenomenon observed most frequently in young children. The onset generally occurs in infants 6 to 30 months of age. Recurrence is common, occurring in approximately one third of children experiencing an initial febrile seizure. The primary adverse consequences of febrile seizures are the emotional distress experienced by patients and their families and the need for medical evaluation, which may involve invasive

testing and substantial expense. Febrile seizures do not cause brain injury and are not associated with subsequent intellectual or neurologic deficits.[20,77]

BENEFICIAL EFFECTS

Fever may be beneficial—by enhancing the host response to infection and by directly inhibiting the infecting agent. Several studies have illustrated that the immune system responds to mildly elevated body temperature by increasing migration of leukocytes, production of interferon, and lymphocyte transformation and phagocytosis.[2,7,60,62] Studies of bacterial infection in reptiles and fish have shown an increased survival rate in groups maintained at approximately 4° C (reptiles) and 2.5° C (fish) above baseline.[14,37] Kluger and Vaughn[39] showed that rabbits infected with *Pasteurella multocida* had improved survival rates at body temperatures of approximately 4.5° C above normal. Although these data are impressive, their clinical significance with regard to humans has yet to be determined.

Fever also may inhibit the growth and survival of some infectious agents. One potential mechanism for this inhibition is the decrease in serum iron and increase in ferritin that are associated with fever, coupled with the increased iron requirement of many bacteria at higher temperatures.[5,38] Fever therapy was used historically to treat neurosyphilis and gonococcal urethritis, correlating with more recent studies that show that certain gonococci and *Treponema* are eradicated at temperatures of 40° C (104° F) and greater.[12,35] Finally, growth of some pneumococci and viruses seems to be impaired at higher temperatures.[26,71,79]

Several studies have found that the treatment of fever with antipyretics is associated with adverse consequences, providing indirect evidence of a beneficial effect of fever. Ahmady and Samadi[2] reported that the use of aspirin in children with measles prolonged the duration of the illness and was associated with an increase in prevalence of respiratory complications and diarrhea. Other investigators have reported that the length of time to total scabbing in varicella was significantly longer in children treated with acetaminophen compared with children treated with placebo.[19] Several studies in animal models and in humans have found prolongation of viral shedding, depressed neutralizing antibody response, and increased nasal symptoms in association with the use of antipyretics.[24,31,74] Although these studies establish that an association exists between reduction of fever and adverse outcomes, they do not prove a causal relationship. The adverse effects possibly are mediated by some direct physiologic effects of antipyretics, rather than indirectly by their impact on fever.

CLINICAL THERMOMETRY

TYPES OF THERMOMETERS

For many years, glass thermometers containing mercury were the most common type of thermometer used to measure body temperature. This type of thermometer is reasonably accurate for most clinical purposes. Although they are still available, use of mercury-containing thermometers has diminished greatly because of environmental concerns about mercury exposure from broken or discarded thermometers. These thermometers have been replaced largely by digital thermometers or glass thermometers containing liquids other than mercury.

Electronic thermometers (often referred to as *digital thermometers*) previously were used primarily in the hospital and office setting. As their cost has decreased, they are used more frequently in the home as well. Electronic thermometers have the advantage over mercury thermometers of requiring a significantly shorter dwell time, that is, the time they must remain in situ to obtain an accurate reading. Hospital-grade electronic thermometers typically have two modes: monitor and predictive. In the monitor mode, these thermometers function similarly to mercury thermometers in that they must remain in place until equilibration occurs, a process that may require several minutes. In the predictive mode, a complex algorithm is used to estimate the final temperature based on measurements made during the first few seconds. Because the predictive mode produces a temperature reading within seconds, it is the mode used most often in clinical settings. Determinations of temperatures using these two modes have been found to correlate well.[22,53]

Infrared thermometers are a more recent addition to the clinician's armamentarium. Devices that determine the temperature by detecting infrared radiation emitted from the ear drum are used most frequently. Tympanic temperature should provide an accurate estimation of the core temperature because its blood supply is derived from the carotid artery. Additional advantages of this type of thermometer are its speed, acceptance by patients, and decreased risk of cross-contamination compared with oral or rectal thermometers. Studies of the accuracy of tympanic thermometers have yielded mixed results, with numerous studies finding tympanic thermometers inaccurate compared with mercury in glass or electronic thermometers.[13,49] Discrepancies seem to be particularly common in infants who are in the first few months of life.[68] Tympanic thermometers should not be used in young infants because of the importance of fever in making management decisions in these patients.[16]

Even more recently, the temporal artery (TA) thermometer has been introduced. TA thermometers use an infrared sensor to determine skin temperature as the device is passed across the forehead and temporal area. The site of highest measured temperature is assumed to represent that of the temporal artery. An algorithm is applied to the measured temperature to estimate the core temperature. Studies to date suggest that TA thermometer temperatures correlate significantly better with rectal and core temperatures than with temperatures determined by tympanic thermometers. The initial data also suggest that TA thermometers are more sensitive at detecting fever in children than in adults. TA thermometers do not seem to correlate well enough with rectal or core temperature measurements, however, to replace rectal thermometry in clinical situations in which accurate measurement of fever is crucial for making decisions about management. The accuracy of TA thermometer readings is adversely affected by sweating and may be affected by vascular constriction or dilation. In addition, data comparing TA and axillary thermometry are lacking.[25,73]

Several other types of thermometers have been developed. Among them are electronic pacifier thermometers, used for obtaining an oral temperature in infants. Although they are appealing in theory, this type of thermometer has the disadvantage of requiring a prolonged dwell time and has not been found to be sufficiently accurate to recommend its use.[57] Another approach to measuring temperature is the use of liquid crystal thermometers that are applied to the skin of the forehead. Results generally have been disappointing when these thermometers have been compared with more standard techniques.[40,66]

MEASUREMENT SITE

The most common locations for measuring body temperature are the mouth, rectum, axilla, and tympanic membrane. Because of the previously noted regional variations in body temperature, each of these sites has its own range of normal temperatures. The oral cavity historically has been the preferred site for measuring temperature in older children and adults. When taking a temperature orally, one should place the thermometer in the sublingual space because the blood supply for structures in this region

is derived from branches of the carotid arteries and should reflect the core temperature accurately. Younger children usually are unable to cooperate adequately to permit the use of oral thermometers. In addition, the oral temperature may be affected by recent ingestion of hot or cold liquids, and it may be altered by tachypnea.

Rectal temperatures are used frequently in younger children. The rectal temperature correlates well with the core body temperature. The rectal temperature may exceed the core temperature (using the pulmonary artery temperature as the reference standard), however, possibly because of the effects of bacterial activity in the rectum. The use of rectal thermometry has the disadvantage of causing the patient discomfort and is contraindicated in patients with neutropenia because of the risks of causing invasive infection via trauma to the rectal mucosa.

Axillary temperatures are appealing because of the ready accessibility of the axillae. Considerable variability occurs in the readings obtained, however, particularly in younger children. One should not rely on axillary temperatures, particularly in neonates and young children.

TREATMENT

As noted previously, fever may have numerous beneficial effects, convincing evidence of harm owing to fever is lacking, and treatment of fever may be associated with undesirable effects. Routine intervention to reduce fever is not warranted. Rather, physicians should individualize the decision to treat fever and the specific method chosen to do so.

INDICATIONS

Antipyretic therapy often is considered for children who have an increased risk of having febrile seizures, either because of age or because of a history of febrile seizures. Although treatment seems rational in this situation, studies of antipyretic therapy to prevent febrile seizures have failed to show its efficacy.[11,65,76] Even this indication should be considered relative rather than absolute.

Antipyretic therapy also should be considered for children with poorly compensated underlying cardiac or pulmonary disease, significant neurologic impairment, or sepsis, and for children with significant alterations of fluid and electrolyte balance. Definitive controlled trials to support these indications are lacking. Rather, the recommendations are based on the metabolic consequences of fever and their potential adverse impact on the underlying disease.

Perhaps the most frequent indication for the use of antipyretics is to improve the patient's comfort. Despite the absence of definitive studies to support this practice and the potential adverse consequences of using antipyresis, such an approach is reasonable in the absence of definitive evidence to the contrary. In some circumstances, improving the patient's comfort may enhance the ability to assess the seriousness of the patient's illness accurately.[6]

ANTIPYRETICS

A wide variety of antipyretic agents is available. In the United States, the drugs used most frequently for treatment of fever in children are acetaminophen and ibuprofen. Previously, aspirin was the antipyretic used most frequently. Aspirin has fallen into disuse for the management of fever in children, however, primarily because of its association with Reye syndrome, particularly when used in managing children with varicella or influenza.[30] In addition, aspirin has a variety of other adverse effects, including inhibition of platelet function, gastritis and gastrointestinal bleeding, and provocation of asthma exacerbations, although this third complication occurs more frequently in adults.[32,59,67] Aspirin has greater toxicity in situations of overdose than do acetaminophen and ibuprofen.

Each of these agents acts to restore normal body temperature by reducing the set-point of the temperature regulatory center in the hypothalamus. The specific mechanism of action seems to be interference with prostaglandin synthesis in the PAOH. When selecting among the available antipyretic agents, one should consider efficacy and potential toxicity.

Similar to aspirin, ibuprofen inhibits prostaglandin synthesis in a variety of tissues outside the central nervous system. It shares many of the toxicities associated with aspirin. One exception is that ibuprofen lacks the association with Reye syndrome.[58] Ibuprofen inhibits platelet function because of its effect on prostaglandin synthesis, but this effect is reversible with discontinuation of the drug, and platelet dysfunction is short-lived compared with the effect of aspirin.[54] Because prostaglandins are important to the integrity of the gastrointestinal mucosa, inhibition by ibuprofen may result in gastrointestinal upset and bleeding. Although ibuprofen has been associated with exacerbations of asthma in some children, the risk seems to be small and may not be greater than that associated with the use of acetaminophen.[41,42]

Acetaminophen has a lengthy track record of safety. When used in the usual therapeutic doses, it has few adverse effects. Acetaminophen inhibits prostaglandin synthase activity, but this action is inhibited by peroxide. Because peroxide is generated at sites of inflammation, acetaminophen has little anti-inflammatory activity. It also lacks the adverse gastrointestinal and platelet effects of aspirin and ibuprofen.

Recommended dosing of ibuprofen is 5 to 10 mg/kg every 6 hours as needed. Acetaminophen is administered at a dose of 10 to 15 mg/kg every 4 hours, but no more frequently than five times per day. An important note for individuals administering these agents is that a variety of over-the-counter combination medications contain one or the other of these agents. Co-administration may result in inadvertent overdosing.

In addition, recognizing that ibuprofen and acetaminophen come in a variety of formulations is important. Acetaminophen is available as infant drops (concentration 10 mg/mL) and children's liquid (concentration 32 mg/mL). Substitution of children's liquid for infant drops without adjusting the volume administered to reflect the difference in concentration may result in serious toxicity. Acetaminophen also is available in suppository form. Absorption varies, however, and is delayed compared with oral administration. In addition, the medication is not distributed uniformly throughout the suppository, resulting in potential dosing errors if the suppositories are divided before use.[8] The use of acetaminophen in suppository form should be discouraged.

The antipyretic efficacy of acetaminophen and ibuprofen has been the subject of numerous clinical trials.[33,78,80,81] These trials have shown uniformly that both are effective antipyretic agents. Ibuprofen seems to result in a greater decrease in temperature than does acetaminophen, however. In addition, the antipyretic effect of ibuprofen is more prolonged, not surprising in light of ibuprofen's longer half-life compared with acetaminophen. These observations were confirmed in a meta-analysis of trials comparing ibuprofen and acetaminophen.[55]

Acetaminophen and ibuprofen frequently are used in combination.[43] Use of alternating doses often is advocated by practicing physicians.[48] The pathways for metabolism of these drugs are distinct, and, theoretically, metabolism of one should not affect the metabolism of the other. Controlled trials documenting safety and efficacy of combination or alternating use are sparse, however. In the only such study to date, using alternate doses of acetaminophen (12.5 mg per dose) and ibuprofen (5 mg/kg per dose) every 4 hours was found to be associated with a more rapid

reduction in fever, lower mean temperature, and fewer caregiver days absent from work and infant days absent from daycare compared with use of either agent alone.[64] The groups assigned to a single agent received dosing that was either on the low end or infrequent, however, compared with usual practice in the United States.

Another approach to antipyretic treatment frequently employed is the use of a second antipyretic when the initial agent is judged to have resulted in an inadequate response. Theoretically, some individuals may have a better antipyretic response to one agent than another. Although the premise is reasonable, sequential use of acetaminophen and ibuprofen remains unproven in terms of efficacy and safety.

Acetaminophen and ibuprofen have been proven to be remarkably safe when used in the recommended doses. Although ibuprofen may be slightly more efficacious in producing and sustaining fever reduction, acetaminophen remains the antipyretic of choice because of its longer track record and more favorable side-effects profile. Because acetaminophen lacks significant anti-inflammatory activity, ibuprofen or another nonsteroidal anti-inflammatory drug may be preferred in febrile conditions for which anti-inflammatory activity is desired (e.g., juvenile arthritis). Limited data suggest that use of acetaminophen and ibuprofen in combination may be safe and more efficacious than is either agent alone. Prudence suggests, however, that combined therapy seldom is warranted for this generally benign condition. Perhaps most important, patients and their parents should be educated to the benign nature of fever and the lack of evidence to indicate that routine treatment, particularly complete suppression, is either necessary or beneficial.

EXTERNAL COOLING

The use of external cooling in the management of fever has a long history. Compared with standard antipyretics, sponging with tepid water is inferior in fever reduction at 2 to 3 hours, although sponging was found to reduce the temperature more quickly than did antipyretics in one trial.[1,3] External cooling without concomitant administration of antipyretics makes little sense from a physiologic standpoint, however. In a febrile patient whose temperature regulatory center set-point has not been reset by administration of an antipyretic agent, external cooling inevitably results in an increase in the body's heat-production mechanisms.

When used in conjunction with an antipyretic agent, the usual goal of external cooling is to reduce the body's temperature more rapidly or to a greater degree. Several studies have compared the use of external cooling combined with antipyretics with antipyretics alone. Results have been mixed; some studies showed no difference in efficacy of the two approaches, whereas others found combination therapy to be superior.[23,29,47,69,72] Even in the studies in which a difference was found, the superiority of combination therapy was shown primarily in the very early phase of treatment. In addition, the use of external cooling usually is uncomfortable for the patient. When external cooling is to be used, sponging with tepid water is preferred. Alcohol and solutions containing alcohol should not be used for this purpose. Absorption of alcohol vapors via the lungs may occur in sufficient quantities to produce toxicity and even death.[50]

CHAPTER 6

Indigenous Flora

Douglas S. Swanson

The terms *indigenous flora* and *normal flora* describe the microorganisms that colonize the internal and external surfaces of healthy individuals.[113] Colonization is the presence of replicating microorganisms on or within a host, without evidence of the development of disease. The microbial agents that compose the normal flora are called *commensal*, *colonizing*, or *endogenous* organisms. They usually do not cause injury to the host and can be divided into categories of resident or transient flora.[29,159] Resident flora are organisms that are present routinely in a specified anatomic location. *Staphylococcus epidermidis* is a resident organism of the

skin, and *Escherichia coli* is a resident organism of the gastrointestinal tract. Transient flora are organisms that are present only temporarily in a certain anatomic location, such as *Staphylococcus aureus* on the skin or *Pseudomonas aeruginosa* in the gastrointestinal tract. Blood, cerebrospinal fluid, urine, bile, and synovial fluid are considered sterile fluids and have no normal flora.

Environmental factors, host characteristics, and microbial properties all can influence the composition of the indigenous flora. Disruption of the balance among these various factors can have a profound impact on the normal flora and their subsequent potential for pathogenicity. Pathogens are microorganisms that are able to cause disease in the host. Strict pathogens, such as *Neisseria gonorrhoeae* and the rabies virus, always are associated with disease and are not considered part of the normal flora. Organisms such as *P. aeruginosa*, *S. epidermidis*, and *Serratia marcescens* are opportunistic pathogens and do not cause disease except in immunocompromised hosts or in special circumstances that support their dissemination. Central venous catheters can become contaminated with *S. epidermidis*, resulting in a bloodstream infection. Similarly, after a dental procedure, transient bacteremia can cause viridans streptococcal endocarditis in a patient with an abnormal heart valve.

Facultative pathogens fall somewhere between strict and opportunistic pathogens. They have the capacity to cause disease in healthy individuals and compose much of the indigenous flora found in the body (e.g., *Streptococcus pneumoniae*, *E. coli*, and *S. aureus*).[149,159]

It is useful for clinicians to have a general understanding of the normal human microbial flora. First, familiarity with the organisms that compose the normal flora may help with the interpretation of culture reports, such as the isolation of diphtheroids from a peripheral blood culture. Second, when an infectious disease is present, knowledge of the indigenous flora can assist in determining the likely causative agents and provide a basis for determining the initial antimicrobial therapy. This knowledge is especially important because of the increasing number of immunocompromised individuals who are vulnerable to endogenous infections. Third, an understanding of the normal flora may assist in making the decision to withhold antimicrobial therapy when a culture report identifies an organism that is considered to be a pathogen but is not for that patient's particular clinical presentation. The isolation of *S. pneumoniae* from a throat culture of a patient with pharyngitis can be disregarded if one recognizes that this organism is a normal part of the nasopharyngeal microbial environment and an unlikely cause of pharyngitis. Finally, clinicians may prescribe broad-spectrum antimicrobial agents more judiciously if they have an appreciation for the role that indigenous flora play as part of the host's defense system.[138]

ACQUISITION OF INDIGENOUS FLORA BY THE NEWBORN

The fetus normally is in a sterile environment in the uterus. The newborn begins to acquire indigenous microbial flora during delivery. Maternal flora provide the initial source of colonizing organisms. Exposure to organisms from other people and environmental sources contributes to the formation of the neonate's eventual normal flora.[139]

The gestational age, mode of delivery, and type of feeding all can affect the formation of a newborn's indigenous flora. Premature infants requiring prolonged hospitalization have a delay in bacterial colonization and more frequently are colonized with hospital flora, especially *Klebsiella*, *Enterobacter*, and *Citrobacter* spp., compared with healthy term newborns.[49,56,63] Infant-to-infant transmission by the hands of health care workers is an important factor contributing to gram-negative colonization of premature neonates.[56] Infants born by cesarean delivery have delayed intestinal colonization with anaerobic bacteria, and gut colonization can remain altered for 6 months after birth.[21,68,106,144] The intestinal flora also are influenced by the newborn's diet. *Bifidobacterium* spp. and a few other anaerobic bacteria dominate the intestinal flora of breast-fed newborns, whereas infants fed formula have a more complex intestinal microbial flora.[6,13,41,109,156,183] As the infant gets older, the composition of the indigenous flora begins to resemble more closely that of an adult.

MECHANISMS OF COLONIZATION

The normal flora differ substantially among the various anatomic sites because of local barriers to colonization. Environmental conditions, such as moisture, pH, oxygen tension, and nutritional supply, influence the ability of microorganisms to establish residence.[55,113] In certain anatomic regions, mucociliary clearance, epithelial cell turnover, and the flow of secretions restrict colonization to specific species of microbes.[113] Additional barriers include specific and nonspecific immune factors, the production of lysozyme, local attachment-blocking proteins, and microbial competition.[37]

The primary mechanisms of bacterial colonization are adherence to epithelial cells, colonization of mucus, and attachment to other colonizing organisms.[37] Adherence of bacteria to epithelial cells occurs primarily by specific binding between microbial surface antigens (adhesins) and epithelial receptor molecules.[12,72,95] Oral bacteria colonize specific sites within the mouth. *Streptococcus salivarius* binds to the epithelial cells of the tongue and buccal mucosa, whereas *Streptococcus mutans* and *Streptococcus sanguis* bind to tooth enamel.[138,180] Normal flora also can be established by the colonization of the mucous layer without bacterial attachment to host cells, as shown in the intestinal tract.[37] Finally, microbes can attach to colonizing organisms through adhesin-receptor binding. This means is established most clearly in the formation of dental plaque.[180]

EXOGENOUS INFLUENCES ON THE NORMAL FLORA

An individual's normal flora tends to remain stable and consistent but can be affected by a variety of exogenous factors. Antibacterial soaps, topical antiseptics, and deodorants can temporarily suppress the skin flora.[14,74,93] Similarly, brushing teeth with fluoride toothpaste reduces dental microflora. Eating fresh fruits and vegetables may provide a source of transient intestinal colonization with *P. aeruginosa*.[96,134] Cigarette smoke has been found to alter the normal flora and increase the number of potential pathogens in the nasopharynx.[26,27] Viral infections can disrupt the normal flora and predispose the patient to development of bacterial superinfections.[32,50,52,61,70,71,107,132,161] Influenza virus infection increases susceptibility to bacterial pneumonia, otitis media, and bacteremia partly by facilitating the adherence of pathogenic bacteria to respiratory epithelial cells.[61,146,184]

Medications can influence the composition of the normal flora. Acid reduction therapy may permit bacterial overgrowth within the stomach and small intestine, resulting in deconjugation of bile salts and malabsorption.[42,67,92,141,164,166,181] Gastric acid suppression also may reduce the number of ingested pathogens needed to cause enteric disease.[181] Antimicrobial agents can alter significantly the indigenous flora and promote colonization with potential pathogens by eliminating susceptible commensals.[10,40,60,76,82,117,122,123] Such changes can lead to superinfections with overgrowing organisms.[5,23,108,185] Antibiotics can reduce the barrier effect of the normal intestinal flora, permitting *Clostridium difficile* to propagate and produce toxins, resulting in pseudomembranous colitis.[9] Antimicrobial effects on the indigenous

flora depend on the type of antibiotic, route, dose, and duration of administration.

Severe or chronic illnesses alone can cause changes in an individual's indigenous flora.[79,89,90,103] Hospitalized patients with severe illness are much more likely to develop pharyngeal colonization with gram-negative bacilli than are hospitalized patients who are physiologically normal.[89,90] Medical devices may alter the host's normal flora. Thomas and colleagues[165] showed that patients requiring placement of nasogastric tubes had significantly greater nasopharyngeal colonization with aerobic gram-negative bacilli compared with patients in a control group.

BACTERIAL COMPOSITION AT SPECIFIC LOCATIONS

SKIN

Because of the presence of moisture and sebum, most skin flora are associated with sweat glands (Table 6–1). Bacterial concentrations are highest on the face, on the neck, in the finger and toe webs, and in the axillae and groin.[115,116] The organisms occupy the most superficial layers of the epidermis and are found primarily around the hair follicles, although some are located deeper within follicles.[11,115,121] Although soaps and other skin cleansers

TABLE 6–1 Common Indigenous Flora at Various Anatomic Sites

Body Site and Type of Pathogen	Resident Flora	Transient Flora
Skin		
Opportunistic pathogens	*Corynebacterium*, *Staphylococcus epidermidis*, *Micrococcus*, *Peptococcus*, *Brevibacterium*, *Acinetobacter*, *Demodex folliculorum*	Viridans streptococci, *Enterococcus*, *Malassezia*
Facultative pathogens	*Propionibacterium acnes*, *Pityrosporum*	*Staphylococcus aureus*, *Enterobacter*, *Escherichia coli*, *Klebsiella*, *Proteus*, group A streptococci, *Candida*, *Trichophyton*
Eye		
Opportunistic pathogens	Coagulase-negative staphylococci, *Corynebacterium*, *Micrococcus*	*Bacillus*, viridans streptococci, *Propionibacterium*
Facultative pathogens	*Haemophilus*	*S. aureus*, *Streptococcus pneumoniae*
Mouth and Oropharynx		
Opportunistic pathogens	Viridans streptococci, coagulase-negative staphylococci, *Haemophilus*, non–group A beta-hemolytic streptococci, *Treponema*, *Veillonella*, *Porphyromonas*, *Prevotella*, *Lactobacillus*, *Peptostreptococcus*, *Bacteroides*, nonmeningococcal *Neisseria*, *Corynebacterium*, *Gemella*, *Granulicatella*	*Eikenella corrodens*
Facultative pathogens	*Fusobacterium*, *Streptococcus mutans*,* *Actinomyces**	Group A streptococci, *Lactobacillus*,* *Neisseria meningitidis*, *Kingella*, *S. pneumoniae*, *Moraxella*, *Candida*, cytomegalovirus, herpes simplex virus
Nose and Nasopharynx		
Opportunistic pathogens	Coagulase-negative staphylococci, viridans streptococci, *Corynebacterium*	Nonmeningococcal *Neisseria*
Facultative pathogens	—	*S. aureus*, *N. meningitidis*, *S. pneumoniae*, *Moraxella*
Stomach		
Opportunistic pathogens	—	*Streptococcus*, *Lactobacillus*
Facultative pathogens	—	*Helicobacter pylori*
Small Intestine		
Opportunistic pathogens	*Lactobacillus*, *Streptococcus*, *Veillonella*, *Prevotella*, *Porphyromonas*, *Bifidobacterium*	*Candida*, *Entamoeba coli*, *Endolimax nana*, *Iodamoeba bütschlii*, *Trichomonas hominis*, *Chilomastix mesnili*
Facultative pathogens	*Bacteroides*, Enterobacteriaceae, *Clostridium*	*Blastocystis hominis*
Large Intestine		
Opportunistic pathogens	*Bifidobacterium*, *Peptostreptococcus*, *Lactobacillus*, *Veillonella*, *Eubacterium*, *Fusobacterium*, *Prevotella*, *Porphyromonas*, *Enterococcus*, *Peptococcus*, *Ruminococcus*	*Candida*, *Corynebacterium*, *Pseudomonas*, *Mycobacterium avium* complex, *E. coli*, *E. nana*, *I. bütschlii*, *T. hominis*, *C. mesnili*
Facultative pathogens	*Bacteroides*, *Clostridium*, Enterobacteriaceae	*Aeromonas*, *B. hominis*, enterovirus
Anterior Urethra		
Opportunistic pathogens	*Corynebacterium*, coagulase-negative staphylococci, viridans streptococci, *Lactobacillus* (women)	*Mycobacterium smegmatis*, *Bacteroides*, *Fusobacterium*
Facultative pathogens	—	Enterobacteriaceae, *Enterococcus*, *Ureaplasma*, *Mycoplasma*
Vagina		
Opportunistic pathogens	*Lactobacillus*, *Streptococcus*, coagulase-negative staphylococci	*Enterococcus*
Facultative pathogens	*Gardnerella vaginalis*, *Mobiluncus*, *Prevotella*, *Actinomyces*	Group B streptococci, *Candida*, *Trichomonas vaginalis*

**Contribute to dental caries.*

substantially reduce the number of most surface bacteria, organisms within hair follicles and sweat glands quickly re-establish the normal flora.[74,93]

The normal skin flora are primarily of coagulase-negative *Staphylococcus* spp. (especially *S. epidermidis*), *Propionibacterium acnes*, *Corynebacterium* spp. (diphtheroids), and *Micrococcus* spp. *P. acnes* emerges at the onset of puberty, occupies hair follicles and sebaceous glands, and is a major contributing cause of acne. *S. aureus* and group A streptococci are not usual residents of the skin but may cause transient colonization.[152] *Acinetobacter* spp. are a common resident of the toe webs. Other gram-negative organisms, such as *Klebsiella*, *Proteus*, and *Enterobacter* spp. and *E. coli*, are uncommon findings and transient residents of the skin. The fungus *Pityrosporum* (*ovale* and *orbiculare*) normally inhabits the skin,[135,136] but *Candida* spp. do not.[34] Many other microorganisms come in contact with the skin, but because of the skin's dryness and presence of organic fatty acids, they are present only briefly and do not propagate.

Newborns

Within hours, a normal full-term infant's skin becomes colonized with microbes. In addition to typical normal skin flora, potential pathogens (group B streptococci, *E. coli*, *Klebsiella* spp.) frequently are recovered from cultures of the external ear canal.[110,125] Obtaining routine surveillance cultures in an attempt to identify infants at risk for acquiring invasive disease is not recommended, however, because their predictive value is limited.[87,110,125]

CONJUNCTIVAE

The mechanical actions of the eyelids and the washing effect of tears containing antimicrobial substances inhibit microbial colonization of the eye; however, normal flora do exist. The conjunctival flora probably originate from the eyelids and the nasolacrimal ducts. The organisms most commonly isolated are coagulase-negative staphylococci, *Corynebacterium*, *Micrococcus*, and *Propionibacterium* spp. Other isolates include *S. aureus*, *Haemophilus* spp., viridans streptococci, *S. pneumoniae*, and *Bacillus* spp.[102,129,138,177]

RESPIRATORY TRACT

The mouth and oropharynx contain several unique microbial habitats. Viridans (alpha-hemolytic and nonhemolytic) streptococci are the most prominent commensals and include *S. mutans*, *S. sanguis*, *S. salivarius*, *Streptococcus milleri*, and *Streptococcus mitis*.[97,138,159] The flora of the gingival crevice include a diverse collection of facultative and anaerobic organisms. More common isolates include *S. mitis*, *S. mutans*, *Actinomyces*, *Fusobacterium*, *Treponema*, *Veillonella*, and *Peptostreptococcus*. *Bacteroides* spp., *S. sanguis*, and *S. mitis* are the initial colonizers of the tooth surface. Dental plaque forms when *S. mutans* and *Actinomyces*, *Fusobacterium*, *Treponema*, and *Veillonella* spp., along with other organisms, attach to the initial bacterial cell layer and each other.[127,180] The buccal mucosa, tongue, and saliva are colonized most heavily by *S. salivarius*, *S. mitis*, and *Veillonella*, *Gemella*, *Granulicatella*, and *Lactobacillus* spp.[1] Asymptomatic pharyngeal carrier rates of group A streptococci in children range from 3 to 50 percent, with the highest prevalence rates associated with school outbreaks of pharyngitis.[35,45,53,78,130,154,157,178,182]

Compared with flora of the mouth and oropharynx, the microbial flora of the nose and nasopharynx are less diverse. Coagulase-negative staphylococci, viridans streptococci, *Corynebacterium* spp., and *S. aureus* are the most prevalent strains isolated. Nasal carriage rates of *S. aureus* average 20 to 35 percent, and the prevalence of methicillin-resistant *S. aureus* nasal colonization has been increasing, with estimates ranging from 0.2 to 22 percent, depending on demographic characteristics.[2,3,31,77,85,98,150,158,170] Colonization of children with *Neisseria*, *Haemophilus*, *Moraxella* spp., and *S. pneumoniae* is a common occurrence.

Pneumococcal colonization of the nasopharynx generally is transient, averaging in duration from 1 to 4 months.[51,66] Increased colonization is seen with younger age, overcrowding, attendance at a daycare center, winter season, and exposure to tobacco smoke. Nasopharyngeal carriage rates of *S. pneumoniae* average 40 to 50 percent in children and 20 to 30 percent in adults.[59] Nasopharyngeal colonization occurs even with the implementation of pneumococcal protein conjugate vaccine; several studies indicate a change in serotype distribution with an increased presence of drug-resistant strains.[54,83,86] Despite the presence of potential pathogens in the nasopharynx, no convincing evidence supports the use of nasopharyngeal cultures to predict the etiology of acute otitis media, pneumonia, or sinusitis.[58,173]

The sinuses and lower respiratory tract generally are assumed to be sterile. In actuality, bacteria from the mouth and nose probably reach these regions daily but are cleared promptly by local defense mechanisms.[138]

During the first week of life, the newborn's oropharynx usually is colonized by maternal vaginal flora, primarily *Lactobacillus* spp. and *Streptococcus viridans*.[28,119] These bacteria gradually are replaced by mouth flora from the mother and caretakers. *S. salivarius* and *S. mitis* predominate. Anaerobes, *S. mutans*, and *S. sanguis* are uncommon findings until teeth erupt.[97] *Ureaplasma* spp. and *Mycoplasma* spp. from the maternal vagina readily colonize the newborn's respiratory tract.[160] They are a suspected, yet still undetermined, cause of chronic lung disease in premature infants.[75,124,176] Enteric bacilli can be recovered from the throats of more than half of normal infants older than 2 months of age.[7]

GASTROINTESTINAL TRACT

The gastrointestinal tract consists of the esophagus, stomach, small intestine, and colon. The esophagus usually is sterile, and the stomach generally harbors only a few bacteria. The digestive enzymes and acid in the stomach destroy most swallowed organisms, or they pass promptly into the small intestine. Among the microflora of the stomach are acid-tolerant organisms, such as lactobacilli and streptococci,[147] and *Helicobacter pylori*, which survives within the mucous layer overlaying the gastric mucosal epithelium.[22,57,91] The worldwide prevalence of *H. pylori* colonization in children ranges from 10 to 90 percent.[162] Factors associated with colonization include lower socioeconomic status, household crowding, ethnicity, and household contact with carriers.[65,128,168] When the gastric pH is increased, nasopharyngeal and fecal-type flora may colonize the stomach.[181]

Low concentrations of *Streptococcus*, *Lactobacillus*, *Veillonella*, and rare *Bacteroides* spp. can be found in the upper small intestine.[17,30,44] Higher concentrations of the same bacteria plus *Bifidobacterium*, *Clostridium*, and Enterobacteriaceae are present in the lower small intestine.[18,114] Small bowel bacterial overgrowth can occur under conditions of gastric achlorhydria, a blind loop, or dysmotility. This syndrome may result in malabsorption and diarrhea.[94]

The colon contains a large and diverse population of microorganisms.[64,151] More microbes occur in this location than anywhere else in the body. For many years, because of inadequate techniques available for culturing strict anaerobic bacteria, *E. coli* was thought to be the principal resident of the large intestine. It has become apparent that the strict anaerobes outnumber the facultative microbes by 1000 to 1, with hundreds of different anaerobic species being isolated from the colon.[147] Molecular analysis of fecal

flora has expanded understanding of the microbial diversity found in the gastrointestinal tract.[48,175] *Bacteroides* and *Bifidobacterium* spp. comprise the largest percentage of fecal flora. Other major organisms in the colon include *Peptostreptococcus*, *Peptococcus*, *Ruminococcus*, *Enterococcus*, Enterobacteriaceae, *Prevotella*, *Porphyromonas*, *Fusobacterium*, *Clostridium*, *Lactobacillus*, and *Eubacterium* spp.

Newborns

The newborn's intestinal flora usually are derived from organisms within the mother's birth canal and from the newborn's environment. Diet can influence the composition of the infant's intestinal flora.[37,41,106,111] Full-term, breast-fed infants are colonized predominantly with *Bifidobacterium* spp. Formula-fed infants have a more complex intestinal flora in which *Bifidobacterium*, *Bacteroides*, *Enterobacter*, *Clostridia*, and *Enterococcus* spp. are prevalent.[6,13,41,109,156,183] Infants delivered by cesarean section have 6 months' delay in colonization with anaerobic organisms.[21,68,106] At 12 months of age, after the introduction of solid foods, all infants have intestinal flora that more closely resemble those of an adult.[41]

Intestinal colonization of very-low-birth-weight infants is delayed, and the development of anaerobic flora is diminished. Anaerobes, especially *Bifidobacterium* and *Lactobacillus* spp., are thought to protect the host against invasion by pathogens. Paucity of these organisms permits bacterial overgrowth with potential pathogens, especially *E. coli*, *Klebsiella*, *Enterobacter*, and *Citrobacter* spp. Researchers suspect that this aberrant intestinal colonization of premature infants contributes to the pathogenesis of necrotizing enterocolitis.[33,43,101,126]

GENITOURINARY TRACT

The endogenous flora of the genitourinary tract normally are confined to the distal portion of the urethra and the vaginal mucosa. The anterior urethra in men and women commonly is colonized with skin flora (coagulase-negative staphylococci, *Corynebacterium* spp., and streptococci) and may contain *Mycobacterium smegmatis* and *Bacteroides*, *Fusobacterium*, *Enterococcus*, and Enterobacteriaceae. The female anterior urethra also contains *Lactobacillus* spp. Asymptomatic colonization with *Ureaplasma urealyticum*, and to a lesser extent with *Mycoplasma hominis*, is a common event in sexually active individuals.[120,163]

The microbial flora of the vagina is influenced profoundly by hormonal factors.[99,100] During the first few weeks of life, estrogen from the maternal circulation creates in the newborn girl a vaginal environment conducive for the growth of *Lactobacillus* spp. This event is followed by development of a scant vaginal flora, containing mostly coagulase-negative staphylococci, *Corynebacterium*, and occasionally Enterobacteriaceae and *Streptococcus* spp. With the onset of puberty, lactobacilli again become the predominant organisms isolated. Coagulase-negative staphylococci and *Corynebacterium* spp. and various anaerobic streptococci also are common findings.[8,73,133] *Enterococcus*, Enterobacteriaceae, and *Candida* spp. are found less frequently.[8] *U. urealyticum* is present in approximately half of premenopausal women, and *M. hominis* is found in fewer numbers.[120,163] The vaginal colonization rate of group B streptococci in pregnant women is 5 to 35 percent.[4] Heavy colonization with *Gardnerella vaginalis*, *Trichomonas vaginalis*, and *Mobiluncus* and *Prevotella* spp. is associated with bacterial vaginosis.[153]

BENEFICIAL EFFECTS OF INDIGENOUS FLORA

It is generally recognized that pathogens first need to colonize the host before causing disease. The indigenous flora help to protect the host against infections through colonization resistance, also called *bacterial interference*.* Colonization resistance is accomplished by several mechanisms, including competition for nutrients, competition for epithelial cell receptors, production of toxins and bacteriocins, and stimulation of the immune response.[19,24,25,169,179] Suppression of the normal flora with antimicrobial therapy correlates with an increased susceptibility to candidiasis,[148] *C. difficile* colitis,[9] and *Salmonella* infection.[81] Use of probiotic agents, live microbial food supplements (e.g., *Lactobacillus*, *Bifidobacterium* spp.), helps restore the normal intestinal microflora during antibiotic therapy and inhibits the growth of potential pathogens.[36,69,143]

The endogenous intestinal flora seem to stimulate the cellular and humoral mucosal immune system.[16,131,167,174] This relationship influences the development of the newborn's immune system. Germ-free animals have underdeveloped, poorly differentiated lymphoidal tissues and low serum immunoglobulin concentrations. These animals have increased susceptibility to experimental challenges with pathogenic microbes.[47] The intestinal microflora also may affect the development of atopic disease and allergy.[20]

The normal flora provide some nutritional supplement for the host. The intestinal microflora ferment undigested carbohydrates into short-chain fatty acids. The short-chain fatty acids affect colonic epithelial cell transport and serve as an energy source for colonic epithelial cells, the liver, and muscle.[39,137,140,142] The intestinal flora also participate in the enterohepatic recirculation of biliary metabolites and the degradation of toxins and carcinogens.[62,114] In addition, normal flora microbes produce essential vitamins, such as vitamins K and B_{12}. Whether humans use these vitamins in any substantial manner is uncertain.[46]

ADVERSE EFFECTS OF THE INDIGENOUS FLORA

The indigenous flora can have unpleasant or even harmful effects on the host and are the source of intestinal gas and body odor. Oral flora are associated with dental caries and periodontal disease. In special circumstances, bacterial overgrowth of normal flora in the small intestine can result in malabsorption, diarrhea, and weight loss.[84,94] Other clinical conditions can create the potential for bacterial translocation, the invasion of indigenous bowel flora across the intestinal mucosa.[15,104] Intestinal toxins from endogenous bacteria may contribute to the encephalopathy, renal failure, and coagulopathy seen in hepatic failure.[37] Injury to the host from endotoxic shock may be caused to some extent by a hypersensitivity response induced by endotoxin from intestinal flora because germ-free animals are highly resistant to the effects of injected endotoxin.[159] Intestinal flora are speculated to cause cancer by metabolically activating carcinogens or by making carcinogenic products.[112] Finally, the intestinal normal flora may have a causative role in failure to thrive, arthritis, and autoimmune disorders.[37]

SUMMARY

The indigenous flora of humans are unique to specific anatomic locations. They are influenced by intrinsic microbial properties, host characteristics, and exogenous factors. Indigenous flora provide clear benefits to the host and potential adverse affects. Familiarity with the normal flora should help clinicians provide improved care for their patients.

CHAPTER 7

Epidemiology of Infectious Diseases

Robert S. Baltimore ✪ Eugene D. Shapiro

Epidemiology is concerned primarily with describing and explaining the occurrence of disease in populations. This chapter is a general review of epidemiology as it relates to infectious diseases important in pediatrics. Readers concerned with the epidemiology of a particular disease should consult the appropriate chapter for the relevant information. The principles and methods of epidemiology must be meshed with biostatistics (presented in detail in Chapter 266) and with information from other fields, including, but not limited to, clinical medicine, microbiology, pathophysiology, immunology, demography, and sociology.

The three types of epidemiology are descriptive, analytic or causative, and experimental. All three types are important in infectious diseases.

Descriptive epidemiology provides accounts of the health experiences of populations, including morbidity and mortality. It may or may not be used to support a hypothesis. The data are of two types—incidence and prevalence. *Incidence* is used to denote the numbers of new cases of or deaths from a given disorder that occurs in a defined population during a specified period. Sequential temporal comparisons often are used for assessing trends, and incidence data frequently are useful for setting public health priorities.

Prevalence is used to denote the number of cases of a disorder in the population (or sample) at a single moment in time. Prevalence data are applicable largely to chronic disorders, such as diabetes mellitus, tuberculosis, or human immunodeficiency virus (HIV) infection, and have no utility when applied to acute disorders, such as measles or infection with respiratory syncytial virus. In addition, in studies of infectious diseases, the prevalence of serologic markers may be used to estimate the immune status of a population or the proportion of a group that has had previous exposure to an infectious agent. Examples that have been useful for vaccine development include meningococcal infections[13] and *Haemophilus influenzae* infections.[2] For certain infections such as tuberculosis and diphtheria, skin testing may serve as a substitute for serologic testing to estimate previous exposure to the agent (or to a vaccine).

Analytic, or *causative*, epidemiology searches for clues to the cause of disease. It is based on the principle that disease does not occur at random in the population and classically considers time, person, and place. In other words, differences exist between individuals who acquire a given disorder and individuals who do not. Identification of these differences may lead to ascertainment of causation, inferences about pathogenic mechanisms, or means of control. These differences may be inherent in the individuals themselves and include biologic characteristics (e.g., hereditary, such as race; acquired, such as immunity) and lifestyle. They may be external and consist largely of environmental risk factors for disease, including various factors that influence the likelihood of exposure to an agent, such as geography, weather, contact with vectors (including other humans), and social and economic conditions. In studies of infectious diseases, considerable overlap exists between descriptive and analytic epidemiology because differences in the distribution of disease by person, place, and time often are obvious in descriptive data and provide clues for further study. Analysis of data may lead to the development of useful hypotheses for studies that then generate new data.

Analytic epidemiologic studies of infectious diseases and studies related to other types of conditions generally fall into three categories. The least frequently used, but nonetheless useful, category is the cross-sectional study. Such studies can be conducted in one of two ways. One might examine apparently comparable populations with differing prevalence rates of a given infection for characteristics that might explain these different rates. Alternatively, if a disorder is sufficiently common, one can determine rates of disease in individuals with and individuals without a suspected risk factor. A classic example is the relationship of sickle-cell trait to resistance to *Plasmodium falciparum* malaria, which was examined in both ways.[1] In studies of variations in the prevalence of the sickle-cell gene in Africa, researchers noted that the trait seemed to be more prevalent in areas with a high incidence of malaria. Based on this observation, other studies were conducted and showed that in hyperendemic areas, individuals with the sickle-cell trait might have some resistance to malaria, permitting selective survival in these areas. This observation led to additional studies of the mechanism of this phenomenon, including examinations of the roles of blood groups and other characteristics of erythrocytes that influence the risk of acquiring malaria.

Another type of causative or analytic epidemiologic study is the *longitudinal cohort study*. In this type of study, incidence of infection and routes of transmission may be determined by examining groups of individuals with differences in exposure, which may include timing, duration, intimacy of contact, or disparate sources or mechanisms of potential transmission. The classic studies of the transmission of group A streptococcal infection in military recruits are excellent examples. One particular finding was that transmission of infection from individuals with streptococcal pharyngitis to others in military barracks occurred at rates inversely related to distances between bunks, which established that transmission occurred largely by intimate respiratory contact with droplets containing hundreds or thousands of organisms, rather than by airborne droplet nuclei.[34] Other studies showed that fomites, naturally contaminated with streptococci, did not contribute significantly to the transmission of infection.[26] Studies by Goldschneider and colleagues,[13] by following a cohort of Army recruits at a training camp, showed that recruits without bactericidal antibody against the prevalent strain of meningococcus were susceptible to infection.

Studies of the transmission of staphylococci to newborns are another example of prospective epidemiologic observation. In the 1950s, outbreaks of staphylococcal disease, sometimes severe, occurred in newborn nurseries. In an effort to determine how these organisms were transmitted to infants by personnel or other infants, researchers investigated nurseries with persistently high rates of colonization of infants.[23] Two types of prospective cohort studies were conducted. One consisted of instituting measures that prevented transmission by all but one or two routes, permitting assessment of the importance of those routes in transmission. The other method was the reverse: Some suspected routes of transmission were blocked, and subsequent colonization of infants was monitored. These studies showed that transmission of organisms from personnel who were carriers or from previously colonized infants occurred primarily via the hands of personnel.

Another type of analytic epidemiologic study useful in infectious disease is the *case-control study*. In cohort studies, the investigator compares individuals who are exposed or not exposed to a given agent. The outcome measure of the study is infection or no infection. In contrast, in a case-control study, the samples being studied comprise individuals who have the infection com-

pared with similar individuals who do not have the infection. From individuals in both groups, historical data about previous exposure are obtained. In a case-control study, the investigator starts with diseased individuals and searches for exposure; in a cohort study, the investigator starts with exposure and follows subjects forward in time for development of the outcome. Case-control studies can be used to show a vaccine's effectiveness in actual field conditions after it has been licensed. Rather than having to show efficacy by following many thousands of volunteers, Shapiro and colleagues[31] showed the efficacy of pneumococcal vaccine by comparing 1054 people with invasive pneumococcal infections with 1054 matched controls, looking at the rate of vaccination in each group. Of the case patients, 13 percent had received pneumococcal vaccine, whereas 20 percent of the controls had received the vaccine (effectiveness was 47 percent for all patients and 56 percent for serotypes represented in the vaccine).

Case-control studies are of particular utility when the disease is rare because a cohort study might require an unwieldy number of subjects. A disadvantage of retrospective studies is that they do not provide an estimate of the risk or rate of disease occurring after exposure (i.e., the proportion of exposed or of unexposed individuals in whom the disorder in question actually did develop).

A third type of epidemiologic study useful in infectious diseases is an *experimental* study—*the clinical trial*. Clinical trials are actually a special kind of cohort study in which the investigator determines which subjects are exposed to an intervention. Clinical trials generally are used to determine the efficacy of preventive or therapeutic measures. As such, they often require previous information from analytic epidemiologic studies and from other basic and clinical studies. Sometimes, studies that are, in effect, clinical trials may provide useful information regarding the cause or routes of transmission of an infection. If a vaccine composed of a single purified antigen is associated with elimination of the disease, this information provides strong evidence that antibody directed against that antigen is protective.

To assess the efficacy of either therapeutic or preventive measures, experimental epidemiologic studies require comparison groups of individuals who do not receive the measure in question. Generally, these individuals are given an older agent, an alternative agent, a placebo, or an agent that would have no effect on the infection in question. Having contemporaneous controls is especially important for diseases that have significant year-to-year variation in incidence, to ensure that a decrease in incidence after introducing an intervention was not just a natural event.

An important component of a controlled clinical trial is that treatment and control groups be as similar as possible in characteristics that may affect the outcome. Clinical trials designed to assess the efficacy of either therapeutic or preventive measures must take into consideration many such factors, which usually include age, sex, socioeconomic status, co-morbid diseases, and likelihood of exposure. In any trial, an effort should be made to balance treated and untreated subjects in terms of recognized factors. Not all variables that may lead to bias in the results are recognized in advance, however. To try to ensure as far as possible that these characteristics are distributed approximately equally between the two groups, the process of randomization almost always is necessary. In addition, true randomization must occur; methods involving odd-versus-even record numbers or birth dates, alternate days of the week, and the like are inappropriate. An optimal method is a system of random numbers, as published in most textbooks of biostatistics or available as computer programs. Randomization avoids selection bias, best defined as underlying differences between the treatment and control groups, whether internal (inherent) or external (e.g., the likelihood of exposure). Randomization ensures only lack of bias because one has no assurance in a small clinical trial that unrecognized confounders are distributed equally among groups being compared. If the size of the sample is large, however, unequal distribution, although not impossible, becomes unlikely. Chapter 266 provides a more extensive discussion of types of bias.

Although the principles discussed here and in Chapter 266 apply to all epidemiologic studies, in studies of infectious diseases, three additional factors contribute uniquely to who is and who is not affected: (1) The cause is a specific external agent (the infecting organism); (2) transmission of the organism to the host is required; and (3) certain host factors, such as immunity to infection or disease, may affect the outcome. Recognition of these factors (the infecting agent, transmission, and immunity) evolved gradually over many years.

HISTORICAL PERSPECTIVES

Epidemiology evolved from the study of great epidemic diseases such as plague, cholera, and smallpox. The periodic waves of these diseases, which were associated with high mortality rates, stimulated the first serious efforts to explain the occurrence of disease on the basis of factors other than supernatural or divine forces.

Fundamental to such explanations was the concept of contagion. This factor long had been implicit in attitudes toward victims of leprosy, as exemplified by such early Christian practices as conducting antemortem funerals for lepers, who then were given a bell and cup and forbidden further human contact or, more drastically, were buried alive or burned at the stake.[28] The English physician Thomas Sydenham (1624-1689) introduced laudanum (derived from opium) as a painkiller; recognized the efficacy of Peruvian bark (quinine) in malaria; and revived the Hippocratic idea of "epidemic constitutions" (of atmospheric nature), which by grafting onto existing illness, gave all concurrent illnesses the character reflecting the then prevailing "constitution." These views persisted in colonial America, where they were expounded by such eminent individuals as Noah Webster (of dictionary fame) and Dr. Benjamin Rush of Philadelphia.[37]

Nonetheless, by the mid-18th century, the theory of contagion had gained acceptance for particular diseases, including measles, syphilis, and smallpox. The theory is alleged to have been exploited in an early act of biologic warfare: Massachusetts colonists reportedly presented the blankets of smallpox victims as gifts to the Indians, who then suffered a decimating epidemic.[9a]

The true origin of the concept of immunity is uncertain, but it was applied first in relation to smallpox. Variolation (inoculation of young people with lesion material expected to induce modified, but immunizing, disease) was practiced in China in the 11th or 12th century and in England and the American colonies in the early 18th century. Also popular in rural England at this time was the theory that cowpox, the minor disease acquired from afflicted cattle, induced immunity to smallpox. This theory was verified by Edward Jenner (reported in 1798) and resulted years later in general acceptance of cowpox vaccine (vaccinia) to protect against smallpox.

The germ theory of disease was stated explicitly in 1855 by John Snow, an English anesthesiologist who took up cholera epidemiology as an avocation. Snow argued that the causative agent of cholera was a living cell that multiplied with great rapidity but was too small to be seen under the microscopes then in use.[32] Louis Pasteur (1822-1895) formally validated the germ theory by showing that the microorganisms responsible for fermentation were not generated spontaneously but came from the air.[25] On this basis, Joseph Lord Lister revolutionized surgery by using carbolic acid to combat atmospheric germs and minimize "putrification" in surgical procedures.[30]

In Pasteur's wake, bacteria were cultured with great frequency from ill individuals and often were identified erroneously as causal agents. Robert Koch (1843-1910), who first isolated the bacterial causes of tuberculosis and cholera, also was the first to introduce scientific rigor into the proof of primary causation. His famed "postulates," to be satisfied before a causal relationship between a bacterium and a disease could be accepted, required that (1) the presence of the agent be shown in every case by its recovery in pure culture; (2) the agent not be found in cases of other disease; (3) the agent, when isolated, be capable of reproducing the disease in experimental animals; and (4) the agent be recovered in pure culture from such experimental disease.[12]

Koch's postulates since have been modified, largely to meet problems posed by viruses. As obligate intracellular parasites, viruses cannot be "cultivated in pure culture." In addition, they often are host-specific and do not produce disease in an animal model. Other considerations that were invoked as elements of proof included the significance of recovery of the agent from diseased tissues, the demonstration of an increase in titer of specific antibody in temporal relation to the disease, and, most conclusive, the specific preventive effect of vaccines containing the viral antigen.[16] One further situation not recognized by Koch is that infections with true pathogens do not always cause disease. We now recognize pathogenicity (defined as the proportion of infections that result in disease) as an important characteristic of infectious disease agents.

CAUSE OF DISEASE

GENERAL CONCEPTS

Causation of infectious diseases is defined in terms of the *primary cause* and *contributing factors* (or secondary causes). The former is the specific microorganism (the agent of disease) without which the particular disease cannot occur. Contributing factors affect the likelihood that infection will occur and help determine that disease will result, given infection. Identification of the causative agent may lead to the development of effective means for providing specific protective immunization (e.g., diphtheria and tetanus toxoids, vaccines against polio and measles). Finding the cause of a disease also may lead to other means of control. An example is the discovery of *Legionella pneumophila* as the cause of legionnaires' disease. The discovery of the organism led to the understanding of how the disease is transmitted—via aerosols from cooling towers, which serve as reservoirs for the bacteria.[8,22] Disinfection of these towers has helped to control legionnaires' disease.

Infection and disease are not synonymous, although infection is necessary for disease to occur. *Infection* denotes colonization, multiplication, and completion of the entire pathogenetic process of the organism in the host, usually including induction of an immune response, but without necessarily producing recognizable pathologic and clinical manifestations. *Disease* is present when pathologic and clinical changes occur with infection. There are many examples of infections that may be either asymptomatic or the cause of serious disease in the host, such as poliomyelitis and mumps. When disease occurs, it may vary in severity among infected individuals. Some infections produce full-blown disease in all infected susceptible individuals; measles is an example. Simple *colonization*, in contrast to infection and disease, is a state in which the organism parasitizes the host at an appropriate site, replicates, and may persist, but it fails to proceed further with the processes of infection and disease, including induction of immunity. The *carrier state*, in which the organism persists over time and can be infective for others, may occur after colonization, infection, or disease. Examples of organisms that behave in this way include group A streptococcus and *Neisseria meningitidis*.

Many contributing factors, largely related to the host and to the conditions of exposure, determine whether colonization occurs and whether the subsequent processes of infection and disease occur. These contributing or risk factors are many and varied, and from the standpoint of the host may include, but are not limited to, age, sex, race, immune status, genetic constitution, and general state of health, including underlying diseases. Similarly, contributing factors unrelated to the host may include climate, the presence of vectors, quality of sanitation, intimacy of exposure, and socioeconomic conditions. These contributing factors vary among infectious diseases and are discussed in chapters about specific infectious agents.

AGENT FACTORS

What characteristics of living parasites are significant epidemiologically? Properties directly important to the occurrence of disease are properties that relate to perpetuation of the agent as a species, properties that govern the type of contact required to infect humans, and properties that determine the production of disease. Also important are characteristics useful in classification and specific identification of agents. Some important characteristics are *intrinsic*, in that they can be described after appropriate direct examination of the agent. Others can be described only on the basis of the behavior of the agents in the host; they are *host related*.

Intrinsic Properties

Precise classification and identification of agents are basic to the specific recognition of infections and related disease. Both depend on intrinsic properties, including morphology (which alone provides the basis for identifying most higher parasites), chemical composition (the type of nucleic acid being important in viral classification), and antigenic character. The last is central to specific identification of agent isolates and antibodies induced by infection. Requirements for growth or replication provide keys to the identification of some bacteria (e.g., sugar fermentation) and many viruses that replicate optimally or only in cultures of certain types of cells incubated at specified temperatures. Rhinoviruses replicate best in human diploid cells incubated at 33° C.

In recent years, rapid development of species detection and classification by genome identification has occurred. The use of whole-genome analysis, molecular analysis of gene fragments, and various methods of polymerase chain reaction has resulted in reclassification of some microorganisms and of rapid identification of pathogens, including microorganisms that cannot be cultivated by conventional means. Developments in this field are expected to shift the clinical microbiology laboratory from morphologic and biochemical tests to molecular tests in the coming years.

Several intrinsic properties relate to transmission and long-term survival of infectious agents. Persistence in the free state outside the host depends on requirements for replication (viruses replicate only within the cells of their host, whereas the nutrient requirements of bacteria often exist in food or milk) and on viability under natural conditions of temperature, moisture, and radiation. The ability of agents to persist determines whether transmission requires direct contact, as with influenza viruses, or can involve indirect mechanisms operating over longer periods. Examples include polioviruses, typhoid bacilli, and the bacterial cause of legionnaires' disease.

The spectrum of animals and arthropods that an agent can parasitize (the host range) helps determine the possibilities for successful links in the transmission and reservoir mechanisms. The broader the range, the greater the possibilities. Agents that use arthropod vectors include St. Louis encephalitis virus and

Borrelia burgdorferi, the cause of Lyme disease. The former can infect many avian and mammalian species and a wide range of mosquitoes, whereas the latter is restricted to a few tick species. Among agents requiring no vector, many infect only humans (diphtheria bacillus, the meningococcus, and measles virus), whereas others have multiple natural hosts (rabies virus, most of the *Salmonella* group of bacteria).

Elaboration of exotoxins is an intrinsic attribute of many bacteria and contributes in varying degrees to disease pathogenesis and indirectly to immunity in many infections. Another attribute, which can operate in two opposing ways, is susceptibility to chemotherapeutic agents or antibiotics. Successful treatment may shorten the period of communicability, as in group A streptococcal and *Bordetella pertussis* infections, but it may lead to relaxed precautions against infection; syphilis and gonorrhea are notable examples.

The instability of some intrinsic characteristics as a result of the emergence of genetically different populations because of mutations, selective pressure, gene or plasmid transfer between bacteria, or genetic recombination can be important. One example is the resistance to chemotherapeutic or antibiotic agents that may result from selective pressure (the probable explanation for the rapid acquisition of multiple antibiotic resistance by gonococci and in HIV or plasmid transfer of resistance to antibiotics among enteric bacteria). Antibiotic resistance is of increasing importance, as exemplified by the appearance of multidrug-resistant *Mycobacterium tuberculosis*, penicillin-resistant pneumococci, and methicillin-resistant staphylococci.

Change in antigenic character can diminish the effectiveness of immunity and complicate specific recognition of infection. Influenza A virus is the classic example, with periodic major changes (shift) occurring in either or both crucial surface antigens, hemagglutinin and neuraminidase, associated with pandemic disease and progressive minor changes in hemagglutinin in the interpandemic period. Finally, the emergence of new diseases, such as St. Louis encephalitis, which first affected humans in Paris, Illinois, in 1932, or the appearance of a known disease in a new reservoir, possibly exemplified by the emergence of West Nile virus in North America, can be the result of adaptation of the agent to a new host.[3,4]

Host-Related Properties

Some epidemiologically important properties of infectious agents can be defined only with reference to specific hosts. Such properties include infectivity, pathogenicity, virulence, and immunogenicity.

INFECTIVITY

Infectivity (ability to invade and multiply in a host) is measured conceptually in terms of the minimal number of infective particles required to establish an infection. This number, which can vary from one host to another and within the same host, depending on the portal of entry, host age, and, in some cases, medications, can be determined only experimentally. Except for benign agents such as rhinoviruses or vaccine strains of polioviruses with which challenge of human volunteers is permissible, the infectivity of agents for humans must be inferred from the facility with which they spread in populations or, more directly, from the frequency with which infection develops in exposed susceptible individuals within a reasonable incubation period (*secondary attack rate*). Some researchers have used prisoners to study infectivity of *Salmonella* and *Shigella*, but the ethics of such studies has been questioned. Measles, varicella, and polioviruses are highly infective because they require few infective particles to cause infection; rubella, mumps, and rhinoviruses have intermediate infectivity; and typhoid and tubercle bacilli have low infectivity. Infectivity and pathogenicity may vary among strains of the same organism. The infectivity of group A streptococci is related directly to the amount of M protein in the cell wall, and strains of *Staphylococcus aureus* that appear identical in the laboratory may differ strikingly in infectivity and virulence. Additionally, some evidence indicates that strains of influenza A may vary in infectivity and virulence independent of preexisting immunity in the host. Contemporary studies show that variation in certain genes that are not ordinarily expressed in the clinical diagnostic laboratory are responsible for these variations in infectivity.

PATHOGENICITY

Pathogenicity (ability to induce disease) is measured in terms of the proportion of infections that result in disease. It ordinarily can be determined readily by studies of the incidence and outcome of naturally occurring infections in humans. This proportion may be affected by the size of the infecting dose and numerous host factors, including age. Highly pathogenic agents include typhoid bacilli, rabies, measles, varicella, and rhinoviruses. Agents of intermediate pathogenicity include rubella, mumps, and adenoviruses; polioviruses and the tubercle bacillus have low pathogenicity.

VIRULENCE

Virulence, offered as a synonym for *pathogenicity* in medical dictionaries, is defined more usefully as a measure of the severity of the disease that does occur. Various criteria may be used: days confined to bed, serious sequelae such as persisting paralysis, and death. The measure of virulence is the number of severe cases over the total number of cases, which when death is the criterion becomes the familiar *case-fatality rate*. With this as our measure, the viral agents previously mentioned fall into a different gradient from that based on pathogenicity. Rabies virus (with a case-fatality rate of nearly 100 percent) qualifies as highly virulent, and poliovirus (with a case-fatality rate of 7 to 10 percent for paralytic disease) can be classed as moderately virulent. Measles, with an occasional death from encephalitis or pneumonia, is far down the scale but is still ahead of mumps, varicella, non-fetal rubella, and rhinoviruses, for which the case-fatality rates are very low. Outcomes of severity short of death can be used in a similar fashion.

IMMUNOGENICITY

Immunogenicity (ability to induce specific immunity) is measured best in terms of the degree and duration of resistance conferred by infection. Although agents may differ with respect to the immunogenicity of their intrinsic "protective antigens," more important factors are the sites of primary infection and disease, and the amount of antigen formed during infection to stimulate a host response. Superficial sites, such as the respiratory mucosa, are guarded chiefly by secretory antibody, which is poorly persistent; agents such as rhinoviruses, which replicate only at such sites, are ineffective stimulants of the systemic immune response. The amounts of the respective toxins released during clinical tetanus and diphtheria usually do not induce satisfactory immunity. In contrast, systemic viral infections, as with measles and yellow fever viruses, induce solid and long-lasting immunity.

Agent-Host Relationship

The infected host provides a shelter in which the agent can multiply and from which it may spread. Key questions involve how long the agent can persist in the host and over what period and by what avenues it can escape. The time relationships and descrip-

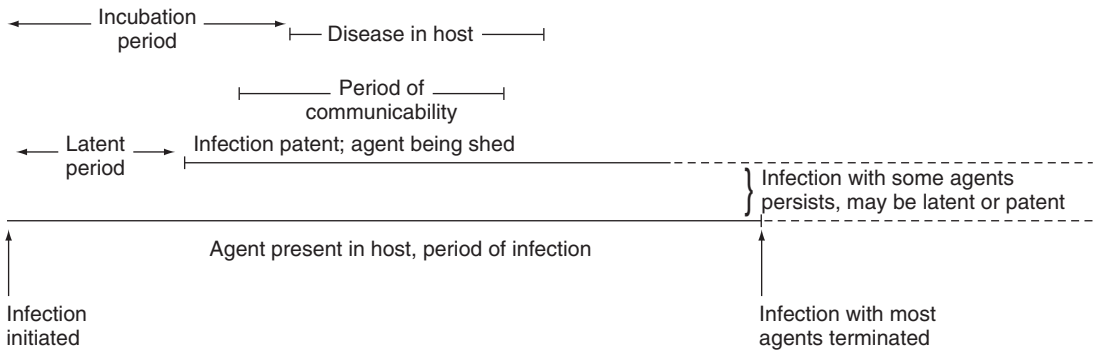

Figure 7–1 Important phases of infection in vertebrate hosts.

tive terms of different phases of infection are suggested schematically in Figure 7–1.

When the agent is not readily recoverable but perhaps is hidden within host cells or at some other site, infection is termed *latent*. Conversely, when the agent is being shed, as in feces or respiratory secretions, or can be recovered from blood or tissues, infection is said to be *patent*. Infections are necessarily latent at first (the *latent period*) and become patent when the agent has multiplied sufficiently for shedding to begin. The *period of communicability* commonly starts soon after initial shedding begins and continues as long as the level of shedding is sufficient for transmission. The rapidity with which disease is spread is related to the length of the latent period, which almost always is shorter (sometimes much shorter) than the better known *incubation period* (time until disease develops). The period of communicability has no consistent relationship to either the occurrence or the duration of disease.

Persistence in the host is important to the agent for as long as escape remains possible. The period of persistence (see Fig. 7–1) varies widely among agents. Infection terminates completely within 2 to 3 weeks with many agents, such as most respiratory viruses, and after a few months with some agents, such as polioviruses or adenoviruses. Truly persistent lifelong infections may become permanently latent as with some herpesvirus group (Epstein-Barr virus, cytomegalovirus) infections. Infection may remain permanently patent (approximately 3 percent of typhoid cases, numerous hepatitis B virus infections), may be intermittently patent (herpes simplex virus infections [HSV]), or after years of latency may recrudesce with patency and associated disease (tuberculosis, Brill disease caused by *Rickettsia prowazekii*, varicella-zoster virus [herpes zoster]).

RESERVOIRS OF INFECTIOUS AGENTS

Reservoir is defined here as the total mechanism responsible for perpetuation of an infectious agent. The reservoir is a continuing chain of transmission from one host to another (including vertebrate and invertebrate species). Chains with long links requiring infrequent transmission are especially favorable to survival of agent species.

Among agents for which humans are the only natural vertebrate host, many contrasting patterns exist. The most common is exemplified by infections with most respiratory viruses, which are characterized by short latent periods (1 to several days) and short periods of communicability (rarely >1 week). The links are short, and frequent transmission is necessary. At the other extreme are long-persisting infections associated with continuous (typhoid carriers, hepatitis B virus, HIV) or intermittent (HSV) *patency* or shedding. The links in this case may be as long as the post-infection life of the host and render generation-to-generation transmission possible. Such transmission also may occur via congenital infection, as in mice infected with lymphocytic choriomeningitis virus. Examples in humans include cytomegalovirus and hepatitis B virus infections. Long links also occur in persistent infections that after many years of latency recrudesce to cause disease and renewed shedding (varicella-zoster virus and *R. prowazekii*).

When infection of invertebrate hosts (vectors) is a link in the chain of transmission, a wide range of reservoir patterns is possible. The simplest involves agents for which humans are the only natural vertebrate hosts (malarial parasites, *R. prowazekii*, dengue virus), with the chain consisting of alternating links of human and vector infection. More commonly, the basic reservoir is a similar alternating chain primarily involving lower vertebrate hosts, with humans being an opportunistic and usually blind-end host. Examples include murine typhus rickettsiae and plague bacillus (both cycling primarily in rats and rat fleas), Lyme disease, and various arboviruses (yellow fever, St. Louis encephalitis). In the case of the latter, the broad vertebrate (numerous avian and mammalian species) and invertebrate (various mosquito species) host range results in very complex patterns that in a given area are defined by the prevalent susceptible host species. The links in these chains are defined temporally by the persistence of patent infection in the vertebrate host and the short life span of the invertebrate host.

Several aspects of infection of the invertebrate (vector) host are important. Typically, infection is acquired in a blood meal and endures for (and does not influence) the life span of the arthropod. Hibernating arthropods may be the long link in the chain by which the agent survives the winter. In at least two instances, infection kills the vector: *R. prowazekii* in the body louse and plague bacilli in the rat flea. As with malaria, infection of the arthropod also may permit completion of an essential stage in the developmental cycle of the agent. Finally, transmission of infection from arthropod to arthropod may be alternate or necessary links in the chain. Transovarial transmission of *Rickettsia tsutsugamushi* (scrub typhus) in mites is essential because the individual mite feeds only once, during the larval stage, on vertebrate hosts. Transovarial transmission also occurs in ticks infected with *Rickettsia rickettsii* (Rocky Mountain spotted fever) and in *Aedes triseriatus* mosquitoes infected with La Crosse virus (California encephalitis), in both cases affording an overwintering mechanism. Venereal transmission of La Crosse virus between mosquitoes also has been shown.[33]

Finally, the inanimate environment can play a role in the reservoir mechanism. Examples are bacteria that can multiply in the free state (salmonellae and staphylococci in food) and agents endowed with unusual survival capacity (tetanus bacillus and *Histoplasma capsulatum*, both of which form highly resistant spores).

It also occurs when a brief sojourn under proper environmental conditions is required for a necessary stage in the life cycle (e.g., hookworm eggs from human feces must hatch into larvae to become infectious).

MECHANISMS OF TRANSMISSION

Transmission, in this context, is defined as the transport of an agent from one vertebrate host to another. It involves escape from the source host and conveyance to and entry into the recipient host. The basic interdependence of these sequential steps is illustrated in Table 7–1, which also presents specific examples of diseases. Although humans are the usual or only source for most agents of human disease, lower vertebrates serve as the major or only (rabies virus) source for some pathogens.

Fomites are intimate personal articles, such as handkerchiefs, playthings, and eating utensils. *Direct contact* includes not only physical contact (shaking hands, kissing, sexual intercourse) but also, in practice, short-range (within 3 ft), airborne transmission by large droplets (>5 μm) containing hundreds or thousands of organisms that descend rapidly to the ground or floor. These heavy droplets are the primary route of transmission of group A streptococcal pharyngitis,[34] pertussis, and influenza virus.

Indirect transmission for respiratory and some other infections includes the acquisition of organisms from dust (e.g., tubercle bacilli), from fomites (inanimate objects in the environment such as bedding), and from airborne droplet nuclei (<5 μm) containing only one or a few organisms that promptly dry, float in the air for long periods, and may be wafted for moderately long distances, such as between rooms or floors in a hospital. Transmission by airborne droplet nuclei is limited to highly infectious agents such as varicella virus. Because respiratory colonization with group A streptococci requires a large inoculum, airborne droplet nuclei play no role in their transmission. Other forms of indirect transmission include inanimate vectors such as food, milk, and water, which are frequent vehicles for spread, particularly of intestinal infections. Another source of indirect transmission is animate vectors, which either may function as a vehicle for transport (as with flies that carry organisms from feces to food) or may be infected. In the latter case, multiplication and transformation in the vector are required for transmission, as with African trypanosomiasis and the tsetse fly.

Conveyance ends when the agent reaches a portal of entry, which to be effective must provide ready access to a tissue in which the pathogen can lodge and multiply. For a given agent, a particular portal (nasal or genital mucosa, oral) often is obligatory or usual, but alternative portals may be possible. Rhinoviruses replicate only in nasal mucosa, whereas typhus rickettsiae typically enter through skin broken by a louse bite but also can infect via ocular or respiratory mucous membranes.

HOST FACTORS

Many biologic and behavioral characteristics of the human host influence the occurrence of infection and subsequent disease. Although the host characteristics to be considered are of widely differing nature, they operate by influencing one or more of the following: degree of exposure, innate susceptibility to infection, and the likelihood of specific immunity. Although much of the following discussion focuses on the individual human host, factors that influence individuals also affect whole human populations.

Infection of the Host

A key principle to be emphasized is the usual existence of a gradient of response to exposure to an infectious agent. Because of this gradient, the occurrence of characteristic overt disease is a notably unreliable measure of the extent of activity of a disease agent. Given a particular exposure, infection may not occur, disease may not result, or the consequences may range from trivial to the fully developed syndrome "characteristic" of the agent. Accumulating data indicate that specific host genes may be responsible for differences in host susceptibility.

An inadequate challenge dose, an unsuitable portal of entry, or specific host immunity also may explain failure of infection to develop. Whether infection causes disease and the extent, nature, and outcome of the resulting disease are determined partly by host-related properties of the agent (pathogenicity and virulence) and partly by host defense mechanisms, a variety of which confront an infectious agent that has reached a site of primary infection. Bacteria and other extracellular parasites stimulate an inflammatory response at the site in an effort to localize the invaders by a retaining fibrin network, and the invaders are destroyed by congregating numerous phagocytic cells. Invader organisms meet sinusoidal passages lined by phagocytic cells in regional (lymph nodes) and bloodstream (bone marrow, spleen, and liver) filters. In addition, clinicians are beginning to understand the importance of so-called innate immunity. This complex network of receptors and responders prevents invader microorganisms from gaining access to tissues. In addition to physical barriers already mentioned, the innate immune system includes a family of receptors known as the Toll-like receptors. These recognition molecules signal the host to activate numerous protective mechanisms. They are discussed in other chapters in this textbook.

Several aspects of the outcome of infection are important, the first being survival of the host. Death is an unsatisfactory outcome not only for the host but also for the many agents for which survival as a species depends on the host. The remaining aspects relate to the surviving host. Was recovery from disease complete,

TABLE 7–1 Typical Modes of Transmission from Host, Conveyance, and Portal of Entry

Agent Shed via	How Conveyed	Portal of Entry	Disease Example
Respiratory secretions	Airborne droplets, fomites, or direct contact	Respiratory	Common cold, influenza, respiratory syncytial virus
Feces	Food, fomites, water, flies	Oral	Poliomyelitis, typhoid, rotavirus
Blood	Arthropod vector, transfusion, needle-stick	Skin—via insect bite, intravenous device	Typhus, dengue, malaria, human immunodeficiency virus, hepatitis B and C
Lesion exudate	Direct contact, sexual intercourse, fomites, flies	Skin, genital or ocular mucous membrane	Syphilis, trachoma, staphylococcal abscess
Aerosols	Droplet nuclei, direct inhalation	Respiratory	Tuberculosis, varicella

or were permanent sequelae present? If the latter, were they stationary (as in paralysis resulting from polioviruses) or potentially progressive (rheumatic heart disease resulting from streptococcal infection, pulmonary tuberculosis)? Another aspect, persistence of the agent, was discussed previously under agent-host relationships. The final aspect is the state of post-infection resistance. If it is incomplete, the recovered host may experience reinfection, with or without disease, and again become a source of infection for others.

Biologic Factors

Biologic factors include characteristics such as age, sex, and race (ethnic group), which are so important and easily ascertained that determining their relationship to occurrence of disease is a usual first step in an epidemiologic description. Biologic factors also include genetic make-up, general health status, and specific immunity.

AGE

The influence of age is illustrated best by patterns of common diseases such as varicella, measles, and mumps before the advent of vaccines. All three diseases occur predominantly in young children, who are affected because of their usual lack of immunity and their high risk of exposure to other children, among whom most infections occur. Older individuals are likely to be immune and, unless they are parents of young children, are unlikely to be exposed to infected individuals. Vaccines that provide only temporary immunity could cause a shift to an older age of presentation in the population.

Age also often is related to the outcome of infections in nonimmune individuals. Demonstration of the influence of age requires that all infections be recognized and classified according to the severity of the resulting disease (if any). When many or most infections are subclinical (as with polioviruses and other enteroviruses), the increase in the case-fatality rate with age is apparent immediately, but special studies to document asymptomatic or mild infections are required to show that the proportion of infections that resulted in clinical disease also increased with age. In contrast, the case-fatality rate for pertussis is highest in young infants. With measles and varicella-zoster virus, initial infection at any age usually results in characteristic disease, but the frequency of serious disease increases with age.

SEX AND RACE OR ETHNIC GROUP

That sex may be a factor is illustrated by the fact that most infectious diseases typically occur more frequently in males than females. The question, with respect to any particular disease, is whether these differences between sexes reflect innate differences in susceptibility to disease or can be attributed to sex-associated differences in behavior, occupation, or stress.

The incidence of many diseases varies greatly between groups defined by race or ethnic group. This variation may be explained by differences in behavior or environment for which socioeconomic status is a marker. Ethnic groups share many genetically determined traits, however, which may include either heightened susceptibility or increased resistance to specific infectious agents. Selective evolutionary pressure may be invoked to explain the greater resistance of whites to tuberculosis and the heightened resistance of blacks to malaria. Differences in host susceptibility based on race, familial clustering, and ethnicity is beginning to be investigated at the genomic level now that the code for the whole human genome has been elucidated. Future investigations likely will be directed at discovering polymorphisms of genes that involve the immune response.

GENERAL HEALTH STATUS

General health status includes the physiologic state, nutritional status, presence of intercurrent disease, and stress. The importance of such factors is commonly accepted in many cases but rarely documented by well-controlled studies. Infancy, during which immune mechanisms are immature, is a period of special vulnerability to many infectious diseases. HSV, enteroviruses, and group B streptococci manifest as disseminated infections in neonates, in marked contrast to their presentation in older individuals. Puberty, associated with rapid growth and change in endocrine balance, is a period of vulnerability to acne and tuberculosis. Pregnancy predisposes to tuberculosis and paralytic poliomyelitis, and varicella is more severe.

Gross protein malnutrition causes definite impairment in the cell-mediated immune response,[17a] a correspondingly increased susceptibility to bacterial and parasitic infections, and increased morbidity and mortality in many viral infections. Viral infections may depress cell-mediated immunity (and increase susceptibility further) to other concurrent infections. In the developing world, where malnutrition may be epidemic, the consequences of diarrhea, measles, and other respiratory virus infections are many times more devastating. Diarrheal diseases also may be the cause and the consequence of malnutrition. Diabetics are especially vulnerable to bacterial infections; measles and pertussis may reactivate quiescent tuberculosis; and, perhaps of greatest importance, otherwise benign respiratory viral infections, notably influenza, may pave the way for development of serious bacterial pneumonia. HIV infection enhances the susceptibility to and severity of tuberculosis, toxoplasmosis, and many other infections.

Finally, stress induced by widely divergent stimuli (including strong emotions, physical exertion, trauma, or excessive heat or cold), according to Selye,[29] may operate through a pituitary-adrenocortical hormonal path to decrease resistance to infections. Widely accepted examples include physical exertion, child-bearing, and rearing of children as factors predisposing to paralytic poliomyelitis and pregnancy and rapid growth during puberty as causes of reactivation of quiescent tuberculosis.

IMMUNITY AND IMMUNE RESPONSE

Immunity and immune response to viruses warrant special attention. Although important in recovery from bacterial infection, antibody response is of questionable significance in viral infections because viruses within cells are inaccessible to antibody, and by the time antibody appears, many or most susceptible cells have been infected already. Nonetheless, the importance of antibody in viral infections is suggested by the great vulnerability of immunodeficient children to vaccine strains of poliovirus, other enteroviruses, and varicella and by the sometimes beneficial effect of passive immunotherapy in progressive vaccinia. The benefits of previous experience with viruses can be seen with the decreased severity of rotavirus infections following the first bout of rotavirus and the protection afforded by varicella-zoster immunoglobulin in highly vulnerable children.

At its maximum (exemplified by post-infection immunity to measles), protection against infection is virtually absolute. At the other extreme (exemplified by many respiratory viral infections), susceptibility to infection persists or wanes as with pertussis, although the severity of related disease may be reduced. In most instances, protection seems to be mediated by antibody, but cell-mediated immunity also may be important. Children with defects in cell-mediated immunity are at particular risk for acquiring infection with varicella, *Pneumocystis carinii*, and otherwise noninvasive fungi.

To the extent that immunity protects the individual against infection or acts to minimize shedding of the agent when infection occurs, an immune host can play little or no part in the

spread of an infectious agent in the population. If a sufficient proportion of a population is immune, an agent transmitted via contact cannot spread, and non-immune members of the population would be spared exposure. The concept of herd immunity assumes that a non-immune individual is protected from a communicable infection by being surrounded by immune individuals. What proportion must be immune to achieve effective *herd immunity* usually is unknown.[10] This concept is valid only in homogeneous, randomly mixing populations in which all possible pairs of individuals have the same probability of making effective contact. Although measles vaccine has been used extensively in the United States, outbreaks of measles continue to occur in segments of the population that failed to accept vaccine, often defined by beliefs, race, economic status, and social behavior.

Human Behavior

Governed largely by habits of the individual and the customs and culture of groups, human behavior greatly influences exposure to and modes of transmission of infectious agents. Cultural factors also underlie attitudes toward preventive and curative practices.

Water is a potential vehicle for many agents. When commonly imbibed without boiling, as in the United States, community water systems constitute potential channels for transmission that usually are well-guarded. Occasional operational failures occur, as exemplified by failure of a water quality–monitoring device in a filtration plant that resulted in an outbreak of *Cryptosporidium* diarrhea affecting an estimated 403,000 individuals in Milwaukee in 1993.[20] Foods and milk, especially items that are consumed raw or after minimal cooking, likewise are excellent vehicles for transmission of disease. Well-known examples include trichinosis from undercooked pork; bacterial enteritis from unpasteurized milk; fish tapeworm from raw fish; and various forms of food poisoning caused by bacterial contamination during handling, poor refrigeration, and inadequate cooking. In recent years, outbreaks of hemorrhagic diarrhea caused by *Escherichia coli* O157:H7, sometimes associated with hemolytic-uremic syndrome, have occurred as a result of improperly prepared products of bovine origin, particularly ground beef.[14]

Closely related to water and foods is the disposal of human excreta. Casual defecation near habitations or in or near running water leads to dissemination of enteric pathogens by filth flies and by water. The use of human feces (night soil) to fertilize crops commonly eaten raw, such as strawberries and lettuce, has an obvious similar potential.

Many more individual types of behavior also are important. Infrequent bathing and laundering of clothes favor infestation with body lice. Inadequate clothing increases exposure to arthropod vectors and, as in young children lightly clad for summer weather, facilitates the exchange of feces. Going barefoot provides exposure to hookworm larvae. Handwashing minimizes the role of hands in indirect transmission of enteric (fecal) and respiratory (nasal secretion) pathogens. Rhinovirus infections result from inserting contaminated fingers into the nose and eyes.[15] Intimate personal contact such as hand shaking, kissing, and play among young children fosters the spread of a wide variety of agents. Even recreation, such as travel, picnics, and camping, may lead to unusual exposure to infectious agents. Sexual behavior is associated with the transmission of numerous infections, including HIV, syphilis, gonorrhea, group B streptococci, and hepatitis B.

