CHAPTER 248

Antibacterial Therapeutic Agents

Ian C. Michelow ✪ George H. McCracken, Jr.

This review of the use of antimicrobial agents is divided into two sections: (1) the clinical pharmacology of currently available antibacterial drugs and (2) the various aspects of administration of antimicrobial agents to infants and children. The second section includes dosage schedules and routes, prophylactic use of antimicrobial agents, considerations in writing orders and prescriptions, and other aspects of administration. Drugs of value in the treatment of disease caused by viruses, fungi, mycobacteria, and parasites are discussed in other chapters dealing with these pathogens. For the most part, only antimicrobial agents approved for use in infants and children by the U.S. Food and Drug Administration (FDA) are discussed, although promising new agents that are likely to be approved are mentioned where relevant.

CLINICAL PHARMACOLOGY

The antibacterial agents of value in treating infectious diseases in infants and children may be classified into five groups:

1. The β-lactams, including penicillins, cephalosporins, carbacephems, monobactams, and carbapenems
2. The glycopeptides (i.e., vancomycin)
3. The aminoglycosides
4. The macrolides, including erythromycin, clarithromycin, and azithromycin
5. Miscellaneous antibacterial agents, including chloramphenicol, clindamycin, colistin, fluoroquinolones, linezolid, rifamycins, the sulfonamides, and the tetracyclines

The following properties that govern the use of each group of drugs in infants and children are considered: mechanism of action, mechanisms of resistance, in vitro efficacy, pharmacokinetics, therapeutic uses, available preparations, and side effects and toxicity.

β-LACTAMS

BIOCHEMICAL STRUCTURE

The β-lactams are a large group of compounds that have in common a four-membered β-lactam ring. The subclasses of β-lactams differ from one another with regard to their side chains and the presence of other ring structures: the penicillins contain

a five-membered thiazolidine α-ring fused to the β-lactam ring,[155] the cephalosporins have a six-membered dihydrothiazine instead of the thiazolidine ring, and the carbacephems have a methylene group replacing the sulfur atom in the dihydrothiazine ring of the cephalosporin nucleus. The β-lactam ring is essential for antibacterial activity, whereas the side chains influence the pharmacologic properties of the β-lactam and the spectrum of antibacterial activity.

MECHANISM OF ACTION

Our understanding of the mechanism of action of the β-lactams has evolved over the past 3 decades. Previously, researchers thought that binding of β-lactam to a bacterial cell membrane–associated enzyme (transpeptidase) blocked the terminal step in synthesis of the peptidoglycan layer of the bacterial cell wall. Cell death would ensue because the weakened cell wall could not withstand the osmotic and mechanical pressure resulting from a growing bacterium.[268] More recent evidence suggested that it is a more complex process involving activation of endogenous autolytic systems[196,270] and inhibition of bacterial enzymes called the *penicillin-binding proteins* (PBPs), which include transpeptidase, carboxypeptidase, and endopeptidase. These enzymes are located beneath the cell wall and are responsible for cell wall synthesis by achieving cross-linkage between peptide chains of peptidoglycans. PBPs are vital for cell division, cell shape, and structural integrity. Because the specific PBPs within each bacterial species and the affinity of each β-lactam antibiotic for a particular PBP differ, some β-lactams have better activity than do others against particular bacteria. The various β-lactam antibiotics can have different morphologic effects on the same bacterial species; this property is thought to be related to specific functions of the PBP to which the β-lactam binds.[257] Some bacteria have a deficiency in the system of autolytic enzymes that results in inhibition, but not killing of the bacteria by a β-lactam that otherwise would be bactericidal. This phenomenon is called *tolerance* and is demonstrated in vitro by a minimal inhibitory concentration (MIC) in the susceptible range and a ratio of minimal bactericidal concentration (MBC) to MIC of 32 or greater.[118]

β-Lactam antibiotics are bactericidal against most susceptible bacteria. The nature of the bactericidal activity has been described as time-dependent, as opposed to the concentration-dependent bactericidal activity of aminoglycosides.[169] Bactericidal activity is thought to be optimal when the concentration of β-lactam antibiotic at the site of infection is 4 to 10 times greater than that of the MIC (or MBC) of the infecting organism. The rapidity and extent of killing are not increased when concentrations exceed that ratio. A more important determinant of bactericidal activity for β-lactams is the length of time during the dosing interval that the concentration of antibiotic exceeds the MIC (time > MIC) for the infecting organism. Optimal bacterial killing correlates with time greater than MIC that exceeds 40 to 50 percent of the dosing interval.[71]

MECHANISMS OF RESISTANCE

Bacteria can acquire resistance to an antibiotic by at least four mechanisms: (1) alteration in the antimicrobial target, (2) decreased uptake of the antibiotic by expression of efflux pumps or by reduction of cell membrane permeability that is determined by porin channels, (3) production of an enzyme that inactivates the antibiotic, and (4) production of an alternative metabolic pathway that bypasses the action of the drug.[262] With respect to β-lactam antibiotics, resistance involves alterations in PBPs leading to decreased affinity for the β-lactam, decreased permeability of the bacterial cell wall resulting in diminished amounts of β-lactam reaching the PBPs, or production of β-lactamases that hydrolyze the β-lactam ring. Hydrolysis of β-lactams is the mechanism that is most significant clinically. Gram-positive bacteria excrete their β-lactamases outside the cell wall, whereas the β-lactamases of gram-negative bacteria remain in the periplasmic space. The spectrum of β-lactamase activity involves the following: narrow-spectrum penicillinases that preferentially hydrolyze penicillins; broad-spectrum β-lactamases that hydrolyze penicillins and cephalosporins equally well; cephalosporinases that preferentially hydrolyze cephalosporins and are resistant to inhibition by clavulanic acid; and ESBLs that hydrolyze first-, second-, and third-generation cephalosporins but are susceptible to inhibition by clavulanic acid; and carbapenemases that inactivate all β-lactams, including imipenem-cilastatin.[51]

PENICILLINS

Although first discovered by Fleming in the late 1920s, penicillin G was not available for general use in the United States for another 20 years. Since that time, numerous semisynthetic penicillins have been developed. The penicillins can be classified into four groups based on their antimicrobial activity, with some overlap (Table 248–1). The spectrum of activity among the compounds within each group usually is similar, whereas differences are attributable to their pharmacologic properties (Table 248–2).

Penicillin G and Penicillin V

Despite the more than 50 years that penicillin G has been in use, some bacteria continue to be exquisitely susceptible. Resistant strains of *Streptococcus pyogenes* (group A Streptococcus) and *Streptococcus agalactiae* (group B Streptococcus) have not emerged. Penicillin G remains the drug of choice for the treatment of disease caused by a wide variety of microorganisms (Table 248–3).

TABLE 248–1 Classification Scheme for Penicillins

Generic Name	Trade Name	Route
Natural Penicillins		
Penicillin G	Many	PO,* IM, IV
Penicillin V	Many	PO
Aminopenicillins		
Ampicillin	Many	PO, IM, IV
Amoxicillin	Many	PO
Amoxicillin/clavulanate	Augmentin	PO
Ampicillin/sulbactam	Unasyn	IM, IV
Bacampicillin	Spectrobid	PO
Penicillinase-Resistant Penicillins		
Cloxacillin	Cloxapen	PO
Dicloxacillin	Dycill, Dynapen, Pathocil	PO
Methicillin	Staphcillin	IM, IV
Nafcillin	Nafcil, Nallpen, Unipen,	IM, IV, PO
Oxacillin	Bactocill, Prostaphlin	IM, IV, PO
Extended-Spectrum Penicillins		
Ticarcillin	Ticar	IM, IV
Ticarcillin/clavulate‡	Timentin	IV
Mezlocillin	Mezlin	IM, IV
Piperacillin†	Pipracil	IM, IV
Piperacillin/tazobactam†	Zosyn	IV

**No longer available.*
†Safety and efficacy have not been established for children younger than 12 years.
‡Safety and efficacy have not been established for children younger than 1 month.
IM, Intramuscularly; IV, intravenously; PO, orally.

TABLE 248–3 Microorganisms for Which Penicillin G or V Is the Drug of Choice

Actinomyces israelii
Bacillus anthracis
Clostridium species
Corynebacterium diphtheriae
Erysipelothrix rhusiopathiae
Leptospira species
*Neisseria gonorrhoeae**
*Neisseria meningitidis**
Pasteurella multocida
Spirillum minus
Staphylococcus aureus†*
Streptobacillus moniliformis
Streptococcus groups A, B, C, D, G; viridans group†; anaerobic strains
Streptococcus pneumoniae†
Treponema pallidum

**Strains that do not produce β-lactamase.*
†Only those without altered penicillin-binding proteins.

The mechanism by which most bacteria have acquired resistance to penicillin G is that of β-lactamase production; resistance caused by altered PBPs occurs less commonly. Most strains of *Staphylococcus aureus* and *Staphylococcus epidermidis* produce penicillinase. *Neisseria gonorrhoeae* gradually developed resistance to penicillin G beginning in the late 1960s by various mechanisms including plasmid-mediated production of a TEM-1–like β-lactamase, as well as chromosomal mutations in at least four genes (*penA*, *penB*, *ponA*, and *mtrR*) that encode increased expression of an efflux pump and alterations in PBPs and porins.[215] Mechanisms of β-lactam resistance in *Bacteroides* spp. and other gram-negative anaerobes include production of class A β-lactamases (penicillinase or cephalosporinase) and class B metallo-β-lactamases that hydrolyze carbapenems, as well as alteration of PBPs.[14] Historically, penicillin has been the antibiotic of choice for treatment of *Neisseria meningitidis* infections, but strains with reduced susceptibility to penicillin have been reported in Europe, South America, Asia, Australia, and the United States, where approximately 15 percent of strains have alterations in PBP2 encoded by the *penA* gene that likely results from mosaic genes derived through transformation with DNA from commensal *Neisseria* spp. in the nasopharynx of colonized individuals. Although penicillin resistance resulting from production of β-lactamase has been reported, such strains are extremely rare.[143]

Of particular concern is the global dissemination of strains of *Streptococcus pneumoniae* resistant to penicillin G as a result of altered PBPs. The first documented clinical case of infection caused by penicillin-resistant pneumococcus was reported in 1967 from Australia. Surveillance data in the United States estimated the average rate of penicillin nonsusceptibility to be 33 percent (high-level resistance, 16%) with the highest incidence of 44 percent reported in the south-central region.[138] However, since the introduction of the pneumococcal conjugate vaccine in 2000, disease in young children caused by vaccine serotypes of penicillin-nonsusceptible *S. pneumoniae* has decreased by approximately 90 percent. Conversely, invasive disease caused by non-vaccine serotypes increased.[162] Currently, approximately 6 percent of pneumococci in the United States exhibit a multidrug-resistance phenotype defined as resistance to penicillin, trimethoprim-sulfamethoxazole (TMP-SMX), erythromycin, clindamycin, and tetracycline.[138] Although penicillin-resistant pneumococcal meningitis has developed in patients who were receiving vancomycin for pneumococcal sepsis,[61] no treatment failures have been documented when the appropriate dosage of vancomycin was administered.

In 2008, the Clinical and Laboratory Standards Institute published new *S. pneumoniae* breakpoints for penicillin because of a reevaluation that showed clinical response to penicillin was being preserved in clinical studies of pneumococcal infection, despite reduced susceptibility response in vitro. Under the former criteria, susceptible, intermediate, and resistant MIC breakpoints for penicillin were <0.06, 0.12-1, and >2 μg/mL, respectively, for all pneumococcal isolates, regardless of clinical syndrome or route of penicillin administration. Those breakpoints remain unchanged for patients without meningitis who can be treated with oral penicillin. However, for patients without meningitis who are treated with intravenous penicillin, the new breakpoints are <2, 4, and >8 μg/mL, respectively. Furthermore, isolates from patients with meningitis are now categorized as either susceptible or resistant, with intravenous penicillin breakpoints of <0.06 or >0.12 μg/mL, respectively. Use of narrow-spectrum agents, such as penicillin, is encouraged to prevent the spread of antimicrobial-resistant *S. pneumoniae* and also the spread of methicillin-resistant *S. aureus* and *Clostridium difficile*, which can result from use of broader-spectrum antimicrobials.

Several oral and parenteral forms of penicillin G are available. Selection of a preparation is based on the pattern of antimicrobial activity, including the peak and duration of activity in serum and tissues, and factors that reflect absorption, distribution, and excretion of the drug. These characteristics of penicillins are as follows:

1. Aqueous (water-soluble) penicillin G produces high peak concentrations of antibacterial activity in serum within 30 minutes after intramuscular administration but is excreted rapidly; thus, the concentration in serum is low within 2 to 4 hours. If aqueous penicillin G is given by the intravenous route, the peak is higher and occurs earlier, and the duration of antibacterial activity in serum is shorter (≈2 hours). Aqueous penicillin G given intravenously is used for severe disease such as meningitis, complicated pneumonia, and endocarditis caused by susceptible pathogens. In such cases, the drug should be administered at frequent intervals, usually every 4 hours, until the infection has been controlled.

2. Procaine penicillin G given intramuscularly produces lower concentrations of serum antibacterial activity (≈10% to 30% of the peak concentration achieved by the same dosage of the aqueous form), but activity persists in serum for as long as 12 hours. Intramuscular administration of procaine penicillin G should be reserved for patients with mild to moderate disease who cannot tolerate oral preparations. A 10-day course of this agent may be used as an alternative to intravenously administered aqueous penicillin G for infants with documented or suspected congenital syphilis.[278]

3. Benzathine penicillin G given intramuscularly is a repository preparation that provides low concentrations of serum activity (≈1% to 2% of the peak concentration achieved by the same dosage of the aqueous form). After administration of this drug, concentrations of penicillin are measurable in serum for 3 weeks or more and in urine for several months. Pain at the site of injection is the major deterrent to widespread use of this unique antibiotic. A combination of the benzathine and procaine salts (900,000 and 300,000 U, respectively) is a less painful treatment and is comparable in efficacy to benzathine alone (1,200,000 U) for the treatment of streptococcal pharyngitis.[22] Benzathine penicillin G is appropriate for only highly sensitive organisms present in tissues that are well vascularized so that the drug can diffuse readily to the site of infection. Thus, benzathine penicillin G is suitable for treatment of children with group A streptococcal pharyngitis or impetigo and for prophylaxis of streptococcal infection in children who have had rheumatic carditis. Current recommendations by the Centers for Disease Control and Prevention (CDC)[278] for management of syphilis include the use of benzathine penicillin G for primary, secondary, and early latent syphilis (<1 year's duration). Benzathine penicillin G also is recommended for infants with suspected congenital syphilis who do not meet the criteria for therapy with a 10-day course of aqueous or procaine penicillin G and whose follow-up can be ensured for repeat serologic testing.

4. Oral preparations of buffered penicillin G (no longer available in the United States) and phenoxymethylpenicillin (penicillin V) are absorbed well from the gastrointestinal tract. The peak concentration of serum activity of penicillin V is approximately 40 percent and that of buffered penicillin G is approximately 20 percent of the concentration achieved by the same dosage of aqueous penicillin G administered intramuscularly. Therefore, oral penicillins may be satisfactory for treating mild to moderately severe infections caused by susceptible organisms. Penicillin V and penicillin G have equivalent activity in vitro against gram-positive cocci, but penicillin V is less active than is penicillin G against *N. meningitidis*, *N. gonorrhoeae*, and susceptible strains of *Haemophilus influenzae*.[155] The benefit of treating streptococcal tonsillopharyngitis with a 10-day regimen of penicillin V for the prevention of acute rheumatic fever is based on indirect evidence derived from rates of pharyngeal eradication of *S. pyogenes* equivalent to those of injectable penicillin, the treatment with proven efficacy.[80,252]

All penicillins are excreted by both glomerular filtration and tubular secretion. The concomitant use of probenecid, a drug that blocks tubular secretion of organic acids, with a penicillin can produce higher peaks and more sustained concentrations of antimicrobial activity. Dosages and dosing intervals may need adjustment when penicillins are administered to persons with altered renal function.

Penicillinase-Resistant Penicillins

The semisynthetic penicillinase-resistant penicillins were developed in response to the emergence of penicillinase-producing staphylococci. The acyl side chain, by means of steric hindrance, prevents hydrolysis of the β-lactam ring by penicillinases. Most strains of *S. aureus* produce penicillinase, regardless of whether the infection is health care–associated or community-acquired. Thus, penicillinase-resistant penicillins are the β-lactams of choice for the initial management of patients with suspected staphylococcal disease. However, alternative effective antimicrobials should be substituted or added if endemic rates of antibiotic resistance exceed 10 to 15 percent or if the severity of the disease warrants empiric treatment of methicillin-resistant *S. aureus* (MRSA).[110] With the exception of methicillin, these agents are active against streptococci and can be used for empiric treatment of infections commonly caused by both staphylococci and streptococci. Because these agents are less active than is penicillin G against streptococci, penicillin G should be used instead of these agents if streptococci alone are isolated from culture. Penicillinase-resistant penicillins have no activity against gram-negative bacteria or enterococci.[181]

Methicillin was the first penicillinase-resistant penicillin to be introduced and was available in parenteral form only. Oxacillin and nafcillin are available in both parenteral and oral preparations. Cloxacillin and dicloxacillin are available in oral forms only and are absorbed more efficiently from the gastrointestinal tract than are the other oral drugs. Differences among these five penicillins include routes of elimination, degree of binding to proteins and degradation by β-lactamases, and in vitro susceptibility.[207] However, all are effective in the treatment of susceptible strains of staphylococcal isolates, and clinical studies have shown them to be equivalent when used at appropriate dosage schedules. Suspension formulations are poorly tolerated because of their unpleasant taste. Disease caused by methicillin-resistant staphylococci was reported shortly after introduction of the drug in the 1960s. Resistance is caused by alterations in PBPs, rather than production of β-lactamase. The *mecA* gene encodes a new PBP2a that has low affinity for β-lactams, thereby resulting in resistance to all β-lactam antibiotics currently available, including penicillinase-resistant penicillins, cephalosporins, and carbapenems. The *mecA* gene is carried on one of four mobile genetic elements known as the staphylococcal chromosomal cassette (SCC)*mec* I to IV that differ in size and the presence of additional resistance genes. The mechanisms of resistance to other antibiotics are unrelated to PBPs and may be plasmid-mediated or chromosomal.[179] SSC*mec* IV is found predominantly in community-acquired strains of MRSA (CA-MRSA) that are not associated with multidrug resistance, whereas SSC*mec* I to III are found typically in health care–associated strains that are resistant to multiple antibiotics including aminoglycosides, clindamycin, fluoroquinolones, fusidic acid, macrolides, rifampin, sulfonamides (TMP-SMX), and tetracyclines.[232] However, these distinguishing characteristics are tending to merge as *S. aureus* becomes increasingly resistant. Coagulase-negative staphylococci, including *S. epidermidis*, are residents of the normal microbial flora of the skin and are occasional contaminants of body fluid cultures. These organisms can be pathogens in certain settings, such as in

neonates, or in infections of prosthetic devices, such as heart valves or cerebrospinal fluid (CSF) shunts. Most strains of coagulase-negative staphylococci produce a penicillinase that inactivates penicillin G, penicillin V, and ampicillin, and many strains have *mecA*-mediated altered PBP2a leading to methicillin resistance. In addition, these methicillin-resistant, coagulase-negative staphylococci frequently are resistant to cephalosporins, erythromycin, and clindamycin. Vancomycin is the drug of choice for pathogenic coagulase-negative staphylococci and severe disease known or suspected to be caused by MRSA. Some experts advocate the addition of nafcillin or oxacillin for empiric therapy for suspected MRSA in patients who are severely ill, although toxicity may be increased with combination therapy.[96,110]

Aminopenicillins

The aminopenicillins are semisynthetic β-lactam antibiotics formed by the addition of an amino group to benzylpenicillin. Amoxicillin differs from ampicillin by the presence of a hydroxyl group on the phenyl side chain. The aminopenicillins were the first penicillins that had activity against some gram-negative organisms, including *H. influenzae*, *Escherichia coli*, *Proteus mirabilis*, *Salmonella* spp., and *Shigella* spp., while retaining activity against penicillin-susceptible, gram-positive bacteria.[206]

When compared with penicillin G, aminopenicillins are significantly more active against *Listeria monocytogenes*, slightly more active against enterococci, equally active against *Actinomyces*, *N. meningitidis*, and clostridial and corynebacteria species, and slightly less active against group A streptococci, group B streptococci, and pneumococci. Aminopenicillins are the drugs of choice for the treatment of infections caused by *L. monocytogenes* and enterococci. Other organisms susceptible in vitro to ampicillin and amoxicillin include non–penicillinase-producing strains of *H. influenzae*, *Moraxella catarrhalis*, *N. gonorrhoeae*, *S. aureus*, *E. coli*, *Salmonella*, and *Shigella*. A survey of health care–associated and community-acquired *H. influenzae* and *M. catarrhalis* strains isolated from the blood and respiratory tracts of children in North America documented ampicillin resistance rates of 34 percent and 99 percent, respectively.[142] The in vitro spectrum of activity for amoxicillin and ampicillin is identical, except amoxicillin is two times less active against *Shigella* and two to four times more active against enterococci and *Salmonella* than is ampicillin.[206]

As seen with penicillin G, the primary means of acquired resistance to aminopenicillins is the production of β-lactamase. However, organisms that are resistant to penicillin G or to methicillin because of altered PBPs—*S. pneumoniae* and *S. aureus*, respectively—also are resistant to aminopenicillins. β-Lactamase–negative, ampicillin-resistant strains of *H. influenzae* have been identified in the United States much less frequently than in Japan (0.2% versus 2.6%, respectively).[134]

The broad-spectrum bactericidal activity of ampicillin and amoxicillin provides the basis for the use of these drugs as empiric therapy for lower respiratory infections and acute otitis media, for which amoxicillin remains the drug of choice.[9] Aminopenicillins are indicated for treatment of susceptible strains of *Shigella*- or *Salmonella*-associated enteric infections as well as susceptible acute and chronic infections of the urinary tract. By bacteriologic and clinical measures, amoxicillin is significantly less effective than is ampicillin for the treatment of shigellosis.[204]

Both drugs are available for oral administration; ampicillin alone is available in a parenteral form. Amoxicillin provides higher and more prolonged serum concentrations than those achieved with equivalent dosages of ampicillin; thus, amoxicillin can be given in lower dosage, two or three times a day rather than four times, as required for ampicillin. An additional advantage of amoxicillin is that absorption is not altered when the antibiotic is administered with food, whereas absorption of ampicillin is decreased significantly when it is given with food. Ampicillin is associated more frequently with diarrhea than is amoxicillin.

Extended-Spectrum Penicillins

Extended-spectrum penicillins are semisynthetic derivatives of ampicillin that have better activity against gram-negative organisms because of a higher affinity for PBPs and greater penetration through the gram-negative outer membrane. Carbenicillin and ticarcillin, the carboxypenicillins, have a carboxyl group replacing the amino group side chain of ampicillin, whereas the acylureidopenicillins have a ureido (urea) side chain (mezlocillin) or ureido and piperazine side chains (piperacillin). Their pharmacologic properties are similar and include susceptibility to hydrolysis by staphylococcal penicillinases and, to a lesser extent, the β-lactamases of gram-negative bacteria. They differ somewhat in their toxicities and spectrum of activity.

The activity of carbenicillin is equivalent to or slightly less than that of ampicillin against non–β-lactamase–producing *N. gonorrhoeae*, *N. meningitidis*, *H. influenzae*, *E. coli*, *P. mirabilis*, *Salmonella* spp., and *Shigella* spp. It is less active than ampicillin against group A streptococci, pneumococci, and enterococci. Its activity is variable against many *Bacteroides fragilis*, *Enterobacter*, and *Serratia* organisms, and it is not active against *Klebsiella*. An oral preparation, carbenicillin indanyl (Geocillin) is active against susceptible strains of *Pseudomonas aeruginosa*, but its production was discontinued in 2008.

The activity of ticarcillin is similar to that of carbenicillin, but it is two to four times more active against some strains of *P. aeruginosa* and less active against gram-positive cocci. In addition, ticarcillin can be used for infections caused by susceptible strains of *Acinetobacter*. Because of its increased activity, ticarcillin may be used in smaller doses than needed with carbenicillin for the treatment of disease caused by gram-negative organisms.

Piperacillin and mezlocillin are parenteral penicillins with a spectrum of activity similar to that of ticarcillin but greater activity in vitro against some gram-negative bacilli and anaerobic bacteria. In vitro studies against *P. aeruginosa* demonstrated that piperacillin has activity that is four times that of mezlocillin and ticarcillin and about eight times that of carbenicillin, the clinical significance of which is unknown. Piperacillin and mezlocillin are more active in vitro than are carbenicillin or ticarcillin against susceptible strains of *E. coli*, *Klebsiella*, *Enterobacter*, *Serratia*, and *B. fragilis*. Furthermore, piperacillin, mezlocillin, and ticarcillin are effective in the treatment of infections caused by susceptible strains of *Citrobacter*, indole-positive *Proteus*, and *Providencia*. Carbenicillin and ticarcillin are disodium salts and contain 4.7 mEq (108 mg) and 5.2 mEq (120 mg) of sodium per gram, respectively. The acylureidopenicillins are monosodium salts that have a lower sodium content (1.9 to 2.2 mEq) than those of the carboxypenicillins. The amount of sodium administered may be of concern when treating certain patients with renal or cardiac disease. Hypokalemia with metabolic alkalosis occasionally occurs with the administration of extended-spectrum penicillins, especially the carboxypenicillins. The penicillin acts as a nonreabsorbable anion in the distal renal tubules, where it affects normal hydrogen exchange and secondarily results in loss of potassium. These extended-spectrum penicillins can bind to platelet adeno-sine diphosphate receptors and thereby result in abnormal platelet aggregation and prolonged bleeding times. This dose-related phenomenon occurs more frequently with the administration of ticarcillin than with the acylureidopenicillins. The effects on platelet function may be a consideration when choosing empiric therapy for a thrombocytopenic patient with suspected gram-negative infection.[280]

When carboxypenicillins or ureidopenicillins have been used as single agents for empiric treatment of patients with severe gram-negative infections, fever and neutropenia, or polymicrobial intra-abdominal infections, bacterial resistance has developed

in 10 to 15 percent of cases during treatment. Combinations of extended-spectrum penicillins with an aminoglycoside demonstrate synergistic in vitro inhibition of certain gram-negative bacteria, including *P. aeruginosa*. Based on in vitro data and clinical experience, extended-spectrum penicillins should be combined with an aminoglycoside in some patients (particularly if immunocompromised) with severe infections, to prevent the development of bacterial resistance.[280] All the extended-spectrum penicillins are available in parenteral formulations only. Because of limited clinical experience in infants and children, piperacillin has not been approved for use in patients younger than 12 years old.

β-Lactam–β-Lactamase Inhibitor Combinations

β-Lactamase inhibitors are compounds that have weak antibacterial activity but can bind irreversibly to the catalytic site of many β-lactamases and render them inactive. The inhibitors currently in use are clavulanic acid, sulbactam, and tazobactam, the latter of which are halogenated penicillanic acid derivatives. All three inhibitors are identical in their mode of activity but differ to some degree in their potency and spectrum of enzyme inhibition. These agents primarily inhibit the plasmid encoded β-lactamases and less frequently the chromosomally encoded β-lactamases. β-Lactamases are classified on the basis of their (1) responses to β-lactamase inhibitors, (2) spectrum of antibiotic substrates (Bush classification, groups 1 to 4), or (3) primary molecular structure (Amber classification); serine β-lactamases are class A, C or D; metalol-β-lactamases are class B. Bush group 2 corresponds to Amber classes A and D, which are encoded frequently by genes carried on plasmids and easily spread among different species, whereas Bush groups 1 and 3 (Amber classes C and B, respectively) are frequently encoded by chromosomal genes and therefore are confined to certain species.[74,218] Chromosomally mediated, inducible Bush group 1 β-lactamases that are produced by certain species of *Citrobacter*, *Enterobacter*, *Morganella*, *Pseudomonas*, and *Serratia* are not inhibited by the β-lactamase inhibitors, and, consequently, they remain resistant to the accompanying β-lactam. However, *Bacteroides*, *Klebsiella*, *Legionella*, and *Moraxella* spp. produce chromosomally mediated β-lactamases that are effectively inactivated. The β-lactamase inhibitors are most effective against *S. aureus*, *H. influenzae*, *M. catarrhalis*, *Bacteroides* spp., *E. coli*, and other Enterobacteriaceae. Clavulanic acid and tazobactam are more potent inhibitors of β-lactamases. Furthermore, clavulanate induces Bush group 1 enzymes. Disks containing β-lactamase inhibitors can be used in the clinical microbiology laboratory to detect pathogens that produce Amber class A extended-spectrum β-lactamases (ESBLs) of the TEM and SHV types that may be overlooked otherwise.[52] β-Lactamase inhibitors have been formulated in a fixed ratio with a β-lactam antibiotic. The spectrum of activity of each combination is determined primarily by the spectrum of activity of the β-lactam. However, many determinants of the inhibitor influence its activity, including its affinity for the β-lactamase and its ability to traverse the gram-negative cell wall to bind to periplasmic β-lactamases.[173] From a clinical perspective, all three β-lactamase inhibitors are considered therapeutically equivalent. The main indication for the use of these combination antimicrobial agents is for the treatment of health care–associated infections or infections caused by susceptible β-lactamase–producing pathogens.

AMOXICILLIN-CLAVULANIC ACID

Amoxicillin combined with potassium clavulanate was introduced in 1984 for oral administration. The pharmacokinetic properties of the two drugs are similar; both are absorbed rapidly and are not affected when taken with meals. Gastrointestinal side effects, including nausea, vomiting, and diarrhea, occur more commonly with amoxicillin-clavulanate than with amoxicillin alone.[154]

The combination drug is equivalent to amoxicillin alone in activity against amoxicillin-susceptible organisms. The addition of clavulanic acid extends the activity of amoxicillin to include β-lactamase–producing strains of *S. aureus* (but not methicillin-resistant strains), *H. influenzae*, *M. catarrhalis*, *N. gonorrhoeae*, *E. coli*, *Proteus*, *Klebsiella*, *Providencia*, *Haemophilus ducreyi*, and some anaerobic bacteria, including *B. fragilis*. Some β-lactamase–producing, gram-negative bacilli are resistant to amoxicillin-clavulanic acid because of either hyperproduction of β-lactamase or production of a β-lactamase that is not susceptible to clavulanate. Amoxicillin-clavulanate is not active against penicillin-resistant *S. pneumoniae* or vancomycin-resistant enterococci.