ENVIRONMENTAL FACTORS

The environment in concept embraces all that is external to the individual human host. There are three broad environmental areas: *physical*, which includes geologic and climatologic or meteorologic features; *biologic*, which consists of all flora and fauna and all living microbial pathogens; and *socioeconomic*, which encompasses the interrelationships of humans. Environmental factors often act through indirect paths, and some have the potential to affect the agent, the host, and the agent-host relationship. Solar radiation is lethal for many pathogens in the free state, helps humans synthesize vitamin D, and can provoke recrudescence of a latent HSV infection and result in recurrent fever blisters. The capacity of humans to modify adverse environmental conditions beneficially is another important factor.

Geographic and Geologic Factors

Spread of infectious agents on a global scale requires their transport, which is influenced by distance alone and by geographic features—mountain ranges, oceans, rivers—that assist or impede travel. The importance of these factors declines as the extent and speed of travel increase, but it remains substantial, especially in developing countries. The minimal effect of geographic barriers in containing highly infective agents is overcome by modern travel, and rapid spread by airline travel is exemplified by epidemics of severe acute respiratory syndrome, which spread from China throughout the world in a matter of weeks.

The natural paths of travel (including waterways), natural harbors, and the location of mineral deposits help determine where populations concentrate. Water supply, dependent in part on geologic formations, is a factor limiting population size and, together with fossil fuels and mineral deposits, influences the type, extent, and location of industrial development. Soil types vary greatly in their ability to hold and purify water and in their capacity to support vegetation, which influences the type and abundance of animal life. Soil is a determinant of the type and importance of agriculture and a major factor influencing the biologic environment.

Climate

The term *climate* describes the typical annual pattern, along with its seasonal variation, of climatologic conditions in a specified region. Such conditions (climatologic factors) include solar radiation, temperature, humidity, barometric pressure, winds, precipitation (and drought), and lightning. These factors can affect infectious disease agents directly. Many microbial agents in the free state are vulnerable to excessive heat and radiation and uncontrolled drying. The life cycles and reservoir mechanisms of many pathogens, including higher parasites, depend on appropriate temperature and humidity. Maturation and hatching of hookworm larvae from ova deposited in the soil require warmth and reasonable humidity, and the multiplication of malarial parasites and arboviruses in their mosquito vectors and the abundance of the vectors are favored by warm temperatures.

The usual seasonal variation in the incidence of specific infectious diseases suggests important influences of climatologic factors, but how they operate may be hard to determine. Overall, respiratory infections occur more frequently in colder months, but within this period (roughly October through mid-May in the Northern Hemisphere), the prevalence of the many respiratory pathogens varies greatly. Rhinoviruses peak in the early fall and spring, and influenza viruses are most active in midwinter. Parainfluenza virus type 1 and 2 infections usually peak in the fall. Increased congregation of people indoors facilitates transmission, and fluctuations in temperature and humidity not only affect the viability of agents in airborne droplet nuclei or on fingers or fomites but also may affect host susceptibility to infection.

Enterically transmitted infections occur most frequently in the warmer months, presumably largely because of season-related changes in host behavior. The outdoor play of scantily clad children facilitates the spread of skin infection and fecally shed agents

such as enteroviruses. Rotavirus infections are an exception in that they occur most frequently in colder months. More completely understood are the seasonal patterns of infections spread by arthropod vectors; these patterns reflect seasonal variations in the abundance and activity of the vectors and the various lower vertebrate host species, which together constitute the reservoir mechanisms of the specific infectious agents. Climate overall, as a major determinant of the biologic environment, helps determine the abundance and the particular species of flora and fauna in a given area.

Longer term changes in climate have been associated with changes in patterns of infection. The hantavirus outbreak in the southwestern United States in 1993 has been attributed to unusually heavy precipitation in the spring of 1993 after 6 years of drought. This precipitation resulted in marked proliferation of the deer mouse population, the reservoir of the virus.[35]

Socioeconomic Environment

Socioeconomic factors depend on the density and distribution of populations; the available natural resources; the level of social, political, cultural, and scientific development; and, most importantly, the interrelationships of people. These factors typically affect health by indirect means, and, because they often are interrelated closely, evaluating the impact of individual factors is very difficult.

The relationship of population distribution and density to the occurrence of infectious diseases is substantial. Increasing density favors the spread of infectious agents to humans from human and nonhuman sources and the occurrence of related disease and development of immunity. In large and dense populations, agents such as measles virus typically infect in early childhood and persist because a sufficient number of new susceptible individuals are added continuously by birth. In smaller populations, the agents are unable to persist and are reintroduced at unpredictable intervals; as a result, manifestations of "childhood" diseases may be delayed for long periods. Populations of urban and rural areas differ not only in relative density, but also in other important ways. Exposure to zoonotic agents, especially agents prevalent in wildlife and livestock, is greater in rural areas, although rats and stray dogs may abound in city slums. Environmental sanitation (protection of water and milk supplies, safe disposal of sewage) often is a personal problem for rural residents but is handled by cooperative effort in urban populations. In addition, the importance of schools and school buses in facilitating exchange of infectious agents is greater in rural areas, where isolation of farm residents otherwise restricts contact between young children.

The basic population unit is *the household*, membership in which has similar implications for health in rural and urban areas. Family members are similar genetically; share a common diet and economic status; are subject to the same cultural, religious, and educational influences; and are exposed to a common local physical and biologic environment. Most important for contact-transmitted diseases, intrafamilial contact is prolonged and increases in intimacy with household crowding. In the wintertime, many homes are insulated, and the windows are closed so that air exchange is poor and exposure to airborne organisms is great. Prolonged contact is especially important for persisting infections such as HSV and tuberculosis. Family size, regardless of the degree of crowding, is particularly important for acute infections because it determines the number of potential introducers who bring home infections acquired elsewhere. The likelihood of exposure in early childhood increases with family size. Except for early infancy, a period of special vulnerability to some agents (e.g., respiratory syncytial virus, pertussis), early exposure is beneficial because most resulting infections are less apt to have serious consequences.

A population with a highly developed *social and political structure*, through its capacity for cooperative action, enjoys many advantages that directly or indirectly benefit health, including provision of preventive and curative health services, effective environmental sanitation, and well-developed educational facilities. Education closely relates to personal health practices that are based on understanding what individuals should do to minimize disease hazards. Schools, where the educational process begins, have been identified already as important factors in the exchange of infectious agents among children, especially agents spread by contact and airborne droplet nuclei. This matter is offset partly by the benefits derived from school-based immunization programs.

Economic status affects the occurrence of diseases indirectly through its relationship to adequacy of housing, nutrition, level of education, and availability and use of health services. It also is related closely to occupation, which may be associated with exposure to specific infections, such as Rocky Mountain spotted fever (forest workers and hikers in the south Atlantic coast states) and ornithosis (workers in poultry-processing plants).

DISEASE OCCURRENCE IN POPULATIONS

Patterns of occurrence of disease that are not random, but instead reflect the influence of underlying causes (risk factors), not only help predict future occurrence of disease but also provide important clues to understanding causation. Describing the pattern of occurrence of disease begins with definition and classification of disease in the individual so that cases can be identified and counted reliably. The occurrence of disease in defined populations can be expressed quantitatively.

INFECTION AND DISEASE IN THE INDIVIDUAL

Epidemiologic interest focuses on the specific etiologic identification of *infection* and *disease*, terms that are not synonyms. Technically, any deviation from normal function or state constitutes *disease*. Because virtually all infections cause at least some deviation from the normal state (e.g., a change in the white cell pattern in blood and mobilization of such cells at the site of infection), they cause disease. In practice, many infections result in no clinical evidence of disease and are important to the individual only for the reason that they induce immunity. Because subclinical infections help define the overall pattern of occurrence of infection and often play a significant role in its spread, their recognition is important epidemiologically. Subclinical infections go unrecognized except when healthy individuals are observed for infection in longitudinal or case-control studies.

Only infections resulting in disease usually come to the attention of the medical community. To the extent that they are recognized etiologically, they provide the earliest and most available indicator of the pattern of infection in the population.

With few exceptions, such as measles and chickenpox, typical clinical syndromes are not pathognomonic and require the clinician to develop a differential diagnosis. Basically, clinical manifestations depend more on the site or sites of disease than on the infecting agent. Because the number of possible disease targets in the body is small and the number of potential agents is large, reasonably distinct clinical entities may be caused by any of several agents. Notable examples include "common colds," approximately 40 percent of which are caused by rhinoviruses and 60 percent by any of many other viruses, and aseptic meningitis, which may be caused by such agents as mumps virus, many enteroviruses, or *B. burgdorferi*.

Infection with a specific agent may have several possible clinical outcomes. Infection with polioviruses usually is (perhaps

80%) subclinical, but can result in brief febrile illness (approximately 15%), aseptic meningitis (4-5%), or classic paralytic disease (<1 percent). The response to agents with multiple potential targets varies even more widely. Group B coxsackieviruses can cause such disparate entities as acute upper respiratory disease, aseptic meningitis, polio-like paralytic disease, myocarditis, and epidemic pleurodynia (Bornholm disease).

Knowledge of the agents active in the community when a given illness occurs helps narrow the differential diagnosis, but confirming etiologic diagnosis requires laboratory assistance: by culturing the agent, direct visualization in specimens, antigen detection, genome identification using molecular techniques, or demonstration of a specific antibody response in tests of "acute" and "convalescent" serum pairs. The diagnosis is most secure when both approaches suggest infection with the same agent. Although demonstration of the agent in relation to the disease site carries special weight (e.g., in a pharyngeal swab specimen from a respiratory illness), its presence could be the result of preexisting persisting infection unrelated to the current illness. Antibody response indicates a newly acquired infection.

DESCRIBING INFECTION AND DISEASE IN POPULATIONS

Sources of Information

Many sources provide data regarding the incidence of infectious diseases, including U.S. Vital Statistics, which tabulates only fatal cases; the Centers for Disease Control and Prevention (CDC), which receives reports of specific notifiable diseases from state health departments and summarizes them in the *Morbidity and Mortality Weekly Report*; and state and local health departments. In the absence of a focused surveillance project, these data vary in their completeness by source and by disease because of underreporting, subjects who are not seen, and errors in diagnosis.

Among the different states, reporting requirements vary, and adherence to these requirements by providers also varies. Reporting is most complete for uncommon but characteristic disorders of unusual interest, particularly if they are severe or fatal and require hospitalization, such as rabies, anthrax, trichinosis, plague, and diphtheria. Reporting is enhanced by outbreaks, as with measles, mumps, and classic pertussis in recent years. Some notifiable infections, such as leptospirosis and atypical pertussis in partially immune individuals, often are unrecognized and are under-reported. Reporting requirements may change from year to year based on CDC or state interests (neonatal sepsis and West Nile infection) or concerns about bioterrorism. Another source of data, often useful in certain areas, is state health department laboratories, which perform specific microbiologic or serologic tests for providers.

Infectious diseases that are not notifiable by law pose a difficult problem. Although necessarily limited in scale, longitudinal studies of defined populations of families have yielded valuable information. Finally, researchers now can use well-designed serosurveys to make reliable estimates of rates of previous infection with agents that induce long-persisting antibody.

International data on the incidence of infectious diseases are less precise except in well-developed countries. For the developing world, the World Health Organization (WHO) and the United Nations International Children's Emergency Fund provide estimates of the incidence of morbidity and mortality from various infectious diseases in different nations based on local reports, which are not always collected systematically. Continuing collection of such data is important for monitoring the effects of the Expanded Program of Immunization, which is directed at controlling the major vaccine-preventable diseases of childhood. More difficult to develop are definitive data about the incidence and causation of the respiratory and diarrheal diseases, which are estimated to kill 6 million children annually in the developing world (approximately 5% of the yearly birth cohort).

For developing these kinds of statistics, it is important to have a definition of disease that is as useful as possible, which means that the sensitivity and specificity of the definition should be so balanced that as many cases of the disease as possible are identified, while avoiding the confusion that occurs when other disorders with overlapping manifestations meet criteria that are too nonspecific. A well-known example of a useful definition of disease is the Jones criteria for the diagnosis of rheumatic fever, established in 1944 at the request of the National Research Council in an effort to bring order out of chaos at a time when the disease was a major problem in the civilian and military populations.[17] These criteria subsequently have been modified to enhance their specificity by making evidence of a previous group A streptococcal infection a sine qua non for the reason that too many cases of polyarthritis of other causes met the original criteria.[9] Similarly, the criteria for the diagnosis of Kawasaki disease were revised more recently to avoid missing some episodes in infants and missing the opportunity to prevent coronary artery aneurysms by using intravenous immunoglobulin.[24]

Recognizing the importance of standardized diagnostic criteria for surveillance of infectious diseases of public health importance, the CDC published in 1990 case definitions for reportable infections.[36] Optimal use of these criteria and reporting of confirmed and probable cases to the proper authorities are of particular importance currently, when for a variety of reasons, some formerly well-controlled contagious diseases are becoming recrudescent (e.g., mumps, pertussis). All states mandate reporting contagious diseases of major public health importance, particularly diseases affecting children.

Definitions of Terms and Rates

Two commonly used (and often misused) terms, *incidence* and *prevalence*, have significantly distinct meanings. *Incidence* refers to new occurrences of infection or disease, in a population of individuals uninfected or without disease at baseline, during a specified period, commonly a year, whereas *prevalence* refers to the state (infected, ill, immune) of individuals in a population at a specified point in time (point prevalence).

To describe variations in occurrence over limited periods within a single population, such as a city or a state, a simple *numerical incidence* (number of cases or infections) often is used—daily or weekly (during an epidemic), monthly (to reflect seasonal patterns), or annually (to compare successive years). Comparisons among different populations or subgroups within a population or at widely separated times in the same population require use of the *incidence rate*, or *attack rate*, which is defined as follows:

$$\frac{\text{No. new occurrences (cases, infections) within a specified period}}{\text{Population at risk at midperiod}} \times 100, 1000, 10{,}000$$

If 10,000 cases of influenza occurred in a city of 200,000 people in a year, the incidence (or attack) rate would be expressed as 5 per 100 per year. In contrast to *incidence*, which is useful for determining acute and chronic conditions, *prevalence* is applied usefully only in describing conditions of long duration (months or years), such as immunity, persisting infection, and chronic disease. In relation to an acute disease such as influenza, we speak of the incidence of disease and the prevalence of immunity (reflected by antibody). Because most interest is in comparisons of different populations or subgroups, prevalence is

expressed customarily as the *prevalence rate*, which is defined as follows:

$$\frac{\text{No. persons (infected, ill or immune) at a given time}}{\text{Population at that time}} \times 100, 1000, 10{,}000$$

For infections transmitted by contact, the frequency with which infection or disease occurs among exposed susceptible individuals provides a measure of the infectivity of the agent. This frequency, called the *secondary attack rate*, is defined as follows:

$$\frac{\text{No. contacts becoming infected or ill within the maximal incubation period}}{\text{Total number of "susceptibles" exposed}} \times 100$$

The secondary attack rate is applied usefully only to closed groups, households, or classrooms, where exposure safely can be presumed for all members. The first, or primary, case is the presumed source of exposure; other cases that occur within the minimal incubation period are called *co-primary cases*. In calculating the secondary attack rate, primary and co-primary cases are excluded from the numerator and the denominator. Cases that occur subsequently within the maximal incubation period constitute the secondary cases. Cases that develop later are excluded as being derived from outside sources or from tertiary spread. The exclusion of immune individuals from the denominator is feasible only for diseases sufficiently characteristic clinically that the history serves to identify them (e.g., measles, chickenpox). Although immune individuals are not readily identifiable in the case of common respiratory diseases, the secondary attack rate based on all exposed members of the group still remains a useful tool. Its value decreases, however, when the period of communicability of the primary case (as with *Mycoplasma pneumoniae*) is longer than the incubation period because distinguishing between secondary and tertiary cases becomes difficult. Finally, the occurrence of death caused by a specific disease is expressed in two different ways. One, the *cause-specific mortality rate*, is defined as follows:

$$\frac{\text{No. deaths from the disease in a given year in a population}}{\text{Total population at midyear}} \times 100{,}000$$

It is a measure of the effect of the disease on the population. The potential significance of the disease to the affected individual is suggested by the *case-fatality rate*, which is defined as follows:

$$\frac{\text{No. deaths from the disease within a specified period}}{\text{No. cases in the same period}} \times 100$$

RELATING INFECTION AND DISEASE TO PERSONAL CHARACTERISTICS

Multiple characteristics may serve to distinguish one individual from another. Some factors are determined at conception—age, sex, ethnicity, genetic make-up, and birth order. Others, far more numerous, are acquired subsequently. They may be biologic (specific immunity, nutritional state), behavioral (smoking, dietary, recreational habits), or socioeconomic (occupation, educational level, marital status). Many of these characteristics relate to exposure to infectious agents or to susceptibility or resistance to the effects of such agents and to the occurrence and severity of disease.

Relative Usefulness and Importance of Characteristics

Although almost any potentially relevant characteristic of an individual patient can be identified, it is not useful for purposes of description unless we can estimate how many people in the population also possess the characteristic. From census data or other accessible records, numbers of people in groups defined by age, sex, race, occupation, or marital status can be estimated easily. Special surveys would need to be conducted to estimate the prevalence of specific immunity or possibly significant exposure, such as to household pets.

The importance of personal characteristics to the description of a disease varies in two ways. One is in the degree of association that exists between a characteristic and a specific disease. Age is associated strongly with disease caused by prevalent contagious agents, whereas sex usually is not. The second way is in the independence or relative interdependence of characteristics as variables. Inherent characteristics, such as age, sex, and ethnic origin, are independent of one another, whereas acquired characteristics rarely are. The nature of interpersonal contacts, degree of personal hygiene, and usual forms of recreation are associated closely with age or sex or both. The common interdependence of characteristics means that before making an inference from a particular association, one should explore association with other, possibly correlated, characteristics.

Age Patterns

The occurrence of infection and disease generally is related so strongly to age that until possible differences in age distribution are taken into account, differences in occurrence among population subgroups defined by other characteristics cannot be interpreted meaningfully. Age as a characteristic is ascertained easily and reliably for affected individuals and the total membership of the relevant population. Description of the age pattern involves computing a series of *age-specific rates* for sequential age groups, usually defined in intervals of 5 years or multiples thereof (e.g., 0 to 4, 5 to 9, 10 to 19). For conditions of pediatric concern, the use of single-year intervals (<1, 1, 2, 3, and 4 years) to cover early childhood may be more informative. In some cases, especially in the first 2 years of life, a breakdown by months of age would be informative.

Affected individuals in an age group form the numerator, and all individuals in the population in that age group serve as the denominator. Rates so computed describe the age profile of immunity at a specified point in time (age-specific antibody prevalence rates), the age profile of new infections or disease (age-specific incidence rates), or the age profile of deaths caused by a disease (disease-specific and age-specific mortality rates). Age-specific incidence rates for acute infectious diseases indicate the risk of disease occurring in each age group and, depending on the disease agent, more or less accurately reflect the underlying age-specific infection rates.

Age Adjustment of Rates

The need to take age distribution into account when comparing disease in different populations is indicated when (1) the rates vary with age and (2) the distribution of the populations by age differs substantially. From published U.S. mortality data for 1983 and 1984, one can compare pneumonia and influenza mortality rates for Alaska and Florida. During those years, 89 deaths were recorded among 986,000 Alaskans at risk, for an annual mortality rate of 9/100,000. In contrast, in Florida, 4703 deaths occurred from pneumonia and influenza among the 21,792,000 residents

at risk for those 2 years, for a rate of 21.6/100,000, nearly 2.5 times that of Alaska. These rates are called *crude mortality rates.* In this instance, these rates are misleading for the reasons that the likelihood of death occurring from pneumonia and influenza increases with age and the age distributions of the populations of these two states differ markedly. National death rates from these infections are nearly 10-fold greater in people 65 to 74 years of age than in people 55 to 64 years of age. For those years, 17.5 percent and 3 percent of the Florida and Alaska populations were 65 years or older.

To make a valid comparison of the pneumonia and influenza mortality rates for these two states, one must perform an age adjustment; this is a simple process that is not detailed here because the method can be found in available texts of biostatistics and epidemiology. Briefly, one determines mortality rates for specific age groups (usually 5 or 10 years) for the two populations and calculates the deaths that would be expected in a common (or standard) population for the same age groupings by using the age-specific rates of the populations being compared, in this instance those of Alaska and Florida. Summation of these expected deaths permits calculation of the rates that would have occurred in the standard population if the age-specific rates of Alaska applied and if the age-specific rates of Florida applied. In this example, the age-adjusted mortality rate for pneumonia and influenza for Alaska is 35.2/100,000, and that for Florida is 21.8/100,000, nearly the reverse of the crude rates. (The combined population of the two states was used as the standard.)

These age-adjusted rates are not true rates; they are used for comparison. Although often applicable to infectious diseases, age-adjusted rates almost always are required for comparisons of morbidity and mortality from chronic diseases.

Sex Patterns

Because sex is a readily ascertained characteristic of the membership of populations, the occurrence of infections and disease in relation to sex is described easily. Its simplest form is the *sex ratio*, or the ratio of cases in males to cases in females. This ratio is meaningful only when, as in childhood, the population is divided approximately equally by sex. Although males exceed females at birth (106:100), the death rate for males exceeds that for females at all ages (average 1.5:1). From approximately age 20 years on, females outnumber males, the difference increasing with age, which means that when comparing sex-specific rates, age adjustment must be made, or, better yet, the age profiles for the sexes should be compared directly so that important differences in the contour can be seen.

Ethnic or Racial Patterns

A third characteristic by which members of the population can be grouped in describing occurrence of disease is race or ethnic origin, the usefulness of which has decreased with the increasing frequency of mixed marriages. The U.S. census classification is based on information collected regarding race and native origin. Individuals of mixed racial parentage are classified by the race of the nonwhite parent or, if both are nonwhite, by that of the father. People of foreign birth are classified by country. Native-born children of foreign-born parents are identified as "foreign stock" and grouped according to parental origin. Census data provide estimates of population subgroups belonging to several "races" (white, black, Native American, Chinese, Japanese) or "foreign stocks" (including foreign born and first generation).

Although controversial currently, this method yields differences in the occurrence of many infections and other diseases among such population subgroups. Knowledge of such differences is useful in case finding and organizing the application of specific preventive measures. Subgroups defined by ethnicity possess some similarity in genetic constitution that may determine susceptibility or resistance to specific agents. They also may be affected distinctively by environmental factors because of voluntary or involuntary differences in behavior and patterns of living.

Disease Patterns in Kinships

Genetically determined susceptibility and resistance to specific infectious agents have not yet been associated clearly with recognized genetic markers that could serve as a basis for defining population subgroups. Most efforts to look for genetic influences have been studies of occurrence of diseases in individuals of differing degrees of relationship within kinships or in the total memberships of different kinships. With rapid advancement in the database of the human genome, considerable interest has been generated in polymorphisms at loci that may define susceptibility to infectious diseases on a genetic basis. Populations with a high prevalence of certain alleles and known to have an increased risk of certain infections could be studied to determine whether the risk is due to abnormal function of the specified gene.

Family Episodes of Infection and Disease

With respect to contact-transmitted infectious diseases, the family is more important as the basic epidemiologic subgroup of a population than for its shared genes. Observation of family units for episodes of infection and related illnesses has contributed significantly to knowledge of the epidemiology of widely prevalent infectious agents. The situation in all family studies begins with one member's infection, acquired from outside the house. That member then exposes the other family members. The introductory infection and any infections in family members who are exposed constitute a family episode, which is described basically in terms of the times of onset of the related infections and the identities (age, sex, position in the family) of the introducer and the infected and uninfected contacts.

Analysis of cumulated episodes of common respiratory illness, observed in the early studies, identified children as the most frequent introducers (important in community spread). Analysis also yielded estimates of the risk of cross-infection occurring within the family, expressed in terms of secondary attack rates among specified members (e.g., younger children) exposed to specified introducers (e.g., a schoolchild or a parent). Generally, the risk in contacts was related inversely to age overall, as a result of the influence of immunity, and to intimacy of within-family contact (ready exchange between spouses and between children nearest in age). Finally, the relationship of time between the onset of illness in the introducer and onset in family members exposed serves to define the range of incubation periods.

Analysis of the episodes can yield additional information concerning such crucial aspects as mode and duration of the agent's shedding; the spectrum of clinical response to infection, including the proportion that is subclinical; and the significance of previous immunity in the face of close exposure, as measured by the frequency and clinical consequences of the reinfections that result. The results of the analysis of adenovirus episodes in the Virus Watch program are illustrative.[11] Virus appears regularly in the feces and less often (approximately 50%) in the pharynx, and shedding may be abortive (a few days only) or continue intermittently for many months. Overall, 50 percent of infections are subclinical, and illness, typically febrile and respiratory, occurs more commonly with pharyngeal excretion (65%) than with only fecal shedding (31%). Immunity is 85 percent protective against infection; re-infections that do occur usually are subclinical. Young children and especially infants younger than 2 years of age are the usual introducers, and within-family

spread depends more on duration than on the mode of virus excretion by the introducer.

Socioeconomic Patterns

Socioeconomic status covers a complex of characteristics, including levels of education and income and, less tangibly, "social standing." The problem is to discover a useful single indicator. One possibility is area of residence as classified by median income or measures that reflect housing standards, such as type of plumbing and average number of individuals per room. Relevant data are available for census tracts, which have proved useful when the tracts are homogeneous.

Occupation of the head of a household seems to be the one attribute most closely reflecting socioeconomic status. On this basis, the British have defined five broad social classes that directly apply to employed adults and can be extended to cover their dependents. These classes, in descending order, are professional, intermediate, skilled, partly skilled, and unskilled occupations. For use in the United States, based on census-recorded occupations, these terms have been translated as follows:

- Professional workers
- Non-farm technical, administrative, and managerial workers
- Clerical, sales, and skilled workers
- Semiskilled workers
- Non-farm laborers
- Farm workers of whatever level are included in a sixth group as agricultural workers

RELATING INFECTION AND DISEASE TO PLACE

Place is of interest, epidemiologically, when occupied by humans and, unless indicated as relating to work, recreation, or travel, refers here to residence. Place usually is classified geographically (hemisphere, continent, nation) but also can be classified usefully by environmental characteristics such as climate, altitude, stage of economic development, population density, and urban or rural nature. Variations in occurrence of disease with place reflect parallel variations in the operation of causative factors and raise the question of whether these factors are to be found in the characteristics of the physical and biologic environment inherent to the place or in the characteristics of the inhabitants. The former is suggested when the age-adjusted risk of disease increases for immigrants and decreases for emigrants, when risk does not vary among the ethnic groups present, and when similar ethnic groups in other places enjoy a lower risk. One also must consider possible differences in reliability and completeness of recognition and reporting of disease.

Global Variation

On the global scale, the WHO collects and publishes information concerning the occurrences of diseases derived from statistics compiled routinely within nations for morbidity from notifiable infectious diseases and for causes of death. The great variations among nations in the quality and availability of medical care and other health services result in corresponding variations in the reliability and completeness of the data collected by the WHO. Generally, basic demographic data and the quality and availability of health services are equally good in well-developed countries, so specific disease rates can be compared. In less-developed countries, demographic data may be inaccurate and medical services may be inconsistent in quality and concentrated in urban populations, within which their availability varies with economic status. Many illnesses and deaths are unattended medically, especially in rural areas, and births commonly are attended by midwives. Because infant deaths are reported more completely than births are, infant mortality rates may be unreliable.

With respect to infectious and parasitic diseases, knowledge of the frequency of disease is less important than is qualitative knowledge of the distribution and spread of disease. Such knowledge guides the application and enforcement of international control measures and is the basis for advice given by physicians to prospective foreign travelers. Important diseases, such as yellow fever, plague, and cholera, because of their high case-fatality rate and characteristic clinical picture, are almost certain to come to attention when substantial numbers of cases occur. Such knowledge may not be publicized, however, or may not be promptly available. Some countries, in the hope that a new outbreak (perhaps of cholera) will be controlled soon, may withhold information to avoid discouraging economically important tourists.

Two additional considerations are relevant to evaluating the disease hazards of foreign travel. One is the fact that recognized occurrence of disease in the indigenous population may be an inaccurate index of risk to a newcomer. Particular agents, such as polioviruses in the past and hepatitis A virus and Epstein-Barr virus at present, may be so prevalent that infections in natives occur so early in life that they usually are subclinical. The second consideration is the nature of the proposed travel. The usual tourist or business traveler visits chiefly larger population centers and popular tourist attractions, where the most important hazards are pathogens transmitted by food or water. Travelers whose activities bring them into more intimate contact with the people and the biologic environment (Peace Corps workers, military personnel) may encounter additional hazards, such as rabies and the locally prevalent arthropod-transmitted pathogens.

As suggested in considering geographic influences on occurrence of disease, the distribution of many diseases is influenced by relevant environmental factors, rather than political boundaries. In depicting (or predicting) the global distribution of a particular disease, identifying regions defined by the presence of factors thought to be important to disease occurrence is useful.

For most agents pathogenic for humans, the chief environmental requisite is a susceptible human population, and most such agents already exist wherever the size and density of the population are sufficient for them to persist. Concern about global spread is limited to a few important pathogens, such as the cholera vibrio and influenza virus. Cholera is a special case in that its spread also depends on poor sanitation. Neither persistence nor even limited spread should occur after its introduction into highly developed areas. Influenza A virus continues to be a major, and so far unstoppable, threat by virtue of its ability to emerge at irregular intervals in a new antigenic coat, which largely negates the pre-existing widespread immunity.

Local Patterns of Infection and Disease

"Local" units of population for which demographic data are readily available in the United States include "large" units, such as counties, metropolitan areas, and large cities, which contain smaller units (smaller cities and towns [within counties] and census tracts [within metropolitan areas and large cities]). The smaller units, including unincorporated areas within counties, often can be characterized by variables (urban or rural nature, population density, socioeconomic status, racial or ethnic group) that may help explain observed differences in the occurrence of specific infections and related diseases.

Particularly in relation to outbreaks of acute infectious diseases, spot maps commonly are used to show the local distribution of individual cases. Placing new pins (a different color each week) to mark the residences of newly reported cases serves to visualize the outbreak's geographic progression. The final distribution of the pins may help identify a major source of infection.

A classic example is the 1854 outbreak of cholera in the Golden Square district of London, in which the clustering of residences of fatal cases helped Snow incriminate the Broad Street pump as the source.[32] Sometimes, place of work is a better guide to the source of infection than place of residence. In another classic study, that of endemic typhus in Montgomery, Alabama, in the early 1920s, the residences of cases (Fig. 7–2) were scattered widely, whereas the workplaces (Fig. 7–3) were concentrated in relation to feed stores and food-handling businesses, all heavily rat-infested. This finding led Maxcy[21] to perform studies showing the basic role of rats and rat fleas in this disease.

TEMPORAL PATTERNS OF INFECTION AND DISEASE

Definitions

The unit of time used can vary from hours to decades to centuries. In describing acute outbreaks, the units are short—hours for

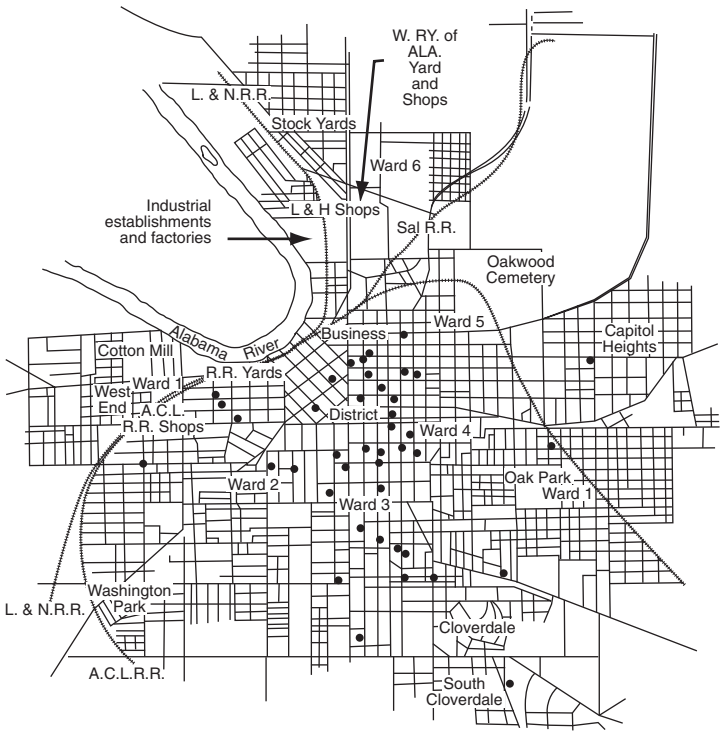

Figure 7–2 Cases of mild typhus (Brill disease) in Montgomery, Alabama, 1922 to 1925, spotted according to residence. *(From Maxcy, K. F.: An epidemiological study of endemic typhus [Brill disease] in the southeastern United States. Public Health Rep.* 41:*2967-2995, 1926.)*

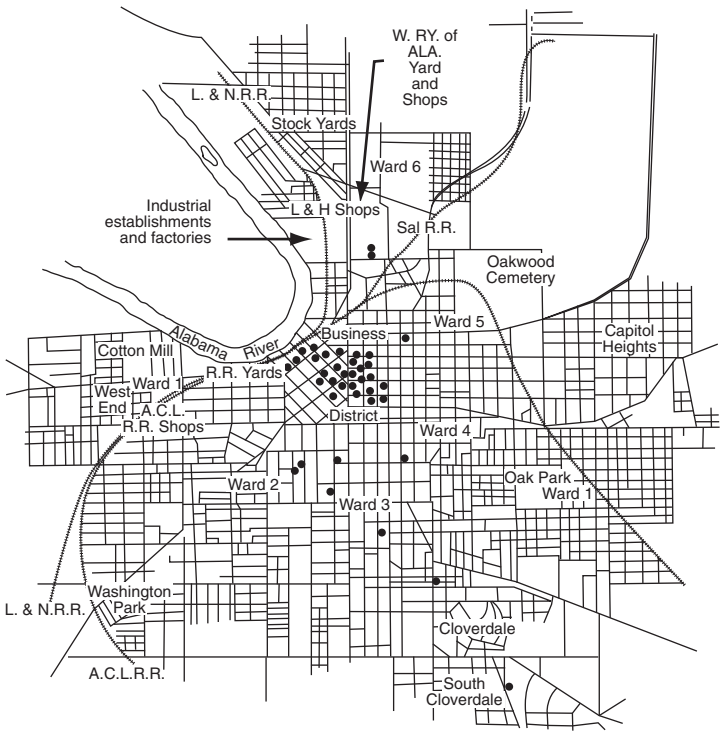

Figure 7–3 Cases of mild typhus (Brill disease) in Montgomery, Alabama, 1922 to 1925, spotted according to place of employment or, if unemployed, according to place of residence. *(From Maxcy, K. F.: An epidemiological study of endemic typhus [Brill disease] in the southeastern United States. Public Health Rep.* 41:*2967-2995, 1926.)*

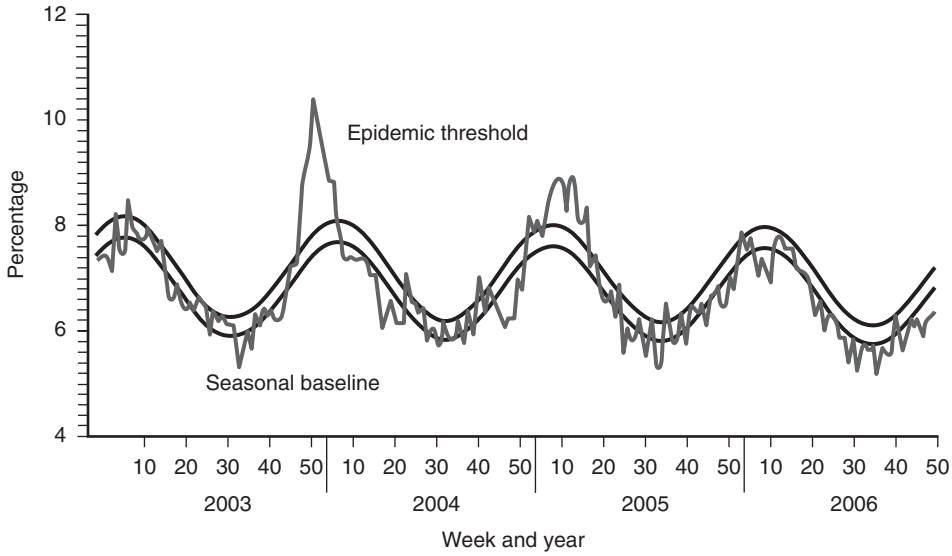

Figure 7–4 Percentage of all deaths attributed to pneumonia and influenza reported by the 122 Cities Mortality Reporting System, by week and year—United States, week ending December 9, 2006. *(From M. M. W. R. Morb. Mortal. Wkly. Rep. 55:1345-1375, 2006.)*

food poisoning, days or weeks for most infectious diseases—whereas long-term time trends are described in longer units of years or decades. Comparisons extending over 1 or more decades may be complicated by changes in diagnostic standards and reporting.

Finally, the meanings of two words commonly used to describe the occurrence of disease over time in a given area should be defined clearly. *Endemic* refers to diseases regularly present. The usual frequency, including expected seasonal variations, is called the *endemic level.* The term *epidemic* applies to any number of cases, small or large, that is a significant increase over the usual, or endemic, level (although just what constitutes a "significant increase" is not clearly defined).

This principle underlies the monitoring of many infectious diseases, deaths, and pneumonia caused by influenza by the CDC. Such monitoring is illustrated in Figure 7–4, in which the weekly ratios of deaths caused by pneumonia and influenza to the total deaths observed from 2003 to 2006 are compared with the ratios expected from use of the time series method[7] and "epidemic threshold," which depicts the upper 95 percent confidence limit. When the observed value exceeds the expected one for 2 successive weeks, an influenza epidemic is indicated. On this basis, epidemics began in week 48 of 2003 and week 9 of 2005.

In practice, especially at the local level, health authorities use the term *outbreak*, rather than *epidemic* (unless the number of cases is very large), to minimize public alarm. The term *pandemic* is used to describe excess disease occurring in many countries, as influenza did in 1957 and 1968.

Time Clusters

Time clusters relate to the recognition and interpretation of events (infections and disease) that occur with some increased frequency within a limited period or clustering in time. An important determinant of clustering of infections is the incubation period. Infection resulting from a known exposure is manifested within a predictable range of time by the initiation of shedding of the agent and the onset of disease (if it occurs). Although the average incubation period of a given disease is remarkably constant, the usual range broadens as the incubation period increases. This range can be estimated by accumulating cases for which the time of exposure is known precisely or approximately and, with this point as day 0 on the time axis, plotting the day of onset of each subsequent case. The width of the resulting cluster provides an estimate of the range of the incubation period. The best estimate is obtained by using only cases with single, clearly timed exposure, such as when contact with the source case occurred only once, as during a playmate's birthday party.

A more readily obtained but less precise estimate is that derived from the cumulative analysis of family episodes of a disease based on the assumption that the initial or primary case is the source of subsequent disease in family contacts. Because the primary case is infectious for several days, on any of which effective exposure may occur, the onset of secondary cases would cluster over a range that theoretically may reflect the true range plus the period of infectivity of the primary case.

Knowledge of the range of incubation periods has several practical implications. For contagious diseases, it can be used to distinguish true secondary cases that occur in families from others arising as a result of extrafamilial sources (cases with onset too soon after that of the primary case are called *co-primary cases*) or representing a second generation of spread within the family (*tertiary cases*). Knowledge of the range of incubation periods also determines the length of time after known exposure that contacts should be observed or possibly held in quarantine for the subsequent development of disease. For poorly contagious diseases, such as typhoid fever, or for noncontagious diseases, such as food poisoning, the distribution of onset in an outbreak can be used to distinguish between "point" epidemics (common time and place of exposure) and outbreaks reflecting exposure to a possibly continuing source. In the former case, onset would fall within the usual range of incubation periods. When the point source is not obvious, investigation can be focused on the interval defined by subtracting the shortest incubation period from the date of onset of the first case and the longest period from the date of onset of the last case.

Short-Term Patterns

EPIDEMICS

"Point" epidemics have a duration limited by the range of the period of incubation of the particular disease because no secondary spread of the agents occurs. Much more commonly, outbreaks or epidemics extend over longer periods. On the basis of the causative agents and the mechanisms of transmission, three distinct types can be recognized.

The first type typically consists of outbreaks of poorly contagious or noncontagious diseases; such outbreaks reflect the new but persisting activity of a source that must be identified and terminated quickly. One example of such a "continuing source" type of outbreak was a community-wide outbreak of salmonellosis in Madeira, California, in 1965, which was traced quickly to the water supply.[27] Unrecognized typhoid carriers working as food handlers and shellfish harvested from sewage-polluted waters contaminated with hepatitis A virus are other examples of outbreaks requiring prompt epidemiologic investigation to identify the source. One of the major causes of point epidemics is food contaminated with *E. coli* O157:H7. More recent outbreaks, such as the contamination of spinach at the growing source, have been reported by the CDC.[6] Often the CDC posts interim reports of investigations on the CDC website (www.cdc.gov) before publication in *Morbidity and Mortality Weekly Reports.*

The element of contagion distinguishes the second type of epidemic, in which disease spreads from person to person. Such epidemics generally are self-limited, and the curve describing them often resembles the bell-shaped curve of a normal distribution. Modification of this curve, as in an abrupt decline from the peak, is the expected result of successful efforts to control the epidemic. Epidemics of contagious diseases occur when the population in which the agent persists or is newly introduced contains a sufficient number of susceptible individuals with contact with one another that is adequate to permit transfer of infection from each new case to, on average, more than one susceptible individual. When this average falls below 1, the curve declines, and when the probability of successful transfer of infection approaches zero, the epidemic stops (typically well before the supply of susceptible individuals has been exhausted).

Reasons that underlie this decline and termination of transmission include seasonal changes in environmental factors that affect viability of the agent, such as temperature and humidity; changes in the behavior of hosts that affect the intimacy of contact, such as indoor school versus outdoor play; and the progressive conversion of individuals from susceptible to immune. Institution of appropriate hygienic precautions likely was an important facet of control and termination of the worldwide outbreak of severe acute respiratory syndrome in 2003.[5] If one assumes constant units on the time axis, the slope of the ascending limb of the epidemic curve is determined by the incubation period (interval between successive cases) and by factors that influence transmission (infectivity of the agent, frequency of adequate contact between susceptible individuals). In the absence of effective control measures, the duration of epidemics of a particular disease depends on the size of the susceptible population and the persistence of favorable environmental factors.

Epidemics of "diseases in nature" constitute the third type. Because susceptible individuals usually are abundant in the human population, these epidemics typically reflect increases in the number of sources of infection in nature. With zoonoses such as arbovirus encephalitis, the initiation, slope of the curve, and duration of the epidemic are determined by the number of susceptible lower vertebrate hosts, the seasonally determined abundance of the vector mosquitoes, and the length of the extrinsic incubation period in the vector. The occurrence of West Nile virus in the United States, which began in August 1999 and has continued with outbreaks in the late summer of each succeeding year in mosquitoes and humans is an example.[3,4]

SEASONAL AND CYCLIC VARIATIONS

Predictable periodic variations in disease take two forms, seasonal and cyclic, neither of which is understood completely in the case of agents infecting only humans. *Seasonal* variations presumably reflect the influence of changes in temperature, precipitation, and length of daylight on the activity of the agent. This variation is readily apparent with respect to diseases, such as Lyme disease (the peak incidence of which typically occurs in the summer months), which depend on lower vertebrate hosts and arthropod vectors, the abundance and activity of which are determined seasonally. Similarly, the increased occurrence of enteric bacterial infections (spread by indirect means) in the warmer months is explainable largely by more rapid bacterial growth in unrefrigerated milk and food, the increase in abundance of flies, and the lack of sanitary precautions associated with summer recreational activities.

The mode of transmission is only a partial determinant of the seasonal pattern. Although the enteroviruses (including polio), the rotaviruses that cause acute gastroenteritis, and hepatitis A virus all are spread chiefly by fecal-oral mechanisms (direct and indirect), the seasonal patterns are distinctly different (late summer and fall for enteroviruses and late winter for rotaviruses and hepatitis A virus). Similarly, although infections with agents present in respiratory secretions and spread by either airborne mechanisms or contaminated fomites occur infrequently in the summer, their seasonal peaks occur at significantly different times. The season of respiratory diseases coincides roughly with the school year. Infections with rhinoviruses occur most frequently in the early fall and late spring, and infections with parainfluenza virus types 1 and 2 occur most frequently in the fall. The annual peaks of RSV vary among fall, winter, and spring. Mumps peaks in late fall, influenza in late winter or early spring, and measles typically in the spring.

Plotting variation over a series of years reveals a roughly regular cyclic variation for some diseases. In larger metropolitan areas, the usual biennial measles epidemic appears as an enlarged annual wave. Before 1950, deaths caused by meningococcal meningitis occurred on a nationwide basis in cycles of 7 to 9 years, a phenomenon presumably terminated by the advent of prophylactic antibiotics. Pandemic influenza A, which provides the most dramatic example of cycling, is explainable by a major change in the antigenic character of the agent.

Long-Term Trends

Except for poliomyelitis during the first half of the 20th century, clearly defined long-term trends in the occurrence of infectious diseases in the United States usually have been downward, and in no case has description or understanding of the mechanisms posed a major difficulty. In the case of poliomyelitis, the increase in the rate of paralytic disease that began about 1880 is attributable to numerous factors, including improved sanitation, which resulted in an expanding proportion of infection occurring among older children and young adults without previous exposure to the viruses. In young infants, most poliovirus infections are benign but produce long-lasting immunity; the older an individual is when infected, the more likely that individual will have paralysis. The frequency of paralytic poliomyelitis is related inversely to the level of sanitation. In the United States, the increase in paralytic disease with epidemics of polio continued unabated (with an apparent sharp increase around 1940 because of changes in reporting criteria) until the widespread use of polio vaccines.

The post-1955 decline in poliomyelitis; the much earlier decline in pertussis and diphtheria; the disappearance of smallpox; and the more recent marked decline in measles, rubella, *H. influenzae* type b, and varicella all are attributable chiefly to widespread use of effective specific vaccines. Similarly, the disappearance of indigenous malaria and the decline of rabies to a negligible level in humans in certain areas reflect the application of a variety of effective control measures.

Emerging Infections

Although in the 1980s one might have said that most infectious disorders had been explored thoroughly epidemiologically and

that little was left to do, this conclusion no longer is the case. Infectious disease epidemiology has become increasingly challenging, and in many ways the problems are more complex and necessitate greater cooperation with additional disciplines, such as microbiology and molecular biology.

In part, this increased complexity is due to so-called *emerging infections*, a term that has come into vogue in recent years and refers to two different groups of disorders. The first is associated with the appearance of previously unrecognized or possibly heretofore nonexistent infections in humans. Well-known examples are legionellosis, hantavirus pulmonary disease, acquired immunodeficiency syndrome (AIDS), Lyme disease, hemorrhagic colitis caused by *E. coli* O157:H7, and Ebola virus infection. The other group includes previously recognized human infections that exhibit changes in epidemiologic behavior or biologic characteristics that enhance their transmission or virulence. These changes usually can be attributed to external influences, such as altered demographics including increasing population and rural-urban migration, international travel, new technology or technologic failure, changes in land use, adaptation of infecting organisms to various influences, and inadequate or underused public health measures.[18] To this list should be added changes in host factors such as immune defenses.

No clear dividing line exists between new infections and old ones that exhibit new behavior. Examples of some with new behavior include multidrug-resistant tuberculosis, penicillin-resistant pneumococcal infections, invasive group A streptococcal (popularly known as flesh-eating bacteria) infections, staphylococcal toxic shock syndrome, community-acquired methicillin-resistant staphylococcal infections, H5N1 influenza ("bird flu"), cryptosporidiosis, and numerous infections that are fostered by immunosuppression or various therapeutic measures such as antibiotics and catheters.

These emerging infections are not minor threats. Although in some instances small populations have been affected to date, the potential for widespread disease of epidemic or even of pandemic proportions exists. This potential can be expected to increase because the demographic and other conditions that have predisposed to the emergence of these infections continue to grow and intensify. Maximal efforts must be expended to reverse this process. To achieve this goal requires worldwide collaborative effort among various disciplines, including epidemiology, microbiology, entomology, immunology, clinical medicine, demography, nutrition, sanitation, and even political science.

The responsibilities of epidemiologists regarding emerging infections may be described in three categories. The first category is surveillance, including recognition of the appearance of a previously unrecognized infection or a new variant of an existing disease. Optimal surveillance requires systematic observations and specific diagnostic criteria to ensure precision. An important part of surveillance is to determine who, when, and where: who is affected (e.g., age and other personal characteristics, contact with others who are ill), when the disorder occurs (e.g., year-to-year variations, season, temporal course of the outbreak), and where it occurs (e.g., geographic locations, urban or rural, local ecology). Second, an important task is to use surveillance and other data to develop an understanding of the epidemiology of the infection, which often provides clues to its etiology and pathogenesis and to approaches to controlling the disease. The third role of epidemiologists is that of monitoring the effects of various control measures, including assessment of the safety and efficacy of new vaccines, such as those for H5N1 influenza, malaria, and AIDS. Chapter 266 contains a description of how the efficacy of vaccines is determined.

The increasing magnitude and speed of international travel enhance the likelihood of global spread of disease and complicate approaches to prevent or contain epidemic infections. Many of the emerging infections are not limited geographically by their ecologic requirements. The nations of the world increasingly depend on each other for surveillance, a task that is not accomplished easily given the logistics; costs (in the face of other needs and priorities, particularly of many developing countries); and the required standardization, collaboration, communication, coordination, and centralized resource for assembly and analysis of surveillance. Although the WHO, the Pan American Health Organization, the U.S. Military and Public Health Service, and various other organizations maintain surveillance systems and laboratories in various parts of the world, these efforts at present are considered to be inadequate except for some infections and in some areas. The development of comprehensive national and worldwide surveillance systems has been urgently recommended.[18]

Upper Respiratory Tract Infections

CHAPTER 8

The Common Cold

James D. Cherry ❂ Delma J. Nieves

The common cold is an acute, communicable, viral disease characterized by nasal stuffiness, sneezing, coryza, throat irritation, and no or minimal fever. Although the terms *upper respiratory infection* and *nasopharyngitis* are used frequently as synonyms for the common cold by physicians and other health care workers, the practice should be discouraged; the term *upper respiratory infection* is too broad, and pharyngitis is not present in most colds. To add to the confusion regarding terminology, "a cold" frequently has an even more inclusive connotation to the layperson.

HISTORY

Although the common cold undoubtedly has had an impact on the events of history, the specific symptom complex in ancient times was overshadowed by more severe contagious problems (influenza, plague, smallpox) and by septic diseases (otitis, mastoiditis, pneumonia) that were complications of upper respiratory viral infections. The name *common cold* most certainly arose from the fact that the onset of symptoms included the feeling of chilliness on exposure to cold. This association was perceived as a cause-and-effect relationship. More than 200 years ago, Benjamin Franklin pointed out that colds were caught from other people rather than by exposure to cold.[140]

In 1914, Kruse[114] showed that colds could be transmitted by the nasal instillation in healthy adults of Berkefeld-filtered nasal washings from ill individuals and that the causative agent was smaller than common bacteria. These findings were confirmed clearly in 1930 by Dochez and associates.[51] The way was paved for more extensive study of respiratory viral infections in 1933 when Smith and colleagues[158] reported the isolation and cultivation of an influenza A virus from a human.

The greatest contribution to the present understanding of the common cold has been the use of human volunteers under carefully controlled conditions. The Common Cold Research Unit at Salisbury, England, was established in 1946,[5,179] and volunteer studies at this institution and studies done in the United States* are responsible for the present understanding of colds in adults.

Although studies of respiratory illness in children also have been extensive, controlled virus challenge trials have not been done. Pediatric studies have been most useful in delineating the spectrum of clinical manifestations by age group and seasonal prevalence rates of the different respiratory viruses.

ETIOLOGIC AGENTS

Initial investigations into the etiology of the common cold were based on the hypothesis that only one etiologic agent needed to be discovered. Subsequent studies revealed that many different groups of viruses were involved etiologically and that many types frequently existed within each group. Table 8–1 lists the agents associated with colds. Each of these agents is covered more fully in other chapters; this chapter presents only an overview. As a group, rhinoviruses are the most common cause of colds in children and adults. Also of major importance in the etiology of colds are reinfections with parainfluenza viruses and respiratory syncytial virus (RSV). Although the quantitative contribution of coronaviruses to colds in children is unknown, they probably are significant contributors. More recent studies also indicate that human metapneumovirus causes colds and lower respiratory infections in children.[38,146,185,186]

Enteroviruses and adenoviruses have been implicated frequently in upper respiratory illnesses, but in most instances, the illnesses do not conform to strictly defined colds. Reoviruses cause colds, but their contribution to the overall incidence is unknown. *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, *Streptococcus pneumoniae*, and *Haemophilus influenzae* infections were identified serologically in one study involving young adults with colds, but in most instances, concomitant viral infections also were noted.[121] The more recently identified human bocavirus also causes coldlike illnesses in some children.[8] Other agents, such as *Coccidioides immitis*, *Histoplasma capsulatum*, *Bordetella pertussis*, *Bordetella parapertussis*, *Bordetella bronchiseptica*, *Chlamydia psittaci*, and *Coxiella burnetii*, also have been associated with illnesses with initial coldlike symptoms.

TABLE 8–1 Infectious Agents Associated with the Common Cold

Category	Agents
Common viruses that usually cause the common cold	Rhinoviruses Parainfluenza viruses Respiratory syncytial virus Coronaviruses Human metapneumovirus
Common infectious agents that occasionally cause illness with common cold symptoms	Adenoviruses Enteroviruses Influenza viruses Reoviruses Human bocavirus
Illnesses with initial symptoms suggestive of the common cold	*Coccidioides immitis* *Histoplasma capsulatum* *Bordetella pertussis*, *Bordetella parapertussis*, *Bordetella bronchiseptica* *Chlamydia psittaci* *Coxiella burnetii*

5-9	3.6	1	3.8	1	8.3
10-16	4.1	2-5	3.7	2-5	8.3
Adult	2.9	6-9	2.7	6-9	6.1
		10-19	1.6	10->11	5.5
		Adult	2.9	Adult	4.8

Data modified from Brimblecombe et al.,[22] Fox et al.,[69] and Badger et al.[10]

EPIDEMIOLOGY

The common cold is an exceedingly frequent illness in childhood. For rhinoviruses alone, more than 100 serologically different viral types can cause this illness. Nonetheless, a general predictability of incidence and seasonal occurrence exists for the common cold. Numerous epidemiologic studies have been conducted on the occurrence of respiratory illnesses, but calculating a precise incidence of the common cold from these studies is difficult because criteria of disease classification have been different. The findings in three carefully performed studies are presented in Table 8–2. Two of these studies were done more than 50 years ago, and the other was done more than 35 years ago. These studies involved a wide range of family life settings, and the average number of colds per year in children varied from three to eight.[10-13,22,69] Adults had on the average approximately one half the number of colds as their children.

In more recent times and in the era of the common use of daycare facilities, studies of the scope and magnitude of those presented in Table 8–2 have not been done. In one study published in the 1980s, the incidence of acute respiratory infections in daycare attendees peaked at 10 per child-year during the second 6 months of life.[46] A study by Wald and associates[181] found that children in home care had 4.7 illnesses per year, whereas the illness rate was 7.1 per year in children in daycare. Of the illnesses, 89 percent in daycare attendees were respiratory infections.

In a study in Arizona, researchers found that 52 percent of 2-year-old children who attended large daycare centers had six to nine colds per year.[15] The conventional spread of colds has its initial focus in the school.[10,13,22] School-age children become infected and introduce secondary infections into the home. Under these conditions, the secondary attack rate was highest in other school-age children and preschool-age children. Generally, the secondary attack rate in adult family members was approximately one half that of the children. The introduction of infection into the family by adults is unusual. In crowded settings, such as a university, infection is common and can be associated with substantial morbidity. In a cohort study of more than 3000 college students, colds and influenza-like illness were common findings and were associated with missed classes, poor performance on class assignments, missed extracurricular activities, and increases in use of medical care.[132]

As noted previously, the present trend toward the use of daycare centers and preschool programs has increased the number of primary infections in younger children and has made them the source from which secondary family infections frequently occur.[130] In a study that involved 606 children who received care at home or in a daycare program during the first 3 years of life, researchers found that children who attended a large daycare facility (six or more unrelated children) had more frequent colds at year 2 and less frequent colds at years 6 through 11 than did the children with home care only.[15]

Close personal contact between children is necessary for the transmission of viruses that cause colds. In the typical pediatric practice office setting, no increased risk for the acquisition of respiratory illnesses by well infants has been shown.[119] Among children, boys tend to have more colds than girls do.[10,22] In the conventional family setting, mothers tend to have at least one more cold a year than their spouses have.[10,22,69,70] The usual incubation period of colds is 1 to 5 days.

In all nonisolated populations, colds occur more frequently during the winter months than during the summer.[50,71,121,179] This seasonal discrepancy in incidence is as apparent in areas of high wintertime mean temperatures as it is in locations with extremely low temperatures. In the tropics, colds are more prevalent during the rainy season. Colds occur throughout the world. In isolated populations in which the number of people is few (e.g., members of Antarctic exploration teams and isolated island communities), colds do not occur unless introduced by a visiting person.[95]

Although colds can be produced regularly in volunteers, the method of transmission of viruses, which results in colds under natural circumstances, is unclear.* In individuals infected with respiratory viruses that cause colds, the greatest concentration of virus is in the nasal secretions. Children tend to have greater concentrations of virus than do adults, and they tend to shed virus for longer periods. Neither secretions related to coughing nor saliva contains appreciable amounts of virus, and both are unlikely sources of contagion. During the process of talking, little virus is disseminated into the air. The greatest amount of virus from an infected individual is contributed to the surrounding environment by sneezing, nose blowing, and the general contamination of external surfaces (including the sufferer's hands) with nasal secretions.

The route of acquisition of virus is by the nose and possibly the conjunctiva. With these facts in mind, one can easily see that a susceptible individual can become infected by the inhalation of virus in droplet nuclei (small particles) resulting from a sneeze, by the direct nasal hit of virus containing large droplets from a sneeze, by nose blowing, or by the inoculation of virus (usually by the fingers of the recipient) from nasal secretions from disseminators that have been transmitted directly or indirectly. In children, most likely the spread either involves close contact with large droplets of nasal secretions containing virus that are applied to the nose from the hands of the future host or occurs by close-range airborne acquisition.

Considerable folklore is related to the catching of a cold. All available evidence to date indicates, however, that cold weather

*See references 23, 26, 41, 44, 45, 49, 79, 81, 85, 93, 101, 106, 124, 150, 168, 179.

per se, chilling, wet feet, and drafts neither cause nor increase the susceptibility of individuals to colds.[52,101] A study of 180 subjects showed that acute cooling of the feet was associated with the onset of common cold symptoms.[107] On day 4, after the cooling of the feet or the control procedure, significantly more subjects in the chilled group thought they were suffering from a cold (14.4%) compared with the control group (5.6%). The subjects who thought they were suffering from a cold had a history of more colds each year compared with subjects who did not develop cold symptoms. In this study, no virologic studies were done, so no evidence exists that the cold symptoms observed were caused by viral infections.

In contrast, in controlled studies in which virologic studies were performed, no increased susceptibility to colds after exposure to chilling conditions was found.[5,52,62] In adults, risk factors for increased susceptibility to colds include stress, smoking, high basal levels of catecholamines, infrequent exercise, low intake of vitamin C, low sleep efficiencies, and lack of diverse social networks.[40,163] Physical stress, as opposed to mental stress, does not seem to be associated with increased susceptibility to colds. In a study of nine healthy men who were competitive cyclists who underwent intensive internal training, the men experienced enhanced performance but had no change in white blood cells, cytokine levels, or the frequency of upper respiratory infections.[56]

PATHOPHYSIOLOGY

The pathophysiology of human infections with viruses that cause colds is presented in the sections of this book covering the individual infectious agents. A general overview is presented here. Few studies on the pathophysiology of respiratory infections have been done in children; the material presented in this section has been derived mainly from studies in adults.* The clinical syndrome of the common cold can occur in association with more than 100 different viral types and in many instances can occur with either a primary infection or a reinfection with a particular viral type.

Although the primary site of virus inoculation in some colds may be on the conjunctival surface, most result from inhalation or self-inoculation of virus onto the nasal mucosa. After acquisition of a virus has occurred, infection of the cells of the local respiratory epithelium develops. This infection varies in the degree of cytopathology on the basis of the viral agent. The infection spreads locally, resulting in an increase in nasal secretions with an increased protein content. Symptoms (nasal stuffiness and throat irritation followed by sneezing) begin on the second or third day and are caused by cellular damage and irritation. Virus shedding is at its maximum in 2 to 7 days, although some shedding may continue for another 2 weeks.

Hilding[94] examined biopsy specimens, scrapings, and smears of nasal secretions and noted that submucosal edema occurred initially, followed by shedding of the ciliated epithelial cells. By the fifth day, the epithelial damage had reached its maximum, with regeneration occurring during the next 10 days. Winther and associates[189] performed similar studies and noted the sloughing of epithelial cells, but they found that the epithelial lining remained continuous with normal cell borders. On the second day of disease, an increase in the number of neutrophils in the epithelium and in the lamina propria occurred. Epithelial mast cells were not involved in the inflammation. The nasal discharge during the second to the seventh day is mucopurulent, owing to its content of desquamated epithelial cells and polymorphonuclear leukocytes.

*See references 9, 36, 53, 109, 133, 136, 148, 155, 168, 178, 179, 188, 193.

In experimental rhinovirus colds in adults, little or no discernible damage to the nasal epithelium has been shown.[80,168,188,190] Arruda and associates[9] noted in adults infected with rhinovirus types 14 and 39 that virus replicates in ciliated and nonciliated cells in the nasopharynx and that only a very small proportion of the cells were infected.

Because damage to the nasal epithelium is not noted in rhinovirus colds, apparently cell death is not the cause of symptoms. Naclerio and colleagues[129] and Proud and associates[147] have found that kinins are generated locally and that their concentrations correlate with the severity of symptoms. The cause-and-effect relationship between kinins and symptoms is questionable, however, because treatment with a bradykinin antagonist failed to lessen symptoms.[176] In addition, steroid therapy was found to reduce the concentration of kinins in nasal wash fluid, but it did not affect clinical symptoms.

More recently, researchers have noted that interleukin-1 (IL-1) may contribute to the pathogenesis of rhinovirus infections.[148] Ongoing molecular and biochemical research has provided information about methods by which rhinoviruses interfere with the host response, induce epithelial expression of IL-6 and IL-8, and mediate infection via activation of kinases and receptor binding activity.[58,111,126,139] Similarly, research into the other viruses of the common cold has helped in the understanding of their similarities and differences, such as the cell-mediated immune response to human metapneumovirus and RSV.[55]

In studies in children with acute upper respiratory infections, IL-1β, IL-8, IL-6, and tumor necrosis factor-α were found to be elevated markedly in nasal lavage fluid.[133] Pacifico and associates[136] found that IL-8 concentrations and white blood cell and neutrophil counts were significantly greater in children with rhinovirus colds than in well children. In an adult volunteer study, Turner and colleagues[178] noted a significant rank correlation between nasal obstruction severity, rhinorrhea severity, and nasal-wash albumin concentrations and the increase in IL-8 concentration from baseline on days 2 to 4 after virus challenge. In a study of 285 children with a parental history of asthma or other respiratory allergy or both, blood specimens were obtained at birth and at 1 year of age.[73] The cytokine responses of mononuclear cells when incubated with phytohemagglutinin, RSV, and a rhinovirus were analyzed. Vigorous IL-13 and interferon-γ responses to phytohemagglutinin and a marked secretion of interferon-γ in response to the viruses were associated with a reduced risk of developing wheezing with viral infections in the first year of life.

Pedersen and colleagues[138] studied nasal mucociliary transport in naturally acquired colds and noted that transport was reduced markedly during the acute illness and that slight impairment remained for approximately 1 month. They point out that because some children have four to six colds during a winter season, these children may have constantly impaired mucociliary transport.

Although viremia has been noted during infections with some of the viruses that cause colds, viremia is not known to occur during the typical common cold. The infection is restricted to the epithelial surfaces of the upper respiratory air passages, including the sinuses and the eustachian tubes. With infection, local interferon is produced and presumably has a major role in controlling the infection.[35] Serum antibody and secretory antibody regularly result from infection. The roles of cell-mediated factors in immunity and disease pathogenesis of colds are unknown.

Levandowski and associates[117] noted in rhinovirus-challenged volunteers that total T cells, and particularly helper T cells, were depressed. The magnitude of this finding correlated with progression of infection and symptoms. In a study in which volunteers received rhinovirus type 39, Skoner and associates[155] found a slight increase in helper ($CD4^+$) and suppressor ($CD8^+$) T cells

during illness. Noting that asthma exacerbations and rhinovirus infections are associated with decreased pH and ammonium levels in exhaled breath condensates, Carraro and colleagues[29] studied whether a direct rhinovirus infection or the host immune response to the infection or both decreased the airway epithelial cell surface pH in vitro. They found that airway epithelial cell pH is affected partly by T-helper type 1 cytokines. This decrease in pH can provide an innate host defense, inhibiting viral replication in the lower airways. By mechanisms not well understood, within already infected cells, low pH is thought to trigger uncoating of rhinoviral RNA from within the endosome, enabling viral replication.[21]

The role of antibody (serum and secretory) in the protection against reinfection and clinical colds is complicated. High levels of secretory and serum antibodies seem to be protective against reinfections.* Clinically abortive colds probably are reinfection colds with early antibody recall. Fleet and colleagues[67] have demonstrated a short-lived heterologous resistance to rhinovirus colds, which probably is not caused by interferon or antibody.

Unexplained constitutional factors also seem to control the clinical manifestations of colds.[152] Although studies have shown genetic disease susceptibility patterns related to tissue types, no studies relating to common respiratory infections have been done.[37] In experimental coronavirus infections in adults, clinical severity correlated with detectable IgE in nasal secretions.[27] This finding suggests that atopy may be related to symptoms in colds caused by coronaviruses. Although clinical symptoms and virologic data suggest that colds are upper respiratory diseases, some studies of pulmonary function also have indicated occult lower respiratory tract involvement.[6,33,142]

CLINICAL PRESENTATION

Because the common cold is caused by more than 100 different viral types, considerable variation in the clinical manifestations occurs. As indicated in the beginning of this chapter, the limits of illness to be considered under the diagnosis of the common cold have been set arbitrarily but rigidly. A disappointing note is that although many comprehensive studies of respiratory viral illnesses of children have been done, little attention has been given to the details of upper respiratory infections.

Illness in children must be considered under two categories—infants and older children. The latter is similar to illness in adults. In studies involving 100 young adults, Jackson and colleagues[99] noted that virtually all patients complained of nasal discharge, nasal obstruction, and sore throat; approximately 80 percent had malaise, postnasal discharge, headache, and cough; slightly fewer than 50 percent reported a feverish feeling and chilliness; and approximately 25 percent noted burning eyes and nasal membranes and muscle aching. In older children, the onset of illness is heralded by dryness and irritation in the nose and a scratchy feeling in the throat.[131] The initial symptoms are followed within a few hours by sneezing and watery nasal discharge; chilly feelings and occasionally muscular aches also are noted. Other complaints include headache, general malaise, anorexia, and low-grade fever.

After a variable period of 1 to 3 days, the illness changes; the nasal secretions become thicker and frequently develop a purulent appearance. Persistent nasal discharge, associated with the trauma of repeated blowing of the nose, leads to excoriation around the nose. Nasal obstruction leads to mouth breathing, which causes drying of the throat, increasing the discomfort in the throat. The usual duration of illness is approximately 7 days, but lingering cough and nasal discharge may persist for 2 weeks or more.[54]

In infants, the manifestations of illness may be more varied. The onset of illness in infants is associated more often with fever (38° C to 39° C [100.4° F to 102.2° F]) than it is in older children. Nasal manifestations in infants are similar to manifestations in older children, but the only other manifestations are irritability and restlessness. Occasionally, coryza is the only symptom. Nasal obstruction may interfere significantly with feeding and sleeping. Vomiting and diarrhea also may occur.

DIFFERENTIAL DIAGNOSIS

Because the clinical entity of the common cold is an arbitrary grouping of signs and symptoms limited to anatomic boundaries and is caused by many different viral types, the approach to the differential diagnosis must consider clinical and etiologic criteria. Many upper respiratory illnesses are caused by numerous infectious agents that should not be confused with colds. A diagnosis of the common cold should not be considered if objective pharyngitis, other enanthema, or evidence of obstructive airway disease is present. Because the common cold is an acute, self-limited disease, the diagnosis should not be considered in a child who has persistent nasal signs or symptoms. Subacute or chronic illness should suggest the possibility of adenoiditis or sinusitis.

The most important differential diagnostic considerations are clinical entities of noninfectious etiology. Allergic rhinitis is a particularly important possibility in a child with "recurrent colds." Careful attention to family history, a search for allergies, the presence or absence of nasal eosinophilia, and the serum IgE value help confirm or exclude this consideration.

Although not reported particularly in pediatric patients, mental stress can lead to vasomotor responses and rhinitis in some susceptible patients. Chemical irritants can cause coldlike symptoms; the clinical response varies greatly among different individuals. Early symptoms of many illnesses, such as pertussis, epiglottitis, measles, and diphtheria, are those of a cold, but in a short time, the more serious nature of the actual illness becomes apparent.

SPECIFIC DIAGNOSIS

The epidemiologic history is the most important aspect of specific diagnosis. In children, if exposure history is requested, a contact usually is uncovered. If strict attention to clinical criteria of the common cold has been adopted, routine laboratory study is unnecessary. Frequently, the physician has an urge to take a throat culture to rule out the possibility of group A streptococcal infection. Usually, one is unnecessary because nasal symptoms are not characteristic of acute streptococcal illness except in infancy, and pharyngitis is not within the limits of the diagnosis of the common cold. The white blood cell count also is of little use.

A specific diagnosis can be made by the isolation of virus from the nasal secretions. It is performed best by using either a nasal-wash technique[84] or a nasopharyngeal swab or aspirate. With laboratory techniques of diagnostic virologic facilities such as those in many university hospitals, parainfluenza viruses, RSV, and most rhinoviruses and influenza viruses are recovered. Direct antigen-detection techniques can be used to identify infections caused by RSV, parainfluenza viruses, adenoviruses, and influenza viruses. Coronaviruses and some rhinoviruses and influenza strains can be recovered only by special laboratory techniques.

TREATMENT

Although literally hundreds of cold remedies are available, few offer any benefit to the pediatric patient, and many may be harmful.* No clinically available antiviral agents have been shown to be effective in the treatment of colds.

In the approach to a child with a cold, the best assumption is that no therapy is indicated in most cases. Specific symptomatic care can be added in the individual case when it is needed. Many children and adults feel miserable when they have a cold, and therapy with an analgesic often is used. Because aspirin is a risk factor for Reye syndrome in children, the use of acetaminophen rather than aspirin is prudent. The dose per single administration of acetaminophen by year of age is the following: younger than 1 year, 60 mg; 1 to 3 years, 60 to 120 mg; 3 to 6 years, 120 mg; 6 to 12 years, 150 to 300 mg; older than 12 years, 325 to 650 mg. Administration may be repeated three to four times daily in young children and every 4 hours in older children. Acetaminophen rarely should be given to infants younger than 6 months of age.

In adult volunteers with rhinovirus infections, acetaminophen was found to be associated with suppression of the serum neutralizing antibody response, and an increase in nasal symptoms was noted compared with subjects who received a placebo.[77] In another adult volunteer study, administration of naproxen resulted in a reduction in headache, malaise, myalgia, and cough compared with placebo.[161]

Relief of nasal obstruction is the most important therapeutic consideration in young children. Locally applied or orally administered, systemically active decongestants are used frequently, but neither their true efficacy nor their adverse effects have been evaluated carefully. Excessive use of sprays and drops with vasoconstrictive drugs can lead to rebound obstruction, which prolongs the illness. The associated drying effect of vasoconstrictive drugs administered orally can be expected to be deleterious to normal mechanisms of clearance. In young infants, sympathomimetic-antihistamine mixtures in oral drop dosage forms particularly are dangerous because respiratory depression may occur.[75] In addition, in a controlled trial, brompheniramine maleate–phenylpropanolamine hydrochloride was found to be no better than a placebo in relieving cold symptoms in children 6 months to 5 years of age.[39] If vasoactive drugs are used, their use should be restricted to times when maximum benefit would occur (i.e., bedtime), and they should be discontinued within 3 days.

The use of isotonic saline drops and gentle aspiration can be very effective in the temporary relief of nasal obstruction in an infant. Also useful is the general humidification of room air because this moisture tends to dilute tenacious nasal mucus so that its elimination is facilitated.

Antibiotics have no place in the routine therapy of common colds.[76,97,105,112,115,118,135,151,159] Occasionally in children, persistent cough is a problem of such magnitude that it disturbs sleep. For cough, codeine and dextromethorphan often are used.[3] No well-controlled studies support either the efficacy or the safety of codeine or dextromethorphan as an antitussive in children, however. Eccles[61] suggested that the apparent efficacy of liquid cough syrups may be due to the sweetness of the products rather than their active ingredients. The proposed mechanism is that a sweet taste may effect cough at the level of the nucleus tractus solitarius by stimulating the production of endogenous opioids.

In the past, antihistamines often have been given to children with colds, but efficacy had not been shown.[184] In more recent years, first-generation antihistamines, but not second-generation products, have been shown to lessen rhinorrhea in adults with colds.[127,128,168,169,176] Doxylamine succinate, clemastine fumarate, chlorpheniramine maleate, and brompheniramine all have been shown to offer benefit in controlled trials. The effect of these antihistamines is due to their anticholinergenic properties. To date, no studies in children have been reported.

A major controversy relates to the efficacy of vitamin C in the common cold prophylactically and therapeutically. In two carefully controlled volunteer studies, the administration of 3 g of ascorbic acid per day did not prevent or alter the symptoms of experimental colds.[153,183] In addition, several large controlled trials in which vitamin C and placebo preparations have been used to prevent and to treat colds have been conducted.[4,28,42,43,63,108,143] In some of these studies, some benefit was reported, whereas in others, no efficacy was noted. Most probably, the reported benefits are a result of statistical artifacts and placebo effect owing to poor study design, rather than specific pharmacologic drug effects. The antihistaminic action of vitamin C[180,194] probably afforded relief to some patients with allergic rhinitis, who thought that their illnesses were colds. Because of the many toxic effects of ascorbic acid,[16] and because its use in treating respiratory illnesses is questionable at best, giving children vitamin C in excess of normal daily requirements seems unwarranted.

For many years, efforts have been made to develop effective rhinovirus chemotherapy, but showing convincing efficacy in natural infection has been a challenge.[137] Interferon alfa-2b administered intranasally has been shown to have some efficacy in the prevention of rhinovirus colds in controlled clinical trials.[160] The effect is variable, however, and adverse effects of the medication are frequent occurrences.[164] Intranasal interferon alfa-2b was ineffective in the treatment of naturally occurring colds but showed some benefit in experimental coronavirus colds.[89,173] Studies in adults using an antiviral anti-inflammatory combination for the treatment of the common cold showed some benefit compared with either agent used alone.[83] However, the irritation caused by intranasal interferon alfa-2b and the drowsiness associated with first-generation antihistamines render these drug combinations suboptimal.

Zinc lozenges have been used to treat the common cold, and the internet and lay literature are full of claims of efficacy. In well-done controlled studies, efficacy has not been shown, however.[59,60,65,104,120,144,172,181] The use of intranasal zinc preparations also is not well validated and raises some concern because of the possible development of the zinc-induced anosmia syndrome.[2,19] In a double-blind, placebo-controlled trial, the use of intranasal corticosteroid (fluticasone propionate) offered no clinical benefit in young adults with colds and induced prolonged shedding of rhinovirus.[149]

In a controlled trial in adults, a soluble intercellular adhesion molecule-1 product (tremacamra) reduced the severity of rhinovirus colds.[177] The antiviral pleconaril induced an early reduction in severity of symptoms in adults with colds caused by rhinovirus.[90] Pleconaril is an antipicornavirus drug that interacts directly with viral capsid proteins. It blocks attachment of virus to cells through intercellular adhesion molecule-1 and subsequent uncoating and release of viral RNA.

In another randomized, double-blind, placebo-controlled trial, the symptomatic efficacy of pleconaril was linked to its in vivo antiviral effects and to the drug susceptibility of the infecting virus.[140] In March 2002, the Antiviral Drugs Advisory Committee of the U.S. Food and Drug Administration voted against recommending pleconaril for approval of its use in the treatment of the common cold in adults. This decision was based on drug interactions, poor risk-to-benefit ratio, and concerns of development of resistant virus.[137]

Clarithromycin, a macrolide antibiotic, enhances mucosal immunity in mice by increasing levels of IL-12, IgA, and IgG.[110]

*See references 2, 7, 14, 18-20, 24, 30, 31, 47, 57, 59, 60, 72, 74, 75, 83, 92, 96, 98, 113, 122, 123, 134, 137, 141, 145, 157, 162, 165, 170, 181, 192.

In a controlled trial, clarithromycin had no effect on the severity of cold symptoms, however. The intranasal administration of nedocromil sodium has been observed to have a beneficial effect on rhinoviral infections in adult volunteers.[17] Mucolytics have emerged as potential therapeutics for modulating the function of airway epithelial cells and altering the course of viral infections.[8,192] Leukoprotease inhibitors and pulmonary surfactant have been shown to be up-regulated by ambroxol—a mucolytic and antioxidant agent.[7,134]

In one study, adults who took sauna baths once or twice a week were found to have fewer colds than did members of a non–sauna-bathing control group.[64] In another study, volunteers with colds did not benefit from inhaling heated vapor.[68]

The list of available and proposed complementary and alternative medicines thought to be useful for the common cold is long.[20,24,57,191] Blinding subjects in placebo-controlled trials can be difficult, and the placebo effect seems to play a significant role in the popularity of all complementary and alternative medicines.[18,20,31,47,92,170] Fluid extracts of *Echinacea* spp. are popular for the prevention and the treatment of colds.[78,168,175] Because several species of *Echinacea* have been used in prevention and treatment studies, criticism of the negative results in some studies has been expressed by *Echinacea* advocates.[20,30,74,113,154,162,165,170]

In a controlled trial, Taylor and associates[166] evaluated *Echinacea* for the treatment of upper respiratory tract infections in children aged 2 to 11 years old. No benefit was noted, and the *Echinacea*-treated children had an increased occurrence of rash. Preparations of North American ginseng have been reported to decrease the frequency of colds in adults.[14,123,145] No controlled studies have been done in children.

PROGNOSIS

The prognosis of common colds in children is excellent. Secondary complications do occur, however, and frequently they require careful and prolonged therapy. The most common complications are otitis media, sinusitis, bacterial adenoiditis, bacterial pharyngitis, and lower respiratory bacterial infections. The primary viral pathogens identified in hospitalized children with lower respiratory tract infections include RSV, influenza A and B viruses, human matapneumovirus, parainfluenza viruses, adenoviruses, rhinoviruses, and enteroviruses.[112] Infections with multiple agents also occur.

PREVENTION

Studies in isolated populations have shown that when a particular respiratory viral infection has run through the entire group, no further respiratory viral illnesses can occur until a new infected individual enters the population. This type of evidence indicates that quarantine or isolation-type practices could prevent colds. The average urban society of today is so complex, however, that prevention through isolation procedures is impractical. Efforts to control the spread of respiratory virus should be minimal and practical. For children with undue susceptibility to complications, contact with crowds or with infected children and adults should be avoided.

The use of virucidal nasal tissues has been shown to reduce markedly the spread of rhinovirus colds in human volunteers and to reduce modestly colds in the family setting, but as yet no commercial products are available.[48,66] Heikkinen and associates[91] found that the intranasal administration of an immunoglobin preparation by nasal sprays twice a day significantly reduced the occurrence of rhinitis in children attending daycare centers. If confirmed, this form of prophylaxis might be useful for selected children. A study showed that organic acids commonly used in over-the-counter skin care and cosmetic products had substantial virucidal activity against rhinoviruses. The amount of acid applied to the hands correlated directly with the prevention of infection in the deliberate infection model.[171,174]

CHAPTER 9

Infections of the Oral Cavity

Constantine Simos ✪ Thomas R. Flynn ✪ Joseph F. Piecuch ✪ Richard G. Topazian

Although most infections of the oral cavity in children are odontogenic and may be treated simply with local measures, the occasional spread of these infections to adjacent or distant fascial spaces or to the maxilla and mandible may result in life-threatening complications. Consequently, careful attention, including liberal use of the dental consultation, should be given to such infections.[16,53]

MICROBIOLOGIC CONSIDERATIONS IN DENTAL INFECTIONS

NORMAL FLORA

That the oral cavity provides an environment favorable to the growth of microorganisms is substantiated by reports of bacterial counts of 10^8 to 10^{11} organisms/mL of saliva.[3,6] More than 30 species of bacteria normally can be identified in saliva in varying proportions, depending on a dynamic interaction of different microbial ecosystems, including the tongue, the gingival crevice, and the presence of plaque.[50,57] Age, anatomic relationships, eruption of teeth, presence of decayed teeth, diet, oral hygiene, antibiotic therapy, systemic disease, cancer chemotherapy,[51] and hospitalization can modify the microbial population. In the older literature, emphasis was placed on the role of *Streptococcus* and *Staphylococcus* spp. in producing odontogenic infections, to the exclusion of most anaerobic bacteria. This emphasis probably was the result of failure to culture satisfactorily for anaerobic organisms, and it is now well known that the ratio of anaerobic to aerobic organisms ranges from 3 : 1 to 10 : 1.[3,7]

The nomenclature of the oral flora is changing rapidly owing to the improved understanding of the genetic make-up of these bacteria provided by molecular biology techniques. Table 9–1 summarizes changes in nomenclature among selected members

TABLE 9–1 Terminology Changes for Selected Oral Pathogens

Older Terminology	Current Terminology
Streptococcus viridans	*Streptococcus anginosus*
	Streptococcus intermedius
	Streptococcus constellatus
	Streptococcus mutans
	Streptococcus sanguis
	Streptococcus mitis
	Streptococcus salivarius
	Streptococcus vestibularis
Streptococcus milleri	*Streptococcus anginosus*
	Streptococcus intermedius
	Streptococcus constellatus
Bacteroides melaninogenicus	*Prevotella melaninogenica*
	Prevotella intermedia
	Prevotella oralis
	Prevotella buccae
	Prevotella denticola
	Prevotella nigrescens
	Porphyromonas asaccharolytica
	Porphyromonas gingivalis
	Porphyromonas endodontalis
	Porphyromonas salivosa
	Porphyromonas circumdentaria
Streptococcus faecalis	*Enterococcus faecalis*
Streptococcus faecium	*Enterococcus faecium*
Peptococcus species	*Peptostreptococcus* species (main oral pathogen is *P. micros*)

TABLE 9–2 Most Frequent Pathogens Isolated from Orofacial Infections in Two Studies

	Percentage of Cases	
Microorganism	***Lewis et al.****	***Sakamoto et al.**†*
Streptococcus milleri	50	65
Peptostreptococcus species	64	65
Other anaerobic streptococci	8	9
Bacteroides (Prevotella) oralis	40	74
Bacteroides (Prevotella) gingivalis	28	‡
Bacteroides (Porphyromonas) melaninogenicus	24	17
Fusobacterium species	14	52

**Data from Lewis, M. A. O., MacFarlane, T. W., and McGowan, D. A.: Quantitative bacteriology of acute dentoalveolar abscesses. J. Med. Microbiol. 21:101-104, 1986.*
†Data from Sakamoto, H., Kato, H., Sato, T., and Sasaki, J.: Semiquantitative bacteriology of closed odontogenic abscesses. Bull. Tokyo Dent. Coll. 39:103-107, 1998.
‡This organism was not reported in this study.

of the oral flora.[8,61,62] Molecular methods based on the polymerase chain reaction allow direct identification of bacterial species to be made from the oral flora and odontogenic infections by isolation of their DNA or RNA or both. These methods have led to appreciation of the true oral flora, for which 60 percent of species are unculturable. In recent years, many new species and phylotypes have been identified in the normal and pathologic oral flora.

The flora of children is similar to that of adults, with several exceptions. At birth, the oral cavity is sterile, but colonization with *Streptococcus salivarius* occurs rapidly. This organism has been found in 80 percent of cultures taken from 1-day-old infants.[63] The percentage of *Streptococcus* spp. decreases from 98 percent at day 1 to 70 percent at 4 months[48] as other organisms become established. *Staphylococcus* spp., *Neisseria*, *Veillonella*, *Actinomyces*, *Nocardia*, *Fusobacterium*, *Bacteroides*, *Corynebacterium*, *Candida*, and a variety of coliforms gradually become established by the time the child reaches 1 year of age. As the deciduous dentition erupts, anaerobic organisms become well established in the gingival crevice, yet the spirochetes, *Bacteroides* and *Prevotella* spp., and related oral anaerobes, which commonly are associated with the gingival crevice in adults, seem to be present in fewer numbers in patients younger than 13 to 16 years.[6,63] Eruption of deciduous teeth also is associated with the establishment of *Streptococcus mutans* and *Streptococcus sanguis*, which adhere to the enamel surface.

PATHOGENIC ORGANISMS

Not all residents of the oral flora are pathogens. In the odontogenic infections caries and periodontal disease, a progression from initiating infections caused by oral streptococci toward a predominance of oral anaerobes in the more severe and long-standing infections apparently occurs. Caries is initiated primarily by *S. mutans*, a member of the alpha-hemolytic *Streptococcus* viridans group. As tooth decay progresses toward the dental pulp, *Lactobacillus* and *Actinomyces* spp. join the carious milieu. Severe pulpal infections generally are caused by a combination of these same oral facultative streptococci plus obligate anaerobes, such as *Porphyromonas endodontalis*, formerly classified as *Bacteroides melaninogenicus*.[66]

Periodontal infections also are polymicrobial; gram-positive aerobes, primarily streptococci, predominate in gingivitis, and the gram-negative anaerobic rods predominate in bone-destroying periodontitis. Juvenile periodontitis (formerly called *periodontosis*), a particularly aggressive periodontal infection in children and adolescents, shows a predominance of *Actinobacillus actinomycetemcomitans* in its cultivable flora.

Orofacial odontogenic infections that spread beyond the teeth and alveolar processes are polymicrobial, yielding on average four to six isolates per case.[5,34,46] With the use of molecular methods, even greater numbers of species can be identified in these infections, ranging from 5 to 18 species per case.[14] Severe orofacial infections have been associated statistically with *Fusobacterium nucleatum*.[24] The concept of the progression from aerobic streptococci to anaerobic gram-negative rods in orofacial infections is supported further by studies that have found a predominance of streptococci in early infections (in the first 3 days of symptoms) and a predominance of anaerobes in late infections.[34] Table 9–2 lists the frequency with which the major pathogens in orofacial infections were isolated in two studies.[26,36,59]

Infections originating from nonodontogenic causes (facial trauma, surgical manipulation, tonsillitis) are included in most studies of soft tissue and fascial space infections, and contamination from the skin or oropharynx might allow aerobic organisms, such as *Staphylococcus aureus* and aerobic *Streptococcus* spp., to become established.[6] In contrast, infections originating solely from the dental periapical tissues are much more likely to be predominantly anaerobic.

A pitfall in the identification of organisms as described in the older literature was the failure to culture satisfactorily for anaerobic organisms. The more current literature recognizes this fact.[37,49] The preponderance of anaerobic organisms in odontogenic infections mandates the use of anaerobic and aerobic culturing techniques in situations in which cultures are indicated.

ANATOMIC CONSIDERATIONS

Most severe orofacial infections develop consequent to dental infection—periapical, periodontal, or pericoronal. Spread occurs along anatomic pathways of least resistance.[3,7,27,35,65] Periodontal and pericoronal infections rarely have major sequelae because

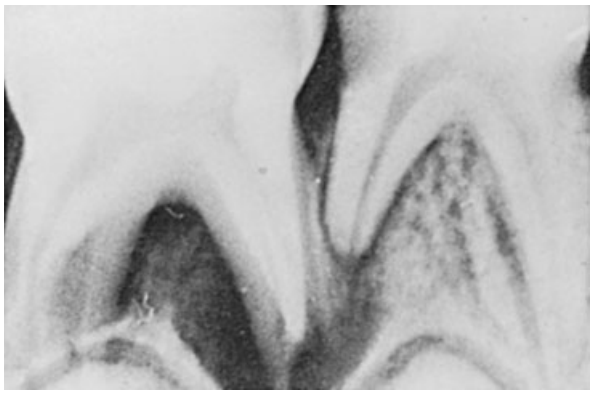

Figure 9–1 Radiolucency representing a chronic periapical abscess involving the mesial root of the deciduous second molar and the distal root of the deciduous first molar. The developing mandibular bicuspids are seen inferior to the deciduous roots. The cause of the abscess is the deep carious lesions in both teeth, which appear to have penetrated the pulp chambers.

they generally drain from the gingival sulcus along the surface of the tooth into the oral cavity. Infections associated with the root apices generally are confined within the bony alveolar process (Fig. 9–1). Should spontaneous intraoral drainage occur through either the periodontium or the pulp chamber, further spread through the marrow spaces is unlikely to occur. If such drainage does not occur, spread through bone (osteomyelitis) or perforation of the cortical plate of the affected jaw may occur. Infections associated with root apices close to the buccal cortical plate generally spread buccally, whereas infections close to the lingual or palatal cortical plate or to the maxillary sinus spread in those directions (Fig. 9–2). When penetration of the cortical plate occurs, infection involves the adjacent soft tissues and may manifest as cellulitis or a soft tissue abscess, which eventually may perforate mucous membrane or skin as a sinus tract (Fig. 9–3).

Perforation of periapical infections through bone follows a typical pattern that results from the position of the root apices in relation to the bony cortex and to muscle attachments (Fig. 9–4). Infections involving maxillary anterior teeth and buccal roots of maxillary posterior teeth generally perforate labially or buccally, whereas infections involving palatal roots of posterior teeth perforate palatally or rarely into the maxillary sinus. The presence of the buccinator muscle attachment superior to the root apices usually confines these infections and fistulas to the oral cavity. In children, maxillary root apices often are superior to the buccinator, however, and infections may spread to the buccal or infraorbital space or to the periorbital tissues. They eventually may drain through the skin.

Infections of the mandibular incisor or canine tooth may spread either labially or lingually because the alveolar process is thin in this area. Labial perforation, which occurs more commonly, may be confined intraorally if the root apices are superior to the origin of the mentalis muscle but may spread extraorally if the apices are inferior to the mentalis attachment (Fig. 9–5). Infections of the mandibular premolar and first molar often perforate buccally, whereas the second and third molars perforate lingually.

When spread of mandibular infections occurs medially, the relationship of the tooth apices to the mylohyoid muscle origin is significant (Fig. 9–6). From the first molar forward, the dental root apices are superior to the mylohyoid, and these infections localize intraorally in the floor of the mouth (sublingual space). The apices of the second and third molars generally are inferior to the mylohyoid, and so the submandibular space is involved, with an extraoral presentation. As in maxillary infections, the relationship of the buccinator muscle to the root apices determines whether the infection spreads intraorally or extraorally.

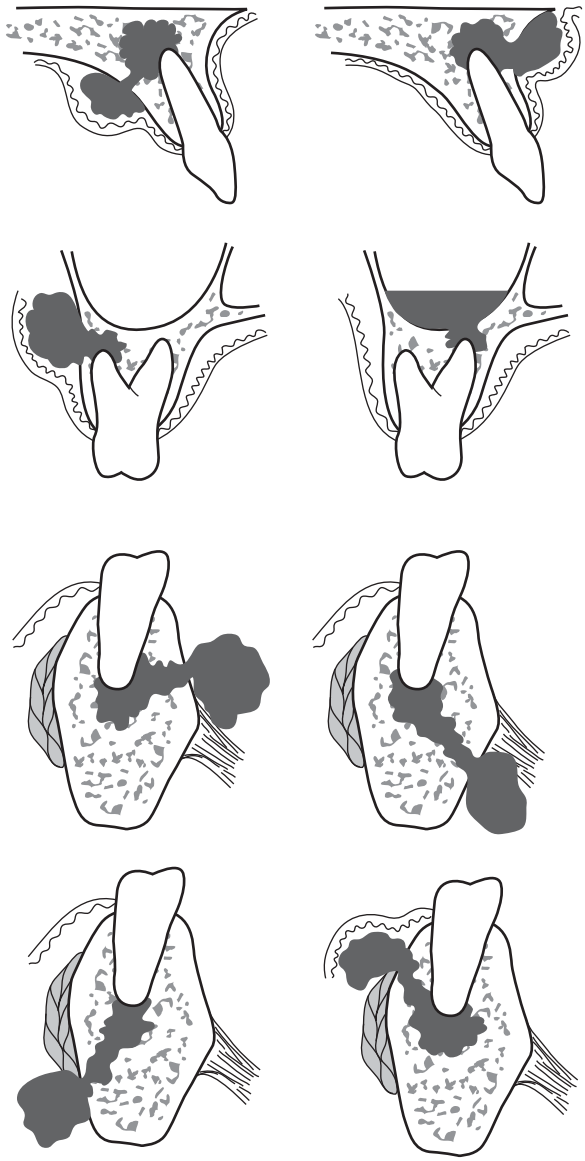

Figure 9–2 Possible pathways of spread of periapical infection. *(From Shafer, W. G., Hine, M. K., and Levy, B. M.: Textbook of Oral Pathology. 2nd ed. Philadelphia, W. B. Saunders, 1963.)*

Two fascial spaces commonly associated with odontogenic infections are the submandibular and masticator spaces.[19,20,35] The submandibular space is formed within the superficial layer of deep cervical fascia inferior to the mylohyoid muscle and inferomedial to the mandible. Anteriorly and posteriorly, it is limited by the bellies of the digastric muscle. Within this space lies the submandibular gland and portions of the facial artery and anterior facial vein. This space is closely approximated to the sublingual and masticator spaces. Infections of the submandibular space may originate in these adjacent spaces and in mandibular posterior teeth.

The masticator space also is formed within the superficial layer of deep cervical fascia. Its name is appropriate because its contents include the masseter, internal and external pterygoid, and temporalis muscles, as well as the mandibular ramus and the inferior alveolar neurovascular bundle. The submandibular, lateral pharyngeal, and retropharyngeal spaces are adjacent.

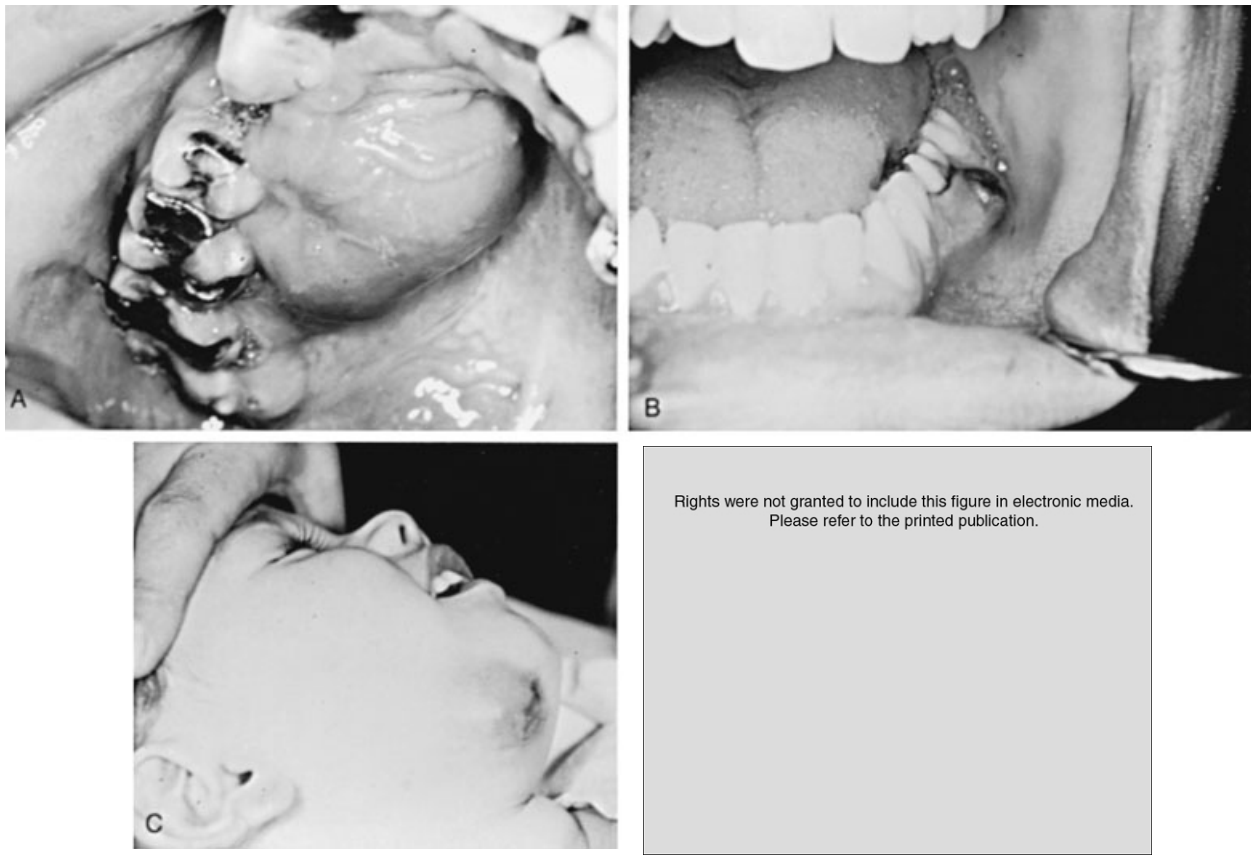

Figure 9–3 Spread of odontogenic infection. **A,** Palatal abscess resulting from infected first premolar. **B,** Intraoral mucosal fistula from periapical abscess of mandibular left first molar. **C,** Soft tissue infection secondary to periapical abscess. **D,** Draining cutaneous sinus tract from a chronically infected lower molar in an adolescent girl. *(**A** from Piecuch, J.: Odontogenic infections. Figure 9–5 Submental space abscess.

Figure 9–6 Relation of tooth apices to the origin of mylohyoid muscle. *(From Waite, D.: Textbook of Practical Oral Surgery. Philadelphia, Lea & Febiger, 1978.)*

Infections of the masticator space may originate in adjacent spaces or spread to it from periapical or pericoronal infections of the mandibular second and third molars and maxillary third molar.

TREATMENT OF ODONTOGENIC INFECTIONS

Patients with odontogenic infections may present with symptoms ranging from minor to life-threatening. Too often, a patient may be given a thorough systemic and extraoral head and neck evaluation while the intraoral search for the etiologic agent is overlooked.

A thorough oral examination begins with an evaluation of the degree of mandibular opening. Interincisal distance on wide opening extends 40 mm or more, even in young children. Painful limitation of the oral opening, or trismus, is associated with inflammation of the muscles of mastication and indicates spread of the infection to the masticator space. In association with a high fever, it can represent a serious turn of events. Teeth are inspected visually for caries by percussion for tenderness and by electric sensitivity or hot and cold stimulation for the pulpal pain response. Gingival tissues are probed for periodontal defects, and salivary glands are palpated for tenderness and milked to observe for purulent discharge from the duct orifices.

GENERAL THERAPEUTIC PRINCIPLES

As with infections elsewhere in the body, the principles of treatment of oral infections involve surgical drainage and antibiotics. Surgical drainage may comprise standard incision and drainage of an orofacial swelling or, in the case of localized periapical infection, endodontic drainage through the pulp or extraction of the offending tooth.

Surgical treatment of odontogenic infections is primary. Dodson and colleagues,[10] in a review of head and neck infections requiring hospitalization of children, found that facial infections of the regions at or above the level of the upper lip and teeth most frequently were upper respiratory or sinus related and that lower face infections primarily were odontogenic. Infections of the upper face resolved without surgery in 65 percent of cases, whereas infections of the lower face resolved without surgery in only 25 percent of cases. Odontogenic infections almost always required some sort of surgical intervention. This finding may be due to the fact that the portal of entry in respiratory infections is through the surface mucosa, whereas the tooth roots carry the invading bacterial pathogens deep into the bone of the jaw, through which the surrounding deep fascial spaces become infected.

Respiratory pathogens frequently are viral, and odontogenic infections almost uniformly are bacterial, which may explain the propensity of odontogenic infections to form abscesses that need to be drained. Odontogenic infections treated with antibiotics only almost always recur in worse form than did their previous manifestation. The indications for treating with antibiotics in addition to appropriate dental surgical therapy are fever, trismus, lymphadenopathy, osteomyelitis, and compromise of the immune system. Minor infections localized to the alveolar processes can be treated by tooth extraction, gingival curettage, or root canal therapy, with or without intraoral incision and drainage, without the use of antibiotics in the non-immunocompromised individual.

Antibiotic selection for odontogenic infections, although ultimately based on Gram stain and aerobic and anaerobic cultures, generally is begun empirically before culture results are available. Penicillin G or penicillin V is the logical first choice for outpatient infections on the basis of lack of toxicity, bactericidal nature, and sensitivity of most streptococci and oral anaerobes to penicillin. Antibiotic sensitivity studies indicate that the oral anaerobes now are largely resistant to erythromycin and most cephalosporins.[52] A study of severe (hospitalized) odontogenic infections found penicillin-resistant organisms in 54 percent of cases and therapeutic failure of empiric penicillin in 21 percent of cases.[13] The duration of previous therapy with β-lactam antibiotics also has been correlated with increased numbers of β-lactamase–producing bacteria in persisting infections. Patients with persisting infection after 3 days of treatment with a β-lactam antibiotic had a 50 percent incidence of β-lactamase–producing bacteria in the infection.[23,31] Clindamycin remains highly effective against the likely oral pathogens, including streptococci and the oral anaerobes; its association with *Clostridium difficile* colitis and its effectiveness in severe orofacial infections indicate that it should be reserved, in this era of increasing microbial resistance to antibiotics, for the most severe cases.

TABLE 9–3 Empiric Antibiotics of Choice for Odontogenic Infections*

Type of Infection	Antibiotic of Choice
Outpatient infections	Penicillin
	Clindamycin
	Azithromycin
Penicillin allergy	Clindamycin
	Azithromycin
Inpatient infections	Clindamycin
	Ampicillin + metronidazole
	Ampicillin + sulbactam
Penicillin allergy	Clindamycin
	Third-generation cephalosporin IV (if the penicillin allergy was not the anaphylactoid type—use caution)

**Empiric antibiotic therapy is used before culture and sensitivity reports are available. Cultures should be taken in severe infections that threaten vital structures.*

The aforementioned considerations suggest that the empiric antibiotics of choice are penicillin in mild odontogenic infections and clindamycin for severe cases or in a patient with penicillin allergy. Table 9–3 lists our recommendations for empiric antibiotic therapy in odontogenic infections.

Second-line antibiotics in odontogenic infections are the cephalosporins, to which effectiveness against the oral anaerobes has been waning, and metronidazole, which is effective against obligate anaerobes only. The safety and effectiveness of metronidazole in children have been established only for treatment of amebiasis.

Other considerations that may be important in the selection of antibiotics for individual cases are as follows: (1) *Eikenella corrodens*, an occasional pathogen in odontogenic infections, is uniformly resistant to clindamycin, which may explain the lack of effectiveness of clindamycin in some cases. (2) Some cephalosporins do not cross the blood-brain barrier in high concentrations, which may be a factor in selection of an antibiotic for an odontogenic infection that is approaching the cranial cavity. Ceftazidime and ceftriaxone cross the blood-brain barrier well. Penicillin is able to cross the blood-brain barrier when the meninges are inflamed. Metronidazole crosses the blood-brain barrier, and its use may be justified in severe odontogenic infections approaching the brain in children. (3) Tetracycline is incorporated permanently into newly formed dentin, causing permanent disfiguring discoloration of the dentition. It should not be used in children until they are at least 9 years old, when all but the third molar teeth would have full crown formation. (4) β-Lactamase inhibitors used in combination with β-lactam antibiotics may improve their effectiveness against resistant anaerobes. A clear clinical advantage of amoxicillin-clavulanate over amoxicillin alone has not been established in adult studies of odontogenic infections, however.[36] (5) Staphylococci are uncommon pathogens in odontogenic infections, and coverage for staphylococci is not indicated in empiric therapy for these infections, although their role in upper respiratory and sinus infections is well known.

NURSING BOTTLE CARIES

Nursing bottle caries is a pattern of tooth decay affecting mainly the primary upper incisors and frequently the upper and lower primary molars in children of bottle-feeding age. It is caused by a practice of putting the child to bed with a nursing bottle filled with a sugar-containing drink, such as milk, fruit juice, or a soft drink. The child sucks on the bottle intermittently during sleep, when salivary secretion is low, and the sugar-containing liquid stays in the mouth for extended periods. This situation provides an excellent environment for the growth of caries-producing organisms, such as *S. mutans*. Nursing-bottle caries can destroy virtually the entire primary dentition of a child as it erupts. Pediatric physicians and dentists should instruct parents to avoid putting their children to bed with nursing bottles or, if they must do so, to use water only in the bedtime drink.

PERIAPICAL ABSCESS

Extension of microorganisms through the root apex leads to the formation of an abscess. Early in this process, the acute abscess is indistinguishable clinically and radiographically from an acute pulpitis, particularly because radiographic evidence of bone destruction may take 7 to 14 days or more to develop. Sensitivity to heat stimulus (relieved by cold), exquisite sensitivity to percussion, and tenderness to finger pressure on the alveolar process are indications that the tooth has become abscessed. Electric pulp testing may be diagnostic if the tooth shows no response to the electric stimulus, but a positive pain response may be equivocal in multirooted teeth. Chronic abscesses are diagnosed more easily by looseness of the tooth, suppuration from draining sinuses or from the gingival crevice (see Fig. 9–3), and radiolucency on the radiographs (see Fig. 9–1). Depending on the path of least resistance, fluctuant areas may be noted in the buccal or lingual mucosa. Spread through the tissues, or cellulitis, may lead to the classic presentation of swollen face, pain, elevated temperature, and malaise.

In 1951, Krogh[31] showed a 3 percent complication rate when 2626 infected teeth were removed at the time of initial presentation. In 1975, Martis and Karakasis[45] published a similar study in which they treated 1376 acute dentoalveolar abscesses by immediate extraction. A 3 percent complication rate was found in this study as well. A complication was defined as further extension of the infection, requiring additional treatment. Hall and associates[22] published a report in 1968 in which 350 patients with odontogenic cellulitis were divided randomly into two groups. The first group had extractions performed on the day of initial presentation, whereas the second group waited (with antibiotics) until the fourth day for surgical treatment to be performed after "localization" had occurred. The investigators' observations showed that extraction did not spread the cellulitis in either group. Patients with earlier extractions recovered more rapidly, whereas patients with delayed treatment had a greater need for incision and drainage, which was twice as likely to be extraoral than intraoral. In 1978, Martis and colleagues[44] showed in a series of more than 2000 patients that extraction without antibiotics in the presence of periapical infection led to the same complication rate as did extraction of noninfected teeth.

Considering the prospect of early relief of symptoms and a 97 percent chance that extraction (or occasionally root canal treatment) will cure the infection, early surgical intervention is mandatory. The use of antibiotics must be determined on an individual basis according to principles outlined previously (Table 9–4).

PERIODONTAL INFECTIONS

Surrounding the teeth is a distinctive, pink keratinized mucosa, the gingiva (Fig. 9–7A). Normal gingiva is attached firmly to the alveolar bone and extends between the teeth as the interdental papilla. A thin cuff of free (nonattached) gingiva surrounds each tooth, and the resulting crevice between the free gingiva and the tooth normally is 1 to 3 mm in depth. It is represented by a thin roll of tissue along each tooth in Figure 9–7A.

Accumulation of food deposits and bacteria in the gingival crevice may result in gingivitis, a localized inflammation of the

free gingiva that manifests as an erythematous, nonpainful swelling of the interdental papillae. In severe cases (see Fig. 9–7B), the gingival architecture may become distorted, and accumulations of plaque are evident. Although gingivitis is prevalent at all ages, affecting more than 50 percent of children[47] and almost all adults to some degree, it often is most severe in compromised hosts, including patients with diabetes and immunosuppressed patients. Poor oral hygiene is the usual precipitating factor for development of gingivitis, and this condition generally responds to dental scaling and improved oral hygiene.

In adolescents and in adults, gingivitis may progress to periodontitis, a progressively severe infection that is characterized by hypertrophied gingivae, tooth mobility caused by irreversible resorption of alveolar bone, and a purulent exudate. This insidious condition usually is painless and may progress for years before being recognized. Localized periodontal treatment and meticulous oral hygiene may arrest the condition.

A rare variant, juvenile periodontitis,[34] usually is localized to the molar and incisor regions of younger, otherwise healthy children. Deep gingival pocketing and severe bone resorption are characteristic of this process and may result in loss of the dentition in these areas. The etiology is thought to involve a gram-negative anaerobe, *A. actinomycetemcomitans*, and localized bacterial inhibition of leukocyte function. Tetracycline in older patients has been useful in combination with periodontal surgery and meticulous home care.

Acute necrotizing ulcerative gingivitis (see Fig. 9–7C) is a specific infection caused by fusiform bacilli and spirochetes. Synonyms include trench mouth and Vincent infection. Erythema at the tips of the interdental papillae soon is supplanted by frank ulceration and foci of spontaneous bleeding. A pseudomembranous necrotic exudate forms along the marginal gingivae and the interdental papillae. The papillae later become blunted. Acute necrotizing ulcerative gingivitis is characterized by pain, foul breath and taste, thick ropy saliva, malaise, and occasionally fever. Theories suggest a concomitant viral etiology. Treatment consists initially of penicillin therapy followed within a few days by localized gingival curettage and oral rinses with 0.5 percent hydrogen peroxide or 0.12 percent chlorhexidine.[40] The safety and effectiveness of chlorhexidine in children have not been established.

TABLE 9–4 Indications for Antibiotic Therapy in Odontogenic Infections

Antibiotic therapy is necessary
Acute-onset facial or oral swelling
Swelling inferior to the mandible
Trismus
Dysphagia
Lymphadenopathy
Fever >38.3°C (>101°F)
Pericoronitis
Osteomyelitis
Antibiotic therapy is *not* necessary*
Asymptomatic periapical abscess
Parulis (draining sinus tract)
Dry socket (alveolar osteitis)
Periodontal disease
Dental extractions
Root canal therapy

**With coexisting immune system compromise, antibiotic therapy may be indicated in some of these conditions.*

PERICORONITIS

Impaction of microorganisms and debris under the soft tissue overlying the crown of a tooth, often a mandibular third molar, or any erupting permanent tooth leads to the development of inflammation. Drainage usually occurs spontaneously from under the flap, localizing the problem. Blockage of natural drainage may lead to spread of infection to adjacent soft tissues and fascial spaces (Fig. 9–8).

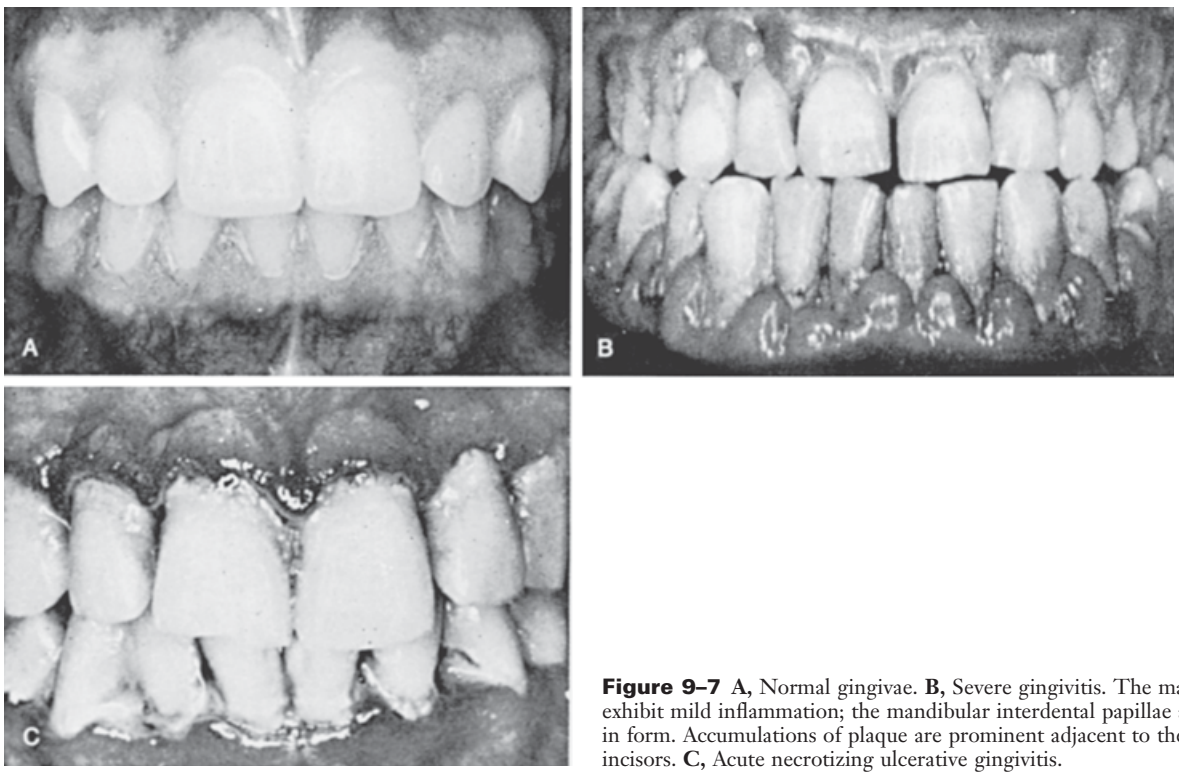

Figure 9–7 **A,** Normal gingivae. **B,** Severe gingivitis. The maxillary gingivae exhibit mild inflammation; the mandibular interdental papillae are distorted grossly in form. Accumulations of plaque are prominent adjacent to the mandibular incisors. **C,** Acute necrotizing ulcerative gingivitis.

Figure 9–8 Pericoronitis.

Pericoronitis is a polymicrobial infection; the periodontal pathogens *Prevotella* and *Porphyromonas* spp. and oral spirochetes, such as *Treponema denticola*, usually are the causative organisms. The *Streptococcus milleri* group bacteria also have been found to have a significant role in acute pericoronitis.[26] These organisms usually are sensitive to penicillin or penicillin combined with metronidazole. Pericoronitis most frequently occurs around the posterior portion of the crown of the lower third molar because it erupts during adolescence. In most cases, partial eruption of the third molar is caused by insufficient length of the horizontal ramus of the mandible to house all of the teeth. Part of the third molar is trapped under the oral mucosa covering the buccinator muscle and the superior pharyngeal constrictor because they form the most anterior portion of the oropharynx. In cases in which room is insufficient for the eruption of the third molar, the pericoronitis becomes recurrent or chronic, and the impacted third molar should be removed.

Lower third molars lie in proximity to the pterygomandibular space, a portion of the masticator space. When these infections spread to involve this space, trismus results, which obscures the infection to clinical examination. The presence of trismus with a history of pain in the third molar region is an ominous sign of infection involving the masticator space, which, although not manifested by external facial swelling, may begin to involve the deeper parapharyngeal spaces. These infections may become life-threatening. The lower third molar is the most frequent offending tooth in severe odontogenic infections requiring hospitalization, and these infections occur most frequently in adolescents and young adults.[24]

Various treatment modalities, including local incision and drainage and extraction of the tooth, are applicable to pericoronitis.[44,58] Antibiotic therapy is used if fever, trismus, or lymphadenopathy is present (see Table 9–4). Resolution of symptoms should occur in less than 1 week.

ORAL MANIFESTATIONS OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION IN CHILDREN

The most common oral lesions found in children with human immunodeficiency virus (HIV) disease are oral candidiasis, herpes simplex virus infections, linear gingival erythema, parotid salivary gland enlargement, and recurrent aphthous ulcerations. In contradistinction to adult HIV infection, HIV-associated periodontitis and gingivitis are much less common. Neoplastic oral manifestations of HIV infection, such as Kaposi sarcoma, non-Hodgkin lymphoma, and hairy leukoplakia, continue to be rare findings. In contrast to adults, children infected with HIV have a greater susceptibility to bacterial infections, especially with encapsulated organisms, such as *Streptococcus pneumoniae* and *Haemophilus influenzae*. Septicemia from an oral focus of infection can become a life-threatening problem in an HIV-infected child, and optimal oral health must be established and vigorously maintained in these children.[33] Routine use of chlorhexidine gluconate 0.12 percent mouth rinse may be helpful in minimizing gingivitis, candidiasis, and bacterial superinfections of the oral cavity, although its safety and effectiveness have not been shown in children.

Oral candidiasis usually is of the pseudomembranous type, which is seen in the oral cavity as a creamy white plaque that is rubbed off easily, leaving a reddened surface mucosa exposed. Because oral candidiasis is rare in normal children older than 6 months, persistence of oral candidiasis for 2 months or more in a child older than 6 months who has not received antibiotic therapy in the past 2 weeks is suggestive of HIV infection. Persistent oral candidiasis indicates acquired immunodeficiency category P-2D3 (symptomatic infection with secondary infectious diseases) in the Centers for Disease Control and Prevention classification of HIV infection in children younger than 12 years.[30]

Oral candidiasis was associated with a decreased survival time in a study of 99 children with perinatally acquired HIV infection. The median time from birth to the manifestation of the first lesion of oral candidiasis was 2.4 years, and the median time from the appearance of lesions to death was 3.4 years, with a relative hazard rate of 14.2.[29]

Treating oral candidiasis lesions is difficult because of frequent recurrence of oral fungal infection with resistant biotypes of *Candida albicans* or colonization by related but more resistant species, such as *Candida krusei*, *Candida parapsilosis*, and *Candida guilliermondii*. Treatment regimens may progress from nystatin to clotrimazole, fluconazole, and amphotericin B, depending on the extent of disease, clinical response, and culture and sensitivity results.[43] Sudden onset of rampant dental caries has been associated with prolonged oral use of sucrose-containing antifungal antibiotic preparations.[69]

Linear gingival erythema, formerly referred to as HIV gingivitis, is the most common form of periodontal disease seen in children with HIV infection. It is described as a fiery red, 2- to 3-mm-wide linear band of inflammation of the gingiva. Pain is not associated with the lesion, but the gingivae are likely to bleed during tooth brushing or even spontaneously. The microbiology of this lesion is unclear, but *Candida* spp. may be a possible cause.

Parotid salivary gland enlargement, which may be painful and become secondarily infected, has been reported in 14 to 30 percent of HIV-infected children. The enlargement apparently is caused by infiltration of the glands by T8 lymphocytes and has been associated with increased survival time. The median time was 4.6 years from birth to development of parotid enlargement

and 5.4 years from development of lesions to death, with a relative hazard rate of 0.38.[29]

Herpes simplex virus infections, although common occurrences in normal children, seem to be particularly severe and recur more often in HIV-infected children. The lesions appear first as multiple clustered vesicles on the lips or keratinized oral mucosa, which soon rupture to leave painful irregular oral ulcers or crusted labial ulcers. Fever and dysphagia may warrant hospital admission for hydration, nutrition, and therapy with parenteral acyclovir. Less severe cases may be treated with oral acyclovir.

Dental caries is increased in pediatric HIV cohorts. The cause of this finding is unclear. It may be due to xerostomia secondary to parotid enlargement in some cases, prolonged use of sucrose-containing antifungal agents in others, and nursing-bottle caries in still others. The association of nursing bottle caries with pediatric HIV infection may be due to their common increased prevalence in urban dwellers with limited economic resources, although nursing-bottle caries also is found frequently in children with other chronic diseases.[69]

COMPLICATIONS OF ODONTOGENIC INFECTIONS

FASCIAL SPACE INFECTIONS

Spread of infection to the fascial spaces may result in dramatic facial swelling and high fever and, if untreated, respiratory embarrassment. The characteristics of the more common fascial space infections related to odontogenic infection are described here.

Infraorbital space infections generally are related to maxillary anterior teeth and are well localized to the infraorbital fossa by the levator labii superioris and levator anguli oris muscles. Facial swelling lateral to the nose is prominent, as is decreased mobility of the upper lip caused by inflammation of these muscles. If the area is fluctuant, intraoral incision and drainage with placement of a small Penrose drain for 1 to 2 days generally are sufficient treatment. Antibiotics are indicated for all infections of the fascial spaces.

Trismus is the hallmark of infection of the masticator space. Trismus is caused by spasm in the muscles of mastication, which define this large potential space. The resulting inability to open the mouth hinders access to the airway for endotracheal intubation. In addition, abscesses of the masticator space may rupture into the oropharynx, causing aspiration of pus, or they may pass easily around the medial pterygoid muscle to involve the lateral pharyngeal and retropharyngeal spaces. Figure 9–9 shows a 6-year-old boy whose lower primary molar abscesses spread to involve the buccal, pterygomandibular, and lateral pharyngeal spaces. Extraoral and intraoral drainage, prolonged intubation, and extraction of the offending teeth were required.

Infections of the submandibular space (Fig. 9–10) may be localized unilaterally or may involve bilateral structures. Treatment of submandibular space infection is via extraoral incision and drainage.

First described in 1836, Ludwig angina consists of infection of the sublingual and submandibular spaces bilaterally and is characterized by hard, brawny swelling and a minimum of suppuration. The tongue often is edematous and raised to the roof of the mouth, with little mobility (Fig. 9–11). Airway obstruction should be considered imminent; the greatest cause of death in Ludwig angina is blockage of the airway by soft tissue swelling, pus, or blood, which occurred in more than 50 percent of its victims in the pre-antibiotic era.[21] In 1940, Williams[72] published a series of 37 cases of Ludwig angina, which reported a 54 percent mortality rate. The airway management policy at that time was emergency tracheotomy if necessary. Three years later, Williams and Guralnick[73] published a series of 20 cases of Ludwig angina treated with a new policy of immediate establishment of airway security by intubation or tracheotomy and aggressive incision and drainage of all anatomic spaces affected by the infection. By these measures, they were able to reduce the mortality rate of this dreaded infection to 20 percent only 3 years later. Antibiotics were unavailable during the course of these two studies. These studies underscore the importance of airway security and aggressive surgical management in the treatment of severe odontogenic infections.

Figure 9–9 Lateral pharyngeal space abscess in a 6-year-old boy. Note the swelling above the hyoid bone and anterior to the sternocleidomastoid muscle. Swelling also occurs in the buccal and submandibular spaces.

Figure 9–10 Submandibular space abscess.

Today, death rarely occurs from severe odontogenic infections, although the need for tracheotomy or prolonged endotracheal intubation is common. The cause of this infection often is odontogenic infection but may include laceration of the floor of the mouth and mandibular fracture. Usually a disease of middle-aged adults, it is a rare occurrence in children but may occur in greater frequency in immunologically compromised children.[18] Surgical drainage of all four spaces, accompanied by vigorous antibiotic therapy, is indicated.

Figure 9–11 Ludwig angina.

NECROTIZING FASCIITIS

Necrotizing fasciitis, which causes a frightening loss of skin and underlying tissues, has received considerable notoriety in the press. Cervicofacial necrotizing fasciitis often is odontogenic and typically causes a superficial spreading of cellulitis that follows the platysma muscle from the cheek down the entire neck to the anterior chest wall (Fig. 9–12A). Figure 9–12B illustrates such a swelling in an 8-year-old boy. The presumptive cause was odontogenic infection of the primary molars, which caused a high fever and a rapidly progressive cellulitis extending from the cheek to the chest. The cause of these infections often is group A streptococci, but a wide variety of microorganisms may be involved.

Wide-spectrum antibiotic therapy is indicated empirically, along with hydration, transfusions if necessary, and support of electrolyte balance, especially with calcium, which may be sequestered by necrotic fat molecules.[1] Timely surgery is important in the management of necrotizing fasciitis. Incision and drainage of the involved spaces, débridement of necrotic tissue, and fasciotomy often are performed as soon as possible after the patient's admission.[71] Hyperbaric oxygen therapy has been advocated as an adjunct in the treatment of necrotizing fasciitis. A significant reduction in the mortality rate and length of hospitalization associated with necrotizing fasciitis has been shown in adults.[71] Necrotizing fasciitis is cited as an indication for hyperbaric oxygen therapy in infants and children and should be considered if available.[70]

ODONTOGENIC SINUSITIS

A significant percentage of cases of sinusitis are odontogenic, especially in adults, because the maxillary sinus follows the erupting permanent tooth roots into the alveolar process. This pneumatization of the alveolar process progresses throughout life and is accelerated by loss of the upper posterior teeth. Dental infections of the periapical upper posterior teeth occasionally rupture through the maxillary sinus floor to involve the paranasal sinuses.

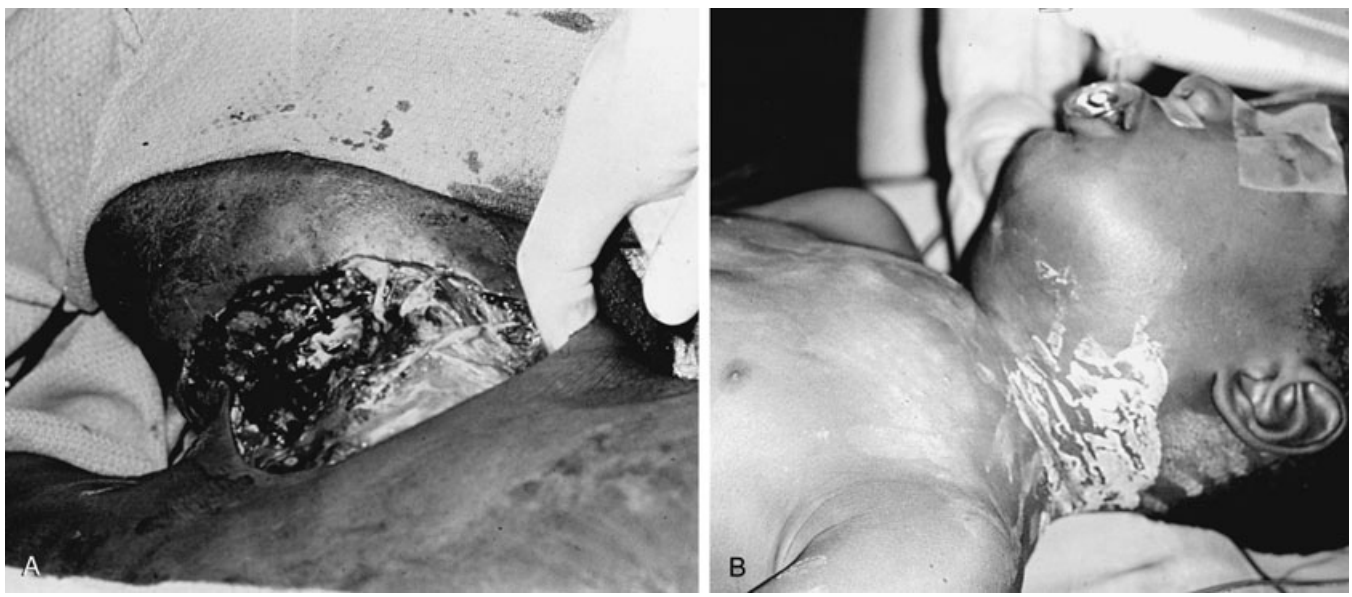

Figure 9–12 **A,** Surgical débridement of necrotic skin and platysma muscle of the left neck of a diabetic female patient with necrotizing fasciitis. Note how easily blunt finger dissection can undermine the skin in the plane of the necrotic platysma muscle. **B,** Necrotizing fasciitis in an 8-year-old boy. Note the swelling extending from the buccal space down the neck and onto the anterior chest wall, following the extent of the platysma muscle. The chalky material on the posterior neck is calamine lotion placed by the patient's mother for vesicles that resembled poison ivy.

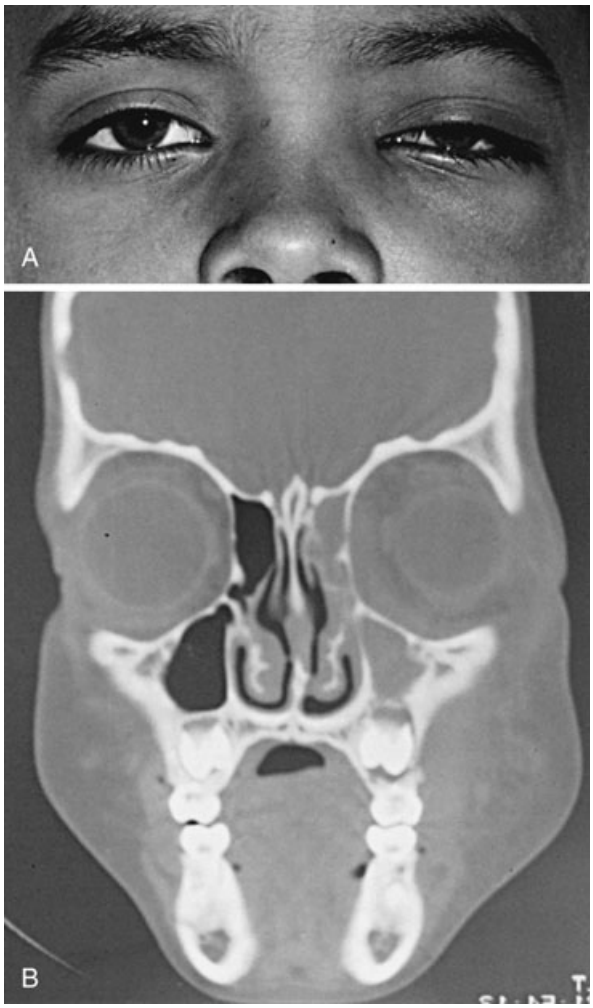

Figure 9–13 **A,** A 9-year-old boy with a left pansinusitis and an abscess of the upper left first primary molar. Note the left periorbital discoloration and swelling, with partial ptosis and displacement of the globe laterally. **B,** Computed tomography scan of the same patient. Note the left maxillary sinus opacification close to the infected tooth, opacification of the ethmoid sinuses, elevation of the periosteum away from the medial orbital wall, and displacement of the globe laterally within the orbit.

Dental infection should be eliminated in the complete treatment of severe recurrent sinusitis in children.

Figure 9–13 illustrates a case in a 9-year-old boy of left pansinusitis, including ethmoiditis and a subperiosteal orbital abscess associated with infected upper primary molars. His treatment involved a team approach of the dental and otolaryngology services for tooth extraction, incision and drainage of the buccal and infraorbital spaces, endoscopic sinus surgery, and external drainage of the orbital abscess.

BUCCAL AND PERIORBITAL CELLULITIS

A child occasionally presents with an acute buccal or periorbital space swelling and cellulitis with no clinically apparent odontogenic cause. These infections tend to occur in young children, usually younger than 36 months. They usually have a history of recent upper respiratory infection or sinusitis. *H. influenzae* type b and *S. pneumoniae* have been implicated as pathogens in these conditions, although the widespread use of conjugated vaccines has reduced drastically the incidence of invasive disease from *H. influenzae*.[17] A possible mechanism for the inoculation of the soft tissues is migration of organisms through emissary veins piercing the thin cortical bone overlying the lateral surface of the maxillary sinus, in cases with existing sinusitis. Unless the infection is severe, incision and drainage usually are unnecessary, and treatment with antibiotics is successful. Blood cultures frequently are positive in more severe cases. The role of lumbar puncture remains controversial in the overall management of infants and young children. The incidence of this infection has declined significantly as a result of the widespread use of *H. influenzae* vaccine.

ORBITAL AND INTRACRANIAL COMPLICATIONS

Odontogenic infections that spread to involve the orbit and the brain are rare. Orbital and intracranial abscesses may have an odontogenic origin, however, and the dental condition of patients with these conditions should be evaluated by a dentist. Probably no more than 5 to 10 percent of orbital cellulitis is odontogenic in origin.[28,74] This infection generally is unilateral and is characterized by proptosis, chemosis, lid edema, and restriction of extraocular motion secondary to edema.[54] No nerve palsies or visual changes are present. Treatment includes surgical drainage, antibiotics, and elimination of the dental infection.

Cavernous sinus thrombosis, which may be difficult to differentiate clinically from orbital cellulitis, is considerably more serious because microorganisms proliferate intracranially. The risk of death is high. Characteristics include bilateral involvement with rapid progression from one eye to the other, proptosis, chemosis, and lid edema. Extraocular movements are limited because of inflammation of the third, fourth, and sixth cranial nerves. Systemic signs of meningeal irritation and ophthalmoscopic evidence of obstruction of the retinal veins also are present.[7,54,65] Treatment includes high doses of parenteral antibiotics, elimination of the causative dental pathosis, and incision and drainage of infected fascial spaces.

Brain abscess and subdural empyema are rare findings today compared with several decades ago. Of the large series of brain abscess cases reported, 0 to 4 percent have been attributed to dental causes.[41,68] All of the studies in which the individual case histories are described disclose a pansinusitis intervening between the dental infection and the brain.[42,60] Odontogenic brain abscesses seem to occur by direct extension through the paranasal sinuses, usually to the frontal lobe through the frontal sinuses. Odontogenic cavernous sinus thrombosis seems to be propagated by an ascending thrombophlebitis.

OSTEOMYELITIS OF THE JAWS IN CHILDREN

Osteomyelitis of the jaws in children usually results from periodontal or, more commonly, periapical infection. Open fracture of the jaws with delayed treatment also is a significant cause of osteomyelitis. Extension from contiguous infections, such as otitis, parotitis, and mastoiditis, occurs much less often.

Osteomyelitis of the jaws occurring in children must be viewed with great concern because it may result in the following problems: (1) loss of primary and permanent teeth; (2) sequestration of segments of the jaws; (3) growth defects, such as mandibular hypoplasia, asymmetry, and ankylosis[12]; (4) disfiguring facial scars and cutaneous fistulas; and (5) lesions suggestive of malignancy, which require open biopsy. For these reasons, osteomyelitis of the jaws in children should be diagnosed rapidly and treated aggressively. Table 9–5 presents a useful classification of this disease.[67]

TABLE 9–5 Osteomyelitis of the Jaws

Suppurative	Nonsuppurative
Acute suppurative	Chronic sclerosing
Chronic suppurative	Facial sclerosing
Primary	Diffuse sclerosing
Secondary	Garré sclerosing
Infantile	Actinomycotic
	Radiation osteomyelitis and necrosis

PREDISPOSING FACTORS

Preexisting systemic disease with accompanying alteration of host resistance plays a major role in the initiation of osteomyelitis of the jaws. It includes such conditions as uncontrolled diabetes, agranulocytosis, leukemia, sickle-cell disease, and febrile illnesses. Conditions that alter the vascularity of bone and the ability to combat infections, including bone tumors, fibrous dysplasia, Paget disease, and radiation to the jaws, also are important predisposing conditions. Major maxillofacial injuries resulting in open fractures of the jaws, especially fractures that are not treated immediately, are an important cause of osteomyelitis.

MICROBIOLOGY

Because the etiology of osteomyelitis of the jaws includes causes other than purely odontogenic infections, the bacterial spectrum is broad. Most instances of osteomyelitis of the jaws are caused by aerobic streptococci (alpha-hemolytic streptococci, *Streptococcus* viridans group), anaerobic streptococci, and other anaerobes, particularly peptostreptococci, fusobacteria, and *Bacteroides* and related genera.[52] Only occasional cases are caused by *S. aureus*, with entry through the skin being the probable route. Other bacteria involved include oral anaerobes, aerobic and microaerophilic cocci, and gram-negative organisms. Specific forms of osteomyelitis are caused by *Actinomyces israelii*, *Treponema pallidum*, and *Mycobacterium tuberculosis*. *Salmonella* organisms have been associated with osteomyelitis of the jaws in patients with sickle-cell anemia.[9]

CLINICAL FINDINGS

Osteomyelitis involves the mandible far more frequently than the maxilla because the poor blood supply to the mandible comes primarily from one major vessel and the periosteal blood supply. Four major forms of the disease, which may be distinguished clinically, are (1) acute suppurative; (2) secondary chronic, which begins as an acute osteomyelitis and becomes chronic; (3) primary chronic, which has no acute phase and always has seemed to be a low-grade infection; and (4) nonsuppurative osteomyelitis. The forms most often seen in children are the acute suppurative, the secondary chronic, and one nonsuppurative form, Garré sclerosing osteomyelitis. These conditions are described in some detail.

SUPPURATIVE OSTEOMYELITIS

Suppurative osteomyelitis usually begins with deep and intense pain in the jaws, high intermittent fever, and an obvious cause, most often a deeply carious or discolored tooth. In the early stages, mental nerve paresthesia occasionally is present. During the course of several days, facial swelling develops, and in 10 to 14 days, teeth begin to loosen, pus exudes around the gingival sulcus, and multiple mucosal or cutaneous sinus tracts form. In addition to the draining sinuses, a firm cellulitis is present in the soft tissues accompanied by trismus and cervical lymphadenopathy. A leukocytosis, ranging typically from 8000 to 15,000 cells/mm^3, is present, although it does not ordinarily reach the levels that are seen in acute osteomyelitis of the long bones. After 10 days to 2 weeks, radiographs may show scattered areas of bone destruction suggestive of a moth-eaten appearance (Fig. 9–14), and periosteal reaction characterized by the laying down of new bone commonly is seen. Smears of specimens and cultures, including cultures of bone sequestra, should be taken whenever possible. Interpretation of cultures must be made with caution because of the possibility of skin and oral contaminants in the specimen.

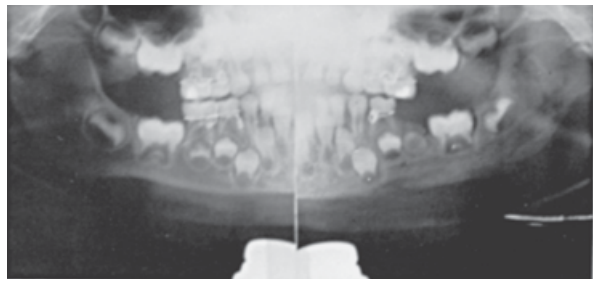

Figure 9–14 Radiograph of the jaws of a 4-year-old girl with suppurative osteomyelitis of the left mandible. The film shows marked destruction of the body and ramus of the mandible.

Initially, antibiotic doses adjusted for age may be given empirically, but the selection of the antibiotic is determined by culture and sensitivity testing of specimens taken directly from the infected site.[15] The antibiotics of choice in mandibular osteomyelitis include amoxicillin-clavulanate, clindamycin, and fluoroquinolones. Fluoroquinolones are excellent choices because of their complete absorption from the gastrointestinal tract and high penetration of bone, but these drugs generally should be avoided in children because they are chondrotoxic during growth. As results from smears and culture are obtained, antibiotics may be changed, unless the infection is responding favorably, in which case no change is made. The involved tooth is removed as early as possible to allow drainage and to provide material for culture.

Antibiotic therapy is continued for at least 2 to 4 weeks after all symptoms subside. If the infection persists, repeated cultures are obtained, and the antibiotic is changed if necessary. The greater vascularity of the jaws may explain their more rapid response to antibiotic therapy and surgery compared with long bones. The duration of intravenous antibiotic therapy in osteomyelitis of the jaws may not need to be as prolonged as in that of the long bones. Consideration should be given to sequestrectomy, saucerization, or the placement of closed-wound irrigation and suction. Saucerization involves the removal of teeth in the immediate area and removal of the overlying buccal plate of bone, allowing access to the medullary portion and sequestra that may be present. Placement of catheters through an extraoral approach occasionally is necessary for closed irrigation and suction. It permits instillation of antibiotics, allowing direct contact with the bone. Hyperbaric oxygen treatment may be considered in chronic cases refractory to antibiotic treatment.[47]

INFANTILE OSTEOMYELITIS

Osteomyelitis of the jaws in a newborn is an uncommon occurrence but warrants special mention because of its serious sequelae. It occurs most often a few weeks after birth and usually involves the maxilla. It is not odontogenic in origin, but is thought to arise from neonatal trauma to oral tissues, hematogenous spread (from

skin, middle ear, mastoid, or tonsils), or an infected nipple.[56] The patient presents with a facial cellulitis centered around the orbit (Fig. 9–15). Irritability and malaise precede development of cellulitis and are followed by marked elevation in temperature, anorexia, and dehydration. Extraorally, inner canthal swelling, palpebral edema with closure of the eye, conjunctivitis, and proptosis may be seen together with a purulent discharge from the nose or from the inner canthus. Oral examination shows swelling of the maxilla on the affected side extending to the buccal and the palatal regions, with fluctuation often present with multiple sinus tracts. *S. aureus* is the organism usually found.

Figure 9–15 Characteristic clinical picture of a 3-week-old child with infantile osteomyelitis. *(Courtesy of Dr. M. Michael Cohen, Sr.)*

Aggressive, prompt treatment must be undertaken to prevent permanent optic damage, neurologic complications, loss of tooth buds and bone, and extension to the dural sinuses. Intravenous penicillin and a penicillinase-resistant penicillin are given simultaneously with surgical drainage of all fluctuant areas, repeated Gram smears, and culture and sensitivity testing. Antibiotics are continued orally for 2 to 4 weeks after all signs of the infection have disappeared. If sequestra form, they should be removed conservatively. Tooth buds may be lost, and surviving teeth may be deformed or discolored after eruption.

GARRÉ SCLEROSING OSTEOMYELITIS

Garré sclerosing osteomyelitis, also known as chronic nonsuppurative sclerosing osteomyelitis and proliferative osteomyelitis of Garré,[4] is notable because of the similarity of some of its characteristics to those of other neoperiostoses. It is characterized by a localized, hard, nontender swelling of the mandible (Fig. 9–16). Lymphadenopathy, hyperpyrexia, and leukocytosis are not present. Garré osteomyelitis is associated commonly with a carious tooth, usually the lower first molar (Fig. 9–17), and a

Figure 9–16 Enlargement of the right side of the mandible in a 12-year-old patient with Garré sclerosing osteomyelitis. The swelling is hard and nontender.

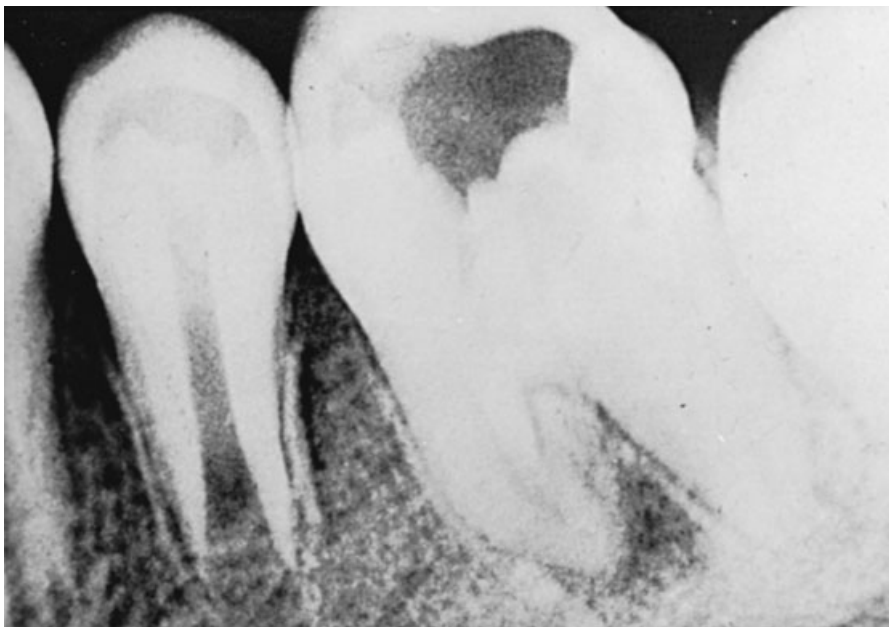

Figure 9–17 Radiograph of a deeply carious lower first molar tooth with periapical spread of infection. It is the usual cause of Garré osteomyelitis.

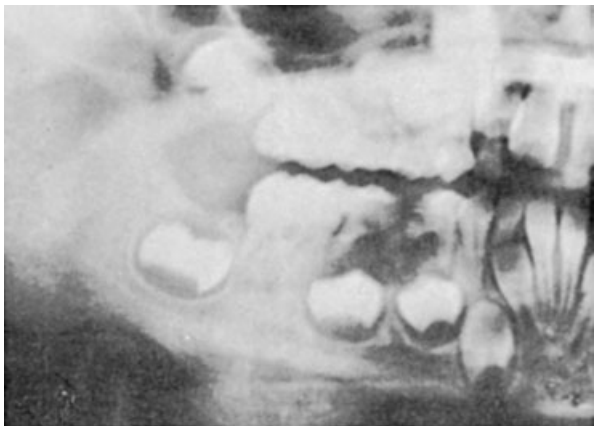

Figure 9–18 Characteristic radiograph of Garré osteomyelitis showing the laminated or onion-peel appearance of the mass. *(Courtesy of Dr. Larry J. Peterson.)*

history of a past toothache. It also may be associated with a recent dental extraction or an infected flap of tissue over an erupting tooth.[39] Radiographs are impressive, showing a focal area of well-calcified bone proliferation that is smooth and that often has a laminated or onion-peel appearance (Fig. 9–18).

Garré osteomyelitis is thought to be a response to a low-grade stimulus, such as a dental infection, which influences the potentially active periosteum of young individuals. Its appearance resembles that of infantile cortical hyperostosis (Caffey disease), osteosarcoma, and Ewing sarcoma, and it must be distinguished from these conditions.[11] Treatment consists of extraction or endodontic treatment of the involved tooth, with continued clinical and radiographic follow-up of the patient to ensure that the new bone formation does not progress. Ordinarily, remodeling occurs over the course of time, but biopsy should be done to rule out neoplasm if the lesion does not regress. No antibiotic therapy is necessary.

HERPES SIMPLEX VIRUS INFECTIONS

Herpes simplex virus type 1 infections[64] commonly are manifested as herpetic gingivostomatitis. Five stages of infection have been identified: (1) primary mucocutaneous infection, (2) acute infection of ganglia, (3) establishment of latency, (4) reactivation, and (5) recurrent infection.

Primary infection is established by direct contact either with individuals who have draining lesions or with an asymptomatic carrier who may continue to shed the virus despite the lack of symptoms. The highest incidence of primary infection seems to be in children 2 to 4 years old. Infants are protected by maternal antibodies, which may explain why this infection is not found in infants younger than 6 months. It appears to have no seasonal variation or male-female difference in incidence.

The incubation period is thought to be approximately 6 days, followed by the development of small vesicles that may coalesce to form larger lesions or ulcers. In severe cases, the lips, gingivae, oral mucosa, and pharynx may be involved. Many patients with primary herpes labialis may be asymptomatic, however, and symptoms may not develop. Healing occurs in 1 to 2 weeks, with gradual crusting of the lesions followed by re-epithelialization.

Latency is thought to continue throughout life, with reactivation occurring at various times, possibly triggered by actinic radiation and emotional or physical stress. Recurrent disease is manifested by vesicles at the mucocutaneous border, which are painful for about 2 days, followed by crusting and complete healing in 7 to 8 days.

Fifty percent of the adult population in industrialized countries and a higher percentage in less-developed countries may have recurrent herpes labialis. Many, if not most, adults who have recurrent "cold sores" are not aware that they can transmit the disease and should be counseled in this regard. Likewise, medical, dental, and nursing personnel should be advised that occurrence of cutaneous lesions (the herpetic whitlow) is possible after direct contact of the practitioner's fingers with lesions during the physical examination.

In treating recurrent herpes labialis in non-immunocompromised adults, acyclovir has been shown to decrease the duration of symptoms by 12 to 24 hours, at a cost of approximately $75.00 per day. Frequent use of acyclovir also may promote the spread of resistant viral strains. The use of acyclovir for treatment of recurrent herpes labialis in non-immunocompromised individuals seems to offer little benefit at significant expense and risk.[55]

CHAPTER 10

Pharyngitis (Pharyngitis, Tonsillitis, Tonsillopharyngitis, and Nasopharyngitis)

James D. Cherry

Pharyngitis is an inflammatory illness of the mucous membranes and underlying structures of the throat. The clinical diagnostic category includes tonsillitis, tonsillopharyngitis, and nasopharyngitis; inflammation also frequently involves the nasopharynx, uvula, and soft palate. Illness usually is acute but also may be subacute or chronic. Establishing the diagnosis of pharyngitis requires objective evidence of inflammation (erythema, exudate, or ulceration). The symptom of sore throat invariably accompanies pharyngitis, but it should not be used as the sole criterion; sore throat is a common complaint of children with colds in whom no objective evidence of pharyngeal inflammation is present.

Although the clinical finding of pharyngitis suggests an almost exclusive group A streptococcal etiology to many physicians, etio-

logic considerations should include a multitude of viruses, bacteria, and other infectious and noninfectious agents. Etiologically, pharyngitis is subdivided into two categories: illness with nasal symptoms (nasopharyngitis) and illness without nasal involvement (pharyngitis or tonsillopharyngitis). In acute illness, nasopharyngitis nearly always is of viral origin, whereas pharyngitis without nasal signs has diverse etiologic possibilities, including bacteria, viruses, fungi, and other infectious agents. In this chapter, nasopharyngitis and pharyngitis without nasal involvement are considered separately.

HISTORY

Although throat inflammation undoubtedly has been a physical finding of disease throughout human existence, only in more recent years has attention been given to pharyngitis as a primary complaint. The throat findings of diphtheria were mentioned in the 3rd century AD,[164] and Vincent angina was noted in the military before the Christian era,[47] but group A streptococcal infection and pharyngitis were not clearly associated until World War II.[30,141] Although Glover and Griffith[62] mentioned streptococcal tonsillitis in 1931, the major reference to streptococci in the preantibiotic era was in association with scarlet fever, erysipelas, and suppurative processes.[23]

NASOPHARYNGITIS

ETIOLOGIC AGENTS

Etiologic agents of nasopharyngitis, categorized by type of lesion, frequency, season of occurrence, and duration of illness, are listed in Table 10–1. The relative importance of nasal and pharyngeal manifestations also is presented. Although Table 10–1 shows three bacterial agents and one rickettsia, most occurrences of nasopharyngitis are caused by viral infections. The specific infectious agents are discussed fully in their respective sections of this book; only an overview is presented here.

Adenoviruses are the most common cause of nasopharyngitis; types 1, 2, 3, 4, 5, 6, 7, 7a, 9, 14, and 15 account for most illnesses.* Nasopharyngitis also commonly occurs with influenza and parainfluenza viral infections.† Although rhinoviral, respiratory syncytial viral, human metapneumovirus, and human bocavirus infections are common occurrences in children and all always have nasal manifestations (coryza), the occurrence of objective pharyngeal manifestations is less common.[20,51,74,77-80,87,111,130,151] Respiratory symptoms with cough, nasal discharge, and pharyngitis frequently occur in children with rotaviral gastroenteritis.[69,100,143]

EPIDEMIOLOGY

Nasopharyngitis is a common illness of childhood. It tends to be most prevalent in young children, in association with primary infections with respiratory viruses. Nasal symptoms with enteroviruses occur less frequently in school-aged children than in preschool-aged children. In contrast, older children rarely have pharyngitis with respiratory syncytial viral, parainfluenza viral, and rhinoviral infections. Nasopharyngitis caused by adenoviral infection is a particularly frequent occurrence in adolescents and young adults in military training.[33,153,170]

Nasopharyngitis occurs more commonly during the cold weather months (see Table 10–1). No apparent sex predilection has been found. The method of transmission is similar to that of other respiratory viral infections (see Chapter 8).

PATHOPHYSIOLOGY

The pathophysiology of nasopharyngitis is discussed in Chapter 8, in the pharyngitis section of this chapter, and in the chapters discussing the individual viral agents. In nasopharyngitis associated with *Haemophilus influenzae* and *Neisseria meningitidis*, the nasal symptoms may result from a concomitant respiratory viral infection.[23]

CLINICAL PRESENTATION

Because nasopharyngitis is caused by many different etiologic agents, a reasonable expectation is varied clinical manifestations. These differences are highlighted in Table 10–1. Fever occurs in nearly all cases of nasopharyngitis. With adenoviral and influenza viral disease, the pharyngeal findings are most prominent; with the other respiratory viruses, coryza is more notable than are pharyngeal complaints. In adenoviral infections, follicular pharyngitis is the rule, and exudate is a common manifestation. In contrast, patients with the other respiratory viral infections usually present with pharyngeal erythema only. Nasopharyngitis of a viral etiology most often is an acute, self-limited disease lasting 4 to 10 days. Generally, adenoviral illnesses tend to be more prolonged than are illnesses resulting from the other respiratory viruses. Other symptoms in nasopharyngitis are related to the causative virus. Parainfluenza and respiratory syncytial viral infections also might have lower respiratory tract findings (laryngotracheitis, pneumonia, or bronchiolitis), and influenza might be associated with more severe, generalized complaints.

Although respiratory symptoms in association with rotaviral gastroenteritis have been noted frequently, little careful clinical study of the respiratory manifestations has been performed. Lewis and associates,[100] in a careful study, observed a statistically significant occurrence of nasal discharge, cough, and red throat in children with rotaviral diarrhea compared with children with diarrhea caused by other agents.

Nasopharyngitis with *H. influenzae* or *N. meningitidis* infections has been noted mainly in patients with septicemia and meningitis. The nasal symptoms (coryza) usually preceded the pharyngitis and severe systemic disease by a few to several days. In Q fever, the predominant finding is pneumonia. With diphtheria, the exudative pharyngitis and constitutional symptoms are most prominent.

PHARYNGITIS, TONSILLITIS, AND TONSILLOPHARYNGITIS

ETIOLOGIC AGENTS

Etiologic agents of pharyngitis categorized by type of lesion, frequency of occurrence, and duration of illness are presented in Table 10–2. Numerous diverse possibilities exist for the differential diagnosis of pharyngitis. The specific agents or factors are presented in their respective sections of this book, and only an overview is given here.

As with all infectious diseases, etiologic prevalence depends on multiple factors (status of the host, age, season, environment, exposure, and type of lesion) that must be considered in each individual case. In otherwise healthy children, the following infectious agents account for more than 90 percent of acute infections with pharyngeal involvement: *Streptococcus pyogenes*; adenoviruses; influenza viruses A and B; parainfluenza viruses

*See references 11, 21, 33, 35, 87, 116, 133, 153, 157, 170.

**Plus signs indicate the relative degree and severity of the lesion (++++, most marked; +, minimal).*
†Each +, 25%.
‡++++, 76 to 100 percent; +++, 51 to 75 percent; ++, 26 to 50 percent; +, 1 to 25 percent.

1, 2, and 3; Epstein-Barr virus; enteroviruses; and *Mycoplasma pneumoniae*.*

Although group A streptococci are suggested frequently[25] as the only worthy bacterial consideration in the etiology of pharyngitis, the data in Table 10–2 indicate broader possibilities. When streptococci with beta-hemolysis recovered from children and adolescents with pharyngitis are typed, group B, C, and G strains occasionally are found.[5,26,28,58,75,166,167] Turner and associates[166] found that of the group C streptococci, only *Streptococcus equisimilis* caused pharyngitis; *Streptococcus anginosus* (*Streptococcus milleri*) was part of the normal oropharyngeal flora.

Laboratory accidents have provided evidence that *H. influenzae* can cause pharyngitis,[129,173] and children with systemic illnesses caused by *H. influenzae* and *N. meningitidis* frequently have an associated marked pharyngitis.[152,174,178] *Arcanobacterium haemolyticum* and *Corynebacterium ulcerans* occasionally cause an illness mimicking diphtheria.[15,68,89,93,107,134] *A. haemolyticum* also causes an illness that has been confused with streptococcal scarlet fever.[46,89,104,107]

Because anaerobic microorganisms are universal constituents of the normal throat flora, assigning etiologic significance to these agents in throat infections frequently is difficult. Vincent stomatitis and angina seem to result from mixed infections with anaerobes.[48,63,106,169] Brook and Gober[14] noted a significant association between encapsulated organisms of the *Bacteroides melaninogenicus* group (*Prevotella melaninogenica*) and acute tonsillitis in children. My impression is that acute and subacute infections with anaerobes account for numerous pharyngeal infections in adolescents in which cultures do not reveal group A streptococci and infectious mononucleosis test results are negative. Gonococcal and treponemal infections should be considered in sexually active or known exposed teenagers and other children.[17,31,49,84,177]

Adenoviral types 1, 2, 3, 4, 5, 6, 7, 7a, 9, 11, 14, 15, and 16 are the most common causes of pharyngitis in young children, and they are prominent etiologic agents in older children and adolescents.* Pharyngeal involvement frequently is overshadowed by other respiratory symptoms (e.g., cough, coryza) in parainfluenza viral infections and by systemic complaints (e.g., fever, exanthem, meningitis) in enteroviral infections.† An enteroviral etiology should be suspected when small ulcerative lesions are noted that involve the soft palate and uvula and the posterior pharyngeal wall (see Chapter 11). Infection with Epstein-Barr virus causes infectious mononucleosis with pharyngeal involvement similar to that resulting from group A streptococcal infection.[76,171] The clinical manifestations of Epstein-Barr virus are age-related; young children rarely have marked pharyngeal involvement.

HIV, human immunodeficiency virus; PFAPA, periodic fever, aphthous stomatitis, pharyngitis, and adenitis (syndrome).

Acquired cytomegalovirus infection causes an infectious mononucleosis–like syndrome, but pharyngitis occurs less commonly than it does in Epstein-Barr virus mononucleosis.[95] Primary and recurrent herpes simplex virus infections occasionally have pharyngeal manifestations.[19,23,43,116] Many illnesses that are ascribed clinically to herpes simplex virus actually are misidentified instances of aphthous stomatitis, however. Virtually all instances of herpes simplex virus infections with pharyngitis also reveal lesions in the anterior mouth and externally around the mouth. Although Koplik spots are known universally as the enanthem of measles, many physicians are unaware of the diffuse nature of the associated measles pharyngitis.[22] Primary infection with human immunodeficiency virus may cause the acute retroviral syndrome with fever, nonexudative pharyngitis, lymphadenopathy, exanthem, arthralgia, myalgia, and lethargy.[6]

The role of *Chlamydia* spp. in the cause of pharyngitis is unclear. Grayston and associates[65,67] noted the occurrence of pharyngitis in adolescents and young adults infected with *Chlamydia pneumoniae*. In a study in children, IgM antibody to *Chlamydia trachomatis* was found in children with pharyngitis.[72] Because cross-reactivity between *C. trachomatis* and *C. pneumoniae* exists, the illnesses studied were likely to be caused by *C. pneumoniae*, rather than by *C. trachomatis*. Ogawa and colleagues[123] noted prolonged and recurrent tonsillitis in association with sexually transmitted *C. trachomatis*.

Mild pharyngitis occurs in young children with *M. pneumoniae* infections; in older children, pharyngeal involvement is more pronounced.[25,61,66,80] In young adult volunteers, *Mycoplasma hominis* was noted to cause pharyngitis.[103] Although lower respiratory tract findings and systemic complaints are most marked in Q fever, moderate subjective and mild objective evidence of pharyngitis also is noted.[41,86,126] Exudative pharyngeal involvement with *Candida* spp. commonly occurs.[98,154] *Candida* infection most commonly occurs in children whose normal throat flora has been disrupted and in children who have a compromised immunologic response.

Recurrent aphthous stomatitis usually involves the anterior oral cavity, but occasionally is noted with extensive pharyngeal and soft palate lesions.[64,144] Although L-forms (spheroplasts) of *Streptococcus sanguinis* can be recovered consistently from the lesions of this disease,[64] their role in the etiology is unclear. In 1987, Marshall and colleagues[110] described a new syndrome, periodic fever, aphthous stomatitis, pharyngitis, and adenitis (PFAPA), and it subsequently has been observed by others.[45,53,82,85,105,125,162]

In 1999, Thomas and associates[162] presented an analysis of data in their PFAPA registry of 94 cases. The male-to-female ratio was 1.8:1, and the mean age of PFAPA onset was 2.8 years (95% confidence interval 2.4 to 3.3). The children had an average 11.5 febrile episodes per year, and the average symptom-free interval between episodes was 28.2 days (99% confidence interval 26 to 30.4 days). The average duration of an episode was 4.8 days, with the temperature being greater than 38.3° C for 3.8 days. The average maximum temperature per episode was 40.5° C (95% confidence interval 40.4 to 40.6° C). Along with the periodic fevers, the children also experienced aphthous stomatitis (67%), pharyngitis (65%), cervical lymphadenopathy (77%), chills (80%), headache (65%), abdominal pain (45%), nausea (52%), diarrhea (30%), cough (20%), coryza (18%), and rash (15%). In addition to fever, 97 percent had one or more of the following: aphthous stomatitis, pharyngitis, or adenopathy. The mean leukocyte count was 13,000 with 62 percent polymorphonuclear leukocytes, and the mean erythrocyte sedimentation rate was 41 mm/hr.

In PFAPA, the episodes persist for several years with unchanged findings and periodicity. In the Nashville data, 41 percent of the children had stopped having episodes after a mean of 4.5 years. Before remission, the episodes decreased in frequency over an extended period.[162] Treatment modalities that have offered relief include ibuprofen (85%) and prednisone (90%). Thomas and associates[162] recommend prednisone or prednisolone treatment (1 mg/kg at the beginning of an attack and the same dose on the next morning and 0.5 mg/kg on days 3 and 4). Tonsillectomy, adenoidectomy, and prophylactic cimetidine administration have been associated with remission in some children.

In Behçet syndrome, the ulcerative lesions are subacute or chronic and usually are not associated with surrounding pharyngeal inflammation.[108] In Kawasaki disease, the pharyngeal mucosa is deeply erythematous.[114]

Pharyngeal involvement is a common occurrence in noninfectious illnesses in which host resistance has been altered. The

lesions usually are ulcerative, but secondary bacterial or fungal overgrowth can lead to marked erythematous and exudative findings.

EPIDEMIOLOGY

Pharyngitis is a common occurrence in children and, as noted in Table 10–2, is the result of many different infectious agents. Generally, bacterial pharyngitis occurs more commonly in the cold weather seasons; an enteroviral etiology is most common in the summer and fall. In younger children, viral pharyngitis tends to occur more frequently than does bacterial disease.[36] It has no apparent sex predilection.

Most diseases associated with pharyngitis require close person-to-person contact for spread. Pathogens are transmitted directly by close-range airborne dissemination or indirectly by the hands of the future host. Several food-borne outbreaks of streptococcal pharyngitis have been reported.[44,52] Prechewing of food by adults also may be a cause of streptococcal pharyngitis in infants.[156]

PATHOPHYSIOLOGY

The pathology and pathophysiology of diseases in which pharyngitis is prominent are presented in the chapters of this book on specific infectious agents (in particular, see Chapters 93, 168, and 178).

CLINICAL PRESENTATION

The clinical findings in pharyngitis are highlighted in Table 10–2. Manifestations related to individual pathogens are detailed in the chapters of this book dealing with the specific agents. The onset of pharyngitis usually is sudden and accompanied by fever and the complaint of sore throat. Frequently, parents observe that the child's breath is not normal, and that the throat and particularly the tonsils are red. Other initial complaints include headache, nausea, vomiting, and sometimes abdominal pain. Anorexia is the rule, as is some degree of lessened activity. Parents also report frequently that the child's cervical lymph nodes are enlarged and tender.

Physical examination usually substantiates the parents' observations—the child is febrile with moderate to severe pharyngeal erythema and some degree of cervical adenitis. As noted in Table 10–2, the pharyngeal response varies. With acute common infections, the basic lesion is erythema. Associated with erythema can be follicular, ulcerative, and petechial lesions and generalized or circumscribed exudative areas. Follicular lesions are most characteristic of adenoviral infections, whereas exudative lesions occur most commonly in group A streptococcal infections and in infectious mononucleosis. Meland and associates[113] noted that the absence of cough and the presence of swollen lymph nodes had the highest specificity in predicting a streptococcal cause of pharyngitis. Ulcerative lesions are observed most frequently in enteroviral infections (see Chapter 178). Petechiae on the soft palate frequently are seen in group A streptococcal infections, but also commonly occur in infectious mononucleosis, measles, and rubella.