Amoxicillin is considered the preferred therapy for low-risk children with uncomplicated, mild to moderately severe disease of the respiratory tract, including initial empiric therapy for otitis media. In children who are at risk for penicillin-nonsusceptible pneumococcal acute otitis media, a 90-mg/kg daily regimen in two divided doses is recommended. Alternative therapy, including amoxicillin-clavulanic acid, should be considered if a β-lactamase–producing organism is known or suspected to be the cause of the disease based on risk factors, treatment experience, or microbiologic results. In 2001, high-dose amoxicillin-clavulanic acid suspension (Augmentin ES-600; 600 mg of amoxicillin/5 mL) was approved for use in children in the United States. The recommended dosage of this formulation is 90 mg/kg/day in two divided doses for the treatment of high-risk patients with acute otitis media.[9] The high ratio (14:1) of amoxicillin to clavulanate optimizes the penicillin dose without intensifying the risks of undesirable adverse effects associated with the β-lactamase inhibitor. The combination drug is useful in areas where the proportion of β-lactamase–producing strains of *H. influenzae* is large (>30%) and where *M. catarrhalis* organisms (most of which are β-lactamase producers) are identified more frequently as pathogens in otitis media, sinusitis, and other respiratory tract infections. Amoxicillin-clavulanate also has been used successfully for the oral treatment of urinary tract, skin, and soft tissue infections, as well as for the treatment of human and animal bite wounds.[52]

AMPICILLIN-SULBACTAM

Ampicillin combined with sulbactam as a parenteral β-lactam–β-lactamase inhibitor combination was approved in 1987. The spectrum of activity of ampicillin-sulbactam is similar to that of amoxicillin-clavulanate. It is most useful as monotherapy for potential polymicrobial intra-abdominal or gynecologic infections and is effective for treatment of soft tissue, urinary tract, and respiratory tract infections. Ampicillin-sulbactam has been shown to be safe and efficacious for the treatment of skin and skin structure infections caused by susceptible organisms in children aged 3 months to 12 years.[16] The combination of ampicillin-sulbactam and an aminoglycoside has efficacy equivalent to that of a combination of ampicillin, clindamycin, and an aminoglycoside for empiric treatment of intra-abdominal infections in children.[66] Ampicillin-sulbactam is potentially useful for multidrug-resistant health care–associated infections caused by *Acinetobacter baumannii-calcoaceticus* complex.[199] Carbapenems and third-generation cephalosporins are comparatively more active against members of the Enterobacteriaceae. Because ampicillin-sulbactam has no activity against certain strains of the Enterobacteriaceae that produce Bush group 1 β-lactamases and *P. aeruginosa*, it should not be used as empiric single-agent therapy for febrile neutropenic patients or severely ill patients with probable bacteremia.

TICARCILLIN-POTASSIUM CLAVULANATE

Ticarcillin combined with potassium clavulanate was approved for use in 1985. It extends the spectrum of activity of ticarcillin

to include β-lactamase–producing strains of staphylococci (but not methicillin-resistant strains), *H. influenzae*, *M. catarrhalis*, *E. coli*, *Klebsiella*, *Proteus*, *Providencia*, *N. gonorrhoeae*, and *B. fragilis*.[63] Ticarcillin-clavulanate also often is active against multidrug-resistant *Stenotrophomonas maltophilia*. Enterococci are moderately resistant to this agent. Because clavulanic acid does not inhibit Bush group 1–inducible chromosomal β-lactamases, *Citrobacter*, *Enterobacter* and *Serratia* spp., as well as de-repressed mutant strains of *P. aeruginosa* that are resistant to ticarcillin because of inducible cephalosporinases, also are resistant to ticarcillin-potassium clavulanate. Ticarcillin-potassium clavulanate is approved for use in children older than 3 months of age for lower respiratory, skin and skin structure, urinary tract, bone and joint, and intra-abdominal infections caused by susceptible pathogens.[34] Treatment of febrile neutropenic adult patients with ticarcillin-clavulanate combined with an aminoglycoside has been shown to be effective.

PIPERACILLIN-TAZOBACTAM

Piperacillin combined with tazobactam was approved for use in adults in 1993. It extends the spectrum of activity of piperacillin to include β-lactamase–producing strains of oxacillin-susceptible *S. aureus*, many members of the Enterobacteriaceae, and virtually all gram-positive and gram-negative anaerobes; its spectrum of activity is superior to that of ceftazidime and other β-lactam–β-lactamase inhibitor combinations. It has greater activity than does ticarcillin-clavulanate against gram-positive and gram-negative bacteria and equivalent activity against gram-positive bacteria compared with ampicillin-sulbactam. Tazobactam, however, does not increase the activity of piperacillin against bacteria with resistance that is mediated by altered cell wall permeability to piperacillin, including certain strains of *P. aeruginosa*. Penicillin-resistant pneumococci, methicillin-resistant staphylococci, *Corynebacterium jeikeium*, most *Enterococcus faecium* strains, and most gram-negative bacteria that produce Bush group 1 β-lactamases (*Citrobacter*, *Enterobacter*, *Morganella*, certain strains of *Pseudomonas*, and *Serratia* spp.) are resistant to piperacillin-tazobactam.[52] Although studies have shown piperacillin-tazobactam to be safe and effective for the treatment of lower respiratory tract, intra-abdominal, pelvic, skin and skin structure, bone, and diabetes-related foot infections in adults, as well as for empiric treatment of febrile episodes in neutropenic adults,[40] the experience in children is limited. The safety and efficacy of piperacillin-tazobactam have not been established for children younger than 12 years of age or neonates. Nonetheless, it is a potentially useful agent that has been used for the treatment of serious or complicated polymicrobial infections in children, especially in febrile neutropenic children, as initial empiric treatment. This antimicrobial agent should be used in combination with an aminoglycoside for serious *P. aeruginosa* infections to prevent the development of resistance. Clinicians also should be aware that administration of piperacillin-tazobactam can cause false-positive *Aspergillus* galactomannan test results for up to 5 days after cessation of treatment.[13]

Adverse Effects and Sensitization

The penicillins are unique among antimicrobial agents in having little dose-related toxicity (Table 248–4). Seizures may occur under circumstances that result in high concentrations of penicillin in nervous tissue: rapid intravenous infusion of single large doses, substantial dosages for prolonged periods of time in patients with impaired renal function, or high concentrations given by the intrathecal route. Confusion, dizziness, seizures, and psychosis caused by toxic concentrations of procaine have been associated with the administration of procaine penicillin G.[255] Nephritis has been associated with the administration of some penicillins, most frequently after the use of methicillin. Bleeding because of drug-induced platelet aggregation has been noted after the administration of carbenicillin and penicillin G.

TABLE 248–4 Adverse Reactions to Penicillins

Type of Reaction	Frequency (%)	Most Frequent*
Electrolyte disturbance		
Sodium overload	Variable	Ticar
Hypokalemia	Variable	Ticar
Hyperkalemia, acute	Rare	PCN G
Gastrointtestinal		
Diarrhea	2-5	Amp
Enterocolitis	<1	Amp
Hematologic		
Hemolytic anemia	Rare	PCN G
Neutropenia	1-4	PCN G, Naf, Ox, Pip
Platelet dysfunction	3	Ticar
Hepatic		
Elevated AST	1-4	Ox, Naf
Neurologic		
Seizures	Rare	PCN G
Bizarre sensations	Rare	Procaine PCN
Renal		
Interstitial nephritis	1-2	Meth
Hemorrhagic cystitis	Rare	Meth
Allergic		
IgE medlated	0.004-0.4	PCN G
Cytotoxic antibody	Rare	PCN G
Immune complexes	Rare	PCN G
Delayed hypersensitivity	4-8	Amp

**All reactions can occur with any penicillin.*
Amp, ampicillin; AST, aspartate transaminase; Meth, methicillin; Naf, nafcillin; Ox, oxacillin; PCN G, penicillin G; Pip, piperacillin; Ticar, ticarcillin.
Modified from Chambers, H. F., and Neu, H.C.: Penicillins. In *Mandell, G.L., Bennett, J.E., and Dollin, R. (eds.): Mandell, Douglas and Bennett's Principles and Practice of Infectious Diseases. 4th ed. New York, Churchill Livingstone 1995.*

Although toxicity may not be a significant concern with the penicillins, sensitization is an important factor.[172] Penicillins are haptens, that is, they are low-molecular-weight compounds too small to elicit an immune response alone, but when bound to a carrier molecule (e.g., host tissues or proteins), they are highly immunogenic in humans. The native penicillin molecule can bind to a protein, as can its major (benzylpenicilloyl) and minor (benzylpenicillin, benzylpenicilloate, benzylpenilloate) determinants. Four types of immune-mediated reactions can occur after the administration of a penicillin (or any drug or antigen): immediate hypersensitivity (immunoglobulin E [IgE]–mediated) reactions, cytotoxic antibody reactions, immune complex reactions (Arthus reaction), and delayed (cell-mediated) hypersensitivity. Allergic reactions also can be classified as (1) immediate (onset ≤1 hour), accelerated (1 to 72 hours), or delayed (>72 hours). Researchers have estimated that an immediate serious reaction occurs in 2 of every 10,000 courses, and fatal reactions occur in 1 of 100,000 treatment courses.[24,266]

1. *Type 1 immediate hypersensitivity reactions* usually occur within 30 minutes after administration and are life-threatening events. The interaction of preformed mast cell–bound IgE antibody to the antigenic determinants of penicillin results in the release of mast cell mediators.[37] Clinical signs include hypotension or shock, urticaria, laryngeal edema, and bronchospasm. Acute anaphylaxis is a rare event after the administration of penicillin, but significant numbers of fatalities occur each year because of the extensive use of these drugs. Children are thought to have fewer systemic reactions than do adults, presumably because of fewer previous exposures to penicillin antigens. Oral preparations are less likely to result in an immediate reaction than are paren-

teral forms, perhaps because antigens are altered in the gastrointestinal tract, absorption is slower, dosages are smaller, or a combination of these factors.

2. *Type 2 cytotoxic antibody reactions* can occur after passive absorption of the benzylpenicilloyl hapten by the membrane of circulating blood cells or by renal interstitial cells, especially when high dosages of penicillins are used for prolonged periods of time. IgM antibody, IgG antibody, or both antibodies to the benzylpenicilloyl antigen bind to the altered cell surface; complement can be activated, and damage to the cell ensues. Cytotoxic antibody reactions usually are manifested more than 72 hours after initiation of antibiotic therapy and include hemolytic anemia, leukopenia, thrombocytopenia, and drug-induced interstitial nephritis.

3. *Type 3 immune complex (Arthus) reactions* occur after the formation of immune complexes between soluble penicillin antigens and IgG and IgM antibodies. The complexes lodge in the skin, joints, kidneys, or other tissue sites. Complement activation occurs, and the clinical manifestations of serum sickness ensue: cutaneous symptoms (urticaria, maculopapular rash, erythema multiforme), polyarthralgia, and fever. The onset typically is 7 to 21 days after initiation of penicillin therapy but can occur after use of the antibiotic has been discontinued. Although serum sickness has been associated with the administration of penicillins, it occurs more frequently after administration of cefaclor.

4. *Type 4 delayed hypersensitivity reactions* involve cellular rather than humoral immunity. On exposure to certain antibiotics, T lymphocytes become sensitized in a major histocompatibility restricted fashion, and they mediate mild to severe reactions that include contact dermatitis, some maculopapular rashes, fixed drug eruption at sites of previous tinea infections, and toxic epidermal necrolysis. Diagnostic tools to detect an antibiotic that induces a type 4 reaction include the delayed reading (>6 hours) intradermal skin test, patch test, and in vitro lymphocyte transformation test. However, these tests have not been adequately standardized for routine use.[266]

Idiopathic reactions are those for which an immune-mediated mechanism has not been proved, but more recent data suggest that these reactions may represent a type 4 hypersensitivity reaction.[266] Included in this category are the morbilliform exanthems, erythema multiforme, photosensitivity reactions, exfoliative dermatitis, and pruritus. Approximately 4 percent of courses of penicillin and up to 9 percent of courses of ampicillin or amoxicillin therapy are associated with a maculopapular rash. In some of these patients, the rash is a manifestation of a primary viral infection such as infectious mononucleosis, for which the penicillin was prescribed inappropriately.

Identifying patients who will have a significant reaction if penicillin is administered remains difficult. Serologic assays (radioallergosorbent tests) for the detection of IgE antibodies to major and minor penicillin determinants are available but are time-consuming, expensive, and less sensitive than is skin testing. Because the immediate reaction is mediated largely by IgE reagin or skin-sensitizing antibody, patients who are likely to respond subsequently with a life-threatening reaction can be identified by the use of intradermal tests with appropriate antigens. Selecting the most appropriate antigens to be used for skin testing, however, has been problematic because many different antigens may play roles in the allergic reaction. At least 10 metabolic breakdown products of the penicillin nucleus have been identified. Other potential antigens include macromolecular impurities present in solutions of the drug, high-molecular-weight penicillin polymers found in poorly buffered penicillin solutions standing for prolonged periods of time, side chains of the various penicillins, and the bacterial enzymes (amidases) used to prepare semisynthetic penicillins. Thus, investigators have had difficulty choosing sensitive and specific antigens to use for skin testing.

The most informative studies of skin test antigens have been those of Levine,[167] who identified two antigens, benzylpenicilloyl poly-L-lysine (Pre-Pen, Taylor Pharmacal, Decatur, IL) and a "minor determinant mixture," a preparation of a dilute solution of aqueous crystalline penicillin G that includes metabolic breakdown products. Only the Pre-Pen reagent is available commercially in the United States. The CDC currently recommends the use of benzylpenicilloyl poly-L-lysine and, if available, a freshly prepared mixture of dilute minor determinant precursors including benzylpenicillin G, benzylpenicilloate, and penicilloyl propylamine, as well as a positive control (histamine) and a negative control (diluent, phenol saline) after a protocol prepared by Beall.[24,278] If the full battery of minor antigens is not available, penicillin G should be used. An epicutaneous (prick) test is performed first. If the patient's history of penicillin allergy is that of a mild reaction, the skin test reagent can be used at full strength; however, if the previous history is suggestive of anaphylaxis, a 1:100 dilution of the reagent should be used for the first prick test, followed by a full-strength test if no reaction with the diluted reagent occurs. If the prick test result is negative, an intradermal test is performed using duplicate 0.02-mL volumes of antigen solutions, and the skin is observed for 20 minutes. A positive result is indicated by a wheal-and-flare reaction in 15 minutes that is more than 2 mm larger than the initial wheal; this result suggests a significant chance that a reaction will occur on subsequent administration of a penicillin. A negative result suggests that a significant allergic reaction will not take place. Although much effort has gone into clinical tests of these antigens, the predictive value of positive and negative results in children remains uncertain. Because of the risk of severe life-threatening reactions when a skin test is performed, having a physician present and resuscitation equipment and medications readily available is prudent.

At present, the physician must rely on the patient's history of an adverse reaction after administration of a penicillin to identify who is likely to be allergic. If the reaction appears to be related to the administration of a penicillin, the drug should be avoided for minor infections. More recent experience suggests that fewer than 10 percent of adults with a history of penicillin allergy have positive skin tests. Of those individuals with negative skin tests, IgE-mediated reactions occur in 4 percent or less if these patients receive penicillin, a rate that is similar to individuals without a history of penicillin allergy.[266] Because no proven alternative therapies to penicillin are available for treating patients with neurosyphilis, congenital syphilis, or syphilis in pregnancy, the CDC recommends skin testing and desensitization of patients considered to have reacted positively to the skin test antigens.[278] If a life-threatening infection should occur and penicillin is clearly the drug of choice, the physician may choose to administer the drug under carefully controlled conditions after desensitization. All penicillins are cross-reactive with regard to sensitization; allergy to any one implies sensitization to all, although cross-sensitivity is considerably less than 100 percent.

CEPHALOSPORINS

The cephalosporins have a broad range of activity that includes gram-positive cocci, gram-negative enteric bacilli, and anaerobic bacteria. Most cephalosporins are relatively resistant to hydrolysis by β-lactamases produced by *S. aureus*, but many are susceptible to gram-negative β-lactamases. Unlike other antimicrobial agents, this group has a high therapeutic-toxic index. For simplicity, the cephalosporins have been categorized as first-, second-, third-, and fourth-generation agents (Table 248–5), based on the pattern of in vitro activity.

Pharmacokinetics

The cephalosporins are available as parenteral and oral products (Table 248–6). Most of the parenteral drugs can be administered by the intravenous or intramuscular routes. Most of the oral

products are absorbed well from the gastrointestinal tract. Esterification of the base compounds of cefuroxime and cefpodoxime is required to enhance gastrointestinal absorption. The presence of food does not alter absorption and, for some antibiotics, even can enhance absorption. Cephalosporins penetrate most tissues and body fluids well, except CSF. The first- and second-generation cephalosporins do not achieve therapeutic CSF concentrations. CSF penetration of third-generation drugs varies but is generally adequate for most major meningeal pathogens, except penicillin-nonsusceptible pneumococci, for which vancomycin is added in the initial empiric regimen.[158] Cefepime, a fourth-generation cephalosporin, reaches adequate CSF concentrations for the treatment of most common invasive pathogens. Because glomerular filtration and tubular secretion are the major modes of excretion, the urinary concentrations achieved are sufficient for the treatment of urinary tract infections. Ceftriaxone has dual excretion by the kidneys and the biliary tract and achieves high concentrations in urine and bile. The presence of moderate to severe renal insufficiency may require adjustment of the dosage or dosing interval for all cephalosporins, except those agents with biliary excretion. Hepatic insufficiency can affect the metabolism of cephalosporins that undergo biliary excretion; however, adjustments in ceftriaxone dosage or dosing interval are required only in the presence of both hepatic and renal insufficiency.

Therapeutic advantages of cephalosporins include concentration-independent bactericidal activity, broad-spectrum antibacterial activity, lack of significant dose-related toxicity, and relative stability against staphylococcal β-lactamases. Certain cautions must be kept in mind when prescribing cephalosporins: none is effective against enterococci, methicillin-resistant staphylococci, *L. monocytogenes*, chlamydial species, and *Clostridium difficile*, and resistance may develop rapidly in closed communities, such as neonatal or pediatric intensive care units, because of inducible chromosomal β-lactamases produced by gram-negative bacteria. Recommended daily dosage schedules are shown in Table 248–10.

First-Generation Cephalosporins

First-generation cephalosporins are effective against gram-positive cocci, including β-lactamase–producing *S. aureus*, and they have variable activity against gram-negative enteric bacilli. Five first-generation cephalosporins currently are available for infants and children: the parenteral drugs cephapirin and cefazolin; the oral products cephalexin and cefadroxil; and cephradine. Cephalothin is not available in the United States. Because cephapirin is painful in intramuscular injections, the intravenous route is preferred. Cefazolin produces higher concentrations in blood than do the other parenteral first-generation drugs. Cefadroxil can be administered in twice-daily doses because of its longer serum half-life. None of these agents will attain appreciable concentrations in the central nervous system (CNS).

These drugs are of value as alternatives to penicillin for disease caused by *S. aureus*, *S. pyogenes*, and susceptible *S. pneumoniae*, and they are active against some strains of community-acquired gram-negative enteric bacilli such as *E. coli*, *P. mirabilis*, and *Klebsiella pneumoniae*. The three oral preparations have comparable activity in vitro and in vivo. First-generation cephalosporins are valuable in children who have a history of non-anaphylactic allergy to penicillin. These drugs have been used to treat staphylococcal and streptococcal skin and skin structure infections, bone and joint infections, pharyngitis, and uncomplicated community-acquired urinary tract infections caused by susceptible bacteria. A meta-analysis revealed that many first-generation and other-generation cephalosporins (cephalexin, cefadroxil, cefuroxime, cefprozil, cefdinir, cefixime, cefpodoxime, and ceftibuten) have equivalent or superior bacteriologic and clinical cure rates compared with penicillin for treatment of group A streptococcal pharyngotonsillitis.[56] Experts disagree on the significance of the results of this meta-analysis. Cefadroxil is effective for the treatment of streptococcal pharyngitis in a once-a-day dosage schedule. Cephalexin has been used for sequential parenteral-oral treatment of staphylococcal osteomyelitis and arthritis occurring after surgical intervention and an initial period of parenteral antibiotic therapy. Cefazolin and cefuroxime are the antibiotics of choice for perioperative prophylaxis in selected surgical procedures.[44] Because first-generation cephalosporins have minimal, if any, activity against *H. influenzae* and *M. catarrhalis* and inadequate activity against penicillin-resistant *S. pneumoniae*, they should not be used for empiric treatment of respiratory tract infections. First-generation cephalosporins should not be used for empiric therapy of suspected severe gram-negative health care–associated infections; a third- or fourth-generation cephalosporin in combination with an aminoglycoside, or other classes of antibiotics, should be selected for this purpose. The safety and efficacy of cefaclor, cefazolin or cephalexin, and cephapirin have not been established for infants younger than 1 month and 3 months, respectively.

Second-Generation Cephalosporins

The second-generation cephalosporins that are approved for use in children consist of two parenteral drugs (cefamandole and

cefuroxime) and three oral preparations (cefaclor, cefuroxime axetil, and cefprozil). Also classified with the second-generation cephalosporins are the cephamycins, of which only one, cefoxitin, is approved for use in children. When compared with the first-generation cephalosporins, the second-generation agents have similar or somewhat less activity against gram-positive cocci but better activity against *H. influenzae*, *M. catarrhalis*, *N. meningitidis*, *N. gonorrhoeae*, and some members of the Enterobacteriaceae. The cephamycins are more active than are the first- or other second-generation cephalosporins against gram-negative enteric bacteria and *B. fragilis*, but they have poor activity against gram-positive cocci.

CEFACLOR

Cefaclor is more active than is cephalexin against *H. influenzae*, *M. catarrhalis*, *E. coli*, and *P. mirabilis* and has activity against staphylococci similar to that of cephalexin. Cefaclor is an unstable compound and is destroyed within 2 hours in human plasma. It is susceptible in vitro to hydrolysis by the β-lactamases produced by approximately 14 percent of *H. influenzae* and 90 percent of *M. catarrhalis* isolates; presumed rates of resistance of *H. influenzae* are considerably higher when pharmacokinetic and pharmacodynamic parameters are taken into account.[134] Although cefaclor is effective therapy for susceptible bacteria causing otitis media, sinusitis, and mild to moderate cases of pneumonia, it is not the preferred empiric agent for these indications because it is not effective against penicillin-nonsusceptible strains of *S. pneumoniae*. The rare but potential risk of serum sickness, as well as the poor stability of this drug to some β-lactamases, has limited its use. The safety and efficacy of cefaclor have not been established for infants younger than 1 month, although the drug has been used successfully to treat neonatal otitis media.

CEFAMANDOLE

Cefamandole is active against gram-positive cocci, including β-lactamase–producing *S. aureus*, and some gram-negative enteric bacteria, and it was the first cephalosporin to be effective for infections caused by *H. influenzae*, including β-lactamase–producing strains. However, this agent is no longer available in the United States. Before the development of cefuroxime, cefamandole was used for respiratory tract, skin, and soft tissue infections in infants and children.[15] Once cefuroxime was approved for use, cefamandole seldom was used because, although its spectrum of activity was comparable with that of cefuroxime, some of its pharmacologic features made it less favorable. Cefamandole does not penetrate the CSF well, and because it contains a methylthiotetrazole side chain, altered hemostasis may occur. Clinical and microbiologic failure in cases of meningitis caused by *H. influenzae* (despite in vitro susceptibility and evidence of CSF penetration) has limited the use of cefamandole to disease in which the development of sepsis is not a concern. The safety and efficacy of this agent have not been established for infants younger than 1 month.

CEFOXITIN

Cefoxitin has excellent activity against anaerobic organisms and is the most active cephalosporin against *B. fragilis*.[27] It has selective activity against gram-negative enteric bacilli, but *Enterobacter* or *Pseudomonas* spp. are inherently resistant. Cefoxitin is resistant to hydrolysis by the β-lactamases produced by gram-positive bacteria and some of the gram-negative β-lactamases. Because it is a potent inducer of Bush group 1 chromosomal β-lactamases, its indiscriminate use should be avoided. Cefoxitin has been shown to be effective for infections involving facultative gram-negative bacilli and anaerobes, such as intra-abdominal, pelvic, and gynecologic infections. When combined with doxycycline, cefoxitin is effective for the treatment of pelvic inflammatory disease.[278] The use of β-lactam–β-lactamase inhibitor combinations or metronidazole, rather than cefoxitin, should be considered for empiric treatment of patients with life-threatening anaerobic infections because as many as 25 percent of *B. fragilis* strains can be resistant to cefoxitin.[4] Higher doses of cefoxitin have been associated with an increased incidence of eosinophilia and elevated aspartate aminotransferase (AST) concentration. A diminished zone of inhibition in cefoxitin disk diffusion assays are useful in the clinical microbiology laboratory to detect inducible or constitutive (stably derepressed) AmpC Bush group 1 β-lactamase production among strains of *Citrobacter*, *Enterobacter*, *E. coli*, *Klebsiella*, *Morganella*, *Providencia*, *Pseudomonas*, and *Serratia*. Identification of this phenotype in vitro is important because these strains have high-level resistance to many classes of β-lactam antibiotics that may not be detected by standard susceptibility assays. Fourth-generation cephalosporins and carbapenems are potentially effective antimicrobial agents for these multidrug-resistant pathogens.[140]

CEFPROZIL

Cefprozil has a structure similar to that of the first-generation cephalosporin cefadroxil. It is more active than are the oral first-generation agents against *S. pyogenes*, *S. pneumoniae*, *Neisseria* spp., *H. influenzae*, *M. catarrhalis*, *E. coli*, *P. mirabilis*, *Klebsiella*, and, to a lesser extent, staphylococci. This drug is hydrolyzed by the β-lactamases produced by approximately 11 percent of *H. influenzae* and 91 percent of *M. catarrhalis* isolates; rates of resistance of *H. influenzae* are likely considerably higher when pharmacokinetic and pharmacodynamic parameters are taken into account.[134] The rate of resistance among *S. pneumoniae* isolates in the United States is approximately 20 percent.[138] Because of its relatively long serum half-life, cefprozil can be administered twice daily. Cefprozil is comparable to penicillin, cefaclor, and erythromycin in the treatment of pharyngitis,[184] and it is equivalent or superior to cefaclor and erythromycin in the treatment of mild to moderate skin and skin structure infections.[211] Cefprozil is approved for the treatment of acute otitis media, mild lower respiratory tract infections, acute sinusitis, and skin and skin structure infections. However, it is not the preferred antibiotic for these indications because it is unlikely to be effective in children with penicillin-nonsusceptible *S. pneumoniae*, *H. influenzae*, or *M. catarrhalis*, on the basis of unfavorable pharmacodynamic parameters.[271] Cefprozil is safe and effective as part of a parenteral-oral antibiotic regimen for the treatment of suppurative skeletal infections in children.[272] The safety and efficacy of cefprozil have not been established for infants younger than 6 months.

CEFUROXIME

When compared with first-generation cephalosporins, this parenteral second-generation cephalosporin is slightly less active against staphylococci but is more active against group A streptococci and pneumococci. Cefuroxime has excellent activity against many members of the Enterobacteriaceae.[208] Its stability to β-lactamases is greater than that of first-generation agents, and it is the only first- or second-generation antibiotic that achieves substantial CSF concentrations. However, cefuroxime is not recommended for treatment of proven or suspected bacterial meningitis because of suboptimal CSF pharmacologic characteristics, particularly in the context of infections caused by *H. influenzae* or nonsusceptible *S. pneumoniae*, for which third-generation cephalosporins (cefotaxime and ceftriaxone) are indicated.[251] Cefuroxime has been approved for the treatment of skin and skin structure infections, lower respiratory tract infections, bone and joint infections, uncomplicated gonorrhea, and uncomplicated urinary tract infections caused by susceptible bacteria. Cefuroxime is most useful for the treatment of infections sufficiently severe to warrant parenteral therapy, in which susceptible *S. aureus*, *S. pneumoniae*, *S. pyogenes*, encapsulated or nonencapsulated *H. influenzae*, and *M. catarrhalis* are probable pathogens, such as suppurative arthritis, orbital cellulitis, or severe pneumonia. Cefuroxime offers the advantage of single-drug therapy for these diseases. The safety and efficacy of cefuroxime have not been established for infants younger than 3 months.

Cefuroxime Axetil

Cefuroxime axetil is an oral form of cefuroxime with a similar spectrum of activity. It is an ester prodrug of cefuroxime that is metabolized to the active drug by intestinal esterases. Oral absorption is increased by the presence of food. When crushed, the tablet has a bitter taste that renders it unpalatable. The suspension has an unpleasant flavor that makes it difficult for some children to tolerate and therefore may limit adherence. The drug may be considered a suitable alternative to amoxicillin for the treatment of otitis media[9] and sinusitis when coverage must include β-lactamase–producing bacteria. Cefuroxime axetil has limited activity against penicillin-nonsusceptible pneumococci and *M. catarrhalis*, of which approximately 22 percent and 50 percent, respectively, of isolates are resistant.[134,138] This agent has been approved for the treatment of uncomplicated urinary tract infection, skin and soft tissue infection, acute bacterial maxillary sinusitis, and lower respiratory tract infection caused by susceptible bacteria. Cefuroxime axetil is an effective alternative to doxycycline and amoxicillin for the treatment of early Lyme disease.[279] The safety and efficacy of cefuroxime axetil have not been established for infants younger than 3 months.

Third-Generation Cephalosporins

Third-generation cephalosporins approved for use in children include the parenteral agents cefotaxime, ceftizoxime, ceftriaxone, and ceftazidime and the oral agents cefixime, cefpodoxime proxetil, ceftibuten, cefdinir, and cefditoren pivoxil. Third- and fourth-generation cephalosporins are the most potent cephalosporins against gram-negative enteric bacteria.[142] Most of them have excellent activity against *H. influenzae*, *M. catarrhalis*, *N. gonorrhoeae*, *N. meningitidis*, group A streptococci, and penicillin-susceptible pneumococci but relatively poor activity against staphylococci. Ceftazidime is the only agent with activity against *P. aeruginosa*. A serious global health concern has emerged because members of the Enterobacteriaceae have developed increased resistance to third-generation cephalosporins on the basis of plasmid-mediated production of ESBLs and AmpC β-lactamases.[221] The parenteral cephalosporins provide high concentrations of drug in serum and adequate concentrations in CSF. Third-generation cephalosporins and aminoglycosides are synergistic in vitro against certain susceptible and resistant strains of *P. aeruginosa* as well as *Serratia marcescens* and other Enterobacteriaceae, including *Enterobacter cloacae*, *E. coli*, *K. pneumoniae*, and *P. mirabilis*.