Occurrences of pharyngitis in children almost always are acute, self-limited diseases. Pharyngitis of viral origin lasts 4 to 10 days, and pharyngitis caused by group A streptococci, if untreated, lasts slightly longer. Subacute and chronic pharyngeal disease is an uncommon occurrence in children, but the etiologic possibilities are numerous (see Table 10–2).

DIFFERENTIAL DIAGNOSIS

As noted in Table 10–2, the differential diagnoses in pharyngitis are numerous, as in nasopharyngitis (see Table 10–1). Although considerable overlap exists in the spectrum of illness in pharyngeal infections, many clues help in ruling in or out certain diagnostic possibilities. The diagnosis of pharyngitis requires carefully eliciting epidemiologic and other historical data (i.e., exposure, season, incubation period, age of patient, associated clinical findings), in addition to observing pharyngeal physical findings.

Most acute instances of nasopharyngitis are of viral origin (see Table 10–1), with adenoviruses accounting for the greatest number of cases. Nasopharyngitis also occurs during epidemic influenza A and B and parainfluenza 1 and 2 infections, and with sporadic parainfluenza 3 infections. In all cases, proper epidemiologic and historical data should be elicited so that early diphtheria and other unusual but treatable illnesses are not diagnosed incorrectly. Retrospective study has indicated that nasopharyngitis occasionally occurs in severe infections from *H. influenzae* and meningococci, so the possible presence of these infections should be considered when the epidemiology suggests it.

Although most cases of pharyngitis without nasal symptoms are caused by viral infections, numerous other etiologic possibilities exist. The approach taken frequently by many physicians is to consider all pharyngitis as being of bacterial origin and to treat it with antibiotics. The initial consideration in a child with pharyngitis should be the duration of illness. Subacute, chronic, and recurrent illnesses (see Table 10–2) generally suggest more unusual problems and require a more deliberate approach. In all instances of acute pharyngitis, ruling out streptococcal disease is mandatory.

SPECIFIC DIAGNOSIS

The epidemiologic history and careful clinical categorization are the most important aspects of specific diagnosis. The most pressing diagnostic need in upper respiratory infections in everyday pediatric practice is distinguishing bacterial from viral disease—who and who not to treat with antibiotics. An approach to the problem is presented in Table 10–3.

A child with the common cold, herpangina, or pharyngoconjunctival fever has a viral disease and does not need therapy with antibiotics. In most instances, when these clinical diagnoses are apparent, performing throat cultures for bacterial pathogens is unnecessary. A child with severe acute pharyngitis with exudate and fever and cervical lymphadenitis also is treated easily because most of these children have disease resulting from group A streptococci.

Only a few children have illnesses at the extremes of those shown in Table 10–3. Most illnesses seen routinely by the physi-

TABLE 10–3 Treatment Considerations in Upper Respiratory Tract Infections

Clinical Entity		Etiology
Common cold, herpangina, pharyngoconjunctival fever		Viral, 100%
↓	Never-Never Land	↓
Marked pharyngitis with exudate and fever and cervical lymphadenitis		Bacterial, 70%

Modified from Cherry, J. D.: Newer respiratory viruses: Their role in respiratory illness of children. In *Schulman, I., et al. (eds.): Advances in Pediatrics. Vol. 20. Chicago, Year Book Medical Publishers, Inc., © 1973. Used by permission.*

cian treating children fall into the large middle area—"never-never land." On clinical grounds, no certain way to make an etiologic diagnosis and specifically to rule out infection caused by *S. pyogenes* exists. Until more recently, the usually recommended approach to management of pharyngitis and nasopharyngitis was to obtain a throat culture to determine whether group A streptococci were present. Because several rapid tests (rapid antigen detection tests [RADT]) for the detection of group A streptococci are available, establishing the immediate diagnosis and providing treatment of streptococcal pharyngitis are possible in the practice setting.* Generally, these rapid tests have high specificity, but sensitivity is suboptimal. If early treatment is desirable today, a reasonable approach to establishing the diagnosis of streptococcal pharyngitis is to do a rapid test. If the test result is positive, specific therapy is instituted. In the case of a negative rapid test result, a routine throat culture is done, and therapy is withheld pending the culture results.[9,39,137]

A question exists regarding whether early treatment of streptococcal pharyngitis is desirable.[40,55,57,136,137] In the public clinic, where following up children with positive throat cultures often is difficult, providing immediate diagnosis and treatment is important. As Pichichero and associates[136,137] and El-Daher and colleagues[40] have shown, early treatment may result in a decreased desirable antibody response, allowing reinfection with type-specific organisms to occur. In settings in which the communication between physicians and parents is satisfactory, an advisable approach in many instances is to withhold the institution of treatment for 1 or 2 days. Gerber and associates[55,57] argue against this approach because providing immediate therapy can reduce the risk of transmission of infection, and they challenge the interpretation of the findings of Pichichero and associates[136,137] and El-Daher and colleagues.[40]

Cultures for other pathogens should be reserved for unusual situations, such as persistent symptoms, indicative epidemiology, or other pertinent historical data. Because *H. influenzae* and *Streptococcus pneumoniae* frequently are part of the normal flora, their isolation is not always etiologically significant. If cultures reveal predominant growths of either *H. influenzae* or *S. pneumoniae*, however, they are likely contributing to the disease process, and antibiotic therapy directed at the specific pathogen would benefit the patient.[23,109,178] When the possibility of disease because of anaerobic agents exists, a Gram-stained smear from an exudative area may be rewarding. When the pharyngeal findings are unique, or when many cases of a similar illness are observed, a viral culture from the throat is indicated.

TREATMENT

The specific treatments of diseases with nasopharyngitis and pharyngitis are discussed in chapters of this book that deal with the individual pathogens. That antimicrobial agents are prescribed inappropriately in children with sore throat and pharyngitis is common knowledge. Based on the etiologic agents noted in Tables 10–1 and 10–2, it is apparent that many infectious agents are associated with nasopharyngitis and pharyngitis, which can be treated effectively with antimicrobial agents. Except in rare specific circumstances, the only common pathogens that require treatment are group A streptococci. The treatment of streptococcal pharyngitis is discussed in detail in Chapter 93. A study noted that physicians prescribed antibiotics to 53 percent of children with sore throat, which is far greater than the 15 to 36 percent likelihood of a group A streptococcal infection.[103] This study also noted that this rate of antimicrobial usage is an improvement from 1995, when the prescribing rate was 66 percent.

Although a multitude of proprietary remedies are available for respiratory infections, and sore throat specifically, none has a place in the care of pediatric patients. Particularly to be condemned are throat lozenges that contain numerous useless ingredients, many potentially harmful. Antibiotic-containing lozenges particularly are to be condemned because they may allow streptococcal disease to go unrecognized. Antiseptic mouthwashes have no value, and decongestants and antihistamines have no proven efficacy and frequently lead to troublesome side effects.

Because children with pharyngitis frequently feel ill, therapy with an analgesic is reasonable. Formerly, aspirin was the analgesic usually recommended. However, because aspirin is an etiologic factor in influenza-associated Reye syndrome and because differentiating influenza viral infections from other respiratory viral infections is difficult clinically, using acetaminophen rather than aspirin is prudent. The dose per single administration of acetaminophen by year of age is as follows: younger than 1 year, 60 mg; 1 to 3 years, 60 to 120 mg; 3 to 6 years, 120 mg; 6 to 12 years, 150 to 300 mg; older than 12 years, 325 to 650 mg. Administration may be repeated three or four times daily in young children and every 4 hours in older children. Acetaminophen rarely should be given to infants younger than 6 months old. In young children, careful attention to adequate hydration is particularly necessary.

PROGNOSIS

Almost all occurrences of nasopharyngitis and pharyngitis are self-limited, and the overall prognosis is excellent. Keeping a constant vigil for streptococcal and other more serious diseases is necessary, however. Failure to diagnose and to treat group A streptococcal infections, syphilis, and other more unusual infections can lead to serious short-term and long-term difficulties.

PREVENTION

Because pharyngitis and nasopharyngitis are caused by infections with many different respiratory pathogens, no practical specific approach to prevention exists. Occasionally, streptococcal disease can be prevented by the judicious use of prophylactic penicillin. For young children or others with undue susceptibility to serious disease with common respiratory pathogens, reducing contact situations (e.g., daycare centers) is prudent. In the 1980s, Paradise and colleagues[127] studied the effect of tonsillectomy on the rate of recurrent throat infections in severely affected children. In this controlled study, children needed to have a history of seven or more episodes of tonsillitis in the preceding year, or five or more episodes in each of 2 preceding years, or three or more episodes in the 3 preceding years. The findings in this study indicated that children in the surgical group had significantly fewer throat infections than occurred in the nonsurgical control group during the ensuing 2 years of follow-up. In a more recent but similar study with less stringent criterion for surgery, Paradise and colleagues[128] found that tonsillectomy or adenotonsillectomy conferred a modest benefit. They concluded, however, that the modest benefit of tonsillectomy or adenotonsillectomy in children with recurrent throat infections does not justify the risks, morbidity, and cost of the operations.

CHAPTER 11

HERPANGINA

James D. Cherry

Herpangina, a fairly frequent, acute febrile illness that occurs in the summer and fall in temperate climates, is characterized by papular, vesicular, and ulcerative lesions on the anterior tonsillar pillars, soft palate, tonsils, pharynx, and posterior buccal mucosa. It is caused by many different enteroviruses.

HISTORY

Zahorsky[48,49] generally is credited with the identification and characterization of the disease spectrum of herpangina. In his first publication in 1920 entitled "Herpetic Sore Throat," he presented the findings in 82 cases. In 1924, he introduced the term *herpangina* so that the clinical entity would not be confused with other diseases of the mouth and throat. In both articles, Zahorsky noted that Moro previously had referred to a similar illness in 1906. Johnsson and Lindahl[19] also reported that similar syndromes had been observed by Trousseau in 1906 and Marfan in 1924 and Moro in 1906. In 1939, Levine and associates[26] described epidemic herpangina in three summer camps, and in 1941, Breese[4] reported 28 cases that he observed during the summers of 1938 and 1940. In 1951, Huebner and associates[18] and Parrott and colleagues[35] established the etiologic relationship of group A coxsackieviruses to herpangina. In 1965, Cherry and Jahn[10] noted from the literature and from their own observations that herpangina resulted from infection with many echoviruses and group B coxsackieviruses as well as group A coxsackieviruses.

ETIOLOGIC AGENTS

Virologic studies in the early 1950s that used suckling mice inoculation indicated that several group A coxsackieviruses were the cause of epidemic herpangina.[18,20,22,35,39,45] In subsequent years, tissue culture techniques became widely used in diagnostic virology, and many studies revealed additional enteroviral types asso-

ciated with herpangina.[10] Except for the initial interest in herpangina in 1950, careful study of the etiology of epidemic disease has not been done. Most herpangina virus-illness associations that have been made during the last 50 years have resulted from secondary findings in other investigations.* Table 11–1 lists viral agents associated with herpangina. In recent years, group B coxsackieviruses and enterovirus 71 have been implicated most frequently. Diagnostic studies using suckling mice inoculation have been performed only rarely during the last 40 years, however. As noted in Table 11–1, herpes simplex virus also can cause a clinical picture suggestive of herpangina.[12,29] Zahorsky[49] suggested that the cause of poliomyelitis also could be etiologic in herpangina because a similar enanthem had been observed in sporadic and epidemic poliomyelitis.

EPIDEMIOLOGY

For a discussion of epidemiology, see sections on coxsackieviruses and echoviruses in Chapter 178.

PATHOPHYSIOLOGY

The pathophysiology of coxsackievirus and the pathophysiology of echovirus infections are discussed in their respective sections in Chapter 178. Simkova and Petrovicova[41] presented specific experimental data related to herpangina. In rhesus monkeys, these investigators found that oropharyngeal lesions typical of herpangina developed 2 to 7 days after oral, intravenous, or subcutaneous administration of coxsackievirus A4. This study indicated that the oropharyngeal lesions were the result of multiplication of virus at the secondary infection site after viremia, rather than a primary manifestation of initial cellular involvement.

CLINICAL MANIFESTATIONS

Although Zahorsky[48,49] and others[18,35] have considered herpangina a specific febrile disease, perhaps a more appropriate approach is to restrict the term *herpangina* to the characteristic oropharyngeal lesions. Herpangina is one of the protean manifestations of enteroviral infections, and it can occur in association with exanthem, aseptic meningitis, encephalitis, acute flaccid paralysis, and other clinical constellations.

The onset of herpangina is typical of most enteroviral infections and is characterized by the sudden awareness of fever.[4,35,48,49] No characteristic prodrome usually is present, but young children may be irritable and occasionally listless and anorexic for a few hours before the febrile state is recognized. The initial temperature can vary, with a range from normal to 41° C (106° F). Generally, the temperature tends to be higher in younger patients. Breese[4] noted that the most common temperature in young children was 39.5° C to 40° C (103° F to 104° F). Older children frequently complain of headache and backache. Vomiting occurs in approximately 25 percent of children younger than 5 years. In one outbreak of illness caused by coxsackievirus A4,[12] initial symptoms were anorexia and drooling (100%); sore throat (50%); coryza (45%); headache (18%); and vomiting, diarrhea, or both (36%).

In most instances of herpangina, the oropharyngeal lesions are present on the first examination at the time of fever or shortly after fever is noted. In the coxsackievirus A4 outbreak described by Forman and Cherry,[12] the enanthem was not observed until 24 to 48 hours after the onset of initial nonspecific symptoms. The characteristic lesions in herpangina are small (1 to 2 mm) vesicles and ulcers. These lesions apparently start as papules, become vesicular, and ulcerate in a short but variable period. In my experience, the lesions most commonly observed are ulcers. Breese[4] noted in many children seen early in the course of the illness that a petechial appearance preceded the appearance of typical vesicular-ulcerative enanthem.

The lesions usually are discrete, with an average of five per patient; some patients have only 1 or 2 lesions, whereas others may have 14 or more. When seen early, the vesicular lesions are observed to enlarge from 1 to 2 mm to 3 to 4 mm during a 2- to 3-day period.[35] Each vesicular and ulcerative lesion is surrounded by an erythematous ring that varies in size up to 10 mm in diameter. The most common site of the lesions is the anterior tonsillar pillars. Lesions also occur on the soft palate, uvula, tonsils, and pharyngeal wall and occasionally on the posterior buccal surfaces. In some cases, additional lesions have been noted on the dorsum or tip of the tongue. By definition, cases in which the primary involvement is on the tongue or anterior mouth and in which the lesions are of a general size greater than 5 mm are not considered to be herpangina.

Aside from the specific lesions, the remainder of the throat appears normal, minimally injected, or mildly erythematous. The usual duration of signs and symptoms is 3 to 6 days. Most cases of herpangina are mild and without complications, but aseptic meningitis and other more severe enteroviral manifestations also occur occasionally. More recently, severe neurologic manifestations have been observed in children with herpangina caused by enterovirus 71.[5,6,8,16,17,21,27,40] During epidemic disease in Taiwan in 1998, children with herpangina and aseptic meningitis, acute

*See references 1-3, 5-8, 10-17, 21, 23-25, 27-32, 34, 36-38.

flaccid paralysis, and rhombencephalitis were described.[16,17,40] In one study, a biphasic course was described, with herpangina occurring first and neurologic manifestations appearing 2 to 5 days later.[17]

Routine laboratory studies are of little value in herpangina. The total white blood cell count may be normal or slightly elevated; the differential count most often is normal.

DIFFERENTIAL DIAGNOSIS

The classic appearance of the oropharynx in herpangina renders establishing the diagnosis easy. Herpangina can be differentiated clearly from bacterial pharyngitis on clinical grounds, so obtaining bacterial cultures seldom is necessary. The follicular lesions of adenoviral infections can be confused with herpangina, but they frequently are exudative, not ulcerative, and associated with a more marked, generalized, erythematous pharyngitis than is seen in herpangina. Additional differential considerations are discussed elsewhere (see Chapters 10 and 178).

SPECIFIC DIAGNOSIS

In most instances, a clinical diagnosis is all that is necessary. Because herpangina is a good indicator of enteroviral disease in a community, however, submission of throat or rectal specimens to a viral diagnostic center can be rewarding.

TREATMENT, PROGNOSIS, AND PREVENTION

No treatment is necessary other than attention to hydration and observation for signs of more severe enteroviral illness. Except in rare instances (associated myocarditis, encephalitis), the prognosis is excellent. No general preventive measures are necessary, but a wise policy is not to expose young children unnecessarily to individuals known to be afflicted.

CHAPTER 12

Pharyngoconjunctival Fever

James D. Cherry

Pharyngoconjunctival fever is an acute, communicable disease syndrome characterized by fever, pharyngitis, and conjunctivitis. It is caused by several serologic types of adenovirus. Illness is epidemic and sporadic.

HISTORY

Shortly after the first isolation of adenoviruses in tissue culture by Rowe and associates[54] in 1953, the clear association of infection with certain adenoviral types and the syndrome of fever, pharyngitis, and conjunctivitis were established.[52] For an approximate 5-year period after the discovery of the adenoviral etiology of pharyngoconjunctival fever, the literature contained numerous confirmatory reports from throughout the world.* In almost all reports, the association between swimming and the contraction of the syndrome was noted. A quick perusal of the reports would suggest that the syndrome and the etiologic agents were new discoveries. Epidemics of pharyngoconjunctival fever–like illness have been noted throughout the 20th century, however. In 1907, Béal[4] in France was perhaps the first to note the syndrome. In the 1920s, epidemics of febrile disease with conjunctivitis associated with swimming in public pools and lakes were noted in Germany[51] and the United States.[2] It is likely that "swimming bath conjunctivitis," as described by Derrick[16] in 1943, was caused by adenoviral infection. An epidemic of conjunctivitis studied by Cockburn and associates[12] in Greeley, Colorado, in 1951 later was proved to have been caused by adenovirus type 3.

In more recent years, reports of pharyngoconjunctival fever have been relatively few.** My experience suggests that this paucity is not because of a decrease in prevalence of the syndrome but because of a general disinterest in the differential diagnosis of viral respiratory disease.

ETIOLOGIC AGENTS

In epidemic pharyngoconjunctival fever, the most likely etiologic agent is adenovirus type 3.† The next most prevalent adenovirus associated with epidemic disease is type 7.[9,17,22,73] One or more epidemics also have been noted with adenoviruses 2, 4, 7a, 11, and 14.[1,7,15,18,19,48,66,67,76] Sporadic occurrences of pharyngoconjunctival fever have been observed in association with infections with adenoviruses 1, 2, 3, 4, 5, 6, 7, 7a, 8, 14, 19, and 13/30 (an intermediate type).‡

EPIDEMIOLOGY

Pharyngoconjunctival fever occurs in large community-wide epidemics, in focal outbreaks, and as sporadic cases. Most major community epidemics have occurred in the summer and have been centered around public swimming facilities. Two community outbreaks involving primarily swimmers have occurred in the winter.[9,23] In swimming-associated outbreaks, infection probably occurs by conjunctival inoculation of adenoviruses from contaminated water. To date, however, the virus has been recovered from the incriminated water in only two outbreaks.[15,46] In one outbreak, adenovirus type 4 was recovered from water samples on two occasions 14 days apart.[15] More recently, adenovirus type 3 was recovered from a pool in which 681 campers had symptoms.[46] In this outbreak, the frequency of swimming and the history of towel sharing increased the risk of acquiring illness. Adenovirus type 3 also was recovered from a sewage outlet area in a lake that was close to a swimming beach.[42]

The incubation period of swimming-associated infections is approximately 5 to 7 days.[6,23,36,67] Secondary cases regularly occur in contacts (most often family members) of swimming-acquired cases. In these instances, the incubation period frequently is slightly longer (9 days).[3,23] This longer period of incubation may be due to a delay in the time of spread of the virus to the contact, rather than an actual prolongation of incubation. Secondary cases probably result from large-droplet respiratory spread to the conjunctiva, the upper respiratory tract, or both. An alternative method would be the contamination of the recipient's hands with eye discharge followed by autoinoculation of the conjunctiva.

In non–swimming-associated outbreaks of adenoviral respiratory illness with appropriate serotypes, conjunctivitis occurs only rarely.[8,21,30,35,41,63] This fact, in conjunction with the finding that pharyngoconjunctival fever occurred after conjunctival administration of virus, but not after nasopharyngeal application in volunteers,[7,58,71] suggests that the conjunctiva must be inoculated directly for the syndrome to occur. After conjunctival inoculation, pharyngeal spread and systemic illness occur. After direct respiratory inoculation, the conjunctiva does not become involved, unless respiratory secretions containing virus are applied to the conjunctiva, presumably by autoinoculation. Hospital outbreaks of pharyngoconjunctival fever–like illnesses have been reported.[20,43] Most instances have occurred in intensive care units. An outbreak of pharyngoconjunctival fever also has been noted in a daycare center.[11]

Although some early epidemic investigations suggested that boys were more susceptible to disease than were girls,[22,66] the incidence of pharyngoconjunctival fever in children does not differ by sex.[6,60] In some cultures, boys had more exposure to swimming and accounted for more cases of illness. In an outbreak that occurred in children hospitalized in Japan for long-term treatment of bronchial asthma, the attack rate was 68.2 percent in boys and only 6.3 percent in girls. This sex difference was attributed to the fact that the boys and girls took separate daily communal baths. Secondary cases in adult family members occur more commonly in mothers than in fathers, presumably because of greater contact with the children.[7,23]

PATHOPHYSIOLOGY

The route of infection with adenoviruses that are capable of causing pharyngoconjunctival fever determines the pathologic manifestations. Conjunctival biopsy specimens in volunteer studies revealed an inflammatory response with lymphocytic infiltration of the submucosal layer.[5,7] Biopsy material from pala-

tine tonsils of infected volunteers revealed hypertrophy and hyperplasia of the lymphoid tissue, with congestion and edema of the surrounding connective tissue.

CLINICAL PRESENTATION

By definition, pharyngoconjunctival fever is a syndrome characterized by fever, pharyngitis, and conjunctivitis. During epidemics, not all children and adults who have the same infection have the complete syndrome triad. Some patients have only pharyngitis, and some have only conjunctivitis. For purposes of this discussion, all descriptions of frequency of signs and symptoms are calculated from the starting point of 100 percent fever, pharyngitis, and conjunctivitis.

Tables 12–1 and 12–2 summarize the frequencies of specific symptoms and signs.* Although some patients have noted mild prodromal symptoms of headache and malaise, the usual onset of illness is abrupt, with sore throat, generalized aches and pains, eye irritation or pain, and fever. Throat complaints vary from mild to severe. In some patients, only a dry, scratchy feeling is reported; others have noted the feeling of a foreign body. On examination, the tonsils and pharyngeal lymphoid tissue are hypertrophied. The degree of pharyngeal redness and infection varies considerably from patient to patient. Approximately one third of affected patients have follicular exudative lesions that cannot be differentiated from streptococcal disease on clinical grounds. Follicular lesions also have been noted on the soft palate, and the papillae of the tongue may be hypertrophied.

Hypertrophy of the adenoids occurs, which results in nasal blockage. Coryza is a common occurrence. Posterior nasal discharge is a common occurrence and leads to cough in many instances. In some investigations, epistaxis has occurred in 20 percent of the cases.[57,66]

*See references 5, 9, 22, 25, 36, 39, 40, 45, 52, 57, 58, 66.

Generally, complaints related to conjunctivitis are fewer than might be suggested by the usual physical appearance. Most patients note some aching or soreness; photophobia and lacrimation are unusual occurrences. The appearance of the palpebral conjunctiva usually is granular. The lesions may be almost microscopic or 2 to 3 mm in diameter. Hemorrhages occasionally are noted on the bulbar surface. Frequently, involvement starts in one eye and does not involve the other eye until 2 or 3 days later. Occasionally, the involvement is restricted to one eye.

Some degree of anterior and posterior cervical lymphadenopathy occurs in most patients. Preauricular involvement occurs surprisingly infrequently when the degree of eye involvement is taken into consideration. Generalized lymphadenopathy is observed in 10 to 20 percent of affected patients, and liver and spleen enlargement occurs frequently.

Most patients complain of generalized symptoms, but the degree varies considerably among affected patients. Temperatures greater than 39° C (102.2° F) occur in more than 50 percent of the patients, and headache is the rule. General malaise and anorexia are common occurrences; gastrointestinal symptoms occur in approximately 25 percent of cases. Vomiting and diarrhea occur most commonly in younger age groups.

Compared with other respiratory viral infections, the duration of illness with pharyngoconjunctival fever is long. In most patients, the fever is sustained or remittent for 3 to 4 days, then temperature gradually returns to normal within 24 to 48 hours. Approximately 10 percent of patients have fever that lasts longer than 7 days. Throat and eye findings usually are improved considerably by the seventh day of illness, but these findings and nasal complaints, fatigue, and headache may persist for 14 days.

Early in the illness, the total white blood cell count is within normal limits or slightly elevated, with a normal differential count or one with a slight increase in polymorphonuclear leukocytes. During convalescence, many patients have a moderate leukopenia with an equal number of lymphocytes and polymorphonuclear cells. Smears from affected conjunctivae usually do not reveal abnormalities on cytologic examination.

DIFFERENTIAL DIAGNOSIS

Because the symptom triad of fever, pharyngitis, and conjunctivitis is virtually unique to pharyngoconjunctival fever, establishing the diagnosis should be easy. The only difficulty on clinical grounds is in trying to assign a specific type of adenovirus. Generally, major epidemic disease is most likely to be caused by type 3 or 7; sporadic cases can occur with types 1 to 8, 14, 19, and 13/30. Manifestations by different adenoviral types have no known differences.

Of some concern in the differential diagnosis is picornavirus epidemic conjunctivitis (acute hemorrhagic conjunctivitis).[44,74,75] Two enteroviruses (coxsackievirus A24 and enterovirus 70) have been implicated etiologically in several extensive outbreaks of disease. Affected patients have had severe conjunctivitis with preauricular lymphadenitis, but fever and pharyngitis have not been prominent associated signs. In one outbreak, 23 percent of patients studied had upper respiratory tract symptoms.[44]

Generalized diseases that occasionally might be confused with pharyngoconjunctival fever include leptospirosis, psittacosis, *Mycoplasma pneumoniae* infection, Q fever, Newcastle disease virus infection, and prodromal measles. Of these illnesses, all but Newcastle disease virus infection have generalized symptoms that are disproportionately more important than the symptoms of either conjunctivitis or pharyngitis. Human infection with Newcastle disease virus could be confused easily on clinical grounds with pharyngoconjunctival fever. A history of exposure to chickens or other fowl should aid in establishing the diagnosis.

Of more difficulty in making a differential diagnosis are illnesses usually characterized by either pharyngitis or conjunctivitis. Occasionally, infections with influenza viruses, parainfluenza viruses, enteroviruses (other than coxsackievirus A24 and enterovirus 70), and Epstein-Barr virus are confusing. Although eye complaints do occur in these illnesses, severe conjunctivitis usually does not occur.

The differential diagnosis of conjunctivitis includes bacterial infections caused by *Haemophilus influenzae*, *Streptococcus pneumoniae*, *Streptococcus pyogenes*, and *Neisseria gonorrhoeae*. In all of these infections, purulent discharge is greater than that usually observed in pharyngoconjunctival fever. *Chlamydia trachomatis* infections are perhaps the most troublesome in the differential diagnosis. In the past, many cases of swimming pool conjunctivitis were attributed to chlamydial infections. Many such reported cases in reality probably were adenoviral infections. *C. trachomatis* infections can be diagnosed by showing characteristic inclusions in Giemsa-stained scrapings from the palpebral conjunctivae, by direct immunofluorescence, by enzyme immunoassay, or by culture. Epidemic adenoviral keratoconjunctivitis is another differential diagnostic consideration. Other differential diagnostic possibilities that should cause no difficulty include cat-scratch fever, tularemia, *Acanthamoeba* keratitis, and allergic conjunctivitis.

SPECIFIC DIAGNOSIS

In most instances, a clinical diagnosis is all that is necessary. Specific viral diagnosis can be accomplished with ease in any routinely equipped diagnostic virology laboratory. Diagnosis can be made by isolation of virus in tissue culture or by direct antigen detection by indirect immunofluorescence, enzyme-linked immunosorbent assay, or polymerase chain reaction analysis.[11,14,53,68] Cultures from the conjunctivae generally are more diagnostically specific than are cultures from the throat. The recovery of an adenovirus (particularly type 2) from the throat in an isolated case does not indicate an etiologic role for the recovered virus. An adenoviral etiology also can be verified by studying paired serum samples for a titer increase to the adenoviral group antigen.

TREATMENT

Generally, no treatment is necessary or effective in pharyngoconjunctival fever. If conjunctivitis persists and becomes purulent, an investigation for bacterial pathogens and appropriate topical antimicrobial therapy are indicated. Use of steroid-containing ophthalmic ointments should be avoided.

PROGNOSIS

The prognosis generally is excellent. Although superficial keratitis occasionally occurs, permanent scarring is not a problem. Sinusitis, otitis media, and bacterial conjunctivitis are rare secondary complications that, if untreated, can result in long-term difficulties.

PREVENTION

Volunteer studies have clearly indicated that infection and presumable resultant antibody are protective against future disease. Protection theoretically could be achieved through immunization, but priority given to study and to implement an immunization program is low. Because the major cause of pharyngoconjunctival fever caused by adenoviruses is swimming in contaminated water, discretion in bathing locations is advised. Swimming pool water should be chlorinated adequately, and pool filtration systems should be inspected daily. Ill individuals should be excluded from swimming pools during their illness and for at least 2 weeks after recovery.

CHAPTER 13

UVULITIS

Ellen R. Wald

Infections of the uvula have been reported infrequently in the medical literature. When the uvula is the most inflamed structure in the posterior pharynx of a febrile child, acute infection should be suspected. Other causes of uvulitis include trauma (from instrumentation), inhalant irritation (from cannabis use), vasculitis, and allergy.[3,5,11]

ETIOLOGY

The main bacterial agents that cause uvulitis in children include *Haemophilus influenzae* type b (Hib) and *Streptococcus pyogenes*.[6] Uvulitis caused by *H. influenzae* may occur concurrently with epiglottitis or as an isolated infection.[8,14] Uvulitis caused by *S. pyogenes* seems always to occur in concert with pharyngitis. Brook[2] reported two cases of uvulitis caused by anaerobic bacteria, *Fusobacterium nucleatum* and *Prevotella intermedia*. No search for viral agents has been conducted. Several cases of uvulitis caused by *Candida albicans* have been described in immunocompetent toddlers.[7] In adults, *Streptococcus pneumoniae* and *H. influenzae* have been reported to cause uvulitis.[4,13] In many patients, an associated epiglottitis has been present.[10,13]

EPIDEMIOLOGY

The epidemiology of uvulitis is the epidemiology of its two etiologic agents, *S. pyogenes* and Hib. It occurs in school-age children 5 to 15 years old (the so-called streptococcal age group) in association with pharyngitis. Similarly, it can be seen in the *H. influenzae* age group (3 months to 5 years) if a child has not received the now routine and universally recommended conjugate vaccine to prevent infections caused by Hib. Cases of uvulitis in association with epiglottitis have been reported in the United States and in England.[2,6,12] Infections caused by *S. pyogenes* and *H. influenzae* occur primarily in the winter and spring, but both types can occur throughout the year.

PATHOGENESIS

Uvulitis is an acute cellulitis characterized by dramatic swelling and erythema. Infection of the uvula probably arises from direct invasion by *S. pyogenes* or Hib; both are recognized as normal nasopharyngeal flora. In the latter case, epiglottitis also may arise by direct extension, and the bacteremia may result secondarily from either the uvula or the epiglottis as a primary site of infection.

Uvulitis that is noninfectious may result from injury, chemical irritation, or allergic inflammation. A child ultimately diagnosed to have Kawasaki disease presented with uvulitis.[5]

CLINICAL MANIFESTATIONS

In a review of five patients with streptococcal uvulitis, all had associated pharyngitis.[6] The patients presented with low-grade fever and sore throat. Three of the five patients experienced a choking or gagging sensation in the pharynx that induced coughing and spitting; one of these patients also presented with drooling. Although pharyngitis was noted on physical examination, the swelling and erythema of the uvula were most dramatic (Fig. 13–1). None of the patients had evidence of respiratory distress.

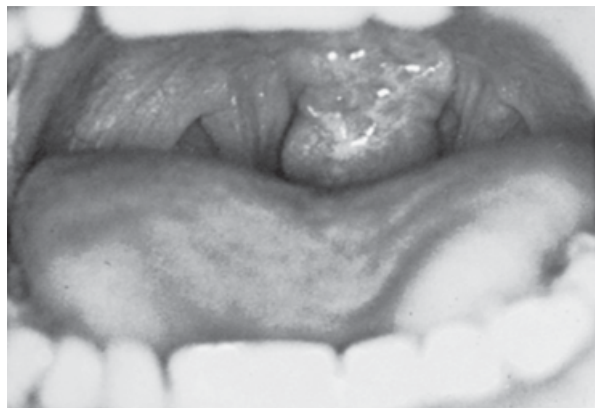

Figure 13–1 Swollen (two to three times normal size) and erythematous uvula in a patient without epiglottitis or pharyngitis.

In most children with uvulitis and epiglottitis, the presentation usually is typical for epiglottitis, with sudden onset of high fever, dysphagia, and increasing respiratory distress. Rapkin[12] reported a case of uvulitis and epiglottitis, however, in which the epiglottitis initially was unsuspected. The same observation has been made in some adults with uvulitis and epiglottitis.[4,10] Lateral neck radiography (performed in one case to evaluate the possibility of a retropharyngeal abscess) belatedly alerted the clinicians to the correct diagnosis.

In patients with uvulitis and no epiglottitis, the presentation may be similar to that of epiglottitis (acute onset of fever, odynophagia, and drooling) or less specific, with fever and irritability or decreased appetite.[8,14] The diagnosis in these cases is provided by physical examination of the oropharynx, which shows a swollen and erythematous uvula (see Fig. 13–1).

DIAGNOSIS

The diagnosis of streptococcal uvulitis is suspected when a school-age child presents with low-grade fever, pharyngitis, and uvulitis. The diagnosis is confirmed by the recovery of *S. pyogenes* from a surface culture of the throat or uvula or both.

The diagnosis of uvulitis caused by *H. influenzae* is suspected in a highly febrile infant or preschool-age child who has uvular inflammation on physical examination. Lateral neck radiography must be performed to evaluate the possibility of epiglottitis, unless obvious signs of upper respiratory obstruction are present, in which case immediate endoscopy is warranted. If epiglottitis is discovered, the airway must be secured, and appropriate parenteral antimicrobials must be initiated after blood and surface culture specimens are obtained. Any surface culture specimen obtained to search for *H. influenzae* must be plated onto chocolate agar. After appropriate culture specimens are obtained, parenteral antimicrobials should be initiated, as in other infections associated with bacteremia caused by *H. influenzae*.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of a patient with acute onset of fever, dysphagia, and drooling includes herpes simplex gingivostomatitis, uvulitis, epiglottitis, severe pharyngitis, and peritonsillar or retropharyngeal abscess. Although being extremely cautious in examining the pharynx of any patient with suspected epiglottitis is appropriate, some children tolerate attempted visualization of the oral cavity without becoming unduly upset. Instrumentation with a tongue blade should be avoided. If the examination does not show gingivostomatitis or peritonsillar abscess, lateral neck radiography should be performed. If epiglottitis or retropharyngeal abscess is confirmed, management of the airway and administration of antimicrobials are indicated for epiglottitis, and incision and drainage and antimicrobials are indicated for retropharyngeal abscess. If the lateral neck is normal and the uvula is inflamed, uvulitis with or without pharyngitis is confirmed.

TREATMENT

Management of uvulitis is guided primarily by the associated pharyngitis or epiglottitis, if either is present. In the case of streptococcal pharyngitis, penicillin therapy for 10 days is most appropriate. These patients usually can be treated orally with penicillin V, 25 to 50 mg/kg/day, administered in two divided doses.

In the case of uvulitis and epiglottitis, management of the airway is most important and can be accomplished by performing nasotracheal intubation or tracheotomy. Appropriate parenteral antibiotic therapy usually is initiated.

In the case of uvulitis without epiglottitis in an infant or preschool-age child, antimicrobial therapy should be planned for possible Hib bacteremia. Generally, approximately 50 percent of respiratory isolates of *H. influenzae* are β-lactamase producing. Administration of an advanced-generation cephalosporin, such as cefotaxime at 200 mg/kg/day in four divided doses or ceftriaxone at 100 mg/kg/day in one dose or two divided doses, is appropriate. In a patient with serious penicillin hypersensitivity, aztreonam at 100 mg/kg/day in three divided doses also is a satisfactory regimen. After the patient has defervesced and has improved clinically, an oral antimicrobial agent can be substituted. The results of blood and surface cultures now can guide therapy. For an ampicillin-sensitive *H. influenzae* infection, amoxicillin at 45 mg/kg/day in two divided doses should be prescribed to complete a 7- to 10-day course of treatment. For β-lactamase-producing *H. influenzae*, a variety of oral agents, including cefixime at 10 mg/kg in a single daily dose, cefuroxime at 30 mg/kg/day in two divided doses, or amoxicillin-potassium clavulanate at 45 mg/kg/day of amoxicillin in two divided doses, can be prescribed.

Resolution was prompt in the two cases of uvulitis allegedly caused by *C. albicans*. One child was treated with topical nystatin, and the other had spontaneous improvement.[7]

CHAPTER 14

Peritonsillar, Retropharyngeal, and Parapharyngeal Abscesses

Nira A. Goldstein ✪ Margaret R. Hammerschlag

A deep neck abscess is a collection of pus in a potential space bounded by fascia.[6] These potential spaces are areas of least resistance to the spread of infection. An infection may begin with a minimal area of cellulitis and progress to a deep neck abscess, which may extend to invade adjacent potential spaces; these spaces frequently encompass vital structures in the neck. Destruction and dysfunction of these structures represent the major complications of deep neck infections.[44]

EPIDEMIOLOGY OF HEAD AND NECK SPACE INFECTIONS IN CHILDREN

Data concerning the frequency of head and neck space infections in children are limited. A survey conducted by the American Academy of Otolaryngology found the incidence of peritonsillar abscesses to be approximately 30 per 100,000 person-years, or approximately 45,000 cases annually in the United States and Puerto Rico.[32] A retrospective study from the Children's Hospital of Pittsburgh identified 117 children with head and neck space infections seen between 1986 and 1992.[72] The patients ranged in age from 1 month to 18 years (mean age 7.8 years).[72] Peritonsillar space infections (cellulitis and abscesses) occurred most frequently, accounting for 61 (49%) cases, followed by retropharyngeal space infections, accounting for 27 (22%) cases. Only three (2%) parapharyngeal space infections were seen during the period of the study. Broughton[14] reported seeing 14 pediatric patients, 15 months to 17 years of age, with retropharyngeal and parapharyngeal space infections during a 9-year period at the University of Kentucky Medical Center. Craig and Schunk[18] described 64

cases of retropharyngeal abscesses in children at the Primary Children's Medical Center in Salt Lake City, Utah, from 1993 to 1998, a higher number of cases than previously reported. Kirse and Roberson[40] reported 73 cases of retropharyngeal space infection from 1989 to 1998, with a twofold to fivefold increase in the number of patients treated in the last 4 years of the study compared with the first 6 years.

Peritonsillar abscesses rarely occur in young children. They occur most frequently in patients in their late teens and early 20s. The mean age of the children with peritonsillar infection in Pittsburgh was 11 years, whereas the mean age of the patients with retropharyngeal space infections was 4 years, similar to the mean age of 4.5 years reported by Thompson and associates[71] in their 36-year review of 65 children with retropharyngeal abscesses treated at the Children's Hospital of Los Angeles. Retropharyngeal abscesses have been reported to occur more frequently in young children. In the Salt Lake City series, the median age was 3 years, and 75 percent of the children were younger than 5 years.[18]

All of the peritonsillar infections were associated with tonsillitis, and 15 percent had antecedent infectious mononucleosis shown by positive monospot test results.[72] Results of a meta-analysis of 15 previously reported series of patients with peritonsillar abscess reported by Herzon[32] found prior tonsillar infection rates ranging from 11 to 56 percent, with an overall rate of 36 percent. The high incidence of peritonsillar abscess reported in the American Academy of Otolaryngology study raised the possibility that the decreasing rate of tonsillectomy might increase the risk for development of peritonsillar abscess.[32]

PERITONSILLAR ABSCESS (QUINSY)

A peritonsillar abscess (quinsy) is circumscribed medially by the fibrous wall of the tonsil capsule and laterally by the superior constrictor muscle. Pus may be localized in the superior pole, midpoint, or inferior pole or rarely may be dispersed, with multiple loculations in the peritonsillar space. The superior pole is the most common location, with a frequency range of 41.2 to 70 percent; the remaining inferior locations account for the balance.[7,10,46]

The etiology of peritonsillar abscesses is not constant. They may occur after any "virulent" tonsillitis, with extension through the fibrous tonsil capsule.

CLINICAL MANIFESTATIONS

The recent history may include a sore throat with occasional unilateral ear pain, malaise, low-grade pyrexia, chills, diaphoresis, dysphagia, reduced oral intake, trismus, and a muffled "hot potato voice." Trismus results from irritation and reflex spasm of the internal pterygoid muscle. Sixty-three percent of the children with peritonsillar infection from the Pittsburgh series had trismus.[72] Impaired palatal motion from edema contributes to the muffled voice.

Physical examination reveals minimal to moderate toxicity, dehydration, and drooling. Inspection of the oropharynx may be compromised by trismus. The soft palate is displaced toward the unaffected side, swollen and red, and frequently palpably fluctuant. The edematous uvula is pushed across the midline (Fig. 14–1). The displaced tonsil and its crypts rarely are coated with exudate. The breath is fetid, and ipsilateral, tender, cervical adenopathy is present. The white blood cell count is elevated, with a predominance of polymorphonuclear leukocytes.

Brodsky and associates[11] attempted to identify the clinical signs that might distinguish peritonsillar abscess from peritonsillar cellulitis in a group of 21 children admitted to the Children's Hospital of Buffalo from 1985 through 1987. No significant difference in age, duration of sore throat, fever, or white blood cell count was noted, although a greater degree of pharyngotonsillar bulge and muffled voice was found in the patients with abscess. Patients with peritonsillar cellulitis improved after receiving 24 hours of intravenous antibiotics, whereas patients with peritonsillar abscess had no change or worsening of symptoms. Blotter and colleagues[8] confirmed these findings in 102 patients admitted to Children's Hospital of Columbus, Ohio, between 1995 and 1998.

In uncomplicated cases, computed tomography (CT) scan has not been as useful as clinical assessment and follow-up evaluation in the management of peritonsillar abscess. CT scans are useful in young children with suspected peritonsillar abscess who are

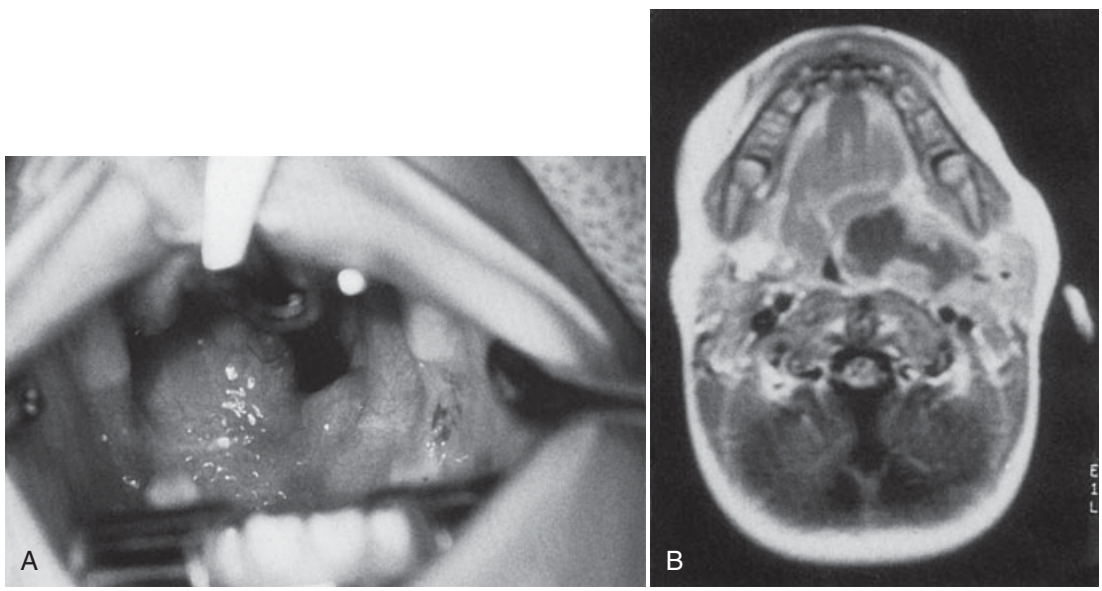

Figure 14–1 Left peritonsillar abscess in an 18-month-old child. *(From Wiatrak, B. J., and Woolley, A. L.: Pharyngitis and adenotonsillar disease. In Cummings, C. W., Flint, P. W., Harker, L. A., et al. [eds.]: Otolaryngology: Head and Neck Surgery. 4th ed. Philadelphia, Elsevier, 2005, p. 4144.)*

not cooperative with examination or children with other suspected deep neck infections.[27]

TREATMENT

Traditionally, management of peritonsillar abscess in children involved hospital admission for intravenous hydration, antibiotic therapy and analgesia, and either intraoral incision and drainage of the abscess or "acute quinsy tonsillectomy" with removal of the medial wall of the abscess. Although older children may tolerate incision and drainage under local anesthetic, the procedure is not well tolerated in young children and carries the risk of potential injury to adjacent vascular structures. The administration of a general anesthetic is required for tonsillectomy in all age groups and often is required for incision and drainage in young children. Acute tonsillectomy often was done to prevent future recurrence of the peritonsillar abscess.

Although it is a commonly accepted clinical observation, a high recurrence rate of peritonsillar abscess has not been well documented. A meta-analysis reported by Herzon[32] of 19 studies from the United States, Europe, and Israel involving 1399 patients found recurrence rates of 10 to 15 percent for peritonsillar abscess. The rates of recurrence seem to be lower in the United States (0 to 17%) than in the series reported from Europe and Israel (3 to 22%). A retrospective analysis of 290 patients treated for peritonsillar abscess found that patients who had a history of recurrent tonsillitis before development of the abscess had a fourfold greater rate of recurrence than patients with no history (40 versus 9.6%).[41] The authors recommended that patients with a history of recurrent tonsillitis before admission be treated with tonsillectomy.[41]

The risks of acute tonsillectomy are not greater than the risks associated with delayed tonsillectomy.[45,51,77] In addition, the morbidity caused by two hospitalizations involving two procedures is reduced by acute tonsillectomy.[4,9,10] An additional benefit of acute tonsillectomy is the ability to evacuate inferior pole abscesses that technically are difficult to drain by needle aspiration or incision and drainage.[46]

Studies have suggested that many peritonsillar abscesses can be managed by simple needle aspiration combined with antibiotic therapy on an outpatient basis.[11,32,58,60,61,66,72,74] An extensive meta-analysis of 10 studies conducted from 1961 through 1994 involving 496 patients with peritonsillar abscesses found that needle aspiration had an overall success rate of 94 percent (range 85 to 100%).[32] This success rate compares favorably with that reported for incision and drainage. Weinberg and associates[74] successfully performed needle aspiration in 41 of 43 children 7 to 18 years old (mean age 13.9 years). All were admitted for intravenous antibiotic therapy, two (5%) required repeated aspiration for resolution, and five (12%) did not respond and required acute tonsillectomy. A pooled analysis of three prospective studies comparing needle aspiration versus incision and drainage showed no significant difference in resolution rates (93.7% for incision and drainage and 91.6% for needle aspiration), but the power was low because of the small sample size.[36] Other studies, which have included adults and children with peritonsillar abscesses, have reported that 0 to 48 percent of patients require hospitalization.[32,51,58,66]

Younger children often require admission to correct dehydration.[27] Younger children also are more likely than are older children to respond to intravenous antibiotics alone and to have negative findings at surgical drainage.[8] The use of conscious sedation has been reported to be a safe and effective approach for the drainage of peritonsillar abscesses in children.[48,67]

In a 10-year retrospective review of 83 children with peritonsillar abscesses by Schraff and colleagues,[61] 65 percent were treated by incision and drainage (51% knife versus 14% needle aspiration), 31 percent had quinsy tonsillectomy, and 4 percent were admitted and treated by intravenous antibiotics alone. Of patients treated surgically, 51 percent of the procedures were done in the emergency department, and 49 percent were done in the operating room. Forty-eight percent of the children required admission, and the average length of stay was 0.9 days (standard deviation 1.37).

A suggested approach to the management of children with peritonsillar abscess is as follows.[33] Cooperative children should undergo needle aspiration of the abscess and treatment with antibiotics. Children who can tolerate liquids orally may be managed as outpatients, and the remainder should be admitted for hydration and administration of intravenous antibiotics. Approximately 4 percent of children require a repeated aspiration for resolution.[32] Children who remain symptomatic after undergoing needle aspiration require incision and drainage or acute quinsy tonsillectomy, depending on the prior history of recurrent tonsillitis. Children who cannot tolerate needle aspiration on initial presentation are admitted for administration of intravenous antibiotics. If no response occurs within 24 hours, incision and drainage or acute tonsillectomy is done, depending on the prior history of recurrent tonsillitis. Delayed tonsillectomy is reserved for children who recover from the peritonsillar abscess without general anesthesia but have a history of recurrent tonsillitis or prior peritonsillar abscess.

Untreated peritonsillar abscess may point, with spontaneous rupture, or extend to the pterygomaxillary space, with potentially fatal complications. Upper airway obstruction, septicemia, and vascular catastrophe may occur. Necrotizing fasciitis also has been reported in adults with peritonsillar abscess.[28,75]

RETROPHARYNGEAL ABSCESS (POSTERIOR VISCERAL SPACE, RETROVISCERAL SPACE, AND RETROESOPHAGEAL SPACE ABSCESSES)

The anterior wall of the retropharyngeal space is the middle layer of the deep cervical fascia, which abuts the posterior esophageal wall (the superior pharyngeal constrictor muscle). The deep layer of the deep cervical fascia circumscribes the posterior wall of this potential space. Inferiorly, these two fasciae fuse to limit the depth of this pocket at a level between the first and second thoracic vertebrae. A retropharyngeal abscess can erode inferiorly through the junction of these fasciae to extend posteriorly into the prevertebral space (Fig. 14–2). Subsequently, pus in the prevertebral space can descend inferiorly below the diaphragm to the psoas muscles.

The retropharyngeal space contains two paramedial chains of lymph nodes that receive drainage from the nasopharynx, adenoids, posterior paranasal sinuses, middle ear, and eustachian tube. These structures are prominent in early childhood and atrophy at puberty.[29] Retropharyngeal abscesses are common occurrences in young children and are thought to be secondary to suppurative adenitis of these retropharyngeal nodes.[3] Other sources of infection are penetrating foreign bodies, endoscopy, trauma, pharyngitis, vertebral body osteomyelitis, petrositis, dental procedures,[72] and branchial cleft anomalies.[35] In one series of 17 cases of retropharyngeal abscesses at the Children's Hospital, Denver, Colorado, 7 children (41%), including 2 neonates (most likely associated with attempts at intubation), had perforations of the hypopharynx or esophagus.[53] In the Pittsburgh series, 63 percent of the children with retropharyngeal abscess had antecedent tonsillitis, pharyngitis, or viral upper respiratory tract infection.[72] Two children had previous trauma; however, no details on the type of trauma were given.

In adults, tuberculosis and syphilis were common causes of retropharyngeal abscesses in the pre-antibiotic era.[56] Four of

The black oblique line represents the level of the drawing in **A.**

seven patients treated for retropharyngeal abscess at Columbia-Presbyterian Medical Center in New York during a 6-year period had serologic evidence of acute primary Epstein-Barr viral infection.[69]

CLINICAL MANIFESTATIONS

The symptoms of retropharyngeal abscess frequently begin insidiously after mild antecedent infection. Signs and symptoms include sore throat, fever, limitation of neck motion, torticollis, neck pain, neck mass, drooling, odynophagia, poor oral intake, and lethargy. Airway stridor or respiratory distress from edema, cellulitis, or an obstructing mass occasionally occurs.[17,18,20,73] Thirty-three percent of the 27 children with retropharyngeal abscess in the Pittsburgh series had torticollis or limitation of neck motion,[72] compared with 53 of the 94 children (83%) in the Las Vegas series.[18] In adults, the symptoms may be milder. Complaints of chest pain by an adult may reflect mediastinal extension.

Early in the course, midline or unilateral swelling of the posterior pharynx occurs. Later, gentle palpation may show a large fluctuant mass in the posterior pharynx. Vigorous palpation should be avoided because it may cause the abscess to rupture into the upper airway. As with other abscesses, the white blood cell count is increased, with a predominance of granulocytes.

Plain films of the neck often are the initial radiologic study, but they must be obtained with the patient in a true lateral position, with the neck in extension, and on inspiration, or the child's retropharyngeal soft tissues may appear abnormally thickened. Widening of the prevertebral soft tissues exceeding the anteroposterior diameter of the contiguous vertebral bodies, or thickening of the retropharyngeal space greater than 7 mm at C2 in children and adults, or 14 mm at C6 in children or 22 mm at C6 in adults suggests retropharyngeal inflammation. Rarely, a prevertebral soft tissue mass, air-fluid level, or gas may be seen. The normal cervical lordosis may be lost or reversed secondary to muscle spasm or local inflammation (Fig. 14–3).

CT scan has rendered the diagnosis and management of deep neck space infections more precise.[12,23,40,43,70,73,76] In contrast to conventional radiologic studies, CT scan distinguishes cellulitis of the neck, which usually does not require surgical treatment, from a deep neck abscess, which does require surgical drainage. With its ability to define differences in tissue density, CT scanning permits an accurate determination of the extent of the abscess and its extension and involvement of adjacent spaces to be made. An abscess is distinguished from cellulitis by a low-attenuation homogeneous area surrounded by a ring enhancement of contrast material (see Fig. 14–3). Kirse and Roberson[40]

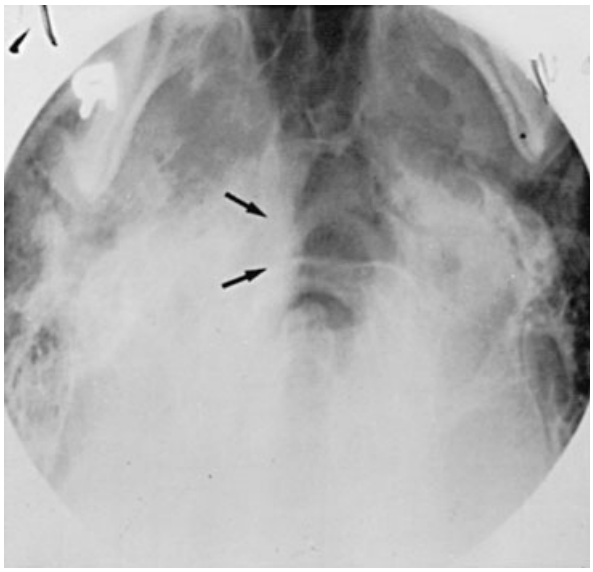

Figure 14–3 Lateral neck radiograph showing a retropharyngeal abscess.

reported scalloping of the abscess wall to be a more useful predictor of the presence of pus than ring enhancement. When more than one space is involved, accurate assessment of these spaces may ensure sufficient surgical drainage. Vascular structures can be identified, as can potential complications such as venous thrombosis. Gas also may be detected by CT.

A 10-year retrospective study from the Massachusetts Eye and Ear Infirmary compared preoperative CT scans with intraoperative findings in 38 patients who underwent surgical exploration of the parapharyngeal or retropharyngeal space within 48 hours after the scans were performed. Overall, the intraoperative findings confirmed the CT scan interpretation in 76.3 percent of the patients.[43] Of the 38 patients, 5 (13.2%) had CT scans indicative of abscesses that were not confirmed at surgery. Exploration of the parapharyngeal or retropharyngeal space revealed cellulitis. The false-negative rate was 10.5 percent. The sensitivity of CT scanning for detection of parapharyngeal or retropharyngeal space abscess was 87.9 percent. Similar findings were reported in the Pittsburgh series; the sensitivity of CT scanning for differentiating an abscess from cellulitis was 91 percent.[72] In three cases, the radiologist's blinded CT scan interpretation did not correlate with the operative findings. Two patients with false-positive interpretations had retropharyngeal infections and underwent needle aspiration. The positive predictive value of CT scans in detection of abscess versus cellulitis was 83 percent. Additional studies have reported that the accuracy of CT in predicting surgical findings was 63 percent, 73 percent, 76 percent, and 92 percent.[23,65,73,76]

TREATMENT

The treatment of choice is administration of intravenous antibiotics and incision and drainage. If the mass is small, a peroral incision with the patient in the Rose position (supine with the neck hyperextended) may provide some drainage, but a slight risk of aspiration exists. If the mass is large and extends lateral to the great vessels, or if fever persists after peroral drainage is performed, an external incision is preferred. A tracheotomy may be required if risk of compromising the airway exists.

Posterior mediastinitis can result from the spread of infection from the retropharyngeal area into the prevertebral space. Other complications may be seen when the abscess extends to the parapharyngeal space and involves the great vessels and cranial nerves.

Reports have documented that patients with small retropharyngeal abscesses may respond to treatment with intravenous antibiotics alone. Broughton[14] described the experience at the University of Kentucky Medical Center, where 8 of 14 patients with deep neck infections seen during a 9-year period were treated successfully by antibiotics alone. All were reported to have small abscesses on CT scan. Possibly some had only cellulitis, however. In the Pittsburgh study, 15 of the children with parapharyngeal or retropharyngeal space infections underwent surgical intervention; 11 (73%) underwent incision and drainage, and 4 (27%) underwent needle aspiration.[72] All had successful outcomes. Twelve (44%) of the children with retropharyngeal infections were treated with intravenous antibiotics alone, and all did well. Ten (37%) of 27 patients in the Las Vegas series with well-defined abscess on CT scan were treated with intravenous antibiotics alone, and no treatment failures occurred.[18]

McClay and colleagues[50] used intravenous antibiotics alone to treat 11 children with deep neck abscesses (retropharyngeal in 8, both retropharyngeal and parapharyngeal in 2) without severe symptoms or airway compromise. Ten children responded and showed clinical improvement within 48 hours, whereas one child required surgical drainage. Close clinical follow-up is mandatory for children treated with intravenous antibiotics alone. Children who do not improve within 24 to 48 hours require surgical drainage.

PARAPHARYNGEAL ABSCESS (PTERYGOMAXILLARY, PHARYNGOMAXILLARY, LATERAL, AND PHARYNGEAL SPACE ABSCESSES)

The potential parapharyngeal or pterygomaxillary space is an inverted conical cavity (see Fig. 14–2B) lying along an oblique axis roughly parallel to the ramus of the mandible (see Fig. 14–2C). The base of the skull at the jugular foramen forms the base of the "cone," and its apex is at the hyoid bone (see Fig. 14–2B). The buccopharyngeal fascia, lateral to the superior pharyngeal constrictor, delineates the medial boundary, and the parotid gland and its partially dehiscent deep layer of the superficial cervical fascia form the lateral wall of this cone. The internal pterygoid muscle and mandible demarcate the cone on its anterolateral aspect. The parapharyngeal space is contiguous with the peritonsillar, submandibular, and retropharyngeal spaces, all of which are potential avenues of egress for an extending parapharyngeal space abscess (see Fig. 14–2A).

The posterior portion of the cone contains the contents of the carotid sheath (carotid artery and internal jugular vein), cranial nerves IX through XII, and the cervical sympathetic chain. The internal pterygoid muscle and fatty connective tissue are anterior.

Involvement of these structures determines the clinical manifestations and complications of the parapharyngeal space abscess. An abscess in the posterior compartment may show medial displacement of the lateral pharyngeal wall and parotid space induration and swelling, with variable overlying facial nerve weakness, carotid artery erosion and hemorrhage,[42] internal jugular vein thrombosis, decreased gag reflex and dysphagia, ipsilateral vocal cord paralysis, weakness of the ipsilateral trapezius muscle, ipsilateral lingual deviation, and Horner syndrome from cervical sympathetic chain involvement.[16]

Extension of the abscess into the anterior compartment causes trismus from irritation of the internal pterygoid muscle. Indura-

tion at the angle of the jaw and medial displacement of the tonsil and pharyngeal wall also occur with an anterior compartment abscess.

By the time a patient with an abscess seeks medical attention, the source of the parapharyngeal space infection may be unclear. Reports indicate variable causes, including incompletely or inadequately treated bacterial pharyngitis, tonsillitis,[3] peritonsillar abscess, dental infections, bacterial parotitis, otitis, mastoiditis (Bezold abscess from a mastoid tip infection traveling along the digastric muscles), petrositis, cervical adenitis with suppuration, cervical vertebral tubercular adenitis in the adult,[5,54] foreign bodies,[16,19] trauma, intravenous drug abuse,[31] branchial cleft anomalies,[68] and cat-scratch disease.[78] Parapharyngeal abscesses seem to be less common than are peritonsillar and retropharyngeal abscesses in children. Only three cases of parapharyngeal abscess and cellulitis were reported in the Pittsburgh series,[72] and only three cases were reported in a 15-year review of pediatric neck abscesses from Rainbow Babies and Children's Hospital in Cleveland, Ohio.[22] Amar and Manoukian[1] reported on 25 children with parapharyngeal abscesses during an 11-year period at Montreal Children's Hospital. Parapharyngeal abscesses occur throughout childhood, with an average age at presentation of 4 to 6 years.[1,63]

CLINICAL MANIFESTATIONS

In addition to the symptoms noted in the preceding description, tender cervical swelling, induration and erythema of the side of the neck, torticollis, sore throat, dysphagia, trismus, hoarseness, malaise, chills, and diaphoresis may occur. Variable low-grade pyrexia with occasional temperature spikes occurs. Examination discloses variable toxicity, respiratory tract distress, laryngeal edema, medial displacement of the lateral pharyngeal wall and inferior tonsil pole, trismus, and, infrequently, drooling. Palpation of the neck reveals a tender, high cervical mass, initially diffuse and later fluctuant. Pharyngeal blood clots may presage erosion of the carotid artery. The complications of parapharyngeal abscesses are related to the structures involved: Involvement of the carotid artery can produce hemiplegia from emboli; internal jugular vein thrombosis with cephalad extension may lead to a cavernous sinus thrombosis, whereas inferior extension leads to internal jugular vein thrombosis. Internal jugular vein thrombosis is characterized by spiking temperature, toxicity with intense diaphoresis, headaches, and increased intracranial pressure. Septic pulmonary emboli occasionally are present.

Extension into the retropharyngeal region by a parapharyngeal abscess may lead to a posterior mediastinitis. Airway obstruction occurring secondary to laryngeal edema and aspiration pneumonia from suppuration of the abscess into the pharynx have been reported. Initially, the parapharyngeal abscess may be difficult to differentiate from a peritonsillar abscess, but the latter usually is less toxic and has a distinct, soft palatal fluctuation.

As described for the diagnosis of retropharyngeal abscess, CT is an extremely useful tool for distinguishing parapharyngeal abscess from cellulitis and for localizing the abscess for surgical planning. In a review of 47 children who presented with deep neck infections to the Children's Hospital of Buffalo during a 5.5-year period, CT scan showed that 34 (77%) of 44 patients who underwent CT scan had involvement of the parapharyngeal and retropharyngeal spaces.[55] The involvement of both spaces had implications for the approach to surgical drainage.

TREATMENT

Intravenous antibiotic therapy with incision and drainage is the primary treatment. An otolaryngologic consultation should be obtained for this potentially complex surgery of the neck. The conventional method of approaching this abscess is an external incision with sufficient exposure to provide immediate access to the common carotid artery for ligation, should erosion of the carotid artery be present.[47]

An intraoral drainage procedure traditionally has been condemned because rapid access to the vital structures of the neck is impossible with this approach. Nagy and associates[55] used an intraoral approach, however, to treat successfully 21 of 22 children with either parapharyngeal or combined parapharyngeal and retropharyngeal abscesses. The authors emphasized that CT with intravenous contrast enhancement showed that all of the abscesses were located medial to the great vessels and were adjacent to the pharyngeal wall. Amar and Manoukian[1] retrospectively compared 15 children with parapharyngeal abscesses who underwent intraoral drainage with 10 patients who underwent external neck drainage and found no complications or recurrences in either group. The children who underwent intraoral drainage had significantly reduced anesthesia time. The duration of intravenous antibiotics and duration of hospital stay also were shorter in the children who underwent intraoral drainage, but the differences between groups were not statistically significant. Cable and coworkers[15] described 12 children presenting to three centers with superior parapharyngeal space abscesses medial to the great vessels who were treated successfully by intraoral drainage using CT-guided systems to assist with localization of the abscess cavity.

The use of CT has made it possible for some patients with parapharyngeal abscesses to be managed with intravenous antibiotics. The number of reported cases is small, however, and usually analyzed with cases of retropharyngeal abscess.[14,55] Nagy and associates[55] used intravenous antibiotics alone to treat 3 (13%) of 24 children with small parapharyngeal abscesses. Sichel and associates[63] used intravenous antibiotics alone to treat successfully 12 children prospectively with infection limited to the parapharyngeal space abscess. Close clinical follow-up is necessary for children with parapharyngeal cellulitis or small parapharyngeal abscesses that are treated conservatively with intravenous antibiotics. Surgical drainage should be performed in children who do not improve within 24 to 48 hours.

In another report, Sichel and colleagues[62] reviewed the CT scans of 29 patients with infections of the parapharyngeal space and divided the patients into two groups: 22 patient with posterior parapharyngeal space infections and 7 patients with anterior parapharyngeal space infections. The patients with posterior infections generally were children who responded well to intravenous antibiotics and did not develop complications. The patients with anterior infections of the parapharyngeal space more commonly were adults who required external drainage in addition to intravenous antibiotics and developed complications including septic shock, respiratory distress, mediastinitis, pericarditis, and lung empyema. The authors suggested that the location of the infection in the fat of the anterior parapharyngeal space resulted in liquefaction of the fat, with formation of pus and rapid spread of the infection to other anatomic spaces.

MICROBIOLOGY OF DEEP NECK ABSCESSES

Group A streptococci (*Streptococcus pyogenes*) and *Staphylococcus aureus* have been considered to be the organisms most frequently associated with pharyngeal space infections. Studies have shown the presence of oral anaerobes in these infections, however; these organisms may be responsible for the gas seen on lateral neck radiographs. This finding is not surprising because the main portals of entry for pharyngeal space infections are the nasopharynx, oropharynx, paranasal sinuses, mastoid, and lower molars, all areas that are colonized with anaerobes.

The most complete microbiologic data available are from studies of peritonsillar abscesses. Flödstrom and Hallander[26] in 1976 reported the results of bacterial cultures on aspirates of pus from 37 patients with peritonsillar abscesses. The ages of the patients were not given. Group A streptococci were isolated from 17 of these patients, whereas 15 had an increase in their antistreptolysin O or anti-DNAase titers. Anaerobes were found in 28 of the cultures, including those of eight patients that also disclosed the presence of streptococci. The most common anaerobic species isolated were fusobacteria (13), peptostreptococci (16), and *Bacteroides* spp. (18). Among the aerobic organisms, *S. aureus* was isolated four times, and *Haemophilus influenzae* was isolated twice. No isolates of aerobic gram-negative enteric organisms were present.

Jokipii and colleagues[37] performed semiquantitative cultures of aspirated pus from 42 peritonsillar abscesses and found similar results. Group A streptococci, the aerobic bacteria isolated most frequently, were isolated in pure culture 4 of 10 times. Anaerobes were more abundant than were aerobes; the most important species, in frequency and quantitatively, were *Bacteroides*, *Peptostreptococcus*, and *Fusobacterium*. Most of the infections were polymicrobial, with two to seven bacteria in 83 percent of the specimens. Subsequent studies from the United States and Finland have reported similar findings.[13,38,60,64]

Kieff and associates[39] found that streptococci were the most frequent isolates; group A streptococci and other non–group A beta-hemolytic streptococci were present in more than 30 percent of patients, and alpha-hemolytic streptococci accounted for another 27.2 percent. The pathogenic role of anaerobic bacteria in peritonsillar abscesses has been reinforced by reports of complications caused by fusobacterial infection in children.[57,59] *Fusobacterium* and *Bacteroides* spp. have been associated with septic thrombophlebitis and pulmonary emboli from the jugular veins.

Data on the microbiology of retropharyngeal and parapharyngeal abscesses in children are more limited. The organisms isolated are similar to those found in peritonsillar abscesses, but with a higher number of anaerobic species. Brook[12] examined aspirated pus from 14 children, 1 to 6 years old (median age 3 years, 2 months), with retropharyngeal abscesses. Anaerobes were isolated from all patients; they were the only organisms isolated in two patients (14%) and were mixed with aerobes in the remainder (86%). The predominant anaerobic species were *Bacteroides*, *Peptostreptococcus*, and *Fusobacterium*. The predominant aerobic species were alpha-hemolytic and gamma-hemolytic streptococci, *S. aureus*, *Haemophilus* spp., and group A beta-hemolytic streptococci. Seventy-one percent of the isolates were β-lactamase–positive and included all isolates of the *S. aureus* group, 6 of 18 of the *Bacteroides melaninogenicus* group (33%), and 2 of 3 of the *Bacteroides oralis* group.

Dodds and Maniglia[22] reported the results of cultures from nine retropharyngeal and three parapharyngeal abscesses from children and adolescents. The organisms isolated were similar to those reported by Brook,[12,13] but the microbiology was not as complete because the study was retrospective and not all specimens may have been processed for anaerobic culture. Streptococcal species were the isolates that occurred most frequently, followed by *S. aureus* and *H. influenzae*. One isolate each of *Fusobacterium necrophorum*, *Escherichia coli*, and *Klebsiella pneumoniae* was found. Asmar[2] performed cultures on material from 17 children with retropharyngeal abscesses; viridans streptococci were isolated from 11 of the abscesses, *S. aureus* from 8, and group A streptococci from 6. The most frequently identified anaerobes were *Peptostreptococcus* spp. Overall, 45 aerobic and 18 anaerobic species were identified.

Rarely, retropharyngeal abscess may result from anterior extension from cervical osteomyelitis. This condition has been described with tuberculosis[56] and atypical mycobacteria causing a retropharyngeal abscess in a similar clinical setting. Barratt and colleagues[3] reported one case of retropharyngeal abscess caused by *Coccidioides immitis* in a 24-year-old woman with Hodgkin disease. The infection also was secondary to cervical vertebral osteomyelitis. Other rare and unusual causes of deep neck abscesses include cat-scratch disease (*Bartonella*),[78] *Streptococcus pneumoniae*,[52] and Kawasaki disease.[34]

Because a large variety of organisms can be found in pharyngeal space infections, obtaining adequate culture specimens is crucial. The optimal material for culture is an aspirate of the pus obtained at operation. Throat swabs or swabs of the abscess obtained after drainage usually are inadequate because of contamination with normal oropharyngeal flora. The pus, when obtained, can be transported in a capped syringe if anaerobic transport media are unavailable. Most pathogenic obligate anaerobes can survive in a purulent exudate, despite extended periods of exposure to air.[25] A Gram stain of the exudate would provide important clues to the bacterial etiology. A Gram stain showing a mixture of organisms suggests a mixed aerobic-anaerobic infection.

Although use of a β-lactamase-resistant antibiotic may be necessary in the treatment of deep neck abscesses because of the presence of β-lactamase-producing bacteria, including *S. aureus* and *Bacteroides* spp.,[12,13,72] results of two studies suggest that penicillin alone was equivalent to broad-spectrum antibiotics for treatment of peritonsillar abscesses.[39,79] Yilmaz and colleagues[79] compared procaine penicillin with intramuscular administration of ampicillin-sulbactam in outpatient treatment of 40 patients with peritonsillar abscesses that were drained perorally. No statistical difference in duration of symptoms and clinical recovery was found between the two groups. Kieff and associates[39] retrospectively evaluated 103 patients with peritonsillar abscesses who were treated with incision and drainage. Fifty-eight patients were treated with broad-spectrum antibiotics including ampicillin-sulbactam, clindamycin, cephalosporins, and metronidazole, alone and in combination; 45 patients were treated with penicillin alone. All patients were hospitalized after drainage, and the clinical outcomes, including duration of hospitalization and fever, did not differ significantly between the two groups. No significant difference in the organisms isolated was found, and failure and complication rates did not differ.

No comparative treatment studies for retropharyngeal or parapharyngeal abscesses have been reported. Treatment in these cases should be based on the results of cultures, as stated before. Drugs that may be effective include penicillin-lactamase inhibitor combinations such as ampicillin-sulbactam, ticarcillin-clavulanic acid, and piperacillin-tazobactam; expanded-spectrum cephalosporins such as ceftriaxone; or penicillinase-resistant penicillins including oxacillin or nafcillin. Cephalosporins, oxacillin, or nafcillin should be used in combination with clindamycin or metronidazole for adequate anaerobic coverage. Erythromycin and other macrolides (azithromycin, clarithromycin) are less satisfactory because of increasing macrolide resistance in group A streptococci and less activity against *Bacteroides fragilis* and *Fusobacterium*.

A study by Hanna and colleagues[30] reported macrolide resistance in 26 percent of group A streptococcal isolates obtained from peritonsillar abscesses seen between August 2001 and July 2002. The routine use of aminoglycoside antibiotics is not indicated because aerobic gram-negative enteric rods rarely are found in these infections. Antibiotic therapy is effective only in conjunction with adequate surgical drainage.

CHAPTER 15

Cervical Lymphadenitis

C. Mary Healy ❂ Carol J. Baker

Cervical lymphadenopathy is enlargement of the lymph nodes in the neck. *Cervical lymphadenitis* implies that there is inflammation of one or more nodes. The inflammatory response by the host is triggered by some form of injury or invasion proximal to the involved lymph node or nodes. The nodes become affected secondarily by drainage through connecting afferent lymphatic channels. The injury may be acute or chronic, infectious or noninfectious. Proper anatomic definition of the inflamed node or nodes,[78] combined with knowledge of the structures of the head and neck drained by them, may allow a portal of entry for infectious agents, the most common cause of cervical lymphadenitis in infants and children, to be identified.

Figure 15–1 illustrates the regional lymph nodes commonly affected in infants and children with cervical lymphadenitis. The superficial cervical lymph nodes lie on top of the sternocleidomastoid muscle along the course of the external jugular vein. They receive afferents from the superficial tissues of the neck, mastoid, superficial parotid (preauricular) nodes, and submaxillary glands. Their efferents terminate in the upper deep cervical lymph nodes. The mastoid lymph nodes overlie the mastoid process of the temporal bone and receive drainage from the parietal scalp and inner surface of the pinna. The occipital lymph nodes lie on the upper part of the trapezius and receive afferents from the occipital scalp and superficial portions of the upper posterior neck. Their efferents terminate in the deep cervical glands, as do the efferents from the mastoid nodes.

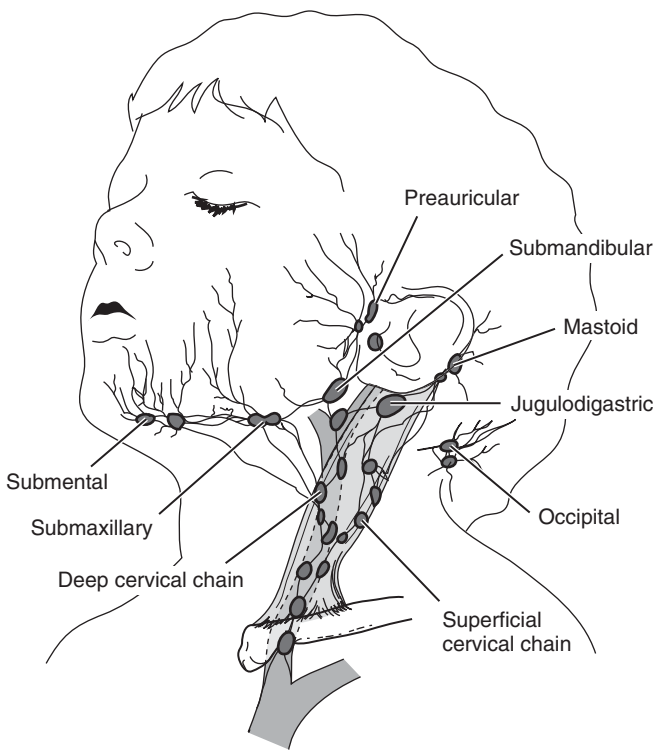

Figure 15–1 The lymphatic drainage and lymph nodes involved in infants and children with cervical lymphadenitis.

The deep cervical lymph nodes lie deep to the sternomastoid muscle along the whole length of the internal jugular vein and are divided into upper and lower groups. The jugulodigastric gland, a member of the upper group, lies at the angle of the jaw below the posterior belly of the digastric muscle. The lymphoid tissue of the palatine tonsil is drained into this gland; it frequently becomes enlarged in patients with "tonsillitis" or with tuberculous infection originating from the tonsils. The larynx, trachea, thyroid gland, and esophagus drain into the lower deep cervical glands. The submental lymph nodes, which lie between the digastric muscles below the myohyoid, receive superficial and deep drainage from the anterior tongue, lower lip, and chin, from both sides of the midline. They send efferents to the submandibular and upper deep cervical glands. The submandibular lymph nodes lie adjacent to the submandibular salivary gland and receive wide, superficial drainage from the lateral aspect of the lower lip, the vestibule of the nose, the cheeks, the medial parts of the eyelids, and the forehead. Deep drainage to these nodes arises from the posterior part of the mouth, gums, teeth, and tongue and from superficial and submental lymph nodes.

Because most of the lymphatic drainage of the head and neck goes to the submaxillary and deep cervical nodes, these glands are involved in more than 80 percent of cases of cervical adenitis in young children. Submental and superficial cervical lymphadenitis is observed less frequently.

EPIDEMIOLOGY

The epidemiology of infectious cervical adenitis is that of its infectious agents. Although cervical lymphadenitis can be a manifestation of focal viral infections of the oropharynx or respiratory tract, often it is part of a more generalized reticuloendothelial response to systemic infection. Viruses commonly associated

with prominent cervical adenitis include Epstein-Barr virus, cytomegalovirus, and human immunodeficiency virus (HIV). In HIV-infected children, cervical adenopathy either may herald or may be a part of the more generalized lymphadenopathy associated with this infection. Although human herpesvirus-6 (HHV-6), the cause of roseola in infants (exanthem subitum), is associated with the development of a mononucleosis syndrome and cervical adenopathy in adults,[3] lymphadenitis is not a prominent feature in children with primary infection.[55] Adenoviral and enteroviral infections are causes of generalized lymphadenopathy rather than of cervical adenitis alone. The epidemiology of cervical adenitis varies with age, geographic location, and socioeconomic status. Generally, lower socioeconomic status is associated with a higher incidence of infection in younger children.

When bacterial in origin, with the exception of group A streptococci and *Mycobacterium tuberculosis*, the agents isolated from these glands are the normal inhabitants of the nose, mouth, pharynx, and skin—*Staphylococcus aureus*, anaerobes, nontuberculous mycobacteria, *Actinomyces* spp.—and person-to-person transmission does not occur. In contrast, group A streptococci and *M. tuberculosis* infection of cervical lymph nodes results from contact with human infection by way of airborne droplets. Except in neonates, for whom male dominance has been reported in cases caused by group B streptococci,[11] infectious lymphadenitis has no gender or seasonal predilection.[13,35]

Any age group may be affected. In neonates, *S. aureus* and group B streptococci are the most common pathogens. Suppurative cervical lymphadenitis caused by *Staphylococcus epidermidis* in an otherwise healthy infant has been reported.[125] Nonetheless, despite the high frequency of nasal colonization by this organism, it remains a rare etiologic agent. There are rare reports of *Streptococcus pneumoniae* causing suppurative adenitis[94] in older children. Some studies[35,141,159] indicate that *S. aureus* has the leading role in infants, whereas in children, either group A streptococci or *S. aureus* is equally likely to be pathogenic. Other reports have varied regarding the relationship between age and probable etiologic agent.[13,24]

Overall, *S. aureus* and *Streptococcus pyogenes* accounted for 65 to 89 percent of consecutive cases in prospectively evaluated series.[13,35,159] Methicillin-resistant *S. aureus* (MRSA) must be strongly considered as a possible etiology because of the increased incidence of nosocomial MRSA and community-associated methicillin-resistant *S. aureus* (CA-MRSA) infections in the United States and elsewhere,[21,42,49,59,61,63,99] and recognition that the highest rates of CA-MRSA colonization and disease are found in children.[42,99] Many studies have shown that CA-MRSA strains predominantly cause skin and soft tissue infections, but a wide spectrum of illness is reported, and invasive CA-MRSA has been associated with a variety of clinical manifestations, including severe illness and death.[59,61,63,101] The impact of the CA-MRSA "epidemic" on pediatric cervical adenitis is less easy to define; however, retrospective and more recent prospective case series report that 6 to 10 percent of CA-MRSA infections manifest as adenitis.[61,63,99] One single-center study found that MRSA was the infectious etiology of no head and neck abscesses from July 1999 through December 2001 but accounted for 34 percent of cases from January 2002 through June 2004.[108]

The epidemiology of bacterial lymphadenitis varies by geographic location. Resurgence of infection with *Yersinia pestis* in the southwestern United States means that, in areas where it is endemic, it also must be considered in the differential diagnosis. Epidemic diphtheria, reported in the Russian Federation in 1990, subsequently spread to several newly independent states in the European region, with the number of reported cases (50,425) peaking in 1995. Although the number of diphtheria cases declined after the implementation of diphtheria control measures, 176 cases from the European region were reported to the World Health Organization (WHO) in 2004, 88 percent from newly independent states. Diphtheria must be added to the list of possible causes of cervical lymphadenitis in that region of the world.[156]

TABLE 15–1 Differentiation of *Mycobacterium tuberculosis* and Nontuberculous Mycobacterial Cervical Adenitis

	NTM MCA	*M. tuberculosis*
Age	1-6 yr	All ages
Ethnicity	White	Black, Asian, Hispanic
Exposure to tuberculosis	Absent	Present
Abnormal chest radiographs	Rare	Often
Residence	Suburban	Urban
TST >15 mm	Uncommon	Often
Bilateral involvement	Rare	Not uncommon

NTM, nontuberculous mycobacteria; TST, tuberculin skin test.