CEFOTAXIME

Cefotaxime has excellent activity against group A streptococci, susceptible pneumococci, *H. influenzae*, *N. meningitidis*, and *N. gonorrhoeae*. Because cefotaxime can be hydrolyzed by AmpC Bush group 1–inducible chromosomal β-lactamases and by ESBLs, it is not active against strains of Enterobacteriaceae that produce these β-lactamases. Cefotaxime is metabolized in the liver to desacetyl cefotaxime, a less active metabolite that may act synergistically with cefotaxime. Although it is metabolized in the liver, cefotaxime is excreted by the kidneys. High serum, tissue, and CSF concentrations of cefotaxime can be achieved at the recommended dosages. The rapid development of resistance by colonizing gram-negative enteric bacilli when cefotaxime was used extensively for initial treatment of neonatal sepsis raised concern that extensive use of newer cephalosporins in the nursery or intensive care units could lead to more rapid emergence of drug-resistant bacteria than had been identified with the traditional regimens of a penicillin and an aminoglycoside. Because of its broad spectrum of activity against many of the common pathogens causing pediatric infections, cefotaxime is used widely for inpatient treatment of lower respiratory tract infections, urinary tract infections, sepsis, intra-abdominal infections, bone and joint infections, and meningitis or ventriculitis caused by susceptible organisms. Studies in neonates have raised concern that when cefotaxime is used routinely as part of an empiric regimen for neonatal sepsis, colonizing gram-negative enteric bacilli can rapidly develop resistance, and certain neonates have adverse outcomes.[62,79] Therefore, it is prudent to reserve cefotaxime for appropriate clinical and microbiologic indications. In 2003, the Clinical and Laboratory Standards Institute (formerly the National Committee for Clinical Laboratory Standards) published new breakpoints for defining the susceptibility of *S. pneumoniae* isolates to cefotaxime and ceftriaxone. The former breakpoints were based on attainable concentrations of these antibiotics in CSF and the level at which it was presumed that meningitis treatment failed because of elevated MICs. According to the former criteria, susceptible, intermediate, and resistant MIC breakpoints for cefotaxime and ceftriaxone were 0.5 μg/mL or less, 1 μg/mL, and 2 or more μg/mL, respectively, for pneumococci. Based on the newer criteria, the original breakpoints should be used for isolates from CSF in patients with suspected meningitis, but isolates causing nonmeningeal syndromes have breakpoints of 1 μg/mL or less, 2 μg/mL, and 4 or more μg/mL, respectively.[58]

CEFTIZOXIME

Ceftizoxime is a parenteral agent with a spectrum of activity similar to that of cefotaxime. Its safety and efficacy have not been established for infants younger than 6 months, and it rarely is used in pediatrics.

CEFTRIAXONE

The antibacterial spectrum of ceftriaxone is similar to that of cefotaxime, with activity against beta-hemolytic streptococci (including groups A, B, C, F, and G), susceptible pneumococci, *H. influenzae*, *M. catarrhalis*, *Neisseria* spp., and many members of the Enterobacteriaceae. Surveillance data from pediatric patients in the United States revealed that no significant resistance has been reported against ceftriaxone among oxacillin-susceptible strains of *S. aureus*.[142] Nonetheless, this drug should not be used as empiric monotherapy for severe infections presumed to be caused by staphylococci because it has minimal activity against MRSA, and its efficacy for treatment of susceptible strains has not been established in children. Ceftriaxone is not active against most strains of *Pseudomonas*. It differs from cefotaxime in its pharmacokinetic properties. Ceftriaxone undergoes extensive protein binding and has a long serum half-life. Because of its broad spectrum of activity against many of the pathogens that commonly cause sepsis, meningitis, and respiratory tract infections in older infants and children, along with its unique pharmacokinetic features, ceftriaxone has been used excessively for outpatient management of febrile infants and young children being evaluated for possible systemic bacterial infection. Single-dose therapy was approved for the treatment of acute otitis media in 1997; a 3-day regimen is recommended as alternative therapy for patients with refractory cases.[9,166]

Ceftriaxone is effective for various sexually transmitted diseases, including the following: chancroid, proctitis, epididymitis (in combination with doxycycline), and different forms of gonococcal disease (neonatal ophthalmia); uncomplicated urethral, endocervical, rectal, or pharyngeal gonorrhea (in combination with doxycycline for treatment of possible coexisting chlamydial infection); and disseminated gonococcal infection, meningitis, or endocarditis.[278] Short-course ceftriaxone therapy for typhoid fever in children is comparable in effectiveness to chloramphenicol therapy.[194] However, duration of ceftriaxone therapy greater than 5 days has been associated with fewer confirmed bacteriologic relapses.[261] Ceftriaxone (or cefotaxime) is recommended for treatment of acute Lyme disease with advanced heart block (14 to 21 days) or meningitis (14 to 28 days).[279] Although third-generation cephalosporins have been used for empiric treatment of health care–associated respiratory, wound, intra-abdominal, and urinary tract infections caused by gram-negative bacteria, administering an aminoglycoside instead of or in addition to a third-generation cephalosporin often is prudent because of the risk of encountering plasmid-mediated, ESBL resistance, or inducing the expression of chromosomally mediated AmpC Bush group 1 β-lactamases.

For infections requiring prolonged therapy (e.g., suppurative arthritis, osteomyelitis, brain abscess) and caused by susceptible organisms, ceftriaxone therapy is cost-effective for use outside the hospital. Once the acute signs of disease have diminished and the child remains in the hospital for only parenteral therapy, discharge and once-daily administration of ceftriaxone in the home or clinic can be considered.

Because of its extensive protein binding, ceftriaxone can displace bilirubin from albumin-binding sites, with the potential risk of inducing kernicterus, although to date this adverse clinical effect has not been reported. Cefotaxime is administered to neonates more often than is ceftriaxone because considerably more information is available on its safety and pharmacokinetics. Ceftriaxone is excreted and concentrated in bile. Gallbladder "sludge," diagnosed by abdominal sonography (and not identifiable by other radiographic techniques), has been demonstrated in some patients who received ceftriaxone. The material appears to be a calcium-ceftriaxone complex and resolves on cessation of the drug. Most patients with ceftriaxone-associated sludge are asymptomatic, but occasionally patients have symptoms of gallbladder disease, and incidents of acute cholecystitis have been reported in a few children.

CEFTAZIDIME

When compared with cefotaxime and ceftriaxone, ceftazidime has poor antibacterial activity against *S. aureus*, is less active against penicillin-susceptible *S. pneumoniae*, and is slightly less active against group A streptococci, but it is more active against *P. aeruginosa*. On a weight basis, ceftazidime is the most effective of all β-lactam antimicrobial agents in vitro against *P. aeruginosa*. It frequently is active in vitro against *P. aeruginosa* strains that are resistant to antipseudomonal penicillins. Resistance to ceftazidime can develop in gram-negative bacteria by the production of ESBLs or because of decreased bacterial cell permeability, as seen

with *P. aeruginosa*, *Acinetobacter*, and some *Serratia* strains. Ceftazidime is indicated for use in the following circumstances: infections suspected to be caused by *Pseudomonas*, including acute exacerbations of chronic pulmonary infections in patients with cystic fibrosis, chronic suppurative otitis media, or malignant otitis externa; thermal injuries, puncture wound infections of the foot, and complicated health care–associated infections; and febrile illnesses in neutropenic patients with cancer or other immunocompromised individuals.

CEFIXIME

Cefixime has a vinyl group instead of a chlorine atom at position 3 of the cephem nucleus and an aminothiazole oxime group, rather than a phenyl glycine side chain. These biochemical changes result in potent gram-negative activity. Cefixime was introduced in 1989 as an oral third-generation cephalosporin with a broad spectrum of activity, including activity against group A streptococci, *H. influenzae*, *M. catarrhalis*, susceptible *S. pneumoniae*, and many members of the Enterobacteriaceae, including *Shigella*, *Salmonella*, *E. coli*, *Klebsiella*, and *P. mirabilis*.[21] Cefixime, like ceftibuten, is distinguished from other extended-spectrum oral cephalosporins by its lack of activity against *S. aureus.* It also is inactive against *Citrobacter freundii*, *Enterobacter*, *P. aeruginosa*, and *Serratia*. Although cefixime has in vitro activity against penicillin-susceptible pneumococci, lower bacteriologic cure rates occurred with cefixime than with amoxicillin when cefixime was used to treat children with pneumococcal acute otitis media.[127] Cefixime is resistant to degradation by certain β-lactamases. Administration of cefixime is facilitated by once-daily dosing,[89] pleasant taste, and stability of the suspension at room temperature. Cefixime is effective therapy for uncomplicated urinary tract infections caused by *E. coli* or *P. mirabilis*, for shigellosis, and for acute otitis media or sinusitis caused by *H. influenzae* or *M. catarrhalis.*[32] Some specialists use cefixime to treat uncomplicated gonococcal infections in children because the drug can be administered orally; however, no reports have been published concerning the safety or effectiveness of cefixime used for this purpose.[278] Clinical studies indicate that the rate of laboratory-confirmed eradication of *Shigella sonnei* in an epidemic setting is higher with a 5-day than with a 2-day cefixime regimen,[182] cefixime alone is equally effective as sequential therapy with intravenous and oral antibiotics in selected febrile infants with urinary tract infections,[30,123] and a 14-day cefixime regimen for treatment of multidrug-resistant *S. typhi* septicemia in children has efficacy comparable to that of a 5-day course of ceftriaxone therapy.[106] Cefixime is not recommended for the treatment of infections frequently caused by staphylococci, such as skin or soft tissue infections, and it is not the most effective agent for the treatment of pneumococcal infections. The safety and efficacy of cefixime have not been established for infants younger than 1 month. Wyeth discontinued manufacturing cefixime in 2002, but the drug was reintroduced in 2004 as a generic formulation (Lapine Laboratory).

CEFPODOXIME PROXETIL

The antibacterial activity of cefpodoxime proxetil is similar to that of cefixime, with the exception of improved activity against staphylococci. Cefpodoxime is active against the following: group A streptococci; susceptible pneumococci; β-lactamase–producing strains of *N. gonorrhoeae*, *H. influenzae*, and *M. catarrhalis*; oxacillin-susceptible *S. aureus*; and many members of the Enterobacteriaceae. It is not active against *Enterobacter*, *Pseudomonas*, *Serratia*, or *Morganella*. Cefpodoxime proxetil, the ester prodrug of cefpodoxime, is cleaved by intestinal esterases to the active drug. Oral absorption is increased by the presence of food. Because of its longer serum half-life, cefpodoxime proxetil can be administered in twice-daily dosing intervals. Cefpodoxime is hydrolyzed by some ESBLs. The unfavorable palatability of cefpodoxime proxetil may adversely affect adherence.[258]

Treatment of group A streptococcal pharyngitis with a 5-day cefpodoxime proxetil regimen is equivalent to therapy with penicillin V and has been approved for this indication by the FDA.[72] A 5-day regimen is approved for the treatment of acute otitis media based on clinical outcomes that are comparable or superior to therapy with amoxicillin-clavulanate, cefaclor, or cefixime.[64] Cefpodoxime is not likely to be effective for the treatment of acute otitis media caused by penicillin-nonsusceptible pneumococci because of its unfavorable pharmacodynamic parameters.[276] It also has been approved for outpatient treatment of community-acquired respiratory tract infections, uncomplicated urinary tract infections, and mild skin and skin structure infections. The safety and efficacy of cefpodoxime proxetil have not been established for infants younger than 5 months.

CEFTIBUTEN

Ceftibuten was approved by the FDA for pediatric use in 1995. The primary active component is formulated as a *cis*-isomer that is converted in serum to the less active *trans*-isomer. The chemical structure and spectrum of antimicrobial activity are similar to those of cefixime. Ceftibuten, like cefixime, is distinguished from other extended-spectrum oral cephalosporins by its lack of activity against *S. aureus.* Its antimicrobial activity against groups A, C, F, and G beta-hemolytic streptococci is good, whereas its activity against groups B and D, as well as viridans streptococci, is poor. Ceftibuten exhibits MICs for penicillin-susceptible pneumococci in the susceptible range, whereas penicillin-nonsusceptible strains are ceftibuten-resistant. When compared with other oral cephalosporins, ceftibuten is the most stable to hydrolysis by β-lactamases produced by Neisseriaceae, *Moraxella*, *Haemophilus*, and Enterobacteriaceae, including most strains of *E. coli* and *K. pneumoniae* that produce Amber class A plasmid-mediated, ESBLs of the TEM, SHV, and OXA types. Ceftibuten is variably active against strains of *Citrobacter*, *Serratia*, and *Morganella*, but it is inactive against *Acinetobacter*, *Pseudomonas*, *Enterobacter*, *Bordetella*, and anaerobic species. It is also a weak inducer of AmpC Bush group 1 β-lactamases produced by *S. marcescens*, *E. cloacae*, and *Enterobacter aerogenes*.[114]

Ceftibuten has excellent bioavailability and a favorable pharmacokinetic profile that facilitates a once-daily dosing schedule.[20] Ten-day treatment regimens have been approved for streptococcal tonsillopharyngitis and acute otitis media caused by *H. influenzae*, *M. catarrhalis*, or *S. pyogenes* because of superior clinical and microbiologic efficacy data for ceftibuten in comparison with penicillin V in children with streptococcal tonsillopharyngitis[224] and comparable clinical efficacy data for ceftibuten versus amoxicillin, amoxicillin-clavulanate, cefaclor, and cefprozil for the treatment of children with clinically defined acute otitis media with or without effusion. However, cumulative data from clinical trials indicate that microbiologic cure rates of pneumococcal otitis media are lower for ceftibuten than for comparable antimicrobial agents.[114] Because of the increasing prevalence of nonsusceptible *S. pneumoniae* isolates, ceftibuten has almost no place in the treatment of acute otitis media, especially in young or otherwise at-risk infants and children.

Ceftibuten also should be considered as alternative therapy for sinusitis caused by susceptible organisms. Although not approved for this indication, ceftibuten achieved clinical success equivalent to and bacterial eradication superior to those reported with TMP-SMX in the treatment of complicated or recurrent urinary tract infections in children.[19] Adverse reactions to ceftibuten, which are limited mainly to the gastrointestinal tract,

occur in approximately 10 percent of children, a rate similar to comparable oral β-lactam antibiotics. The safety and efficacy of ceftibuten have not been established for infants younger than 6 months.

CEFDINIR

Cefdinir was approved in 1999 for the treatment of acute otitis media in children. It has a broad spectrum of in vitro antimicrobial activity, favorable pharmacokinetics, a convenient once- or twice-daily dosage schedule, superior palatability, a low rate of adverse events, and proven clinical efficacy against common childhood pathogens.[125,156] When compared with cephalexin, cefaclor, cefuroxime, cefixime, and cefpodoxime, cefdinir has equivalent or superior MICs for groups A, B, C, F, and G streptococci, viridans streptococci, and oxacillin-susceptible staphylococci. Its in vitro activity against penicillin-susceptible and penicillin-nonsusceptible strains of *S. pneumoniae* is equivalent to that of cefuroxime and cefpodoxime but superior to that of other oral cephalosporins. Cefixime and cefpodoxime have superior activity against *H. influenzae* (including β-lactamase–producing strains), whereas cefdinir and cefuroxime have comparable activity against this pathogen. The activity of cefdinir against *M. catarrhalis* is similar to that of cefixime, cefpodoxime, and cefuroxime but superior to that of earlier-generation cephalosporins. Cefdinir is stable to hydrolysis by many common Enterobacteriaceae-produced β-lactamases. However, activity against these pathogens is variable. Cefdinir is inactive against strains of enterococci, methicillin-resistant staphylococci, *Legionella*, *Listeria*, *Acinetobacter*, *Citrobacter*, *Enterobacter*, *P. aeruginosa*, *Serratia*, *Stenotrophomonas*, and most anaerobes.[115]

Based on comparative clinical and microbiologic efficacy trials, administration of cefdinir should be considered for children with the following: (1) acute bacterial otitis media caused by β-lactamase–positive or β-lactamase–negative strains of *H. influenzae* and *M. catarrhalis* or penicillin-susceptible strains of *S. pneumoniae* as either a 5- or 10-day regimen; cefdinir has efficacy equivalent to that of cefuroxime and cefpodoxime but superior palatability and therefore should be considered as an alternative to other second-line regimens; however, use of amoxicillin-clavulanate or of three single daily doses of parenteral ceftriaxone is recommended if penicillin-nonsusceptible pneumococci are suspected or proven[9,10,156]; (2) group A streptococcal tonsillopharyngitis in 5- or 10-day dosage schedules; (3) acute maxillary sinusitis caused by susceptible organisms; and (4) uncomplicated skin and skin structure infections caused by oxacillin-susceptible *S. aureus* or group A streptococci.[141] Although cefdinir is not approved for treatment of urinary tract infections, microbiologic data support its potential utility for community-acquired uncomplicated urinary infections.[39] The safety and efficacy of cefdinir have not been established for infants younger than 6 months.

CEFDITOREN PIVOXIL

Cefditoren pivoxil was approved by the FDA in 2002 for oral treatment of acute exacerbations of chronic bronchitis, pharyngitis, tonsillitis, and uncomplicated skin and soft tissue infections in adults and adolescents aged 12 years or older. Cefditoren is similar to cefdinir and cefpodoxime in its antibacterial activity. It is stable to hydrolysis by many common Enterobacteriaceae-produced β-lactamases. Cefditoren has the greatest in vitro antimicrobial activity of all oral cephalosporins against *S. pneumoniae*. The inactive metabolite pivalate is eliminated by the kidneys in combination with carnitine as pivaloylcarnitine. Although cefditoren transiently decreases serum concentrations of carnitine, the clinical significance of this is not clear, but no adverse effects have been reported.[183]

Fourth-Generation Cephalosporins

CEFEPIME

Cefepime, the prototypic agent of this class of antibiotics, was approved by the FDA in 1996. It is distinguished from other cephalosporins by the following characteristics: rapid penetration of outer-membrane porins into the periplasmic space of gram-negative bacteria, facilitated by its net neutral charge; enhanced stability against hydrolysis by inducible or constitutively expressed chromosomally mediated AmpC Bush group 1 β-lactamases and Amber class A plasmid-mediated SHV- and TEM-type ESBLs; and increased binding affinity to multiple PBPs. These factors contribute to cefepime's expanded spectrum of activity and improved efficacy against gram-negative pathogens when compared with third-generation cephalosporins.

The in vitro activity of cefepime encompasses a broad range of gram-positive and gram-negative organisms, including the following: oxacillin-susceptible staphylococci; approximately 75 percent of penicillin-resistant strains of *S. pneumoniae*; viridans streptococci; most strains of Enterobacteriaceae, including, most notably, ESBL-producing strains of *E. coli* and *K. pneumoniae*; and AmpC-mediated resistant *Enterobacter* spp., and *Citrobacter* spp., as well as approximately 90 percent of *P. aeruginosa* isolates. Furthermore, bacteria in which resistance to third-generation cephalosporins develops by means of single-step mutations usually remain susceptible to cefepime. Clinical and laboratory data also indicate that selection of cefepime resistance, specifically among *Enterobacter* spp., and *P. aeruginosa*, is rare. As with other cephalosporins, cefepime is inactive against enterococci, methicillin-resistant staphylococci, *S. maltophilia*, and many anaerobic organisms.[142,152]

Cefepime is indicated for the parenteral treatment of lower respiratory tract, urinary tract, skin and skin structure, and intra-abdominal (in combination with anaerobic antibacterial agents) infections, as well as for empiric monotherapy in pediatric patients with cancer who have fever and neutropenia, for whom cefepime has been shown to be as effective as is meropenem, piperacillin-tazobactam, or ceftazidime with or without an aminoglycoside. In comparative clinical and microbiologic efficacy trials, cefepime as a single antibacterial agent was equivalent to third-generation cephalosporins for the most common childhood pathogens. In addition, cefepime is as safe and well tolerated as are other cephalosporin antibiotics.[42,201,250]

Cefepime should be reserved for complicated community-acquired, health care–associated, or polymicrobial infections, penicillin-resistant and third-generation cephalosporin-resistant pathogens, and patients with cystic fibrosis and *P. aeruginosa* lung infections. Cefepime concentrations in CSF reach approximately 3 to 6 μg/mL (9% of the peak plasma concentration) in children with bacterial meningitis. Therefore, achievable CSF concentrations exceed the MICs of common CNS pathogens by at least 10-fold, except for penicillin- and cephalosporin-nonsusceptible *S. pneumoniae*.[36] Currently, data are insufficient to recommend cefepime as single-agent therapy for meningitis. The safety and efficacy of cefepime have not been established for neonates, but data extrapolated from pharmacokinetic studies among preterm and term infants support a dose of 30 mg/kg every 12 hours for infants younger than 14 days of age, regardless of gestational age. This dosage should provide antibiotic exposure equivalent to or greater than the approved dose of 50 mg/kg every 8 to 12 hours in older infants and children.[55]

Adverse Effects

The cephalosporins, like the penicillins, are safe for children and have almost no dose-related toxicity. The most common reactions are local, including pain at the injection site or thrombophlebitis with parenteral administration and mild gastrointestinal

complaints with oral dosing. Hypersensitivity reactions occur in approximately 1 to 3 percent of treatment courses and include morbilliform rash, urticaria, and pruritus. Drug fever has been associated with the administration of cephalosporins. Nonspecific antibiotic-associated diarrhea and, less commonly, *C. difficile* toxin–mediated colitis can occur after use of cephalosporin.

Other adverse effects are rare, and some are unique to one or a few cephalosporins. Physicians should be alert for uncommon reactions, including reversible neutropenia, which can occur after prolonged use of high-dosage cephalosporins, Coombs-positive hemolytic anemia, and bleeding. Altered hemostasis because of hypoprothrombinemia can result when using any cephalosporin that contains a methylthiotetrazole side chain (cefamandole, cefotetan, and moxalactam). These agents act as competitive inhibitors of vitamin K–dependent carboxylase, which converts clotting factors II, VII, IX, and X to their active forms. Gallbladder sludging, biliary pseudolithiasis, and symptomatic obstructive biliary disease rarely have been associated with the administration of ceftriaxone.[284]

The cephalosporins may produce allergic reactions similar to those caused by the penicillins. Cross-sensitization exists among the cephalosporins, and allergy to one cephalosporin implies allergy to all. Various degrees of immunologic cross-reaction of penicillins and cephalosporins have been demonstrated in vitro and in animal models.[220] Previously quoted studies suggested that the frequency of allergic reactions to cephalosporins ranges from 5.4 to 16.5 percent in adult patients with a history of penicillin allergy and from 1 to 2.5 percent in those without such a history. The incidence of hypersensitivity to unrelated drugs is increased in some patients who are allergic to penicillin, a finding thus suggesting that excipients in antibiotic preparations may be responsible for these reactions.[247] Most patients who are thought to be allergic to penicillin receive cephalosporins without adverse reaction. Data indicate that the risk of an allergic reaction to a cephalosporin challenge among penicillin-allergic subjects with positive skin test responses is 4 percent. Therefore, the following options are available for individuals with positive skin test responses for penicillin hypersensitivity: administration of an alternative non–β-lactam antibiotic, administration of a cephalosporin by graded challenge, or desensitization to the cephalosporin. Individuals with a history of penicillin allergy who have negative penicillin skin test responses may receive cephalosporins because they are at no higher risk than the general population of experiencing allergic reactions.[171] In the absence of penicillin skin testing, a cephalosporin may be used with caution as an alternative to penicillin in children who have an ambiguous history of rash; however, cephalosporins should be avoided in patients with a known immediate or accelerated reaction to a penicillin. Currently, skin testing to evaluate for cephalosporin hypersensitivity is not possible because the potential cephalosporin haptens are unknown, and no standardized antigen exists.

Some products may cause unexpected reactions, such as bile sludge attributed to ceftriaxone and serum sickness–like disease described with cefaclor. A generalized pruritic rash, similar to erythema multiforme, developed in some children treated with cefaclor along with fever, purpura, and arthritis with pain and swelling in the knees and ankles. The signs appeared 5 to 19 days after the start of therapy and generally disappeared within 4 to 5 days after discontinuing use of the drug. The children had no previous history of allergy to a penicillin or cephalosporin.[200] Levine compared adverse reactions in children who received cefaclor (1017 patients, 2513 courses) or amoxicillin (1009 patients, 2358 courses). Serum sickness (defined as arthritis or arthralgia in addition to a rash or urticaria) or erythema multiforme occurred in 11 children (1.1%) who received cefaclor but in none of those who received amoxicillin.[168] Studies suggest that serum sickness–like reactions to cefaclor are associated with lymphocyte sensitization.[150]

CARBACEPHEMS

Carbacephems have a carbon atom at position 1 of the dihydrothiazine ring (cephem nucleus), rather than a sulfur atom. The only carbacephem currently available is loracarbef. Loracarbef is structurally similar to cefaclor but has greater chemical stability in solution. The antibacterial spectrum of loracarbef is similar to that of second-generation cephalosporins. When compared with cefaclor, loracarbef has similar activity against penicillin-susceptible pneumococci, group A streptococci, and oxacillin-susceptible *S. aureus* and greater activity against *H. influenzae* and *M. catarrhalis*, including β-lactamase–producing strains.[84] Loracarbef is not active against *P. aeruginosa*, *Enterobacter*, *Citrobacter*, indole-positive *Proteus*, or *B. fragilis*.

Loracarbef is more stable than cefaclor to hydrolysis by β-lactamases but can be hydrolyzed by ESBLs. Loracarbef is available for oral administration only. It is absorbed rapidly and well; however, absorption is decreased when the agent is taken with food. Loracarbef has a longer serum half-life than do some of the penicillins and can be given twice daily. It is excreted by the kidneys. Loracarbef is relatively well tolerated. Gastrointestinal complaints, including diarrhea, nausea, and vomiting, are the adverse effects most frequently reported, but they occur in less than 5 percent of treatment courses. The safety and efficacy of loracarbef have not been established for infants younger than 6 months.

Loracarbef can be used as an alternative to penicillin or erythromycin for the treatment of group A streptococcal pharyngitis.[83] The effectiveness of loracarbef is similar to that of amoxicillin and amoxicillin-clavulanate for the treatment of acute otitis media caused by susceptible bacteria.[94] Loracarbef is not effective against penicillin-nonsusceptible pneumococci; therefore, it is not considered appropriate for empiric therapy of acute otitis media.[9] For the treatment of mild to moderate skin and skin structure infections, the efficacy of loracarbef is comparable to that of cefaclor. Loracarbef has been approved for use in the treatment of acute bacterial sinusitis and uncomplicated urinary tract infections caused by susceptible bacteria.

MONOBACTAMS

Aztreonam is the prototype monobactam, a name that refers to the unique monocyclic nucleus. This drug has aerobic, gram-negative antibacterial activity similar to that of ceftazidime, but it has no significant gram-positive activity. Unlike most β-lactam antibiotics, aztreonam has the advantage of not inducing β-lactamase activity, and its molecular structure confers a high degree of stability to hydrolysis by β-lactamases. The mechanisms of antibiotic resistance of some gram-negative bacteria include expression of efflux pumps, reduced expression of outer-membrane porin proteins, and production of AmpC-type β-lactamases or ESBLs. Approximately 15 percent of Enterobacteriaceae in North America are resistant to aztreonam.[242] Although it is a β-lactam, aztreonam is weakly immunogenic and can be used in patients with minor forms of β-lactam allergy. Its use in pediatrics is indicated as a secondary agent for the intravenous treatment of lower respiratory tract, skin and soft tissue, urinary tract, and intra-abdominal infections caused by susceptible pathogens. Higher doses of aztreonam may be warranted for pediatric patients with cystic fibrosis. Aztreonam and aminoglycosides are synergistic in vitro against most strains of *P. aeruginosa*, many strains of Enterobacteriaceae, and other aerobic gram-negative bacilli. Aztreonam lysinate for inhalation is a novel monobactam formulation being investigated for *P. aeruginosa* respiratory infections in patients with cystic fibrosis. The safety and efficacy of aztreonam have not been established for infants younger than 9 months or for children with impaired renal function. However,

aztreonam has been used with favorable outcomes in premature and term neonates, as well as in young infants.

CARBAPENEMS

Carbapenems differ from penicillin by virtue of the substitution of a sulfur atom by a carbon atom at position 1 of the β-lactam ring and possession of an unsaturated bond between carbon atoms at positions 2 and 3 in the structure. The carbapenem class of antimicrobial agents exhibits the broadest spectrum of activity of all β-lactam antibiotics; these agents are active against most clinically significant gram-positive and gram-negative pathogens, including anaerobic organisms. Because they are acid-labile in the stomach, they must be administered parenterally.[70] Three carbapenems, imipenem-cilastatin, meropenem, and ertapenem, are approved for use in children.

Imipenem-Cilastatin

Imipenem-cilastatin was the first carbapenem evaluated for the treatment of severe bacterial infections in children. Extensive hydrolysis of imipenem by dehydropeptidase I in the proximal renal tubule results in the production of a potentially nephrotoxic inactive metabolite. Consequently, imipenem must be administered with cilastatin, an inhibitor of dehydropeptidase I. Despite favorable in vitro efficacy against a broad spectrum of bacterial pathogens, the clinical suitability of this antibiotic is limited because of the drug's epileptogenic potential, especially in children with bacterial meningitis. Imipenem causes seizures presumably by acting as a competitive inhibitor of γ-aminobutyric acid, an inhibitory neurotransmitter.[70] Of concern is that imipenem acts as a strong inducer of production of ESBL and may select for β-lactam resistance.[74] Imipenem-cilastatin is indicated for children with severe non-CNS infections caused by susceptible organisms. The dose must be reduced for children with impaired renal function. With the advent of meropenem, imipenem-cilastatin became used less frequently in pediatrics.

Meropenem

Meropenem was approved for use in children in 1996. It is structurally related to imipenem. However, it is more stable against degradation by renal dehydropeptidase I and therefore does not require co-administration with cilastatin. On the basis of its superior safety and efficacy, meropenem generally is considered the preferred carbapenem for treatment of childhood infections.

MECHANISMS OF ACTION

As with other β-lactam antibiotics, meropenem is bactericidal against susceptible bacteria because it inhibits bacterial cell wall synthesis. The *trans* configuration of the hydroxyethyl side chain and hydrogen atoms protect the parent β-lactam structure from inactivation by the most common β-lactamases, including almost all Bush groups 1 and 2 (Amber classes A, C, and D) β-lactamase–producing organisms, including those that produce ESBLs (*Citrobacter*, *Enterobacter*, *E. coli*, *Klebsiella* spp., and *P. mirabilis*) or AmpC β-lactamases (*Citrobacter*, *Enterobacter*, *Pseudomonas*, and *Serratia*). In addition, the pyrrolidine side chain enhances the compound's antipseudomonal activity.[74]

MECHANISMS OF RESISTANCE

Resistance may be intrinsic or acquired and is mediated by numerous mechanisms: (1) some strains of *P. aeruginosa* are deficient in the cell wall porin proteins (OprD) that usually facilitate intracellular penetration; (2) efflux pumps in some gram-negative bacteria are capable of excreting carbapenems; (3) *S. maltophilia* and some other gram-negative pathogens possess uncommon metallo-β-lactamases, the so-called carbapenemases (Bush groups 3a and 3b; Amber class B), which form a diverse group of β-lactamases comprising the IMP- and VIM-families, and SPM-1 and GIM-1 enzymes; these carbapenemases have the ESBL and AmpC antibiotic substrate profile; (4) some gram-negative bacteria possess clavulanic acid-inhibited carbapenemases consisting of the *K. pneumoniae* carbapenemases (KPCs) (Bush group 2f; Amber class A) or OXA enzymes (Bush group 2d, Amber class D); and (5) MRSA strains and *E. faecium* have altered PBPs, which account for their inherent resistance. Furthermore, meropenem acts as a weak inducer of ESBLs.[41,74] At present, the risk that a single-step spontaneous mutation causes resistance among *Pseudomonas* spp. appears to be low.

IN VITRO ACTIVITY

Meropenem has equivalent or slightly less in vitro potency than imipenem does against gram-positive pathogens, but it is significantly more active against gram-negative organisms. The spectrum of activity of meropenem encompasses streptococci (excluding many strains of penicillin- and cefotaxime-nonsusceptible *S. pneumoniae)*, oxacillin-susceptible staphylococci, ampicillin-susceptible enterococci, *L. monocytogenes*, *H. influenzae*, *N. meningitidis*, Enterobacteriaceae, most strains of *P. aeruginosa*, and anaerobes (including β-lactamase–positive strains of *B. fragilis*). Pathogens resistant to meropenem are *Stenotrophomonas*, MRSA, *E. faecium*, approximately 10 percent of *Pseudomonas* strains, and most strains of penicillin- and cefotaxime-nonsusceptible *S. pneumoniae*.[41,49,275] In vitro tests indicate that meropenem acts synergistically with aminoglycoside antibiotics against some isolates of *P. aeruginosa*.[131]

PHARMACOKINETICS

Meropenem exhibits nearly linear pharmacokinetics; increases in dosage result in approximately proportional increases in the peak plasma concentration and area under the plasma concentration-time curve (AUC).[33] Only 2 percent of the drug is bound to plasma proteins, and the drug is distributed widely into tissues and fluids.[70] The elimination half-life declines with increasing age (premature neonates, 2.9 hours; term neonates, 2 hours; children, 1.1 hours; adults, 1 hour) and is longer than that for imipenem. Because meropenem is cleared primarily by glomerular filtration, the dosage should be reduced in children with renal dysfunction.[41] Furthermore, meropenem is cleared efficiently by hemodialysis; therefore, it should be administered after the patient undergoes this procedure. Pharmacodynamic studies indicate that a favorable bacteriologic outcome is best predicted by the duration of the dosing interval for which the meropenem plasma concentration exceeds the MIC_{90} of the target pathogen.[70] Accordingly, a dose of 20 mg/kg every 8 hours achieves optimal plasma concentrations (50 to 60 μg/mL) for systemic infections that do not involve the CNS,[35] whereas a dose of 40 mg/kg every 8 hours is recommended for patients with cystic fibrosis because of accelerated drug excretion.[124] Penetration of meropenem through inflamed meninges is approximately 8 percent of the mean plasma concentration. Consequently, a dose of 40 mg/kg every 8 hours is required to achieve mean peak CSF concentrations of 0.9 to 6.5 μg/mL and to ensure effective treatment of bacterial meningitis.[70,213] An every-12-hour administration schedule probably is appropriate for neonates because of their immature renal function.[33]

INDICATIONS FOR USE

The FDA has approved meropenem as monotherapy for susceptible organisms causing intra-abdominal infections and bacterial

meningitis in children older than 2 months. Meropenem should be reserved for the treatment of cephalosporin-resistant nosocomial pathogens, severe polymicrobial infections with favorable susceptibility profiles, and infections that fail to respond to other antimicrobial agents. Meropenem monotherapy has clinical and microbiologic efficacy equivalent to that of third-generation cephalosporin-based regimens for septicemia and infections of the CNS, abdominal cavity, lower respiratory tract, urinary tract, and skin.[43,213] In addition, meropenem monotherapy has been shown to be equivalent to ceftazidime and amikacin and to piperacillin-tazobactam for empiric treatment of febrile children with neutropenia.[67,219] Clinical efficacy against cephalosporin-resistant pathogens also has been demonstrated in patients with cystic fibrosis.[124] In view of increasing resistance of pneumococci to β-lactam antibiotics, it is prudent to administer vancomycin with meropenem for empiric treatment of suspected bacterial meningitis until CSF microbiologic results are available. Combination therapy with aminoglycosides should be considered for suspected or proven *P. aeruginosa* infections in view of emerging resistant strains and potential antibiotic synergy. The effectiveness of meropenem for neonatal infections has been assessed in small, noncomparative studies that demonstrated a favorable clinical response in neonates in whom previous conventional therapy had failed.[131]

ADVERSE EFFECTS

Data from well-designed clinical trials indicate that meropenem has clinical and laboratory adverse event profiles that are equivalent to those of comparable antibiotic regimens. In contrast to treatment with imipenem-cilastatin, no increased risk of seizures exists in children with or without meningitis who are treated with meropenem,[157] presumably because meropenem has less affinity than does imipenem for the γ-aminobutyric acid receptor. Meropenem can be given intravenously as small-volume bolus injections (over a course of 3 to 5 minutes) without inducing nausea or vomiting. The most common adverse reactions include diarrhea (4%), rash (2%), and vomiting (1%).[41]

β-LACTAM ANTIBIOTICS NOT APPROVED FOR USE IN CHILDREN

Several β-lactam antibiotics available in the United States are not approved for use in children. These agents include the following: cefonicid, a second-generation cephalosporin; cefotetan, a cephamycin; and cefoperazone, a third-generation cephalosporin. Several extended-spectrum cephalosporins and carbapenems that have activity against MRSA are undergoing clinical investigation.

Ertapenem

Ertapenem is a newer, long-acting, parenteral carbapenem that initially was approved for use in adults in 2001. An indication for children was approved in 2005. However, clinical experience with this agent in children is limited. Ertapenem is distinctive because it is administered in a single daily dose in adolescents and adults and is stable against hydrolysis by many β-lactamases except metallo-β-lactamases produced by certain bacterial nonfermenters, particularly *Pseudomonas* and *Acinetobacter*.[183] Apart from these organisms, its antimicrobial spectrum is similar to that of meropenem. Ertapenem has restricted activity against methicillin-resistant staphylococci, penicillin-nonsusceptible pneumococci, enterococci, *Pseudomonas* spp., and *Acinetobacter* spp.[151] The agent may be administered by intravenous or intramuscular routes. It exhibits nonlinear pharmacokinetics because of its concentration-dependent protein binding. The drug is excreted renally, and dosages need to be adjusted in patients with renal insufficiency.

Ertapenem is indicated for the treatment of patients 3 months of age and older with complicated intra-abdominal infections, complicated skin and soft tissue infections, community-acquired pneumonia, complicated urinary tract infections, and acute pelvic infections. Ertapenem is not recommended for the treatment of meningitis because drug concentrations in the CSF are subtherapeutic. The recommended dose in patients 3 months to 12 years of age is 15 mg/kg given parenterally twice daily, up to a maximum of 1 g/day. In older children and adults, the recommended dose is 1 g given once daily. The recommended duration is up to 14 days for intravenous administration. The most common adverse reactions, which include diarrhea, vomiting, and pain at the site of infusion, have comparable rates to those of other parenteral broad-spectrum β-lactam antimicrobials. Seizures have been reported in patients receiving ertapenem and may occur more commonly in individuals with underlying seizure disorders, brain lesions, or renal dysfunction.

VANCOMYCIN

Vancomycin, first isolated from *Amycolatopsis orientalis* (formerly called *Streptomyces*, then *Nocardia*) in soil samples from Borneo, is a high-molecular-weight, complex, soluble glycopeptide.[222] Because of a lack of adequate therapy for penicillinase-producing staphylococci, vancomycin was approved expeditiously by the FDA in 1956 before exhaustive pharmacologic and toxicologic studies had been performed. Original preparations contained fermentation byproducts that caused significant toxicity. Once the penicillinase-resistant penicillins were developed, vancomycin no longer was indispensable until the emergence of methicillin-resistant staphylococci in the late 1970s.

MECHANISMS OF ACTION

Vancomycin is slowly bactericidal against most susceptible gram-positive bacteria, except enterococci, for which it is bacteriostatic. It forms complexes with the D-alanyl-D-alanine portion of peptide precursor units and thus prevents polymerization of the phospho-disaccharide-pentapeptide-lipid complex and cross-linking of peptidoglycan during the second stage of cell wall synthesis. Because the site of action of vancomycin is distinct from that of β-lactam antibiotics, no cross-resistance among the drugs and no competitive inhibition exist. Like penicillin, vancomycin exerts its antimicrobial effect on bacteria in the active growth phase. Additionally, vancomycin alters cytoplasmic membrane permeability and impairs RNA synthesis. Animal infection models suggest that the drug exhibits time-dependent bactericidal activity against susceptible organisms, as well as a moderately long in vitro post-antibiotic effect. The most important pharmacokinetic-pharmacodynamic parameter that correlates with antimicrobial efficacy is the ratio of the 24-hour AUC to the MIC (24-hour AUC/MIC).[71] A lag phase before the onset of rapid killing has been demonstrated in serum-killing studies.[2]

MECHANISMS OF RESISTANCE

Resistance can be categorized into three types: tolerance, acquired resistance, and inherent resistance. Some susceptible gram-positive bacteria, especially enterococci, are tolerant to the bactericidal activity of vancomycin; that is, vancomycin inhibits but does not kill the bacteria (MBC/MIC ratio > 32). Staphylococci tolerant to vancomycin can have autolysin deficiencies. Although most resistance to vancomycin by gram-positive bacteria is

acquired, three genera of gram-positive organisms are inherently resistant to vancomycin: *Erysipelothrix*, *Leuconostoc*, and *Pediococcus*. Five genes code for acquired vancomycin resistance in enterococci: *VanA*, *VanB*, *VanC*, *VanD*, and *VanE*.[198] The *VanA* gene that encodes the VanA phenotype (vancomycin MIC > 256 and teicoplanin resistance) is on a plasmid that is easily transferable by conjugation to other enterococci. The VanB phenotype also is transferable and encodes vancomycin but not teicoplanin resistance. The presence of an inducer such as vancomycin or teicoplanin, another glycopeptide that has not been approved for use in the United States, activates the transcription of genes that encode ligases necessary for resistance to vancomycin. Some enzymes make cell wall precursors ending in D-alanyl-D-lactate located at the end of the pentapeptide side chain, to which vancomycin binds with very low affinity. Other enzymes inhibit or alter the synthesis of endogenous cell wall precursors ending in D-alanyl-D-alanine, to which vancomycin is unable to bind. The finding that vancomycin resistance genes can be transferred experimentally from vancomycin-resistant enterococci to staphylococci highlights the potential risk of spread of resistance by means of naturally occurring plasmid- or transposon-mediated conjugative systems.[198] Although vancomycin resistance can affect susceptibility to other investigational glycopeptides, no cross-resistance exists between vancomycin and other unrelated antibiotics. Resistance to vancomycin rarely develops during appropriate therapy, perhaps because of its multiple mechanisms of action, but prolonged or indiscriminate use of the drug can contribute to selective pressure and result in the development of vancomycin-resistant enterococci colonizing the gut. Of great concern is the emergence of invasive strains of multidrug-resistant enterococci (≤14% of health care–associated enterococcal strains)[178] and staphylococci, for which only a few therapeutic options exist, including linezolid and other antimicrobials not approved for use in children such as quinupristin-dalfopristin, daptomycin, and tigecycline (a novel glycylcycline antibiotic).The first strains of *S. aureus* with intermediate resistance to vancomycin/glycopeptide (VISA/GISA), defined as having MICs of 8 or 16 μg/mL, were detected in the United States in 1997. Soon thereafter, three cases of vancomycin-resistant *S. aureus* (VRSA; MIC = 32 μg/mL) were isolated. The mechanism for this high-level vancomycin resistance involves the horizontal transfer of a transposon containing *vanA* and associated genes from vancomycin-resistant enterococci.[232] Glycopeptide-resistant isolates were found to have thicker extracellular matrices, a characteristic that may cause vancomycin to become trapped in the outer layers of the cell wall and may limit access to the cytoplasmic membrane where the functional targets are located. Pneumococci tolerant to vancomycin were described first in 1999.[212] These strains escape lysis and killing by vancomycin because of an alteration in the regulation of autolysin. Their prevalence is 4 to 10 percent of nasopharyngeal and invasive isolates, and they are associated with increased mortality when etiologic in meningitis.[239] The CDC recommends that the use of vancomycin be restricted appropriately to reduce the risk of inducing vancomycin resistance.[57]

IN VITRO ACTIVITY

The in vitro spectrum of activity for vancomycin is limited to gram-positive aerobic and anaerobic bacteria, with little, if any, activity against aerobic or anaerobic gram-negative bacilli, except *Chryseobacterium meningosepticum*. Group A streptococci, pneumococci, *Corynebacterium* spp., and *C. difficile* are highly susceptible to vancomycin, whereas *L. monocytogenes*, microaerophilic and anaerobic streptococci, enterococci, coagulase-positive and coagulase-negative staphylococci, *Bacillus anthracis* and other spp., *Lactobacillus*, *Actinomyces*, and other *Clostridium* spp. have higher MIC values that are still in the susceptible range. Pathogens resistant to vancomycin include *Erysipelothrix* and *Leuconostoc* and *Pediococcus* spp. that can cause serious infections in immunocompromised patients. The bactericidal activity of vancomycin combined with gentamicin has been shown to be synergistic in vitro against strains of enterococci (provided there is no high-level gentamicin resistance; MIC > 2000 μg/mL), nonenterococcal group D streptococci, viridans streptococci, and most methicillin-susceptible *S. aureus* and MRSA. Addition of rifampin, gentamicin, or both, results in improved cure rates for *S. epidermidis* prosthetic valve endocarditis.[178] Although vancomycin has activity against many gram-positive bacteria, it is not the most active agent for these organisms, but it is the drug of choice for multidrug-resistant bacteria such as methicillin-resistant staphylococci and highly penicillin-resistant and cephalosporin-resistant pneumococci.

PHARMACOKINETICS

Intravenous administration of vancomycin is preferred because intramuscular injection causes pain and tissue necrosis. Intravenous preparations must be diluted further in normal saline or dextrose solutions before beginning slow infusion. Vancomycin is approximately 55 percent bound to serum proteins and diffuses well into most body tissues, with adequate concentrations achieved in pericardial, pleural, ascitic, bone, and synovial fluids, but not in aqueous humor or bile. Vancomycin does not diffuse well into CSF in the absence of inflamed meninges, but CSF concentrations of 7 to 21 percent of concomitant serum levels can be achieved during therapy for meningitis when higher doses (15 mg/kg every 6 hours) are administered. The bone-to-serum ratio of vancomycin is 10 percent, but this figure increases up to 30 percent in infected bone. Vancomycin remains active at pH 6.5 to 8, and concentrations achieved in abscess fluid approximate serum levels.[178] Intrathecal or intraventricular administration has been used infrequently for CNS infections that are difficult to eradicate.[177] Vancomycin is not metabolized significantly and is excreted by glomerular filtration. The mean serum elimination half-life in adults with normal renal function is 6 hours. For children, it ranges from 5 to 10 hours in newborns and 4 hours in older infants to 2 to 3 hours in children. In anephric patients, the elimination half-life extends to 7 or more days. Hemodialysis removes small amounts of vancomycin, whereas peritoneal dialysis may reduce serum concentrations by approximately 40 percent. Nomograms and patient-individualized bayesian dosing regimens have been used for vancomycin dosing in renal failure in adults.[163,192]

INDICATIONS FOR USE

Because of the potential for development of resistance, vancomycin should be reserved for patients with moderate to severe infections caused by vancomycin-susceptible bacteria that are resistant to other antibiotics. Vancomycin can be used for the treatment of infections caused by β-lactam–susceptible and vancomycin-susceptible bacteria in patients with hypersensitivity reactions to β-lactam antimicrobial agents. Empiric therapy for patients with ventricular shunt-related and catheter-associated infections frequently includes vancomycin to provide activity against coagulase-negative staphylococci. Vancomycin can be used in combination with gentamicin, rifampin, or both, for bactericidal synergistic activity to treat documented prosthetic device–related *S. epidermidis* infections, methicillin-resistant staphylococcal endocarditis, or endocarditis caused by high-level penicillin-resistant, aminoglycoside-susceptible strains of enterococci. *S. epidermidis* infections of long-term intravenous catheters usually

can be cured without removal of the device.[178] In addition, vancomycin is the drug of choice in patients with immediate-type hypersensitivity to penicillins and other β-lactam antibiotics for prophylaxis (gastrointestinal or genitourinary procedures) or treatment of endocarditis caused by streptococci, enterococci, and staphylococci.[17,73] Empiric treatment of bacterial meningitis suspected or proved to be caused by *S. pneumoniae* in children 1 month old or older should consist of vancomycin in addition to a third-generation cephalosporin until susceptibility data are available; if cephalosporin resistance is documented, rifampin should be added to the regimen. However, vancomycin need not be used if compelling evidence implicates pathogens other than *S. pneumoniae*, such as the observation of gram-negative diplococci on a CSF smear. Vancomycin also is indicated for the treatment of infections with penicillin-resistant streptococci, *C. jeikeium*, and *Bacillus* spp. penicillin-resistant enterococci, as well as for bacteremia, pneumonia, cellulitis, and osteomyelitis caused by methicillin-resistant staphylococci. Some experts advocate the addition of nafcillin, oxacillin, gentamicin, or rifampin for optimal coverage of oxacillin-susceptible *S. aureus* in severely ill patients who are receiving empiric treatment with vancomycin because certain strains of staphylococci are tolerant to vancomycin.[110] Proof of enhanced efficacy with combination therapy in this setting is lacking. Although nonabsorbable oral vancomycin is effective therapy for *C. difficile* colitis, oral metronidazole represents first-line therapy; vancomycin should be given only for metronidazole treatment failures, to limit the development of vancomycin-resistant enterococci. Vancomycin is among the agents of choice for the treatment of meningitis caused by *C. meningosepticum*.

ADVERSE EFFECTS

The purification of vancomycin allegedly decreased the frequency of adverse reactions noted several decades ago. The most common adverse effect is "red man" or "red neck" syndrome, or glycopeptide-induced anaphylactoid reaction, manifested as flushing of the face and upper part of the trunk, pruritus during vancomycin infusion, angioedema, and, rarely, hypotension. Vancomycin directly causes release of histamine from mast cells by non–immune-mediated mechanisms. Because it is a dose- and rate-dependent reaction, administering doses less than 500 mg, prolonging the infusion period to at least 1 hour, or doing both, decreases the risk of occurrence. Pretreatment with H_1-receptor antagonists (diphenhydramine, hydroxyzine) prevents the development of this reaction, and symptoms usually resolve promptly after discontinuation of the infusion.

Controversy surrounds the issue of vancomycin-induced ototoxicity and nephrotoxicity.[48] Such toxicity has not been demonstrated in experimental animal models. Although numerous cases of toxicity in humans have been reported, the literature is difficult to interpret because of confounding variables, including recent or concurrent use of aminoglycosides or other ototoxic or nephrotoxic agents, lack of identification of antecedent otologic or renal disease, and inconsistencies in sampling methods when measuring serum vancomycin concentrations. Tinnitus and high-tone hearing loss have been associated with the administration of vancomycin, particularly when the peak serum levels exceed 50 μg/mL. If vancomycin is ototoxic, whether toxic peak or toxic trough serum concentrations are responsible is not clear. Several studies suggest an increased risk of nephrotoxicity when aminoglycosides are used concurrently with vancomycin, especially when they are administered for longer than 21 days.[107] Other adverse effects seen occasionally with the use of vancomycin include reversible neutropenia, thrombocytopenia, drug fever, and macular rash.

The usefulness of serum vancomycin concentration determinations is controversial because a definitive relationship between vancomycin concentration and either adverse effects or clinical outcome has not been proved.[55,191] Until the significance of vancomycin serum concentration determinations has been clarified, monitoring has been suggested for the following clinical situations only: (1) patients with altered renal function, including premature infants; (2) patients receiving larger than normal dosages, especially those with meningitis in whom adequate CSF values are necessary; (3) anephric patients undergoing hemodialysis (to avoid subtherapeutic vancomycin concentrations during prolonged dosing intervals); and (4) patients receiving concomitant therapy with nephrotoxic agents.[191] Because serum vancomycin values commonly are subtherapeutic in the first days of treatment for severe sepsis, presumably because of larger volumes of distribution of vancomycin in these ill children, we recommend an initial dosage of 60 mg/kg/day in four divided doses.

Daptomycin has been approved for treatment of adults with complicated skin and soft tissue infections and with endocarditis and sepsis. It is a parenteral lipopeptide that disrupts cell membrane potential, and, unlike vancomycin, it is rapidly bactericidal against MRSA strains. Pediatric experience is limited. Other semisynthetic glycopeptides in development such as televancin or the glycopeptide approved for adults, dalbavancin, may have some advantage over vancomycin and daptomycin in that resistance of MRSA is less likely because of their dual mechanisms of action.

AMINOGLYCOSIDES

Aminoglycosides are natural and semisynthetic compounds that consist of at least two amino sugars bound by a glycosidic linkage to a hexose nucleus, the aminocyclitol ring. A more appropriate name would be aminoglycosidic aminocyclitols. Streptomycin, isolated from *Streptomyces griseus*, was the first aminoglycoside and was available for use in 1944. Many aminoglycosides have been isolated or developed since that time. The suffix denotes the origin of the aminoglycoside: those ending with the suffix *-mycin* were derived from *Streptomyces* spp., whereas those ending with *-micin* were derived from *Micromonospora* spp. Currently, eight aminoglycosides are approved for use in the United States (Table 248–7), and several more are available in other countries. Despite the development of less toxic antibiotics with broad-spectrum activity, aminoglycosides continue to fulfill an essential role in the treatment of severe infections caused by aerobic gram-negative bacilli and enterococci.

MECHANISMS OF ACTION

Against susceptible bacteria, aminoglycosides demonstrate rapid, concentration-dependent bactericidal activity.[87,274] They

TABLE 248–7 Classfication Scheme for Aminoglycosides

Aminocyclitol Ring	Family	Member
Streptidine	Streptomycin	Streptomycin
2-Deoxystreptamine	Kanamycin	Kanamycin Amikacin Tobramycin
2-Deoxystreptamine	Gentamicin	Gentamicin Netilmicin
2-Deoxystreptamine	Neomycin	Neomycin Paromomycin

exert their effect by binding irreversibly to the 30S subunit of the bacterial ribosome, which results in inhibition of protein synthesis and induction of translational errors. Bacterial uptake of aminoglycosides can be facilitated by concomitant therapy with cell wall–active antibiotics such as β-lactams or vancomycin. Penetration of the outer membrane of gram-negative bacteria is mediated by a self-promoted uptake process involving aminoglycoside-induced disruption of magnesium bridges between adjacent lipopolysaccharide molecules. Passage through porin channels is unlikely because of the large size of aminoglycosides. Subsequent transport into cytoplasm and attachment to the 30S ribosomal subunit require two energy- and oxygen-dependent steps, energy-dependent phases I and II (EDP-I and EDP-II), that use an electrochemical proton gradient. EDP-I is inhibited by hyperosmolarity, low pH, and anaerobic conditions. Unlike other protein synthesis inhibitors, which usually are bacteriostatic, aminoglycosides are bactericidal. Binding of aminoglycosides to the 30S subunit does not prevent formation of the initiation complex of peptide synthesis. However, it disrupts elongation of the peptide chain by impairing the proofreading process, an impairment that results in translational inaccuracy. Aberrant protein products may be inserted in the cell membrane and cause altered permeability. The primed amino sugar and 2-deoxystreptamine groups are essential for the ribosome-specific activity of aminoglycosides.[189]

MECHANISMS OF RESISTANCE

The prevalence of acquired aminoglycoside resistance is relatively low, and its development during therapy is an unusual event. Bacteria can acquire resistance to aminoglycosides because of alterations in the bacterial target, reduced bacterial cell permeability or uptake, or modification of the antibiotic by bacterial enzymes, the last being most significant clinically.[76] Mutations in the aminoglycoside-binding site of the 30S ribosome have been associated with high-level resistance to streptomycin but not to other aminoglycosides, possibly because, unlike streptomycin, they bind to multiple sites on the ribosome. Facultative aerobic bacteria causing infection in sites with reduced oxygen tension, anaerobic bacteria, and such fermentative bacteria as streptococci are inherently resistant to aminoglycosides because they are unable to generate an electrochemical proton gradient sufficient for aminoglycoside transport into the cytoplasm. Other bacteria can acquire resistance because of reduced permeability or lack of transport, as demonstrated in staphylococci, in which resistance to aminoglycosides quickly develops when monotherapy is administered. *P. aeruginosa*, other nonfermenting gram-negative bacilli, and, less frequently, members of the Enterobacteriaceae can acquire a moderate level of resistance to all aminoglycosides as a result of various mechanisms that interfere with uptake, cytoplasmic transport, or regulation of the anaerobic respiratory pathway. Plasmid-mediated production of aminoglycoside-modifying enzymes is the most common mechanism of acquired resistance. Many enzymes have different substrate specificities, several of which can be elaborated simultaneously in the same bacterium. These acetyltransferases, nucleotidyltransferases, and phosphotransferases interact with amino or hydroxyl groups on the aminoglycoside and modify the aminoglycoside so that it binds poorly to the 30S ribosome, thereby usually resulting in high-level resistance.[189] Gentamicin and tobramycin each is susceptible to at least five modifying enzymes, whereas amikacin possesses an aminohydroxybutyryl group that prevents enzymatic modification at multiple sites. Consequently, more than 80 percent of gentamicin-resistant strains of Enterobacteriaceae and 25 to 85 percent of gentamicin-resistant *P. aeruginosa* strains are susceptible to amikacin.[160]

IN VITRO ACTIVITY

The in vitro antibacterial spectrum of aminoglycosides includes a wide range of aerobic gram-negative bacilli, many oxacillin-susceptible staphylococci, many enterococci, and some mycobacteria.[190] Some gram-negative bacilli, including *Burkholderia cepacia* and *S. maltophilia*, are consistently resistant to all aminoglycosides. The spectra of activity of gentamicin, tobramycin, and netilmicin are similar, and strains resistant to one usually are resistant to the others. The major advantage of tobramycin currently is its activity against some strains of *Acinetobacter* and indole-positive Proteae (*Morganella* spp., *Proteus* spp., *Providencia* spp.) that are resistant to gentamicin.[231] Because many aminoglycoside-modifying enzymes are active against gentamicin, tobramycin, and netilmicin but inactive against amikacin, amikacin frequently is prescribed for empiric treatment of nosocomial gram-negative bacillary infections. Amikacin also has activity against the *Mycobacterium avium* complex (MAC), some rapidly growing mycobacteria, and *Nocardia asteroides*. Netilmicin is less active than are other aminoglycosides against *P. aeruginosa*, but it can have activity against some gentamicin-resistant, aerobic, gram-negative bacilli. Although gentamicin, tobramycin, amikacin, and netilmicin have similar spectra of activity, susceptibility testing is recommended because of geographic and interhospital variation in resistance patterns. Lack of activity against *P. aeruginosa*, *Klebsiella*, and *Serratia* has limited the use of kanamycin. Streptomycin is inactive against many gram-negative enteric bacilli but does have activity against *Francisella tularensis*, *Yersinia pestis*, and *Mycobacterium tuberculosis*.

PHARMACOKINETICS

Aminoglycosides have in common many pharmacokinetic characteristics. They are highly polar, water-soluble compounds that are positively charged cations at neutral pH. Their antibacterial activity is pH-dependent, with increased activity at higher pH. They are relatively resistant to degradation at various temperatures and pH values. After parenteral administration, aminoglycosides are distributed rapidly in extracellular body water, with slow accumulation in tissues. The volume of distribution is decreased (with respect to total-body weight) in obese patients and is increased in patients with illnesses associated with edema, such as severe infections, burns, congestive heart failure, and ascites. With the exception of proximal renal tubular cells and possibly inner ear hair cells, penetration into other body compartments is impaired because of lipid insolubility, polycationic charge, and size of the aminoglycoside. Proximal renal tubular cells absorb aminoglycosides through carrier-mediated pinocytosis, and as a result, renal cortical concentrations exceed those in plasma. Aminoglycosides do not penetrate the blood-brain barrier in the absence of meningeal inflammation, but with inflammation, approximately 20 to 25 percent of the serum concentration penetrates the CSF. These CSF concentrations are low in relation to the MIC of the meningeal pathogen for which it is given. Thus, because of this narrow therapeutic-toxic index, monotherapy for gram-negative bacillary meningitis with aminoglycosides is not recommended. Aminoglycosides are not metabolized and, after parenteral administration, are excreted unchanged in the kidney by glomerular filtration, with approximately 5 percent of excreted drug reabsorbed in the proximal tubular cells. Minimal amounts are excreted in saliva and feces. Urine concentrations exceed those in plasma by 25 to 100 times.

After intramuscular injection, aminoglycosides are absorbed completely, and peak serum concentrations are achieved within

90 minutes, except in some disease states that interfere with tissue perfusion, such as hypotension. When administered intravenously, the infusion should be given slowly over the course of 30 to 60 minutes to avoid the development of potential adverse effects. Peak serum concentrations are achieved within 30 to 60 minutes after infusion. Because of the polar nature of these drugs, absorption after oral administration is insignificant and inadequate to treat systemic infections, but aminoglycosides can accumulate in the presence of renal failure and result in concentrations sufficient to cause toxicity. Although aminoglycosides are nonirritating when they are instilled into pleural or peritoneal spaces, their absorption is rapid and can result in significant toxicity. In contrast, instillation into the lateral ventricles or irrigation of the bladder has not been associated with significant systemic absorption. When compared with parenteral administration, aerosol administration of aminoglycoside results in higher concentrations in bronchial secretions and less toxicity.[228] Indiscriminate use of topical aminoglycosides in the form of ointments, creams, or ophthalmic solutions may lead to the rapid development of aminoglycoside resistance, especially in immunocompromised patients.