The distinctive epidemiologic features of mycobacterial infection are summarized in Table 15–1. Scrofula caused by *M. tuberculosis* is a rare disease. When it does occur, it usually affects adults and older children. In contrast, children with atypical mycobacterial infection almost always are 1 to 6 years old, live in suburban or rural communities, and have no history of contact with *M. tuberculosis*.* Although *M. tuberculosis* is an infection acquired primarily by inhalation, the gastrointestinal tract or the respiratory tract may serve as the primary portal of entry for nontuberculous mycobacteria.[47,104,114,119] There seems to be an ethnic predilection for nontuberculous mycobacterial infection to occur in whites and for tuberculous infections to occur in blacks, Hispanics, Asians, and the Australian Aboriginal population.[103,139]

The advent of the HIV pandemic had a major impact on the nature and frequency of mycobacterial infections. A marked increase in the incidence of tuberculous infection occurred in HIV-infected adults and children, with annualized case rates for tuberculosis in HIV-infected children increasing from 58 per 100,000 during the years 1981 to 1985 to 478 per 100,000 during the years 1990 to 1992.[51] The availability of highly active antiretroviral therapy (HAART) resulted in significant decreases in the incidence of opportunistic infections, including tuberculous and nontuberculous mycobacterial infections, in HIV-infected children.[48]

The presence of tuberculosis infection in the community means that all children are at risk of exposure to an infectious adult.[20] The annual tuberculosis rate in the United States decreased steadily during the years 1993 through 2005, but the annual decline has decelerated.[31] Of additional concern is the frequency with which drug-resistant tuberculosis is being detected in industrialized and developing countries. During the years 2000 through 2004, 33 percent of tuberculous isolates from industrialized countries were multidrug-resistant (e.g., resistant to isoniazid and rifampin, first-line drugs in the treatment of tuberculosis), and 6 percent were classified as extensively drug-resistant (resistant to isoniazid, rifampin, and three of the six classes of second-line antituberculosis drugs).[32]

The incidence of nontuberculous mycobacterial infections has increased since the 1980s, although some of this apparent increase most likely has resulted from improvements in diagnostic methods. Nontuberculous mycobacteria are ubiquitous and are found in food, water, animals, and soil. An association between cervical adenitis caused by atypical mycobacteria with cold weather is prompted by observations that 68 percent of cases occur in the winter and spring months,[83,112,155] and the disease exhibits a steady incidence throughout the year in cold climates.[47]

*See references 19, 33, 36, 41, 47, 69, 80, 84, 112, 120, 134, 149, 155.

A 10-year Canadian retrospective study reported that 70 percent of cases occurred in girls; however, most reports suggest no gender difference.[112]

Until the 1970s, *Mycobacterium scrofulaceum* was the usual etiologic agent isolated from children, followed by *Mycobacterium avium–intracellulare*.[155] This trend has reversed, with *M. avium–intracellulare* now accounting for 50 to 98 percent of culture-proven cases.[43,58,79,83,102,103,142,155] Previously uncommon species, such as *Mycobacterium kansasii*, *Mycobacterium malmoense*, *Mycobacterium fortuitum*, *Mycobacterium haemophilum*, and *Mycobacterium bohemicum*, also are being detected more frequently.* Some of these uncommon species probably are responsible for many cases of culture-negative mycobacterial lymphadenitis because of their fastidious growth requirements. New diagnostic methods have led to case reports of cervical adenitis secondary to slow-growing species, such as *Mycobacterium lentiflavum* and *Mycobacterium interjectum*.[37,53,57,116,136] Cervical lymphadenitis caused by *Mycobacterium chelonae* is rare, usually involves the submandibular glands, and typically occurs in patients with an antecedent history of dental pathology.[5]

Cervical lymphadenopathy may be the direct result of infection with HIV per se. The development of acute tender adenitis in an HIV-infected child should provoke a search for another etiology, however. Although the typical childhood pathogens remain the most common pathogens in this setting, as in other immunocompromised children, opportunists also should be sought.[51] Patients with HIV infection beginning therapy with potent antiretroviral agents may develop new-onset mycobacterial lymphadenitis (tuberculous and nontuberculous mycobacteria). When this lymphadenitis occurs, it is more localized, is associated with more sinus formation, and is more often caused by nontuberculous mycobacteria (*M. avium–intracellulare*) than by *M. tuberculosis*.[115]

Cat-scratch disease is a common cause of lymphadenitis in children and young adults.[23] In 1988, English and associates[40] first isolated a pleomorphic gram-negative bacillus, later identified as *Afipia felis*, from lymph nodes of patients with cat-scratch disease. *Bartonella henselae* (formerly called *Rochalimaea henselae*), a morphologically similar but genetically distinct pleomorphic gram-negative bacillus, now is recognized as the cause of most cat-scratch disease.[1]

The cervical nodes are the second most common site of cat-scratch disease involvement. Although unusual and severe manifestations of this infection have been described, it remains mostly a mild, self-limited infection in children and adolescents, with no ethnic predilection. Seasonal variation with an increased incidence in fall, winter, and early spring does occur in temperate zones. A history of animal contact with cats usually can be elicited.[26] The importance of bites and scratches by kittens in transmitting this disease has been well defined.[91] However, the absence of a history of traumatic contact with cats in a substantial number of cases has raised the possibility that other modes of transmission exist. Zangwill and associates[161] suggested that fleas might serve as vectors of transmission. Their hypothesis is strengthened by the detection of *Bartonella* DNA by polymerase chain reaction in collections of fleas from cats owned by two infected patients.[161]

PATHOPHYSIOLOGY

Although cervical lymphadenitis is a common entity in pediatric clinical practice, little information exists regarding its pathogenesis. Viral cervical adenitis may be part of either a local response to viruses invading the oropharynx or respiratory tract (e.g., adenoviruses, coxsackieviruses) or a more generalized reticuloendothelial response to systemic viral infection (e.g., Epstein-Barr virus, cytomegalovirus, HHV-6, HIV). Infection attributed to group A streptococci and *S. aureus* is presumed to enter the cervical lymphatics from the oropharynx (group A streptococci) and anterior nares (*S. aureus*). In a patient with group A streptococcal pharyngitis or tonsillitis, whether infection remains localized at the pharyngotonsillar tissues or spreads to cervical lymph nodes and results in suppuration primarily is a function of host response. Although peak attack rates for group A streptococcal pharyngitis are observed among school-age children, suppurative cervical adenitis is an uncommon occurrence. In contrast, infants and children younger than 3 years old rarely have group A streptococci isolated from throat cultures, but this age group more commonly has suppurative cervical lymphadenitis.[118]

In infections attributed to *S. aureus*, colonization of the anterior nares is thought to be a prerequisite for cervical lymphadenitis. Brook and Winter[22,23] arrived at this conclusion because organisms of identical phage types were isolated from the anterior nares and the cervical abscesses of their patients. An investigation of children in St. Louis found no such correlation between isolates from nasal and cervical node cultures.[13] The role of *S. aureus* as a primary pathogen has been the subject of some debate. In most series, 30 percent of aspirates yield mixed cultures of *S. aureus* and group A streptococci, and frequently significant elevations of antistreptolysin O titer are found in the sera of patients whose lymph nodes yielded a pure culture of *S. aureus*.

In a California study, 65 percent of patients had node aspirates yielding a pure culture of *S. aureus*, and 41 percent exhibited an immune response to one or more of the extracellular antigens of group A streptococci.[159] Similarly, the finding that many children improve with penicillin or ampicillin treatment, despite the high prevalence of penicillin resistance among *S. aureus*, suggests that, although streptococci and staphylococci may coexist in these nodes, staphylococci may play a subsidiary role as secondary invaders. Most children with isolates of *S. aureus* from suppurative lymph nodes show no evidence of coexistent streptococcal infection or viral upper respiratory infection. In this more common circumstance, *S. aureus* apparently has the capacity to be a primary invader.

Recovery of anaerobic bacteria from cervical nodes suggests invasion of the lymphatics by mouth flora, often as a result of local tissue destruction by periodontal disease.[24] The delineation of the pathophysiology of cervical lymphadenitis of diverse bacterial etiology requires an understanding of the interaction between a given microorganism (e.g., inoculum size, elaboration of extracellular enzymes, ability to adhere to epithelium) and the host (e.g., humoral and surface immune capacity, degree of trauma).

Tuberculous cervical lymphadenopathy occurs within months of the initial exposure, through pulmonary infection and involvement of the regional and then more distant lymph nodes. It is a rapid process; chest radiographic evidence of active pulmonary disease often is seen. Nontuberculous mycobacteria are ubiquitous in the environment. Oropharyngeal acquisition and local infection lead to lymph node involvement. Most children with nontuberculous mycobacterial cervical lymphadenitis are immunocompetent, although a more recent study suggests that children who develop necrotic nodes may have deficient production of interferon-γ.[102] Despite *M. avium* skin test positivity being linked with pet birds, no clear relationship with lymphadenitis has been shown.[75] The observation that discontinuation of childhood bacille Calmette-Guérin vaccination has been associated with an increase in atypical mycobacterial infection in many countries suggests that this vaccine may have a protective effect.[150] Progressive cervical adenitis developing after bacille Calmette-Guérin vaccination also has been reported.[105]

*See references 10, 43, 58, 79, 83, 102, 103, 111, 112, 142, 155.

CLINICAL PRESENTATION

The clinical manifestations of cervical lymphadenitis vary considerably but are consistent with the diverse etiologies associated with cervical node enlargement in infants and children. To categorize the mode of presentation as either acute or subacute and chronic is useful because, although the boundaries are ill-defined and much overlap exists, common etiologies tend to fall consistently within one or another category. Cervical lymphadenitis of acute onset may be categorized further as either bilateral or unilateral. In most situations, acute, bilateral cervical adenitis is either part of a generalized reticuloendothelial response to a systemic infection or a localized reaction to acute pharyngitis. The presence or absence of associated features (e.g., pharyngitis, enanthems or exanthems, generalized adenopathy, hepatosplenomegaly) aids in making the differentiation.

Acute unilateral cervical lymphadenitis is caused by streptococcal or staphylococcal infection in 53 to 89 percent of cases.[13,35,62,159] In newborns, *S. aureus* is the most common cause, and clinical features are similar to those seen in older children. Group B streptococci have been described as causative in a "cellulitis-adenitis" syndrome in infancy.[11] These infants differ from infants with staphylococcal adenitis in that they are younger; more often are male; and have a greater incidence of systemic symptoms, irritability, and anorexia; 94 percent have associated bacteremia. The typical patient presents with fever, facial or submandibular cellulitis, and ipsilateral otitis media.[11] Isolated cervical adenitis caused by group B streptococci also has been described.[44]

Patients with disease attributed to *S. aureus* or group A streptococci typically are 1 to 4 years old (70-80% of cases), and the male-to-female ratio is equal. Clinically, there is little that helps to differentiate streptococcal from staphylococcal infections. Cervical adenitis can occur as part of the "streptococcosis" syndrome of infancy, with an onset heralded by coryza, an irregular low-grade fever, nasal discharge with excoriation and crusting around the nares, vomiting, and loss of appetite. Lymph node enlargement occurs within a few days of onset and resolves, as do other symptoms, without treatment within 6 to 8 weeks.[118] Suppuration of cervical glands may occur at any time during this interval but seldom does so if antimicrobial therapy is given early in the illness. Group A streptococci also should be suspected as a cause of cervical adenitis in a patient with typical vesiculopustular or crusted lesions of impetigo involving the face or scalp.

Systemic symptoms in children with staphylococcal or streptococcal cervical adenitis usually are minimal or absent unless associated with cellulitis, metastatic foci of infection, or bacteremia. The primary site of lymph node involvement by frequency is submandibular (50-60%), upper cervical (25-30%), submental (5-8%), occipital (3-5%), and lower cervical (2-5%).[13,35,157] Involved nodes generally vary in size from 2 to 6 cm in diameter, and one fourth to one third suppurate. Patients with lymphadenitis caused by *S. aureus* are more likely to have suppuration and a longer duration of symptoms and signs before diagnosis than are patients with disease caused by other bacterial agents (Fig. 15–2).[13,141] Among patients who develop suppurative adenitis, 86 percent do so within 2 weeks of onset.[157]

Approximately one third of patients in one study had concomitant lymphadenopathy at other anatomic sites.[13] A history of recent upper respiratory tract symptoms, including sore throat (40%), earache or coryza (16%), and impetigo (32%), is a frequent finding, as are signs of pharyngitis, tonsillitis, or otitis media.[13,35] These factors do not help to delineate the etiology, however. Hepatomegaly or splenomegaly is a rare occurrence and, if present, should suggest bacteremia or generalized disease processes (e.g., infectious mononucleosis, reticuloendotheliosis, tuberculosis, HIV infection).

Figure 15–2 A 2-year-old boy with fever and unilateral inflammation of the cervical lymph nodes of 2 days' duration. Needle aspirate culture of this nonfluctuant node grew *Staphylococcus aureus*. Antistaphylococcal therapy resulted in complete resolution of adenitis without surgical drainage.

Kawasaki disease may manifest as a febrile illness associated with bilateral or unilateral cervical lymphadenopathy and may be confused with more common acute pyogenic infections.[152] Other features (e.g., conjunctivitis, oral manifestations, changes in the peripheral extremities, polymorphic erythematous rash) are required criteria for the diagnosis.[95] Although originally termed *mucocutaneous lymph node syndrome*, unilateral lymph node enlargement of at least 1.5 cm is the most inconsistent feature.[15,95] Lymphadenopathy usually subsides when the fever subsides, although in some cases it may follow a more chronic course.

The rapid development of painful lymphadenitis, quickly succeeding the sudden onset of fever, chills, weakness, and headache, is a classic presentation of infection caused by *Y. pestis* (bubonic plague). The groin is the site most often involved. Other locations, including the cervical area, may be affected, however. Establishing the diagnosis and providing treatment quickly are crucial because infection can be fulminant.

In cases of diphtheria, cervical adenopathy develops secondary to infection of the posterior structures of the mouth and proximal pharynx. A whitish gray membrane covers the mucosal surfaces. In severe cases, the cervical adenopathy, which typically is bilateral, can result in a "bull neck" appearance.

Careful physical examination of the head and neck, particularly areas drained by affected lymph nodes, may yield important clues about etiology. The presence of periodontal disease is associated with a higher incidence of anaerobic organisms causing adenitis[24]; the history or presence of tick bites suggests the possibility of tularemia[135]; and the presence of papular or pustular lesions, suggesting an inoculation site, raises the possibility of rarer causes of infection, including *Nocardia*, actinomycosis, sporotrichosis, plague, cutaneous diphtheria, and cat-scratch disease.

Mycobacterial infections, cat-scratch disease, and toxoplasmosis are more common entities presenting as subacute or chronic lymphadenitis. The epidemiologic and clinical features that aid in the differentiation of typical and nontuberculous mycobacterial infections are summarized in Table 15–1. The clinical manifestations virtually are identical (Fig. 15–3).[19,30,97] Typically, a child presents with a history of painless, (so-called cold) cervical node swelling. The submandibular cervical nodes

Figure 15–3 A 4-year-old boy who had bilateral nontender enlargement of lymph nodes of 6 weeks' duration without other symptoms. Placement of a TST resulted in 18-mm induration, excisional biopsy acid-fast stain was positive, and cultures grew *Mycobacterium tuberculosis*.

usually are involved in nontuberculous mycobacterial infection,* whereas other cervical nodes are involved more frequently with *M. tuberculosis*.[4,19,65,90,127] As the infection progresses, the skin overlying the node may develop a pinkish or violaceous discoloration caused by increased vascularity, although the skin temperature is not increased. This finding may be followed by adherence of the skin to the underlying mass. If left untreated, fluctuance and spontaneously draining sinus tracts may develop.

A patient with *M. tuberculosis* is more likely than one with atypical mycobacterial disease to be older than 4 years of age and to have generalized lymphadenopathy (10-20% of cases), bilateral node enlargement (10% of cases), a history of exposure to tuberculosis (93% of cases), and an urban residence.[19,90,107] No differences have been noted, however, with regard to duration of adenopathy, fever, and presence or absence of constitutional symptoms. An abnormal chest radiograph has been noted in 28 to 71 percent of cases caused by *M. tuberculosis*,[127,128,138,149] in contrast to the 98 to 100 percent of normal chest radiographs found in patients with nontuberculous mycobacterial adenitis.[47,126,127,142,148]

In a summary of 447 reported childhood cases of nontuberculous mycobacterial infections from 15 countries, Lincoln and Gilbert[74] detected only 6 cases of bilateral cervical node involvement, 4 with abnormal chest radiographs, and none with nodal enlargement other than cervical. Similar findings have been reported by other investigators.[126,148] Intradermal tuberculin skin testing with purified protein derivative uncommonly produces more than 15 mm of induration at 48 hours in a child with nontuberculous mycobacterial infection, but reactions between 5 and 15 mm are common.[76,86] Reactions of 10 to 20 mm can occur with *Mycobacterium marinum* and *M. fortuitum* infection.[114] Tuberculin skin test positivity may persist, even when children are retested many years after infection.[155]

Cat-scratch disease may manifest days to weeks after the initial inoculation. Characteristically, a history of contact with a cat or kitten or a scratch is present. Later, when the primary lesion may have healed, tender regional adenopathy appears. Although axillary nodes most frequently are affected, 25 percent of children have isolated cervical node involvement. Middle cervical and parotid nodes are involved more often than are submandibular ones.[122] Constitutional symptoms, present early in the course of the illness, usually are mild and may have resolved by the time the adenitis appears. Fever is observed in one fourth of patients and, if present, has a mean duration of 5 to 7 days.[85] Nodes suppurate in one tenth to one third of patients.[28,29] Rare manifestations include Parinaud syndrome,[26] encephalopathy,[82] exanthems[28] (usually of the erythema nodosum type), and osteolytic lesions.[27]

Acquired toxoplasmosis may manifest as regional lymphadenopathy, frequently with posterior cervical node involvement.[93,121,146] Most children exhibit few, if any, constitutional symptoms. If present, fatigue and generalized myalgia are prominent. The characteristic location combined with a history of exposure to cats or of eating undercooked meats should raise this diagnostic possibility, and the diagnosis may be confirmed by appropriate serologic testing. It is an uncommon etiology for cervical adenopathy in children living in the United States.

Chronic, recurrent cervical adenitis forms part of the periodic fever, aphthous ulcers, pharyngitis, cervical adenitis (PFAPA) syndrome, a chronic syndrome first described in 1987.[92] It is characterized by periodic episodes of high fever greater than 39° C lasting 3 to 6 days and recurring every 3 to 8 weeks in association with aphthous ulcers, pharyngitis, and cervical adenitis, although symptoms such as abdominal pain, nausea, diarrhea, and headache also are described in 20 to 73 percent of children.[147] In most children, the onset of disease occurs before they reach 5 years of age, the syndrome is self-limited, and recovery without long-term sequelae is the rule. Oral corticosteroids are effective in aborting an attack.[72,109,147]

Kikuchi-Fujimoto disease, also called *subacute necrotizing lymphadenitis*, is an uncommon disorder of uncertain etiology that also may manifest as cervical adenopathy, with or without fever. This disorder was described first in 1972 and seems to have a predilection for Asian women 25 to 30 years old, who generally have a benign course with spontaneous resolution over 3 to 4 months.[46,151] Kikuchi-Fujimoto disease also has been reported in children, typically adolescents, although cases in children 2 years old are documented.[34,71,73,153]

In contrast to the 4:1 female predominance documented in adult series, pediatric Kikuchi-Fujimoto disease occurs more commonly in boys (male-to-female ratio ranges from 1.2:1 to 1.9:1). The most common presentation is unilateral or bilateral lymphadenopathy of multiple nodes. In most cases, posterior cervical chain nodes are involved, and affected nodes may be painful and tender. Fever is an inconsistent symptom. Extranodal manifestations include malaise, nightsweats, weight loss, maculopapular skin rashes, gastrointestinal symptoms, hepatosplenomagaly, arthritis, and aseptic meningitis. Associated laboratory findings include leukopenia (33-100% of cases with prolonged fever), elevated erythrocyte sedimentation rate, mild anemia, elevated C-reactive protein, and elevated liver enzymes.

Diagnosis is established by biopsy of the lymph nodes and not by fine-needle aspiration cytology, showing lymphadenitis with focal proliferation of reticular cells accompanied by histiocytes and extensive nuclear debris. Lymph node biopsy also has been associated with prompt resolution of fever.[34] Treatment generally is supportive, although steroids are reported to provide more rapid resolution of symptoms. The prognosis is favorable; most cases of Kikuchi-Fujimoto disease resolve within 6 months, although a recurrence rate of 3 to 4 percent is recorded. Some children subsequently develop autoimmune disorders, most commonly systemic lupus erythematosus, and regular clinical follow-up looking for signs of evolving autoimmune disorder is

*See references 4, 19, 43, 58, 79, 83, 84, 90, 126, 127, 142, 148, 155.

required.[100,132,153] Whether Kikuchi-Fujimoto disease is infectious or genetic in nature, perhaps the result of infection with a single novel agent or a nonspecific host response to any of a variety of agents, remains to be determined.

Another rare but important cause of cervical lymphadenitis in association with generalized lymphadenopathy or hepatosplenomegaly is hemophagocytic syndrome. This diagnosis should be considered if the aforementioned features occur with prolonged fever, cytopenia in at least two cell lines, low fibrinogen, and high ferritin and triglyceride serum levels.[110] Other features include rash, respiratory distress, hypotension, and coagulopathy. The diagnosis is confirmed by showing hemophagocytosis in bone marrow or lymph node biopsy specimens. Finally, when presented with a history of subacute or chronic lymphadenitis, careful physical examination should be undertaken to exclude obvious local causes (e.g., seborrhea, head lice, tinea capitis, chronic otitis media) before an extensive diagnostic work-up is initiated.

DIFFERENTIAL DIAGNOSIS

Cervical swellings are encountered frequently in pediatric practice, and most of them represent lymph nodes. When considering the diagnostic possibilities in patients with cervical lymphadenitis, one first must ascertain whether or not the pathologic process involves a lymph node, then whether or not its cause is infectious, and, if infectious, the likely etiologic agent. The duration of the cervical swelling aids in the differential diagnosis because most tumors or developmental anomalies have been noted for weeks. Rapid enlargement may occur in the latter, but usually it occurs as a result of secondary infection. Location is a helpful clue because midline masses rarely represent lymph nodes and the most common neck masses of congenital origin (thyroglossal duct cyst, branchial cleft cyst, and cystic hygromas) all have characteristic anatomic locations.

Of the midline masses, thyroglossal duct cysts are the most common.[66,117] These cysts may occur anywhere from the foramen cecum to the thyroid, are midline, and move on protrusion of the tongue. They may have an associated sinus tract, midline or just lateral to it, from which cloudy mucus sometimes can be expressed. They may become infected secondarily, but, in the noninfected state, these cysts are nontender, smooth, and round with well-defined margins. Thyroglossal duct cysts must be differentiated from other midline masses, including epidermoid cysts, lipomas, thyroid tumors, and the rare midline lymph node.

The second most common benign congenital neck mass is the branchial cleft cyst. It usually arises from the second branchial cleft and lies at the anterior border of the sternocleidomastoid muscle. Although such cysts usually manifest as skin dimples, they may become infected secondarily and manifest as inflammatory swellings or draining sinus tracts. A careful examination should detect a sinus tract. Branchial cleft cysts can occur in individuals of any age, but usually occur in school-age children.

Cystic hygromas, considerably less common than thyroglossal duct or branchial cleft cysts, are the third most frequent cause of congenital neck masses. These arise from lymphatics derived from either the jugular vein or the mesenchymal tissue. They may occur elsewhere but usually are found posterior to the sternocleidomastoid muscle in the supraclavicular fossa. Most cystic hygromas appear in the first 2 years of life, many being noted at birth or soon thereafter. They are soft, compressible tumors that transilluminate well, and, although benign in themselves, they may cause symptoms through pressure exerted on surrounding structures. Confusion may arise when cystic hygromas increase in size in association with an upper respiratory tract infection. The latter causes increased lymph flow so that the hygroma persists while other lymph nodes decrease in size after resolution of the infection. In most circumstances, palpation and transillumination readily distinguish these congenital malformations.

These four cervical masses—thyroglossal duct cysts, thyroid tumors, branchial cleft cysts, and cystic hygromas—accounted for 63.7 percent of lesions in children with persistent cervical masses reported by Moussatos and Baffes.[97] Other lesions included neurogenic tumors, parotid tumors, and miscellaneous benign tumors (12.3%). The remainder of masses represented lymph nodes. As a rule, masses located completely anterior to the sternocleidomastoid muscle are benign. The exception is the thyroid tumor.[97] Malignancies that mimic cervical lymph nodes usually are located in the posterior triangle or are multiple masses extending across the anterior and the posterior triangles. In contrast, approximately 50 percent of masses in the posterior triangle represent malignancies, most of which are of lymphoid origin. Although most cysts and tumors manifest as solitary, unilateral, nontender masses, lymph nodes of noninfectious etiology frequently are multiple and bilateral, and they may be mildly tender.

Noninfectious chronic inflammatory involvement of cervical lymph nodes may represent a variety of uncommon, usually benign, but sometimes malignant entities (Table 15–2). Fifty percent of malignant neck masses in children are caused by Hodgkin and non-Hodgkin lymphomas. Neuroblastoma is the second most common malignancy, accounting for 15 percent. The likelihood of a given diagnosis is age-dependent, with neuroblastoma being more common than Hodgkin disease in younger age groups.[62] Thyroid tumors are the third most frequent neck

malignancies. Other entities to be included in the differential diagnosis include leukemia,[25] metastatic carcinoma,[97] phenytoin-induced pseudolymphoma,[25] serum sickness,[25] storage disorders (Gaucher disease, Niemann-Pick disease), collagen vascular disease,[25] sarcoidosis,[64] sinus histiocytosis with massive lymphadenopathy,[12,124] and reticuloendotheliosis or histiocytosis X. Except for malignancies, these disease entities almost always are associated with lymphadenopathy that is not limited to the cervical region and have a variety of clinical and laboratory findings that allow the correct diagnosis to be made.

Numerous infectious agents have been reported in association with cervical adenitis in infants and children (Table 15–3). Among patients evaluated prospectively with needle aspirate cultures of affected lymph nodes, *S. aureus* or group A streptococci are the organisms most frequently isolated.[13,24,35,141,159] No significant difference has been reported that distinguishes between patients with adenitis caused by streptococci or staphylococci with respect to gender, ethnicity, dental problems, symptoms, presence of fever, or site or size of lymph nodes. In patients from whom *S. aureus* is isolated, a longer duration of disease before diagnosis is established, a larger percentage of fluctuant lymph nodes,[13,141] and a tendency toward slower resolution are found.[34] Most patients with bacterial cervical lymphadenitis, including patients with mycobacterial infection, are 1 to 6 years old. Older children are more likely to have negative lymph node aspirate cultures.[13,134,141]

In early studies, anaerobes rarely were associated with cervical adenitis.[13,35] Proper bacteriologic techniques for the isolation of

Figure 15–4 A 9-year-old boy who developed high fever and markedly tender submental lymph node inflammation after a tooth extraction. Cultures from this fluctuant mass grew three anaerobes and viridans streptococci.

these fastidious organisms allowed Brook[24] to report anaerobes alone in 18 percent and mixed anaerobic and aerobic bacteria in 20 percent of patients, suggesting that anaerobic organisms may play a more significant role in the etiology of cervical lymphadenitis than recognized previously. An older child with "negative" cultures, especially a child with poor dental hygiene or periodontal disease, may have anaerobic infection, as did the 9-year-old boy in Figure 15–4. Needle aspiration of this cervical mass yielded *Peptococcus*, *Peptostreptococcus*, *Bacteroides fragilis*, and viridans streptococci. Resolution of the lymphadenitis occurred promptly after incision and drainage and penicillin therapy.

Dental disease or manipulation also should suggest the possibility of cervicofacial actinomycosis (lumpy jaw). These patients have a chronic submandibular mass and frequently a fistula from the skin to the oral cavity.[16] Less frequently occurring bacteria,[70] viruses, fungi, and parasites can cause cervical lymphadenitis in children, but these patients usually have less evidence of acute inflammation, with or without adenopathy at additional sites, and historical and physical findings that suggest unusual causes of cervical lymph gland enlargement.

SPECIFIC DIAGNOSIS

A detailed history to ascertain preceding dental problems, presence of skin lesions, animal exposure (including exposure to fleas and ticks), duration of illness, presence of associated symptoms, contact with tuberculosis, presence of risk factors for HIV infection, drug usage (especially phenytoin) or other unusual ingestions (undercooked meat, unpasteurized dairy products), recent travel outside the geographic region of residence, and sites of occult infection drained by the affected node may yield important diagnostic clues in a patient with cervical lymphadenitis. Physical examination should include careful inspection for the presence of dental disease, noncervical lymphadenopathy, hepatosplenomegaly, and oropharyngeal or skin lesions.

Radiologic evaluation of adenitis is unnecessary in most mild to moderate cases. Ultrasonography often is performed when the presenting neck mass is very large, is increasing in size, or has not responded to initial antibiotic therapy. It is useful in diagnosing suppuration and expediting incision and drainage. High-resolution and color Doppler ultrasonography (with or without contrast enhancement) defining longitudinal-to-transverse nodal

ratio and vascularity patterns has had some success in differentiating benign and malignant lymph nodes in adults.[2,96,98,158,160]

In children in whom most adenopathy is infectious or reactive in etiology, ultrasonography is less discriminating. In one study of 35 children, ultrasonography showed significant differences in lymph nodes in 22 children with a diagnosis of Kawasaki disease compared with 8 children with bacterial lymphadenitis, but findings were similar to those of children with lymphadenitis secondary to Epstein-Barr virus infection.[144]

In another study of 146 children, unilateral lymph nodes and cystic necrosis were found only in lymphadenitis caused by cat-scratch disease or bacterial or tuberculous infection.[113] Individual sonographic findings were nonspecific for diagnosis, although these findings combined with clinical signs were helpful. No patients with nontuberculous mycobacterial adenitis were evaluated in this study. Nodal calcifications and spread of nodal masses into the subcutaneous tissues by ultrasonography and characteristic low-density, ring-enhancing lesions with minimal or absent inflammatory stranding of subcutaneous fat seen on computed tomography and magnetic resonance imaging have been reported with nontuberculous mycobacterial adenitis in children.[54,58,77,123] These findings may be helpful in differentiating this etiology from other bacterial causes when the diagnosis is not suspected clinically or early in the course. Differences in clinical presentation between the two entities should obviate the need for such imaging, however, in all but the most complicated of cases.

In the acute stage of cervical lymphadenitis, needle aspiration of the affected node is a valuable diagnostic tool. Sixty to eighty-eight percent of patients with acute cervical lymphadenitis subjected to needle aspiration of the affected node for bacterial and mycobacterial culture have an etiologic agent recovered.[13,24,65,159] Only inflamed nodes should be aspirated, but they need not be fluctuant. No serious complications of this procedure have been recorded.

The largest or most fluctuant node should be selected, and the skin should be cleansed and anesthetized. Skin anesthesia can be induced effectively using a topical anesthetic cream (e.g., lidocaine-prilocaine [EMLA]) placed on the selected aspiration site under an occlusive dressing 30 to 45 minutes before the procedure. An 18- or 20-gauge needle attached to a 20-mL syringe is used. If no material is aspirated, 1 to 2 mL of sterile *nonbacteriostatic* saline is injected into the node, and it is reaspirated. The aspirate should be inoculated directly from the syringe onto aerobic (including chocolate agar) and anaerobic media, onto Sabouraud agar (fungi), and into a broth medium suitable for the early detection of mycobacteria, such as the Bactec radiometric assay. In the last-mentioned system, the release of labeled carbon dioxide in an automated ion chamber system can detect mycobacteria 12 to 17 days after inoculation of the broth.[133] Gram and acid-fast stains are mandatory, and their reading serves as a guide to initial antimicrobial therapy.

Polymerase chain reaction assays used to identify tuberculous and nontuberculous mycobacteria have successfully confirmed their presence in gastric aspirates and in specimens obtained from lymph nodes by aspiration or biopsy.[39,45,52,53,131,136] This technique shows great promise in rapidly providing a specific diagnosis, but it is not yet routinely available.

Thioglycolate broth and anaerobically incubated blood agar plates are incapable of providing optimal conditions for the isolation of many anaerobic bacteria.[13] Optimal methods for cultivation of fastidious anaerobes should be employed because anaerobic organisms may be recovered in 20 percent of cases.[24] Cultures of infected skin lesions and exudates on tonsils also should be done, but not to the exclusion of needle aspiration.

Isolation of group A streptococci from the throat or skin cultures of a patient with lymphadenitis does *not* confirm the etiology of the lymph node inflammation. Patients have been noted to have isolation of group A streptococci from throat and of *S. aureus* from lymph node aspirate cultures.[13,118] Tuberculin skin tests should be performed. Induration of 15 mm or greater suggests infection with *M. tuberculosis*, whereas reactions of 5 to 14 mm may be caused by either a tuberculous or a nontuberculous mycobacterial infection.[86]

In an attempt to develop a rational approach to the use and interpretation of differential skin testing, Huebner and associates,[60] using tuberculin skin tests and nontuberculous mycobacterial antigens, studied 144 children with chronic cervical adenopathy, of whom 123 had mycobacterial culture results available. The low incidence of tuberculosis within the study population (four cases) precluded making an interpretation regarding the utility of these antigens in distinguishing disease caused by *M. tuberculosis* from that caused by other mycobacteria. Children with culture-confirmed mycobacterial lymphadenopathy had significantly larger reactions to nontuberculous mycobacterial antigens than did children with microscopy-negative and culture-negative results. The study was terminated prematurely because of an unacceptably high incidence of a blistering skin reaction to nontuberculous mycobacterial antigens.

Intradermal skin testing, using a crude extract from affected nodes, historically has been used to establish the diagnosis of cat-scratch disease.[28] A diagnosis usually is reached, however, based on the presence of regional adenopathy, a history of cat exposure (particularly if the patient has a history of a scratch or a primary skin lesion), and negative laboratory studies for other causes of lymphadenopathy. *B. henselae*, the more common etiologic agent of this disease, can be isolated from blood if lysis-centrifugation blood cultures or the Bactec blood culture system is used. Isolates may be identified using a commercially available system (Microscan Rapid Anaerobe Panel; Baxter, Sacramento, CA).[1] Serologic methods for the detection of IgG antibodies to *B. henselae* are available[1,161] and should be considered the gold standard diagnostic method. In few cases, a lymph node biopsy should be undertaken to exclude other, more serious, pathologies.

If, after the aforementioned evaluation, the etiology of adenitis remains uncertain, or lymphadenopathy has persisted with no detectable response to antimicrobial therapy, a more intense diagnostic evaluation is indicated. Studies may include a complete blood count; serology for Epstein-Barr virus, cytomegalovirus, HHV-6, HIV, histoplasmosis, coccidioidomycosis, toxoplasmosis, tularemia, *B. henselae*, and *Brucella*; and a radiograph of the chest. If the diagnosis remains in doubt, and the node persists, enlarges, is hard, or is fixed to the adjacent structures, biopsy *should* be performed. Biopsy material should be submitted for the studies outlined earlier for lymph node aspirate cultures and for routine histology; Giemsa, periodic acid–Schiff, and methenamine silver stains; and, in select cases only, viral cultures. If the histology reveals noncaseating granulomas and the child has a history of cat exposure, the most likely diagnosis is cat-scratch disease,[85,87] and serologic testing is indicated. Sarcoidosis involving lymph nodes would have a similar histology but is rare in children and a condition in which isolated cervical node involvement has not been observed.[64,130]

Older children are more likely to have negative cultures of lymph node aspirates[13,141] and to be more frequent candidates for excisional lymph node biopsy. They also are more likely to have lymphomas. It is important that appropriate tissue be excised, especially from adolescents, so that precise diagnostic interpretation can be done. This interpretation can be facilitated by the proper selection of a lymph node to be biopsied; intact removal of the node chosen; and proper fixation, cutting, and staining of the specimen. If only one node or one anatomic group of nodes is enlarged, the largest node should be excised. If several groups of lymph nodes are involved, the site for biopsy should be selected according to the likelihood of diagnostic yield. Biopsy specimens from the lower neck and supraclavicular area have the highest yields.[67] Other areas, including the upper cervical, submandibular,

axillary, and parotid lymph nodes, are much more likely to be affected by reactive hyperplasia, which may or may not be related to the underlying disease process. If lymphoma is suspected, needle biopsies or frozen sections are contraindicated.[18,25]

Even under optimal conditions, many reactive processes, including rheumatoid arthritis, toxoplasmosis, phenytoin-induced adenopathy, dermatopathic adenitis, and infectious mononucleosis, have been noted to simulate lymphoma.[25] Obtaining a thorough history and performing appropriate serologic studies should provide sufficient information for the physician to exclude reactive processes known to simulate lymphoma.

TREATMENT

Optimal management of a child with cervical lymphadenitis depends on an accurate assessment of the underlying etiology. Because almost all cases are associated with infectious agents, every effort should be made to ascertain the etiologic agent so that specific therapy can be initiated. Aspiration of the affected lymph node for Gram and acid-fast stains serves as a guide for initial therapy, and culture and antimicrobial susceptibility form the basis for prescribing specific treatment in patients with bacterial lymphadenitis.[13,35] When the patient presents with typical findings of acute bacterial lymphadenitis, however, empiric therapy may be undertaken without prior needle aspiration. In this situation, close follow-up is essential because failure to show some clinical response after 48 hours of therapy is an indication for this diagnostic procedure to be done.

Acute suppurative cervical lymphadenitis most frequently is caused by infection with *S. aureus* or group A streptococci.[13,22,35,129,141,159] In nodes that progress to abscess formation, *S. aureus* is the most frequent agent isolated,[13,35,129] and drainage is mandatory. Because of the frequency of infection caused by *S. aureus* or group A streptococci, empiric antimicrobial therapy should be directed against these two agents. Penicillinase-resistant penicillins should be used. If the patient requires parenteral therapy and CA-MRSA is not common in the area, oxacillin, nafcillin (150 mg/kg/day), or cefazolin (75 to 100 mg/kg/day) may be used.

When oral therapy is deemed to be adequate, cloxacillin (50 mg/kg/day), dicloxacillin (25 mg/kg/day), or cephalexin (25 to 50 mg/kg/day) is recommended. Augmentin, the fixed combination of amoxicillin and clavulanic acid, provides good activity against methicillin-susceptible staphylococci and streptococci and has an expanded spectrum of activity against the oral anaerobic organisms. These features, combined with its palatability, render it an attractive alternative to the traditional penicillinase-resistant penicillins. Clavulanate-associated diarrhea can be problematic in some children, however. In penicillin-allergic patients, cephalosporins may be used. Once-daily ceftriaxone (50 to 100 mg/kg/day) is an attractive and effective alternative to the parenteral antibiotics that require more frequent administration.

In areas where CA-MRSA is prevalent, clindamycin (30 mg/kg/day) for parenteral or oral use is appropriate for empiric or alternative therapy. In addition to its good activity against anaerobes and methicillin-susceptible *S. aureus*, clindamycin is effective against most CA-MRSA isolates. Because of reports that clindamycin resistance is increasing among CA-MRSA isolates, however, close clinical follow-up to ensure a therapeutic response has been achieved is mandatory when clindamycin therapy is chosen.[42,59,61,63,99] In a severely ill child needing hospitalization or with signs of airway compromise, vancomycin (45 mg/kg/day) is appropriate in combination with another agent until culture results are obtained. Trimethoprim-sulfamethoxazole (10 mg/kg/day of the trimethoprim component) is an alternative choice for oral therapy of CA-MRSA infections[42,59,61,99] but should not be used initially because it is not active against group A streptococci.

Antibiotic therapy may need to be modified if an obvious primary focus of infection suggests a different etiologic agent. In a patient with periodontal or dental disease, adequate anaerobic activity is mandatory, and therapy with penicillin V (50 mg/kg/day), augmentin (40 mg/kg/day), or clindamycin (30 mg/kg/day) should be initiated, pending results of cultures.

Patients with marked lymph node enlargement, moderate to severe systemic symptoms, or concomitant cellulitis frequently require parenteral therapy for the first few days. This therapy allows for a high concentration of the antimicrobial agent within the inflamed tissue and may promote more rapid localization, especially in patients with staphylococcal adenitis. Although the use of parenteral drugs has to be individualized, most infants and children with staphylococcal or streptococcal lymphadenitis respond to orally administered antimicrobials.

Adenitis caused by group A streptococci should be treated with penicillin G (100,000 IU/kg/day) or penicillin V (50 mg/kg/day) for a total of 10 days. In a child with penicillin allergy, erythromycin ethyl succinate (40 mg/kg/day) or cephalexin (25 to 50 mg/kg/day) may be used. Both drugs have been shown to be effective in the treatment of cervical lymphadenitis.[13,22] Treatment should be continued for at least 10 days or approximately 5 days after signs of local inflammation and systemic toxicity have disappeared, whichever is longer. If required, analgesics should be given and not overlooked in infants and children too young to verbalize their discomfort. The average duration of antibiotic therapy is 10 days, unless abscess formation occurs late in the first or early in the second week of treatment.[13] In this situation, incision and drainage are indicated,[13,23,35] and therapy should be continued until resolution of the acute process occurs, usually within another 5 to 7 days.

Some clinical improvement is to be expected within 48 hours after initiation of therapy and is manifested by a decrease in inflammation and tenderness of the lymph node and a decrease in the maximum daily temperature. The size of the lymph node may not show evidence of regression at this stage, and total resolution of fever should not be expected. It is important to record accurate measurements of the node at the time of presentation because a subjective evaluation is an unreliable indicator of lymph node evolution during therapy. If no clinical improvement is noted by 48 hours, needle aspiration is recommended. The history and physical examination should be reassessed, and a more detailed laboratory evaluation should be initiated.

In a study of 284 children admitted to the hospital with acute cervical adenitis, age younger than 1 year and node involvement for more than 48 hours before admission predicted the need for node aspiration.[81] Regression of the size of a lymph node is slow, usually requiring 4 to 6 weeks or more. Persistence of significant enlargement beyond 6 to 8 weeks, even in the face of good initial response to antimicrobial therapy, demands that an underlying disorder be excluded. When signs of acute inflammation have resolved, prolonged antimicrobial therapy is of little value because penetration of antimicrobials through the fibrous capsule of the node is poor.[22] Spontaneous regression occurs in most patients, although it may require several weeks. Uncommonly, reactivation of inflammation may occur, and a meticulous search for an untreated primary source of bacterial infection, such as secondarily infected dermatitis, infestation, foreign body, or dental abscess, should be undertaken. Re-treatment should include specific measures to eliminate the predisposing condition.

If Gram stain of the lymph node aspirate suggests a microorganism other than *S. aureus* or group A streptococci, initial antimicrobial therapy should be directed at the most likely agent until culture results are known. Because attempts to perform careful Gram stains and careful anaerobic cultures of lymph node aspirates in most reported series have been limited, the large number

of infants and children with sterile aspirates may be attributed partly to a failure to isolate fastidious anaerobes indigenous to the mouth. These microorganisms should respond to penicillin G therapy. For penicillin-resistant organisms, clindamycin is a useful alternative drug.

For infants in the first 2 months of life, group B streptococci and *S. aureus* are important pathogens to consider in selecting initial therapy. Penicillinase-resistant penicillins are active against both agents, unless the occurrence of CA-MRSA is frequent, in which case clindamycin or vancomycin should be considered for initial therapy. If group B streptococci are isolated, penicillin G can be substituted. Final bacteriologic identification and antimicrobial susceptibility tests should be the ultimate guide to selecting specific antimicrobial therapy in all patients. Treatment of cervical lymph node infections associated with rarely encountered bacteria, fungi, and parasites listed in Table 15–3 is discussed under those specific disease entities.

Although controversy exists as to whether cervical adenitis associated with *M. tuberculosis* in a child is truly a localized process, only rarely do patients have disseminated infection.[36,51,106] When infection is not localized, pulmonary or hilar lymph node involvement is a common finding.[36,65,107,159] A 2-month regimen of isoniazid (10 mg/kg/day), rifampin (15 to 20 mg/kg/day), pyrazinamide (30 mg/kg/day), and ethambutol (15 mg/kg/day) is recommended for the treatment of uncomplicated pulmonary tuberculosis or isolated cervical lymphadenitis in children. Triple therapy is given daily for the first 2 months of therapy, after which isoniazid and rifampin are administered, either daily or on a twice-weekly basis, for the ensuing 4 months. Directly observed therapy is preferred.[6]

In areas where multiple-drug resistance in *M. tuberculosis* is prevalent, streptomycin (20 to 40 mg/kg/day) or another aminoglycoside (kanamycin, amikacin, or capreomycin) is added for initial treatment until drug susceptibilities are known.[6] The addition of a fifth drug should occur after consultation with an expert in the field because these drugs may have toxic effects, and careful assessment of the risks and benefits is warranted. Detailed discussion of the treatment of tuberculosis in children is provided in Chapter 107. Response to antituberculous therapy is usual, with rapid resolution of symptoms and marked regression of lymph nodes within 3 months. Nodes remain palpable for months, however, because scarring and fibrosis are regular accompaniments to resolution of disease. Draining sinuses, a common complication of lymph node aspiration or incision, and drainage before the advent of effective antituberculous chemotherapy no longer develop.[107]

Cervical lymphadenitis attributed to nontuberculous mycobacteria is much more common in a young child than that caused by *M. tuberculosis.* These microorganisms exhibit in vitro resistance to commonly employed antituberculous drugs. Resistance particularly is common among *M. scrofulaceum* and *M. intracellulare*. Surgical excision is the treatment of choice for nontuberculous mycobacterial lymphadenitis,* and total removal of all the visibly affected nodes is recommended.[4,8,30,56,112,114,120,126,155] Early (within 1 month of onset) removal of affected nodes was associated significantly with better esthetic results in one series.[83] Thorough curettage has been found to be effective,[84,106] but results in higher relapse rates.[43]

Antimicrobial therapy alone is less effective.[90] The new macrolides clarithromycin and azithromycin, rifampin and its analogue rifabutin, ethambutol, amikacin, and cefoxitin show activity against nontuberculous mycobacteria.[38,143] Clarithromycin monotherapy and combination therapy with clarithromycin and ethambutol or rifampin have had some success in the treatment of nontuberculous lymphadenitis.[17,50,58,79,80,84,145] In the largest retrospective case series, 22 children received clarithromycin either alone or in combination with other antimycobacterial agents without surgery, and only one recurrence was documented.[80]

In another study, 10 children (7 of whom had initial incision and drainage or aspiration) were treated for 1 to 14 months with a regimen of clarithromycin (20 to 30 mg/kg/day) in combination with ethambutol (12.5 to 19 mg/kg/day) or rifampin (6 to 20 mg/kg/day). Five children were cured; the remainder needed further surgical procedures.[58] Six of seven patients treated for 6 months in another series had not relapsed after a mean follow-up of 3 years.[79] Rifabutin was used in all children in this study, resulting in side effects in four (neutropenia, yellow skin pigmentation), which disappeared after dose reduction. In HIV-infected children receiving protease inhibitors, rifabutin generally is contraindicated, but it can be given at a much reduced dosage (indinavir or nelfinavir is the preferred protease inhibitor) if deemed necessary.[8]

Despite the lack of prospective studies, macrolide-containing regimens are promising options for the treatment of nontuberculous mycobacterial adenitis for which complete excision of the affected node would endanger the facial nerve or its branches, or if a reduction in size of the swelling would facilitate a complete and esthetic excision at a later stage. The optimal duration of therapy is unknown, but regimens of 4 to 6 months or longer are usual. Expert opinion should be sought, especially as new mycobacterial species are described. Currently, macrolide (clarithromycin or azithromycin) monotherapy or combination therapy should be viewed as a valuable adjunct when surgery is not feasible or is refused.

Cat-scratch disease usually is a benign, self-limited disorder requiring no specific therapy. The use of antimicrobials is controversial, but rifampin, trimethoprim-sulfamethoxazole, azithromycin, ciprofloxacin, and parenteral gentamicin may be useful in promoting fever defervescence and in clinical resolution of systemic cat-scratch disease.[7,9,14,89] If the lymph node progresses to fluctuance, needle aspiration may hasten resolution and relieve discomfort. Surgical excision may be required in a few patients who have persistent problems despite having needle aspiration, or who develop draining sinuses.

PROGNOSIS

With effective antimicrobial therapy, complete resolution of cervical lymphadenitis caused by *S. aureus*, group A streptococci, and *M. tuberculosis* is the rule. Delay in establishing the diagnosis or initiating therapy may prolong the clinical course and may result in complications or sequelae, such as sinus tracts (mycobacteria),[19,33,107] abscess formation,[23] cellulitis or bacteremia (*S. aureus* and *S. pyogenes*),[13] acute glomerulonephritis (group A streptococci),[35] disseminated disease (*M. tuberculosis*),[65] or mycotic carotid artery aneurysm.[154] Except for abscess formation, these complications are rare events. Although lymph node infection caused by *S. aureus* is more likely to result in abscess formation, at least one study has noted a significantly greater duration of infection before treatment in patients in whom *S. aureus* was isolated from the abscess cavity cultures.[13] The extracellular products of this organism (e.g., coagulase, fibrinolysin, hyaluronidase) partly explain its propensity for abscess formation, which may occur in 50 to 70 percent of patients.[23,35,157]

Even in patients whose course is complicated by suppuration, appropriate drainage in conjunction with specific antimicrobial therapy results in prompt resolution of signs and symptoms, and relapse occurs only rarely. Today, surgical excision of affected nodes seldom is recommended except when the disease is caused by nontuberculous mycobacteria, in which case surgical excision remains the treatment of choice. Antimicrobial therapy has been

*See references 8, 38, 43, 83, 88, 112, 114, 120, 137, 142.

responsible for the disappearance of the events commonly associated with cervical adenitis historically, including thrombosis of the internal jugular vein, rupture of the carotid artery, generalized septic embolic phenomena, mediastinal abscess, purulent pericarditis, and even death.[68,140,157]

With the advent of effective antituberculous agents, the prognosis for tuberculous cervical adenitis also is excellent. When surgical excision is performed early in the course of lymphadenitis caused by nontuberculous mycobacterial infection, resolution can be anticipated.[43,83,112,120,126,137] Persistent and recurrent disease is the most frequent complication encountered.[155] Macrolide monotherapy and combination therapy are useful in ameliorating these complications or in cases for which surgery is not feasible.[114,137] Cat-scratch disease usually is a benign, self-limited disorder only rarely requiring therapeutic intervention, such as needle aspiration, to relieve pain.

PREVENTION

Providing appropriate medical and, occasionally, surgical therapy of predisposing conditions (e.g., dental caries, abscess, group A streptococcal pharyngitis or nasopharyngitis, purulent otitis media, impetigo, other infections involving the face and scalp) and minimizing the exposure of infants and children to adults with active tuberculosis should reduce the incidence of cervical lymphadenitis. Some authors suggest that decreased exposure to animals may result in fewer infections,[13] especially for adenitis attributed to toxoplasmosis or *Bartonella*.[29,121]

CHAPTER 16

Parotitis

Judith R. Campbell

Parotitis, inflammation of the parotid gland, is caused by a variety of infectious agents and noninfectious systemic illnesses. Several terms are used to describe the clinical presentations and etiologic processes that lead to parotid gland swelling and inflammation. *Suppurative parotitis*, first described in the 1800s, is a serious bacterial infection in neonates and postsurgical patients.[49] *Epidemic parotitis*, particularly prevalent in the pre-vaccine era, was caused primarily by mumps virus infection.[56] In the postvaccine era, this form of parotitis also is caused by other viral pathogens and is referred to as *viral parotitis*. Rarely, a more indolent, slowly progressive, granulomatous infection may occur that is referred to as *granulomatous parotitis*. *Recurrent parotitis of childhood* is a unique illness that is characterized by multiple episodes of acute and subacute parotid gland swelling. The histologic findings in

Trauma

this disease include architectural changes in the ducts and chronic inflammation. Many noninfectious systemic illnesses cause persistent or recurrent parotid gland swelling and inflammation, which is referred to as *chronic parotitis*. Bilateral parotid enlargement is a frequent presentation of human immunodeficiency virus (HIV) infection as part of *diffuse infiltrative lymphocytosis syndrome*.

PATHOPHYSIOLOGY

Despite the various agents that cause parotitis, involvement of the gland occurs mainly by three mechanisms. The most common mechanism is a localized infection limited to the gland and surrounding structures. Parotitis may be a manifestation of a systemic infection, as in mumps, or rarely may develop secondary to hematogenous seeding during periods of transient bacteremia. Several common contributing factors and pathophysiologic mechanisms lead to swelling of the gland. The parotid is well encapsulated and consists of superficial and deep lobes that are separated by the facial nerve. The parotid duct (Stensen duct) traverses the buccal soft tissue anteriorly and exits opposite the second upper molar. Thin, watery secretions from the parotid gland cleanse the ductal system and have some bacteriostatic properties, preventing accumulation of bacteria and debris.[36] Factors that predispose individuals to the development of parotitis include side effects of certain drugs and diseases that lead to dehydration, xerostomia, or ductal obstruction (Table 16–1).[36,49] Decreased salivary flow allows retrograde migration of bacteria. Stasis in the ductal system, caused by ductal ectasia, inflammation, calculi, or strictures, allows proliferation of bacteria and inflammation within the gland.

ETIOLOGY

Infectious parotitis may be caused by aerobes, anaerobes, mycobacteria, and viruses (Table 16–2). In all age groups, *Staphylococcus aureus* is the organism most commonly associated with suppurative parotitis.[47,49] Gram-negative pathogens (e.g., *Escherichia coli* and *Klebsiella* and *Pseudomonas* spp.) also may cause suppurative parotitis, particularly in neonates and debilitated or hospitalized patients.[11,31,48,49] The role of anaerobic organisms in this infection has become apparent, especially when poor oral hygiene and oral pathology are associated features.[4,5,39] In cases of recurrent

Human immunodeficiency virus

parotitis of childhood, *Streptococcus* spp. are the bacteria most commonly isolated.[21,42,46] Granulomatous parotitis most often is caused by *Mycobacterium tuberculosis* and may occur in the absence of systemic or disseminated tuberculous disease.[36,44,52] Other causes of granulomatous parotitis include *Mycobacterium avium–intracellulare*, *Actinomyces* spp., and gram-negative intracellular organisms (*Francisella tularensis* and *Brucella* spp.).[25,36,59]

In the postvaccine era, the most common viral cause of parotitis still is the paramyxovirus mumps virus. Coxsackieviruses, Epstein-Barr virus, influenza A virus, parainfluenza viruses, adenovirus, human herpes virus–6, herpes simplex virus, cytomegalovirus, and lymphocytic choriomeningitis virus all have been implicated in cases of parotitis.[1,2,16,28,30,32,35,36]

CLINICAL PRESENTATION AND DIAGNOSIS

A detailed history and physical examination are crucial in assisting the clinician in determining the most likely etiology of parotid gland swelling. One should determine the onset and duration of symptoms, their periodicity, and the character of salivary secretions. In addition, the presence of a systemic disease must be excluded. Examination of the parotid gland is achieved best by simultaneous palpation of the intraoral and extraoral salivary structures. Gentle external pressure should be applied to the gland, and the parotid duct should be examined for evidence of purulent secretions or surrounding erythema.

Suppurative parotitis occurs most commonly in neonates or patients with dehydration, poor oral hygiene, malnutrition, immunosuppression, oral trauma, sepsis, or any medication or

disease that decreases salivary secretions.[18] Most often, the disease is unilateral; however, bilateral suppurative parotitis may occur in 17 percent of cases.[42] The disease is characterized by acute onset of pain, swelling, warmth, and induration of the involved gland and purulent discharge from the Stensen duct. Associated physical findings include fever, trismus, malaise, and cervical adenitis. In suppurative parotitis, Gram stain and culture (aerobic and anaerobic) of purulent material from the duct can provide a specific microbiologic diagnosis. In addition, elevation of the white blood cell count with a neutrophil predominance may help differentiate this form of parotitis from viral parotitis and parotid disease of a noninfectious etiology.

Mumps is the most common form of viral parotitis and is characterized by a prodrome of fever, malaise, anorexia, and headache. Usually, the following day, unilateral or bilateral earache and parotid tenderness develop. The gland or glands enlarge during the subsequent 2 to 3 days, and the orifice of the Stensen duct is erythematous and swollen, yet secretions from the duct are clear. At the point of maximal swelling, the angle of the jaw is obliterated, and the earlobe is lifted upward and out. The other salivary glands are involved in 10 percent of cases.[42] Rare systemic manifestations of mumps infection include epididymo-orchitis, meningitis, meningoencephalitis, and oophoritis. More recent outbreaks of confirmed and probable mumps emphasize that this infection may occur in highly immunized populations.[6] In 2006, more than 5000 cases of probable mumps were reported to the Centers for Disease Control and Prevention. Of these, 54 percent were laboratory confirmed or linked epidemiologically to a confirmed case. Although the median age was 22 years, patients ranged in age from 1 month to 96 years. Most cases were from the Midwest (Iowa, Kansas, Wisconsin, Illinois, Nebraska, and South Dakota), and many of the patients had received two doses of measles-mumps-rubella (MMR) vaccine.[6]

Other viral agents may produce similar clinical manifestations and can be differentiated from mumps only by culture and hemagglutination inhibition, complement fixation, or enzyme-linked immunosorbent assay serology.[16] In viral parotitis, the white blood cell count may be normal, slightly elevated, or depressed, with a lymphocytic predominance.

Granulomatous parotitis typically manifests as a painless, slowly enlarging mass without surrounding inflammation. It may be misdiagnosed as a slow-growing tumor until the correct diagnosis often is made by biopsy and culture. *M. tuberculosis* and *M. avium–intracellulare* may cause infection in the parenchyma of the gland or in intraglandular or periglandular lymph nodes.[43,59] Clinical evidence of systemic tuberculous disease usually is absent. Parotitis has been observed as an extension of nontuberculous cervical adenitis.[59] Actinomycosis of the parotid gland causes a slowly enlarging, nodular, nontender gland; associated oral or cervicofacial infection usually is present. Fistulas draining yellow or white material with sulfur granules are common findings.[25]

Recurrent parotitis of childhood is rare, with onset that typically occurs before the child reaches 10 years of age and a peak incidence at approximately 6 years of age.[17,42] Some authors hypothesize that an underlying congenital abnormality, such as sialectasis, is a common predisposing feature.[33,43] Others suggest that selective IgA deficiency may be a contributing variable.[19] Clinically, these children experience repeated episodes of fever, pain, and unilateral swelling of the parotid gland. Purulent material often can be expressed from the Stensen duct and, when cultured, often yields streptococcal organisms. Sialography and ultrasound reveal multiple areas of sialectasis throughout the parotid glands bilaterally, even if only one side is symptomatic. The frequency of attacks varies, and each episode of parotitis may last 2 weeks, when it resolves spontaneously.[10] Several authors have noted that recurrences become less frequent with increasing age and that the disease tends to cease at the onset of puberty or early adulthood.[17,42]

HUMAN IMMUNODEFICIENCY VIRUS AND PAROTID ENLARGEMENT

Salivary gland enlargement has been recognized as a common finding in children infected with HIV since before the era of highly active antiretroviral therapy. The prevalence of this manifestation in HIV-infected individuals is 0 to 58 percent.[46] More recently, in a retrospective report of oral lesions in a cohort of HIV-infected children from Brazil, Miziara and colleagues[40] noted the prevalence of parotid gland enlargement to be 7.6 percent. Although parotid enlargement occurred more commonly in children older than 5 years of age, the prevalence did not differ between children who were receiving antiretroviral therapy without protease inhibitors and children who were receiving highly active antiretroviral therapy.

The exact pathophysiology is unknown, but proposed mechanisms include lymphoepithelial cysts, lymph node enlargement within the gland, cytomegalovirus or Epstein-Barr virus infection, and diffuse infiltrative lymphocytosis syndrome of the gland.[46] This entity in HIV-positive children possibly is associated with the HLA-DR5 and HLA-DR11 phenotype, but the significance of this finding is unclear.[27,46,55] Bilateral parotid enlargement frequently is seen as part of diffuse infiltrative lymphocytosis syndrome, which is characterized by proliferation of $CD8^+$ lymphocytes within the circulation and is of unclear etiology. Growth of the parotid is secondary to infiltration of CD8 lymphocytes into the gland, follicular hyperplasia of intraparotid lymphoid tissue (as occurs in lymph nodes throughout the body in HIV infection), and development of diffuse intraparotid, lymphoepithelial cysts.[8,37] Epstein-Barr virus has been proposed as an impetus for CD8 lymphoproliferation because the virus has been isolated from parotid tissue of some affected patients.[9] The absence of positive serology for the virus renders it an unlikely causative agent, however. HIV, which may be the inciting agent, has been detected in dendritic cells, macrophages, and lymphocytes isolated from the parotid glands of affected patients.[9]

Parotid enlargement may be present in 20 to 50 percent of children with HIV infection and acquired immunodeficiency syndrome (AIDS).[29,33,54,57] The median time from birth to development of parotid enlargement is 4.6 years, and often it is the first manifestation of HIV infection acquired during the perinatal period in an otherwise healthy older child.[27,29] HIV-positive children with enlarged parotid glands tend to have a slower progression to death than do HIV-positive children with oral herpes or candidiasis.[29] Usually, both parotid glands are involved, and an affected patient presents with enlarged, tender parotid glands, xerostomia, and increased serum amylase level.[7] Severity of pain and size of the gland tend to fluctuate without apparent cause. This manifestation of HIV infection and AIDS is still commonly seen in developing countries where access to antiretroviral therapy is limited.

The differential diagnoses for parotid enlargement in an HIV-positive patient include viral and bacterial parotitis. Some patients have preexisting xerostomia that may increase their susceptibility to parotitis. In addition, the immunocompromised state of patients with AIDS may predispose them to development of infection of the parotid gland with other agents, such as cytomegalovirus, Epstein-Barr virus, bacteria, mycobacteria, and fungi.[23,51,58,61] Noninfectious etiologies, such as non-Hodgkin lymphoma or Kaposi sarcoma, also should be included in the differential diagnosis of parotid gland enlargement in an HIV-infected patient, although these manifestations usually are observed in adults.

DIFFERENTIAL DIAGNOSIS

Parotitis most often is diagnosed based on clinical presentation, microbiology, serology, and response to empiric therapy. Ultrasound may be useful as a screening tool to prompt more sensitive modalities if the ultrasound scan is abnormal.[41] Computed tomography is most useful in the presence of anatomic defects, radiolucent calculi, or abscess formation in the parotid gland.[50] X-ray sialography is the gold standard in examining the parotid gland ducts; however, sialography is contraindicated in the setting of acute infection. Magnetic resonance sialography is a promising alternative and has several advantages. In contrast to x-ray sialography, magnetic resonance sialography is not contraindicated during acute parotitis and does not require injection of contrast material or involve manipulation of the Stensen duct.[20] Nonetheless, experience with magnetic resonance sialography is limited, and this mode alone may not be sufficiently sensitive to detect tertiary salivary ductules or calculus disease.[20,61]

Noninfectious causes of parotid swelling and inflammation include collagen vascular diseases (Sjögren syndrome and systemic lupus erythematosus), metabolic disorders (hepatic disease, hyperlipoproteinemia, hyperuricemia), endocrine disorders (diabetes mellitus, hypothyroidism), tumors, leukemic infiltration, drugs (antineoplastic chemotherapy), and poisons (iodine).[36,42,47] Sjögren syndrome, the most common cause of noninfectious parotitis, is caused by lymphocyte-mediated destruction of the exocrine glands.[24,47] Patients with this disease have diminished or absent glandular secretions and mucosal dryness; xerostomia and keratoconjunctivitis sicca are prominent clinical features. In addition, the parotid glands are enlarged bilaterally, are firm, and have an irregular contour. Sialography reveals sialectasia, and saliva from these patients has unique biochemical characteristics. Antibodies to nuclear antigens SS-A and SS-B can be detected in the sera of patients with Sjögren syndrome.[47] Patients with chronic noninfectious parotitis have changes in the ductular architecture or strictures that can predispose them to episodes of infectious parotitis.

TREATMENT

Treatment of parotitis includes rehydration, parotid massage, discontinuation of any medications that diminish salivary flow, and sialalogues (e.g., lemon drops, hard candy, chewing gum), which increase salivary flow.[3,36,47,49] In cases of suspected suppurative parotitis, a broad-spectrum antibiotic regimen that is effective against *S. aureus*, *Streptococcus* spp., gram-negative organisms, and anaerobes should be administered empirically, pending specific culture results. Antibiotic regimens frequently employed include penicillinase-resistant penicillins, first-generation cephalosporins, and clindamycin in combination with an aminoglycoside.[3] Vancomycin should be used if MRSA is the likely pathogen. If the patient has been hospitalized for a prolonged period, or if the predominant organisms on Gram stain of the purulent discharge are gram-negative, ceftazidime should be considered as initial empiric therapy.[47,49]

Surgical incision and drainage of purulent fluid are indicated if there is slow or no response to medical therapy or fluctuant increases.[53] The treatment of viral parotitis consists of antipyretics, analgesia, and hydration. In cases of mycobacterial infection, excision of the gland may be required, in addition to administration of specific antimycobacterial therapy.[44,52] Reports have described successful treatment with clarithromycin and azithromycin of parotitis caused by atypical mycobacteria.[22] In contrast, actinomycosis of the parotid gland is managed medically with penicillin G.[25] Children with recurrent parotitis should be treated with antibiotics during acute episodes, but chronic suppressive antimicrobial therapy is not recommended.

Tympanic neurectomy involves severing the parasympathetic secretomotor fibers of the tympanic plexus to the parotid. This procedure attenuates secretion from the gland and relieves sialectasis and further episodes of parotitis in more than 70 percent of patients.[15,45] Only 10 to 20 percent of these patients require parotidectomy for persistence of symptoms beyond puberty.[13] Although it is the optimal treatment for complete resolution of recurrent parotitis, parotidectomy carries a risk for facial nerve injury. More recently, Nahlieli and colleagues[43] described the use of endoscopy to diagnose and endoscopic irrigation to treat children with recurrent parotitis.

COMPLICATIONS

With improved fluid management of postsurgical patients and the use of broad-spectrum antimicrobial agents, complications secondary to infectious parotitis now are rare events. In neonates or immunocompromised patients, sepsis may be a severe complication of this infection. Abscess formation may result from delayed or ineffective therapy. Compromise of the facial nerve may occur and can resolve with successful treatment of the infected gland.[38] The most serious and rare complication is extension to other structures of the head and neck and along fascial planes to the face, external auditory canal, jugular vein, mandible, and mediastinum.

PREVENTION

Suppurative parotitis can be prevented in postsurgical patients by maintaining adequate hydration and good oral hygiene. The most common form of viral parotitis, mumps, can be prevented by appropriate vaccination. Between 1968 and 1993, a 99 percent reduction in the incidence of new cases of mumps occurred.[60] In the mid-1980s and more recently in 2006, a resurgence of the incidence of mumps in previously vaccinated populations was noted.[6,12,26] The most recent outbreaks occurred among college students and young adults in several states, raising concern of waning immunity in this highly vaccinated population.[6] The current recommendation is to provide two doses of live mumps vaccine for school-age children (i.e., grades kindergarten through 12) with MMR vaccine and to ensure that students in college or other post–high school educational institutions also have received two doses of MMR vaccine.[6,14]

CHAPTER 17

SINUSITIS

James D. Cherry ✪ Nina L. Shapiro

Sinusitis is an inflammation of the mucosal lining of one or more of the paranasal sinuses. Although this inflammation of sinus mucosa most probably occurs to some degree with every upper respiratory tract infection that produces rhinitis, most of these episodes apparently have a spontaneous resolution.[94] Studies during the last 2 decades estimate that 5 to 10 percent of upper respiratory infections are complicated by acute sinusitis.[2,167,184] This rate range represents a significant increase from earlier reports,[36] possibly because of a greater awareness of the illness and improved imaging techniques. The growing number of

children in daycare has led to an actual increase in the incidence of upper respiratory tract infections.[182,184] In addition, recognition that sinus infection can have a negative effect on the health of children with chronic pulmonary disease has increased the interest in this disease.[108]

When considering a diagnosis of sinusitis in a child, the major problem is to distinguish simple upper respiratory tract infection or allergic inflammation from secondary bacterial infection of the sinuses. Unless complications such as periorbital cellulitis or cavernous sinus thrombosis render the diagnosis obvious, the clinician has no reliable way to establish a diagnosis of acute sinusitis in the office setting. Sometimes, symptoms and signs of sinusitis occur simultaneously with rhinitis, but most often, they occur after an episode of rhinitis. Infection in the sinuses usually persists after the preceding rhinitis has resolved. Sinusitis is classified by the duration of clinical symptoms: acute (≤3 weeks), subacute (3 to 10 weeks), and chronic (>10 weeks). Available data comparing acute and subacute sinusitis are sparse; both entities may have a similar etiology, diagnosis, and prognosis; the distinction seems to be arbitrary and to have no clinical significance.

HISTORY

Purulent sinusitis and its relationship to orbital inflammation have been known for more than 2000 years.[71] Highmore, a 17th-century English physician and anatomist, is given credit for the separation of dental and antral disease.[130] Hunter indicated the importance of surgical drainage in purulent sinusitis and suggested perforating the partition between the maxillary antrum and the nose.[130] During the first half of the 20th century, sinusitis was responsible for considerable morbidity and mortality, and surgical care of sinusitis frequently was lifesaving. Since the advent of antibiotics, sinusitis has had a lower medical profile. Interest in this topic has increased, however. Some factors involved in this increased interest include the advent of the newer surgical techniques of functional endoscopic sinus surgery that yield comparable results to sinus puncture and aspiration,[163] which now have been applied to children; improved diagnostic imaging studies; and the greater social importance of upper respiratory tract infections for parents who must be absent from work to seek treatment for their children.[108]

ANATOMY

All the paranasal sinuses develop as outpouchings of the nasal cavity. Three shelflike structures—the inferior, middle, and superior turbinates—are on the lateral nasal wall. The superior turbinate is not well developed in the first year of life.[194] Beneath each turbinate is the corresponding meatus into which the sinuses open; that is, the frontal, maxillary, and anterior ethmoid sinuses open into the middle meatus. The sphenoid and posterior ethmoid cells open high in the nasal vault into the superior meatus.[175]

The maxillary sinuses develop early in the second trimester of fetal life as lateral outpouchings in the posterior aspect of the middle meatus. They are present at birth,[6,115,146,194] with floors being barely below the attachment of the inferior turbinates.[175] They expand rapidly by the time the child is 4 years of age.[194] Ultimately, at full size, the lateral borders of the maxillary sinuses reach the lateral orbital rims. The position of the floors of the sinuses is determined by the eruption of the dentition.[175] The ostia of the maxillary sinuses are located high on the medial walls of the sinuses, which impedes gravitational drainage of secretions; ciliary activity is required to move secretions from the body of the maxillary sinuses through the ostia into the nose.[175]

The ethmoid sinuses develop in the fourth month of gestation[175] and are present at birth.[115,146,194] They are not a single large cavity but a grouping of cells, 3 to 15 in number, each with its own opening or ostium. They have a honeycombed radiographic appearance and are small anteriorly and large posteriorly. The walls of the ethmoid labyrinth, especially the lateral walls bordering on the orbits, are thin; they are referred to as the *lamina papyracea*.[175]

Development of the frontal sinuses is variable. In adults, 80 percent have bilateral frontal sinuses, 1 to 4 percent have agenesis of the frontal sinuses, and the remainder have unilateral hypoplasia. The position of the frontal sinuses is supraorbital after the child reaches 4 years of age, but they are not distinguished radiographically from the ethmoid sinuses until the child is 6 to 8 years old. The frontal sinuses do not reach adult size for another 8 to 10 years.[175]

The onset of development of the sphenoid sinuses occurs during the child's first 2 years of life, but they remain rudimentary until the child is approximately 6 years of age. They have reached their permanent size, although not their permanent shape, by the time the child is 12 years old.[194]

Although the full development of the sinuses may take 20 years, by the time the child is 12 years old, the nasal cavity and the paranasal sinuses nearly have completed their development and have reached adult proportions.[194] Sinus disease in postpubertal adolescents is similar to that in adults.

The mucosal lining of all the paranasal sinuses is composed of ciliated columnar epithelium and goblet cells.[149] It is continuous and similar to the lining of the nasal cavity except that the mucosa in the nose is thicker and contains more glands. The epithelium of all the paranasal sinuses and nasal cavity is covered in part by a mucus blanket.

PATHOPHYSIOLOGY

The pathogenesis of sinus infection undoubtedly is similar to that of otitis media. The middle ear, with its extension, the eustachian tube, and the paranasal sinuses normally are sterile, but their contiguous areas (nasopharynx and nose) have a dynamic microbial flora. Under normal conditions, ciliary function with mucus flow can be expected to keep the sinuses clear of pathogens. The cilia within the sinuses propel the mucus toward their respective ostia, and from there, nasal ciliary action moves the mucus blanket posteriorly toward the pharynx. Insults that damage the ciliary epithelium and affect the morphology, number, and function of cilia and insults that alter the production or viscosity of the mucus blanket lead to obstruction of the flow of mucus, however, which allows the inoculation of numerous microorganisms into the sinuses that can lead to infection. In a study in adults in whom sneezing, coughing, and nose blowing were stimulated or initiated voluntarily, intranasal pressures were measured, and the deposition of contrast medium (which before the initiation of the event had been inoculated into the nasopharynx) was determined by computed tomography (CT) scan.[66] Results of this study showed that nose blowing introduced viscous fluid into the maxillary sinuses, whereas coughing or sneezing did not generate enough pressure to propel fluid into the sinuses. When instituted, sinus infection is complicated further by inflammatory obstruction of the ostium leading to the nose.

Recurrent chronic sinusitis implies a problem with local mucociliary defense, a defect in systemic immunity, or a fixed anatomic sinus obstruction. Often, the predisposing factors work in tandem, as in a child with a septal deformity and a viral illness.[108] In chronic sinusitis, the mucosa is thickened, and marked edema, vessel dilation, and infiltration of inflammatory cells are present.[166] Goblet cells are decreased in density, and seromucous glands are increased in density compared with their

presence in normal sinuses. The most important factor leading to purulent sinus infection in children and in adults is upper respiratory viral infection.[20,44,108,184]

Wald and colleagues[184] in a large prospective study involving children younger than 3 years of age showed a doubling of the rate of sinusitis (defined as upper respiratory symptoms persisting >15 days) among children in a daycare setting compared with children not in daycare. The differences presumably were due to increased exposure to viral respiratory illnesses. Radiographic studies in children with acute colds regularly indicate abnormalities of the maxillary sinuses, suggesting that the infection involves these areas.[111] These asymptomatic sinus opacifications may persist for 2 weeks after the symptoms of the upper respiratory illness have resolved.[41,92,175] Viral infection that involves the sinuses rarely is differentiated from its primary manifestations, such as the common cold, nasopharyngitis, and influenza, and recovery is the rule. If the effect of the viral infection on the mucosal surface is severe, and is associated with the inoculation of one or more pathogenic bacterial agents and obstruction of an ostium, disease occurs.

The mechanisms by which upper respiratory viral infections set the stage for secondary bacterial infection in the sinuses are complex. Using in situ hybridization, rhinovirus RNA was shown inside epithelial cells of maxillary sinus in 50 percent of a small number of adults with acute sinusitis.[128] This finding is remarkable because in experimental rhinovirus infections, only a small percentage of nasal epithelial cells were noted to contain rhinovirus RNA.[7] These differences may reflect only differences in inoculum between experimental and natural infection, but they may indicate heavier infection in the sinuses than in the nose. Symptoms in upper respiratory viral infections are not caused by extensive damage to ciliated nasal epithelium, but rather to aspects of the host response (see Chapter 8).[7,67,120,122,126,131,132,193]

Other irritants can set the stage for sinus infection. Swimming in ocean, lake, or chlorinated pool water can lead to sinus involvement. Drying of the nasal mucosa, which occurs commonly during the winter in cold climates, may be a precipitating factor. Children with respiratory allergies are prone to sinusitis,[53,101,135-137] and allergy probably is the second most prevalent predisposing factor in childhood sinusitis, acting through mucosa congestion and perhaps depressing local and systemic immune responses.[108,151] The treatment of respiratory allergies may contribute to sinusitis because ciliary damage occurring after the administration of nasal decongestants has been shown in organ culture and animal studies.[41,42,116] Richards and colleagues[141] reported a diagnosis of atopy in 62 percent of a selected cohort of pediatric patients who had documented recurrent sinusitis and were referred to allergy clinics in Los Angeles. Dental infections or extractions also can lead to maxillary sinusitis if the tooth root is adjacent to the maxillary sinus floor.[32]

Sudden change in pressure, as with diving or during descent in an airplane, physically can overcome local mucociliary defense mechanisms and lead to the sudden onset of acute sinusitis.[119] Defects of ciliary function, such as those occurring in the immotile cilia syndrome and Kartagener syndrome, predispose a child to chronic sinusitis.[47,78,89,137,146,155] Refractory sinusitis also occurs commonly in children with primary and acquired immunodeficiency diseases.[28,108,117,147,152,168,179] A growing population of immunocompromised children undergoing treatment for malignancies and organ transplantations and young patients with maternally transmitted and blood-transmitted acquired immunodeficiency syndrome constitute another growing population with a potential for developing sinusitis that is difficult to manage. Finally, anatomic obstruction caused by septal deformities, craniofacial anomalies, foreign bodies, adenoidal hypertrophy, or nasal masses or polyps predisposes children to sinusitis. Nasal polyps in young children usually are not caused by allergies and should be an indication for evaluation for cystic fibrosis.[108]

Immunologic mechanisms are important in the pathogenesis of sinus infections, as indicated by the high prevalence of chronic sinus infections in children with immunodeficiencies.[28,108,117,147,152,168] Sinus and nasal mucus contains IgA, IgG, and IgM and lysozymes.[25,145] Secretory IgA, which is produced locally, is the predominant immunoglobulin in nasal mucus.[69] IgG antibodies in nasal mucus result from passive leakage from plasma cells in the epithelium and submucosa and from the serum.[16] Generally, with the patient's increasing age and as a result of previous exposures, these immunoglobulins develop species-specific and type-specific antibodies that block epithelial colonization by specific microorganisms.

Shapiro and associates[152] studied 61 children with refractory sinusitis and found that 34 had abnormal immunologic studies. Abnormal findings included poor response to pneumococcal type 7 antigen after immunization, IgG3 subclass deficiency, low serum IgA or IgG values, and elevated serum IgE values.

ETIOLOGY

Although most studies on the etiology of sinusitis have involved adults, adequate pediatric data are available. The findings in studies of adults can be applied appropriately to adolescents.

Examining the results of anterior nasal cultures from normal subjects and from subjects with respiratory illnesses is important to clear up confusion regarding the make-up of normal flora. During early investigations of the common cold, Shibley and associates[153] noted that in a group of 13 subjects followed for 4 to 9 months, neither *Haemophilus influenzae* nor hemolytic streptococci were obtained from nasal culture when the subjects were well. When the study subjects were ill with colds, *H. influenzae* was recovered from 9 percent of the cultures, and hemolytic streptococci were recovered from 6 percent. In a study of 500 consecutive medical patients, Jacobson and Dick[83] noted in all but two instances that the recovery of pneumococci and hemolytic streptococci from the nose correlated with nasal or sinus disease. Studies in children have disclosed more varied results. Dunlap and Harvey[44,70] recovered *H. influenzae*, pneumococci, and hemolytic streptococci from the noses of normal children with some consistency. These investigators were interested in carriage and spread of organisms, however, and the state of well-being of their subjects was not delineated clearly.

Orobello and colleagues[123] found that cultures of ipsilateral middle meatus correlated well with maxillary (83%) and ethmoid (80%) sinus cultures. Nasopharyngeal cultures correlated less well, however, with only 45 percent and 40 percent of maxillary and ethmoid sinus cultures being similar.

Yang[195] studied children in a day nursery and noted that neither pneumococci nor *H. influenzae* could be recovered from the noses of well children. Hays and Mullard[73] only rarely could find *Streptococcus pneumoniae*, beta-hemolytic streptococci, or *H. influenzae* in nose cultures from normal children. In an extensive study, Box and associates[15] noted pneumococci in nasal specimens of 38 percent of children without respiratory illness, but in only 3 percent was the growth of great magnitude (>100 colonies per plate). In the same study, *Haemophilus* spp. and beta-hemolytic streptococci were recovered from 14 percent and 1 percent of the cultured specimens from noses. In comparison, in the same study, pneumococci and *Haemophilus* spp. were recovered from 57 percent and 25 percent of the cultures of patients with respiratory illness.

In a more recent study involving 49 children with sinusitis, Ilki and associates[81] found a strong correlation with throat cultures positive for *H. influenzae*, *S. pneumoniae*, or *Moraxella catarrhalis*. Similar organisms were recovered from sinus aspirates.

TABLE 17–1 Etiologic Agents in Sinusitis Analyzed by Patient Age and Type of Illness

Data from references 8, 14, 18-20, 23, 28, 31, 43, 45, 50, 51, 60, 86, 87, 90, 93, 103, 107, 125, 137, 172-174, 181, 185, 186.

In a study performed in the Finnish military, nasal cultures from 183 healthy recruits revealed the following frequencies of specific organisms: *H. influenzae*, 4 percent; *S. pneumoniae*, 1 percent; *M. catarrhalis*, 3 percent; and *Streptococcus pyogenes*, 0 percent.[87] In contrast, in 185 recruits with acute maxillary sinusitis, the percentages of nasal isolates for the same organisms were 61 percent, 25 percent, 7 percent, and 6 percent, respectively. In 91 percent of cases in which a sinus aspirate culture yielded an isolate, the same organism was found in a nasal sample. Similar results have been obtained in other studies done in adults with acute sinusitis, in which nontypeable *H. influenzae* and *S. pneumoniae* account for approximately 74 percent of all bacterial strains recovered in sinus aspirates.[68] In all studies, *Staphylococcus aureus* clearly is part of the normal nasal flora. *S. aureus* is present in well or sick children approximately 50 percent of the time.