Antimicrobial dosing in newborns and young infants differs from that in older children and adults because of developmental changes in renal function and increased total-body water composition. Neonates and young infants have a larger volume of distribution and a reduced glomerular filtration rate; these differences are more pronounced in very-low-birth-weight premature neonates.[225] Therefore, twice-daily regimens have been the standard of care in newborn infants for years. Once-daily gentamicin dosing (4 mg/kg) in term neonates has been studied extensively and is used routinely in many nurseries; no differences in effectiveness or toxicity have been observed.[274] The aminoglycoside dosing schedule currently approved for use in older infants and children is a three-times-daily regimen. Because aminoglycosides demonstrate concentration-dependent bactericidal activity, higher peak serum concentrations result in more extensive and more rapid killing.[274] Aminoglycosides also demonstrate a post-antibiotic effect against susceptible aerobic gram-negative bacilli in vitro and in vivo.[282] Furthermore, host leukocytes display enhanced phagocytosis of aminoglycoside-exposed bacteria in vitro, referred to as post-antibiotic leukocyte enhancement.[93] The higher the peak serum concentration, the longer is the duration of the post-antibiotic effect. In the presence of normal renal function, the serum concentration is low or undetectable before the administration of the next dose (trough value), but antibacterial activity persists because of the post-antibiotic effect. These characteristics favor single-daily dosing. Numerous studies in adults have shown that once-daily dosing of aminoglycosides (amikacin, gentamicin, tobramycin, or netilmicin) is either equivalent or superior to multiple-daily dosing with regard to clinical and bacteriologic effectiveness, nephrotoxicity, ototoxicity, mortality, and cost-effectiveness.[274] The Hartford nomogram originally described by investigators from Hartford, Connecticut, commonly is used to guide extended-interval aminoglycoside dosing for adults. In adults, a single serum concentration of gentamicin or tobramycin is obtained 8 to 12 hours after the start of the infusion of the first dose and plotted on the nomogram to determine the appropriate dosing interval.[99] Similar nomograms for children have not been validated. Nonetheless, published guidelines support 7.5 mg/kg per dose of gentamicin for infants and children up to 10 years of age; for adolescents and adults, 6 to 7 mg/kg per dose is appropriate.[69,274] Extended-interval aminoglycoside dosing is contraindicated if the patient's volume status is altered (third spacing, thermal injury > 20 percent total-body surface area), optimal dosing regimen is predefined (cystic fibrosis, endocarditis), renal function is impaired, or immune status is compromised.

INDICATIONS FOR USE

The major use of aminoglycosides in children (usually in combination with other antibacterial agents) is for serious infections caused by gram-negative enteric bacilli, including neonatal sepsis, sepsis in a child with malignant disease or an immunologic defect, abdominal and systemic infections associated with spillage of fecal contents into the peritoneum, endocarditis caused by certain susceptible bacteria, and complicated urinary tract infections. Because gentamicin is the least expensive aminoglycoside and the one with which physicians have the most experience, it often is considered the first-line agent for empiric treatment of suspected aerobic gram-negative bacillary infections in institutions with minimal background resistance. Combinations of an aminoglycoside and a cell wall–active antibiotic have been used for synergistic bactericidal activity. Gentamicin or streptomycin, in combination with penicillin G, ampicillin, or vancomycin, is recommended for the treatment of endocarditis caused by susceptible enterococci, viridans streptococci, or *Streptococcus bovis*. Administration of gentamicin for 3 to 5 days, in combination with an antistaphylococcal agent, should be considered for the treatment of staphylococcal endocarditis.[17] An aminoglycoside combined with an acylureidopenicillin, ceftazidime, cefepime, or a carbapenem is recommended for serious infections caused by *P. aeruginosa*. Amikacin often is used for empiric treatment of nosocomial aerobic, gram-negative, bacillary infections in patients in institutions having significant resistance to gentamicin and tobramycin. Streptomycin is indicated for use alone or in combination with other antibiotics for the treatment of tularemia and plague and in combination with other agents for the treatment of tuberculosis, brucellosis, and enterococcal endocarditis. For such purposes, gentamicin could be a more suitable agent for some of these conditions, such as brucellosis, tularemia, and plague. Paromomycin is too toxic for parenteral use, but when administered orally, it has been useful in the treatment of asymptomatic intestinal amebiasis, *Dientamoeba fragilis* infection, and *Giardia lamblia* infection during pregnancy.

ADVERSE EFFECTS

Although aminoglycosides have intrinsic toxicity, allergic reactions are uncommon. All aminoglycosides can injure the proximal renal tubules, the cochlea, the vestibular apparatus, or a combination thereof and can cause neuromuscular blockade, but the risk varies with each agent. Because aminoglycosides do not induce a significant inflammatory response, pain at intramuscular injection sites and phlebitis at intravenous infusion sites are unusual. Hypersensitivity reactions and drug fever are rare events.

Many theories have been postulated regarding the mechanism of nephrotoxicity,[188] including inhibition of lysosomal phospholipases within the proximal renal tubules. Clinical findings include a mild, nonoliguric decrease in the glomerular filtration rate that typically is reversible. When compared with traditional dosing, once-daily dosing causes similar or lower rates of nephrotoxicity.[69,274] In humans, nephrotoxicity has been associated with prolonged duration of therapy at high dosages, previous aminoglycoside therapy, administration of drugs to critically ill patients with intravascular volume depletion or hyponatremia and to those with impaired kidney function, and concomitant administration of other potentially nephrotoxic agents such as amphotericin B and loop diuretics.[78]

The mechanism by which aminoglycosides cause vestibular and cochlear ototoxicity has not been elucidated fully. Cochlear damage is manifested as tinnitus or high-frequency hearing loss, whereas vestibular toxicity is associated with vertigo, nystagmus, and ataxia.[12] Damage can be unilateral or bilateral. Occasionally,

the ototoxicity is reversible, but permanent damage occurs commonly. Mild cochlear damage may not be recognized because the high-frequency hearing range is affected first. Conventional audiograms that do not test high-frequency ranges may not detect cochlear injury. Delayed onset of high-frequency hearing loss has been observed in humans. Factors that increase the risk for development of aminoglycoside ototoxicity in humans include impaired renal function and prolonged duration of treatment. Although elevated serum peak and trough concentrations are thought to contribute to ototoxicity, a specific threshold for peak or trough concentrations has not been established. Neuromuscular blockade can occur after rapid intravenous infusion, after extensive peritoneal irrigation, or during routine parenteral aminoglycoside administration in patients with underlying conditions that affect the neuromuscular junction, such as myasthenia gravis and botulism, or during concomitant administration of agents that act on the neuromuscular junction, such as succinylcholine. Hypomagnesemia in the neonate may predispose to hearing loss.

To avoid toxicity and ensure therapeutic values, concentrations of aminoglycosides in serum should be monitored in all patients who have impaired renal function or who receive other nephrotoxic medications or prolonged treatment; such monitoring is particularly relevant to preterm, low-birth-weight infants. Monitoring also should be considered in obese and undernourished children, children with severe burns, and those with chronic disease, for which the volume of distribution of the drug can be altered (e.g., cystic fibrosis).

MACROLIDES

Erythromycin, isolated from *Streptomyces erythreus* found in a soil sample in the Philippines, was the first macrolide and was available for use in 1952. Many natural and semisynthetic erythromycin derivatives have been developed since then, three of which are approved for use in pediatrics: erythromycin, clarithromycin, and azithromycin. Macrolide antibiotics consist of a large lactone ring attached by a glycosidic bond to one or more amino or neutral sugar moieties. Erythromycin and clarithromycin have 14-membered lactone rings, whereas azithromycin, an azalide antibiotic that is grouped with the macrolides, has a tertiary amino group inserted in its 15-membered ring. In addition to similarities in chemical structure, these macrolides have similar antibacterial spectra, mechanisms of action, and mechanisms of resistance, but they differ in their pharmacokinetic characteristics.

MECHANISMS OF ACTION

Macrolide antibiotics reversibly bind to the 50S ribosomal subunit and inhibit protein synthesis. Initial studies suggested that the antibacterial activity of erythromycin usually was bacteriostatic, but against some actively growing, susceptible bacteria, large concentrations of erythromycin were bactericidal.[117] Clarithromycin and azithromycin usually are bacteriostatic, but they are bactericidal against *S. pyogenes*, *S. pneumoniae*, and *H. influenzae*.[285] Macrolides cause dissociation of peptidyl-tRNAs from bacterial ribosomes that results in accumulation of intracellular peptidyl-tRNA and depletion of the free tRNA pool, with toxic effects for bacteria.[263] The specific target appears to be the 23S ribosomal RNA. Macrolides block the entrance to the tunnel in the 50S ribosomal subunit through which many, if not all, nascent peptide chains exit the ribosome. By blocking the exit tunnel, macrolides induce premature dissociation of peptidyl-tRNAs from the ribosome just after initiation of protein synthesis. Erythromycin interferes with binding to the 50S ribosome by chloramphenicol and clindamycin, thus suggesting common or overlapping binding sites for these agents.

MECHANISMS OF RESISTANCE

Many gram-negative bacteria are inherently resistant to macrolides because of the relative impermeability of their outer membrane. Other bacteria can acquire resistance by production of enzymes that modify and inactivate the macrolide, active efflux of the antibiotic, and alteration of their ribosomal targets.[165] Two mechanisms by which bacteria can alter their ribosomes and acquire macrolide resistance have been identified. High-level resistance because of an altered protein component in domain V of the 50S ribosomal subunit has occurred after a one-step chromosomal mutation. Such resistance has been demonstrated in *M. avium*, *Helicobacter pylori*, *Treponema pallidum*, and *Propionibacterium* spp. Plasmid-mediated macrolide, lincosamide, streptogramin B (MLS_B) resistance occurs when a single adenine residue within a conserved region of domain V of the nascent 23S rRNA component of the 50S ribosomal subunit is methylated. Such methylation results in an altered common target that confers cross-resistance to macrolides (erythromycin and clarithromycin), azalides (azithromycin), lincosamides (clindamycin), and streptogramin B (quinupristin-dalfopristin).[165] The production of methylases is encoded by a class of genes referred to as *erm* (*e*rythromycin *r*ibosome *m*ethylation), nearly 40 of which have been characterized in a wide range of microorganisms, including gram-positive species, spirochetes, and anaerobes. Twenty-one classes of *erm* genes with less than 80 percent sequence homology have been designated unique letters. Pathogenic bacteria comprise one of four major classes: bacteria in classes *erm*(A) and *erm*(C) typically are in methicillin-resistant or methicillin-susceptible strains of staphylococci, respectively; members of class *erm*(B) are mostly in streptococci and enterococci; and class *erm*(F) usually is associated with anaerobic pathogens.[236] These genes are exchanged easily among different strains by plasmids, transposons, or bacterial conjugation. Resistance mediated by *erm* can be constitutive or inducible. When bacteria with inducible MLS_B resistance are exposed to a macrolide inducer (erythromycin, clarithromycin, or azithromycin), inactive methylase mRNA undergoes rearrangements that permit ribosomes to translate the methylase coding sequence. The diversity of inducible macrolide-resistant genotypes results in complex phenotypes, particularly among streptococci and enterococci with *erm*(B) genes, whereas constitutive production of a methylase generally confers a predictable high-level cross-resistance to all MLS_B antibiotics. Staphylococci that are resistant in vitro to 14- and 15-membered ring macrolides but susceptible to 16-membered ring macrolides, clindamycin, and streptogramins B should routinely undergo further testing with a double-disk diffusion test to screen for an erythromycin-induced, D-shaped zone of bacterial inhibition around a clindamycin disk. A positive D-test indicates that the *Staphylococcus* isolate has inducible MLS_B resistance and that use of clindamycin can result in clinical treatment failure, presumably related to selection of constitutive mutants in patients with severe infections and large bacterial inocula.[165] Similar inducible resistance phenotypes may be observed among various strains of streptococci for which the use of clindamycin should be discouraged.

Macrolide resistance associated with active efflux is caused by two classes of pumps: a plasmid-mediated, adenosine triphosphate (ATP)–binding cassette (ABC) transporter encoded by the *msr*(A) gene and found in *Staphylococcus* spp., and a protein of the major facilitator superfamily (MFS) found in streptococci and enterococci and encoded by the *mef*(A) gene. The MsrA pump confers a macrolide and streptogramin B (MS_B) pattern of resistance that can be distinguished from the MLS_B-inducible pheno-

type by the double-disk diffusion D-test. The Mef(A) pump affects only 14- and 15-membered ring macrolides (M phenotype).[165] Less commonly, bacteria produce enzymes that inactivate macrolides, including acetyltransferases, esterases, phosphotransferases, or glycosylases found in some strains of Enterobacteriaceae, but macrolides are not used to target these pathogens. Therefore, this mechanism of low-level resistance is not clinically important.[236] A causal association between erythromycin resistance and antibiotic use, probably mediated by selection pressure, was suggested by a nationwide epidemiologic study in Finland in which reduction of the use of erythromycin over the course of time was associated with a steady decline in erythromycin resistance among *S. pyogenes* isolates from throat swabs and pus specimens.[254] Conversely, increased consumption of macrolides in Spain since 1995 was related to an increase in macrolide resistance.[111]

IN VITRO ACTIVITY

Erythromycin is effective in vitro against a diverse group of microorganisms, including *Bacteroides* spp., *Bordetella pertussis*, *Chlamydophila* spp., *Corynebacterium diphtheriae*, *H. pylori*, the bacterium of legionnaires' disease *(Legionella pneumophila)*, mycoplasmas *(Mycoplasma pneumoniae* and *Ureaplasma urealyticum)*, spirochetes *(T. pallidum)*, and anaerobic and aerobic gram-positive cocci *(S. pneumoniae*, *S. pyogenes*, and penicillinase-producing and non–penicillinase-producing strains of oxacillin-susceptible *S. aureus)*. Erythromycin is active against *Campylobacter jejuni*, *N. meningitidis*, *N. gonorrhoeae*, and, to a lesser extent, *H. influenzae*. Macrolide resistance among diverse pathogens is increasing worldwide, and the clinical consequences are topics of active research.[103,133,159]

The newer macrolides have spectra of activity similar to that of erythromycin. When compared with erythromycin, clarithromycin has equivalent or greater activity against *M. catarrhalis*, *H. influenzae*, *M. pneumoniae*, *Chlamydia pneumoniae*, *Chlamydia trachomatis*, *L. pneumophila*, *U. urealyticum*, and *N. gonorrhoeae.* Clarithromycin is two to four times more active against most erythromycin-susceptible streptococci and staphylococci. However, pneumococci that are resistant to erythromycin (≤48% in certain regions[157]) also are resistant to clarithromycin and azithromycin; rates of macrolide resistance among pneumococci tend to correlate with rates of penicillin resistance.[285] Clarithromycin also has activity against organisms that are resistant to erythromycin, including *H. pylori*, *Toxoplasma gondii*, *Mycobacterium leprae*, MAC, and *Mycobacterium chelonae*.

When compared with erythromycin, azithromycin has less activity against gram-positive bacteria, including *S. pneumoniae*, but has better activity against gram-negative bacteria, including *Vibrio cholerae* and some Enterobacteriaceae such as *Shigella* spp. The in vitro activity of azithromycin against *M. pneumoniae*, *C. pneumoniae*, and *L. pneumophila* is similar to that of erythromycin and clarithromycin. Azithromycin is more active than is erythromycin against *C. trachomatis* and *U. urealyticum* and two- to eightfold more active than is erythromycin or clarithromycin against *M. catarrhalis*, *H. influenzae*,[18,186] *N. gonorrhoeae*, and *H. ducreyi.* Azithromycin has activity against *T. gondii* and, although less than that of clarithromycin, against MAC organisms. Azithromycin and clarithromycin are highly effective in vitro against *Borrelia burgdorferi*, *Bartonella henselae*, and *Bartonella quintana.*

PHARMACOKINETICS

The macrolides differ in pharmacokinetic properties (Table 248–8). Clarithromycin[116] and azithromycin[109] are gastric acid-stable and relatively well absorbed from the gastrointestinal tract, whereas erythromycin is acid-labile, and absorption varies with the oral preparation. Macrolides undergo metabolism by the hepatic microsomal cytochrome P-450 system. Erythromycin and clarithromycin, but not azithromycin, are inhibitors of the cytochrome P-450 enzyme system (CYP3A and CYP1A subclasses) and can interact with other drugs that are metabolized by this system.[216] Most of the metabolites are inactive, with the exception of 14-(*R*)-hydroxyclarithromycin, an active metabolite that can act additively or synergistically with clarithromycin. The lipophilic macrolides are distributed well in tissues and fluids, except CSF. High intracellular concentrations are achieved, but with the exception of azithromycin, the macrolides rapidly diffuse out of cells when extracellular concentrations are low. Clarithromycin and azithromycin are transported actively into leukocytes and macrophages. High concentrations of clarithromycin are present in the nasal mucosa, tonsils, and pulmonary epithelial lining fluid and alveolar cells.[68] Tissue concentrations of clarithromycin and azithromycin exceed those found in plasma by 2 to 20 times and 10 to 100 times, respectively. The favorable cellular penetration probably contributes to the efficacy of clarithromycin and azithromycin in the treatment of intracellular pathogens. Furthermore, sustained intracellular concentrations of azithromycin facilitate short-course therapy for pharyngitis and acute otitis media and single-dose therapy for chlamydial sexually transmitted diseases.[109] Isolated cases of intravascular bacterial infections developing during macrolide therapy for focal infections have been reported and evoke concern that, despite elevated tissue concentrations, low serum concentrations may not treat systemic infections consistently.[159] Erythromycin and azithromycin are eliminated primarily by biliary excretion, whereas clarithromycin is excreted predominantly by the kidneys. A reduction in the dosage of clarithromycin may be required in patients with moderate to severe renal insufficiency. Because of their longer serum half-life, azithromycin and clarithromycin can be administered in a once- and twice-daily regimen, respectively, as compared with the three- or four-times-daily dosing necessary for erythromycin.

Because erythromycin base is unstable at the low pH of the stomach, better-absorbed products were prepared by the addition of protective enteric coating or by alteration of the chemical structure through the formation of salts and esters. Salt and ester derivatives include ethylsuccinate or propionate (esters), stearate

(a salt), and estolate (salt of an ester). Estolate provides the highest concentration of antimicrobial activity in serum, but controversy continues about which preparation provides the most biologically active drug at the site of infection. Because the base is the active component, all erythromycin preparations must be hydrolyzed to the base after absorption. Formulations of erythromycin base include tablets, delayed-release tablets, and capsules. Erythromycin estolate is marketed in capsule form, suspension, and tablets. Erythromycin ethylsuccinate is available in suspension, tablets, and chewable tablets. Erythromycin stearate is only in tablet form in the United States. Parenteral preparations of erythromycin include the lactobionate and gluceptate derivatives. Intramuscular administration of these forms is painful and should be avoided. Clarithromycin can be taken without regard to food, whereas azithromycin should be taken at least 1 hour before or 2 hours after a meal. Clarithromycin is available in suspension (125 and 250 mg/5 mL) and in tablet (250- and 500-mg) forms. Azithromycin is manufactured in 250-mg capsules and as a suspension (100 and 200 mg/5 mL). Azithromycin for intravenous injection has not been approved for use in children younger than the age of 16 years, although pharmacokinetic data are available.[135]

INDICATIONS FOR USE

Erythromycin is approved for the treatment of chlamydial conjunctivitis, pneumonia and urethritis, mycoplasmal and *Legionella* pneumonia, group A streptococcal sinusitis and pharyngitis, mild pneumococcal pneumonia, uncomplicated skin and soft tissue infections caused by susceptible organisms, diphtheria, pertussis, erythrasma, listeriosis, and nongonococcal urethritis and as second-line therapy for gonococcal urethritis. It also is approved for use as a preoperative bowel preparation, for penicillin-allergic persons as prophylaxis for bacterial endocarditis and rheumatic fever, and for the treatment of syphilis in nonpregnant individuals. In the context of increasing prevalence of erythromycin resistance among common pathogens, newer macrolides or other classes of antibacterial agents may be more effective for certain infections.

Clarithromycin is approved for treatment of the following: bacterial exacerbations of bronchitis; streptococcal pharyngitis; mycoplasmal, chlamydial, and pneumococcal community-acquired pneumonia; acute maxillary sinusitis; and uncomplicated skin and soft tissue infections caused by susceptible bacteria. However, increasing rates of clarithromycin resistance among common pathogens of the respiratory tract and skin structures have been associated with treatment failure.[98,133] Clarithromycin and amoxicillin or metronidazole in combination with bismuth compounds, H_2-receptor antagonists, or proton pump inhibitors are recommended for the treatment of *H. pylori*–associated peptic ulcer disease. Clarithromycin also is approved for prophylaxis of disseminated MAC infections in children and adults with advanced human immunodeficiency virus (HIV) infection. Furthermore, clarithromycin, in combination with other antimycobacterials, is an effective therapeutic agent for disseminated MAC infections, but safety has not been established for this indication in children younger than the age of 20 months. The safety and efficacy of clarithromycin have not been established for infants younger than 6 months.

In adults, azithromycin is approved for treatment of the following: bacterial exacerbations of bronchitis; chlamydial and gonococcal cervicitis and urethritis; chancroid; streptococcal tonsillitis and pharyngitis; uncomplicated skin and soft tissue infections caused by susceptible bacteria; and acute otitis media and pneumonia caused by *H. influenzae*, *M. catarrhalis*, and *S. pneumoniae*. It also is approved in adults for prophylaxis of disseminated MAC infection in patients with advanced HIV infection. Pediatric indications include the following: group A streptococcal pharyngitis; acute otitis media caused by *H. influenzae*, *M. catarrhalis*, and *S. pneumoniae*; and mild community-acquired pneumonia caused by *S. pneumoniae*, *H. influenzae*, *M. pneumoniae*, or *C. pneumoniae*.

Five-day regimens have been approved for the treatment of pharyngitis (12 mg/kg/day) and otitis media (single dose of 10 mg/kg followed by 5 mg/kg/day). A randomized clinical trial comparing azithromycin with high-dose (90/6.4 mg/kg/day) amoxicillin-clavulanate for the treatment of acute otitis media revealed that the β-lactam–containing regimen achieved superior bacteriologic and clinical outcomes for all bacterial pathogens including penicillin-resistant *S. pneumoniae* and *H. influenzae*.[122] Consequently, consensus guidelines do not recommend azithromycin or clarithromycin for empiric treatment of acute otitis media unless the patient has a type 1 hypersensitivity reaction to penicillins.[9] Shorter courses of azithromycin for uncomplicated group A streptococcal pharyngitis (20 mg/kg/day for 3 days)[65] or acute otitis media (single dose of 30 mg/kg)[11] have been found to be equally effective as standard therapy but have not been approved by the FDA. A clinical study suggested that a 5-day course of azithromycin for localized cervical lymphadenopathy caused by *B. henselae* (cat-scratch disease) is beneficial.[23] The CDC recommends azithromycin for the treatment of chlamydial genital infections, nongonococcal urethritis, and chancroid (a single 20-mg/kg dose; maximal dose, 1 g)[278] and for prophylaxis of disseminated MAC infection in HIV-infected children.[145] Data supporting the use of azithromycin for treatment of ophthalmia neonatorum caused by *C. trachomatis* are limited to one small study in which a single oral dose of 20 mg/kg/day for 3 days appeared effective.[278]

Although the safety and efficacy of azithromycin and clarithromycin have not been determined for infants younger than 6 months old (or for pregnant or lactating women), these antimicrobials are recommended as first-line agents for treatment and postexposure prophylaxis of pertussis in individuals older than the age of 1 month, based on their in vitro effectiveness, safety and efficacy in older children, and more convenient dosing schedule. Duration of therapy or prophylaxis for pertussis is 14 days for erythromycin (40 to 50 mg/kg/day in four divided doses), 7 days for clarithromycin (15 mg/kg/day in two divided doses), and 5 days for azithromycin (10 mg/kg as single daily doses for infants <6 months of age; 10 mg/kg as a single dose on day 1, then 5 mg/kg/day on days 2 to 5 for infants and children ≥6 months of age). Azithromycin is the preferred macrolide for postexposure prophylaxis and treatment of pertussis in neonates because it has fewer adverse effects compared with erythromycin and no association with infantile hypertrophic pyloric stenosis.[269] A multicenter study established that children with cystic fibrosis chronically infected with *P. aeruginosa* had significantly improved lung function and clinical end-points associated with azithromycin treatment three times per week.[245] This effect may not persist. Studies in endemic regions showed that a single dose of azithromycin is as effective as is standard therapy with erythromycin for treatment of cholera in children.[153] A 5-day course of azithromycin (20 mg/kg/day; maximum dose, 1 g) is an effective treatment for uncomplicated typhoid fever in children and adolescents.[100] One to six doses of azithromycin for trachoma have been shown to be equivalent to prolonged topical treatment with oxytetracycline-polymyxin ointment.[77]

ADVERSE EFFECTS

The macrolides usually are well tolerated and relatively safe. The most common adverse effect is gastrointestinal disturbance, which can occur with the administration of any macrolide but is associated most commonly with the use of erythromycin. It is a

dose-related phenomenon. Because it acts as a motilin receptor agonist, gastrointestinal symptoms (nausea, vomiting, diarrhea, flatulence, and abdominal cramps) can occur with orally or parenterally administered erythromycin. Enteric coating of erythromycin does not decrease the incidence. Rapid intravenous infusions of erythromycin can result in thrombophlebitis. Cholestatic hepatitis is an unusual, but serious, macrolide toxicity. It occurs more commonly in adults and possibly in pregnant women and is associated most frequently with the estolate preparation.[45] The onset typically begins approximately 16 days after initiation of therapy and is manifested as fever, pruritus, jaundice, elevated liver function tests, and, occasionally, rash, leukocytosis, and eosinophilia. Signs and symptoms resolve after discontinuation of the macrolide but recur with subsequent therapy. Transient hearing loss has been described after the administration of large dosages of erythromycin lactobionate. *Torsades de pointes* is an uncommon reaction to intravenous infusions of erythromycin. A sevenfold increase in the rate of infantile hypertrophic pyloric stenosis was temporally associated with and probably causally related to the prophylactic use of erythromycin in neonates during a pertussis outbreak in a community hospital.[126] Gastrointestinal disturbances occur less frequently with clarithromycin and azithromycin, principally because lower dosages are required for effective therapy.

A common and potentially serious toxicity is that of drug interactions.[216] Macrolides are metabolized by hepatic microsomal cytochrome P-450 enzymes. Drug interactions can occur during concomitant therapy with two or more drugs that undergo hepatic microsomal P-450 metabolism. One proposal for this drug interaction suggests that the macrolide is *N*-demethylated to a nitrosoalkane that interacts with and inactivates the microsomal enzyme. Toxicity can occur because of interference with metabolism and consequent accumulation of the second drug. The ability to inactivate the enzyme varies with each macrolide; erythromycin is a more potent inhibitor than is clarithromycin. Azithromycin has not been associated yet with nitrosoalkane formation and resulting drug interactions, but caution should be exercised with concomitant administration of warfarin, digitoxin, and antacids. Drugs with which macrolides can interact include astemizole, benzodiazepines, buspirone, carbamazepine, cimetidine, cisapride, cyclosporine, digoxin, methylprednisolone, rifampin, tacrolimus, terfenadine, theophylline, triazolam, verapamil, warfarin, zidovudine, and certain protease inhibitors, among others.[216]

MISCELLANEOUS ANTIBIOTICS

CHLORAMPHENICOL

Chloramphenicol, originally derived from *Streptomyces venezuelae* obtained from soil near Caracas, Venezuela, in 1947, now is prepared synthetically. It is a chemically unique agent that contains an aromatic nitro group, an *N*-dichloroacetyl substituent, and two chiral centers. The availability of less toxic and equally or more effective agents has limited the usefulness of chloramphenicol in the United States.

Mechanisms of Action

Chloramphenicol reversibly binds to the 50S subunit of 70S bacterial ribosomes and thereby inhibits protein synthesis. The mechanism of action involves suppression of peptidyltransferase activity, with a resultant inability to form peptide bonds and elongate the peptide chain.[253,281] Because the ribosomal binding sites of chloramphenicol overlap with those of macrolides, clindamycin, and linezolid, concomitant use of these antibiotics can result in antagonism and should be avoided. Chloramphenicol usually is bacteriostatic, but it can be bactericidal when high concentrations are achieved against highly susceptible organisms such as meningococci and *H. influenzae*.

Mechanisms of Resistance

The most common mechanism of acquired resistance is plasmid-mediated production of chloramphenicol acetyltransferases (CATs), which acetylate chloramphenicol and render it unable to bind to the ribosomal target. Numerous *cat* genes encode classical (type A) or novel (type B) CATs and may be associated with multidrug-resistance phenotypes. This resistance has been documented in many different genera of bacteria, including *H. influenzae*, members of the Enterobacteriaceae, *Neisseria*, streptococci, and *S. aureus*. Less commonly, multiple specific or multidrug transporter mechanisms (efflux pumps) and chromosomal or plasmid-mediated alterations in permeability have resulted in chloramphenicol resistance in a wide range of bacteria including *B. cepacia*, *E. coli*, *H. influenzae*, *P. aeruginosa*, and *S. typhi* (in the absence of OmpF protein). More recently described alterations in bacterial 23S rRNA have been associated with chloramphenicol resistance by inducing frameshift mutations and readthrough of stop codons.[267] In addition, isolated cases of resistance in *Bacillus subtilis* because of altered ribosomes and in anaerobes because of inactivation of chloramphenicol by nitroreduction have been reported.[253]

In Vitro Activity

Chloramphenicol has broad-spectrum activity against aerobic and anaerobic gram-positive and gram-negative bacteria, chlamydiae, mycoplasmas, spirochetes, and rickettsiae.[233] It is bactericidal against susceptible strains of *H. influenzae*, *N. meningitidis*, and penicillin-susceptible *S. pneumoniae*, whereas it is bacteriostatic against most other susceptible microorganisms.[227] Frequently susceptible aerobic gram-positive cocci include groups A and B beta-hemolytic streptococci, viridans streptococci, and penicillin-susceptible pneumococci. Because penicillin-resistant pneumococci may be tolerant to chloramphenicol in vitro, meaning that concentrations of drug necessary to kill these pneumococci are approximately 30-fold higher than necessary to inhibit the organism, verifying chloramphenicol susceptibility by MBC testing is prudent, especially when treating meningitis.[101] Usually, chloramphenicol is active against oxacillin-susceptible *S. aureus*, but susceptibility patterns vary with the use of chloramphenicol, and more suitable alternatives for therapy exist. Susceptible gram-positive bacilli include *Bacillus* spp., *L. monocytogenes*, *C. diphtheriae*, *Clostridium* spp., and *Eubacterium*. Most *N. meningitidis* and *N. gonorrhoeae* organisms are susceptible.[143] However, several high-level chloramphenicol-resistant strains of meningococcus belonging to serogroup B were isolated from the CSF of children in Vietnam.[102] The susceptibility of Enterobacteriaceae, including that for *Salmonella* and *Shigella* spp., is variable. Other gram-negative bacilli frequently susceptible to chloramphenicol include *B. pertussis*, *B. cepacia*, *Brucella* spp., *C. jejuni*, *F. tularensis*, *H. influenzae*, *Pasteurella multocida*, *Pseudomonas pseudomallei*, *V. cholerae*, and *Y. pestis*. Virtually all obligate anaerobes are susceptible.