Pneumococci, *H. influenzae*, *M. catarrhalis*, and *S. pyogenes* seldom are found in the nose of a healthy child and should suggest a nasal or paranasal infectious illness. The recovery of *S. aureus* cannot be correlated with disease, however.

A review of many reports of children indicates that *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis* are the etiologic agents that occur most commonly in acute and subacute ethmoid and maxillary sinusitis.* In one of the studies[186] of sinus aspirates from 50 children, *S. aureus* was not isolated from the maxillary sinus. Several studies of pediatric patients with chronic sinusitis suggest an increased importance of anaerobes and staphylococcal species.[19,21,39,179] In other studies in children with chronic sinusitis who have undergone surgery, a predominance of coagulase-negative staphylococci, viridans streptococci, and *S. aureus* was noted.[118,123] Several studies[55,71,190] documenting that *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis* were the most common etiologic agents were concerned primarily with orbital involvement; 50 to 85 percent of cases of orbital cellulitis had radiographic evidence of sinusitis. Orbital complications of ethmoiditis primarily affect children. *Staphylococcus* spp., *S. pneumoniae*, and other streptococci have been found in children with orbital involvement from ethmoiditis[3] or frontal sinusitis.[54]

Table 17–1 lists etiologic agents of sinusitis by age of patient and type of illness. In all age groups and in acute, subacute, and chronic disease, *H. influenzae* and *S. pneumoniae* are the principal pathogens in most cases. Also, a large number of different

*See references 55, 71, 73, 77, 78, 107, 115, 172-174, 181, 186, 190.

bacterial species have been recovered from the sinuses of affected patients. In young children, more than 90 percent of all cases of sinusitis are caused by five organisms: *H. influenzae*, *S. pneumoniae*, *M. catarrhalis*, *S. aureus*, and *S. pyogenes*. In adolescents, the same organisms, plus largely penicillin-sensitive anaerobes, account for most cases. As noted in Table 17–1, a variety of gram-negative enteric and other bacilli have been recovered from patients with sinusitis, in most instances from patients who have had various forms of antibiotic therapy before culture. Organisms previously considered to be nonpathogens, such as *Staphylococcus epidermidis*, have been implicated etiologically.

Although clinically recognized sinusitis has occurred rarely in patients with *Mycoplasma pneumoniae* infection, Griffin and Klein[61] noted radiographic evidence of sinusitis in approximately two thirds of a group of Navy recruits with *M. pneumoniae* pneumonia. In adults with chronic suppurative maxillary sinusitis, mycoplasmas have been sought but not recovered.[14,60,161] Bhattacharyya and colleagues[14] noted L-forms in 21 percent of all sinuses in patients with chronic disease.

In a study of 25 adults with chronic rhinosinusitis, *Chlamydia pneumoniae* was recovered from nasopharyngeal samples in 2 patients, but not from any of 10 healthy controls.[45] In addition, the patients were more likely than control subjects (20 percent) to have serum IgG antibody titers to *C. pneumoniae* of 1:64 or greater (72%). IgA antibody titers to *C. pneumoniae* of 1:32 or greater also were more prevalent in the patients (48%) than in the controls (10%). In a study involving 20 children with chronic sinusitis, Cultrara and colleagues[31] cultured material from 13 bilateral endoscopic ethmoidectomies with maxillary antrostomies, 10 adenoidectomies, and 3 bilateral maxillary sinus lavages. They isolated *C. pneumoniae* from a nasopharyngeal swab and adenoid tissue from a 6-year-old child.

Fungal diseases of the sinuses have been well described in adults.[188] Acute fulminate fungal sinusitis is seen in immunosuppressed individuals and is associated with high morbidity and mortality rates.[33,158] *Aspergillus* spp. are the most common fungal causes of sinusitis. Many cases of chronic sinusitis from which a microorganism is not recovered have been thought to be caused by *Aspergillus* spp. infections.[88] The presence of eosinophils, Charcot-Leyden crystals, and hyphae found retrospectively, and not noted on the original examination, in mucus recovered from sinuses suggests that some cases of chronic sinusitis may represent *Aspergillus* hypersensitivity. This allergic aspergillosis in the sinuses is similar to allergic bronchopulmonary aspergillosis. In a series of six patients who were 8 to 16 years of age and had allergic aspergillosis sinusitis, all presented with nasal polyposis and facial deformity, indicating advanced disease.[110] Mucormycosis, an infection caused by Zygomycetes (formerly Phycomycetes), is seen in immunocompromised children and adults.[85] *Drechslera* spp., *Bipolaris* spp., and *Curvalaria lunata* have been added to the list of fungi that can cause sinusitis in children.[13,23,51,157]

Although sinusitis has been reported as a complication of Epstein-Barr virus infection, the sinus infections seem to be a complication of steroid treatment and not specifically the viral infection.[57] *Nocardia* spp. have been reported as a cause of acute sinusitis in an adult transplant recipient[142] and of chronic sinusitis in immunocompetent and immunocompromised individuals.[170]

EPIDEMIOLOGY

Although sinus involvement occurs commonly with respiratory viral infection, sinusitis seldom is identified as a specific illness in previously healthy children. In a survey of all office visits, totaling 2613, Breese and colleagues[17] noted only 6 children (0.23%) in whom the initial diagnosis was sinusitis. The true incidence of sinusitis in childhood is unknown. In 1989, Wald and colleagues[181] estimated that 0.5 to 5 percent of upper respiratory tract infections are complicated by acute sinusitis. More recent estimates by the same authors have been 10 percent.[184] The most recent estimates of greater incidence could be related to a heightened awareness and concern for lost work days by working parents, a possible correlation between pulmonary problems in an increasing number of children with chronic lung disease, better imaging techniques, increased interest in endoscopic sinus surgery,[163] more disease because of more exposure as a result of more children being in daycare,[108] and an increased recognition or perhaps incidence of allergy-related illness.[140,141] Seasonal prevalence has not been studied, but a reasonable assumption is that disease would increase during the cold weather months because it is the time of greatest respiratory viral activity. Cases in older children also can be expected to occur more frequently in association with swimming.

Although it is not well documented, sinusitis seems to be more of a problem in geographic areas where marked temperature changes occur. In children, sinusitis seems to occur more commonly in boys than in girls.[72,115] Ueda and Yoto[167] found abnormal findings in the maxillary sinuses in 135 (6.7%) of 2013 children who presented to an outpatient department with upper respiratory symptoms; of this group, 65 percent were boys, and 35 percent were girls. Manning and associates[109] found similar distribution in a group of 60 children diagnosed by CT or magnetic resonance imaging (MRI). Host factors are important in sinusitis because the illness occurs more commonly in allergic children; in children with chronic ear infections; and in patients with cystic fibrosis, primary humoral immunodeficiencies, and Kartagener syndrome.[22,78,121,146] Although an association between sinus disease and asthma seems to exist, controversy continues regarding whether sinusitis and other upper airway stimuli can induce asthma.[52,141,150,196] A review of hospital admissions of patients with status asthmaticus at the Children's Hospital of Los Angeles showed a marked increase in admissions, and sinusitis was diagnosed in 23 percent.[140] Children with various immunologic defects frequently have sinusitis.

Sinusitis is noncontagious from person to person, but point-source outbreaks are possible from swimming in heavily contaminated water. A cluster of seven cases of invasive nosocomial fungal sinusitis in severely neutropenic patients has been described. It was caused by the release of airborne fungal spores from soil reservoirs that were distributed during hospital construction during a 2-year period.[104]

CLINICAL PRESENTATION

The clinical symptoms of sinusitis vary by age. Older children and adolescents have localized complaints similar to those of adults, whereas in young children, the findings are related less clearly to the sinuses.[176] Table 17–2 presents the overall frequencies of symptoms, signs, and laboratory findings for acute, subacute, and chronic disease.

In young children, disease involves only the ethmoid and maxillary sinuses. In these children, illness frequently has its onset after they have had an upper respiratory viral infection. A period of general improvement may occur, however, between the acute respiratory illness and the onset of symptoms related to sinus infection. The most prominent symptom in all children, and particularly in children younger than 10 years of age, is persistent rhinorrhea. The discharge frequently is purulent, but it occasionally can be serous or watery. Associated with rhinorrhea is cough, which becomes more prominent with increasing duration of disease. The cough particularly is troublesome at night because it is caused by the stimulation of the sinus drainage as it traverses the pharyngeal wall. The posterior drainage also occasionally causes vomiting. Fever is of variable occurrence in

TABLE 17–2 Clinical Findings in Acute, Subacute, and Chronic Sinusitis of Children

	Occurrence (%)	
	Acute and Subacute Sinusitis	*Chronic Sinusitis*
Symptoms		
Fever	50	20
Rhinorrhea	80	80
Cough (persistent and evening)	50	90
Pain/headache	30	30
Sore throat	20	20
Periorbital swelling	30	0
Vomiting	20	10
Allergic history	20	40
Malodorous breath	20	20
Signs		
Rhinorrhea	80	80
Temperature ≥38.3°C (≥101°F)	20	0
Sinus tenderness	20	10
Otitis media	40	60
Posterior pharyngeal pus	0	10
Transillumination positive	30	10
Periorbital swelling	30	0
Malodorous breath	20	20
Laboratory		
Abnormal radiographs	100	100
Maxillary	90	90
Ethmoid	40	40
Frontal and sphenoid	10	10
Unilateral	70	10
Bilateral	30	90
Erythrocyte sedimentation rate elevation	50	10
White blood cell count elevation with an increased percentage of band form neutrophils	40	10

Data from references 3, 10, 72, 75, 84, 89, 91, 115, 121, 141, 146, 159, 178, 187.

sinusitis and generally is related inversely to age and duration of illness. Malodorous breath often is reported by parents. The first evidence of illness in some children is fever and periorbital swelling. In most instances, periorbital cellulitis is a manifestation of ethmoid sinusitis.

Although facial pain and headache are frequent complaints of sinus disease in adults, they have been noted in only approximately one third of the cases in children and are unusual occurrences in young children. The main symptom in older children and adolescents is rhinorrhea. In older patients with more chronic disease, the nasal symptoms may be minimal or absent. Troublesome postnasal drip is a frequent complaint.

Acute isolated sphenoid sinusitis in children is rare but often misdiagnosed because the symptoms are vague and there are no specific physical findings.[112] Findings include fever, headache, and neurologic symptoms. Swimming and diving are possible predisposing factors.

Physical signs in sinusitis also differ by age. Nasal discharge is the most frequent finding in all age groups. Young children are more likely to have a serous or watery discharge, however, than are adolescents. Elevation of temperature occurs more commonly in acute disease and in association with orbital cellulitis. Sinus tenderness, a common finding in older patients, is noted only rarely in children. Particularly significant is tenderness with percussion of the upper molars. Examination of the throat frequently reveals free exudate. Occasionally, the breath is malodorous.

The ears are abnormal in almost half of all patients with sinusitis. In acute disease in young children, it can be acute otitis media, but usually the findings are more suggestive of serous disease. Acute sinusitis frequently is unilateral, whereas chronic disease more often is bilateral.

Children with chronic sinusitis frequently have only minimal complaints. The parent notes that the child does not feel well and frequently reports that the child has had a persistent respiratory infection for months. In a series of children with chronic (>3 months) upper respiratory complaints who were referred to allergy clinics, 60 percent had sinusitis.[121] In this study, the combination of moderate to severe rhinorrhea and cough with minimal sneezing was reported to have a specificity of 95 percent and a sensitivity of 38 percent in predicting the presence of chronic sinusitis. In the referred children in this study, sinusitis was found in 63 percent of atopic children and in 75 percent of non-atopic children.

Laboratory studies other than cultures and radiography are not useful in the evaluation of a child with sinusitis. Herz and Gfeller[75] noted that in their study, erythrocyte sedimentation rates were elevated in only approximately half of the patients, and leukocytosis occurred in only one third. Generally, younger children with orbital cellulitis and ethmoid sinusitis are more likely to have elevated sedimentation rates and white blood cell counts. The American Academy of Pediatrics (AAP) Subcommittee of Sinusitis and Committee on Quality Improvement has recommended that the diagnosis of acute bacterial sinusitis be based on clinical criteria in children who present with upper respiratory symptoms that are either persistent (nasal or postnasal discharge of any quality with or without daytime cough for >10 to 14 days) or severe (temperature >39° C and purulent nasal discharge present concurrently for at least 3 or 4 consecutive days in a child who appears ill).[4]

COMPLICATIONS

Serious complications, including meningitis, osteomyelitis, cavernous sinus thrombosis, and epidural, subdural, brain, and orbital abscesses, occur in untreated sinusitis.* Signs and symptoms of neurologic involvement in sinusitis frequently call for aggressive surgical management of the sinusitis and the intracranial and paracranial lesions. Osteomyelitis of the frontal bone may be a complication of frontal sinusitis[9] and may manifest as Pott puffy tumor if a subperiosteal abscess also is present.

DIFFERENTIAL DIAGNOSIS

Differential considerations in sinusitis are few and are more concerned with whether sinus involvement in a particular child is the primary event or a secondary problem related to a more general host defect. Children with recurrent and chronic sinusitis should be evaluated for respiratory allergy, cystic fibrosis, immunologic deficiency, and Kartagener and other immotile-cilia syndromes.

Foreign bodies in the nose can be mistaken for sinusitis, as can cysts in the maxillary antra. Nasal structural defects (congenital and acquired), such as palatal clefts, unilateral choanal atresia, nasal polyps, and septal deviation, can be confused with sinusitis, but more commonly these problems are predisposing factors in sinus infections.

Dental infections frequently are mistaken for maxillary sinus disease. Dental infections can lead by direct extension to sinus involvement. Primary infections in the region of the eye also

*See references 1, 46, 56, 57, 96, 113, 124, 133, 148, 189, 192.

occur without sinus disease. In young children, a chronic infection of the adenoids can be confused clinically with sinusitis. Infections with *Bordetella pertussis* can be confused with subacute sinusitis.

SPECIFIC DIAGNOSIS

Although persistent nasal symptoms and the presence of other clinical findings as listed in Table 17–2 indicate a diagnosis of sinusitis, the only certain way to make the diagnosis is by obtaining radiographs and cultures reflecting sinus flora. Although some physicians have suggested that maxillary sinus radiographs frequently are abnormal for normal children,[111,154] other data indicate that normal children older than 1 year of age seldom have abnormal radiographs.[92] During infancy, the maxillary sinuses are so small that minimal mucosal edema may "opacify" a sinus on a radiograph. In young children, radiographic examination should consist of two views: lateral and Waters. In older children, Caldwell and basal projections also should be performed. Radiographs in acute upper respiratory viral infections as a rule are abnormal; these radiographs are not false-positive ones, but are the result of viral infections. From a therapeutic point of view, sinus radiographs usually should not be obtained unless nasal symptoms in an upper respiratory illness have not shown signs of improvement after 5 to 7 days.

Plain-film radiographic examination has been supplanted mainly by CT and MRI for the diagnosis of sinusitis. Many endoscopic sinus surgeons consider CT to be a mandatory part of the preoperative evaluation. MRI is useful in cases that may be complicated by orbital or intracranial extension. The high prevalence of incidental sinus opacification in asymptomatic infants and children noted radiographically has been confirmed by CT studies.[35,58,76] Since the advent of MRI, researchers have realized that many incidental sinus abnormalities also occur in adults. These findings in children and adults may be from subclinical or resolving respiratory infections or may be due to unrecognized allergies.[34]

CT has been recognized widely as the standard for the diagnosis of paranasal sinus disease.[12] In particular, coronal thin-section images offer excellent delineation of lesions in the osteomeatal complex.[197] Obtaining axial images is useful for evaluating periorbital and intraorbital complications.[49] In some institutions, a so-called screening CT of the sinuses is performed with a limited number of slices.[64] It can be offered at a cost and radiation exposure that are similar to those associated with plain-film studies, but with much greater accuracy. Some young children and infants require sedation for CT, which limits its suitability.

The AAP Subcommittee of Sinusitis and Committee on Quality Improvement has recommended that imaging studies are not necessary to confirm a diagnosis of clinical sinusitis in children 6 years of age or younger.[4] The need for radiographic evidence as a confirmatory test in children older than 6 years with severe symptoms is controversial. The American College of Radiology considers that the diagnosis of acute uncomplicated sinusitis should be made only on clinical grounds.[114] CT scans of the sinuses should be reserved for patients in whom surgery is being considered as a management strategy.[4] In a meta-analysis of acute uncomplicated sinusitis in children,[82] poor concordance was observed among clinical criteria, plain radiographs, CT scans, ultrasonography, and fluid aspiration. More studies are necessary to determine the optimal set of clinical criteria and other laboratory or radiologic studies for diagnosis of this condition.

Which radiographic technique (plain radiography, CT, or MRI) is selected for evaluation of a child with presumed sinusitis should be determined by availability of techniques and the expertise of the radiologist and by clinical symptoms. Radiographs, in most instances, should not be obtained early in the illness of children with uncomplicated upper respiratory complaints because of the high incidence of transient abnormalities.[5] Radiography is indicated for children with continuing symptoms of sinusitis after extensive medical therapy or for children with possible complications of sinusitis. CT is optimal.[5] A limited CT scan with axial cuts may be obtained. It allows for excellent visualization of sinus anatomy and pathology while limiting the radiation exposure to the child. A limited sinus CT scan has radiation similar to that of a sinus plain-film series. In the absence of low-cost screening CT, plain radiography should be the initial imaging study in most children who have symptoms of sinus disease.[34] Children who have periorbital swelling or proptosis should undergo immediate contrast-enhanced CT studies in axial and coronal planes. If symptoms or CT findings suggest intracranial extension, MRI should be performed.[5,34]

Although ultrasonography would seem to offer an alternative to sinus radiography, some question remains about its dependability unless one normal air-filled maxillary sinus or one opacified maxillary sinus is present for comparison.[174,185] The hallmark of specific diagnosis in sinusitis is similar to that of other infectious diseases: the culture of infected material. Many physicians erroneously considered it an impossible task because of the inability of obtaining material directly from the sinuses of children. As discussed in the section on etiology, nasal cultures that are properly performed reveal the causative organism in most instances. Nasal culture should be taken from the region of the maxillary ostium in the middle meatus. Culture specimens should be obtained from this area and not from the nasopharynx. Wald and associates[185] found no correlation between bacteria isolated directly from the maxillary sinuses and nasopharyngeal and throat culture isolates. Best results are obtained when a vasoconstrictor, such as 0.25 percent phenylephrine hydrochloride, is administered first and the culture specimen is obtained with a wire-cotton swab under direct vision. With this technique, material frequently can be obtained as it comes from the sinus ostium. Bilateral cultures always should be obtained. In serious cases, such as in children with neurologic complications or in treatment failures, performing antral puncture for culture can be lifesaving. Anaerobic and aerobic cultures should be performed on any material recovered by antral puncture.

TREATMENT

ACUTE AND SUBACUTE SINUSITIS

The successful treatment of acute and subacute sinusitis in children depends primarily on the administration of an appropriate antibiotic in adequate dosage for a sufficient period.[4,180] In most instances, therapy should be instituted before obtaining the results of cultures. Antibiotic selection in this situation is not a great problem in children because the etiologic agent is *H. influenzae*, *S. pneumoniae*, *M. catarrhalis*, *S. aureus*, or *S. pyogenes* in more than 90 percent of acute cases.

Initial selection of an antibiotic should be based on the severity of the clinical illness and must take into consideration the antibiotic resistance patterns of the common causative organisms and the cost and ease of administration of the treatment regimen. Today, approximately 50 percent of nontypeable *H. influenzae* and 100 percent of *M. catarrhalis* strains produce β-lactamases and are resistant to amoxicillin.[37,38] In addition, 15 to 38 percent of *S. pneumoniae* strains have either intermediate (7-19%) or complete (7-19%) penicillin resistance.[11,26,40]

The AAP Subcommittee of Sinusitis and Committee on Quality Improvement, in their "Clinical Practice Guideline: Management of Sinusitis," recommended amoxicillin as first-line therapy for children younger than 2 years of age suspected of having acute bacterial sinusitis of mild to moderate severity, who

do not attend daycare, and who have not been treated recently with an antimicrobial agent.[4] They recommend an amoxicillin dose of either 45 mg/kg/day in two divided doses or 90 mg/kg/day in two divided doses. They recommend cefdinir (14 mg/kg/day in one or two doses), cefuroxime (30 mg/kg/day in two divided doses), or cefpodoxime (10 mg/kg/day once daily) for the child who is "allergic" to amoxicillin if the past allergic reaction was not a type 1 hypersensitivity reaction. If the past allergic reaction was of a type 1 nature, they recommend clarithromycin (15 mg/kg/day in two divided doses) or azithromycin (10 mg/kg/day on day 1 followed by 5 mg/kg/day as a single dose for 4 days). They suggest clindamycin (30 to 40 mg/kg/day in three divided doses) as an alternative therapy for the penicillin-allergic patient who is known to be infected with a penicillin-resistant pneumococcal strain. Their recommendation is based on the safety, tolerability, low cost, and narrow spectrum of amoxicillin, and a calculated success rate based on data regarding treatment of acute otitis media.

The AAP committees further recommended that children who did not improve while receiving the lower amoxicillin dose, children with more severe illness, and children who attend daycare should be treated with high-dose amoxicillin-clavulanate (80 to 90 mg/kg/day of amoxicillin component in two divided doses). For children with vomiting, a single dose of ceftriaxone (50 mg/kg/day) given either intravenously or intramuscularly is suggested. After this regimen, the child's therapy is switched to an oral regimen.

The committees' suggestions presented above applied only to children younger than 2 years of age; however, because the spectrum of etiologic agents is similar to that for older children, it should also apply for those older than 2 years of age.

In contrast to the AAP committees' recommendations, we consider that a more appropriate approach is to use only high-dose amoxicillin or amoxicillin-clavulanate (90 mg/kg/day in two divided doses). The duration of treatment in the outpatient setting has not been studied adequately. Wald[178] suggests that therapy should be continued for 7 days after the child becomes symptom-free.

A seriously ill child should be hospitalized, and therapy for β-lactamase–producing staphylococci and highly resistant pneumococci should be implemented, in addition to coverage for amoxicillin-resistant *H. influenzae* and *M. catarrhalis*. This coverage is achieved with vancomycin (40 mg/kg per 24 hours every 6 hours) and cefotaxime (100 to 200 mg/kg per 24 hours every 6 hours) or ceftriaxone (100 mg/kg per 24 hours every 12 hours). Therapy should be adjusted on the basis of clinical response and culture results. The dosage and duration of antimicrobial therapy in sinusitis are crucial considerations. Penicillins penetrate the sinuses poorly.[9,48,65,85,105] The duration of therapy should be a minimum of 10 days.

The relief of obstruction at the sinus ostia and the establishment of drainage are time-honored principles of therapy. To achieve these goals, locally applied and systemically active vasoconstrictive drugs are used. To date, no evidence supports their therapeutic effectiveness, however. The beneficial effects of oral, systemically active, vasoconstrictive drugs are hampered by the fact that their drying effect may be deleterious to the mucus blanket. Topical vasoconstrictor drugs (e.g., phenylephrine hydrochloride and oxymetazoline) are plagued by rebound vasodilation. We consider that these drugs should be used rarely in acute disease; their main use is to relieve pain caused by obstruction, and they should be used only for 2 to 3 days.

CHRONIC AND RECURRENT SINUSITIS

Allergic disorders are common in chronic and recurrent sinusitis.[108,177] Children should be evaluated for allergy, and, when identified, specific treatment should be employed. Specific allergens and irritants should be avoided (e.g., through air filtering, removal of pets, avoidance of tobacco smoke), and pharmacologic management should be implemented.

Nasal saline washes (twice daily in each nostril) are useful because they liquefy secretions and enhance mucociliary transport, which improves sinus drainage and ventilation. Antihistamines may be useful if allergic rhinitis is a contributing factor to the chronic sinus infection. Anti-inflammatory agents also may be useful. In selected cases, use of either topically applied corticosteroids or cromolyn sodium may be beneficial. Corticosteroids should be used carefully because their use occasionally can lead to superinfection in the sinuses with *Pseudomonas* spp., other highly resistant gram-negative bacilli, or fungi. For effective corticosteroid use, Wald[177] suggests using a topical decongestant first so that the steroid preparation can reach the affected areas better.

In chronic or recurrent disease, antimicrobial treatment should be based on culture and sensitivity data. Specific antimicrobial agents are the same as the agents used in acute and subacute disease, but treatment should be prolonged for 3 weeks or more and for 7 days after the resolution of symptoms. *Aspergillus* and *Bipolaris* spp. and other fungal infections require prolonged therapy with an antifungal agent to which the specific agent is susceptible. Itraconazole, ketoconazole, and fluconazole all have been effective in selected cases. Allergic fungal sinusitis can be treated with endoscopic sinus débridement of all fungal and polypoid disease, followed by topical and systemic corticosteroids and close follow-up, including frequent endoscopic cleaning.[30,96,97,134] Allergic aspergillosis of the sinuses can be managed with topical steroids without specific antifungal therapy (see Chapter 28).

In the past, surgical therapy for sinusitis in children was of questionable benefit. Surgical therapy included diagnostic and therapeutic irrigation; permanent drainage procedures in children with complications of sinusitis and in children who had immune defects; and such procedures as adenoidectomy,[99,169] septoplasty, and turbinectomy to relieve anatomic obstructions to improve nasal and sinus ventilation. In one uncontrolled study of children with otitis media with effusion and sinusitis, the sinusitis was improved 6 months after adenoidectomy in 56 percent of children, whereas only 24 percent of similar children who did not undergo surgery had similar improvement.[162]

Historically, creating nasoantral windows was the most common major surgical procedure for treating chronic sinusitis in children.[62,118] Long-term success with this procedure was poor, however, because of the high rate of closure of the windows. A new interest in sinus surgery has resulted from the introduction of endoscopic techniques. Several studies have found endoscopic surgery to be safe and effective.[63,98,106,129,144] Pediatric endoscopic sinus surgery now is recognized as a viable option for children with chronic recurrent sinusitis refractory to medical therapy.[27,102,138] A meta-analysis of 832 children who underwent endoscopic sinus surgery from 1986 to 1996 revealed an overall 88.4 percent positive outcome after surgery.[74]

The goal of functional endoscopic sinus surgery is to remove obstruction at the osteomeatal complex where the mucociliary flow from the frontal, maxillary, and ethmoid sinuses converges.[98,144] This removal results in improved drainage and restoration of normal physiologic function of the frontal, maxillary, and ethmoid sinuses. Surgery involves an anterior ethmoidectomy and enlargement of the natural ostium of the maxillary sinus. Follow-up surgery performed 2 to 3 weeks after the initial surgery sometimes is necessary to remove crusts, blood clots, any stenting material, granulative tissue, and adhesions.[187]

In a study of 210 children with a history of chronic sinusitis for 3 months or longer, functional endoscopic sinus surgery

resulted in successful outcomes in 165 (79%).[98] The follow-up period was 3 to 36 months (mean 18 months), and all of the infections in these children had failed to respond to prior extensive medical management. In this series, no major complications occurred.

Functional endoscopic sinus surgery should be considered for children with chronic or recurrent sinusitis that has failed extensive, prolonged, and adequate medical management.[102] Many pediatric otolaryngologists have resumed performing adenoidectomy as a surgical intervention before proceeding with functional endoscopic sinus surgery.[156] This management includes specific antimicrobial therapy for specific organisms identified by culture; the diagnosis and treatment of allergic and other contributing conditions, such as cystic fibrosis, asthma, or immunologic disorders; and a trial of prophylactic antimicrobial agents.

Orbital and intracranial abscesses and cavernous sinus thrombosis secondary to sinus infection require emergency surgery, which often is lifesaving.[143,148,189,192] Cellulitis, osteomyelitis, and meningitis also frequently require surgery if they do not respond to antimicrobial therapy.[143] Surgery in these cases involves drainage of the sinuses and abscesses. Endoscopic techniques may allow for intranasal drainage and avoidance of development of facial scars.[6] If an intracranial complication involves an intracranial abscess, concomitant craniotomy along with functional endoscopic sinus surgery may be required.[59] Surgical procedures also may be indicated for a child with acute or chronic disease resulting from an identified underlying problem, such as an immunologic deficiency.[191]

PROGNOSIS

The prognosis of identified and adequately treated sinusitis in otherwise normal children is excellent. Frequently, children have subnormal health because sinusitis goes unrecognized; it may be treated only partially because of other clinical impressions, which contributes to the chronicity of the problem. Sinusitis is likely to be recurrent in children with a history of previous chronic disease and in children with repeated adverse exposure, such as swimming in contaminated or irritating water. Children with allergic respiratory disease also are likely to have frequent recurrences. Sinusitis in an immunocompromised child frequently is resistant to cure; long-term continuous therapy can be beneficial in such patients. Signs and symptoms of neurologic involvement in sinusitis frequently call for aggressive surgical management of the sinusitis and the intracranial and paracranial lesions.

Paranasal sinusitis also has been noted occasionally to be associated with bronchial asthma.[127,136] Its successful treatment has resulted in clearing of the asthma.[80,150]

PREVENTION

Sinusitis, as such, is not preventable in most instances. In some individuals, change of lifestyle can do much to improve the situation, however. Sinusitis in some children is related to their swimming habits and can be controlled by elimination of swimming or perhaps by the use of nose plugs. Good allergic management, including intranasal corticosteroid or cromolyn therapy, prevents sinus disease in certain atopic children. Relief of nasal airway obstruction caused by allergic rhinitis, enlarged adenoids, or other anatomic problems also should help to prevent sinusitis. Early attention given to persistent nasal discharge also can be expected to lessen the damage associated with sinus infection.

CHAPTER 18

Otitis Externa

Ellen M. Friedman ❂ Tulio A. Valdez

Otitis externa constitutes one of the most common otolaryngologic encounters in the emergency department. This condition is addressed commonly as *swimmer's ear* or *tropical ear* because it often occurs after a history of repeated water exposure and it occurs more commonly in warm and humid environments. This condition became of significant interest to the medical field during World War II because of its high incidence among the troops in the South Pacific. During World War II, otitis externa accounted for 50 to 70 percent of the caseload for otolaryngologists in the South Pacific.[22]

Today, otitis externa accounts for 7.5 million annual ototopical prescriptions in the United States and is a significant cause of discomfort because of the associated pain and conductive hearing loss.[36] This chapter discusses knowledge of the basic anatomy of the external canal, different etiologies of otitis externa, and treatment and prevention that are needed by the pediatric practitioner managing this condition.

NORMAL ANATOMY

The external ear is composed of the auricle and external auditory canal (EAC). The auricle of the ear is a skin-covered cartilaginous structure on the temporal region of the head and is an extension of the EAC. The EAC is divided into two regions—a lateral cartilaginous portion and a medial bony portion that ends at the tympanic membrane.

The cartilaginous portion of the canal makes up approximately 40 percent of its 2.5 cm total length and typically is directed slightly upward and backward. This shape and the presence of cerumen help to prevent water and foreign objects from entering the canal.[24] In the anterior portion of the cartilaginous canal are the fissures of Santorini, which provide a route for the spread of infection from the canal into the adjacent parotid and surrounding tissues. The bony canal makes up the remainder of the canal length and is directed slightly downward and anterior. The isthmus, which is the narrowest portion of the canal, corresponds to the bony-cartilaginous junction.

The sensory innervation of the EAC is complex and includes contributions from the fifth, seventh, ninth, and tenth cranial nerves. This sensory innervation is responsible for the exquisite pain associated with otitis externa.[24] The skin of the entire EAC consists of keratinizing stratified squamous epithelium. It is the only keratinizing epithelium that lacks eccrine sweat glands.

Differences exist in the canal skin of the cartilaginous canal and the bony canal. The cartilaginous canal skin is thicker and contains rete pegs, dermis, dermal papillae, hair follicles, and sebaceous and cerumen glands, which are absent in the bony canal. The thinner skin of the bony canal lacks dermal papillae and rete pegs. The lack of subcutaneous tissue in the bony canal allows the tight attachment of the skin to the underlying periosteum, rendering the bony canal wall more vulnerable to trauma.

PROTECTIVE MECHANISMS OF THE EXTERNAL EAR

Three major defense mechanisms protect the EAC and lateral surface of the tympanic membrane: the tragus and antitragus, the skin with its cerumen coat, and the isthmus of the canal. The tragus and antitragus provide a partial barrier to the entrance of the foreign bodies into the EAC.

The skin of the cartilaginous canal contains many hair cells and sebaceous and apocrine glands, such as cerumen glands. Together, these three adnexal structures are termed the *pilosebaceous unit* and provide a protective function in the EAC. Migration of the skin of the EAC also helps to keep the canal free of debris. The pattern of migration is from the tympanic membrane laterally and radially away from the umbo.[1,24] Glandular secretions combine with sloughed squamous epithelium to form an acidic coat of cerumen, one of the primary barriers to infection of the canal. Cerumen is composed of lipids that are hydrophobic, and its major function is to waterproof the canal. Racial and gender differences that exist in the characteristics of cerumen do not seem to have any major clinical significance. Whites and African-Americans produce cerumen with higher levels of lipids compared with Asians, who produce cerumen with higher levels of proteins. Cerumen in males also has been shown to be higher pH than that in females.[18] The acidic nature of cerumen has been shown to inhibit bacterial and fungal growth.[11,18,23]

The canal normally is a self-protecting and self-cleansing structure. The cerumen coat gradually works its way to the lateral part of the canal and sloughs externally. Instrumentation and excessive cleansing of the canal can alter this primary protective barrier and may lead to infection (Table 18–1).

NORMAL BACTERIAL FLORA

The normal bacterial flora of the EAC is a combination of aerobic (80%) and anaerobic (20%) organisms.[9] Aerobic bacteria include *Staphylococcus epidermidis*, alpha-hemolytic streptococci, diphtheroids, and *Pseudomonas aeruginosa*.

In a study by Stroman and colleagues[42] of 291 bacteria isolated from cerumen, 99 percent were gram-positive, whereas of 302 bacteria isolated from the canal, 96 percent were gram-positive. Staphylococci accounted for 63 percent of the cerumen bacteria and the canal bacteria. *Staphylococcus auricularis* is the isolate found most frequently (23% in cerumen and 21% in canal), and *S. epidermidis* is the second most commonly isolated bacteria from cerumen and canal (14% and 17%, respectively). After staphylococci, the coryneform bacteria (diphtheroids) are the organisms most frequently isolated. The third most frequently recovered bacteria belong to the streptococci and enterococci groups. *Alloiococcus otitidis* was isolated with the greatest frequency (>95%) in the cerumen and the canal.[42]

In addition, seven species of *Bacillus* were isolated in the canal and cerumen. From the Micrococcaceae family, *Micrococcus luteus* was isolated most frequently from the canal and cerumen. *Turicella otitidis* was the primary coryneform recovered: 58 percent from cerumen and 65 percent from the canal. *Corynebacterium auris* was the second most frequently isolated coryneform: 12.5 percent from the canal and 12.3 percent from cerumen. Twenty-one other species of coryneforms (including 10 previously undefined species of *Corynebacterium* and 4 of *Microbacterium*) were isolated as well. Coryneforms represented 22 percent of the bacteria in cerumen and 19 percent in the canal. *Propionibacterium acnes* and a variety of *Peptococcus* spp. make up the anaerobic flora.[42]

Contact dermatitis

ACUTE OTITIS EXTERNA

Acute otitis externa is an infection of the EAC that often is the end result of a combination of factors. Bacterial and fungal infections of the EAC occur when the natural defenses break down, resulting in a significant reduction in the amount of cerumen, an injury to the skin of the canal, or a shift of the normal canal flora. Humidity, heat, and maceration all produce itching, which often leads to manipulation and instrumentation of the canal, which in turn leads to additional trauma. Otitis externa may be caused by insults that result in the removal of the protective lipid film from the canal, allowing the entrance of organism to the apopilosebaceous unit. Rapid proliferation of bacteria occurs as a result of the warm, dark, and moist canal environment.

Inflammation and infection can cause canal edema or complete obstruction of the canal in severe cases, with purulent discharge. If the infectious process goes untreated, it leads to cellulitis of the auricle and surrounding area.

Symptoms of otitis externa, in addition to pruritus and drainage, include pain and tenderness on palpation or manipulation of the external ear. Pain arises as the soft tissues and skin of the canal distract the periosteal lining of the bony canal. Pain is severe enough to interfere with daily activities and is the major reason for medical consultation.

HISTORY AND PHYSICAL EXAMINATION

Otitis externa is a clinical diagnosis. Interrogation often reveals a history of exposure to water, previous auricular instrumentation, or trauma. The physician should inquire about predisposing factors, such as diabetes, immunosuppression, history of eczema, or previous radiation therapy, all of which may predict a more complicated course.

On physical examination, the pinna may appear swollen or erythematous or may be protruding. Primary care practitioners and emergency department personnel frequently establish the diagnosis of mastoiditis based on auricular protrusion. On manipulation of the auricle, the patient often experiences severe pain. Tragal tenderness is another key feature of this disease. A hand-held otoscope often suffices to establish the diagnosis, but the microscope is recommended for full cleaning of the ear canal. The pinna may appear erythematous with edema and eczematization (Fig. 18–1).The canal appears swollen with various grades of patency, depending on the severity of the infection. Purulent discharge combined with keratin debris usually fills the canal. It is important to attempt to visualize the tympanic membrane if the canal is not completely obstructed. Absence of drainage from the middle ear confirms the diagnosis of otitis externa.

PATHOGENS IN ACUTE OTITIS EXTERNA

Common bacterial pathogens that cause otitis externa include *P. aeruginosa*, *Staphylococcus aureus*, *Escherichia coli*, and *Proteus* spp. (Table 18–2). *Pseudomonas* have been found to be the

Figure 18–1 Patient with acute otitis externa, with purulent drainage from the ear canal with mild edema and erythema of the pinna. (See companion Expert Consult web site for color version.)

Candida parapsilosis

predominant organism in various studies.[4,7,35,38] Historically, *Pseudomonas* have accounted for 50 to 80 percent of bacteria isolated from cases of chronic otitis externa.[4,29,31,35,38] In a study by Roland and Stroman,[35] gram-negative bacteria accounted for 53 percent of recovered organisms; 45.3 percent were gram-positive. In this same study, *P. aeruginosa* accounted for 37.7 percent of the total number of isolates, whereas a newly identified species, *Pseudomonas otitidis*, accounted for 2.3 percent of recovered organisms.[35]

Staphylococci are the most common gram-positive organism recovered in cases of otitis externa, accounting for 25 percent of the cases. *S. epidermidis* is the most common staphylococcal species recovered, followed by *S. aureus*. Coryneforms are the second largest group of gram-positive bacteria isolated from cases of otitis externa.[35]

Other organisms that have been identified as pathogens include *Enterobacter*, *Klebsiella*, *Serratia*, *Proteus*, and *E. coli*. Although *Microbacterium* spp. previously were considered normal flora, more recently they have been identified at a 10 times higher rate in infected ears compared with normal controls. *Microbacterium* also have been the single recovered isolate in treatment failures and re-infections.[35]

MANAGEMENT OF ACUTE OTITIS EXTERNA

No consensus exists about the most effective treatment for otitis externa. Treatment usually includes thorough cleaning and suctioning of the purulent debris and application of topical agents. Topical treatment has been shown to be effective and is the mainstay of treatment. A wick usually is placed in the canal to provide adequate delivery of the topical solution. Without the wick and adequate cleaning of the canal, the topical drops may not achieve adequate penetration and are ineffective. When topical therapy is prescribed, various options, including multiple antibiotics, antiseptics, steroids, and combination agents, are available.[9,10,18,34,36] Topical antimicrobial therapy increased absolute clinical cure rates of acute otitis externa by 46 percent and bacteriologic cure rates by 61 percent compared with placebo.[36] Freedman[20] compared topical neomycin/colistin/hydrocortisone with topical placebo and found less severe edema and itching by day 3 and less severe edema, itching, redness, scaling, and weeping by day 7.[36] Without treatment, approximately 15 percent of patients with acute otitis externa have clinical cure within 10 days; however, the cure rate increases to 65 to 85 percent when topical antimicrobial therapy is administered.[20,36]

Rosenfeld and colleagues[36] performed a meta-analysis to assess topical antiseptics and antibiotics and found comparable clinical cures at 7 to 14 days. The most common antiseptics used in the treatment of otitis externa include acetic acid, boric acid/ethyl alcohol and aluminum acetate, and *N*-chlorotaurine.

Topical antibiotic preparations usually are divided into two groups: quinolones and non-quinolone antibiotics. Non-quinolone antibiotics, such as polymyxin, neomycin, gentamicin, tobramycin, and oxytetracycline, have been the mainstay of treatment for otitis externa for several decades. Most of these agents have some degree of ototoxicity, however, which renders them undesirable in the case of a tympanic membrane perforation or a patent pressure equalizing tube.[26,32] The introduction of quinolones in the late 1980s for management of otitis externa and malignant external otitis provided a non-ototoxic alternative treatment. Topical antibiotic therapy allows for the administration of high concentrations of antibiotics, which can overcome organisms with high minimal inhibitory concentrations. Rosenfeld and colleagues[36] reported comparable clinical cure rates for topical quinolone antibiotics compared with non-quinolones at 3 to 4 days, 7 to 10 days, and 14 to 28 days. This same study found no differences in adverse effects between the two antibiotic groups.

More recent studies have reported pseudomonal resistance to fluoroquinolones. Berenholz and colleagues[6] reported 33 percent ciprofloxacin resistance in cases of necrotizing otitis externa.[6] Other studies have shown strains of *S. aureus* and *S. epidermidis* that have developed quinolone resistance.[34] One of the most common mistakes in the treatment of otitis externa is not identifying a tympanic membrane perforation and draining middle ear as the source of the infection, which may have treatment implications because of the ototoxicity of some compounds.

CHRONIC OTITIS EXTERNA

Chronic otitis externa is an inflammatory condition of the ear canal skin. This condition generally is caused by the loss of the protective coating of cerumen and oils secondary to constant mechanical débridement, such as with cotton applicators or with repeated water exposure. Associated pruritus leading to self-cleaning perpetuates the vicious cycle. The ear canal with chronic otitis externa often is more vulnerable to bacterial superinfection.[33] *S. aureus* and *P. aeruginosa* have been shown to secrete proteases that may continue to establish pathologic skin conditions in the EAC in cases of chronic otitis externa.[27] Treatment of chronic otitis externa involves débridement and application of topical anti-inflammatory agents, such as corticosteroids. Cessation of habitual canal manipulation is necessary for achieving a

positive response. For recalcitrant cases, surgical removal of the canal skin and replacement with skin grafts may be required.

OTOMYCOSIS

Otomycosis is a fungal infection of the skin of the external canal. Otomycosis often is the result of superinfection of chronic bacterial infection of the external canal or middle ear. All fungi have three basic growth requirements—moisture, warmth, and darkness—all of which commonly are present in the EAC. The most common fungus is *Aspergillus* spp., although *Candida* spp., *Actinomyces* spp., and Phycomycetes also have been reported.[7] Pruritus is the primary clinical manifestation. Patients also complain of feeling moisture in their ears. Physical examination commonly shows a white, black, or dotted gray membrane in the EAC. Diagnosis often is confirmed with a fungal culture.

Thorough cleaning with removal of the matted fungal debris and topical application of an acidifying solution, such as aluminum sulfate–calcium acetate (Domeboro), or of a drying powder, such as boric acid, often is adequate treatment. Antifungals such as clotrimazole cream or solution (Lotrimin) also may be used. It is important to assess for perforation of the tympanic membrane because antifungals can be ototoxic.[16,26] Gentian violet usually is well tolerated in patients with mastoid cavities, but it permanently stains skin and clothing. Many patients with refractory otomycotic infections have had previous canal wall mastoid surgery and require a hearing aid with a closed mold. Because the patient relies on the hearing aid virtually all day, trauma associated with placing and removing the hearing aid throughout the day can cause a significant problem. Ointments are not recommended for patients with closed hearing aids because they may promote fungal growth secondary to the accumulation of moisture.

NECROTIZING OTITIS EXTERNA

Necrotizing otitis externa is an infection of the EAC that spreads to the surrounding subcutaneous tissues and can lead to osteomyelitis of the skull base.[15] This condition was described first by Chandler[12,14] and was referred to as *malignant otitis externa* because of the aggressive extension of the disease and the poor outcome. Survival rates have improved during the past 2 decades as a result of increased awareness, allowing for earlier diagnosis and treatment.[15,16] Patients often are diabetic, immunocompromised, or undergoing post-radiation therapy.[5,37,39] The infection often begins as any other acute otitis externa involving the bony-cartilaginous junction and often extends through the fissures of Santorini to involve the parotid region. Facial paralysis can occur as a complication of this disease and does so more commonly in children than in adults in cases of necrotizing otitis externa.[30] Facial nerve paralysis in necrotizing otitis externa often is permanent.[13]

P. aeruginosa is the most common pathogen in necrotizing otitis externa. *Proteus mirabilis* also has been reported as a causal agent in some cases.[15,16] Necrotizing otitis externa should be suspected in the presence of a pseudomonal infection that does not resolve and may be associated with facial nerve paralysis. The presence of granulation in the external canal at the bony-cartilaginous junction also should raise suspicion of necrotizing otitis externa.

Diagnostic imaging, including computed tomography or magnetic resonance imaging, of the temporal region often is required.[21] The most common finding of extension beyond the ear canal is retrocondylar fat infiltration.[25] A gallium 67 scan often is diagnostic in the early course of the disease and provides a good way to monitor the efficacy of treatment. A positive technetium 99m scan is diagnostic for acute osteolytic osteomyelitis because it measures osteoclastic activity, but it may remain positive long after the infection has subsided. For this reason, a technetium 99m scan is not ideal for monitoring treatment response.[41]

Treatment of necrotizing otitis externa often involves multiple surgical débridements combined with topical and intravenous antibiotics. Hyperbaric oxygen also has been tried in patients, with some success.[17] In diabetic patients or immunocompromised patients, coadjuvant treatment to control the primary condition is crucial and should be initiated immediately.

DIFFERENTIAL DIAGNOSIS

Not every condition that manifests with pain and purulent discharge from the EAC is otitis externa. Multiple other entities that may manifest with one or more similar symptoms include relapsing polychondritis, suppurative otitis media, and herpetic infections.

Relapsing polychondritis is a progressive inflammatory disorder affecting cartilage. When it involves the ear, it usually involves the pinna and the cartilaginous portion of the EAC, manifesting as swelling and erythema.[3] This condition can affect any cartilaginous structure, including the trachea, the nasal septum, and the larynx. Destruction of the cartilage by inflammatory infiltrates is followed by granulation, fibrosis, and calcifications. It often is accompanied by arthralgias involving one or more joints and rarely affects only one ear.

Herpes simplex and herpes zoster also can affect the EAC. Both conditions manifest with painful vesicles along the EAC (Fig. 18–2) and can be accompanied by facial nerve paralysis (Ramsay Hunt syndrome or herpes zoster oticus).[2,43] Treatment is with antivirals, such as acyclovir or famciclovir.

Dermatologic conditions also can give the appearance of otitis externa. Allergic and contact dermatitis can manifest with erythema, weeping areas, and itching. Allergic dermatitis is a delayed hypersensitivity reaction resulting from substances such as poison

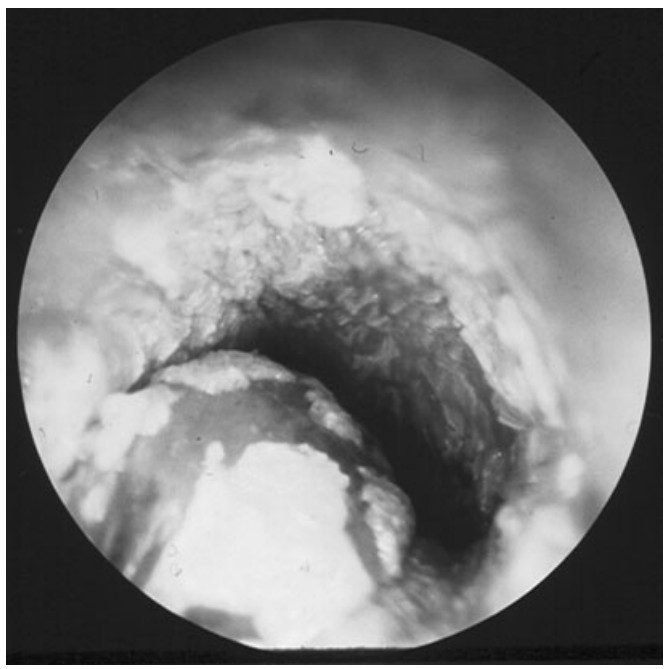

Figure 18–2 Ear canal with multiple vesicles from herpes zoster oticus. (See companion Expert Consult web site for color version.)

ivy, rubber, and nickel compounds.[28,40] Treatment is with administration of topical steroids and removal of the causative agent.

CONCLUSION

Understanding the external ear anatomy and its physiology allows clinicians to comprehend better the natural history of the diseases that affect this region. Despite improvements in diagnostic imaging techniques, no substitute exists for a good history and physical examination to differentiate among various conditions with a similar presentation. Treatment of otitis externa should focus on achieving relief of the acute condition; at the same time, clinicians should try to help prevent recurrences in patients with higher risk factors.

CHAPTER 19

OTITIS MEDIA

Jerome O. Klein ✪ Charles D. Bluestone

The term *otitis media* denotes inflammation of the mucoperiosteal lining of the middle ear. *Acute otitis media* (*AOM*) is the rapid onset of signs and symptoms of acute infection within the middle ear. *Otitis media with effusion* is an inflammation of the middle ear in which a collection of liquid is present in the middle ear space, and no signs or symptoms of acute infection are present. *Middle ear effusion* denotes liquid in the middle ear. The effusion may be serous, a thin, watery liquid; mucoid, a thick, viscid, mucus-like liquid; purulent; or a combination of these forms. Fluctuating or persisting loss of hearing is present in most patients who have middle ear effusion; hearing impairment is the most frequent complication of AOM or otitis media with effusion. Suppurative complications of otitis media occur when inflammation and infection extend beyond the mucoperiosteal lining of the middle ear (e.g., mastoiditis, epidural abscess). An extended review of otitis media in infants and children was written by the authors and published in 2007.[25]

INCIDENCE AND EPIDEMIOLOGY OF ACUTE OTITIS MEDIA

AOM is one of the most common infectious diseases of childhood. A survey of diagnoses made in office practices in the United States in 1990 identified 24.5 million visits for which the principal diagnosis was otitis media; the number of diagnoses of otitis media had increased from 9.91 million visits recorded in 1975.[171] In Boston, Teele and associates[187] found that about 33 percent of pediatric office visits for illness of any kind were attributable to AOM or otitis media with effusion. The same group of investigators reported that 62 percent of children had had at least one episode of AOM by the time they reached 1 year of age, and 17 percent had experienced three or more episodes.[188] By 3 years of age, more than 80 percent of children had experienced at least one episode of AOM, and 46 percent had had three or more episodes. A similar preponderance of cases of AOM during the first or second year of life with a decline in incidence rate thereafter has been reported by investigators from locations as diverse geographically as Finland[152,175]; Sweden[88]; Cleveland, Ohio[118]; Huntsville, Alabama[86]; and Galveston, Texas.[17] The results of these studies suggest that by the time children reach 3 years of age, they may be categorized into three groups of about equal size relative to acute infections of the middle ear: one group is free of ear infections; a second group may have occasional episodes of otitis media, usually associated with infections of the respiratory tract; and a third group is otitis-prone, subject to repeated (three or more) episodes of acute infection.

A prospective study beginning in 1991 of more than 2000 children in Pittsburgh, Pennsylvania, surveyed during the first 2 years of life provided insight into the prevalence of otitis media, the amount of antibiotic used, and the proportion of children who required surgery for severe and recurrent disease.[142] Middle ear effusion was present 20.4 percent and 16.6 percent of the time during the first and second years of life, respectively; mean number of days of antimicrobial therapy for otitis media was 41.9 and 48.6 in the first and second years of life, respectively (>90% of all antibiotic treatment in the first 2 years of life was for otitis media); and 1.8 percent and 4.2 percent of the children had myringotomy and insertion of tympanostomy tubes in the first and second years of life, respectively.

Three factors are likely to alter the incidence and epidemiology of AOM in the United States in the next few years: (1) the introduction of the seven-valent pneumococcal conjugate vaccine (PCV7) in 2000; (2) the publication of management guidelines by the American Academy of Pediatrics (AAP) and the American Academy of Family Physicians (AAFP) in 2004, which included minimal criteria for establishing the diagnosis of AOM and an option of "watchful waiting," rather than immediate use of antimicrobial drugs; and (3) the educational campaign of the Centers for Disease Control and Prevention (CDC) and other professional groups to influence parents and physicians to avoid inappropriate uses of antimicrobial agents for trivial, usually viral, respiratory tract infections because of concern for development of multidrug resistance. Any one or all of these factors may play a role in decreasing the number of diagnoses of AOM, altering the microbiology of AOM, decreasing the number of surgical procedures for severe and recurrent otitis media, and reducing the volume of antimicrobial agents used in infants and children.

HOST RISK FACTORS

Table 19–1 lists the risk factors for developing severe and recurrent AOM. The peak age-specific attack rate occurs between 6 and 18 months of age. The frequent occurrence of otitis media in otherwise healthy infants is partly a reflection of the fact that the eustachian tube of the young child is shorter, floppier, straighter, and more horizontal than the eustachian tube of the older child. Organisms from the nasopharynx reach the middle ear more readily than they do in older children. By 3 years of age, the incidence of AOM decreases because of changes in the child's anatomy and physiology and maturing immune mechanisms. Children who have had little or no experience with otitis media by the time they reach age 3 years are unlikely to develop problems with middle ear infections, unless some predisposing factor, such as tumor or fracture of the base of the skull or a facial bone or acquired immunodeficiency, occurs.

TABLE 19–1 Risk Factors for Severe and Recurrent Acute Otitis Media

Male gender
Familial aggregation—disease in siblings and parents
Very low birth weight (<1500 g) and gestational age <33 wk
Early onset of disease
Race—Native American, Alaskan Eskimo, Australian Aborigine
Poverty—crowded living conditions, poor sanitation, lack of access to medical care
Prone sleeping position
Use of pacifier
Not breast-fed
Group daycare
Exposure to smoke and environmental antigens
Congenital or acquired immunodeficiency

AOM, similar to most bacterial infections in children, seems to occur more commonly in boys than in girls.[188] A genetic predisposition to AOM has been shown by a study in twins.[37] Histories of severe and recurrent ear infections in siblings and parents are found frequently in families with an otitis-prone child.[61,188] Although prematurity has not been associated previously with predisposition to middle ear infection, a study from the Netherlands suggests that a gestational age of younger than 33 weeks and very low birth weight (<1500 g) are risk factors for developing recurrent otitis media.[51] Age at first episode of AOM is associated significantly with recurrent episodes.[188]

Race and ethnicity as predisposing factors may be difficult to separate from poor social and economic conditions. Particularly high rates of the disease have been observed among Eskimos,[94,153,163] Native Americans,[141] and Australian Aboriginal children.[126] Factors of poverty predisposing children to development of respiratory infections and otitis media include crowded living conditions, poor sanitation, and limited access to medical care.[121]

Although most children with recurrent and severe otitis media have no obvious predisposing factor, a few have altered host defenses, including anatomic changes (e.g., cleft palate or uvula, submucous cleft), alterations of normal physiologic defenses (e.g., patulous eustachian tube, barotrauma), and congenital or acquired immunologic deficiencies (e.g., immunoglobulin deficiency, chronic granulomatous disease, malignancy). Active middle ear disease is a constant event in children with cleft palate.[134,136] Children with acquired immunodeficiency syndrome have a higher age-specific incidence of otitis media beginning at 6 months of age compared with uninfected children.[8] Nasotracheal intubation has been identified as a factor in the development of AOM and otitis media with effusion in neonates and older children.[15,48,145]

ENVIRONMENTAL RISK FACTORS

An increased incidence of respiratory infections, including otitis media, among children in group daycare compared with children

receiving home care has been documented in the United States,[78,128,165] Sweden,[80] and Finland.[3,174] A survey of children in Memphis, Tennessee, found that children in daycare experienced more episodes of otitis media and were more likely to have placement of ventilation tubes.[9] By the second year of life, 21 percent of children in Pittsburgh observed from birth who were in group daycare (7 children or more) had surgical procedures for middle ear disease (almost all were myringotomy and placement of tubes) compared with only 3 percent of children in home care.[198] The increase in incidence of otitis media from 9.91 million office visits in 1975 to 24.5 million office visits in 1990 is associated with increased usage of group daycare for young infants.[171]

Placing infants in daycare usually is necessitated by the professional needs of one or both parents. Paid maternal leave, as is fostered in some European countries, results in an increased proportion of mothers who are breast-feeding and delayed entry of infants into out-of-home daycare. In the Czech Republic, paid maternal leave is available to all women for 9 months after giving birth and is optional to the child's third birthday. Paid parental leave now is reaching a stage of discussion and experimental programs in the United States. The Federal Family and Leave Act guarantees 6 weeks of unpaid leave, but more generous programs are available in Massachusetts, Vermont, Maryland, and Washington.

Infants who are breast-fed have fewer incidents of ear disease than infants who are bottle-fed. In a Boston, Massachusetts, study,[188] breast-feeding for 3 months or more was associated with decreased risk of developing AOM in the first year of life. Although bottle-fed infants are placed in a reclining or horizontal position and breast-fed infants are held in a vertical position, the data suggest that a constituent of breast milk is the important factor and not position during feeding. Of children with cleft palate who were provided breast milk or formula in a similar container, children who received breast milk had fewer cases of middle ear effusion.[139]

Sleep position and use of a pacifier have been identified as risk factors for recurrent episodes of AOM. More episodes of AOM were identified in infants who slept prone (compared with infants who slept supine) in an investigation of 14,000 infants in Bristol, England.[62] Use of a pacifier increased the risk for development of recurrent AOM in Finnish children attending daycare centers.[129] More than three episodes of AOM occurred in 29.5 percent of children younger than 2 years of age using pacifiers compared with 20.6 percent of children not using pacifiers; in children 2 to 3 years old, the incidences of recurrent AOM were 30.6 percent and 13.2 percent, respectively.

Allergy to environmental antigens plays a role in congestion of the mucosa of the eustachian tube. Exposure to smoke can result in goblet cell hyperplasia, mucus hypersecretion, ciliostasis, and decreased mucociliary transport.[192] The availability of a biochemical marker, cotinine, in saliva, serum, or urine has rendered documentation of passive exposure to tobacco smoke more reliable than that provided by history alone. High concentrations of serum cotinine were associated by Etzel and colleagues[53] with increased incidence of AOM and increased duration of middle ear effusion. Kim and colleagues[98] in Houston, Texas, documented the association of invasive pneumococcal infections in children and adults with increased environmental exposures to sulfur dioxide (a marker for air pollution) and higher counts of ragweed pollen.

Studies in the United Kingdom and the United States show seasonal variation in the occurrence of AOM. The pattern within a period of 1 year is sinusoidal, with the peak incidence in December through March and lowest incidence in July through September.[87,123] These findings do not correlate with general climatic conditions because the U.S. studies were performed in Texas and Washington, D.C., and the United Kingdom study was done in northern England. The incidence coincides, however, with the peak incidence of respiratory infections in both countries.

COST ANALYSES

Analyses of cost of management of otitis media have provided additional insights into the epidemiology of otitis media. Direct costs of an episode of otitis media include health care visits, cost of drugs, consultations, surgical procedures, audiometry and remedial speech and language visits, and hospitalizations related to severe AOM or its complications. Indirect costs include transportation, babysitters, and lost time from work. The average total cost of treating an episode of otitis media was estimated to be $116[93] to $131 in 1997 and 2000.[32] In 1996, the combined cost of AOM and its sequelae was estimated to be more than $5 billion every year. Mean costs of surgical procedures for severe and recurrent AOM in a managed care population in northern California for 1997 included myringotomy and placement of tympanostomy tube at $1400, mastoidectomy at $5062, and adenoidectomy at $1500.[32]

ETIOLOGIC AGENTS

The microbiology of otitis media has been documented by cultures of middle ear effusions obtained by needle aspiration (Table 19–2). In 1906, German investigators studied the bacteriology of AOM by aspiration of middle ear fluids. Many microbiologic studies were done, most in European otolaryngologic centers, before the introduction of antimicrobial agents. In the 1960s, investigative studies of the bacteriology of AOM were done in pediatric clinics and offices. Group A streptococcus was the dominant pathogen throughout the early studies but diminished in importance as more cases of mild and moderate disease were studied in pediatric programs, in contrast to the more severe disease referred to otolaryngologic centers. *Streptococcus pneumoniae*, which had been second to group A streptococci in frequency in the studies before 1960, now became the pathogen most frequently identified, followed by *Haemophilus influenzae* and *Moraxella catarrhalis*. More recent studies suggest the extensive use of the conjugate pneumococcal vaccine may have resulted in a decrease in the number of episodes of AOM caused by *S. pneumoniae* and a proportional increase in the incidence of disease caused by *H. influenzae* and *M. catarrhalis*.[21,34]

Bacteria may be isolated from middle ear fluid in approximately two thirds of patients with AOM. The finding that approximately one third of patients have sterile cultures may reflect limitations of bacterial culture methods because antigen detection tests often indicate the presence of pneumococcal capsular polysaccharide in sterile middle ear fluids.[107,113] In addition,

TABLE 19–2 Bacterial Pathogens Isolated from Middle Ear Aspirates in Infants and Children with Acute Otitis Media (Percentage of Children with Pathogen, 1985-1992)*

From Bluestone, C. D., and Klein, J. O.: Otitis Media in Infants and Children. 4th ed. Hamilton, Ontario, B. C. Decker, 2007.

polymerase chain reaction for bacterial genome sequences has identified DNA of *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis* in patients with otitis media with effusion whose cultures were negative for these bacterial species.[149] Concomitant isolation of two or more organisms in the same effusion occurs in 7 percent of cases. Disparate results of cultures in children with bilateral AOM occur in approximately 20 percent of cases.[144] The detection of bacterial biofilms in the middle ear mucosa of children with chronic otitis media raises the possibility of metabolically active bacteria in culture-negative middle ear effusions.[71,149]

Several clinical situations warrant special consideration: (1) The occurrence of purulent conjunctivitis in association with AOM (conjunctivitis-otitis syndrome) usually is attributable to nontypeable *H. influenzae*[27,28]; (2) AOM occurs commonly among children hospitalized in intensive care units, and the bacteriology may be reflective of the hospital environment[48]; (3) renewed signs of AOM within 14 days usually represent relapse, whereas signs occurring 21 or more days after a prior infection are likely to indicate a new infection or recurrence[33]; and (4) children with tympanostomy tubes may develop AOM caused by organisms associated with otitis externa and AOM (e.g., *Staphylococcus aureus*, *Pseudomonas aeruginosa*, *Staphylococcus epidermidis*, *S. pneumoniae*, and *H. influenzae*).[164]

The bacteriology of otitis media with effusion mimics that of AOM.[64,65,124,155,170,181] In contrast, the etiologic agents of chronic suppurative otitis media with persistent perforation include *P. aeruginosa*, *S. aureus*, anaerobic bacteria, and enteric gram-negative bacilli.[29,96,133] *Mycobacterium tuberculosis* is a rare but important cause of chronic suppurative otitis media with persistent perforation.[200]

Bacteria found in middle ear aspirates usually are present in the nasopharynx of children with AOM, but multiple pathogens may be present in the nasopharynx that are not present in the middle ear.[54] Although not useful for specific microbiologic diagnosis of AOM, nasopharyngeal cultures are valuable for monitoring antibiotic susceptibility patterns of bacterial pathogens associated with AOM. Several investigators have noted quantitative differences in the nasopharyngeal flora of patients with and without otitis media, and these differences may play a role in the pathogenesis of middle ear disease. Long and colleagues[111] described a significant association between the recovery of abundant *H. influenzae* (at least 50% total colony count) from the nasopharynx and bacteriologically confirmed otitis media. An additional finding was that a semiquantitative nasopharyngeal culture was sensitive and specific in predicting the middle ear pathogen. Similar nasopharyngeal colonization rates for *S. pneumoniae* occur in ill and healthy children.[79,110,111] Gray and coworkers[70] have correlated the occurrence of AOM with nasopharyngeal acquisition of new serotypes of *S. pneumoniae*.

S. pneumoniae is the most frequent cause of severe AOM and suppurative complications. Of the 90 antigenically distinct pneumococcal serotypes, only few serotypes are responsible for most cases of otitis media. In more recent surveys, the most common types responsible for AOM in order of decreasing frequency were types 19F, 23, 14, 6B, and 3 (Table 19–3). All of these types except serotype 3 are included in the conjugate vaccine, PCV7. The serotypes responsible for sequential episodes of AOM were described by Austrian and colleagues.[5] Of interest is the constancy of the four most frequently isolated types in recurrent episodes. Other features of interest in the study are (1)

simultaneous infection of the middle ear fluid by two pneumococcal types, (2) isolation of the same type in consecutive episodes, and (3) isolation of the same type after an intercurrent episode caused by another type. At present, monitoring of pneumococcal serotypes responsible for AOM and invasive pneumococcal diseases is important in determining the durability of efficacy of the conjugate pneumococcal vaccine.

Otitis media caused by *H. influenzae* almost always is associated with nontypeable strains.[84,85,178] The clinical presentation of AOM caused by nontypeable *H. influenzae* usually is less severe than acute infection caused by *S. pneumoniae*, as measured by temperature elevation, ear pain, suppurative complications, and perforation of the tympanic membrane. Before the introduction of the conjugate *H. influenzae* type b vaccine, approximately 10 percent of children with *Haemophilus* spp. otitis had disease caused by type b, and approximately one fourth of these children had concurrent or subsequent bacteremia or meningitis.[74] *H. influenzae* causes AOM in all age groups, including older children and adolescents.[166,168] Of *H. influenzae* strains isolated from middle ear fluids, 30 to 60 percent produce β-lactamase.[105,173,195]

Although *S. pneumoniae* and *H. influenzae* are responsible for most cases of bacterial otitis media, *M. catarrhalis* and group A streptococci are responsible for some cases and should be considered in choosing appropriate antimicrobial agents. The incidence of AOM caused by *M. catarrhalis* in most studies is less than 10 percent but was noted to be 22 percent and 27 percent in 1983 reports from Pittsburgh[105] and Cleveland,[173] respectively, and 18.4 percent in a study of Finnish children observed between 1995 and 1997.[97] Most strains of *M. catarrhalis* isolated from middle ear fluids produce β-lactamase, and some patients fail to improve if they are treated with a β-lactamase-susceptible drug.

During the pre-antibiotic era, otitis media caused by group A streptococci frequently was associated with scarlet fever and often was of a severe and destructive form. In recent years, group A streptococci have been isolated frequently in some studies from Scandinavia but have been found infrequently in most studies from the United States. A survey of Israeli children identified group A streptococci in 350 of 11,311 episodes (3.1%) of AOM during 1999 to 2003. The incidence of mastoiditis was higher for patients with streptococcal AOM than for patients with other pathogens.[169]

Tuberculous otitis was an occasional cause of severe middle ear disease at the turn of the 20th century in the United States and western Europe and still occurs in developing countries. Otitis caused by *M. tuberculosis* is characterized by a painless, watery otorrhea through single or multiple perforations of the tympanic membrane.[176] Other bacteria, including *S. aureus* (which occurs infrequently in the United States but is the etiologic agent in 10% of cases in Japan[6]), gram-negative enteric bacilli (responsible for approximately 20% of otitis media cases in neonates, but a rare finding in older infants), anaerobic bacteria, *Clostridium tetani*, and *Corynebacterium diphtheriae*, are responsible for occasional cases of AOM.

Chlamydia trachomatis[190] has been identified in infants 6 months of age and younger, often associated with pneumonia. The role of *Chlamydia pneumoniae* in AOM is uncertain.[131,183]

The clinical history suggests that viral infection serves as a frequent initiating event of AOM by producing congestion of the mucosa of the upper respiratory tract. Epidemiologic data support an association between viral respiratory infection and the occurrence of AOM.[77] Upper respiratory tract infection with respiratory syncytial virus, influenza viruses, and adenoviruses was associated with a greater risk for developing otitis media than was infection with other viruses. Early studies identified a low viral isolation rate from middle ear fluid in patients with otitis media. A virus was isolated from only 29 of 663 (4.4%) specimens obtained by tympanocentesis and reviewed by Klein and Teele in 1976.[104] A higher virus identification rate in middle ear fluid using culture and antigen detection has been reported.[41,99,162]

Pitkaranta and colleagues[148] used reverse transcriptase polymerase chain reaction to identify viruses in middle ear fluids of children with AOM and otitis media with effusion; evidence of rhinovirus was found in 22 percent and 19 percent, respectively, and respiratory syncytial virus was found in 18 percent and 8 percent, respectively. Ruuskanen and colleagues[159] summarized eight studies published between 1982 and 1990 using immunoassay or isolation; virus was identified in middle ear fluids in 17 percent of the samples—as a single agent in 6 percent and in combination with a bacterial pathogen in 11 percent. Viruses identified in middle ear fluids have included respiratory syncytial virus, influenza viruses, adenoviruses, parainfluenza viruses, enteroviruses, and rhinoviruses.

Concomitant isolation of viral and bacterial pathogens from middle ear fluid seems to be a common finding.[41,162] A survey of the microbiology of new-onset otorrhea in 79 children with tympanostomy tubes identified bacteria in 92 percent, viruses in 70 percent, and bacteria and viruses in 66 percent.[158] In an accompanying commentary, Chonmaitree[40] noted that AOM no longer should be considered a pure bacterial disease and that antibacterial treatment may not result in optimal outcome in some cases because of viral co-infection.

ETIOLOGY IN NEONATES

Clinical investigators have performed needle tympanocentesis to isolate bacterial pathogens causing otitis media in the first 6 weeks of life. Four studies included 169 infants.[14,20,172,189] Bacteria were isolated from middle ear fluid in 68 percent of cases. As in older children, *S. pneumoniae* and *H. influenzae* were the organisms most frequently isolated. Other than the more frequent occurrence of disease caused by gram-negative enteric organisms (approximately 20% cases) and the occasional isolation of other neonatal pathogens (e.g., group B streptococci), the bacteriology of otitis media in this age group was similar to that in older children.

PATHOGENESIS

The pathogenesis of otitis media is likely to follow a similar sequence of events in most children. The patient has an antecedent event (usually caused by an upper respiratory viral infection) that results in congestion of the respiratory mucosa throughout the respiratory tract, including the nose, nasopharynx, eustachian tube, and middle ear; congestion of the mucosa in the eustachian tube results in obstruction of the narrowest portion of the tube, the isthmus. The obstruction results in negative pressure in the middle ear and then development of middle ear effusion. The secretions of the mucosa of the middle ear, which usually drain through the eustachian tube, now have no egress and accumulate in the middle ear. The effusion may be asymptomatic (i.e., lacking the signs and symptoms of acute infection) and is termed *otitis media with effusion*. If pathogenic bacteria or viruses that colonize the nasopharynx are present in the middle ear after obstruction of the eustachian tube has occurred, the organisms multiply, resulting in an acute suppurative infection, with an abscess, and characterized by signs and symptoms of acute infection such as fever and otalgia.[24,25,66,161] For children with recurrent episodes of AOM or otitis media with effusion, anatomic or physiologic abnormalities of the eustachian tube seem to be predisposing factors.

It also is possible that subtle changes in immune response occur that predispose a child to frequent episodes of otitis media. Experimental studies provide evidence that virus-induced

Figure 19–1 Persistence of middle ear effusion after onset of acute otitis media. OME, otitis media with effusions. *(Modified from Teele, D. W., Klein, J. O., and Rosner, B. Figure 19–2 The middle ear. *(From Klein, J. O., and Daum, R. S.: The Diagnosis and Management of the Patient with Otitis Media. Copyright Biomedical Information Corporation, New York, 1985.)*

impairments in neutrophil migration and bacterial killing also may be important in the pathogenesis of AOM.[2]

With growth of the skull and change in the position, length, and width of the eustachian tube over the course of time, the predilection to otitis media in accompanying acute infections of the upper respiratory tract in the first 3 years of life diminishes, and the patient has fewer episodes of AOM. Children younger than 3 years of age with similar respiratory infections are predisposed to the complication of acute infection of the middle ear, whereas older children challenged by the same microorganism have signs of upper respiratory infection but need not have a complicating ear infection.

The pathogenesis of persistent middle ear effusion or otitis media with effusion is uncertain. An effective antimicrobial agent sterilizes the acute bacterial infection of AOM. The middle ear effusion, now sterile, may persist for weeks to months. The median duration of middle ear effusion after AOM is approximately 23 days (Fig. 19–1). The type of antibacterial drug used does not seem to alter the duration of fluid in the middle ear after acute infection occurs.

PATHOPHYSIOLOGY

TYMPANIC MEMBRANE

In the presence of otitis media, changes in the tympanic membrane occur rapidly. The presence of congested blood vessels, edema (which obscures normal landmarks), and bulging or sagging of Shrapnell membrane indicate not only a myringitis (inflammation of the tympanic membrane) but also the presence of fluid in the middle ear space. Blebs that appear on the surface epithelium are a consequence of AOM or edema or hydropic degeneration of the membrane.

Inflammation may occur on outer epithelial or inner mucosal sides of the fibrous layer (middle layer) of the drum. In severe cases, infection may involve the fibrous layer itself. The membrane thickens as a result of edema and infiltration of polymorphonuclear leukocytes. All three layers of the drum may undergo dissolution, owing to pressure necrosis resulting from the expanding middle ear abscess or thrombophlebitis of tympanic veins, with resulting perforation. With evacuation of the contents of the middle ear abscess, healing may be rapid, and the perforation usually seals within a few days. In the process of healing, metaplasia of the epithelium, hyaline degeneration, calcium deposition, and scar formation may occur.

Occasionally, when a perforation is close to the margin of the annulus or occurs in Shrapnell membrane, the skin of the external auditory canal (EAC) and the surface squamous epithelium of the tympanic membrane may grow through the aperture and invade the middle ear. This event may lead to formation of a cholesteatoma (epidermal inclusion cyst). Even if the perforation heals, a differential in gas pressure across the tympanic membrane caused by malfunction of the eustachian tube may result in resorption of gas in the middle ear cavity and negative pressure in the middle ear, which causes retraction of Shrapnell membrane or an atrophic scar into the middle ear or mastoid attic.

EUSTACHIAN TUBE

The eustachian tube is approximately 3.8 cm long in an adult. It opens in the fossa of Rosenmüller and extends upward, backward, and laterally to open in the upper anterior wall of the tympanic cavity (protympanum). In a child, the tube is shorter and floppier. The eustachian tube is composed of two portions: the cartilaginous portion extending into the nasopharynx and the bony portion originating in the middle ear. The upper third of the tube is bony; the middle ear opening is the widest; and the medial end (the part joining the cartilaginous eustachian tube), or isthmus, is the narrowest. Pneumatic peritubal air cells arising from the middle ear cavity surround it and can extend to the petrous apex. The internal carotid artery lies anteromedial to this region (Fig. 19–2).

The lower two thirds of the eustachian tube is a narrow, slitlike, fibrocartilaginous passage. It makes a 160-degree angle with the bony portion at its junction. The cross section of the tube

looks like a shepherd's crook, with a cartilaginous superior and medial surface and a fibrous lateral surface.

Three muscles are associated with the eustachian tube. The tensor tympani muscle lies on top of it; the levator palatini muscle lies under it; and the tensor palatini muscle arises on the tube, scaphoid fossa, and spine of sphenoid and then courses around the hook of the hamulus and forms an aponeurosis with its mate (from the opposite side) in the soft palate. This muscle is the only one that acts directly on the eustachian tube.

The eustachian tube area, protympanum, and hypotympanum are lined by ciliated columnar epithelium with goblet cells or secretory cells. The epithelium is continuous with the upper airway system and paranasal sinuses. This area also contains a well-defined subepithelial connective tissue layer, which thins out and may be absent nearing the antrum and mastoid air cell system. The movement of the cilia and mucus blanket always is toward the eustachian tube and nasopharynx. The tube is surrounded by a plexus of lymphoid channels. It has an arterial supply from a branch of the middle meningeal or accessory meningeal artery and from branches of the artery of the pterygoid canal. The nerve supply is from the tympanic plexus (ninth cranial nerve) (sensory) and sphenopalatine ganglion (sympathetics and parasympathetic palatine fiber).

The bony portion is rigid and patulous; the medial two thirds normally is held closed by elastic recoil of the fibrocartilaginous tissue. Contraction of the tensor palatini muscle that inserts in the anterolateral wall opens the tube on swallowing. On average, an adult swallows once per minute while awake and once every 5 minutes while asleep. Suckling infants usually swallow five times per minute.

Mucus and ciliary action flow from the middle ear to the eustachian tube. The eustachian tube acts as a unidirectional valve that favors outflow from the middle ear to the pharynx. Reverse flow can be induced by an increase in pressure in the nasopharynx (Valsalva, barotrauma). During occlusion of the eustachian tube, oxygen and carbon dioxide (and other gases) are absorbed from the middle ear by diffusion into the rich vasculature, and a negative pressure is created. A patent eustachian tube is a crucial prerequisite for subsidence of middle ear disease.

DIAGNOSIS

To establish uniformity of diagnosis, the clinical practice guideline published by the AAP and the AAFP proposed criteria for diagnosis of AOM.[4] The diagnosis required (1) a history of acute onset of signs and symptoms, (2) the presence of middle ear effusion, and (3) signs and symptoms of middle ear inflammation. The presence of middle ear effusion was identified by any of the following: (1) bulging of the tympanic membrane, (2) limited or absent mobility of the tympanic membrane, (3) air-fluid level behind the tympanic membrane, or (4) otorrhea. Signs or symptoms of middle ear inflammation were identified by either erythema of the tympanic membrane or otalgia that results in interference with or precludes normal activity or sleep. The following sections expand these definitions.

CLINICAL PRESENTATION

Children with AOM may have nonspecific signs and symptoms, including fever, irritability, headache, apathy, anorexia, vomiting, and diarrhea. Signs of respiratory viral infection, including cough and coryza, usually are present before the specific signs of ear infection occur. Fever occurs in approximately one third[167] to two thirds[127] of children with otitis media.

Specific signs and symptoms associated with otitis media and its complications and sequelae include the following:

1. Otalgia, or ear pain, is the most common complaint of infants and children with AOM. The symptom is suggested in young infants who are pulling at the ear or excessively irritable. Some infants do not have earache; Hayden and Schwartz[77] identified absence of ear pain in approximately one fifth of 335 consecutively diagnosed episodes of otitis media, usually among children older than 2 years of age.
2. Otorrhea is discharge from the middle ear through a perforation in the tympanic membrane or from the EAC when inflamed. The acute perforation usually is central in the membrane. Relief of the pressure on the tympanic membrane results in immediate pain relief and usually a decrease in temperature. Because the tympanic membrane has a dense network of blood vessels, rapid repair of the membrane occurs, and the perforation usually is unapparent within 24 to 72 hours. If the tympanic membrane seals and mucous membrane infection still is present, fluid may reaccumulate with renewed acute signs of otitis media.
3. Hearing loss occurs whenever fluid fills the middle ear space, whether the fluid is associated with acute infection or with otitis media with effusion. When fluid fills the middle ear space, the median hearing loss is 25 dB (the equivalent of having plugs in the ear canals).[59]
4. Vertigo occurs but is not a common complaint of children with otitis media. Vertigo occurs more commonly in unilateral than bilateral disease and may be caused by labyrinthitis. Older children describe a feeling of spinning, whereas younger children may not be able to verbalize these symptoms but manifest disequilibrium by falling or stumbling.
5. Tinnitus is an uncommon complaint in children, but when it does occur, the symptom often is caused by otitis media and eustachian tube dysfunction.
6. Swelling around the ear, especially in the postauricular area, may be a sign of mastoiditis.
7. Facial paralysis in children occurs as a complication of AOM or chronic otitis media with perforation of the tympanic membrane or as a result of an enlarging cholesteatoma.
8. Conjunctivitis has been associated with AOM caused by nontypeable strains of *H. influenzae*. The conjunctivae are injected, with tearing or purulent discharge.[28]
9. Craniofacial anomalies, such as cleft palate, mandibulofacial dysostosis, and Down syndrome, may predispose to frequent ear disease. Hypernasal speech suggests velopharyngeal insufficiency.

EXAMINATION OF THE EAR

OTOSCOPY

Examination of the ear should begin with observation of the auricle and the external auditory meatus. Palpation of the periauricular areas should be done to indicate presence of periostitis or diffuse external otitis. The ear canal should be examined for inflammation or cerumen that obstructs vision of the tympanic membrane.

For proper assessment of the tympanic membrane and its mobility, a pneumatic otoscope in which the diagnostic head has a secure seal should be used. The speculum should have the largest lumen that can fit comfortably into the child's cartilaginous external auditory meatus. The important landmarks of the tympanic membrane that can be visualized with the otoscope are indicated in Figure 19–3. The otoscopic examination should include observation of the following conditions of the tympanic membrane:

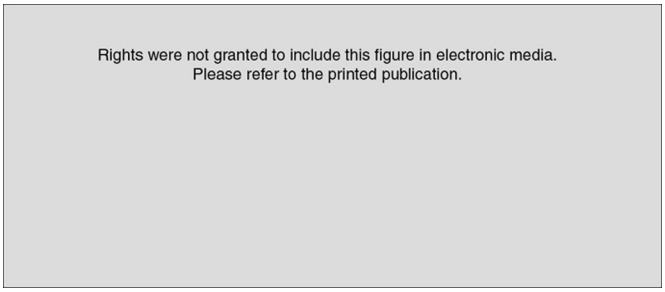

Figure 19–3 Important landmarks of the tympanic membrane that usually can be visualized with the otoscope. *(From Bluestone, C. D., and Klein, J. O.: Otitis Media in Infants and Children. 4th ed. Hamilton, Ontario, B. C. Decker, 2007, p. 156.)*

- *Position*: Normal is slightly convex; bulging indicates increased pressure from positive air pressure or fluid; a retracted drum indicates negative pressure with or without effusion; fullness of the tympanic membrane is apparent initially in the posterosuperior portion of the pars tensa and the pars flaccida because these two areas are the most highly compliant parts of the membrane.
- *Appearance and color*: The normal color is pearly gray and translucent; any congestion of the mucous membrane of the middle ear would be reflected in congestion of the vessels of the tympanic membrane and appear pink; a blue discoloration suggests blood in the middle ear associated sometimes with basal skull fracture; the inflamed middle ear mucosa usually is reflected in a bright red tympanic membrane.
- *Integrity of the membrane*: All four quadrants of the tympanic membrane should be inspected for presence or absence of perforation, retraction pockets, or cholesteatoma.
- *Mobility*: Application of positive and negative pressures by the pneumatic otoscope enables the viewer to determine the presence of an air-filled space (rapid excursion of the membrane on positive and negative pressures) or a fluid-filled space (limited or no excursion of the membrane); a middle ear with negative pressure does not respond to otoscopic negative pressure, and a middle ear with high positive pressure does not respond to otoscopic positive pressure (Fig. 19–4).

TYMPANOMETRY

Tympanometry measures the compliance of the tympanic membrane (Fig. 19–5).[30,45,120,150,154,191] Under normal circumstances, the pressure in the middle ear virtually is the same as the external ambient pressure; the eustachian tube functions to equate middle ear pressure to atmospheric pressure. If for any reason a pressure differential occurs across the tympanic membrane, stress is applied to the drum. Middle ear compliance varies as a function of the pressure differential across the tympanic membrane. When blockage of the eustachian tube with no fluid in the middle ear occurs, the tympanometry curve has a shape similar to that observed on a normal tympanogram, but the point of maximal compliance is shifted to the negative pressure side because maximal compliance is reached when the tympanic membrane reaches a peak of compliance (i.e., when EAC pressure is reduced to the same level as in the middle ear).

If ossicular discontinuity or a flaccid or atrophic tympanic membrane is present, the drum is highly compliant, and a highly peaked tympanogram is obtained. Abnormal tympanograms obtained in the presence of fluid in the middle ear are characterized by the following:

1. Reduced height of the curve (i.e., the middle ear has reduced compliance)
2. Shift to negative pressure sides of the curve and point of maximal compliance (i.e., eustachian tube blockage)
3. A flat curve without definite peak, the most characteristic feature

Although tympanometry with the electroacoustic impedance bridge has proved to be a satisfactory method for detecting the presence of fluid in the middle ear cavity, technical difficulties exist in obtaining accurate readings in infants and children, including the requirement for a secure seal of the probe in the ear canal, the need for a period of quiet to obtain an accurate reading, and decreased accuracy in infants younger than 7 months of age (because of the highly compliant EAC in infants <7 months).[143] In addition, only a few of many instruments currently on the market in the United States have data about sensitivity and specificity based on tympanometric patterns of otoscopic results before myringotomy.[57,130] Less persuasive data are available from studies correlating tympanometry and otoscopy findings.[30,120,150]

ACOUSTIC REFLECTOMETRY

The acoustic otoscope, or reflectometer (Ear Check Pro; Innova Medical, Lenexa, KS), is a handheld instrument that uses a microphone in the probe tip placed in the opening of the child's external ear canal. A professional and a consumer model were developed. The tip measures the level of transmitted and reflected sound from a less than 90 dB sound source that varies from 1800 to 4400 Hz in a 750-msec period. Acoustic energy is reflected back toward the probe tip from the ear canal and eardrum. The operating principle is based on the fact that a sound wave in a closed tube would be reflected when it strikes the end of the tube. Sound reflectivity is measured in units that indicate the status of a fluid-filled or air-filled middle ear.[44] Babonis and associates[7] found that tympanometry and reflectometry had comparable accuracy in predicting middle ear effusion documented by myringotomy. Acoustic reflectometry has some technical advantages compared with tympanometry: Accurate readings can be obtained in crying children, and a secure seal of the probe tip in the ear canal is not required.

AUDIOMETRIC TESTS

Audiometric testing may be employed to measure auditory acuity and evaluate conductive hearing losses, but assessment of hearing is an inaccurate method for identifying middle ear effusion. Hearing loss is the most prevalent complication of otitis media and is present uniformly whenever fluid fills the middle ear. The audiogram usually reveals a mild to moderate conductive hearing loss (median 25 dB).[59] Obstruction of the eustachian tube early in the clinical course of otitis media results in absorption of gases from the middle ear and drum retraction. The reduced compliance of the drum results in increased stiffness in the ossicular chain system. The audiogram reveals a low-frequency conductive hearing loss. As serous effusion appears and the middle ear fills with serum and pus, the ossicular system has an increased mass applied to it, and the audiogram flattens out, resulting in a high-frequency conductive hearing loss.

TYMPANOCENTESIS AND MYRINGOTOMY

Tympanocentesis, a needle aspiration of the middle ear effusion, is used primarily for establishing the presence or absence of an effusion and for microbiologic study. Because cultures of the

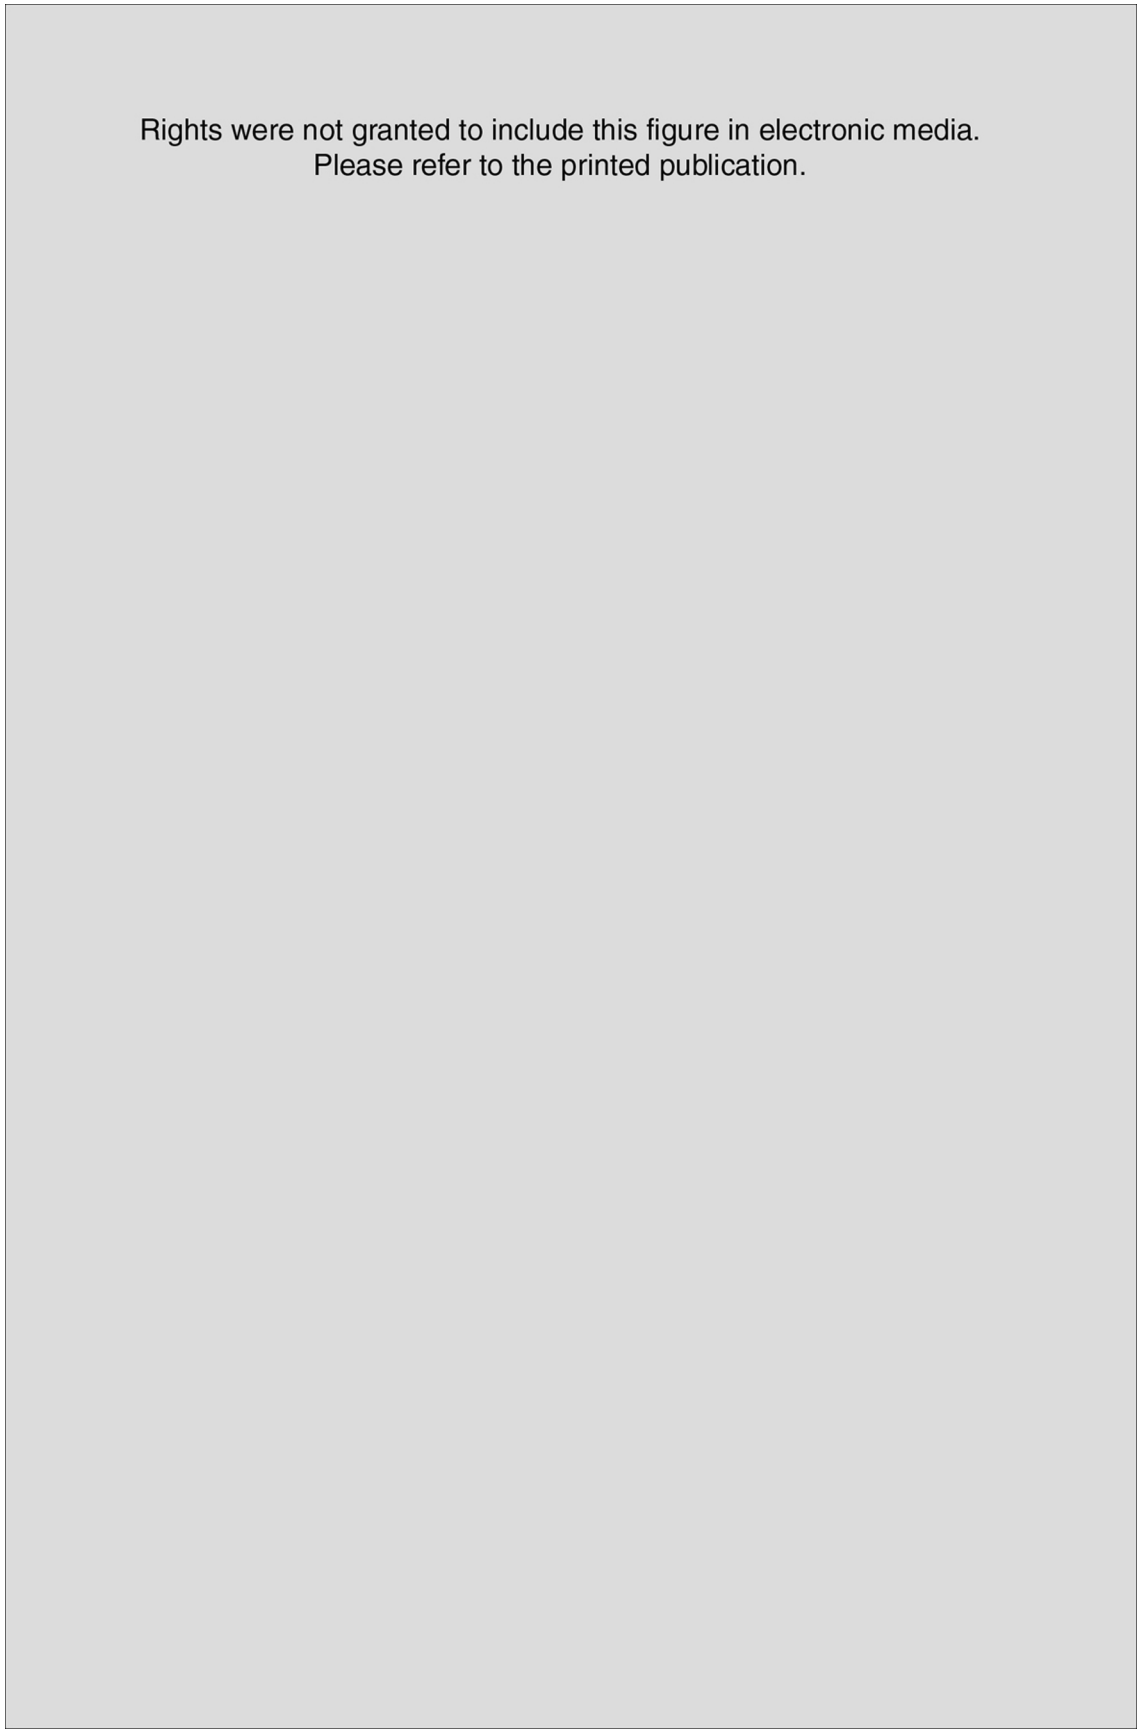

Figure 19–4 Otoscopic views and corresponding lateral sections through the tympanic membranes and middle ear show the various positions of the drum with their respective anatomic landmarks. *(From Bluestone, C. D., and Klein, J. O.: Otitis Media in Infants and Children. 4th ed. Hamilton, Ontario, B. C. Decker, 2007, p. 153.)*

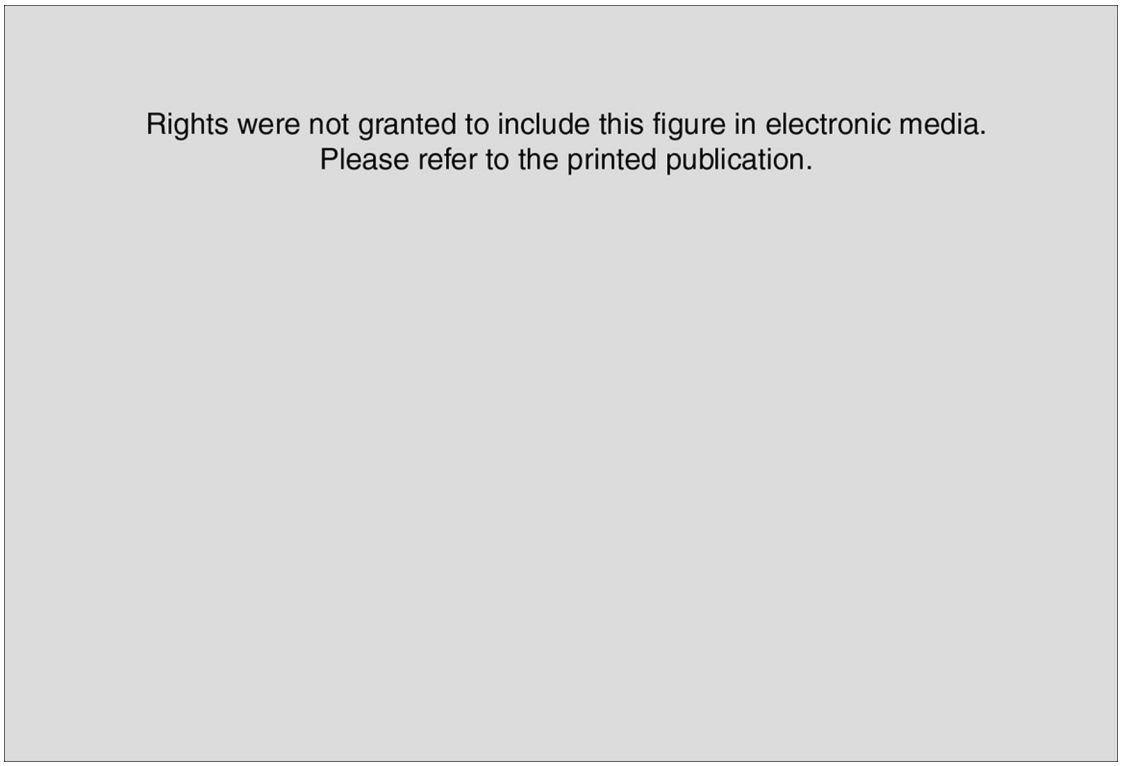

Figure 19–5 Tympanogram types related to presumptive conditions of the middle ear. *(From Bluestone, C. D., and Klein, J. O.: Otitis Media in Infants and Children. 4th ed. Hamilton, Ontario, B. C. Decker, 2007, p. 171.)*

upper respiratory tract are of limited value in providing specific microbiologic diagnosis of otitis media, only materials obtained by aspiration of the middle ear abscess can be considered a true reflection of the etiology of AOM. Myringotomy is an incision in the anterior lower quadrant of the tympanic membrane for therapeutic drainage. Tympanocentesis or myringotomy should be considered in patients who at onset appear toxic or are seriously ill, in patients who are toxic after initiation of antimicrobial therapy, in the presence of suppurative complications (including mastoiditis and meningitis), and in immunologically deficient patients in whom an unusual organism may be present.

RADIOGRAPHY

Radiographic evaluation of the temporal bone is indicated when complications or sequelae of otitis media are suspected or present. Plain radiographs are of limited value in the diagnosis of osteitis of the mastoid or cholesteatoma; computed tomography and magnetic resonance imaging are more precise and should be obtained if a suppurative intratemporal or intracranial complication is suspected.

DIFFERENTIAL DIAGNOSIS

Inflammation or foreign body in the external ear canal may produce ear pain simulating that of AOM. When external otitis or furunculosis of the EAC is present, the patient often has severe itching in the ear canal and pain elicited by manipulation of the pinna. The canal may be narrowed and so tender that performing an otoscopic examination is impossible.

An erythematous tympanic membrane may be caused by an upper respiratory tract infection with congestion of the mucosa lining the entire respiratory tract, including the middle ear. A "red drum" also may be produced by trauma or aggressive examination of the EAC and may appear suddenly in a crying child.

Otalgia may be associated with infections of the tonsils, adenoids, teeth, nasopharynx, hypopharynx, or larynx. Tumors in those regions can refer pain to the ipsilateral ear along the tenth cranial nerve. Lymphomas, leukemias, and rhabdomyosarcomas involving the palate, nasopharynx, or base of the skull eventually occlude one or both eustachian tubes, producing serous effusions and otalgia.

AOM must be differentiated from an acute exacerbation of an unrelated disease in a patient with persistent middle ear effusion. Because fluid persists for weeks to months after each episode of AOM, an intercurrent infection, not associated with middle ear disease, may be misdiagnosed as AOM because of the presence of acute systemic signs of an infectious illness plus a middle ear effusion. This event may be one of the reasons for overdiagnosis of AOM. At present, no technique, other than tympanocentesis, is readily available to distinguish a relapse of AOM from a new and recurrent episode of AOM or from an intercurrent and unrelated infection associated with persistent middle ear effusion.

OTITIS MEDIA WITH EFFUSION

The presence of an asymptomatic middle ear effusion has many synonyms, such as secretory, nonsuppurative, and serous otitis media, but the most acceptable term is *otitis media with effusion*. After every episode of AOM, fluid persists in the middle ear for weeks to months (see Fig. 19–1).[186] In a study of children with AOM in Boston, 70 percent of the patients still had effusion at 2 weeks, 40 percent had effusion at 1 month, 20 percent had effusion at 2 months, and 10 percent had effusion at 3 months. Similar results of persistent middle ear effusion after an episode of AOM have been noted in all other clinical studies of AOM. The incidence or prevalence of otitis media with effusion that is

unrecognized by parents and not brought to medical attention has been studied extensively.[35,56,147] The prevalence of effusion varied with age and the time of year. Incidence of otitis media with effusion peaked during the second year of life and was more prevalent in winter than in summer months.[56,147,182] In some children, the duration of otitis media with effusion may be only 1 or several days.[18] Because hearing loss is present whenever fluid fills the middle ear space, physicians are concerned about the many children with prolonged time spent with effusion; the accompanying hearing loss; and possible adverse effects on speech, language, and cognitive development.

Bacteria can be recovered from one third to one half of specimens obtained at the time of myringotomy or tympanostomy tube insertion.[64,65,124,155,170] The bacteriology in such cases has mimicked closely the bacteriology of AOM, with *S. pneumoniae* and *H. influenzae* being the predominant organisms isolated. The significance of this finding at present is unknown. The bacteria merely may colonize middle ear fluid without producing inflammation, or they may play a role in the production or persistence of middle ear fluid. In addition to live bacteria, nonviable bacteria, pneumococcal capsular polysaccharide, and endotoxin have been found in chronic middle ear effusions.[47,64,107]

Much attention has been given to the nature and composition of the middle ear effusion. The presence of biologic mediators of inflammation in the middle ear fluid has been shown[16,108,177]; they include chemotactic factors, macrophage-inhibiting factors, activated complement, histamine, prostaglandins, leukotrienes,[90,91,125] and immune complexes.[197] Elevated levels of IgA, IgE, IgM, and IgG also have been noted in serous effusions.

Clinical evaluation depends on otologic examination and audiologic and tympanometric testing. Symptoms of this disease include conductive deafness, which usually is fluctuant and may be position-dependent. The patient may have a dull ear ache or a sensation of fullness in the ear. The eardrum usually is dull with a poor light reflex and may be retracted. Color may be pale pink or have a ground-glass appearance.

COMPLICATIONS AND SEQUELAE

Intracranial suppurative complications of otitis media, including meningitis, brain abscess, and lateral sinus thrombosis, are uncommon occurrences today in developed countries (Fig. 19–6). Intratemporal complications that occur within the aural cavity and adjacent structures of the temporal bone are seen more commonly. They include acute and chronic perforation of the tympanic membrane, chronic suppurative otitis media, mastoiditis, cholesteatoma and retraction pocket, adhesive otitis media, tympanosclerosis, and ossicular discontinuity and fixation. The most frequent complication is hearing loss that occurs whenever the middle ear cavity is filled with fluid.

HEARING LOSS

Fluctuating or persisting hearing loss is present in most children who have middle ear effusion; impairment of hearing is the most prevalent complication of otitis media with effusion. Audiograms of children with middle ear effusion usually reveal a mild to moderate conductive loss of 15 to 40 dB.[59] With such deficits, the softer speech sounds and voiceless consonants may be missed. The hearing loss is not influenced by the quality of fluid in the middle ear; ears with thin fluids are impaired to the same degree as are ears with fluids of gluelike consistency.[31,199] The hearing impairment usually is reversed with resolution of the effusion. Uncommonly, permanent conductive hearing loss occurs because of irreversible changes from the inflammatory reaction, resulting in adhesive otitis media or ossicular discontinuity. High negative pressure in the middle ear or atelectasis in the absence of effusion also may cause conductive loss.

Sensorineural hearing loss after a case of AOM may occur as a result of increased tension and stiffness of the round-window membrane and is reversible. A permanent sensorineural loss may occur as a result of spread of infection or products of inflammation through the round-window membrane.[112]

Figure 19–6 Intratemporal complications and sequelae of otitis media include the following: A, Infectious eczematoid dermatitis. B, Cholesteatoma. C, Retraction pocket of tympanic membrane. D, Tympanosclerosis. E, Perforation of tympanic membrane. F, Chronic suppurative otitis media. G, Cholesterol granuloma. H, Ossicular discontinuity. I, Facial paralysis. J, Adhesive otitis media with fixation of the ossicles. K, Hearing loss. L, Petrositis. M, Labyrinthitis. N, Mastoiditis with extension into the neck (Bezold abscess). *(From Bluestone, C. D., and Klein, J. O.: Otitis Media in Infants and Children. 4th ed. Hamilton, Ontario, B. C. Decker, 2007, p. 329.)*

EFFECTS OF OTITIS MEDIA ON DEVELOPMENT OF THE CHILD

Children with severe or recurrent otitis media have prolonged time spent with middle ear effusion. Hearing impairment accompanies the effusion in most children. If the hearing impairment occurs at a time of rapid intellectual growth, the result may be impaired development of speech, language, and cognitive abilities (Fig. 19–7). Because language acquisition is dynamic during infancy, any problems in receiving or interpreting sound signals might have a significant effect on development of speech and language. Softer speech sounds and voiceless consonants, in particular, may be missed or confused when effusion is present in the middle ear.

Although many studies have been done and are reviewed in a clinical practice guideline (*Otitis Media with Effusion in Young Children*) published by the Agency for Health Care Policy and Research of the U.S. Department of Health and Human Services,[182] the limitations of design of many of the studies and inconsistencies of the results limit the ability to make conclusions about the effect of otitis media on development. The interested reader should consult the guideline for a valuable review and extensive bibliography. A study by Paradise and colleagues[140] indicates that early placement of ventilating tubes in children with prolonged time spent with middle ear fluid did not measurably improve developmental outcomes at age 3 years. Nonetheless, some infants and young children with recurrent otitis media and prolonged time spent with middle ear effusion possibly have substantive loss in potential for development of speech, language, and cognitive abilities. Selected references about long-term outcomes of otitis media include studies by Gravel and Wallace,[69] Teele and colleagues,[185] and Friel-Patti and associates[60] and reviews by Berman[13] and Klein.[103]

CHILD BEHAVIOR AND QUALITY-OF-LIFE OUTCOMES

Disturbances in the child's behavior associated with otitis media have been reported to include restlessness, frequent disobedience, impaired task orientation in the classroom, short attention span and distractibility, attention deficits, and restricted social interaction. Only selected children may be most affected. Paradise and colleagues[141] found that stress in the parent-child relationship and behavior problems were highest among children from the most socioeconomically disadvantaged homes.

A working parent who has spent a sleepless night attending to a child who is fretful because of ear pain may have work-related and home-related stress. Chase[39] described the response of parents of 1-year-old children to structured interaction tasks; parents of a child who had one or more episodes of otitis media were less effective in gaining the child's attention, less able to respond effectively when the child was distracted from the task, and less able to help the child understand and perform the task.

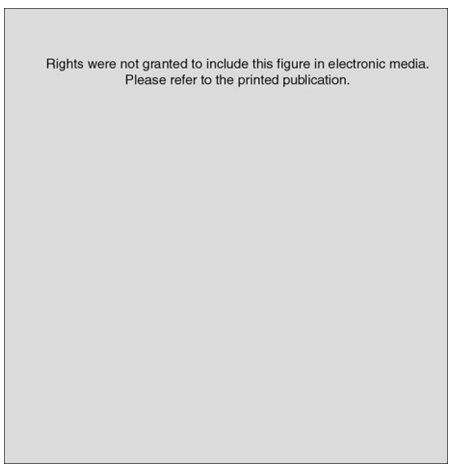

Figure 19–7 Long-term sequelae of middle ear effusion. *(From Bluestone, C. D., and Klein, J. O.: Otitis Media in Infants and Children. 4th ed. Hamilton, Ontario, B. C. Decker, 2007, p. 333.)*

PERFORATION OF THE TYMPANIC MEMBRANE

Acute perforation (not caused by trauma) usually is secondary to AOM but also may occur during the course of otitis media with effusion. The perforation occurs because of pressure of the expanding middle ear contents on the membrane, resulting in local ischemia and tissue damage, usually in the central portion of the membrane. With rupture, the middle ear contents are discharged into the external ear canal, with instant relief of pain and defervescence in acute infection occurring. Because the membrane is highly vascular, the perforation may seal quickly and not be evident within hours to days. If the mucous membrane of the middle ear remains inflamed, fluid may reaccumulate behind the resealed tympanic membrane.

Chronic perforation may occur after an acute episode, spontaneous extrusion, or removal of a tympanostomy tube. If squamous epithelium grows at the edges of the perforation, healing may be prevented, and the perforation persists. The term *chronic suppurative otitis media* is limited to a stage of ear disease in which chronic inflammation of the middle ear and mastoid occurs and in which a nonintact tympanic membrane (caused by perforation or tympanostomy tube) and otorrhea are present. Mastoiditis usually is present, and a cholesteatoma may have formed.

CHOLESTEATOMA

A cholesteatoma usually is a cystic structure lined by squamous epithelium resting on a fibrous strand. The contents of the cyst are the products of desquamation, keratinization, and pus formulation. A cholesteatoma may invade, causing local bone erosion and destruction of the ossicular chain. Aural cholesteatomas can be classified as congenital or acquired.

A congenital cholesteatoma is a congenital rest of epithelial tissue and appears as a white cystlike structure within the middle ear or temporal bone. Acquired cholesteatoma may be secondary to implantation of epithelial tissue or may be a sequela of otitis media or a retraction pocket, or both. Implantation cholesteatoma may develop either from epithelium that has migrated through a perforation of the tympanic membrane or from intraaural epithelium remaining after middle ear or mastoid surgery. Infection caused by such organisms as *S. aureus*, *P. aeruginosa*, *Proteus* spp., nonhemolytic streptococci, and *Aspergillus* spp. may be present. The process of alternating infection and healing causes the advancement of squamous epithelium into the middle ear and antrum.[55,109,160] The persistent infection also stimulates proliferation of the mucoperiosteum of the attic region, creating an accelerated tissue growth (increased production of collagenase) and a destructive and expansive process. It is characterized by a foul smell, pus, squames, and bone destruction.

Management of cholesteatoma is surgical removal of the entire cyst. Antimicrobial therapy may be necessary if secondary infection is present.

ADHESIVE OTITIS MEDIA

Adhesive otitis media is a result of healing after chronic inflammation of the middle ear and mastoid. Fibrous tissue proliferates in the muscosal lining and may impair movement of the ossicles

and result in conductive hearing loss. Adhesive changes may bind the eardrum to the ossicles and surrounding middle ear structures and cause resorption of the ossicles.

TYMPANOSCLEROSIS

Tympanosclerosis, or scarring of the tympanic membrane, may be a sequela of chronic middle ear inflammation or trauma. White plaques are present in the tympanic membrane, with nodular deposits in the submucosal layers. The histopathology is marked by hyaline degeneration resulting from a healing reaction characterized by fibroblastic invasion of the submucosa followed by thickening and fusion of the fibers.

OSSICULAR DISCONTINUITY AND FIXATION

Ossicular chain abnormalities, including osteitis, may be secondary to chronic inflammation in the middle ear or the presence of a retraction pocket or cholesteatoma. The long process of the incus most commonly is involved. Erosion of the blood supply, cholesteatoma, or adhesive otitis media may be the cause of the bone erosion and disarticulation. Conductive hearing loss is present to a varying degree. Diagnosis may be assisted by computed tomography or magnetic resonance imaging.

MASTOIDITIS

Reports from Denmark,[146] Italy,[114] and the United States[95] indicate that mastoiditis continues to be an important complication of AOM in developed countries, although at a low rate. In developing countries, untreated otitis media may lead to persistent perforation of the tympanic membrane, dysarticulation of ossicles, and mastoiditis. Berman[12] estimated that mastoiditis occurred as a complication of otitis media in developing countries in 0.74 percent of cases of otitis, based on community and school surveys, and in 1.7 to 18 percent, based on hospital clinical record reviews. In a survey of eight children's hospitals in the United States between 1993 and 1998 for pneumococcal diseases, Kaplan and colleagues[95] identified 34 children with pneumococcal mastoiditis; serogroup 19 accounted for 57 percent of the isolates. The cases occurred primarily in children younger than 2 years of age.

At birth, the mastoid consists of a single cell, the antrum, connected to the middle ear by a small channel, the aditus ad antrum. Pneumatization of the mastoid bone occurs soon after birth and usually is extensive by the time the child reaches 2 years of age. Likely, whenever AOM occurs, some degree of mastoiditis is present. With healing of the middle ear infection, healing of the mastoid also occurs. In a few cases, mastoid disease progresses with hyperemia and edema of the mucosal lining of the pneumatized cells, accumulation of serous and then purulent exudates in the cells, demineralization of the cellular walls and necrosis of bone, and formation of abscess cavities caused by coalescence of adjacent cells after destruction of the cell walls. Pus may escape into contiguous areas, including the posterior cranial fossa, middle cranial fossa, sigmoid and lateral sinuses, canal of the facial nerve, semicircular canals, and petrous tip of the temporal bone.

Signs of acute mastoiditis with periostitis include fever, otalgia, postauricular erythema, tenderness, and slight swelling. The pinna may be displaced inferiorly and anteriorly.

Initial management of acute mastoiditis includes administration of parenteral antibiotics and myringotomy to provide drainage of the middle ear and mastoid contents. Surgical drainage of the mastoid should be performed if the symptoms of the acute infection, including fever and otalgia, persist. If the infection progresses, causing destruction of the bony trabeculae, a mastoid empyema, mastoidectomy should be performed to prevent spread of the infection to adjacent structures.

PETROSITIS

Petrositis occurs when suppurative infection extends from the middle ear and mastoid into the petrous portion of the temporal bone. Signs of petrositis include pain behind the eye, deep ear pain, persistent ear discharge, and sixth nerve palsy. The triad of pain behind the eye, aural discharge, and sixth nerve palsy is termed *Gradenigo syndrome*. Management is similar to that described earlier for mastoiditis.

LABYRINTHITIS

Spread of AOM into the cochlear and vestibular apparatus through the round (less commonly, the oval) window results in inflammation of the labyrinth. The signs of labyrinthitis include sudden, progressive, or fluctuating sensorineural hearing loss or vertigo in association with otitis media or mastoiditis. Signs of suppurative labyrinthitis (in the absence of meningitis) warrant performing aggressive otologic surgery and administering parenteral antimicrobial therapy.

MENINGITIS

Meningitis may be associated with middle ear infections in three circumstances:

1. *Direct invasion*: A suppurative focus in the middle ear or mastoid spreads through the dura, extends to the pia-arachnoid, and causes generalized meningitis.
2. *Inflammation in an adjacent area*: The meninges may become inflamed if there is suppuration in an adjacent area, such as the mastoid air cells.
3. *Concurrent infection*: Otitis media arises by spread of bacteria from the upper respiratory tract, and meningitis concurrently invades the blood from the upper respiratory focus.

Children with cochlear implants are at risk for development of meningitis. Although the implant has been implicated in the subsequent development of meningitis, some children likely had an underlying congenital inner or middle ear malformation that provided a pathway for the bacterium to enter the brain.[23]

FACIAL PARALYSIS

Facial paralysis may occur as a sequela of AOM because of exposure of the facial nerve in the middle ear cleft caused by a bony dehiscence. The palsy usually is unilateral. The paralysis usually resolves with medical therapy for AOM, but if paralysis of the facial nerve persists, decompression may be necessary.

OTHER SUPPURATIVE COMPLICATIONS

The middle ear and mastoid air cells are adjacent to the dura of the posterior and middle cranial fossa, the sigmoid venous sinus of the brain, and the inner ear (Fig. 19–8). Suppuration in the middle ear or mastoid may spread to these structures, producing suppurative complications, such as meningitis, extradural abscess, subdural empyema, focal encephalitis, brain abscess, and lateral

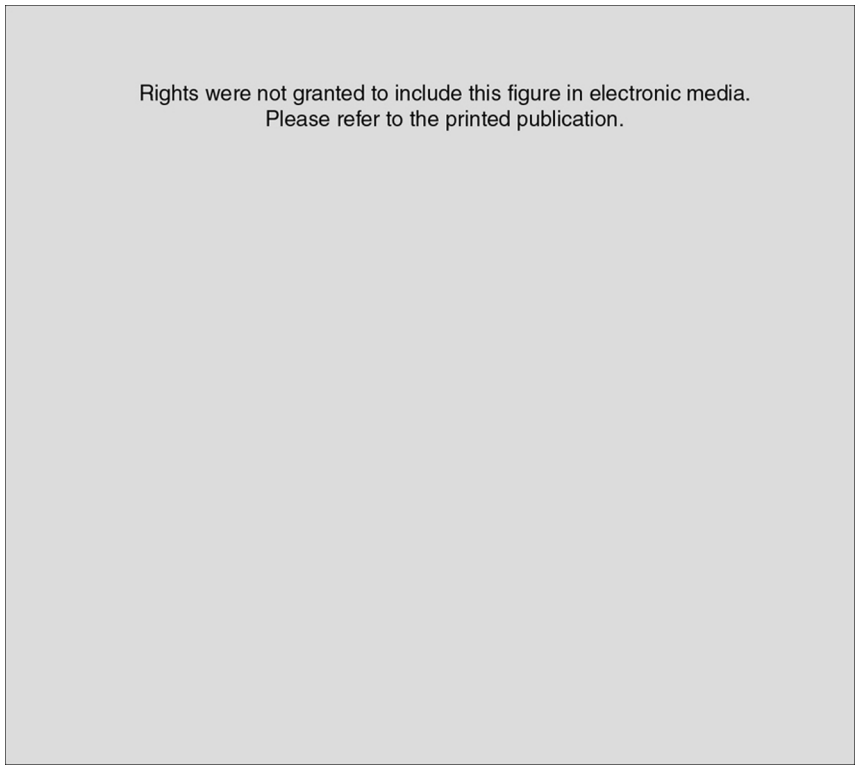

Figure 19–8 Suppurative complications of otitis media and mastoiditis. A, Subperiosteal abscess. B, Extradural abscess. C, Subdural empyema. D, Brain abscess. E, Meningitis. F, Lateral sinus thrombosis. *(From Bluestone, C. D., and Klein, J. O.: Otitis Media in Infants and Children. 4th ed. Hamilton, Ontario, B. C. Decker, 2007, p. 434.)*

sinus thrombosis. Intracranial complications should be suspected when a child with acute or chronic otitis media develops persistent and severe headache, severe otalgia, and change in affect or level of responsiveness. Conversely, children with diagnosed intracranial infection, such as meningitis, should have middle ear or mastoid disease assessed as the origin of the central nervous system disease.

Intracranial extension of infection from the middle ear into the intracranial area may occur because of any of the following:

1. Progressive thrombophlebitis, permitting infection to spread through the intact bone
2. Erosion of the bony walls of the middle ear or mastoid
3. Extension along preformed pathways, such as the round window, dehiscent sutures, skull fractures, and congenital or surgically acquired bony dehiscences.

The microbiology, pathogenesis, diagnosis, and management of intracranial complications of otitis media and mastoiditis are discussed extensively elsewhere (see Chapters 20, 37, 38, and 42).

MANAGEMENT OF ACUTE OTITIS MEDIA

Management of AOM focuses on the choice of an appropriate antimicrobial agent or an option to observe initially rather than treat. Decongestants and antihistamines may provide some comfort for a patient who has congestion of the upper respiratory tract, but they provide no benefit in terms of earlier resolution of the middle ear infection. The antimicrobial agent should have a spectrum of activity that includes *S. pneumoniae* and *H. influenzae* and have documented clinical and microbiologic efficacy, limited side effects, availability in a convenient dosage schedule, palatability when provided in suspension, and reasonable cost. When treated with appropriate antimicrobial therapy, a patient should have substantial resolution of signs and symptoms within 72 hours and absence of signs of relapse, recurrence, or suppurative sequelae.

TABLE 19–4 Daily Dosage Schedule for Antimicrobial Agents Useful in Acute Otitis Media

Agent	24-Hr Dosage
Amoxicillin	40-80 mg/kg in 2-3 doses
Amoxicillin-clavulanate	40-80 mg/kg in 2 doses (90 mg/kg in 2 doses for Augmentin ES-600)
Cefprozil	30 mg/kg in 2 doses
Cefpodoxime	10 mg/kg in 2 doses
Cefaclor	40 mg/kg in 2-3 doses
Cefixime	8 mg/kg in 1 dose
Cefuroxime axetil	30 mg/kg in 2 doses
Loracarbef	30 mg/kg in 2 doses
Ceftriaxone	50 mg/kg in 1 dose* (1-3 days)
Ceftibuten	9 mg/kg in 1 dose
Cefdinir	14 mg/kg in 1-2 doses
Erythromycin-sulfisoxazole	50 mg/kg erythromycin, 150 mg/kg sulfisoxazole in 4 doses
Clarithromycin	15 mg in 2 doses
Azithromycin	30 mg/kg in 1 dose (1 day) 10 mg/kg in 1 dose (3 days) 10 mg/kg in 1 dose (day 1); 5 mg/kg in 1 dose (days 2-5)
Trimethoprim-sulfamethoxazole	8 mg trimethoprim, 40 mg sulfamethoxazole in 2 doses

**Intramuscular route.*

Table 19–4 lists the daily dosage schedules of 15 oral or parenteral antimicrobial agents approved for the indication of therapy of AOM. In addition, ofloxacin otic and ciprofloxacin (combined with dexamethasone) otic have been approved by the

U.S. Food and Drug Administration (FDA) for treatment of AOM in children with tympanostomy tubes in place.

CLINICAL IMPLICATIONS OF ANTIBIOTIC RESISTANCE

Increased resistance of bacterial pathogens to available antimicrobial agents has been a constant concern since the introduction of antimicrobial agents. Multidrug-resistant pneumococci add complexity to the choice of optimal antimicrobial agents for AOM. At present, the incidence of strains of pneumococci that are nonsusceptible to penicillin averages approximately 25 percent in the United States but is more than twice that in southeastern and southwestern states. Reasons for the regional differences are unknown. The major risk factors for presence of multidrug-resistant pneumococci are recent (within 30 days) administration of an antimicrobial agent and attendance in daycare. In addition, the increasing proportion of β-lactamase–producing strains of *H. influenzae* and *M. catarrhalis*, now 30 to 75 percent in the United States, warrants consideration in choice of optimal agents.

DIFFUSION OF ANTIMICROBIAL AGENTS INTO MIDDLE EAR FLUIDS

Most antimicrobial agents of value for treatment of AOM achieve significant concentrations in middle ear fluid. The concentrations are generally parallel to, although lower than, concentrations of drug in serum. Purulent fluids have higher concentrations of drug than do mucoid or serous fluids. Penicillins and cephalosporins achieve concentrations in middle ear fluids that are approximately one fifth to one third the levels present in serum. Sulfonamides and erythromycin achieved middle ear concentrations that were approximately 50 percent of serum concentrations. An extensive review of concentrations achieved in middle ear fluids is provided in the textbook *Pediatric Otolaryngology*, edited by Bluestone, Stool, and Kenna.[26]

STERILIZATION OF MIDDLE EAR FLUIDS BY ANTIMICROBIAL AGENTS

To define the ability of antimicrobial agents to eradicate bacterial pathogens from middle ear fluids of children with AOM, investigators have used serial aspirates of the infected fluids.[46,82,83,119,122] The initial aspirate identifies the bacterial pathogen of the acute middle ear infection; the second aspirate, obtained days after initiation of therapy, defines the ability of the drug to eradicate the infection. The results of these tests generally are consistent with data available from in vitro assays of the drugs against the major bacterial pathogens and the concentrations of drug achieved in the middle ear fluids.[100] Penicillin-susceptible pneumococcal infections were sterilized by most penicillins, cephalosporins, and macrolides; failure rates of 10 percent or more were identified only in infections treated with cefaclor, cefixime, and cefpodoxime; sulfonamides alone were ineffective, but trimethoprim-sulfamethoxazole was effective.

Dagan[46] reviewed sterilization of middle ear fluids by antimicrobial agents for pneumococci that were penicillin-susceptible and penicillin-nonsusceptible. The sterilization of middle ear fluids infected with susceptible strains was consistent with prior data. Nonsusceptible strains were less readily eradicated from the middle ear fluid, and the failure rates were twofold or more than those for penicillin-susceptible strains. The failure rates for penicillin-nonsusceptible versus penicillin-susceptible strains were 20 percent versus 10 percent for amoxicillin, 53 percent versus 0 percent for ceftriaxone administered as one dose, 9 percent versus 0 percent for ceftriaxone administered as three consecutive daily doses, 62 percent versus 10 percent for cefaclor, 92 percent versus 5 percent for azithromycin, and 79 percent versus 0 percent for trimethoprim-sulfamethoxazole.

Sterilization of middle ear fluids infected with *H. influenzae* was influenced by the strain differences—β-lactamase–positive or β-lactamase–negative for β-lactam drugs. Failure rates for amoxicillin were 21 percent when the strain was β-lactamase–negative, but were similar to placebo (60%) when the strain produced β-lactamase. Ceftriaxone eradicated all isolates of *H. influenzae* whether or not they produced β-lactamase. Cefuroxime axetil was more effective (15% failures) compared with cefaclor (40% failures). Failures for azithromycin were comparable to placebo (57% versus 52%). Although similar data based on dual ear aspirates are unavailable for middle ear infections caused by *M. catarrhalis*, the high proportion of β-lactamase–producing strains suggests microbiologic results similar to those of *H. influenzae*.

STERILIZATION OF MIDDLE EAR FLUIDS WITHOUT ANTIBACTERIAL AGENTS

Using the same technique of dual aspirates to identify the microbiologic efficacy of antibacterial drugs, Howie[81] identified sterilization of infected middle ear fluids without drugs. A placebo replaced active therapy in the dual aspirate study: 2 to 7 days after the initial aspirate identified the presence of pneumococci or *H. influenzae*, 19 percent of the pneumococci and 48 percent of the *Haemophilus* strains no longer were present. The differential clearing of the bacteria with persistence of most pneumococci but resolution of one half of the infections caused by nontypeable *H. influenzae* likely is associated with some immune or bacteriostatic factor in the middle ear inflammatory exudate that acts to inhibit growth of these organisms. These data of spontaneous resolution need to be considered in evaluating the efficacy of new and old antibacterial drugs.

INITIAL OBSERVATION RATHER THAN ANTIMICROBIAL AGENT THERAPY

Before the introduction of sulfonamides in 1936, management of AOM included watchful waiting or, when the suppurative process produced severe clinical signs, use of myringotomy to drain the middle ear abscess. Spread of infection to the mastoid, meninges, or other intracranial foci was a feared complication of otitis media. Early therapeutic trials identified the value of using antimicrobial agents for resolution of clinical signs and decreased incidence of suppurative complications. Most children with AOM respond clinically without use of antimicrobial agents. Children who improve without antimicrobial drugs include one third with AOM who have a bacteriologically sterile effusion and are presumed to have a viral infection and children who have bacterial infections that clear without antimicrobial agents (19% of pneumococcal infections, 48% of infections caused by nontypeable strains of *H. influenzae*, and approximately 75% of AOM caused by *M. catarrhalis*).[100] Because of the increased incidence of bacterial pathogens resistant to available antimicrobial agents, and the data associating extensive use of the drugs with development of resistant strains, limiting the use of antimicrobial agents for children with AOM has been suggested. The option of observation and symptomatic treatment rather than initial antibiotic treatment has been advocated in Western Europe based on studies by van Buchem and colleagues.[193,194] In the United States, interest in this management increased with concerns for multidrug resistance resulting from the extensive use of antimicrobial agents, but the recommendations of the CDC and the AAP in 1998 focused on increasing the accuracy of diagnosis, avoiding use of

antimicrobial agents for otitis media with effusion, and continuing use of these drugs for treatment of AOM.[50]

The AAP and the AAFP in 2004 altered their positions and for the first time provided a guideline for an observation option for selected patients.[4] The guideline recommended that observation without use of antimicrobial agents could be considered in a child older than 24 months of age with uncomplicated AOM with nonsevere signs (mild otalgia, temperature <39º C orally in the past 24 hours) when follow-up was ensured, and antibacterial agents could be started if symptoms persisted or worsened. Table 19–5 lists the options considered in the guidelines.

CHOICE OF ANTIMICROBIAL AGENTS

Oral amoxicillin remains the first-line antimicrobial agent for treating AOM because of the expected low failure rates. The drug-resistant *S. pneumoniae* Therapeutic Working Group of the CDC[49] and the 2004 guidelines of the AAP and the AAFP[4] suggested that an increase in dosage used of amoxicillin for empiric treatment from 40 to 45 mg/kg/day to 80 to 90 mg/kg/day would be effective for more nonsusceptible strains of *S. pneumoniae*. The 2004 guidelines for initial treatment and treatment failures are listed in Table 19–6.

The guideline differentiates treatment choice of drug by severity of signs. Children with nonsevere disease may be treated initially with high-dose amoxicillin, but children with severe signs should be treated with amoxicillin-clavulanate. The use of high-dose amoxicillin-clavulanate responds to concern about failure of amoxicillin in cases of AOM caused by β-lactamase–producing *H. influenzae*. If failure occurred because of a high-level resistant strain of *S. pneumoniae*, however, the same dosage of amoxicillin in the combination would not be advantageous. Cefuroxime axetil, cefpodoxime, and cefdinir have equivalent profiles in vitro against *S. pneumoniae* and *H. influenzae*. Because of bitter taste, cefuroxime and cefpodoxime are not well accepted by young patients, and the better taste of cefdinir increased acceptability and compliance. Intramuscular ceftriaxone was most effective in eradicating nonsusceptible pneumococci when provided in three daily doses, but an alternative regimen is to provide a single dose and, if signs do not resolve at 48 hours, to proceed to a second or third dose.[102]

TABLE 19–5 Guidelines for Management of Acute Otitis Media from the American Academy of Pediatrics and American Academy of Family Physicians[4]

Age (mo)	Certain Diagnosis*	Uncertain Diagnosis
<6	Antibiotics	Antibiotics
6-24	Antibiotics	Antibiotics if severe; observe if not severe†
>24	Antibiotics if severe; observe if not severe†	Observe

**Certain diagnosis = middle ear effusion, rapid onset, symptoms of middle ear inflammation.*
†Not severe = mild otalgia; temperature <39ºC orally or <39.5ºC rectally in past 24 hr.

DOSAGE SCHEDULES

Dosage schedules of the antimicrobial agents of value for therapy of AOM have been determined on the basis of studies of the pharmacokinetics and results of clinical trials (see Table 19–4).

DURATION OF THERAPY

Duration of therapy is based on clinical trials and tradition. Most clinical trials and standard pediatric practice include a 10-day course of an antimicrobial agent. The FDA approved a 5-day schedule of once-a-day azithromycin administered orally based on studies comparing the clinical efficacy of 5-day azithromycin with 10-day amoxicillin-clavulanate courses. These data suggest that short courses of therapy may be appropriate for many children with AOM, although some children (likely children with severe and recurrent disease) would require more prolonged schedules.

CLINICAL COURSE AFTER INITIATION OF THERAPY

The clinical course of a child who receives appropriate antimicrobial therapy includes significant resolution of acute signs within 48 to 72 hours. Instructions to the parent should indicate the need to contact the physician if the signs or symptoms worsen at any time or are unimproved at 72 hours. Persistent ear pain or systemic signs, such as fever, signal the need for re-evaluation to examine for other foci of infections, to determine the need for another antimicrobial agent, or to perform tympanocentesis or myringotomy to incise and drain the middle ear abscess and culture the fluid to identify the pathogen. If a new antibiotic is

TABLE 19–6 Recommended Antibacterial Agents for Patients Who Are Being Treated Initially with Antibacterial Agents or Who Have Failed Initial Management with Antibacterial Agents

From American Academy of Pediatrics.[4]

needed, one with β-lactamase stability and activity against penicillin-resistant pneumococci (if such information is available from local surveillance studies) should be chosen.

Follow-up visits should be made to determine that the child has recovered from the acute infection and to diagnose persistent middle ear effusion if it is present. The utility of the traditional 10- to 14-day visit was reassessed by Hathaway and coworkers[75] and Mandel and colleagues[116]; these investigators concluded that the follow-up visit can be extended to 4 to 6 weeks after onset of treatment in children whose parents thought the disease had resolved at 10 to 14 days. For children who still had signs or symptoms of disease (other than persistent middle ear effusion), the 10- to 14-day visit was recommended. Visits at 4 to 6 weeks and repeated at 1-month intervals if effusion is present are valuable in determining the duration of middle ear effusion after the acute episode and identifying children who may be candidates for placement of tympanostomy tubes.

SYMPTOMATIC THERAPY

Administration of antipyretics and analgesics and application of local heat usually are helpful in treating a child with an acute painful and febrile episode. Acetaminophen or ibuprofen is recommended for children with mild to moderate pain. Topical agents such as benzocaine may provide brief benefit in patients older than 5 years of age. Narcotic analgesia with codeine or analogues should be reserved for patients with moderate or severe pain. An oral decongestant, such as pseudoephedrine hydrochloride, may relieve nasal congestion, and antihistamines may help patients with known or suspected nasal allergy. The efficacy of antihistamines and decongestants for resolution of middle ear effusion is unproven.

MANAGEMENT OF ACUTE OTITIS MEDIA IN A CHILD WITH TYMPANOSTOMY TUBES

Children with tympanostomy tubes also experience AOM. Because the tube permits drainage of the middle ear fluid and an abscess does not develop, the major pathology is inflammation of the mucous lining of the middle ear, and the dominant clinical sign is otorrhea. The bacterial pathogens include those responsible for AOM (*S. pneumoniae*, *H. influenzae*, and *M. catarrhalis*) and bacteria that may invade the middle ear from the EAC (*S. aureus* and *P. aeruginosa*). Although amoxicillin or amoxicillin-clavulanate is the usual choice for treatment of AOM in a child with tympanostomy tubes, ofloxacin otic and ciprofloxacin-dexamethasone otic were effective for children who presented with acute otorrhea. The efficacy of the otic suspensions for AOM in children with tympanostomy tubes indicates that high concentrations of drug reach the middle ear mucosa and result in eradication of bacterial pathogens. Additional advantages of otic versus systemic antimicrobial administration include lesser systemic adverse events (e.g., diarrhea) and absence of effect on the upper respiratory flora, and absence of selection of resistant bacteria.[67,157]

MANAGEMENT OF OTITIS MEDIA WITH EFFUSION

The following options have been investigated for management of a child with prolonged middle ear fluid or with otitis media with effusion:

1. Another 10-day course of a broad-spectrum antimicrobial agent that has activity against β-lactamase–producing organisms has been recommended because bacterial pathogens are found in approximately one fourth of patients with otitis media with effusion; a meta-analysis of blinded studies identified resolution of effusion in 14 percent of cases.[182]

2. Myringotomy or myringotomy and tympanostomy tubes drain the middle ear fluid, aerate the middle ear space, and permit the middle ear mucosa to return to normal.[117]

3. Adenoidectomy with or without tonsillectomy for children who have recurrences after an initial placement of tympanostomy tubes is controversial.[63] A Finnish study concluded that adenoidectomy did not reduce the incidence of AOM in otitis-prone children younger than 4 years of age who received tympanostomy tubes.[72]

4. Steroid therapy alone or with an antibiotic has been shown to be effective in some children with otitis media with effusion. Berman[11] recommended a regimen of prednisone, 1 mg/kg/day (given orally in two doses) for 7 days, with an antibiotic for 14 to 21 days. Children without a history of varicella infection who have been exposed to the virus in the month before receiving treatment should not be given prednisone because of the risk for developing disseminated disease. The guidelines published by the Agency for Health Care Policy and Research concluded that the data were insufficient in sample size or duration of observation to recommend use of steroids for otitis media with effusion.[182]

Topical or systemic nasal decongestants, antihistamines, and anti-inflammatory agents,[1,196] alone or in combination, have been found to be of limited or no value in the management of otitis media with effusion.

We favor an initial course of a broad-spectrum antibiotic for children with otitis media with effusion for 3 or more months. If the effusion does not resolve, use of tympanostomy tubes is the most efficient method for managing prolonged middle ear effusion. The use of tympanostomy tubes first was suggested more than 100 years ago by Politzer, but the procedure did not become readily available until it was reintroduced by Armstrong in 1954. Myringotomy and placement of ventilating tubes result in the following immediate benefits to the patient with otitis media with effusion:

- The effusion is drained, and the fluid-filled space is aerated.
- The middle ear secretions, which constantly are being formed by the secretory cells of the mucosa, are drained.
- The chronically diseased mucosa (characterized by hypertrophic secretory cells) returns to normal.
- The hearing impairment caused by the middle ear fluid disappears.
- Concern for effects of hearing loss on development of speech and cognitive abilities is diminished.
- The child who was not responsive or attentive (a condition often unrecognized as hearing impairment by the parent) becomes more social and more involved with siblings, parents, and playmates.

The procedure may be disadvantageous for the following reasons:

- General anesthesia is required.
- The cost is significant.
- Although uncommon, sequelae, such as persistent otorrhea, permanent perforation, scarring of the membrane, and cholesteatoma, may occur.

In addition, developmental outcomes may not be improved after early rather than delayed insertion of tympanostomy tubes.[138]

Current recommendations for pediatric otitis media with effusion include follow-up visits for 1 to 2 months after the acute

episode. When the effusion persists for 3 or more months, the child should receive medical treatment with a course of antibiotics (2 to 3 weeks) or in conjunction with a 7-day regimen of prednisone. If the effusion fails to resolve with medical management, the child should be referred to an otolaryngologist for consideration of placement of tympanostomy tubes with or without adenoidectomy.[117,137]

PREVENTION

ADVISING PARENTS

Parents of children who have severe and recurrent otitis media or risk factors for developing middle ear infections should be advised of measures that may reduce the incidence of infection, such as breast-feeding; enrolling children in small, rather than large, group daycare centers; and reducing exposure to tobacco smoke. In addition, data about the risks for developing recurrent otitis media associated with the prone sleeping position and use of a pacifier, although requiring corroboration, may be added to the discussion with the parent. Physicians also may advise parents that the seasonal incidence of otitis media suggests that their child's condition is expected to improve in late spring and summer and that aggressive measures of management, including chemoprophylaxis and surgery, may be postponed until the course of disease has been determined in the next respiratory season.

PNEUMOCOCCAL VACCINES

A pneumococcal polysaccharide vaccine was introduced in the United States in the 1970s, but it had limited efficacy in infants 2 years of age and younger and only a modest effect in prevention of AOM. In February 2000, the FDA approved a safe and effective seven-valent conjugate pneumococcal vaccine (PCV7) that was immunogenic in infants 2 months of age. By December 2005, more than 80 million doses had been distributed in the United States (Peter Paradiso, personal communication). PCV7 has been effective in decreasing the incidence of invasive disease and, to a lesser extent, the incidence of AOM. The results of two large PCV7 clinical trials have been published: (1) an evaluation of the efficacy of the vaccine for prevention of invasive bacterial disease, pneumonia, and otitis media in approximately 38,000 Northern California infants[19,58] and (2) a clinical and microbiologic study of the efficacy of PCV7 for prevention of AOM in 1662 Finnish infants.[52] A clinical trial of an 11-valent polysaccharide vaccine conjugated with an outer membrane protein of nontypeable *H. influenzae* was found to be effective in infants in the Czech Republic and Slovakia against AOM caused by *S. pneumoniae* and *H. influenzae*.[151] A 13-valent vaccine is currently being studied for safety and immunogenicity. Table 19–7 lists the serotypes included in the various pneumococcal vaccines.

In the Northern California study, the efficacy of PCV7 for prevention of episodes of AOM was based on clinical criteria. The vaccine was 7.8 percent effective in preventing episodes of AOM, antibiotic prescriptions decreased by 5.8 percent, and 24.9 percent fewer surgical procedures (most were placement of ventilating tubes) were performed in children immunized with PCV7 compared with children who received the control vaccine (conjugate polysaccharide meningococcal group C).

The Finnish trial provided microbiologic data based on aspirates of middle ear fluids in children who had AOM. Children who received PCV7 had 6 percent fewer episodes of AOM; culture-confirmed pneumococcal episodes were reduced by 34 percent. Children who received PCV7 experienced a 57 percent reduction in episodes caused by pneumococcal serotypes included in the vaccine and a 51 percent reduction in episodes caused by cross-reactive pneumococcal serotypes. A 33 percent increase in episodes of AOM caused by nonvaccine pneumococcal serotypes and an 11 percent increase in episodes caused by *H. influenzae* occurred (Table 19–8).

An 11-valent pneumococcal polysaccharide vaccine conjugated with an outer membrane protein of nontypeable *H. influenzae* was found to be effective against AOM caused by *S. pneumoniae* and *H. influenzae* (GlaxoSmithKline Biologics), but it has not been approved (as of May 2008) for immunization of infants in the United States or elsewhere.[151] The vaccine prevented 52 percent of episodes of AOM caused by pneumococcal vaccine serotypes and 35.3 percent of episodes caused by nontypeable *H. influenzae*.

Adapted from data published in Eskola, J., Kilpi, T., Palmu, A., et al.: Efficacy of a pneumococcal conjugate vaccine against acute otitis media. N. Engl. J. Med. 344:403-409, 2001.

The 23-type polysaccharide vaccine currently available produces an independent antibody response in children 2 years of age or older and in adults. Studies of polysaccharide vaccines in Finland and the United States have indicated that the vaccines were effective in preventing type-specific pneumococcal otitis media if an adequate immune response occurred, but the number of types producing an adequate response in children younger than 2 years was limited.[115,179,184] Administration of the polysaccharide vaccine in older children may provide protection against types not included in PCV7 and has been recommended by the AAP and the Advisory Committee on Immunization Practices of the Surgeon General for high-risk children ages 2 years and older who have received PCV7. For children 2 years old and older who continue to have severe and recurrent AOM, use of the polysaccharide vaccine after administration of PCV7 may be valuable for protection against additional pneumococcal serotypes.

INFLUENZA VIRUS VACCINES

Influenza virus vaccine resulted in a reduction in cases of influenza A and a 36 percent decline in otitis media in children attending a daycare center.[42] A similar reduction (30%) in episodes of febrile otitis media also was reported in children after administration of a live, attenuated cold-adapted intranasal vaccine.[10] Annual administration of influenza virus vaccines should be part of the strategy for reducing the incidence of AOM for children with recurrent and severe disease.

CHEMOPROPHYLAXIS

Use of chemoprophylaxis has succeeded in reducing the number of new symptomatic episodes of AOM in children who have a history of recurrent infections. Children at risk for developing severe and recurrent disease should be considered for chemoprophylaxis despite the concern for development of resistant strains of bacterial pathogens after use of the regimen of a modified dosage of an antimicrobial agent. Results of controlled clinical trials of modified courses of antimicrobial agents compared with trials in which placebo or historical controls were used have been reviewed.[101] Most of these studies used a sulfonamide or a broad-spectrum penicillin. Most reports indicated benefit to the enrollees in reduction of new episodes when they were compared with controls: Amoxicillin efficacy was 44 to 67 percent, and sulfonamide efficacy was 40 to 88 percent (although the efficacy of sulfonamides was reported as only 8% in one study).

We recommend the following protocol based on the results of these studies. Criteria for enrollment should include three documented episodes of AOM in 6 months or four episodes in 12 months. Because children who have episodes of acute infection early in life or have siblings with severe and recurrent ear infections are prone to develop otitis media, prophylaxis also should be considered for children who have one episode in the first 6 months of life plus a family history of ear infections or who have two episodes in the first year of life.

A sulfonamide or amoxicillin is the agent used most often and provides the advantages of demonstrated efficacy, safety, and low cost. The drug is administered at half the therapeutic dose (administered once a day). Amoxicillin is given at a dose of 40 mg/kg, and sulfisoxazole is given at a dose of 50 mg/kg. Chemoprophylaxis should be provided during the fall, winter, and early spring months (when respiratory tract infections are most frequent) for 6 months.

Children, when free of signs of acute infection, should be examined at approximately 2-month intervals to determine whether middle ear effusion is present. Management of prolonged middle ear effusion should be considered separately from prevention of recurrences of acute infection.

Acute infections are expected to occur, although at a lower rate, during the course of prophylaxis. The infection should be treated with an alternative regimen. Amoxicillin-clavulanate or intramuscular ceftriaxone would be a suitable alternative, regardless of the prophylactic agent used.

SURGICAL OPTIONS

When nonsurgical methods of prevention fail to prevent recurrent otitis media, surgery is a reasonable option. Among the options that have been shown to be effective is insertion of tympanostomy tubes, with or without adenoidectomy. Casselbrant and colleagues[36] randomly assigned children into treatment groups receiving amoxicillin, tympanostomy tube placement, or placebo and found that amoxicillin and insertion of the tympanostomy tube were effective. With the current concern about the association of low-dose, long-term antimicrobial prophylaxis and emergence of resistant otitis pathogens,[49] myringotomy and placement of tympanostomy tubes may be more desirable than antimicrobial prophylaxis. When tympanostomy tubes extrude and the child continues to have recurrent episodes of otitis media, replacement of the tympanostomy tubes in conjunction with adenoidectomy has been shown to be effective.[137] As shown by Paradise and coworkers,[135] neither adenoidectomy nor adenotonsillectomy is effective in children not treated previously with tympanostomy tubes, when prevention of otitis media is the only indication.

CHAPTER 20

Mastoiditis

Karen Lewis ✪ Nina L. Shapiro ✪ James D. Cherry

Mastoiditis, a suppurative infection of the mastoid air cells, is a potential complication of all cases of otitis media caused by the continuity of the mucoperiosteal lining of the mastoid with that of the middle ear.[20] The spectrum of disease in mastoiditis ranges from asymptomatic cases with apparent spontaneous resolution to progressive disease with life-threatening complications.[7] Since the advent of antibiotic therapy, mastoiditis is seen much less frequently, but the complications remain similar.[17,19,21,81] With mastoiditis occurring less commonly, physicians are less apt to consider the diagnosis, especially when the clinical picture has been masked by antibiotic therapy or when the process is chronic and of low grade. Appropriate antibiotic therapy, often accompanied by surgical drainage, can halt and prevent serious complications if mastoiditis is diagnosed early.

HISTORY

Before the advent of antibiotics, mastoiditis was a frequent complication of otitis media that could be treated only by expectant waiting or surgery.[32,36] When surgery was used, many patients with mastoiditis were cured by simple mastoid drainage alone, with a mortality rate quoted at 2 percent.[36] Intracranial complications of mastoiditis carried a very grave prognosis, however. In the pre-antibiotic era, between 1928 and 1933, 25 of every 1000 deaths at Los Angeles County Hospital in California were caused by intracranial complications of otitis media, such as meningitis, venous sinus thrombosis, and brain abscess. In contrast, between 1949 and 1954, only 2.5 per 1000 deaths at the same hospital were caused by complications of otitis or mastoiditis. The use of antibiotics in treating mastoiditis initially led to a marked decrease in the surgical approach to treatment of this illness.[7,81] The realization that infection can persist and that complications of mastoiditis can occur even while the patient is receiving antibiotic therapy has resulted in the present-day approach of combined antibiotics and surgery.*

BACTERIOLOGY

The bacteriology of acute mastoiditis differs from that of acute otitis media (AOM) (Table 20–1). For decades, the predominate bacterial cause of AOM was *Streptococcus pneumoniae*, with *Haemophilus influenzae* being the second most common isolate. Since the introduction of pneumococcal conjugate vaccine, nontypeable *H. influenzae* is the most frequent pathogen isolated (57%) in AOM, with *S. pneumoniae* being the second most common (31%), *Moraxella catarrhalis* the third most common (7-10%), and group A beta-hemolytic streptococcus the fourth most common (3-10%).[59] Studies on acute mastoiditis (defined as symptoms of <1 month's duration) show that *S. pneumoniae* is the most common isolate, with *Streptococcus pyogenes* and *Staphylococcus aureus* as the second and third most common isolates, respectively.[17,19,25,28,49,54,80]

H. influenzae has been isolated from the middle ear of patients with mastoiditis, but less often than one would expect, given its frequent recovery in AOM without mastoiditis. Gram-negative bacteria, enterococci, anaerobes, and *Mycobacterium tuberculosis* also have been isolated occasionally in patients with acute mastoiditis. An increased incidence of penicillin-resistant *S. pneumoniae* infections has occurred, leading to a higher likelihood of mastoiditis being a complication of otitis media.[53,80] The percentage of pneumococcal mastoiditis caused by penicillin-resistant strains increased from 25 to 44 percent between 1994 and 1998, without an increase in the total number of cases of pneumococcal mastoiditis.[30] Although *M. catarrhalis* is a common cause of otitis media, it rarely is noted in association with mastoiditis.[35]

The bacteriologic spectrum of chronic mastoiditis differs from that of acute mastoiditis. Aerobic cultures of chronic mastoiditis and chronic otitis media show predominantly *S. aureus* and gram-negative bacilli, especially *Pseudomonas aeruginosa*.[4,13,61] In addition, a wide variety of anaerobic organisms can be isolated from an infected mastoid and middle ear.[4,13] Brook[4] studied the aerobic and anaerobic bacteriology of chronic otitis media (of ≥3 months' duration) in 24 children. Anaerobic isolates alone were found in 17 percent, aerobic organisms alone were found in 4 percent, and mixed aerobic and anaerobic infections were found in 79 percent. All cases had from two to seven different bacterial isolates. *Peptococcus* spp., *Actinomyces* spp., and *Bacteroides melaninogenicus* (*Prevotella melaninogenica*) were the most commonly isolated anaerobic organisms. Seventeen patients were infected with β-lactamase–producing organisms (i.e., *S. aureus* or *P. melaninogenica*, *Bacteroides fragilis*, or other *Bacteroides* spp. that were resistant to ampicillin).

M. tuberculosis currently is an uncommon cause of mastoiditis in the United States but continues to be a cause of chronically draining ears in lower socioeconomic groups and immigrants from endemic areas.[5,45,47] Case reports of mastoiditis implicate such organisms as nontuberculous mycobacteria,[52] *Aspergillus fumigatus*,[23] *Paragonimus*-like trematodes,[55] *Nocardia asteroides*,[43] *Actinomyces* spp.,[67] *Blastomyces dermatitidis*,[30] and *Histoplasma capsulatum*.[43] *Pneumocystis carinii* otitis media and mastoiditis have occurred as the first manifestation of acquired immunodeficiency syndrome.[18]

ANATOMY AND PATHOPHYSIOLOGY

The mastoid process comprises the posterior part of the temporal bone and, as such, is adjacent to many important structures. Within the mastoid is an interconnecting system of air cells divided by bony septa that drain superiorly into the middle ear via a narrow aditus.[7,20] Only the superior portion of the mastoid airspace, the antrum, is present at birth; pneumatization of the mastoid starts soon after birth and usually is completed by the time the child is 2 years of age.[2,36] Structures lying anteromedial to the mastoid process include the middle ear and ossicles, the facial nerve, the posterior bony wall of the external auditory canal, the jugular vein, and the internal carotid artery. Posteromedially, the mastoid borders the posterior cranial fossa and the sigmoid sinus. Superiorly, the mastoid borders the middle cranial fossa. Medially, the mastoid cortex encases the cochlea and semicircular canals. The soft tissues and muscles of the lateral neck are located inferiorly. Any or all of these adjacent structures can be affected by extension of a suppurative process in the mastoid.

A certain amount of mastoid inflammation accompanies all cases of otitis media because the mastoid airspaces are continuous with the middle ear cavity and both are lined by a continuous mucoperiosteum.[2,20] The first stage of an ear and mastoid

infection is associated with hyperemia of the middle ear and the mastoid air cell mucosa. If the infection persists, an exudative stage develops, with serum, fibrin, polymorphonuclear cells, and red blood cells accumulating in the middle ear and mastoid. The accumulation of purulent exudate increases the middle ear pressure, eventually resulting in perforation of the tympanic membrane, followed by drainage of mucopurulent matter from the middle ear and mastoid air cells. Some children also have such marked mucoperiosteal swelling that the drainage of pus from the mastoid is blocked. The pus under pressure creates an environment of local acidosis, hypoxia, and ischemia, causing decalcification and resorption of the bony septa. The term *coalescent mastoiditis* is applied to this process because, with the destruction of the bony septa, the mastoid air cells coalesce into large cavities. Osteomyelitis of the adjacent bone may develop, with subsequent bony erosion and eventual extension of the infection into surrounding structures.[2,20]

Congenital cholesteatomas usually manifest as a "squamous pearl" in the anterosuperior quadrant of the middle ear, abutting the tympanic membrane. They may be associated with recurrent otitis media.[42] Acquired cholesteatomas often are a result of chronic infections and tympanic membrane perforation. The perforation allows for squamous material from the external auditory canal to enter the middle ear space.[57] This tissue contains osteolytic enzymes, leading to bony erosion or mastoid air cell obstruction.[50] Cholesteatomas also may cause slow, insidious erosion of underlying bone, predisposing the patient to extramastoid spread of infection months or years later.[20,61]

CLINICAL PRESENTATION

The classic presentation of acute mastoiditis is a febrile child with ear pain, postauricular swelling, and postauricular tenderness developing days to weeks after the beginning of development of AOM (Fig. 20–1).[17,19,49,54,80] If antibiotics were used to treat AOM, the child may have seemed to improve, only to become ill again while still receiving therapy or after the antibiotics were stopped;

conversely, the child may not have responded to the antibiotics at all. Examination of the tympanic membrane in acute mastoiditis usually shows that it is abnormal.[19,25,49] Early in the course of illness, periosteal inflammation produces swelling and tenderness and sometimes redness over the mastoid process.[2,19] Palpable postauricular fluctuance occurs later, when pus from the mastoid air cells breaks through the underlying bony cortex and forms a subperiosteal abscess.[24] In children older than 1 year of age, the most common area where fluctuance is felt lies behind the ear, where it pushes the earlobe up and out; however, in children younger than 1 year, the fluctuance often may occur above the ear, pushing the pinna down and out.[19]

Chronic mastoiditis is a much more indolent disease process than is acute mastoiditis. It develops when long-standing middle ear disease, usually having a duration of months to years, has been present.[61] Fever and postauricular swelling may or may not be present. Persistent or intermittent drainage of mucopurulent matter from a previously perforated eardrum suggests chronic mastoiditis. Hearing loss and ear pain also may accompany chronic mastoiditis.[61] All these symptoms can be mild enough to be ignored until serious intracranial suppuration occurs. Persistent ear drainage, persistent ear pain, or an otitis media nonresponsive to antibiotics should prompt a search for mastoiditis.

COMPLICATIONS

Complications of mastoiditis include subperiosteal abscess,[24] Bezold abscess,[15,63] facial nerve paralysis,[71] meningitis,[7,19] brain abscess,[7,19] cerebellar abscess,[2] epidural abscess,[2] subdural empyema,[3] labyrinthitis,[20] venous sinus thrombophlebitis,[12,33,56,73] bacteremia,[7,44] benign intracranial hypertension,[3] osteomyelitis of the temporal bone with occasional extension to adjacent bones,[2,20] hearing loss,[58] septic pulmonary emboli,[29] and cerebrospinal fluid otorrhea.[20] Subperiosteal abscesses appear as a postauricular fluctuant mass that obscures the postauricular sulcus. They occur when pus in the mastoid breaks through the bony cortex or extends along vascular channels and dissects under the overlying periosteum.[24]

A Bezold abscess develops when a mastoid infection erodes through the bony cortex of the inferior aspect of the mastoid tip and dissects down the tissue planes to form a deep neck abscess. Fluctuance over the mastoid is not felt. Rather, swelling and tenderness are present below the mastoid process and under the sternocleidomastoid muscle.[15]

The facial nerve runs close to the mastoid and the middle ear, rendering it vulnerable to injury when extension of mastoid or middle ear infection occurs.[20] Pressure on and inflammation of the facial nerve from symptomatic or asymptomatic mastoiditis can lead to transient or permanent facial nerve paralysis that usually is unilateral, although bilateral facial palsy from mastoiditis can occur.[2,71]

Because the temporal bone that houses the mastoid air cells constitutes the floor of the middle and posterior cranial fossae, bony erosion from osteomyelitis, preexisting bony defects, or spread of infection along vascular channels can allow for intracranial spread of mastoid infections into the middle and posterior cranial fossae. The infection may remain confined to the extradural space as an extradural abscess, or it may penetrate the dura and produce a subdural empyema, a brain abscess, a cerebellar abscess, or meningitis.[2,20]

Invasion of infection into the bony labyrinth through the oval or round window triggers a labyrinthitis. Initial tinnitus, hearing loss, nausea, and dizziness progress to severe vertigo, ear pain, vomiting, nystagmus, and difficulties with balance.[20]

Intracranial venous sinus thrombophlebitis is a rare but potentially fatal complication of mastoiditis.[2,20,33,56,69,73] The lateral aspect of the sigmoid sinus is formed by the temporal bone. Venous sinus thrombophlebitis results when an underlying mastoiditis extends through the temporal bone in close proximity to the lateral or sigmoid venous sinus. A perisinus abscess initially is formed, followed by formation of a mural thrombus in the sinus wall. The thrombus eventually may occlude the entire sinus, or it may suppurate and spread along the sinus, resulting in septicemia, increased intracranial pressure, septic emboli, and extension of infection to other intracranial structures.[12,16] The classic findings of a septic thrombosis of the lateral sinus are spiking fevers, shaking chills, and tenderness along the jugular vein associated with acute or chronic otitis. A palpable "cord" at the jugular vein (indicating a jugular vein thrombus) also may be present. When only a perisinus abscess is present, or if the patient is being treated partially with antibiotics, the only symptoms may be a low-grade fever and headache.[22,69]

Benign intracranial hypertension can be seen in association with lateral sinus obstruction secondary to mastoiditis and is termed *otitic hydrocephalus.* Rarely, otitic hydrocephalus can be seen with mastoiditis in the absence of lateral sinus thrombosis. The decreased venous drainage caused by the venous sinus obstruction results in increased intracranial pressure, headache, papilledema, and sixth nerve palsy without enlarged ventricles or a space-occupying lesion.[20,22]

Permanent conductive hearing loss occurs when the middle ear mastoid infection is severe enough to damage or destroy the ossicles. Tuberculous mastoiditis classically manifests with marked conductive hearing loss that often is irreversible.[40]

Osteomyelitis secondary to mastoiditis can spread to adjacent bones. Involvement of the petrous portion of the temporal bone produces a syndrome, described by Gradenigo in 1907, with a triad of abducens paralysis or paresis, severe pain in the distribution of the trigeminal nerve, and suppurative otitis media; additional cranial nerve deficits also may occur.[6,39] Antibiotics may mask the classic signs of petrositis and allow progression to severe intracranial complications, such as meningitis and epidural abscess. Petrositis may be suspected only when antibiotic and surgical management for mastoiditis fails to control chronic ear drainage.[20]

M. tuberculosis mastoiditis is an uncommon finding but should be considered in children who have chronic ear discharge despite having received antibiotic therapy.[40,45] Children can go for months or years with chronic draining ears before the diagnosis of tuberculous mastoiditis is considered.[5,47] Children from lower socioeconomic homes, immigrants from endemic areas, and children with tuberculosis contacts in the family are at risk. The classic presentation in the pre-antibiotic era was an afebrile young child with painless persistent watery ear drainage, an enlarged preauricular lymph node, a history of tuberculosis contact, and often facial nerve paralysis.[64,72]

Tuberculous mastoiditis not always is painless.[76] Sometimes, the diagnosis initially is suspected only when a mastoidectomy wound does not heal.[38,61] Early in the course of the disease, physical examination may reveal small yellow spots (caseating granulomas) on a thickened and hyperemic tympanic membrane. These spots coalesce early and produce tympanic membrane perforations.[38] The discharge through these perforations initially is watery, but later it becomes purulent.[37] Pale, avascular granulation tissue is abundant throughout the middle ear and mastoid and often is seen in the external auditory canal and around the tympanic membrane perforation.[5,64,76] Preauricular and postauricular nontender, enlarged lymph nodes may be present,[37,43] and early and severe hearing loss is characteristic.[76] Often, there is evidence of tuberculosis elsewhere in the body.[76] A 5–tuberculin unit purified protein derivative skin test usually, but not always, is positive.[47]

DIFFERENTIAL DIAGNOSIS

Postauricular swelling, a chronically draining ear, or radiographic evidence of mastoid abnormalities also can appear in other disease entities. Postauricular lymphadenopathy can occur secondary to a scalp infection, causing postauricular swelling. The swelling would be discrete, would not displace the pinna, and would not obliterate the postauricular sulcus.[19] Severe otitis externa may lead to periauricular cellulitis, with postauricular swelling, erythema, and tenderness.[27] Mumps can cause parotid swelling, pushing the earlobe up and out, but the swelling is over the parotid gland, rather than located postauricularly. Histiocytosis,[41] acute lymphocytic leukemia,[48] acute myelogenous leukemia,[70] Burkitt lymphoma,[74] aneurysmal bone cysts,[10] and other benign and malignant tumors of the mastoid bone[8] also can manifest with symptoms clinically suggestive of mastoiditis. Kawasaki disease may mimic acute mastoiditis with postauricular lymph node swelling and ear pain.[62] Children with severe and recurrent ear infections may have an underlying congenital or acquired immunodeficiency.

SPECIFIC DIAGNOSIS

The diagnosis of mastoiditis can be made on clinical grounds alone when a child has an acute episode of fever, otitis media, and posterior auricular tenderness and fluctuance. Temporal bone computed tomography (CT) always is recommended to confirm the diagnosis. Mastoiditis is much less likely when swelling and tenderness over the mastoid process are absent, such as when an infection has been masked by antibiotic treatment or when it has extended to an area other than over the mastoid process. Mastoiditis needs to be considered in all cases of otitis media not responding to antibiotics and in all intracranial suppurative diseases that do not have an apparent focus.

Obtaining an aspirate from the middle ear is an important part of properly diagnosing and managing mastoiditis. Gram stains of aspirates from the middle ear are quite accurate and, as such, can help in the initial selection of antibiotic therapy for chronic mastoiditis. Brook[4] found that in 24 children with tympanocentesis, half of the Gram stains showed a complete correlation with subsequent culture results and the other half showed a partial correlation (one bacterial species was not seen). Leukocytes were seen on all the Gram stains. In addition, cultures from the middle ear accurately reflect mastoid disease.[19,44]

Ginsburg and associates[19] compared the results of cultures of middle ear aspirates and mastoid cultures in 16 patients with acute mastoiditis and found that the same bacterial species was isolated from both sites. A sterile aspiration through an intact tympanic membrane gives the most accurate culture information. If the tympanic membrane is perforated, the purulent drainage may be contaminated by colonizing ear canal flora. An aspirate for culture generally should be obtained from the ear drainage, preferably from as close to the perforation as possible. Aspiration of postauricular fluctuance also is useful in identifying the responsible organisms.[24,54] In addition, specimens should be obtained directly from the mastoid at surgery. All of them should be sent for aerobic and anaerobic cultures with proper anaerobic transport technique. If the child has had a chronic ear infection, or if the child is in a high-risk population for acquiring tuberculosis, mycobacterial stains and cultures also should be obtained and a purified protein derivative should be placed.

A lumbar puncture should be performed if the clinical presentation suggests meningeal irritation. A CT scan should be obtained before performing the lumbar puncture if papilledema or a suggestion of focal intracranial extension is present. Lymphocytosis of the cerebrospinal fluid suggests a parameningeal focus of infection. An immunologic evaluation should be considered if a child has had recurrent episodes of otitis media leading to mastoiditis.

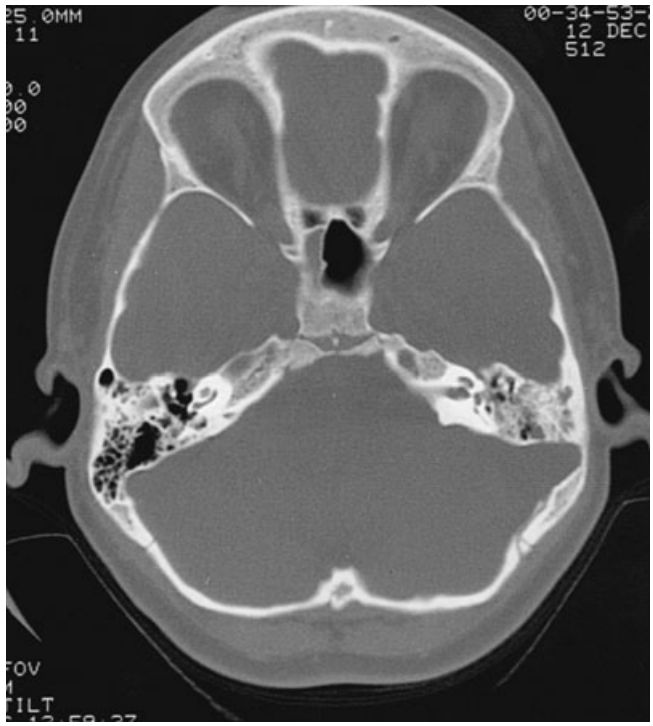

Figure 20–2 Computed tomography scan of the head of a 12-year-old boy with left lateral sinus thrombosis and increased intracranial pressure complicating left mastoiditis. The left mastoid air cells are opacified with marked loss of the fine bony septa, in contrast to the right mastoid air cells.