Pharmacokinetics

After oral administration, absorption of chloramphenicol is rapid and complete. Bioavailability is approximately 80 percent after oral administration, but it is only 70 percent after an intravenous dose because approximately 30 percent of the parenterally administered dose is excreted in urine before hydrolysis of the succinate ester to the active form. Intramuscular injection results in peak

serum concentrations comparable to those achieved after intravenous infusion. Because of its lipid solubility, chloramphenicol diffuses rapidly and widely into tissues and fluids.[233] The highest concentrations are achieved in the liver and kidneys, with high concentrations present in urine, and therapeutic concentrations are achieved in aqueous and vitreous humor. CSF concentrations range from 21 to 50 percent and from 45 to 89 percent of serum values in the presence of uninflamed and inflamed meninges, respectively. Brain tissue concentrations exceed those in plasma. Chloramphenicol also is distributed into pleural, ascitic, and synovial fluids, as well as saliva and breast milk. Protein binding ranges from 32 percent in premature newborns to 50 to 60 percent in adults. Chloramphenicol palmitate and chloramphenicol sodium succinate are esterified prodrugs of chloramphenicol. Orally administered chloramphenicol palmitate is hydrolyzed to active drug by pancreatic esterases in the small intestine before absorption. After intravenous infusion, chloramphenicol sodium succinate is hydrolyzed rapidly to active drug in the kidneys, liver, and lungs. Ninety percent of active chloramphenicol is conjugated to the inactive glucuronide primarily by the liver. Immature metabolic function of the liver in the fetus and newborn results in inadequate conjugation of chloramphenicol, with subsequent accumulation of toxic concentrations of active drug. Peak serum concentrations in children after a dose of 25 mg/kg range from 19 to 28 μg/mL, whereas in adults receiving doses of 12.5 mg/kg, peak serum values of 11 to 18 μg/mL can be achieved. Although metabolized to inactive metabolites by the liver, chloramphenicol is excreted by the kidneys: 5 to 10 percent as active drug and 80 percent as inactive metabolites. The elimination half-life is significantly longer but variable, and serum concentrations are unpredictable in neonates.[233] Dosage adjustments should be considered in persons with severe hepatic insufficiency or combined hepatic and renal insufficiency and in patients receiving drugs that compete for hepatic P-450 cytochrome oxidases, such as phenytoin, phenobarbital, and rifampin. Chloramphenicol is not removed by peritoneal dialysis or hemodialysis, but charcoal hemoperfusion may lower serum concentrations.

Formulations of chloramphenicol available include chloramphenicol palmitate in an oral suspension of 150 mg base/5 mL, 250-mg capsules of chloramphenicol base, and chloramphenicol sodium succinate for parenteral use. Other formulations include 1 percent cream for topical use, 0.5 percent otic solution, 0.5 percent ophthalmic solution, and 1 percent ophthalmic ointment.

Indications for Use

Because of its low therapeutic-toxic index, use of chloramphenicol should be reserved for serious infections for which less toxic agents are ineffective or contraindicated. In some developed countries, chloramphenicol has been replaced by third-generation cephalosporins for the treatment of bacterial meningitis and by clindamycin or metronidazole for the treatment of anaerobic infections. Ceftriaxone is a safe and effective alternative to (1) chloramphenicol for the treatment of acute typhoid fever[194] and (2) long-acting oily chloramphenicol for epidemic meningococcal meningitis in sub-Saharan Africa.[203] Infections for which chloramphenicol may be indicated include the following: pneumococcal, meningococcal, and *H. influenzae* meningitis in β-lactam–allergic individuals; brain abscesses caused by susceptible anaerobic bacteria resistant to other agents; acute typhoid fever; and rickettsial infections (typhus, Q fever, Rocky Mountain spotted fever). Doxycycline is preferred for treatment of rickettsial infections in children, even those younger than 9 years of age. Chloramphenicol is not indicated for the treatment of trivial infections, prophylaxis of infections, or treatment of typhoid carrier states.

Adverse Effects

Hematologic adverse events associated with the use of chloramphenicol include hemolytic anemia in patients with the Mediterranean type of glucose-6-phosphate dehydrogenase deficiency, reversible bone marrow suppression, and aplastic anemia. Reversible bone marrow suppression is a dose-related phenomenon. It usually occurs when serum concentrations exceed 25 μg/mL, as can be seen when administering large dosages, during prolonged therapy, or in patients with impaired liver function. Although mammalian cells contain 80S ribosomes, rather than the 70S ribosomes found in prokaryotes, mitochondria possess 70S ribosomes. A proposed mechanism of myelosuppression involves inhibition of mitochondrial protein synthesis in host bone marrow stem cells.[253] Dose-related bone marrow suppression is manifested by peripheral anemia with or without reticulocytopenia, leukopenia, and thrombocytopenia and bone marrow findings of increased cellularity, cytoplasmic vacuolization, and maturation arrest of erythroid and myeloid precursors. In contrast, aplastic anemia is a rare, often fatal idiosyncratic reaction that is unrelated to the dosage, duration, or route of therapy. The pathogenesis is understood less well but possibly is related to DNA damage from toxic metabolites of chloramphenicol produced by nitroreduction.[281] The incidence ranges from 1 in 25,000 to 40,000 courses. Onset can begin during therapy but typically occurs weeks to months or rarely years after therapy has been discontinued. Manifestations include peripheral pancytopenia and hypoplastic or aplastic marrow.

Gray syndrome or gray baby syndrome is a rare, but serious and potentially fatal adverse event that usually occurs in newborns but has been described in older children and adults with hepatic insufficiency. Most often, this syndrome occurs when serum chloramphenicol concentrations exceed 40 μg/mL, and it is thought to be a result of inhibition of mitochondrial electron transport in liver, skeletal muscle, and myocardium. The onset typically begins 2 to 9 days after initiating therapy. Manifestations include hypothermia, tachypnea, blue-gray skin color (cyanosis), abdominal distention, emesis, unresponsiveness, and refractory metabolic acidosis that can progress to vasomotor collapse and death within 2 days.

Uncommon side effects include the following: hypersensitivity reactions such as drug fever, rash, urticaria, anaphylaxis, and a Herxheimer-like reaction during therapy for syphilis, typhoid fever, and brucellosis; gastrointestinal symptoms, including nausea, emesis, diarrhea, and an unpleasant taste; and neurologic symptoms such as peripheral neuritis, headache, mental confusion, and optic neuritis, the last of which may not be entirely reversible.

Chloramphenicol can inhibit the metabolism of other drugs metabolized by the hepatic microsomal cytochrome P-450 system and thus result in the accumulation of alfentanil, barbiturates, cyclophosphamide, phenytoin, antidiabetic sulfonylureas (more common with chlorpropamide and tolbutamide than with glyburide and glipizide), and warfarin during concomitant therapy.[5] Because some agents such as rifampin, phenobarbital, and phenytoin are potent inducers of hepatic microsomal enzymes, when they are given concomitantly with chloramphenicol, metabolism is enhanced, and serum concentrations of active chloramphenicol are reduced. Other drug interactions include a reduction in the effectiveness of estrogen-containing oral contraceptives when used concurrently with chloramphenicol and a delay in the response to vitamin B_{12}, folic acid, and iron. A mild disulfiram-like reaction can occur when alcohol is ingested during chloramphenicol therapy. Both cimetidine and chloramphenicol have rare associations with aplastic anemia; a few reports of concomitant use resulting in aplastic anemia have been documented, thus suggesting a potential for additive or synergistic risk. Concomitant acetaminophen therapy has been the subject of controversy;

some studies suggest that co-administration can prolong the elimination half-life of chloramphenicol, but other reports suggest no effect or enhanced metabolism of chloramphenicol. Lincosamides and macrolides can have an antagonistic effect when they are administered concurrently with chloramphenicol because of competition for ribosomal binding sites. Chloramphenicol is physically incompatible in solution with many drugs, including tetracyclines and vancomycin.

Because of considerable variability in serum chloramphenicol concentrations, the narrow therapeutic-toxic index, and the potential for drug interactions, monitoring serum concentrations of chloramphenicol and peripheral blood counts during therapy is prudent, particularly for neonates.

COLISTIN (COLISTIMETHATE SODIUM; POLYMYXIN E)

Colistin is a cationic, cyclic polypeptide antibiotic that is structurally and pharmacologically related to polymyxin B. Colistin is less active in vitro and less toxic than is polymyxin B. Colistin was discovered in 1949 and is obtained from cultures of *Bacillus polymyxa* subspecies *colistinus*. The polymyxins have been used extensively for decades in topical ophthalmic and otic solutions. However, because of reports of common and serious nephrotoxicity and neurotoxicity, parenteral use of these drugs was abandoned in the early 1980s, except for treatment of multidrug-resistant, gram-negative bacterial infections in children and adults with cystic fibrosis. The emergence of gram-negative bacteria resistant to most classes of antibiotics and the lack of effective new antimicrobial agents led to the reconsideration of colistin as a valuable therapeutic option. Studies of patients who received intravenous polymyxins for the treatment of serious multidrug-resistant *P. aeruginosa* and *A. baumannii* infections, including pneumonia, bacteremia, and urinary tract infections, led to the conclusion that these antibiotics have acceptable effectiveness and considerably less toxicity than was reported previously.[149]

Mechanisms of Action

Colistimethate sodium is inactive until it is hydrolyzed to sulfomethylated derivatives and colistin, which acts as a cationic detergent with both lipophilic and lipophobic components. It damages the cytoplasmic membrane by displacing calcium and magnesium and binding to anionic lipopolysaccharide molecules and leads to permeability changes in the cell membrane, leakage of osmotically active intracellular metabolites and nucleosides, and cell death. Furthermore, colistin binds and neutralizes the lipid A portion of lipopolysaccharide in vitro; however, the clinical implications of this anti-endotoxin activity are unknown.[88]

Mechanisms of Resistance

Gram-negative bacteria can develop resistance to colistin by means of inherited or acquired mechanisms. Inherited mutations occur infrequently and are not influenced by exposure to colistin. Acquired resistance rarely may be induced by prolonged exposure to the drug. Studies of polymyxin-resistant *P. aeruginosa* have suggested that the development of resistance arises from modifications of the cell membrane, such as reductions in lipopolysaccharide, certain proteins or lipids, or magnesium or calcium. Currently, no evidence of efflux pump or enzyme-mediated resistance exists. Complete cross-resistance occurs between colistin and polymyxin B, but not other antimicrobial agents.

In Vitro Activity

Colistin is highly active against many strains of aerobic gram-negative bacteria, including *Acinetobacter*, *Citrobacter*, *E. coli*, *Enterobacter*, *H. influenzae*, *Klebsiella*, *Morganella morganii*, *P. aeruginosa*, *Salmonella*, *Shigella*, and variable numbers of *Stenotrophomonas* strains. However, the antibiotic is inactive against most strains of *Brucella*, *B. cepacia*, *Edwardsiella*, *Proteus*, *Providencia*, *Serratia*, gram-negative cocci, gram-positive bacteria, and anaerobic bacteria. The Clinical Laboratory Standards Institute defined bacterial resistance to colistin as an MIC of 4 μg/mL or greater. However, the sulfate form of colistin, which usually is used for in vitro testing, often is four- to eightfold more active than is the sulfomethyl form, which is used in the parenteral formulation. Limited in vitro and clinical data suggest that synergism exists with colistin and other antimicrobial agents such as aminoglycosides, antipseudomonal β-lactams, fluoroquinolones, rifampin, and TMP-SMX.[88,149]

Pharmacokinetics

The pharmacologic evaluation of the polymyxins was performed decades ago. Consequently, pharmacokinetic and pharmacodynamic information is limited. Colistin is not absorbed from the gastrointestinal tract and must be given parenterally. The drug is distributed widely in the body, except for bones and synovial, pleural, and pericardial fluids. In a reported case of multidrug-resistant *A. baumannii* meningitis in an adolescent, parenterally administered colistin achieved a concentration in the CSF that was 25 percent of the serum concentration, and it cured the infection.[137] More than 50 percent of the agent binds to serum proteins. Colistimethate sodium and its metabolites are excreted mainly by the kidneys through glomerular filtration. Therefore, the dosage and frequency of administration should be decreased in children with renal impairment. Colistin is rapidly bactericidal against susceptible bacteria in a concentration-dependent manner, and it has a post-antibiotic effect.[88,149] Considering these pharmacologic parameters, there may be a theoretical benefit of administering colistin less frequently with higher doses, but no clinical data validate this hypothesis.

Indications for Use

Colistin has been administered intravenously to infants and children of all ages for the treatment of acute or chronic infections caused by susceptible gram-negative organisms, particularly multidrug-resistant strains of *Pseudomonas* and *Acinetobacter* in patients with cystic fibrosis or complicated health care–associated infections. Colistin should be reserved for use when other more effective and less toxic antimicrobial agents are contraindicated or ineffective. The dosage of colistimethate sodium is expressed in terms of colistin. The usual parenteral dosage for adults and children with normal renal function is 2.5 to 5 mg/kg (75,000 to 150,000 IU/kg)/day divided into two to four doses, depending on the severity of infection (maximum, 300 mg/day). Intramuscular administration is not recommended because it causes severe pain at the injection site. Experience with the use of colistimethate sodium administered by nebulization for multidrug-resistant, gram-negative respiratory infections in patients with cystic fibrosis is extensive. Successful use of colistimethate sodium by the intraventricular route also has been reported. Colistin sulfate in combination with neomycin sulfate and hydrocortisone acetate is available in the United States for otic use. Colistin sulfate for oral administration no longer is available in the United States. Polymyxin B sulfate is available for topical use.[88]

Adverse Effects

Nephrotoxicity and neurotoxicity are the most serious adverse effects and occur most frequently when the drug is administered in higher than recommended doses, in patients with renal insufficiency, or in combination with other nephrotoxic agents.

Progressive azotemia or acute tubular necrosis may occur, but renal dysfunction usually is reversible when the antibiotic is discontinued. Renal function should be monitored closely during therapy, and colistin should be discontinued immediately if urine output diminishes or concentrations of blood urea nitrogen or creatinine increase. Transient effects on the nervous system, including dizziness, weakness, paresthesia, numbness, vertigo, ataxia, blurred vision, and slurred speech may occur, but these symptoms are reversible and may be alleviated by reducing the dosage of colistin. Coma, psychosis, seizures, and noncompetitive neuromuscular blockade causing apnea also have been reported and warrant prompt discontinuation of the drug.

FLUOROQUINOLONES

Fluoroquinolone antibiotics are derivatives of nalidixic acid. When compared with nalidixic acid, fluoroquinolones have the following: (1) a broader spectrum of activity that includes aerobic gram-negative enteric organisms, particularly Enterobacteriaceae, *Haemophilus* spp., *Neisseria* spp., *M. catarrhalis*, nonenteric gram-negative bacilli such as *P. aeruginosa*, oxacillin-susceptible staphylococci, some streptococci, bacteria associated with atypical pneumonia, certain genital pathogens, and certain strains of mycobacteria; (2) better penetration into tissues; (3) good intracellular penetration; and (4) rapid bactericidal activity.

Mechanisms of Action

Fluoroquinolones are the only class of antibacterial agents in clinical use that directly inhibit DNA synthesis. They bind to bacterial DNA gyrase and topoisomerase IV. Inhibition of bacterial gyrase causes relaxation of the supercoiled DNA that leads to termination of chromosomal replication and interference with cell division and gene expression. Inhibition of the activity of topoisomerase IV leads to separation of two united DNA molecules and subsequent interference with cellular replication.

Mechanisms of Resistance

A growing concern is that widespread use of fluoroquinolones among adult populations has been associated with resistance rates, especially among Enterobacteriaceae, that exceed 50 percent in some regions. Mechanisms of resistance include chromosomal mutations in genes that encode fluoroquinolone target enzymes (DNA gyrase and topoisomerase IV), efflux pumps, or porin (outer-membrane diffusion) channels. Newly identified plasmid-mediated resistance determinants in strains of *K. pneumoniae*, *E. coli*, *Enterobacter*, and other enteric bacteria include the following: (1) Qnr, a protein that protects DNA gyrase from quinolone action and is associated with multidrug resistance; and (2) a variant of the aminoglycoside acetyltransferase found in gram-negative bacteria that is capable of inactivating ciprofloxacin.[170,238] Fluoroquinolone-resistant strains of *N. gonorrhoeae* are common findings in many parts of the world and are spreading in the United States, especially in California and Hawaii. The CDC no longer recommends fluoroquinolones for treatment of gonorrhoea in the United States.[278] Other bacteria with increasing rates of resistance include *S. pneumoniae* (≈3% to ciprofloxacin with a breakpoint ≥ 4 μg/mL versus no resistance to levofloxacin as of 2004 among invasive pediatric isolates in the United States[90]) and intestinal pathogens such as *C. jejuni*, *Shigella* spp., *Salmonella* spp., certain strains of *K. pneumoniae*, *E. coli*, *P. aeruginosa*, among others.[7]

In Vitro Activity

Levofloxacin and moxifloxacin have greater potency than does ciprofloxacin against gram-positive cocci, and moxifloxacin has enhanced activity against anaerobic bacteria, although in some series, approximately 50 percent of invasive *Bacteroides* spp. are resistant to moxifloxacin.[108] Ciprofloxacin remains the most potent marketed fluoroquinolone against gram-negative bacteria, particularly against some strains of *P. aeruginosa*, *Providencia* spp., *Proteus* spp., and *S. marcescens*. In vitro studies of newer and investigational fluoroquinolones against penicillin- and cephalosporin-resistant pneumococci indicate excellent activity, whereas activity of ciprofloxacin, norfloxacin, and ofloxacin is limited. Fluoroquinolone use for MRSA and oxacillin-resistant, coagulase-negative staphylococci is limited because resistant mutants can be selected relatively easily, thus leading to treatment failure and relapse. Constitutive high-level resistance exists among MRSA isolates from patients with CA-MRSA infections in some areas of the United States. Although MICs tend to be lower for newer (e.g., moxifloxacin, gatifloxacin) as compared with older (e.g., ciprofloxacin, levofloxacin) fluoroquinolones, genes conferring fluoroquinolone resistance in *S. aureus* confer resistance to the entire class of agents.[110] Activity against enterococci is marginal or absent. Fluoroquinolones are effective against atypical pneumonia pathogens (*Chlamydophila pneumoniae*, *L. pneumophila*, *M. pneumoniae*) and certain genital pathogens (*C. trachomatis*, *U. urealyticum*, *Mycoplasma hominis*). Ciprofloxacin, levofloxacin, and moxifloxacin are active in vitro against certain strains of *M. tuberculosis*, *Mycobacterium fortuitum*, *Mycobacterium kansasii*, and *M. chelonae* and are less active against MAC. No quinolone antibiotic has been shown to be active against *T. pallidum*.

Pharmacokinetics

The fluoroquinolones generally have excellent bioavailability that is not substantially affected by food, with values of 70 percent for ciprofloxacin, 85 percent for moxifloxacin, and greater than 95 percent for ofloxacin and levofloxacin. These drugs have large volumes of distribution, and they concentrate in the kidneys and in urine (except moxifloxacin, which undergoes hepatic metabolism and biliary excretion). This class of agents has favorable pharmacokinetic properties in children, and their efficacy correlates best with the 24-hour AUC/MIC ratio because of a combination of concentration-dependent killing and post-antibiotic effect. These properties suggest that large doses given at relatively infrequent intervals would be most effective.[248] However, based on pharmacokinetic studies, doses for patients with cystic fibrosis should be higher and more frequent than for patients without cystic fibrosis, and the dosage should be decreased in proportion to increasing body weight. Fluoroquinolones can interact with a variety of other drugs including caffeine, cyclosporine, dideoxyinosine, nonsteroidal anti-inflammatory drugs, theophylline, and other agents that prolong the QT interval. Co-administration with antacids, ferrous sulfate, and multivitamins containing zinc can reduce oral bioavailability.

Indications for Use

Fluoroquinolones have been used extensively in adults for the treatment of skin and soft tissue, skeletal, and intra-abdominal infections, as well as infections of the urinogenital, gastrointestinal, and respiratory tracts. Fluoroquinolones commonly used in adults include the second-generation agents, ciprofloxacin and levofloxacin, and the fourth-generation agent, moxifloxacin. Other agents with limited indications include enoxacin, ofloxacin, lomefloxacin, norfloxacin (second-generation), and gemifloxacin (third-generation). Four agents have been withdrawn from the market in the United States: gatifloxacin, grepafloxacin (causes cardiac toxicity), sparfloxacin, and trovafloxacin (causes hepatotoxicity). Ciprofloxacin, levofloxacin, and moxifloxacin are FDA approved for the treatment of uncomplicated skin infections caused by susceptible organisms in adults. However, none of the

fluoroquinolones is FDA approved for treatment of MRSA infections.

Use in pediatric patients has been limited because of the potential for inducing cartilage damage that leads to arthropathy, as demonstrated in juvenile animal studies. However, no convincing evidence exists that quinolone-induced arthropathy occurs in humans. Reversible arthralgia and tendinopathy have a temporal association with fluoroquinolone use. Fluoroquinolones are not approved for use in children and adolescents younger than 18 years, except in the following situations: (1) complicated urinary tract infections and pyelonephritis attributable to *E. coli* in children 1 year old and older (approved by the FDA in 2004) and (2) exposure to aerosolized *B. anthracis* to prevent onset or progression of disease. However, these drugs have been used in certain clinical settings, such as cystic fibrosis, primarily because they are the only oral antibiotics with activity against *P. aeruginosa*. Furthermore, ciprofloxacin is the only fluoroquinolone available in a suspension formulation (250 mg and 500 mg [base]/5 mL). In 2002 alone, approximately 500,000 prescriptions for fluoroquinolones were written in the United States for individuals younger than 18 years old.[7] These agents, particularly ciprofloxacin, have been used to treat the following: exacerbations of chronic pseudomonal pulmonary infections in patients with cystic fibrosis; complicated urinary tract infections caused by multidrug-resistant bacteria; chronic suppurative otitis media associated with *P. aeruginosa*; osteochondritis attributable to *P. aeruginosa*; shigellosis, *C. jejuni*, and other bacterial causes of enteritis; multidrug-resistant typhoid fever; cholera; infections in neutropenic patients with cancer; in combination with other agents to treat multidrug-resistant mycobacterial disease; and multidrug-resistant gram-negative bacillary septicemia or meningitis (no controlled trials in children with meningitis have been reported using currently licensed agents).[7,54,243,249] Fluoroquinolones also effectively eradicate nasopharyngeal carriage of susceptible meningococci. One study showed that children with acute otitis media and otorrhea through tympanostomy tubes had better clinical outcomes with fewer adverse effects when they were treated with ciprofloxacin-dexamethasone otic suspension compared with high-dose amoxicillin-clavulanic acid suspension.[85] Although gatifloxacin is not approved for use in children and currently is not available in the United States, noncontrolled studies confirmed that it is safe and effective for treatment of recurrent acute otitis media and acute otitis media when therapy with standard antimicrobials has failed.[223]

The current recommendation is that parenteral and oral fluoroquinolones should be reserved for situations in which no effective, safe, and nonrestricted alternative antimicrobial agents are available to treat complicated or multidrug-resistant bacterial infections. Appropriate uses should be limited to the following clinical situations: exposure to aerosolized *B. anthracis*; urinary tract infections caused by *P. aeruginosa* or other multidrug-resistant, gram-negative bacteria; chronic suppurative otitis media or malignant otitis externa caused by *P. aeruginosa*; acute or chronic osteomyelitis or osteochondritis caused by *P. aeruginosa*; exacerbations of pulmonary disease in patients with cystic fibrosis who have *P. aeruginosa* colonization and for whom oral therapy is appropriate; susceptible mycobacterial infections as part of a combination regimen; gram-negative bacterial infections in immunocompromised hosts in whom oral therapy is appropriate or resistance to alternative agents is present; gastrointestinal infections caused by multidrug-resistant *Shigella* spp., *Salmonella* spp., *V. cholera*, or *C. jejuni*; and proven bacterial septicemia or meningitis caused by multidrug-resistant pathogens that are susceptible only to fluoroquinolones, that have failed to respond to approved agents, or that require use of a fluoroquinolone because of life-threatening hypersensitivity to alternative agents.[7]

Adverse Effects

Adverse events associated with fluoroquinolone therapy occur in 3 to 17 percent of adult and pediatric patients and cause discontinuation of treatment in 1 to 2 percent. The most common reactions are gastrointestinal, minor CNS disorders, and allergic rashes.[248] Other infrequent adverse reactions include photosensitivity, disorders of glucose homeostasis, prolongation of the QT interval with rare cases of torsade de pointes particularly among patients with long QT syndrome, leukopenia, and anaphylactoid reactions. Reversible tendinitis and tendon rupture occur uncommonly in adults.

LINCOSAMIDES

Lincosamide antibiotics consist of an amino acid linked to an amino sugar. Lincomycin, elaborated by *Streptomyces lincolnensis* variety *lincolnensis*, originally isolated from a soil sample near Lincoln, Nebraska, was the first lincosamide available for use. Clindamycin, a semisynthetic derivative of lincomycin produced by the substitution of a chlorine atom for a hydroxyl group at position 7, was available for use in the early 1970s. Because clindamycin has increased antibacterial activity and better oral absorption than does lincomycin, lincomycin rarely is used.

Mechanisms of Action

Lincosamides bind to the 50S subunit of susceptible bacterial ribosomes close to the peptidyl transferase center and thereby inhibit protein synthesis. Data indicate that clindamycin causes dissociation of peptidyl-tRNAs from the ribosome, depletion of free tRNA pools, and prevention of the egress of nascent peptides through a tunnel in the 50S subunit.[263] Because the ribosomal binding sites for lincosamides overlap with those of chloramphenicol and erythromycin, concurrent use of these agents can result in antagonism and should be avoided. Lincosamides usually are bacteriostatic but can be bactericidal against highly susceptible microorganisms in the presence of high lincosamide concentrations.

Mechanisms of Resistance

Some bacteria, including members of the Enterobacteriaceae and *Pseudomonas* and *Acinetobacter* spp., are inherently resistant to lincosamides, most likely because of relative impermeability of the outer membrane of the cell wall. Acquired resistance can develop as a result of altered ribosomal targets and, less commonly, lincosamide inactivation, whereas resistance as a result of reduced lincosamide uptake has not been described. Two mechanisms by which bacteria can alter their ribosomes and acquire lincosamide resistance have been identified. High-level resistance because of an altered protein component of the 50S ribosomal subunit after a one-step chromosomal mutation confers resistance to erythromycin and often to the lincosamides. Plasmid-mediated MLS_B resistance occurs when adenine residues on the 23S RNA component of the 50S ribosomal subunit are methylated, and an altered target is created that confers cross-resistance to macrolides, lincosamides, and streptogramin B. The production of ribosomal methylases is encoded by the *erm* class of genes.[236] This resistance can be constitutive or inducible and can be seen in staphylococci, streptococci, and *Bacteroides* spp. Erythromycin is the most potent inducer of MLS_B resistance in staphylococci, whereas any macrolide, lincosamide, or streptogramin B can be an inducer in streptococci. Some strains of *B. fragilis* can have inducible MLS_B resistance that is not detected easily by disk agar diffusion susceptibility testing[259] but

is recognizable because of frequently concurrent high-level erythromycin resistance. An MS pattern of resistance that is plasmid-mediated results in macrolide resistance as a result of active ATP-dependent efflux pumps encoded by the *mef*(A) and *msr*(A) genes. Isolates with these resistance genotypes are resistant to 14- and 15-membered ring macrolides and streptogramin B but not to clindamycin.[180] Rarely, staphylococci produce a plasmid-mediated, nonconjugative nucleotidyltransferase that inactivates lincosamides and results in high-level resistance to lincomycin and tolerance to clindamycin (MBC/MIC ratio >32).

In Vitro Activity

Both lincosamides are effective in vitro against gram-positive cocci, whereas clindamycin also is active against a wide range of anaerobic bacteria. Clindamycin is many times more active than is lincomycin and is as active as or slightly more active than is erythromycin against staphylococci, pneumococci, group A streptococci, and viridans streptococci. Unlike erythromycin, the lincosamides do not have clinically significant activity against *H. influenzae*, *M. pneumoniae*, or *Neisseria* spp. Clindamycin is active against many gram-positive cocci, including penicillinase-producing and non–penicillinase-producing staphylococci and groups A, B, C, and G beta-hemolytic streptococci and pneumococci, but it is not active against enterococci or most health care–associated methicillin-resistant staphylococci. Rates of in vitro inducible *erm*-mediated MLS_B resistance among CA-MRSA isolates vary widely, ranging from 4.5 percent in Houston[148] to 94 percent in Chicago.[97] Presence of this type of resistance can be detected in erythromycin-resistant strains of *S. aureus* with the use of the double-disk diffusion assay (D-test), in which clindamycin- and erythromycin-impregnated disks are placed 15 to 20 mm apart on Mueller-Hinton agar that has been inoculated with a standardized (0.5 McFarland) suspension of *S. aureus*. The finding of a D-shaped blunting of the circular zone of inhibition around the clindamycin disk on the side closest to the erythromycin disk indicates the presence of in vitro–inducible MLS_B resistance. These isolates have a high rate of mutation to constitutive clindamycin resistance, a trait that would confer a selective advantage during clindamycin therapy. The use of clindamycin for D-test–positive *S. aureus* infections has been reported to result in treatment failure in a few patients. Therefore, alternative effective antimicrobial agents should be sought, or, if empiric clindamycin therapy has been initiated, response to therapy should be carefully monitored.[110,180] Erythromycin and lincosamide resistance in pneumococci and group A streptococci has been increasing. Surveillance studies revealed rates of clindamycin resistance among multidrug-resistant pneumococci to range from 12 to 19 percent in the United States and Europe, respectively.[138] Most facultative aerobic gram-negative bacilli, with the exception of *Campylobacter* spp. (including *C. jejuni* and *C. fetus*) and *H. pylori*, are inherently resistant to clindamycin. Anaerobes frequently susceptible to clindamycin include the following: the anaerobic gram-negative bacilli *Bacteroides*, *Fusobacterium*, *Prevotella*, and *Porphyromonas* spp.; the non–spore-forming gram-positive bacilli *Propionibacterium*, *Eubacterium*, and actinomyces; the anaerobic gram-positive cocci *Peptococcus*, *Peptostreptococcus*, and microaerophilic streptococci; and many *Clostridium* organisms, excluding *C. difficile*, *Clostridium sporogenes*, and *Clostridium tertium*. Clindamycin resistance does occur, especially in *Fusobacterium varium*, the non-*fragilis Bacteroides* group, an increasing proportion of *B. fragilis* isolates (≤≈30% in some series),[4] and as many as 20 percent of anaerobic gram-positive cocci. When combined with other agents, clindamycin is active against certain other pathogens such as *Babesia*, *Plasmodium*, *Pneumocystis jiroveci*, and *T. gondii*.