Peripheral white blood cell counts in mastoiditis may be normal or elevated, often with an increase in band-form neutrophils.[25,49] The erythrocyte sedimentation rate often is elevated in acute mastoiditis, but it usually is normal in chronic mastoiditis.[58]

Mastoiditis often can be diagnosed on clinical findings alone. When a patient is not improving on medical therapy, radiologic imaging of the temporal bone is needed. Changes in the temporal bone are seen best by CT scan.[66] Early in the course of mastoiditis, nonspecific clouding of the middle ear and mastoid is seen. With time, necrosis and coalescence of the bony septa occur. Other CT findings in mastoiditis include hypoaeration of the mastoid and adjacent bony destruction. Figure 20–2 shows a CT scan of a child with unilateral mastoiditis complicated by lateral sinus thrombosis and elevated intracranial pressure. Magnetic resonance imaging is valuable to search for suppurative intracranial complications of mastoiditis.[65,66] In addition, sometimes magnetic resonance angiography or venography (or both) is indicated to diagnose sigmoid sinus thrombosis.[8]

TREATMENT

The pediatrician and the otolaryngologist should work together in the management of a child with suspected or proven mastoiditis because all children with mastoid infections are potential surgical candidates. Some kind of drainage for the middle ear should be provided early in the course of therapy for therapeutic and diagnostic purposes. The drainage could consist of tympa-

nocentesis with subsequent tympanostomy tubes or a myringotomy.[19,25,49,54,80] A specific etiologic diagnosis is more important today than in the past because of the increasing incidence of infections caused by penicillin-resistant pneumococci and methicillin-resistant, coagulase-positive staphylococci.[1,14,26,31,51,60,75]

If the patient has an acute onset of posterior auricular swelling and tenderness with minimal or no posterior auricular fluctuance and no signs of intracranial complications, he or she is likely to respond to antibiotic therapy alone.[25,49,54,79]

Indications for surgical intervention include postauricular fluctuance; a history of chronic ear drainage with postauricular swelling or bony changes on radiographs; facial nerve palsy; nausea, vomiting, and vertigo suggestive of labyrinthitis; meningitis; brain abscess; venous sinus thrombosis with or without intracranial hypertension; epidural or subdural empyema; and petrositis. In addition, if the patient initially is treated medically, a mastoidectomy is indicated if progression of postauricular swelling or fluctuance or persistence of fever, ear pain, or purulent ear drainage occurs while the child is receiving parenteral antibiotics.[17,20,25,49,54,68]

All surgical treatment should include culture of the middle ear or mastoid, either by tympanocentesis or during surgery. If a notable middle ear effusion is present, drainage of the middle ear and equalization of pressure should be done by placement of a tympanostomy tube or a wide circumferential myringotomy.

If postauricular subperiosteal abscess or a Bezold abscess is present, incision and drainage need to be performed. Incision and drainage should be combined with myringotomy and tube placement. In addition, consideration should be given to performing a simple mastoidectomy to remove any diseased mastoid cells or inflammatory mucosa. When a mastoidectomy is done, a biopsy specimen of the inflammatory tissue should be sent to the laboratory for examination to exclude lesions such as eosinophilic granuloma or rhabdomyosarcoma.

For intracranial complications (e.g., subdural or cerebral abscess), a mastoidectomy needs to be performed. Draining the mastoid at the same time as draining the intracranial abscess has been done safely in the same operative setting.[34]

If a patient is found to have a cholesteatoma, a modified radical mastoidectomy, with complete removal of the cholesteatoma, should be performed. A child with a cholesteatoma is likely to need a second-look operation at a later date to monitor for recurrent disease.

Ototopical drops should be included in the postoperative care. Ciprofloxacin ear drops seem to be less toxic than aminoglycoside drops.[11,77,78] All children with mastoiditis should have audiograms performed to help distinguish a purely conductive loss (indicative of middle ear involvement) from a sensorineural loss (a sign of inner ear involvement).

The initial choice of antibiotics for mastoiditis must be made empirically, based on the knowledge of the most likely organisms. Because acute mastoiditis most often is caused by *S. pneumoniae* or *S. pyogenes* and less often by *S. aureus* and *H. influenzae*, oxacillin (150 mg/kg/day divided every 6 hours) and cefotaxime (200 mg/kg/day divided every 6 hours) can be recommended. In cases of severe illness or when possible central nervous system involvement is present, initial administration of vancomycin (60 mg/kg/day intravenously every 6 hours) instead of oxacillin often is desirable because of the possibility that resistant pneumococci or staphylococci are present.

In cases of chronic mastoiditis in which symptoms have been present for longer than 1 month, *S. aureus*, gram-negative bacilli (especially *P. aeruginosa*), and anaerobes are seen more frequently. A broad-spectrum combination of intravenous antibiotics is recommended: an aminoglycoside, such as gentamicin (7.5 mg/kg/day divided every 8 hours), for gram-negative bacillary coverage and a semisynthetic penicillin, such as ticarcillin-clavulanate or piperacillin-tazobactam (200 to 300 mg/kg/day divided every 6 hours). These semisynthetic penicillins are synergistic with gentamicin against *P. aeruginosa*, and they are effective against anaerobes and methicillin-sensitive *S. aureus*. The antibiotics can be adjusted based on the identification and sensitivities of the organisms isolated from the pretherapy cultures. For an intracranial extension of infection caused by *P. aeruginosa*, better penetration of cerebrospinal fluid can be obtained with an antipseudomonal cephalosporin such as cefepime (150 mg/kg/day divided every 8 hours) rather than ticarcillin-clavulanate or piperacillin-tazobactam.

The approach to antibiotic therapy for acute and chronic bacterial mastoiditis should conform to the principles of therapy for osteomyelitis. Treatment is begun with intravenous antibiotics. Intracranial extension of infection or mastoiditis with an organism for which no effective oral antibiotic (e.g., *P. aeruginosa*) exists requires long-term intravenous antibiotic therapy. Otherwise, after the patient has responded well clinically, high-dose oral antibiotic therapy can be considered (e.g., two or three times the normal dose of an oral cephalosporin).[46] Total duration of therapy should be for a minimum of 3 weeks and possibly longer, depending on the severity of illness, the causative organism, and the clinical response. Optimally, the causative organisms and their sensitivities should be known, and an oral agent to which the organisms are sensitive is needed. An oral regimen should not be attempted if vomiting or diarrhea is present because either one would prevent adequate oral absorption. Following the sedimentation rate may be helpful in monitoring treatment. The oral antibiotic should be given strictly every 6 hours rather than four times a day to ensure around-the-clock therapeutic drug levels.

No study has examined the optimal antituberculous chemotherapy for mastoiditis. If *M. tuberculosis* mastoiditis is probable or diagnosed, antituberculous chemotherapy should be started as recommended for tuberculosis of the bone (see Chapter 107).

If fever, purulent ear drainage, or ear pain persists despite antibiotic therapy and surgery, further evaluation is needed to search for either resistant organisms or a persistent site of infection that requires additional surgical drainage. In addition, a slow response to therapy should raise the possibility of an underlying immunodeficiency.

PROGNOSIS

The prognosis of mastoiditis depends on the extent of the infection and the causative organism. Mastoiditis that is treated adequately early in the course of illness before the onset of intracranial extension has a very good prognosis. Facial nerve paralysis is reversible early on,[64,71] and benign intracranial hypertension resolves with treatment of the mastoiditis.[20] Permanent neurologic deficits and death may occur if mastoiditis extends to cause meningitis, brain abscesses, epidural abscess, subdural empyema, or venous sinus thrombophlebitis. Symptoms of mastoiditis may recur if antibiotic therapy is of insufficient duration or if surgical débridement of an infected bone or of an infected cholesteatoma is inadequate. Sensorineural and conductive hearing deficits are reversible early on in mastoiditis; however, chronic infection may produce irreversible hearing loss.

PREVENTION

Early adequate antibiotic treatment of otitis media reduces significantly a child's risk for developing mastoiditis. In addition, rapid treatment of known mastoiditis along with early investigation of persistent ear drainage, persistent ear pain, or an otitis media that is not responding to antibiotic management decreases the risk for developing suppurative complications associated with mastoiditis.

CHAPTER 21

Epiglottitis (Supraglottitis)

James D. Cherry

Epiglottitis (supraglottitis) is an illness characterized by inflammation and edema of the epiglottis and frequently also of the arytenoepiglottic folds and ventricular bands at the base of the epiglottis.[43] This disorder usually is caused by *Haemophilus influenzae* type b (Hib), and it mainly is a disease of children. The illness is characterized by rapid onset and progression, and without treatment, death caused by obstruction of the airway occurs. Epiglottitis in children is a pediatric otolaryngologic emergency.

HISTORY

The early history of epiglottitis is obscure, probably because of the importance of diphtheritic croup.[44] In 1887, Baron[9] described in detail a 30-year-old woman with epiglottitis who recovered after treatment with hot poultices and steam with tincture of benzoin. In 1900, Theisen[200] described three cases in the United States. Not until the early 1940s did acute epiglottitis become recognized as a definite clinical entity caused by Hib.[3,18,183] In 1948, Rabe,[155] in a study of 347 children with "infectious croup," presented evidence for the division of the clinical illness into three etiologic categories: diphtheritic croup, viral croup, and Hib croup (acute epiglottitis). Since the early 1990s, a dramatic decrease in the number of cases of epiglottitis has occurred in developed countries because of the widespread use of Hib conjugate vaccines.[4,34,64,70,78,80,126,136,138,152,209,215,227]

EPIDEMIOLOGY

In the pre-vaccine era, the epidemiology of invasive Hib disease varied markedly among different population groups.[215,216] Epiglottitis also differed by population group, but this variation was not related necessarily to the rate of overall Hib invasive disease in the population. For example, among Alaskan Eskimos and Navajo Native Americans, whose risk for acquiring invasive Hib disease was 4 to 10 times that of most other American populations, epiglottitis was not recognized among 295 patients with invasive Hib illness.[49,216]

Of Hib invasive disease, the percentage of cases of epiglottitis varied markedly among different localities. For example, in Israel, only 0.3 percent of invasive Hib infections were epiglottitis, whereas in Ireland, Wales, northeast England, Sydney (Australia), and Denmark, the percentage of epiglottitis cases varied between 16 and 32 percent.[50,68,91,109,135,154] In Minnesota and Dallas County, Texas, only 6 and 3 percent, respectively, of invasive Hib infections were epiglottitis.[142] In contrast with these findings in the United States, Europe, and Australia, the most common manifestation of invasive Hib infection in Sweden was epiglottitis.[46,206] In Sweden, the incidence of epiglottitis in children 14 years of age or younger in 1981 to 1983 was 10 per 100,000 per year. The annual incidence in Minnesota and Dallas County, Texas, in children 5 years of age or younger in 1982 to 1984 was 5.4 and 4.4 cases, respectively, per 100,000 per year.[143]

In children in the United States in the pre-vaccine era, the peak occurrence of epiglottitis was during the third year of life, and 72 percent of all cases occurred in children 1 to 5 years of age.[13,16,20,47,65,97] The disease occurred more commonly in boys than in girls; in 8 studies with 611 cases, 58 percent of cases were in boys.[13,16-18,20,47,65,97,141]

In specific geographic areas, marked differences in the yearly percentage of cases of epiglottitis occurred, but no intercity, national, or international cycles of illness were demonstrated.[13,16,47,65,97,141] Seasonal prevalence varied by locality but was not marked. The greatest number of cases in three studies occurred in the winter and spring,[20,97,141] whereas Baxter[16] observed more cases during the summer and in November, and Cohen and Chai[47] found no seasonal pattern.

Epiglottitis is a disease that occurs most commonly in temperate climates.[67,100] In several U.S. military hospitals, a wide geographic variation in incidence was noted; no cases were found among 4625 admissions at Gorgas Hospital in Panama, whereas 1 of 600 admissions to Elmendorf Hospital in Alaska was for epiglottitis.[13] In the past, acute epiglottis had not been reported in either Taiwan or Hong Kong.[96]

Epiglottitis also occurs in adults but less commonly than in children.[71,133,195,207] Annual rates in Rhode Island, Denmark, Finland, and northern California were 1.0, 0.9, 0.2, and 1.8 per 100,000, respectively. In both Ireland and Israel, rates of reported epiglottitis in adults appear to be increasing.[19,84] Whether these increases are true increases or are the result of increased awareness is not apparent.

In the present Hib conjugate vaccine era, the incidence of epiglottitis has fallen dramatically in all countries employing routine immunization, as has the incidence of all invasive disease caused by *H. influenzae*.[4,34,64,73,80,126,136,138,152,209,215,227] In northern Finland, the incidence in children 4 years of age or younger fell from 7.6 per 100,000 before 1988 to 0 per 100,000 after 1988.[4] In Sweden, in the 10-year period from 1986 to 1996, the rate of

epiglottitis in children younger than 14 years fell from 8.2 per 100,000 to less than 1 per 100,000.[74] At the Children's Hospital of Philadelphia, the average annual incidence of epiglottitis declined from 10.9 per 10,000 admissions before 1990 to 1.8 per 10,000 admissions from 1990 through 1992.[80] In this study, investigators also noted that the median age of patients increased from 35.5 months before 1990 to 80.5 months in the post-1989 period.

In recent years, an increase in incidence of invasive Hib disease, including acute epiglottitis, has been reported in England.[136] Many of the cases have occurred in children who had received Hib conjugate vaccine at 2, 3, and 4 months of age but not a booster dose in the second year of life.

ETIOLOGY

Acute supraglottitis in children in the pre-vaccine era almost always was caused by Hib. Lemierre and colleagues[120] and Sinclair[183] first called attention to "Hib laryngitis." This variant of laryngitis was characterized by marked swelling of the epiglottis and arytenoid regions, high fever, and shock. All 10 children described by Sinclair[183] had Hib bacteremia. Rabe[155] recognized a form of "croup" associated with epiglottitis and Hib bacteremia; 25 of 28 blood cultures (89%) yielded this organism. Table 21–1 summarizes 34 pediatric series from the pre-vaccine era with reported blood culture data. In children, 1570 of 2279 (69%) had blood cultures performed; Hib was isolated from 1191 of 1570 (76%).

As the clinical entity gained recognition, the frequency with which blood cultures were obtained and the yield of Hib increased. During 17 years of experience with epiglottitis in Denver, Colorado,[141] researchers found that 40 percent of all blood cultures yielded Hib; however, 70 percent yielded this organism during the last 5 years of the study.

Supraglottitis with bacteremia caused by other organisms in children rarely occurs, but cases have been noted more frequently during the last decade. The following pathogens have been impli-

cated in this regard: *Streptococcus pneumoniae*[20,65,127]; *Staphylococcus aureus* (including one case in a 5-day-old baby)[11,31,61,127]; *Haemophilus parainfluenzae*[32,204]; group A,[17,112,186,222] group B,[125,228] group C,[8,176] and group G[92] streptococci; *Pseudomonas aeruginosa*[113] (in a patient with severe combined immunodeficiency syndrome); untypeable and *H. influenzae* type a[32]; and *Bacillus* spp.[127] *Candida tropicalis* was isolated from the blood of a 3½-year-old girl with supraglottitis who had been the recent recipient of an autologous bone marrow transplant.[214]

Candida albicans was noted in a case in a newborn whose mother had vaginal candidiasis and in a 6-year-old boy with chronic mucocutaneous candidiasis.[2] *Candida* spp. epiglottitis was noted in two children infected with human immunodeficiency virus (HIV),[145,181] and *C. albicans* epiglottitis was observed recently in a 2-year-old girl who was immunocompromised as a result of receiving chemotherapy for a primitive neuroectodermal tumor.[132]

The possibility that supraglottitis could be caused by a virus has been noted: a 16-month-old child with type 1 herpes simplex virus stomatitis complicated by stridor and respiratory distress had an epiglottis and arytenoepiglottic folds that were edematous and covered with vesicular lesions resembling those in the oral mucosa.[26] An 18-year-old girl had supraglottitis that also was caused by herpes simplex virus.[138] In addition, parainfluenza type 3 and influenza type B viruses were isolated from the nasopharynx of two children with supraglottic inflammation.[83] *Haemophilus paraphrophilus*[101] was recovered from the epiglottic surface of a single patient, as was *Moraxella catarrhalis* in another patient.[211]

In adults, Hib also has been the major cause of epiglottitis, but other organisms occur more commonly in adults than in children.[9,29,30,43,45,51,66,71,72,76,77,86,88,94,95,99,106,108,133,146,147,162,175,182,186,193,195,205,206] In 1992, Daum and Smith[54] reviewed 474 published cases of epiglottitis in adults, 293 of whom had blood cultures performed; 79 of those cultures (27%) yielded *H. influenzae*. Of these positive cultures, 43 were Hib; 35 isolates were not typed, and one isolate was not Hib. Trollfors and associates[206] in Sweden found that blood cultures were obtained from 185 of 356 (52%) adult patients, and *H. influenzae* was isolated from 53 percent of them. Of these, 53 were Hib, and the type of the remaining 45 was not known.

S. pneumoniae was reported to be isolated from the blood of 18 adults with supraglottitis, 10 of whom were receiving immunosuppressive therapy or were infected with HIV-1,[23,30,93,104,106,118,155,163,164,179] and *H. parainfluenzae* was isolated from the blood of 5 patients.[45,69,128,172,218] In Denmark between 1995 and 2002, *H. influenzae* type f was recovered from 13 cases of epiglottitis in adults.[36] Numerous other infectious agents have been implicated in case reports of adults with supraglottitis.[27,29,56,72,76,77,94,95,98,103,124,129,137,144,146,147,159,160,165,175,185,192,230] These agents include *Pasteurella multocida*, *Kingella kingae*, *Klebsiella pneumoniae*, group A and B streptococci, *Bacteroides* spp., *Fusobacterium necrophorum*, *Vibrio vulnificus*, *Serratia marcescens*, *S. aureus*, *Neisseria meningitidis*, *Aspergillus flavus*, and herpes simplex virus. Epiglottitis has been reported as a complication of infectious mononucleosis caused by Epstein-Barr virus infection.[39]

Epiglottitis also can result from noninfectious causes. Hot foods and water can cause thermal epiglottitis, as can poisoning with corrosive agents including cocaine alkaloid.[16,105,110,115] Hereditary angioedema may manifest with findings typical of epiglottitis.[149]

ANATOMY

The thin, elastic, leaflike epiglottic cartilage is attached to the anterior surface of the thyroid cartilage by the thyroepiglottic ligament (Fig. 21–1). The hyoepiglottic ligament also provides support and anchors the epiglottis to the hyoid bone. The superior aspect of the epiglottis arches slightly posteriorly. Stratified squamous epithelium covers the anterior surface of the epiglottis and the superior third of the posterior portion; respiratory epithelium covers the remaining posterior surface. The stratified squamous epithelium is loosely adherent and creates a large potential space for the accumulation of inflammatory cells and edema fluid.

The arytenoepiglottic folds arise from the epiglottis and terminate posteriorly near the paired arytenoid cartilages. These structures commonly are involved in the supraglottic infection and occasionally are the site of serious disease without epiglottitis per se.[16] Immediately anterior to the epiglottis are the valleculae epiglotticae, where saliva pools before deglutition.

PATHOPHYSIOLOGY

Supraglottic cellulitis with marked edema involving the epiglottis, arytenoepiglottic folds, ventricular bands, and arytenoids is the hallmark of this illness. As the edema increases, the epiglottis curls posteriorly and inferiorly. Inspiration tends to draw the inflamed supraglottic ring into the laryngeal inlet, whereas expiration is unopposed.[177] This "ball-valve" mechanism is thought to produce slight hypoxia without hypercapnia.[167] Diffuse infiltration with polymorphonuclear leukocytes, hemorrhage, edema, and fibrin deposition can be seen microscopically; this infiltration can progress to microabscesses, with Hib occasionally seen in the tissue.[100,162] Frank abscess formation has been documented in adults.[19,124,129,160,165,192,219,225] Infection of the supraglottic larynx

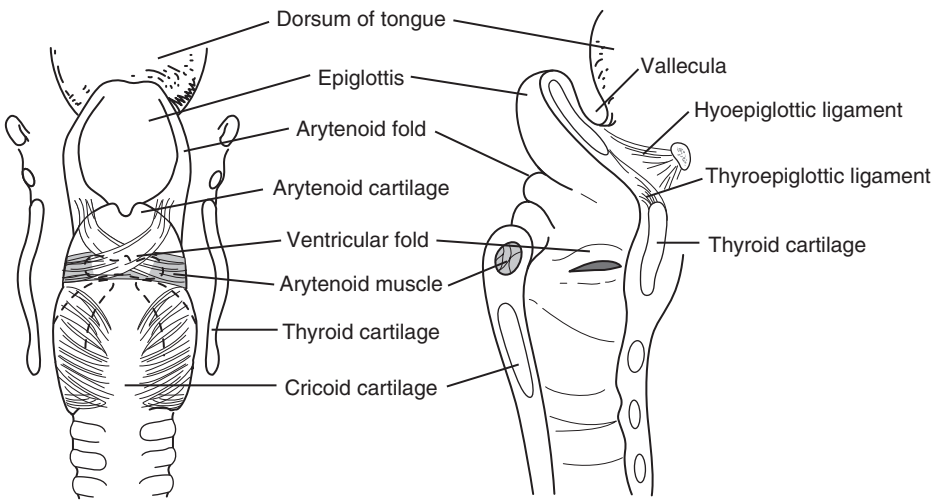

Figure 21–1 Anatomic relationships of the supraglottic larynx. Posterior view *(left)* and sagittal view *(right)*.

may spread inferiorly to involve the paraglottic space,[87] but as a rule, neither upward extension into the laryngeal lymphatics nor downward extension into the subglottic region occurs.[18,100]

Infection of the supraglottic structures probably arises from direct invasion by Hib with subsequent development of bacteremia. The bacteremia appears to be relatively short in duration and of low concentration, as suggested by several observations: (1) the serum concentration of the capsular polysaccharide is directly proportional to the concentration and duration of bacteremia,[168] (2) children with epiglottitis have less Hib capsular polysaccharide in their sera than do patients with meningitis,[217] and (3) the density of Hib in blood is significantly lower in patients with epiglottitis than in patients with meningitis.[117,166,194] In 23 patients with epiglottitis, the geometric mean number of organisms was 123 colony-forming units (CFU)/mL, whereas the geometric mean number in 43 patients with meningitis was 2203 CFU/mL ($p < .001$).[117]

What predisposes the epiglottitis to infection is unknown. Possibly, mild trauma to the epiglottis occurs during food intake. This trauma could result in damage to the mucosal surface, which, in turn, could allow the invasion of organisms that already were present in the upper respiratory tract. Also possible is that a viral infection damages the mucosal surface and thus predisposes the patient to secondary bacterial infection.

Acute-phase sera in most children with epiglottitis lack specific bactericidal and hemagglutinating antibody. Seroconversion regularly occurs after infection.[30,130]

Conflicting evidence exists relating to a possible genetic difference between patients with Hib epiglottitis and other individuals.[5,82,198,225] Whisnant and associates[225] surveyed human leukocyte antigens (HLA) and erythrocytic antigens among 30 children with epiglottitis and 20 patients with meningitis. HLA-A11 was found in 17 and 3 percent of the patients with meningitis and epiglottitis, respectively ($p < .01$). HLA-B5 occurred in 13 and 3 percent of patients with epiglottitis and meningitis, respectively ($p < .05$), whereas HLA-B40 occurred more often (23% versus 10%) in patients with meningitis than in those with epiglottitis ($p < .05$). Moreover, the frequency of HLA-A28 and HLA-B17 was higher among the patients with epiglottitis than in uninfected control subjects.[225] However, the results of another study did not confirm these observations.[82]

The distribution and frequency of MNS erythrocyte antigens in patients with epiglottitis may differ from those observed in others. For example, the NNSS genotype occurred in 6.4 percent of patients with epiglottitis and in 0.5 percent of healthy control subjects ($p < .0002$),[225] but this difference was not confirmed.[82] However, the results of two studies suggest that the MNS genotype occurs less often in patients with Hib meningitis than in patients with epiglottitis.[82,225] In one study, white children with Hib meningitis lacked G2m(n), an allotype antigen of IgG2 subclass heavy chains, more frequently than did control subjects.[5] In another study in a white population in Finland, however, this difference was not noted.[197] The frequency of the Km(1) immunoglobulin allotype in children with epiglottitis did not differ significantly from the prevalence of that marker in blacks or whites. However, in blacks with Hib meningitis, the Km(1) marker occurred less frequently in patients than in control subjects.[82] The identification of one outer-membrane protein subtype of Hib that was associated relatively infrequently with epiglottitis suggests that isotype-specific differences in the propensity of Hib to cause epiglottitis may exist.[196]

CLINICAL MANIFESTATIONS

The classic onset of epiglottitis in children is abrupt, and progression of disease is rapid; careful history on occasion reveals the occurrence of a trivial antecedent upper respiratory tract infection.* The total duration of illness before hospitalization usually is less than 24 hours and occasionally is as short as 2 hours. In one study in which 142 medical records of children with epiglottitis were reviewed, the duration of illness before tracheotomy was performed was found to be 12 hours or less in 73 percent and more than 24 hours in only four patients.[47]

The most common presentation of acute epiglottitis in children includes the sudden onset of fever, severe sore throat, dysphagia, and drooling. Airway obstruction always occurs and is rapidly progressive. It is manifested by distress on inspiration, a choking sensation, irritability, restlessness, and anxiety. The speech is muffled or thick sounding, but hoarseness usually does not occur. The child usually insists on sitting up in a characteristic posture with the arms back, the trunk leaning forward, the neck hyperextended, and the chin pushed forward. This posture increases the diameter of the obstructed airway.

In contrast to acute laryngotracheitis, in which marked inspiratory stridor occurs, the degree of observed stridor in epiglottitis often is not severe. This apparent lack of respiratory distress often leads the unwary physician to underestimate the severity of the child's illness. With progression, the air exchange becomes progressively worse, and hypoxia, hypercapnia, and acidosis develop. These developments cause increased irritability, restlessness, and disorientation, and if an artificial airway is not established, the child will experience sudden cardiorespiratory arrest.

Fever occurs in virtually all children; most temperatures are between 38.8° C and 40.0° C (101.8° F and 104° F). Blood leukocyte counts almost always are elevated; the mean total count was approximately 20,000 cells/mm^3 in five studies.[4,20,47,97,221] The differential cell count reveals an increased percentage of neutrophils and band forms; most patients have absolute band counts that are more than 500 cells/mm^3.

The clinical picture of epiglottitis in adults is more indolent than that in children.[19,86,191,231] Berger and associates[20] reviewed 118 cases of acute epiglottitis seen between 1986 and 2000. Of these patients, 33 percent were admitted to the hospital within 1 day of the onset of symptoms, and 77 percent were admitted within 3 days of onset. Symptoms on admission were as follows: sore throat, 85 percent; odynophagia, 83 percent; temperature elevation, 38 percent; respiratory difficulties, 34 percent; muffled voice, 25 percent; and drooling, 7 percent. In two other studies, an average of 1 to 3 days elapsed before medical aid was sought. The mean temperature was 38.2° C (100.7° F), and some patients were afebrile; the temperature range was 36.6° C to 40.0° C (97.8° F to 104° F). Blood leukocyte counts averaged 17,000/mm^3 (range, 8000 to 32,000/mm^3).[86,191] Sore throat and dysphagia were universal occurrences. Zwahlen and Regamy[231] reviewed the clinical features of 100 reported adult cases of epiglottitis. Of these patients, 78 percent had dyspnea, 49 percent had dysphonia, 41 percent had cyanosis, and 38 percent had stridor. Forty-six percent had edema of the neck. A precordial purring or fluttering sensation was described by one adult patient.[169] In three cases in adults, Ehara[63] noted on physical examination that all had tenderness of the anterior neck over the hyoid bone.

DIFFERENTIAL DIAGNOSIS

The hallmarks of the successful management of acute epiglottitis are an awareness of the condition and an understanding of the rapidity of its progression. A correct early diagnosis frequently is lifesaving. Acute epiglottitis must be differentiated from seven other conditions with symptoms of acute upper airway obstruction. Aspects of the differential diagnosis are presented in the text in Chapter 22 and in Table 22–4.

*See references 13, 14, 18, 20, 30, 33, 47, 65, 86, 97, 99, 122, 127, 130, 131, 141, 150, 155, 184, 213, 224.

In epiglottitis, the important differential points are as follows: the lack of a croupy cough; the presence of a swollen, cherry-red epiglottis; the sitting posture of the child with the chin pushed forward, as well as a reluctance or refusal to lie down; and the relatively greater apprehension and anxiety of the child than the degree of chest retraction suggests. In contrast, the child with acute laryngotracheitis has a normal epiglottis on examination, always has a typical barking cough, is comfortable in a supine position, and frequently appears to have only minimal apprehension in spite of retractions in which the sternum appears to be indenting 2 inches or more.

Acute angioneurotic edema that involves the epiglottis can mimic acute epiglottitis. However, in this condition, the temperature usually is normal, and the patient appears less toxic. This condition usually is brought on by a specific allergic reaction after the ingestion of a food or medication.

Supraglottitis should be considered in children with uvulitis because the clinical features of these disorders may overlap, and both infections may be present. Concomitant uvulitis and epiglottitis were described in association with Hib bacteremia in children[107,158] and with *S. pneumoniae* bacteremia in an adult.[223] Isolated uvulitis has been associated with Hib bacteremia and group A beta-hemolytic streptococcal pharyngitis.[107,123] Uvulitis in the absence of epiglottitis was described in a child with odynophagia, drooling, and Hib bacteremia.[123]

A foreign body lodged in a vallecula or the larynx or in penetrating posterior pharyngeal tissues may cause signs and symptoms that mimic those of acute supraglottitis.[220] A paravertebral collection of pus, from cervical osteomyelitis or parapharyngeal abscess, rarely can spread anteriorly and can produce acute "croup." Congenital anomalies and laryngeal papillomas can be excluded by their chronic course. *C. albicans* has caused neonatal laryngeal obstruction without radiologic epiglottitis.[153]

Infection of supraglottic structures by *Mycobacterium tuberculosis* occurs less commonly than does glottic involvement; tuberculous laryngitis is an exceedingly rare occurrence in children and always is associated with pulmonary lesions.[62] The onset is considerably more insidious than is that of Hib supraglottitis. Nasopharyngeal diphtheria may mimic acute epiglottitis and may be associated with a serosanguineous nasal discharge.

Chronic epiglottic enlargement with edema was observed in two children with cancer who had received radiation therapy to the neck. These clinical features were not confused with those of acute supraglottitis, although one patient had dysphagia and snored.[229] Severe, chronic inflammatory epiglottitis with associated granulomatous lymphangitis was found on histologic examination of tissue obtained from a 19-month-old black child who had epiglottic enlargement without erythema for 3 months.[220] "Tuberculoid" granulomatous lesions were seen at histologic examination of an epiglottic biopsy specimen obtained from a 22-year-old man, HIV status unknown, who presented with weight loss, sore throat, and dysphonia of 1 month's duration.[140] The epiglottitis and arytenoepiglottic folds of this patient were erythematous and edematous.

Lymphangiectasis of the epiglottis produced airway obstruction with stridor and intermittent cyanosis in a 4-month-old white boy. On histologic examination, the epiglottis consisted of multiple dilated lymphatic vessels lined by a single layer of epithelial cells with no discernible wall. The stroma contained scattered lymphocytes and a few neutrophils. This lesion spontaneously regressed, and the child's condition was normal at 1 year of age.[208]

SPECIFIC DIAGNOSIS

The clinical picture of sore throat, dysphagia, drooling, anxiety, and inspiratory distress without significant stridor and the characteristic sitting position should suggest the presumptive diagnosis in most cases. The definitive anatomic diagnosis is made by the visualization of the epiglottis, and the etiologic diagnosis is confirmed by culture of an organism from the blood or the surface of the epiglottis. An Hib origin also can be established by the demonstration of antigenemia or antigenuria.[189,217]

In the typical case, the epiglottis is fiery red and greatly swollen. In children, the epiglottis can be seen by simple depression of the tongue with a tongue blade. In older children and adults, indirect or direct laryngoscopy usually is necessary to confirm the diagnosis. On occasion, the obstruction is caused by swelling of the ventricular bands and the arytenoepiglottic folds so that the epiglottis may appear relatively normal.

Major controversy exists concerning the safety of using a tongue depressor to examine a child with suspected epiglottitis because sudden cardiorespiratory arrest has been noted to occur. However, most instances of cardiorespiratory arrest that I am aware of occurred after the child was forced into a supine position rather than because of the examination itself.[42] In many instances, patients with presumptive epiglottitis can be examined, while they are in an upright position, by using tongue blade or indirect laryngoscopy.

Case management should be individualized. In the child with moderate or advanced disease, the clinical diagnosis should be apparent without having to do an intraoral examination. In this situation, intraoral examination should not be performed, but the child should be prepared for the establishment of an airway. This preparation should be rapid but controlled so that intubation can be performed in an operating room.

The diagnosis of epiglottitis can be established by the classic appearance on a lateral neck radiograph (Fig. 21–2).[156,221]

Figure 21–2 Acute epiglottitis. A lateral neck radiograph from a child with acute epiglottitis showing the swollen epiglottis (thumb sign) encroaching on the airway. (*Courtesy of Dr. Ines Bouchat.*)

However, my opinion is that this radiographic procedure rarely is necessary; all too often, it leads to a delay in providing the necessary definitive therapy.[47,100,139] The use of the lateral neck radiograph should be reserved for subacute cases in which the specific diagnosis after completion of a clinical examination is not clear.

The lateral film of the neck, delineating the soft tissues, taken with the patient upright, gives the best view of the upper airway anatomy (see Fig. 21–2). The hypopharynx is dilated; normal cervical lordosis may be replaced by a straight or kyphotic contour. The valleculae are narrowed and may be obliterated. A thickened mass of tissue stretching from the valleculae to the arytenoids emphasizes the appropriateness of the term *supraglottitis*. In adults with epiglottitis, the widths of the epiglottis and arytenoepiglottic folds uniformly exceed 8 and 7 mm, respectively.[174]

When performed, radiography of the neck in the anteroposterior projection usually reveals that tracheal narrowing is absent. However, some children with acute supraglottitis have localized subglottic narrowing indistinguishable from that found in acute laryngotracheitis.[178,187]

All patients with suspected epiglottitis should have a blood culture, and a culture specimen should be obtained from the surface of the epiglottis when an artificial airway is established. Today, cultures are of increasing importance because of the change in epidemiology of Hib infection and the resulting increased likelihood that an organism other than Hib may be causing the illness. A white blood cell count with a differential also may provide useful information. In children who have received antimicrobial treatment before cultures were obtained, performing a direct antigen test for Hib on the blood and urine is worthwhile.

TREATMENT

The treatment of acute epiglottitis should be relatively simple in that it involves only two main aspects of therapy: an airway must be established, and an appropriate antimicrobial agent needs to be administered. However, in the past, the mortality rate from epiglottitis varied from 0 to 32 percent,[47,86] a finding suggesting major differences in the implementation of treatment.

Most deaths occur in transit to the hospital or within the first few hours after arrival. Once the diagnosis is suspected, the patient should be attended constantly by individuals skilled in resuscitation with appropriate equipment for airway stabilization and ventilatory support. Delays of 2 or 3 hours have proved fatal; every effort should be made to reduce the time needed to secure a patient's airway and to initiate antibiotic therapy, before which unnecessary stress should be avoided. In most cases, radiographic confirmation should be omitted. Blood tests, extensive history taking, and delay in transport should be eliminated.

Medical centers and pediatric services that have planned protocols for the diagnostic investigation and treatment of patients with suspected acute epiglottitis generally have better morbidity and mortality statistics than do services that do not have such protocols in place. Pediatricians, radiologists, otolaryngologists, and anesthetists may contribute to the assessment and management of a case; defining roles and responsibilities of each service in advance minimizes confusion and renders the institution of care easier.

SECURING THE AIRWAY

In general, the cornerstone of all management plans is the establishment of an airway in all children in whom the diagnosis of epiglottitis is made.[44] In 1938, Sinclair[183] recognized that tracheostomy was lifesaving. Berenberg and Kevy[19] advocated hospitalization for all patients with epiglottitis but tracheostomy only "if necessary." However, Bass and associates[13] presented a compelling argument for performing routine tracheostomy. Among 83 patients with documented epiglottitis, 11 of whom were adults, these authors noted that 16 (19%) had life-threatening obstruction when they were first seen. An additional 14 (17%) progressed to this point within 6 hours of admission; 9 of the 83 (11%) required emergency tracheostomy while they were hospitalized. Of these 9, 2 died, and 1 suffered anoxic brain damage. All 9 were being monitored carefully, with bedside tracheostomy equipment available and trained personnel nearby. Six of the adults required tracheostomy for survival.[13] Margolis and colleagues[131] noted that elective tracheostomy, performed at the time of diagnosis, eliminated fatalities in 15 consecutive patients. This observation was in contrast to 4 deaths in 20 patients observed until tracheostomy "was required."

A large body of literature attests to the safety and efficacy of nasotracheal intubation as a replacement for tracheostomy,* which has a complication rate of 50 percent.[199,224] Biologically inert tubes, with their decreased risk of complicating subglottic stenosis,[180] and the recollection that endotracheal tube insertion was a universal approach before tracheostomy[139] was an accepted procedure led to the routine use of nasotracheal intubation in this disease. Nasotracheal intubation requires a shorter duration of airway maintenance: 32 patients with epiglottitis managed with tracheostomy had a mean duration of intubation of 7.5 days and a mean hospitalization of 8.8 days. In contrast, a nasotracheal tube was used for a mean of 38 hours with a 6.5-day hospitalization in 5 patients.[139] Diaz and Lockhart[57] managed 104 patients with nasotracheal intubation. The mean intubation time was 53 ± 14.9 hours; 7 patients (6.8%) extubated themselves, and 2 required reintubation. Laryngeal edema occurred in 3 patients (2.9%) who had been intubated. In 2 patients, subglottic granulations required excision.

My position, as well as that of Daum and Smith,[54] is that the argument for performing elective tracheostomy or, preferably, intubation in all children with supraglottitis is compelling, and the procedure should be performed immediately after the diagnosis is established. Whether this "stimulus-response" approach is necessary for adults with epiglottitis is controversial.[12,70,86,151,177,182,191,226] Mayo Smith and associates[133] compared selected clinical features in adults with epiglottitis at the time of diagnosis who died or who received an artificial airway with those of adults who recovered without airway intervention. Few differences emerged. Patients who died or who were managed with airway intervention had respiratory distress and bacteremia more often than did those who recovered without airway intervention. Obviously, the presence of bacteremia was not known on presentation. Moreover, the mortality rate among all adults managed expectantly was 4.6 percent, a figure comparable to the mortality rate (6.1%) of children in a series reported before recommendations were made for routine securing of the airway at diagnosis.[40,133] The preponderance of evidence until very recently has suggested that securing the airway in all adults with supraglottitis by nasotracheal intubation should reduce mortality rates.[7,10,12,13,21,22,51,106,133] However, Frantz and associates[71] reported an analysis of 129 cases of acute epiglottitis in adults in which no deaths occurred in the cohort, and 85 percent of these patients were managed without airway intervention.

In the large series reported by Berger and colleagues[20] involving 118 cases, 19 had airways established on admission (16 endotracheal intubation, 2 tracheotomy, 1 cricothyrotomy), and 6 other patients subsequently required either endotracheal intubation or tracheotomy. The remaining 93 patients were managed successfully without the need for airway intervention. Fifty-eight

TABLE 21–2 Size of Nasotracheal Tubes Recommended for Children with Acute Supraglottitis

Age	Size (mm)
Birth-6 mo	3.0
6 mo-3 yr	3.5
3-5 yr	4.0
>5 yr	4.5

Data from Rabe, E. F.: Infectious croup: III. Haemophilus influenzae type b croup. Pediatrics 2:559-566, 1948.

of the patients were treated with intravenous corticosteroids in addition to antibiotics, and these patients tended to have more prolonged hospital stays than those who did not receive steroids (5.7 ± 4.1 days versus 4.7 ± 4.3 days; $p = .2$).

To aid in intubation and to reduce long-term sequelae, most investigators have advocated use of a nasotracheal tube 0.5 to 1.0 mm smaller than that predicted by the patient's age.[89,139,171] Recommendations for tube size are shown in Table 21–2. Published criteria for extubation (summarized in reference 14) include those based on duration of therapy and those based on daily examination of the epiglottis and supraglottic structures by direct laryngoscopy[55] or fiberoptic bronchoscopy.[148,210]

Long-term complications of nasotracheal intubation are rare. Thirty-three children with epiglottitis who were managed with nasotracheal intubation (mean duration of intubation, 55 hours) were evaluated 1 to 8 years later. By history and measurement of peak expiratory flow rates, no complications were found.[171] Although additional long-term data are necessary to ensure absence of residua, elective nasotracheal intubation appears to be the procedure of choice.

Several reports documented the recognition of idiopathic pulmonary edema before[119] or, more commonly, after[25,55,59,73,102,190,202] insertion of an endotracheal tube to relieve laryngeal obstruction caused by epiglottitis. One hypothesis to explain this phenomenon is that airway obstruction produces markedly negative intrapleural pressure with increased venous return to the right side of the heart, with decreased left ventricular output and increased pulmonary blood volume.[116] These changes increase the pulmonary microvascular pressure and produce pulmonary hyperemia and edema. Endotoxemia may play a role in altering vascular permeability, but it is not necessary for recognition of this complication of airway obstruction because abrupt onset of pulmonary edema was described when airway obstruction caused by croup, foreign body, and malignant neoplasm was relieved acutely.[37] The frequency of pulmonary edema as a complication of intubation in supraglottitis was approximately 9 percent,[187] and it has occurred in an adult.[161] Continuous positive airway pressure in all intubated patients with epiglottitis probably will provide prophylaxis against this complication,[57,73] but controlled data are lacking.

ANTIBIOTICS

The mainstay of antibiotic therapy for acute epiglottitis in the recent past has been ceftriaxone (50 to 100 mg/kg/day given every 12 hours intravenously) or cefotaxime (100 to 200 mg/kg/day given every 6 hours intravenously) because virtually all cases in both children and adults were caused by Hib. However, in the present conjugate vaccine era, the incidence of all invasive Hib disease has decreased dramatically. Therefore, in children previously vaccinated, the cause is likely to be another organism. Culture results today have added significance because one possible cause that would require a change in therapy is *S. aureus*.

No controlled data exist about the duration of antimicrobial administration, but a course of 7 days seems appropriate. In the event that group A streptococci are isolated from the airway, penicillin is the drug of choice. A first-generation semisynthetic penicillinase-resistant penicillin or vancomycin (if methicillin-resistant *S. aureus* is suspected) should be used for *S. aureus*, whereas erythromycin is indicated for *Corynebacterium diphtheriae*.

OTHER SUPPORTIVE MEASURES

Some authors have advocated corticosteroid therapy on the basis of anecdotal experience in patients with epiglottitis, but no controlled data exist to support its use, and such therapy may be hazardous: among 91 patients with epiglottitis who received corticosteroid therapy, 4 (4%) had evidence of bleeding from the gastrointestinal tract that was sufficient in 2 patients to require transfusion,[58] a phenomenon observed by other investigators.[111] Therapy with racemic epinephrine is without benefit.

Expert respiratory nursing care is essential. Inadvertent extubation must be avoided, particularly in the first 24 hours. Judicious use of sedatives that do not appreciably depress respiration may be appropriate.

COMPLICATIONS

Extraepiglottic complications are not common occurrences in children with acute epiglottitis. In a study involving 72 children with epiglottitis, investigators noted that 25 percent had pneumonia, 25 percent had cervical adenitis, 8 percent had tonsillitis, and 5 percent had otitis media.[141] The other common invasive manifestations of Hib infections (meningitis, arthritis, and cellulitis) rarely are found in conjunction with epiglottitis.[141,170]

PREVENTION

PROPHYLAXIS OF HOUSEHOLD CONTACTS

In the pre–conjugate vaccine era, household contacts of patients with Hib infection were at increased risk for acquiring Hib infection.[81] Whether an increased risk occurred in daycare contacts was unresolved.[53] Although contacts of patients with Hib epiglottitis younger than 5 years are colonized less frequently than are contacts of patients with other Hib invasive infections,[52] secondary disease was described in household contacts when an index patient had epiglottitis.[1,78,79,203] Secondary Hib epiglottitis was described in a child[1] and two adults who were household contacts of a patient with Hib meningitis.[78,79] Hib epiglottitis occurred in two siblings who presented with the condition within 1 day.[85]

Rifampin prophylaxis, 20 mg/kg/day (600 mg/dose maximum) for 4 days, is recommended for all unvaccinated members of a patient's contact group when the index patient has Hib epiglottitis and at least one contact in the group is 4 years of age or younger.[6,41]

The recognition that adults occasionally may acquire secondary infection, particularly epiglottitis, on exposure to children with invasive Hib infection prompted some experts to extend prophylaxis to all of a patient's contact groups, regardless of the presence of one or more contacts who are 4 years of age or younger. All experts, however, recommended that adults and older children be made aware of the signs and symptoms of Hib disease, particularly when the patient's contact group would not receive prophylaxis under current guidelines.

CHAPTER 22

Croup (Laryngitis, Laryngotracheitis, Spasmodic Croup, Laryngotracheobronchitis, Bacterial Tracheitis, and Laryngotracheobronchopneumonitis)

James D. Cherry

The term *croup* is used to identify several different respiratory illnesses characterized by varying degrees of inspiratory stridor, cough, and hoarseness resulting from obstruction in the region of the larynx. The etiology of croup syndromes is diverse, and the consideration of noninfectious possibilities in the differential diagnosis is of major importance. Table 22–1 classifies etiologic considerations in supraglottic, laryngeal, and infraglottic acute obstructions.

Epiglottitis (see Chapter 21) and diphtheria (see Chapter 101) are mentioned here only for historical perspective and as a consideration in differential diagnosis. Croup is discussed under the subheadings of laryngitis, laryngotracheitis, spasmodic croup, laryngotracheobronchitis, bacterial tracheitis, and laryngotracheobronchopneumonitis.

TABLE 22–1 Clinical Considerations in Acute Supraglottic, Laryngeal, and Infraglottic Obstructions

Infectious
Acute epiglottitis
Laryngitis
Laryngeal diphtheria
Laryngotracheitis
Laryngotracheobronchitis
Laryngotracheobronchopneumonitis
Bacterial tracheitis
Spasmodic croup
Mechanical
Foreign body
Secondary to trauma resulting from intubation
Extrinsic or intrinsic mass
Allergic
Acute angioneurotic edema

HISTORICAL ASPECTS

The word *croup* is derived from the Anglo-Saxon word *kropan*, "to cry aloud."[35] Until the 20th century, most crouplike illnesses were thought to be diphtheria. Diphtheritic croup is an ancient disease that has been traced to the time of Homer. The historical trail of diphtheria disappeared in the 5th century and did not reappear until 1100 years later. In the 16th century, epidemics were noted in Europe. Top[217] credits Bretonneau for differentiating diphtheritic croup from spasmodic croup in 1826. In the middle third of the 20th century, the history of croup was marked by three important events: (1) the rapid decline in incidence of diphtheria associated with the use of toxoid; (2) the introduction and widespread use of antibiotics; and (3) the advent of tissue culture techniques, resulting in the establishment of viruses as etiologic agents. After these three events occurred, a prevalent academic view was that all croup was of viral etiology, and bacteria generally were dismissed as causative agents.[36,42,64,180] A careful review of many publications from the first half of the 20th century indicates, however, a causative role for several bacteria, in addition to *Corynebacterium diphtheriae*, in croup.* Bacterial croup (bacterial tracheitis) was rediscovered in 1979.†

In the 1940s, Davison[48] separated spasmodic croup from other, more severe forms of croup. The clinical and pathologic aspects of this entity were poorly defined, and today it often is not separated clinically from more severe forms of croup.

TABLE 22–2 Classification and Definition of Infectious Illnesses Involving the Larynx and Infraglottic Region

Category	Other Terms	Definitions
Laryngitis		Inflammation of larynx resulting in hoarseness; usually occurs in older children and adults in association with common upper respiratory viral infection
Laryngeal diphtheria	Membranous croup, true croup, diphtheritic croup	Infection involving larynx and other areas of upper and lower airway due to *Corynebacterium diphtheriae*, resulting in gradually progressive obstruction of airway and associated inspiratory stridor
Laryngotracheitis	False croup, virus croup, acute obstructive subglottic laryngitis	Inflammation of larynx and trachea usually caused by infection with parainfluenza and influenza viruses
Laryngotracheobronchitis and laryngotracheobronchopneumonitis	Membranous laryngotracheobronchitis, pseudomembranous croup	Inflammation of larynx, trachea, and bronchi or lung or both; usually similar in onset to laryngotracheitis, but more severe illness; bacterial infection frequently has causative role
Bacterial croup	Bacterial tracheitis, membranous croup, membranous tracheitis, membranous laryngotracheobronchitis, pseudomembranous croup	Severe form of laryngotracheitis, laryngotracheobronchitis, or laryngotracheobronchopneumonitis due to bacterial infection
Spasmodic croup	Spasmodic laryngitis, catarrhal spasm of the larynx, subglottic allergic edema	Illness characterized by sudden onset at night of inspiratory stridor; associated with mild upper respiratory infection without inflammation or fever but with edema in subglottic region

TERMINOLOGY

The terminology and classification of infectious illnesses involving the larynx and infraglottic region have evolved over time. Classifications often have mixed etiologic systems with anatomic systems and have led to confusion. Croup often has been presented in articles under the heading of *laryngotracheobronchitis* when the authors actually were discussing laryngotracheitis and spasmodic croup.[112,138,149,176,188,196,214] The term *membranous croup* has been used as the title for articles dealing with bacterial croup.[53,89] This use is confusing because membranous croup historically was diphtheria. Many articles dealing with bacterial croup also have been titled *bacterial tracheitis*.* This term seems inappropriate because most cases of bacterial croup seen today have lower respiratory tract involvement in addition to tracheal findings. Table 22–2 lists the classifications and definitions used in this chapter. In the present era, the physician's knowledge of the clinical symptoms of croup and of the relationship of history and physical findings to the needs of therapy and general prognosis basically has declined.

ETIOLOGY

The etiologic agents in laryngitis, laryngotracheitis, spasmodic croup, laryngotracheobronchitis, and laryngotracheobronchopneumonitis are presented by frequency and severity of illness in Table 22–3. Laryngitis is a common manifestation of infection with many respiratory viruses in older children, adolescents, and adults. Outbreaks of laryngitis in closed population groups (e.g., boarding schools and military training camps) most frequently are caused by adenovirus types 4 and 7, and community outbreaks most often are noted in association with epidemic influenza. Sporadic instances of laryngitis most often are caused by adenoviral infections. Laryngitis also has been reported in association with group A streptococcal infections; the incidence of this association has varied from 2 to 40 percent.[17,155,222]

Generally accepted today is that acute laryngotracheitis and spasmodic croup, which rarely are differentiated clinically, are caused by infection with many different viruses. Although numerous studies of respiratory viral infection exist, almost no attempt has been made to delineate the differences in etiologic spectrum by severity of illness.

Parainfluenza virus type 1 is the most common cause of acute laryngotracheitis and is responsible for frequent and clearly delineated fall and winter epidemics. Croup with parainfluenza type 2 virus seldom is severe but occasionally is related to small outbreaks. Parainfluenza virus type 3 is a frequent cause of sporadic but severe illness.

The most severe laryngotracheitis has been noted in association with influenza A viral infections. Respiratory syncytial virus and several different adenoviruses frequently are isolated in croup. Generally, these illnesses are not severe, but lower respiratory involvement occasionally is a problem. Laryngeal, tracheal, and bronchial involvement commonly occurs in measles.[36] Although rhinoviruses, *Mycoplasma pneumoniae*, enteroviruses, herpes simplex virus, and reoviruses have been associated with croup, they generally cause only minimal distress. More recently, croup has been noted in association with infection with the novel coronavirus NL63, human bocavirus,[8a] and human metapneumovirus.[5a,38,224] Recurrent croup may be due to infection with a human papillomavirus.[239]

Bacteria, other than *Haemophilus influenzae* in epiglottitis and *C. diphtheriae* in membranous croup, generally were dismissed as causative agents in croup until more recently.[42,64,180] Many publications on laryngotracheobronchitis from the first half of the 20th century indicate a role for several common bacterial pathogens.* In 1979, bacterial croup was rediscovered,[111] and numerous reports of this illness have been published since then.†

	Cryptosporidium	−	No	++	90

*++++, *most frequent;* +++, *frequent;* ++, *occasional;* +, *rare;* −, questionable.
†++++, most severe; +++, severe; ++, not severe; +, minimal distress.

In the reports from the preantibiotic era, *Streptococcus pyogenes* was the pathogen implicated most frequently. Since 1979, *Staphylococcus aureus* has been the agent implicated most commonly. Other important bacteria are *Streptococcus pneumoniae* and *H. influenzae*. More recently, *Moraxella catarrhalis* has been found to be the causative agent in several cases.[11,67,116,236] In most instances, bacterial croup is likely to be the result of bacterial superinfection in viral disease.* *Cryptosporidium* also has been recovered from the trachea of an infant with a subacute illness.[90]

EPIDEMIOLOGY

Croup accounts for approximately 15 percent of lower respiratory tract disease seen in pediatric practice. In a large 11-year study in a pediatric practice in Chapel Hill, North Carolina, Denny and associates[56] noted the incidence of croup by age and sex. The highest attack rate occurred in children 7 to 36 months of age. Few cases occurred after the sixth birthday. Hoekelman[94] studied the occurrence of illness prospectively in 246 full-term, first-born, well infants during their first year of life. Three infants (1.2%) had croup during the study year. The analysis of a pediatric practice with approximately 3000 active records and approximately 10,000 yearly visits of children younger than 5 years old disclosed five cases of croup in a group of 50 consecutive hospitalized patients.[18]

Although croup occurs occasionally in older children, most cases occur within the first 3 years of life. A review of 211 children hospitalized for croup during a 2-year period at Cardinal Glennon Memorial Hospital for Children in St. Louis showed that 26 percent of the cases were in infants younger than 1 year old, and 73 percent were in children younger than 3 years.[75] Similar data on age have been reported by others.[56,64,69,188,195]

Croup occurs more commonly in boys than in girls.[56] In our studies, two of every three hospitalized children were boys.[75] Berg,[10] Kravitz,[130] and Rosales and Davenport[188] noted similar sex-related illness ratios. Figure 22–1 shows the 3-year seasonal pattern of croup as manifested by emergency department visits at Cardinal Glennon Memorial Hospital for Children. In each of the years, late fall–early winter peaks occurred. In the Chapel Hill studies, an increase was noted in the number of croup cases beginning in September, with a peak in October and November and then a decrease during the next 7-month period.[56] In a 2-year emergency department study in Toronto involving 1700 cases, the peak month of visits and hospital admissions was found to be October.[195] Marx and associates[144] reviewed the National Hospital Discharge Survey data for hospitalizations for croup between 1979 and 1993. They also examined Centers for Disease Control and Prevention laboratory-based surveillance data and published reports with virus isolation studies. Major peaks in hospitalizations for croup occurred in October of odd-number years at the time of peak parainfluenza virus type 1 activity. Minor peaks in hospitalizations for croup occurred each year in February when influenza A, influenza B, and respiratory syncytial viral infections were common occurrences. Epidemic peaks of acute laryngotracheitis reflect community-wide activity with parainfluenza 1 and 2 viruses or influenza A or B outbreaks.[56,83,144]

In the Toronto study, the time of the visit to the emergency department was analyzed.[195] The peak number of visits occurred between 10 P.M. and 4 A.M. During this period, approximately 17 percent of the children seen were admitted to the hospital. In contrast, of children seen between noon and 6 P.M., approximately 50 percent were admitted to the hospital. A study of croup hospitalizations in Ontario over 14 years from 1988 to 2002 noted a biennial midautumn peak and an annual summer trough throughout the entire study period.[194] A striking finding in this study was a marked decrease in hospitalizations for croup after the winter of 1993-1994. This decrease continued in linear fashion for the remainder of the study duration. The authors suggest that the decreasing trend in croup hospitalizations was likely due to the increasing use of corticosteroid treatment in patients who presented to emergency departments with croup.

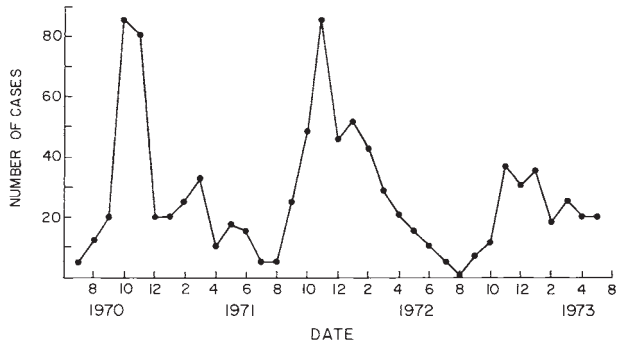

Figure 22–1 Seasonal occurrence of croup, Cardinal Glennon Memorial Hospital for Children emergency department, July 1970 to June 1973.

Because croup is caused by the same viruses that cause other respiratory illnesses, the method of spread probably is similar for all (see discussion of the common cold in Chapter 8). In children, most spread involves close person-to-person contact, with large droplets of virus-containing nasal secretions being applied to the nose from the hands of the future host or by close-range airborne acquisition. Parainfluenza viruses are common causes of colds in adults, so older individuals with trivial illnesses may be the source of more severe childhood croup.

PATHOLOGY

Laryngoscopic studies in acute laryngotracheitis reveal redness and swelling of the lateral walls of the trachea, just below the vocal cords.[48,49,211] Because the subglottic trachea is surrounded by a firm cartilaginous ring, the inflammatory swelling can occur only by encroaching on the patency of the airway; the subglottic space often is reduced to a slit 1 to 2 mm wide. As the disease progresses, the tracheal lumen becomes obstructed further by a fibrinous exudate, and its surface is covered by pseudomembranes composed of the exudative material. The vocal cords frequently are swollen, and their mobility is impaired.

Histologic study of postmortem material from the larynx and trachea reveals marked edema and cellular infiltration in the lamina propria, submucosa, and adventitia. The cellular infiltrate includes histiocytes, lymphocytes, plasma cells, and polymorphonuclear leukocytes.[19,20,157,167,185] The cotton rat model of laryngotracheitis caused by human parainfluenza virus type 3 reveals pathologic findings similar to those noted in human postmortem studies.[168] This model also indicates the time course of events. Early in the course of an infection (first 2 to 4 days), moderate mucosal and submucosal inflammatory infiltrates were noted in the subglottic and proximal tracheal regions. The infiltrates initially contained lymphocytes and neutrophils, and subsequently a mononuclear infiltrate with lymphocytes and macrophages in the submucosa was noted. Cell injury was most marked on days 6 to 8 after infection. The ciliated epithelial cells were blunted, with loss of cilia in large patches. By 12 days after infection, the region reverted to a nearly normal appearance.

*See references 23, 39, 63, 89, 110, 137, 148, 159, 160, 162, 166.

The older literature indicates that classic laryngotracheobronchitis and the same disease with pneumonia represent the extension of disease from the trachea to the bronchi and alveoli. The progressive obstructive disease with exudate and pseudomembrane obstruction at the bronchial and bronchiolar levels usually is the result of secondary bacterial involvement. In bacterial croup, the tracheal wall is infiltrated with inflammatory cells, and ulceration, pseudomembranes, and microabscess formation occur.* In addition to the findings in laryngotracheitis of viral origin, thick pus is present within the lumen of the trachea and lower air passages.[91,116,136,148] Spasmodic croup is an enigma because it occurs in association with respiratory viral infections similar to those that cause more severe laryngotracheitis. Using direct laryngoscopy, Davison[49] noted that the subglottic tissues in spasmodic croup showed noninflammatory edema.

PATHOGENESIS

Although the eventual site of clinically important pathologic change in laryngotracheitis is within the larynx and trachea, the initial acquisition of infection is similar to that of other respiratory viral infections and occurs within the upper air passages, including the nasal and pharyngeal epithelial surfaces. After acquisition of virus, infection of the cells of the local respiratory epithelium develops and spreads locally to involve the larynx and trachea. The initial symptoms of nasal stuffiness and throat irritation reflect the primary sites of involvement. Studies in organ culture systems and in the cotton rat model have shown that several respiratory viruses inhibit tracheal ciliary function and eventually lead to marked destruction of the epithelium and evidence of viral infection in the lamina propria.[126,168,182] In uncomplicated croup, failure of gas exchange within the lung, in addition to hypoxia resulting from subglottic tracheal obstruction, may occur.[163,214]

Parainfluenza viruses types 1, 2, and 3 all are significant causes of respiratory infections in children (see Chapter 191). Infection with parainfluenza virus type 3 occurs in most infants, whereas infections with types 1 and 2 generally occur more frequently in older children. Only a third of children have antibodies against these two viral types by the time they reach age 4 years.

Because parainfluenza viral infections are common occurrences in young children, and because only a few get croup, host factors probably are important factors in the pathogenesis. In contrast with the numerous studies of the pathogenesis of bronchiolitis and respiratory syncytial virus infection, few similar studies relating to parainfluenza viruses and croup have been reported.[37]

The above-presented pathologic data suggest that the findings in laryngotracheitis are directly virus-related (parainfluenza viruses types 1, 2 and 3 and influenza virus types A and B) owing to the direct cytopathic effect of a virus or related to the concomitant host response or perhaps both.[37] In the cotton rat model, the use of topical steroid therapy led to a significant reduction in the degree of inflammatory infiltrates and cell injury, which suggests that the host response contributes to the pathologic findings.[168] The pathogenesis of laryngotracheobronchitis and laryngotracheobronchopneumonitis is similar to that described previously, but with the extension of infection to the lower respiratory tract and, usually, the occurrence of secondary bacterial infection.

Many studies suggest that allergic factors play a role in recurrent croup.[24,93,165,223,229,230,231,238,235] Welliver and associates[230] found that children with croup caused by parainfluenza viral infections had titers of IgE-specific antibody in their nasopharyngeal secretions that were 3.6-fold higher than titers of similarly infected children with only upper respiratory infections. The children with croup had a cell-mediated immune response to parainfluenza virus that was 1.6-fold greater than that of the children with only upper respiratory infections.

In a subsequent review, investigators noted that an atopic disposition might be associated with the development of croup.[229] Children with croup caused by a parainfluenza virus had specific IgE antibodies and released histamine into the airway more frequently than did control patients with parainfluenzal viral upper respiratory infections. They also noted that children with recurrent croup had several atopic features, such as positive skin tests to environmental allergens, and were more likely to develop asthma when they grew older. Also, some children with a history of recurrent croup develop stridor with histamine challenge.

The above-mentioned studies by Welliver and associates[229,230] and other reports make it easy to accept a role of atopy in recurrent croup. What is difficult to explain, however, is why many apparent primary infections result in only spasmodic croup. As I have suggested previously, initial sensitization may be parainfluenza virus group–specific and not type-specific.[37] This proposal suggests that early infection (primary infection) with parainfluenza virus type 3 would set the stage for spasmodic croup with parainfluenza viral types 1 and 2. The primary infection itself could have been mild owing to transplacentally acquired antibody.

CLINICAL PRESENTATION

ACUTE LARYNGITIS

Table 22–4 summarizes clinical characteristics of laryngitis. Laryngitis is mainly a disease of older children, adolescents, and adults that is disturbing but self-limited. The specific clinical manifestation is hoarseness. Other symptoms depend on the causative infectious agent. Adenoviruses and influenza viruses cause the most severe instances of laryngitis. With these viruses, fever usually occurs, and sore throat, headache, muscle aches and pains, and prostration are common symptoms. In contrast, patients with laryngitis resulting from rhinoviral, parainfluenza viral, or respiratory syncytial viral infections have minimal or no fever and few systemic complaints. They usually have pronounced nasal symptoms (coryza and stuffiness), however. Occasionally, hoarseness may persist, which may be a result of secondary bacterial infection of the upper respiratory tract.

ACUTE LARYNGOTRACHEITIS

Although the clinical spectrum of acute laryngotracheitis varies considerably, its manifestations usually are significantly different from the manifestations of the other acute diseases with obstruction in the region of the larynx (see Table 22–4). Onset of illness usually is not alarming and suggests the onset of a cold. Initial symptoms are nasal complaints and include dryness, irritation, and coryza. Ordinary cough and the complaint of sore throat occur frequently. Fever is a usual occurrence within the first 24 hours, which is not true of the common cold. After a period as short as a few hours, but usually after 12 to 48 hours, upper airway obstructive signs and symptoms are seen. The cough first becomes "croupy" (sounding like a barking seal), and then evidence of respiratory stridor (difficulty associated with inspiration) gradually increases. Examination at this time reveals a child with a hoarse voice, coryza, a normal or minimally inflamed pharynx, and a slightly increased respiratory rate with a prolonged inspiratory phase. Temperature nearly always is between 37.8° C and 40.5° C (100° F and 105° F).

TABLE 22-4 Differential Diagnosis of Acute Obstruction in the Region of the Larynx

Category	Acute Epiglottitis	Laryngeal Diphtheria	Laryngitis	Acute Laryngotracheitis	Laryngotracheobronchitis and Laryngotracheobronchopneumonitis (Including Bacterial Tracheitis)	Spasmodic Croup	Foreign Body	Acute Angioneurotic Edema
Common age of occurrence	1-8 yr	All ages	Older children and adults	3 mo to 3 yr	3 mo to 3 yr	3 mo to 3 yr	All ages	All ages
Past and family history	Not contributory	No or inadequate immunization	Not contributory	Family history of croup	May be family history of croup	Family history of croup; perhaps previous attack	Occasional history of ingestion	Allergic history; perhaps previous attack
Prodrome	Occasionally coryza	Usually pharyngitis	Usually stuffy nose or coryza	Usually coryza	Usually coryza	Minimal coryza	None	Occasionally cutaneous allergic manifestations
Onset (time to full-blown disease)	Rapid; 4-12 hr	Slowly for 2- to 3-day period	Variable; 12 hr to 4 days	Moderate but variable; 12-48 hr	Usually gradually progressive; 12 hr to 7 days	Sudden; always at night	Usually sudden	Rapid
Symptoms on presentation Fever	Yes; usually 39.5° C (103° F)	Yes; usually 37.8° C to 38.5° C (100° F to 101° F)	Yes; 37.8° C to 39.4° C (100° F to 103° F) with adenoviral and influenza viral infections; usually minimal with other viruses	Yes; variable, 37.8° C to 40.5° C (100° F to 105° F)	Yes; variable, 37.8° C to 40.5° C (100° F to 105° F)	No	No, unless secondary infection	No
Hoarseness and barking cough	No	Yes	Yes	Yes	Yes	Yes	Usually no	No
Dysphagia	Yes; usually severe	Usually yes	No	No	No	No	Frequently yes	Yes
Inspiratory stridor	Yes; moderate to severe	Yes; minimal to severe	No	Yes; minimal to severe	Yes; usually severe	Yes; moderate	Variable	Yes

TABLE 22–4 Differential Diagnosis of Acute Obstruction in the Region of the Larynx—cont'd

Category	Acute Epiglottitis	Laryngeal Diphtheria	Laryngitis	Acute Laryngotracheitis	Laryngotracheobronchitis and Laryngotracheobronchopneumonitis (Including Bacterial Tracheitis)	Spasmodic Croup	Foreign Body	Acute Angioneurotic Edema
Toxic appearance	Severe	Usually no	No	Usually minimal	Usually moderate; may be severe	No	No	No
Signs on presentation								
Oral cavity	Pharyngitis and excessive salivation	Membranous pharyngitis	Normal or mild to moderate pharyngitis	Usually minimal pharyngitis	Usually minimal pharyngitis	Normal	Normal	Pale appearance
Epiglottis	Cherry-red and swollen	Usually normal; may contain membrane	Normal	Normal	Normal	Normal	Normal	Swollen and pale
Radiographs	Swollen epiglottis on lateral film	Not useful	Not useful	Subglottic narrowing on PA film	Subglottic narrowing on PA film; irregular soft tissue densities within trachea on lateral film	Not useful	May reveal foreign body	Swollen epiglottis on lateral film
Laboratory								
Leukocyte count	Usually markedly elevated with increased percentage of band forms	Usually elevated with increased percentage of band forms	Usually normal	Mildly elevated with >70% polymorphonuclear cells	Variable; usually mildly elevated with 70% polymorphonuclear cells; may be increased band count	Normal	Normal, unless secondary infection	Normal; sometimes eosinophilia
Bacteriology	Throat and blood cultures yield *Haemophilus influenzae* type b	Smear and culture from membrane reveal organism	Usually normal flora in throat; occasionally *Streptococcus pyogenes* in throat	Only important if secondary infection suspected	Normal throat flora; tracheal culture often yields *S. pyogenes*, *Staphylococcus aureus*, *Streptococcus pneumoniae*, or *H. influenzae*	Normal flora	Only important if secondary infection suspected	Normal flora
Clinical course	Rapidly progressive; cardiorespiratory arrest occurs within hours if not treated	Slowly progressive obstruction of airway	Hoarseness persists at a constant degree about 4-7 days; occasionally persists 2-3 wk	Variable speed of progression of obstruction; usually does not require surgical intervention	Degree of obstruction usually severe; persists 7-14 days; frequently requires surgical intervention	Symptoms of short duration with treatment; repeated attacks common	Variable depending on size and substance of foreign body	Variable; sometimes leads to rapid asphyxia without therapy

Data from references 48, 49, 53, 63, 70, 76, 89, 91, 111, 136, 137, 152, 215.

The speed of progression and final degree of upper airway obstruction vary. Some children have hoarseness and barking cough but no other evidence of obstruction; in these cases, the symptoms last approximately 3 to 7 days, with a gradual return to normal. In other cases, the obstruction is progressive and leads to severe respiratory distress with supraclavicular and infraclavicular and sternal retractions, cyanosis of varying degrees, and apprehension. With hypoxia, the cardiac rate increases, and the child becomes restless. Without intervention, asphyxial death occurs rapidly in some children. In others, the problem of hypoxia is more prolonged, and respiratory fatigue may lead to the patient's demise. The duration of illness in a severely affected child, regardless of therapy, is rarely less than 7 days and frequently is 14 days.

Laboratory study in acute laryngotracheitis is of only minimal value. The white blood cell count frequently is greater than 10,000 cells/mm^3, and polymorphonuclear cells predominate.[32,164] Very high white blood cell counts (>20,000/mm^3) with numerous band-form neutrophils should suggest bacterial superinfection or the possibility of acute epiglottitis. The posteroanterior chest radiograph reveals the subglottic narrowing (steeple sign), and a lateral neck radiograph indicates the size of the epiglottis.

ACUTE LARYNGOTRACHEOBRONCHITIS AND LARYNGOTRACHEOBRONCHOPNEUMONITIS (BACTERIAL TRACHEITIS)

Laryngotracheobronchitis and laryngotracheobronchopneumonitis are far less common occurrences than are laryngotracheitis and spasmodic croup; however, these illnesses occur more commonly than generally realized.* These entities may be considered an extension of acute laryngotracheitis, as numerous descriptions in the literature suggest.† The severity of the illness is due to secondary bacterial infection. Initial symptoms and signs are similar to those of laryngotracheitis (see Table 22–4). An afflicted child usually has mild to moderately severe illness for 2 to 7 days and then suddenly becomes markedly worse. Occasionally, upper and lower airway obstructions seem to occur simultaneously. In many children, the distress from tracheal obstruction is of such magnitude that the symptoms and signs of lower respiratory involvement go unnoticed. Symptoms and signs associated with extension of disease to the bronchi, bronchioles, and lung substance include rales, air trapping, wheezing, and a further increase in the respiratory rate. Obstruction in these illnesses usually is of such a degree that either intubation or tracheostomy is necessary.

Several instances of laryngotracheobronchopneumonitis with toxic shock syndrome have been observed.[21,31,166,202,209] Generally, children with these staphylococcal infections initially have the onset of croup, then the more severe manifestations of bacterial tracheitis develop, and finally the exanthem and other manifestations of toxic shock syndrome develop. An infant with tracheitis and supraglottitis caused by *M. catarrhalis* has been described.[2] Other findings in laryngotracheobronchitis and laryngotracheobronchopneumonitis are presented in Table 22–4.

SPASMODIC CROUP

In recent years, the clinical entity of spasmodic croup has been incorporated by many physicians into the overall diagnosis of croup. Although distinguishing mild cases of laryngotracheitis from spasmodic croup is difficult at the onset in some instances, the delineation of the two entities is important from prognostic and therapeutic perspectives (see Table 22–4).

Spasmodic croup occurs in children 3 months to 3 years old. The onset always is at night, and the characteristic presentation occurs in a child who previously was thought to be well or to have had a mild cold with coryza as the only symptom. The child awakens at night with sudden dyspnea, croupy cough, and inspiratory stridor. There is no fever. The symptoms apparently are the result of sudden subglottic edema; relief is achieved easily by general reassurance and administration of moist air. The occurrence of spasmodic croup tends to run in families, with repeated attacks occurring in some children. After one attack, the child is likely to have another attack the same evening and on three or four successive evenings. These attacks can be prevented by employing mild sedation at bedtime and ensuring that the bedroom air is adequately humidified.

DIFFERENTIAL DIAGNOSIS

The therapeutic approaches to the various acute obstructions in the region of the larynx vary markedly. Establishing a correct diagnosis is essential and frequently lifesaving. Table 22–4 lists the differential points of eight conditions with symptoms and signs of acute upper airway obstruction.

The most frequent serious differential diagnostic problem is the recognition of acute epiglottitis and its separation from the less fulminant laryngotracheitis. In epiglottitis (a rare disease in children today because of universal immunization with *H. influenzae* type B conjugate vaccines), the important differential points are lack of a croupy cough; the presence of a swollen, cherry-red epiglottis; the sitting posture of the child with the chin pushed forward and a reluctance or refusal to lie down; and the relatively greater apprehension and anxiety of the patient than the degree of chest retraction suggests. In contrast, a child with acute laryngotracheitis has a normal epiglottis on examination, always has a typical barking cough, is comfortable in a supine position, and frequently appears to have only minimal apprehension, despite retractions in which the sternum appears to be indenting 2 inches or more.

Early in the course of epiglottitis, the diagnosis can be confirmed only by the observation of the epiglottis, which can be done without difficulty.[127] Later in the disease, the posture of the child and the history of rapidly progressing disease render the differential from laryngotracheitis readily apparent, so examination of the epiglottis directly (a dangerous procedure if the child is forced to lie down) or indirectly by a lateral neck radiograph rarely is indicated and usually is contraindicated.

Laryngotracheobronchitis and laryngotracheobronchopneumonitis can be recognized by signs of lower respiratory involvement (rales, air trapping, wheezing, and pulmonary infiltrates on the radiograph). Bacterial disease should be suspected in laryngotracheobronchitis and laryngotracheobronchopneumonitis and when symptoms and signs become worse in laryngotracheitis. A lateral radiograph can be useful in the evaluation because it may reveal soft tissue densities within the trachea. Lateral neck and chest radiographs are regarded by many physicians as definitive tests to determine whether to rule out epiglottitis and laryngotracheitis. In a careful study by Stankiewicz and Bowes,[203] the sensitivity and specificity of both radiographs were low, however.

Although a rare occurrence today, laryngeal diphtheria always should be considered and ruled out in croup. Important in this regard are the history of immunization, the pharyngeal evidence of diphtheria, the relative slowness of the disease to progress, and a greater degree of hoarseness caused by direct laryngeal membrane formation.

*See references 11, 34, 39, 53, 58, 59, 63, 67, 85, 89, 91, 98, 111, 116, 136, 137, 148, 153, 160, 209, 236.

†See references 9, 19, 20, 47, 48, 68, 81, 102, 116, 150, 167, 180, 181, 184, 185.

Spasmodic croup rarely should be confused with acute laryngotracheitis, but a perusal of the literature indicates that the two entities most commonly are considered laryngotracheitis, which is unfortunate because prognostic considerations for the two entities are different. Spasmodic croup always is of sudden onset at night, occurs without fever, and is relieved by simple therapeutic modalities.

The possibility of a foreign body and angioneurotic edema always must be considered in upper airway obstructive disease. Differential points are presented in Table 22–4. Rarely, acute upper airway obstruction occurs in adolescents as a result of psychogenic and emotional factors.[80,120,192]

SPECIFIC DIAGNOSIS

The epidemiologic history frequently is an important factor in establishing a specific diagnosis. Obtaining bacterial culture specimens from the throat, laryngeal region, and blood is helpful in diagnosing epiglottitis and important in identifying laryngotracheitis, laryngotracheobronchitis, and laryngotracheobronchopneumonitis when secondary infection is suspected. The white blood cell count should be obtained because it can be helpful when secondary bacterial infection is considered.

A specific etiologic diagnosis can be made by the isolation of virus or its identification by a direct antigen test from a nasopharyngeal specimen. The diagnostic virologic facilities of many medical centers enable rapid identification of parainfluenza viruses, respiratory syncytial viruses, adenoviruses, most rhinoviruses, and influenza viruses to be established.

TREATMENT

During the last 65 years, the treatment of croup has created considerable controversy: tracheostomy versus no tracheostomy, intubation versus tracheostomy, warm versus cold humidification, antibiotics versus no antibiotics, corticosteroids versus no corticosteroids, sedation versus no sedation, and racemic epinephrine therapy versus mist therapy alone. Few of these controversies have been resolved scientifically, but the passage of time has lessened the importance of some of the discrepant opinions.

Of most importance in the evaluation of therapeutic modalities and the specific approach to therapy in croup is making an accurate differential diagnosis. A look at the most important controversy (the use of steroids) indicates that in most instances, cases of spasmodic croup, in which a favorable outcome invariably can be expected, were not separated clinically from cases of laryngotracheitis, in which the outcome is less predictable.

ACUTE LARYNGOTRACHEITIS AND SPASMODIC CROUP

In managing acute laryngotracheitis and spasmodic croup, each case must be treated individually; one child may need minimal therapy, whereas another may require consideration of all modalities. In all children with acute laryngotracheitis, attention should be given to the anxiety and apprehension of the patient and parents. The parents should be reassured immediately, and it is important that the child is not separated from them. Physical examination should be done rapidly by one physician, and all but absolutely necessary procedures should be deferred.

In the past, mist therapy was the cornerstone of management of croup. In more recent years, the value of this therapy has been questioned.[15,135,156,193] It had been my opinion, as expressed in previous editions of this book, that mist therapy in croup was useful. The results of a large randomized controlled trial[193] and the extensive review by Moore and Little[156] indicate, however, that mist treatment offers no benefit in treatment.

Oxygen should be administered to a child who is hypoxemic from respiratory distress. The studies of Newth and associates[163] and Taussig and colleagues[214] indicate that mild hypoxemia occurs more commonly than is realized clinically. The drying effect of oxygen is counterproductive to the removal of tracheal exudate, so it should not be used routinely.

Since 1952, numerous communications in the English medical literature have described the use of corticosteroids in croup. Nine double-blind, controlled studies were conducted before 1989.[61,62,107,127,132,134,199,207,210] In 1964, Eden and Larkin[62] noted no difference between control and methylprednisolone therapy in a study of 50 children with acute croup. In 1967, Eden and colleagues[61] studied another 50 patients and could find no benefit from dexamethasone compared with a control preparation. Sussman and colleagues[210] also could not show any benefit from dexamethasone therapy.

In contrast to these three studies, Skowron and coworkers[199] noted a slight benefit regarding duration of stridor, retractions, fever, and days in the hospital in a group receiving dexamethasone. They suggested, however, that steroids not be used routinely for laryngotracheitis because the overall benefits were minimal, and a potential risk exists in administration of steroids. In 1969, James[107] noted that dexamethasone-treated patients recovered from obstructive symptoms more quickly than did the control group. In another study involving 30 children, Leipzig and associates[134] concluded that dexamethasone in an adequate dose (0.3 mg/kg initially and repeated in 2 hours) given intramuscularly hastens the recovery from uncomplicated croup. This study and its predecessors have major inadequacies in design.[33,220] In a study with 72 children, Koren and colleagues[127] noted that dexamethasone did not offer any benefit to patients with laryngotracheitis but did decrease significantly the respiratory rate in children with spasmodic croup compared with placebo-treated control subjects. Although these findings were statistically significant, the benefits were not clinically significant.

Two additional modest studies of the use of dexamethasone in croup were published in 1988 and 1989, as was a meta-analysis of the evidence from the various randomized trials and a set of related editorials and a review.[4,115,132,198,200,207] Kuusela and Vesikari[132] concluded that dexamethasone was beneficial in acute spasmodic croup, and Super and associates[207] concluded that dexamethasone is beneficial in reducing the overall severity of moderate to severe acute laryngotracheitis during the first day of treatment.

The 1989 meta-analysis suggested that the use of steroids in children hospitalized with croup resulted in a significantly increased number with clinical improvement 12 hours and 24 hours after treatment and a reduced incidence of endotracheal intubation than occurred in the control subjects.[115] In this analysis, improvement at 12 hours was noted to be greater in the children who received higher initial doses of steroid (≥125 mg of cortisone) than in children who received lower doses.

In the early 1990s, nebulized steroids were evaluated in the treatment of croup, which led to another round of testimonials, controlled studies, and treatment articles supporting the efficacy of steroids.* Since the 1989 meta-analysis, more than 15 additional, controlled, steroid treatment trials have been performed, and another meta-analysis was published in 1999.[5] Finally, a large

*See references 5, 45, 84, 86, 101, 106, 108, 114, 122-125, 186, 187, 198, 229.

controlled trial of oral dexamethasone for mild croup was published in 2004, and a comprehensive meta-analysis was published in 2005.[13,190] Also published more recently are many articles comparing doses, types, and methods of administration of steroids and a further round of commentaries.*On the basis of the three meta-analyses and the specific studies analyzed, most reviews on the management of croup recommend the routine use of steroids (administered orally, intramuscularly, or by nebulization) in the treatment of croup.†

In the past, when I reviewed the data on the use of steroids in croup, what concerned me was that the specific clinical entity that was being treated was poorly defined and that no evidence indicated that steroids worked in any illness other than spasmodic croup.[33] Of most concern to me today is that the risks of steroid use have not been evaluated and that, because of small sample sizes in all but two of the available studies, they cannot be evaluated by meta-analysis.