Pharmacokinetics

Oral absorption of lincosamides occurs rapidly. The presence of food delays but does not decrease the absorption of clindamycin, but it does reduce the absorption of lincomycin. Concomitant administration of kaolin- or attapulgite-containing antidiarrheal agents can decrease absorption; therefore, these agents should not be administered within 2 hours before or 3 to 4 hours after oral lincosamides are given. Lincosamides are distributed rapidly and widely to most tissues and fluids, including saliva, sputum, respiratory tissue, pleural fluid, soft tissues, bones and joints, brain, prostate, semen, appendix, and peritoneal fluid.[202,217] Lincosamides are transported actively into macrophages and polymorphonuclear leukocytes, and high concentrations are achieved in bile, urine, and bone. Penetration into CSF is limited, unless inflammation is present. In experimental pneumococcal meningitis, concentrations of clindamycin in CSF were approximately 10 percent of the corresponding serum values. Lincosamides are highly protein-bound, with values ranging from 70 to 75 percent for lincomycin and 92 to 94 percent for clindamycin. The inactive palmitate and phosphate esters are hydrolyzed in the liver to clindamycin, the active agent. Clindamycin undergoes hepatic biotransformation to active and inactive metabolites. Ten percent of absorbed lincomycin is excreted unchanged in urine, 3 percent is excreted unchanged in feces, and the remainder is excreted as inactive metabolites, primarily in the biliary system. Elimination is delayed in the presence of severe hepatic insufficiency alone or severe concurrent renal and hepatic impairment, and, therefore, adjustments in dosages may need to be made. Formulations of lincosamides available for use include lincomycin hydrochloride in 250- and 500-mg capsules and in solution for parenteral use. Clindamycin phosphate, a water-soluble ester of clindamycin and phosphoric acid, is available for parenteral use. Oral formulations include clindamycin palmitate hydrochloride granules reconstituted to 75 mg base/5 mL and clindamycin hydrochloride capsules in 75, 150, and 300 mg of the base compound. Clindamycin also is available as a topical solution, gel, lotion, foam, pad, and vaginal cream and suppository.

Indications for Use

Lincomycin can be used for the treatment of serious infections caused by susceptible strains of staphylococci, pneumococci, other streptococci, or anaerobic organisms, but it rarely is used in pediatric patients. Clindamycin is effective against and has been approved for treatment of the following: susceptible strains of staphylococcal bone and joint infections[91]; anaerobic pelvic infections, including pelvic inflammatory disease, nongonococcal tubo-ovarian abscess, and postsurgical vaginal cuff infections; anaerobic intra-abdominal infections, including peritonitis and abscesses; pneumonitis, empyema, and lung abscesses caused by anaerobes and as a second-line agent for infections caused by susceptible strains of pneumococci and staphylococci; anaerobic septicemia; and skin and soft tissue infections caused by anaerobes, susceptible strains of staphylococci, and streptococci. Clinical prediction rules relating to resistance among community-acquired, community-onset health care–associated and traditional nosocomial staphylococcal isolates are becoming less reliable because certain strains with distinctive genetic determinants of virulence (e.g., *pvl* genes) and antibiotic resistance (e.g., SSC*mec*) are tending to predominate.[128,195] Prevalences of constitutive and inducible MLS_B resistance in community-associated *S. aureus* infections generally are increasing in the United States, although rates vary geographically and temporally as a function of predominant circulating clones.[59] Based on current experience, clindamycin should not be used for empiric therapy of suspected *S. aureus* infections if the local clindamycin resistance rate exceeds 10 to 15 percent. Conversely, clindamycin

is effective in treating serious infections caused by clindamycin-susceptible (D-test–negative) CA-MRSA infections, including bacteremia, osteomyelitis, suppurative arthritis, pleural empyema, and skin and soft tissue infections.[146,180] Clindamycin also is effective and has been approved as a topical agent for acne vulgaris. Unconfirmed retrospective data suggest that clindamycin in combination with a β-lactam antibiotic, with surgery if indicated, may be the most effective treatment of invasive *S. pyogenes* infections.[283] Other infections for which clindamycin may be effective but has not been approved for therapy include acute otitis media caused by penicillin-resistant pneumococci that has failed to respond to other antibacterial agents,[9] chronic suppurative otitis media or chronic sinusitis in which anaerobes may play a role, chronic pharyngeal carriers of group A streptococci,[260] odontogenic infections, toxoplasmosis of the CNS (in combination with pyrimethamine), uncomplicated falciparum malaria[161] or babesiosis (in combination with quinine), and mild to moderate *P. jiroveci* pneumonia in patients with acquired immunodeficiency syndrome (AIDS) (in combination with primaquine).[28] Because of poor penetration into CSF, this drug is not approved for the treatment of meningitis. Clindamycin is a third-line agent for endocarditis prophylaxis for upper respiratory tract, dental, or oral procedures in persons allergic to or intolerant of amoxicillin and erythromycin. Oral and intravenous formulations of clindamycin are approved for use in infants and children of all ages. The bitter taste of the oral suspension may limit compliance.

Adverse Effects

The most frequent side effects include generalized morbilliform-like rash and mild, self-limited diarrhea occurring in as many as 10 percent and in 2 to 20 percent of patients, respectively. Other gastrointestinal disturbances include anorexia, nausea, vomiting, flatulence, abdominal pain, and a metallic taste. Pseudomembranous colitis, a serious and sometimes fatal illness, is the adverse event posing the most concern. Most antibiotics have been associated with pseudomembranous colitis, but those most frequently implicated include ampicillin, lincosamides, and cephalosporins. The incidence of lincosamide-associated pseudomembranous colitis varies from 0.1 to 10 percent. Antibiotic-associated pseudomembranous colitis is caused by overgrowth of toxin-producing strains of *C. difficile*; at least two extracellular toxins are elaborated: toxin A, a potent enterotoxin; and toxin B, a cytotoxin.[46] The risk of developing disease is increased in elderly patients and those with chronic, debilitating conditions. Pseudomembranous colitis is unrelated to the total antibiotic dosage, duration of therapy, route of administration, or underlying disease. The onset most frequently occurs between days 4 and 9 of therapy, but signs and symptoms develop in one third of patients 2 to 10 weeks after discontinuation of the antibiotic. More than 80 percent of patients have fever, leukocytosis, crampy abdominal pain, and watery diarrhea, and 5 to 10 percent have bloody diarrhea. Sigmoidoscopic findings include plaquelike lesions on colonic or rectal mucosa consisting of polymorphonuclear leukocytes, chronic inflammatory cells, fibrin, and epithelial debris. Treatment includes prompt discontinuation of the antibiotic, avoidance of antiperistaltic agents, and oral administration of metronidazole. However, several factors that limit the effectiveness of metronidazole include occasional resistance of *C. difficile*, absence of convenient oral preparations for children, and complete absorption of the drug in the upper gastrointestinal tract so that bactericidal levels are achieved erratically in the lower gastrointestinal tract. Although this indication in children has not been approved by the FDA, metronidazole is considered the drug of choice. Use of a nonabsorbable oral vancomycin formulation is potentially effective. However, because of its expense, bad taste, associated relapse rate of 20 percent, and potential to induce resistance in enterococci, vancomycin should be reserved for children who fail to respond to metronidazole therapy. Potential alternative therapies for multiple recurrences of pseudomembranous colitis include probiotics, certain strains of yeast, solution of fresh stool from healthy donors, or cholestyramine.[46] An approved agent for traveler's diarrhea, rifaximin, has been shown to be effective in a few patients with recurrent or persistent *C. difficile* infection.

Other less common adverse events include the following: hypersensitivity reactions such as urticarial rash, drug fever, and eosinophilia; transient neutropenia, agranulocytosis, or thrombocytopenia; and a mild, reversible elevation in hepatic transaminases. Caution must be exercised when administering lincosamides to newborns; fatal gasping syndromes have been described that possibly are related to the preservative benzyl alcohol.

Drug interactions include incompatibility with many agents in solution, including ampicillin, barbiturates, calcium gluconate, phenytoin, and magnesium sulfate, as well as interaction with hydrocarbon-containing inhalational anesthetics. Lincosamides are weak neuromuscular blockers,[256] but they can enhance neuromuscular blockade when they are administered concurrently with neuromuscular blockers. Chloramphenicol and macrolides can have an antagonistic effect when they are administered concurrently with lincosamides because of competition for ribosomal binding sites.

LINEZOLID

Linezolid is the first of a new class of oxazolidinone antibiotics that was approved for use in children by the FDA in 2002. Linezolid is a totally synthetic compound with favorable activity against multidrug-resistant, gram-positive bacteria.[82]

Mechanisms of Action

Linezolid inhibits an early stage of ribosomal protein synthesis by binding to a unique site, domain V on the bacterial 23S ribosomal RNA of the 50S subunit, and prevents formation of a functional 70S initiation complex. Inhibition of this process interferes with the bacterial translation process. Furthermore, linezolid causes ribosomes to shift reading frames and to read through stop codons, thereby affecting translational fidelity.[267]

Mechanisms of Resistance

Rarely, mutations conferring resistance have been reported in the peptidyl transferase region of the 23S rRNA genes. Cross-resistance between linezolid and chloramphenicol is caused by a single nucleotide mutation in the peptidyl transferase center.[267] Cross-resistance between linezolid and other classes of antibiotics that target the ribosome such as aminoglycosides, macrolides, lincosamides, and streptogramins rarely occurs because these agents target a distinct mechanism of protein elongation. Resistance to linezolid has been reported in as many as 4 percent of clinical isolates of enterococci, particularly *E. faecium*, *S. aureus*, and coagulase-negative staphylococci.[86] Predisposing factors include indwelling devices, undrained abscesses, and prolonged administration of linezolid, particularly if subtherapeutic antibiotic concentrations are achieved.[237]

In Vitro Activity

Time-kill studies demonstrated that linezolid is bacteriostatic against enterococci and staphylococci and bactericidal against most strains of streptococci. Linezolid is active against MRSA, coagulase-negative staphylococci, and vancomycin-resistant enterococci. Furthermore, linezolid has broad activity against

Nocardia and rapidly growing mycobacteria, as well as slowly growing tuberculous and nontuberculous mycobacteria.[47]

Pharmacokinetics

Dosage adjustment is not necessary when switching from intravenous to oral formulations because the oral bioavailability is approximately 100 percent. Absorption is not significantly affected by food. The antibiotic is distributed to well-perfused tissues and has a relatively low protein binding (31%) that contributes to the high degree of penetration into bone, muscle, fat, alveolar cells, lung extracellular lining fluid, and CSF. Linezolid is metabolized primarily by oxidation and has no interaction with the cytochrome P-450 enzymes. The elimination half-life in children is less than 5 hours and is shorter than in adults. The disposition of linezolid varies as a function of age with faster clearance and greater volume of distribution in children younger than 11 years of age. The AUC values for children are lower than those for adults, whereas preterm neonates (gestational age <34 weeks) within the first week of life have larger AUC values than do many full-term neonates and older children. The pharmacokinetics of linezolid in adolescents 12 years of age and older is not significantly different from that of adults. Dosage adjustment is not necessary for patients with renal insufficiency or mild to moderate hepatic insufficiency.[144]

Indications for Use

Safety and effectiveness of linezolid have been established for pediatric patients from birth through 17 years of age. Intravenous and oral linezolid is indicated for treatment of children with (1) uncomplicated and complicated skin and skin structure infections caused by oxacillin-susceptible or oxacillin-resistant *S. aureus*, *S. pyogenes*, or *S. agalactiae*; (2) community- and health care–associated pneumonia caused by penicillin-susceptible strains of *S. pneumoniae* or oxacillin-susceptible or oxacillin-resistant *S. aureus*; and (3) infections caused by vancomycin-resistant enterococci.[147] The recommended dosage for newborns (≥34 weeks' postconceptual age) and children up to the age of 11 years is 10 mg/kg, given intravenously or orally every 8 hours for 10 to 14 days for pneumonia and complicated skin and skin structure infections and for 14 to 28 days for pneumonia or bacteremia caused by vancomycin-resistant enterococci. The 10-mg/kg dose is administered every 12 hours for 5- to 11-year-old children with uncomplicated skin and soft tissue infections and for premature neonates (gestational age < 34 weeks) within the first week of life. The dose for adolescents older than 11 years and adults is 600 mg every 12 hours, with a 1200-mg daily limit. Linezolid offers a safe therapeutic alternative to vancomycin for multidrug-resistant, gram-positive bacteria and has the additional advantage of being available in an oral liquid preparation (100 mg/5 mL), which facilitates sequential intravenous-oral therapy.[81,136,144,147] Safety and efficacy of therapy for longer than 28 days have not been evaluated in controlled clinical trials. Currently, no indication exists for treatment of mycobacterial infections, although linezolid has been used successfully for certain nontuberculous infections.

Adverse Effects

Data from multiple trials indicate that linezolid is safe and well tolerated, with adverse events similar to those of comparative drugs. The most common drug-related adverse events are diarrhea, nausea, vomiting, rash, and headache.[244] However, dose- and duration-dependent reversible myelosuppression, including mild to moderate anemia and thrombocytopenia and rarely neutropenia, have been reported in children treated with linezolid.[187,244] Therefore, weekly monitoring of complete blood counts is recommended in patients who receive linezolid for longer than 2 weeks, have preexisting myelosuppression, or receive other myelosuppressive antibiotics. Other rare adverse effects that warrant prompt evaluation include peripheral and optic neuropathy, lactic acidosis, and the serotonin syndrome in patients receiving concomitant selective serotonin reuptake inhibitors. The oral suspension formulation contains phenylalanine, which is contraindicated in children with phenylketonuria.

RIFAMYCINS

The rifamycins are a group of complex macrocyclic antibiotics that were isolated from *Streptomyces mediterranei* in the early 1960s. Rifampin (rifampicin) and rifabutin are structurally related, semisynthetic broad-spectrum antibiotics derived from rifamycin B and S, respectively. These agents avidly bind to the β subunit of the DNA-dependent RNA polymerase, prevent attachment of the enzyme to DNA, and thus block initiation of RNA transcription and protein synthesis. Rifabutin was approved in 1992 for prevention of disseminated MAC disease in adults with advanced HIV infection. Single-point mutations that determine resistance develop rapidly when rifamycins are used alone. Therefore, these antibiotics should be administered in combination with other antimicrobial agents when indicated. Rifaximin also is a semisynthetic derivative of rifamycin that was approved by the FDA in 2004 for the treatment of individuals 12 years of age or older who have nondysenteric and afebrile traveler's diarrhea caused by noninvasive strains of *E. coli*.[3]

In Vitro Activity

Rifampin usually is bactericidal, but it may be bacteriostatic, depending on the organism and drug concentration. Rifamycins have excellent in vitro activity against the following: many gram-positive cocci, including many methicillin-resistant staphylococci and penicillin-nonsusceptible *S. pneumoniae* (enterococci are notable exceptions); some gram-negative organisms, including meningococci, gonococci, and *H. influenzae*; *Legionella*; *C. trachomatis*; *T. gondii*; *M. tuberculosis*; and *M. leprae*. Rifampin is active against *M. kansasii*, but not against most other species of atypical mycobacteria. In contrast, rifabutin is active against most atypical mycobacteria, except *M. chelonae*. Rifabutin also is more active than is rifampin against rifampin-susceptible strains of *M. tuberculosis* and is active against approximately one third of rifampin-resistant strains.[174,193] Resistance to rifampin is mediated by point mutations in the *rpoB* gene that encodes the β subunit of the DNA-dependent RNA polymerase as well as alterations in membrane permeability. Surveillance data documented that 3 percent of meningococcal isolates in the United States are resistant to rifampin.[149] Rifaximin has activity against most enteric bacterial pathogens including *C. difficile*, *C. jejuni*, *E. coli*, *H. pylori*, *Salmonella* spp., *Shigella* spp., *V. cholera*, and *Yersinia enterocolitica*.[3]

Pharmacokinetics

Rifampin and rifabutin are highly lipid-soluble and highly protein-bound (72% to 89%) molecules. Consequently, they are well absorbed from the gastrointestinal tract and have excellent intracellular penetration. The drugs reach therapeutic concentrations in the CSF (≈10% to 20% of simultaneous serum concentrations), particularly in the presence of inflammation of the meninges. They are metabolized primarily by the liver through deacetylation, and 30 to 40 percent of the drug is excreted by the biliary system. In the presence of hepatic dysfunction, dosage adjustments are necessary, whereas no alteration in dosage is required for children with renal dysfunction. In adults, rifabutin

has a significantly longer mean terminal half-life than does rifampin (45 versus 2 to 5 hours).[230] Rifampin, however, has a very long post-antibiotic effect. Rifaximin is poorly absorbed, with a bioavailability of less than 0.4 percent. Therefore, dosage adjustment of rifaximin for hepatic or renal dysfunction is not necessary, and the agent is unlikely to interact with medications metabolized by the cytochrome P-450 system.

Indications for Use

The only situation in which rifampin should be considered for use as a single antibacterial agent is for prophylaxis of infection, because resistance to rifampin develops rapidly when this agent is used alone for therapeutic purposes. Prophylaxis with rifampin monotherapy is indicated to eradicate nasopharyngeal colonization in close contacts of individuals with infections caused by *H. influenzae* type b[112,197] and *N. meningitidis*,[26] as well as index cases with these infections, unless they were treated with third-generation cephalosporins.

The use of rifampin, combined with two or three other bactericidal antituberculosis agents for the treatment of active tuberculosis, as well as its combined use with clofazimine and dapsone for the treatment of leprosy, is considered an essential component of effective regimens. The effect of adding rifampin to certain antibiotics for treatment of other infections often is unpredictable and may result in synergistic, additive, indifferent, or antagonistic activity. In some patients, rifampin can be considered part of a combination regimen for the treatment of the following: (1) meningitis caused by penicillin- and cephalosporin-resistant *S. pneumoniae* in combination with a third-generation cephalosporin and vancomycin; (2) shunt- or catheter-associated staphylococcal infections, often with removal of the foreign material; (3) *S. aureus* implant-related orthopedic infections in combination with an effective agent; (4) non–life-threatening susceptible MRSA skin and skin structure infections in combination with TMP-SMX with the theoretical benefit of eradicating MRSA carriage, considering that rifampin achieves high concentrations on mucosal surfaces; (5) prosthetic valve endocarditis caused by staphylococci; (6) complicated or severe *B. henselae* infection (cat-scratch disease); (7) brucellosis in combination with TMP-SMX, a tetracycline, or an aminoglycoside[176]; (8) MAC-associated disseminated disease or lymphadenitis, if not completely resectable, in combination with ethambutol and azithromycin or clarithromycin; (9) *L. pneumophila* pneumonia in combination with a macrolide if response to macrolides alone is poor; and (10) multidrug-resistant *S. maltophilia* in combination with colistin (colistimethate sodium; polymyxin E) based on favorable in vitro data.[149,174] Furthermore, rifampin- and minocycline-impregnated central venous catheters have been used successfully in adults to prevent catheter colonization and bloodstream infection with gram-positive and gram-negative pathogens, as well as with *Candida* spp. The American Academy of Pediatrics recommends selective use of these catheters in infants weighing more than 3 kg and children if the local catheter-related bloodstream infection rate exceeds 3.3 per 1000 catheter days and if the standard protective procedures already have been implemented.[75,214] In the last circumstance, surveillance for resistance is important. Many physicians use rifampin combined with antistaphylococcal agents for treatment of disseminated MRSA infection without evidence from controlled studies of its effectiveness.

Rifabutin is effective for the treatment of most mycobacterial species, *H. pylori*, and *T. gondii* in adults. Limited data are available for the treatment of MAC infections in children with HIV infection. Clinical studies in adults with advanced HIV infection indicate that administration of daily clarithromycin or weekly azithromycin is superior to rifabutin alone for prophylaxis of MAC infection.[193] The safety and efficacy of rifabutin for prophylaxis of MAC infection in children have not been established.[145]

Rifampin is available in capsule (150- and 300-mg) and intravenous formulations. Rifabutin is available only in capsule (150-mg) form. A suspension can be compounded by the pharmacy, or the capsule contents can be mixed with thick, sweet food for infants and young children. Absorption of rifampin is optimal if administered 1 hour before or 2 hours after a meal, whereas a high-fat meal decreases the rate, but not the total amount, of absorption of rifabutin. The use of fixed-dose combinations of rifampin, isoniazid, and pyrazinamide is not recommended for children. Although the safety and efficacy of rifapentine, a rifamycin antibiotic similar in structure and activity to rifampin and rifabutin, have not been established for children younger than 12 years old, a pharmacokinetic study indicated that dosages in children need to be greater than those for adults to achieve comparable systemic exposure.[29] The approved dosage of rifaximin for the treatment of traveler's diarrhea in adolescents and adults is 200 mg three times per day for 3 days. A dosage of 400 mg twice per day for 3 days apparently is equally effective and may be better tolerated by patients. Rifaximin should not be used to treat systemic infections or mucosally invasive enteric infections. Rifaximin is not indicated currently for the treatment of dysenteric diarrhea secondary to *Shigella*, *Salmonella*, or *Campylobacter* spp. infection or for the treatment of complicated diarrhea with fever, systemic toxicity, or bloody stools. The role of this agent for prophylaxis of traveler's diarrhea is being studied.[3]

Adverse Effects

Adverse events associated with rifampin include gastrointestinal disorders, rash, hepatotoxicity, hypersensitivity, and a flulike syndrome. Adverse reactions to rifabutin include gastrointestinal disorders, rash, leukopenia, neutropenia, and, rarely, uveitis, although safety data in children are limited. The parenteral form of rifampin is associated with thrombophlebitis. Routine determination of serum aminotransferase concentrations is not recommended for children receiving brief or prolonged courses of therapy, except for those with clinical evidence of hepatitis or severe or disseminated tuberculosis. In these situations, at least monthly measurements should be performed. In addition, patients should be warned that rifamycins discolor urine, tears, sweat, and feces and permanently stain soft contact lenses. Because rifamycins induce hepatic cytochrome P-450 enzyme activity, they may interact with other medications administered concurrently and cause decreased concentrations of some antiretroviral agents, particularly protease inhibitors, azole antifungal agents, barbiturates, oral contraceptives, clarithromycin, cyclosporine, digoxin, sulfonylureas, thyroxine, and warfarin (Coumadin). Conversely, rifamycin serum drug concentrations may increase if it is administered with other drugs that inhibit hepatic enzymes, and the dose of rifamycin antibiotic may need to be reduced by as much as 50 percent. Rifabutin induces hepatic enzymes to a lesser extent than does rifampin and therefore has less potential for drug interactions.[174,193] Rifaximin is well tolerated and has an excellent safety profile.

SULFONAMIDES

Sulfachrysoidine (Prontosil), discovered in the 1930s, was the first sulfonamide developed. Sulfonamides are broad-spectrum antimicrobial agents derived from sulfanilamide (*para*-aminobenzene sulfonamide) and are structural analogues of *para*-aminobenzoic acid (PABA); they compete with PABA and result in interference with nucleotide synthesis. Sulfanilamide was manipulated to form other compounds with expanded antimicrobial activity and reduced toxicity. Sulfonamides are

distributed widely in fluids and tissues. The preparations currently available have greater solubility than earlier compounds and are less likely to cause crystalluria. Sulfonamides available for single-agent use include sulfacytine (Renoquid), sulfadiazine, sulfamethizole (Thiosulfil Forte), SMX (Gantanol), and sulfisoxazole (Gantrisin). Sulfonamide combinations, including TMP-SMX and erythromycin ethylsuccinate-sulfisoxazole acetyl (EES-SSX), are used frequently in pediatrics.

Trimethoprim-Sulfamethoxazole

TMP is a diaminopyrimidine antibiotic available for single-agent use. Combinations of TMP and sulfonamides were used in the late 1960s because of presumed synergistic antibacterial activity, although clinical evidence of synergy is equivocal. Because SMX has rates of absorption and elimination similar to those of TMP, it was the sulfonamide selected for combination. Iclaprim is a novel diaminopyrimidine currently in clinical development with a broad spectrum of activity that includes TMP-resistant strains of *S. aureus* (including MRSA and VRSA), *S. pneumoniae* (including penicillin-nonsusceptible strains), *P. jiroveci*, *Neisseria*, *M. catarrhalis*, and *C. pneumoniae*.[119]

MECHANISMS OF ACTION

SMX competitively inhibits dihydropteroate synthetase, the bacterial enzyme that assimilates PABA into dihydrofolic acid; such inhibition results in a reduction in dihydrofolic acid synthesis and therefore a reduction in the amount of tetrahydrofolic acid, a cofactor for nucleotide synthesis.[121] Only bacteria that must synthesize folic acid are potentially susceptible. SMX is bacteriostatic when used alone and can be inhibited by PABA and its derivatives (procaine and tetracaine). TMP reversibly binds and inhibits dihydrofolate reductase, an enzyme that reduces dihydrofolic acid to tetrahydrofolic acid; this activity results in diminished amounts of folic acid, an essential cofactor in nucleic acid production.[50] TMP is bacteriostatic when used alone, but in combination with SMX against susceptible bacteria, bactericidal activity can be achieved by blockade of sequential steps in folic acid metabolism. The effect of sulfonamide on bacteria is circumvented in mammals, which obtain folate from food sources. The reaction inhibited by TMP is similar in bacteria and mammals but differs quantitatively in the extent of binding of the drug to the enzyme; mammalian dihydrofolate reductase is 60,000 times less sensitive to TMP than is the enzyme in susceptible bacteria.

MECHANISMS OF RESISTANCE

Bacteria can be inherently resistant to either agent or can acquire resistance to TMP, SMX, or both agents. Resistance to SMX and other sulfonamides is associated with hyperproduction of PABA, as demonstrated in strains of *Neisseria* and staphylococci, or is caused by an altered dihydropteroate synthetase enzyme with lower affinity for sulfonamides, as found in *E. coli*, *N. meningitidis*, and *S. pneumoniae*.[265] Chromosomally mediated resistance to TMP on the basis of mutations in the *dhfr* gene has been observed in strains of *S. pneumoniae*, *H. influenzae*, *E. coli*, *Pediococcus*, *B. fragilis*, and *Nocardia* and *Clostridium* spp. Furthermore, *P. aeruginosa*, *K. pneumoniae*, and *S. marcescens* are inherently resistant to TMP because of cell wall impermeability. Acquired resistance to TMP can be plasmid-mediated or chromosomally mediated and occurs in members of the Enterobacteriaceae and in staphylococci, and streptococci. Mechanisms of acquired TMP resistance include cell wall impermeability, thymine auxotrophy, resistant dihydrofolate reductase, and overproduction of dihydrofolate reductase, the most common being plasmid-mediated production of dihydrofolate reductases, which are encoded by at least 20 genes. Resistance to sulfonamides is encoded by the *dhps* family of genes that include the *fol*P, and *sul*I and *sul*II genes. The *sul*I gene usually is linked to other transferable resistance genes, often in the transposons that belong to the Tn*21* family. Despite the reduced use of sulfonamides, the genetic determinants for sulfonamide resistance probably persist because of the efficient integron transfer mechanisms.[130] Bacterial resistance to both TMP and SMX can develop as a result of altered cell wall permeability or alternative metabolic pathways (e.g., thymine auxotrophy), whereby they obtain thymine or thymidine from the environment.[265]

IN VITRO ACTIVITY

TMP-SMX has activity against a broad spectrum of gram-positive cocci and gram-negative enteric pathogens. TMP is more active than is the sulfonamide, but the mixture is significantly more effective than is either drug alone. Synergism is more likely to occur when the bacteria are susceptible to both drugs, but it can occur even when the bacteria are resistant to only one agent. Bacteria with potential susceptibility to the combination include *Aeromonas hydrophila*, *Brucella*, *B. cepacia*, *Campylobacter*, *E. coli*, *H. influenzae*, *M. catarrhalis*, some environmental mycobacteria, *N. gonorrhoeae*, *Nocardia*, *P. jiroveci*, *Proteus*, *Salmonella*, *S. marcescens*, *Shigella*, oxacillin-susceptible *S. aureus*, *S. maltophilia* (usually with a β-lactam–lactamase inhibitor combination), penicillin-susceptible *S. pneumoniae*, and *Y. enterocolitica*. However, high levels of resistance to TMP-SMX among strains of penicillin-nonsusceptible *S. pneumoniae*, methicillin-resistant staphylococci, *M. catarrhalis*, *H. influenzae*, *Neisseria*, *E. coli*, *Klebsiella*, *Salmonella*, *Shigella*, *Campylobacter*, *P. aeruginosa*, *Acinetobacter*, *Nocardia*, *Actinomyces*, mycobacteria, *Bacteroides*, *Clostridium*, and *C. pneumonia* limit the usefulness of this antibacterial agent.[130]

PHARMACOKINETICS

Optimal synergistic activity occurs when a 1:20 ratio of TMP and SMX serum concentrations is attained, as can be achieved after the administration of a fixed 1:5 ratio of TMP to SMX. Both agents are absorbed rapidly and fairly well when administered alone and in combination. Both penetrate most body fluids and tissues, although TMP frequently penetrates extravascular tissues to a greater degree than does SMX. Both agents cross the placenta, are excreted in breast milk, and diffuse into pleural, peritoneal, and synovial fluid and CSF. Protein binding varies from 40 to 60 percent for TMP and from 60 to 70 percent for SMX. Both drugs are metabolized in the liver to inactive metabolites. The primary route of elimination is by the kidneys, with small amounts excreted in bile and feces. Dosage adjustments are required for renal impairment.

Available preparations include an oral suspension containing 40 mg of TMP and 200 mg of SMX per 5 mL, tablets containing 80 mg of TMP and 400 mg of SMX, double-strength tablets consisting of 160 mg of TMP and 800 mg of SMX, and a parenteral solution.

INDICATIONS FOR USE

TMP-SMX is approved for the treatment of acute exacerbations of chronic bronchitis in adults, enterocolitis caused by susceptible *Shigella* organisms, acute otitis media caused by susceptible strains of *H. influenzae* or pneumococcus, *P. jiroveci* pneumonia, traveler's diarrhea caused by *Shigella* and enterotoxigenic *E. coli*, and acute or chronic urinary tract infections. Although the combination is not approved for use and not usually prescribed as a first-line antibiotic, TMP-SMX has been effective therapy for typhoid fever, brucellosis, nocardiosis, sinusitis, biliary tract infections, and bone and joint infections caused by susceptible organisms.

Because early studies did not evaluate the effect of prolonged or recurrent therapy on somatic growth or bone marrow function in children, TMP-SMX was not approved for prophylaxis or prolonged treatment of otitis media. It is not recommended for treatment of group A streptococcal tonsillopharyngitis because it does not eradicate the organism or reliably prevent the nonsuppurative sequelae. TMP-SMX is not recommended as first-line monotherapy for community-acquired pneumonia, acute otitis media, or skin infections caused by *S. pyogenes* because of frequent resistance among the etiologic pathogens and absence of efficacy data. TMP-SMX is not FDA approved for the treatment of any form of staphylococcal infection. However, the medical literature contains reports of the successful use of TMP-SMX alone or in combination with one or more agents such as rifampin in the treatment of *S. aureus* infections, including MRSA.[110] TMP-SMX is recommended as an alternative agent to macrolides for treatment of pertussis in individuals 2 months of age or older.[269] TMP-SMX also is an important prophylactic agent that is indicated to prevent bacterial, *P. jiroveci*, and other infections in the following clinical settings: immunosuppressed oncology or post-transplant patients, individuals with HIV who meet clinical and hematologic criteria or certain infants who are exposed in utero to HIV, patients with urinary tract infections who are at risk for having recurrent disease, and patients with chronic granulomatous disease or other congenital immunodeficiency syndromes.

ADVERSE EFFECTS

Most of the side effects occurring during administration of TMP-SMX are caused by the sulfonamide. Gastrointestinal disturbances and hypersensitivity reactions are the adverse events most commonly observed. Anorexia, nausea, vomiting, diarrhea, drug eruption, and photosensitivity reactions can occur in 1 to 4 percent of patients. Hypersensitivity reactions that develop less frequently include erythema nodosum, erythema multiforme (including Stevens-Johnson syndrome), urticaria, anaphylaxis, and thyroid damage. Drug-induced hepatitis has been described but is an unusual event. CNS side effects include vertigo, ataxia, headache, and aseptic meningitis. TMP-SMX can affect renal function when it is administered to persons with underlying renal disease, but the side effect usually is reversible after discontinuation of therapy. Crystalluria occurred more commonly with earlier preparations because of low solubility. SMX has a greater tendency to cause crystalluria than do other sulfonamides that are currently available because of slower absorption and excretion, but with adequate fluid intake, alkalinization of the urine usually is unnecessary. Interstitial nephritis and tubular necrosis seldom are associated with the use of TMP-SMX. Blood dyscrasias can be a limiting factor to the administration of TMP-SMX. Acute hemolytic anemia has been described after the use of TMP-SMX in patients with glucose-6-phosphate dehydrogenase deficiency. Although they are uncommon in patients with normal hematopoietic systems, aplastic anemia, agranulocytosis, leukopenia, and thrombocytopenia can occur. Prolonged use can result in megaloblastic anemia because of impaired folate utilization. Administration of sulfonamide can trigger an acute attack of porphyria. Sulfonamides can displace bilirubin from albumin-binding sites. In neonates, especially premature infants, the activity of sulfonamides can be increased as a result of reduced conjugation by the immature liver. Because of the increased risk of development of kernicterus from sulfonamide displacement of bilirubin, the use of sulfonamides during the last month of pregnancy and in the first 2 months of life is discouraged.

Drug-drug interactions with TMP-SMX are numerous. Sulfonamides can displace other drugs from albumin-binding sites and thereby result in increased effective activity of the second drug, as can be seen with the concurrent administration of methotrexate, phenytoin, sulfonylurea hypoglycemic agents, thiazide diuretics, and warfarin. Drugs that, when co-administered, can displace sulfonamides from binding sites and lead to increased effective sulfonamide activity include indomethacin, probenecid, and salicylates. Agents that reduce the effect of sulfonamides include methenamine, which results in insoluble urinary precipitates of the sulfonamide, and derivatives of PABA. Sulfonamides are physically incompatible with many drugs, among them aminoglycosides, chloramphenicol, insulin, lincomycin, methicillin, tetracycline, and vancomycin.

Erythromycin Ethylsuccinate–Sulfisoxazole Acetyl

The combination of EES and SSX in a fixed ratio expands the spectrum of antibacterial activity. The mechanism of action, mechanisms of resistance, pharmacokinetics, and adverse events for EES-SSX are the same as those for each individual drug. Because EES-SSX is effective in vitro against common pathogens causing otitis media in children, it was approved for the treatment of acute otitis media.[38] However, it is not effective against many strains of pneumococci and no longer is recommended for empiric therapy of acute otitis media.[9] Although it is not approved for use, it can be effective therapy for sinusitis caused by *H. influenzae*, susceptible pneumococci, and *M. catarrhalis.* Albeit uncommon, its principal use today in pediatrics is for the treatment of acute otitis media caused by susceptible pathogens in patients with β-lactam hypersensitivity.

TETRACYCLINES

Chlortetracycline, also known as Aureomycin, was the first natural tetracycline discovered when isolated from *Streptomyces aureofaciens* in 1948.[92] Many tetracyclines have been developed since then. Those currently marketed include the natural agents tetracycline, oxytetracycline, and demeclocycline and the semisynthetic agents doxycycline and minocycline. Their basic structure consists of a hydronaphthacene nucleus with four fused rings. They differ from each other biochemically by substituent variations at carbons 5, 6, or 7. Their mechanisms of action and mechanisms of resistance, as well as their spectra of activity, are similar, but the analogues differ in the degree of activity and in pharmacokinetic properties. Tigecycline is a novel intravenously administered glycylcycline that is related structurally to minocycline. It is approved for use in adults with complicated skin and skin structure infections (including MRSA) and complicated intra-abdominal infections. It is bacteriostatic, with improved activity against multidrug-resistant bacteria, and it has no cross-resistance with other classes of antimicrobial agents.

Mechanisms of Action

Tetracyclines passively diffuse through outer-membrane porins and then traverse the cytoplasmic membrane by energy-dependent active transport. Tetracyclines are actively concentrated by most bacterial cells but not by mammalian cells, a characteristic that explains the selective action of these drugs against bacteria. Tetracyclines are bacteriostatic agents that reversibly bind to the 30S subunit of 70S bacterial ribosomes and inhibit protein synthesis. Because attachment of aminoacyl-tRNA to the ribosome acceptor site is prevented, the bacteria are unable to add amino acids to the growing peptide chain.

Mechanisms of Resistance

In many bacteria, including members of the Enterobacteriaceae, *P. aeruginosa*, staphylococci, streptococci, and *Bacteroides*, resistance to tetracyclines has developed. Resistance in most bacteria results from the acquisition of new genes often associated with

mobile elements such as plasmids or transposons, but it can also be chromosomally mediated. The genes encoding for acquired resistance are called *tet* (tetracycline)–resistance or *otr* (oxytetracycline)–resistance determinants. Resistance to one tetracycline usually implies resistance to all; however, many tetracycline-resistant bacteria are susceptible to doxycycline, minocycline, or both. At least 38 acquired tetracycline- and oxytetracycline-resistance genes have been identified that mediate (1) energy-dependent efflux of tetracycline (the most common type of resistance mechanism), (2) protection of the ribosomes from the action of tetracycline, or (3) enzymatic inactivation of tetracycline.[235] *Tet* genes that encode membrane efflux proteins are different in gram-positive and gram-negative bacteria. Efflux has been found in a wide range of bacteria including *Acinetobacter*, *Aeromonas*, *Chlamydia*, the Enterobacteriaceae, *Haemophilus*, *Moraxella*, *Neisseria*, *Pseudomonas*, staphylococci, *Stenotrophomonas*, *V. cholerae*, and others. Less commonly, ribosomal protection by a soluble ribosomal protection protein encoded by different *tet* and *otr* genes has been found in a wide variety of aerobic and anaerobic gram-positive and gram-negative bacteria. The precise mechanism by which ribosomal protection protein mediates resistance to tetracyclines is being investigated. Researchers have hypothesized that these protection determinants produce allosteric disruption of the primary tetracycline binding site that causes the tetracycline molecules to be released from the ribosome. Enzymatic inactivation of tetracycline, encoded for by other *tet* genes, has been demonstrated in in vitro studies of *Bacteroides*, and *E. coli*, but the clinical significance has not been established.[235] Susceptibility of staphylococci to this class of agents typically is tested using tetracycline. However, this approach may overestimate the prevalence of resistance to doxycycline and minocycline. Although the prevalence of tetracycline resistance remains relatively low among CA-MRSA isolates, resistance in some strains has been associated with *tet*K, a finding indicating that doxycycline and minocycline may be effective treatment options. However, because data are sparse on clinical outcomes associated with the use of minocycline or doxycycline to treat infections caused by tetracycline-resistant *S. aureus* strains, these agents are not recommended.[110]

In Vitro Activity

Tetracyclines are broad-spectrum antibiotics with activity against aerobic and anaerobic gram-positive and gram-negative bacteria, chlamydiae, mycoplasmas, rickettsiae, and spirochetes. Activity against gram-negative bacteria has been limited by the emergence of tetracycline-resistant strains. Most *P. aeruginosa* and many *Shigella* and *Salmonella* organisms are resistant. Penicillin-susceptible strains of *N. gonorrhoeae* and *N. meningitidis* usually are susceptible to tetracyclines, but penicillin-resistant strains of *N. gonorrhoeae* are not. Gram-negative organisms with continued susceptibility to tetracyclines include *A. hydrophila*, *Brucella*, *Campylobacter*, some *Haemophilus* organisms, *Helicobacter*, *P. multocida*, *Plesiomonas shigelloides*, and *Vibrio.* Tetracyclines are active against some gram-positive bacilli, including *Actinomyces israelii*, *B. anthracis*, many clostridia, *Listeria*, and *Nocardia.* Tetracyclines have excellent activity against *C. pneumoniae*, *M. pneumoniae*, and rickettsiae. Other organisms for which tetracyclines have activity include *Mycobacterium marinum* and *B. burgdorferi.* The more lipophilic agents doxycycline and minocycline generally are more active than the others. Minocycline has excellent activity against susceptible staphylococci, and both doxycycline and minocycline are more active than is tetracycline against *S. aureus* and some streptococci, but they have no activity against enterococci and group B streptococci. Because of extensive plasmid-mediated resistance in pneumococci, therapy with tetracycline should be avoided. Doxycycline and minocycline are more active in vitro than are the other agents against anaerobic bacteria, but alternative antimicrobials are preferred for anaerobic infections because more than 50 percent of *B. fragilis* isolates are resistant, and susceptibility among other anaerobes is highly variable.[234]

Pharmacokinetics

The five tetracycline compounds available for systemic use can be classified by duration of activity: tetracycline and oxytetracycline are short-acting agents, demeclocycline is intermediate-acting, and doxycycline and minocycline are long-acting agents (Table 248–9). Oral administration is the preferred route because thrombophlebitis is associated with intravenous infusion, and pain is associated with intramuscular injections. Oral absorption ranges from 58 percent for the short-acting agents to 100 percent for the long-acting ones. The presence of food decreases the absorption of demeclocycline, oxytetracycline, and tetracycline. Because tetracyclines form insoluble complexes in the gut with aluminum, calcium, iron, magnesium, zinc, and other bivalent and trivalent cations, co-administration with milk and other dairy products, antacids, calcium or iron supplements, cathartics, and other agents can reduce absorption and should be avoided. Differences in lipid solubility affect penetration of tissues by the various tetracyclines. All agents readily penetrate many tissues and fluids, among which are pleural, ascitic, and synovial fluids, sinus secretions, sputum, bone, teeth, and breast milk. Tetracyclines can cross the placenta. The highest concentrations are achieved in bile and can exceed serum concentrations by 5 to 20 times. Therapeutic concentrations of doxycycline can be achieved in tonsillar and pulmonary tissues, the eye, and the prostate, and high concentrations are achieved in myometrial and endometrial tissue and the kidney.[246] Minocycline penetrates into sputum,

TABLE 248–9 Pharmacokinetics of Tetracyclines

Drug	Oral Absorption (%)	Protein Blinding (%)	Primary Route of Excretion	Approximate Half-Life* (hr)
Short Acting				
Oxytetracycline	58	35	Renal	6-10
Tetracycline	75-77	65	Renal	6-11
Intermediate Acting				
Demeclocycline	66	91	Renal	10-17
Long Acting				
Doxycycline	90-100	93	Biliary	12-22
Minocycline	90-100	76	Biliary	11-23

**Normal renal function.*
Modified from USP DI: Information for the Health Care Professional. Vol. 1. Thomson MICROMEDEX, 2006.

saliva, and tears, as well as into cells of the vestibular apparatus.[139] Minocycline is biotransformed to inactive metabolites by the liver; the other tetracyclines are not metabolized, although whether doxycycline is metabolized is not clear. Oxytetracycline, demeclocycline, and tetracycline are eliminated unchanged in urine. Approximately 10 percent of minocycline is excreted unchanged in urine, 20 to 35 percent is excreted unchanged in feces, and the remainder is excreted as inactive metabolites in urine and feces. Thirty to 40 percent of doxycycline is excreted in urine; the remainder is excreted by the biliary tract and by diffusion through the intestinal wall, where some of it is chelated and prevented from reabsorption and enterohepatic cycling. Dosing of short- and intermediate-acting tetracyclines must be adjusted for renal failure.

Systemic formulations available in the United States include tablets, capsules, delayed-release capsules, and suspensions for many of the tetracyclines, as well as parenteral preparations of doxycycline, minocycline, and oxytetracycline. Ophthalmic and topical preparations also are available.

Indications for Use

With few exceptions, tetracyclines no longer are the drugs of choice for many infections because of the availability of cephalosporins and semisynthetic penicillins with equivalent or greater activity and less frequent side effects. As a result of the potential for dental toxicity, tetracyclines are not recommended for use in children younger than 9 years old, except for specific infections for which alternative therapy is potentially more toxic, such as chloramphenicol for Rocky Mountain spotted fever and ehrlichiosis.[1] Approved indications in the United States include treatment of actinomycosis, anthrax, brucellosis, inclusion conjunctivitis, psittacosis, Q fever, rickettsialpox, Rocky Mountain spotted fever, typhus, relapsing fever, syphilis, trachoma, yaws, and Vincent's necrotizing gingivostomatitis caused by *Fusobacterium*, as well as infections caused by *Bacteroides* spp., *Bartonella bacilliformis*, *C. fetus*, *F. tularensis*, *M. pneumoniae*, *V. cholerae*, *Y. pestis*, and others. Because of its excellent tissue penetration and spectrum of activity, doxycycline is the preferred tetracycline for treatment of atypical pneumonia caused by *M. pneumoniae* and *C. pneumoniae*, intra-abdominal or pelvic infections, and several sexually transmitted diseases, including granuloma inguinale, chlamydial infections, *U. urealyticum* infection, nongonococcal urethritis, pelvic inflammatory disease (plus cefoxitin, ampicillin-sulbactam or single dose ceftriaxone with or without metronidazole), acute epididymitis (plus ceftriaxone), proctitis (plus ceftriaxone), and prostatitis.[278] Doxycycline is an alternative drug for (nonpregnant) penicillin-allergic patients with primary, secondary, or late latent syphilis. Although minocycline is effective in eradicating nasopharyngeal carriage of meningococcus, its potential for vestibular toxicity precludes its use for this purpose. For prevention of Lyme disease after a recognized tick bite, a single dose of doxycycline may be offered to adults (200-mg dose) and to children older than 8 years of age (4 mg/kg, up to a maximum dose of 200 mg), provided the following criteria are met: (1) the attached tick can be identified reliably as an adult or nymphal *Ixodes scapularis* tick that is estimated to have been attached for more than 36 hours on the basis of the degree of engorgement of the tick, (2) prophylaxis can be started within 72 hours of tick removal, and (3) the local rate of infection of these ticks with *B. burgdorferi* is more than 20 percent. Doxycycline (4 mg/kg/day in two divided doses, up to 100 mg per dose) is indicated in children older than 8 years of age and adults for treatment of erythema migrans, isolated cranial nerve palsy, uncomplicated cardiac disease, and uncomplicated arthritis.[279] Topical tetracyclines have been used extensively for the treatment of acne vulgaris and other dermatologic illnesses.[129]

Adverse Effects

Gastrointestinal disturbances are the most common side effects associated with tetracycline and include anorexia, nausea, emesis, flatulence, and diarrhea. These symptoms occur less frequently with minocycline. Esophageal ulceration has been associated with the oral administration of tetracyclines.[95] All tetracyclines except doxycycline can cause a negative nitrogen balance, with an elevation in blood urea nitrogen that usually is not significant except in the presence of underlying renal insufficiency. Demeclocycline can cause nephrogenic diabetes insipidus and, for this reason, has been used for treatment of the syndrome of inappropriate antidiuretic hormone secretion. Rarely, tetracyclines have been associated with hepatic injury, as manifested by elevated transaminases and diffuse vacuolar fatty metamorphosis on biopsy, with or without pancreatitis. The effect is dose-related, and the risk is increased with pregnancy, malnutrition, and preexisting renal or hepatic disease and in patients receiving other hepatotoxic agents. The use of tetracyclines in children younger than 9 years of age is relatively contraindicated because tetracyclines chelate with calcium and can be deposited in developing bones and teeth and lead to a transient decrease in bone growth, permanent tooth discoloration, and enamel hypoplasia. The risk that these side effects will occur with one course at an appropriate dosage is low; the degree of tooth discoloration is associated with the total dosage administered.[113] Minocycline has been associated with reversible vestibular toxicity. All tetracyclines have been noted to cause pseudotumor cerebri, a benign elevation in intracranial pressure that is reversible after discontinuation of the drug. Some data suggest that an increased risk may exist with the concurrent use of tetracycline and isotretinoin. Tetracyclines have been associated with an exaggerated sunburn reaction after sun exposure. This risk occurs most frequently with demeclocycline and rarely with minocycline. Hypersensitivity reactions occur infrequently and include morbilliform rash, urticaria, exfoliative dermatitis, and, rarely, anaphylaxis. Hyperpigmentation of the mucosal membranes, skin, and nails has been reported with the use of tetracycline, particularly minocycline.

Drug-drug interactions are numerous. A decrease in absorption of tetracyclines can occur with the co-administration of oral antacids, bismuth subsalicylate, iron, kaolin or pectin, zinc sulfate, and other divalent or trivalent cations that chelate the antibiotic. A reduced effect of tetracyclines because of increased metabolism is associated with the concomitant use of doxycycline with barbiturates, carbamazepine, phenytoin, rifampin, and alcohol in heavy drinkers. Co-administration with tetracyclines can increase the effect of oral anticoagulants, digoxin, lithium, and theophylline and can decrease the effect of oral contraceptive agents and oral iron. Tetracyclines can inhibit the in vitro bactericidal activity of penicillins and aminoglycosides. Other drug-drug interactions include benign intracranial hypertension with the concomitant administration of vitamin A, severe nephrotoxicity with the co-administration of methoxyflurane and tetracycline, and localized hemosiderosis with amitriptyline and minocycline.

SELECTED ASPECTS OF THE ADMINISTRATION OF ANTIMICROBIAL AGENTS

DOSAGE SCHEDULES FOR INFANTS AND CHILDREN

Dosage schedules of antimicrobial agents commercially available in the United States for infants (beyond the newborn period) and children are listed in Table 248–10. The list is subdivided into

TABLE 248–10 Daily Dosage Schedules for Antimicrobial Agents in Pediatric Patients Beyond the Newborn Period

Agent, Generic (Trade name)	Route	Mild to Moderate Infections*	Severe Infections*
Penicillin G, crystalline (numerous)	IV, IM	100,000-250,000 U ÷ into 4 doses	250,000-450,000 U ÷ into 6 doses
Penicillin G, procaine (numerous)	IM	50,000 U once daily (congenital syphilis); 300,000 (<60 lb) or 600,000-1,000,000 U (≥60 lb) ÷ into 1 or 2 doses for Group A streptococcal infections	Inappropriate
Penicillin G, benzathine (Bicillin)	IM	300,000-600,000 U (<60 lb)† or 900,000 U (≥60 lb)† for Group A streptococcal infections; 50,000 U/kg (up to 2,400,000 U)† for syphilis	Inappropriate
Penicillin V, phenoxymethyl penicillin (numerous)	PO	25-50 mg ÷ into 3-4 doses	Inappropriate
Penicillinase-resistant penicillins			
Cloxacillin (Cloxapen)	PO	50-100 mg ÷ into 4 doses	Inappropriate
Dicloxacillin (Dynapen, Dycill, Pathocil)	PO	25-50 mg ÷ into 4 doses	Inappropriate
Methicillin (Staphcillin)	IV, IM	100-200 mg ÷ into 4 doses	200-300 mg ÷ into 4-6 doses
Nafcillin (Nafcil, Unipen, Nallpen)	IV, IM	50-100 mg ÷ into 4 doses	100-200 mg ÷ into 4-6 doses
Oxacillin (Prostaphlin, Bactocill)	IV, IM	100-150 mg ÷ into 4 doses	150-200 mg ÷ into 4-6 doses
Aminopenicillins			
Amoxicillin (numerous)	PO	25-90 mg ÷ into 2-3 doses	Inappropriate
Amoxicillin + clavulanate (Augmentin)	PO	45-90 mg ÷ into 2-3 doses	Inappropriate
Ampicillin (numerous)	IV, IM	100-200 mg ÷ into 4 doses	200-400 mg ÷ into 4-6 doses
	PO	50-100 mg ÷ into 4 doses	Inappropriate
Ampicillin + sulbactam (Unasny)	IV	100-200 mg of ampicillin ÷ into 4 doses	200-400 mg of ampicillin ÷ into 4-6 doses
Extended-spectrum penicillins			
Mezlocillin (Mezlin)	IV, IM	Inappropriate	200-300 mg ÷ into 4-6 doses
Piperacillin (Pipracil)	IV, IM	Inappropriate	200-300 mg ÷ into 4-6 doses
Piperacillin + tazobactam (Zosyn)	IV	Inappropriate	240-300 mg of piperacillin ÷ into 3-4 doses
Ticarcillin (Ticar)	IV, IM	100-200 mg ÷ into 4 doses	200-300 mg ÷ into 4-6 doses
Ticarcillin + clavulanate (Timentin)	IV	Inappropriate	200-300 mg ÷ into 4-6 doses
Monobactams			
Aztreonam (Azactam)	IV, IM	90 mg ÷ into 3 doses	120 mg ÷ into 4 doses
Cephalosporins			
Cefadroxil (Duricef)	PO	30 mg ÷ into 2 doses	Inappropriate
Cefazolin (Ancef, Kefzol)	IV, IM	50 mg ÷ into 3 doses	50-100 mg ÷ into 3-4 doses
Cephalexin (Keflex, Keftab)	PO	25-100 mg ÷ into 4 doses	Inappropriate
Cefaclor (Ceclor)	PO	20-40 mg ÷ into 2-3 doses	Inappropriate
Cefoxitin (Mefoxin)	IV	Inappropriate	80-160 mg ÷ into 4-6 doses
Cefprozil (Cefzil)	PO	15-30 mg ÷ into 2 doses	Inappropriate
Ceftibuten (Cedax)	PO	9 mg once daily	Inappropriate
Cefuroxime (Kefurox, Zinacef)	IV, IM	Inappropriate	100-150 mg ÷ into 3-4 doses
Cefuroxime axetil (Ceftin)	PO	20-30 mg ÷ into 2 doses	Inappropriate
Loracarbef (Lorabid)	PO	15-30 mg ÷ into 2 doses	Inappropriate
Cefdinir (Omnicef)	PO	14 mg ÷ into 1-2 doses	Inappropriate
Cefditoren (Spectracef)	PO	200-400 mg twice daily†§	Inappropriate
Cefixime (Suprax)	PO	8 mg ÷ into 1-2 doses	Inappropriate
Cefotaxime (Claforan)	IV, IM	Inappropriate	100-180 mg ÷ into 4-6 doses
Cefpodoxime proxetil (Vantin)	PO	10 mg ÷ into 2 doses	Inappropriate
Ceftazidime (Fortaz, Tazicef, Tazidime, Ceptaz)	IV, IM	Inappropriate	100-150 mg ÷ into 3 doses
Ceftriaxone (Rocephin)	IV, IM	Inappropriate	50-100 mg ÷ into 1-2 doses
Cefepime (Maxipime)	IV, IM	Inappropriate	100-150 mg ÷ into 2-3 doses
Carbapenems			
Ertapenem (Invanz)	IV, IM	Inappropriate	30 mg ÷ into 2 doses
Imipenem-cilastatin (Primaxin)	IV, IM	Inappropriate	60-100 mg ÷ into 4 doses
Meropenem (Merrem)	IV	Inappropriate	60-120 mg ÷ into 3 doses
Macrolides			
Azithromycin (Zithromax)	PO	10 mg on day 1, then 5 mg thereafter; 12 mg for pharyngitis	Inappropriate
Clarithromycin (Biaxin)	PO	15 mg ÷ into 2 doses	Inappropriate
Erythromycin base (numerous)	PO	30-50 mg ÷ into 4 doses	Inappropriate
Erythromycin estolate (llosone)	PO	30-50 mg ÷ into 4 doses	Inappropriate
Erythromycin ethylsuccinate (E.E.S., EryPed, Erythro)	PO	30-50 mg ÷ into 4 doses	Inappropriate

TABLE 248–10 Daily Dosage Schedules for Antimicrobial Agents in Pediatric Patients Beyond the Newborn Period—cont'd

Agent, Generic (Trade name)	Route	Mild to Moderate Infections*	Severe Infections*
Erythromycin gluceptate (llotycin)	IV	Inappropriate	20-50 mg ÷ into 4 doses
Erythromycin lactobionate (Erythrocin)	IV	Inappropriate	20-50 mg ÷ into 4 doses
Erythromycin Stearate (Erythrocin, Erythrocot, My-E)	PO	30-50 mg ÷ into 4 doses	Inappropriate
Lincosamides			
Clindamycin (Cleocin)	IV, IM	Inappropriate	20-40 mg ÷ into 3-4 doses
	PO	8-20 mg ÷ into 3-4 doses	Inappropriate
Vancomycin (Vancocin)	IV	Inappropriate	40-60 mg ÷ into 4 doses
Aminoglycosides			
Amikacin (Amikin)	IV, IM	Inappropriate	15-22.5 mg ÷ into 3 doses
Gentamicin (Garamycin)	IV, IM	Inappropriate	5-7.5 mg ÷ into 3 doses‖
Kanamycin (Kantrex)	IV, IM	Inappropriate	15-30 mg ÷ into 3 doses
Netilmicin (Netromycin)	IV, IM	Inappropriate	5-7.5 mg ÷ into 3 doses
Paramomycin (numerous)	PO	25-35 mg ÷ into 3 doses	Inappropriate
Streptomycin (numerous)	IM	Inappropriate	20-40 mg ÷ into 1-2 doses
Tobramycin (Nebcin)	IV, IM	Inappropriate	6-7.5 mg ÷ into 3-4 doses
Tetracyclines			
Doxycycline (numerous)	PO	2.2-4.4 mg ÷ into 1-2 doses	Inappropriate
Tetracycline (numerous)	PO	25-50 mg ÷ into 4 doses	Inappropriate
Chloramphenicol (Chloromycetin)	IV	Inappropriate	50-100 mg ÷ into 4 doses
	PO	Inappropriate	50-100 mg ÷ into 4 doses
Sulfonamides			
Erythromycin ethylsuccinate-sulfisoxazole (Pediazole, Eryzole)	PO	50 mg erythro/150 mg sulfa ÷ into 4 doses	Inappropriate
Sulfadiazine (numerous)	PO	100-150 mg ÷ into 4 doses	Inappropriate
Sulfisoxazole (Gantrisin)	PO	150 mg ÷ into 4 doses	Inappropriate
Trimethoprim-sulfamethoxazole (Bactrim, Septra, Sulfatrim, Cotrim)	PO	8-12 mg trimeth/40-60 mg sulfa ÷ into 2 doses	Inappropriate
	IV	Inappropriate	10-20 mg trimeth/50-100 mg sulfa ÷ into 4 doses
Fluoroquinolones			
Ciprofloxacin (Cipro)	PO	20-30 mg ÷ into 2 doses	Inappropriate
	IV	Inappropriate	20-30 mg ÷ into 2 doses
Rifampin (Rifadin, Rimactane)	PO	10-20 mg ÷ into 1-2 doses	20 mg ÷ into 2 doses
	IV	Inappropriate	20 mg ÷ into 2 doses
Metronidazole (Flagyl)	PO	15-50 mg ÷ into 3-4 doses	Inappropriate
	IV	Inappropriate	30 mg ÷ into 4 doses
Linezolid (Zyvox)	PO	Inappropriate	20-30 mg ÷ into 2 or 3 doses
	IV	Inappropriate	20-30 mg ÷ into 2 or 3 doses
Quinupristin-Dalfopristine (Synercid)	IV	Inappropriate	22.5 mg ÷ 3 doses
Colistimethate sodium (Colistin, Coly-Mycin M)	IV, IM	Inappropriate	2.5-5 mg ÷ into 2-4 doses

**Total daily dosage (per kg). For larger children, maximal dosages may apply.*
†*Total dose.*
‡*No longer available in the United States.*
§*Not approved for children younger than 12 years of age.*
‖*A dose of 4 mg/kg once daily is used commonly in neonates. A dose of 6-7.5 mg/kg once daily in older children is investigational.*
IM, intramuscularly; IV, intravenously; PO, orally; SC, subcutaneously.

dosage schedules for mild to moderate and for severe disease. Oral regimens are used for mild to moderate infections caused by susceptible organisms in areas that are well vascularized and in which adequate concentrations of drug are achieved at the site of infection. Parenteral administration should be considered for severe infections, especially those caused by less susceptible organisms that produce disease in areas in which diffusion of drug is limited.

DOSAGE SCHEDULES FOR NEWBORN INFANTS

The clinical pharmacology of antimicrobial agents administered to newborn infants is unique and cannot be extrapolated from data derived from older children or adults. The physiologic and metabolic processes that affect the distribution, metabolism, and excretion of drugs undergo rapid changes during the child's first few weeks of life. The increased efficiency of kidney function after the infant's first 7 days requires an increase in dosage and a decrease in the interval between doses of penicillins and aminoglycosides for maintaining therapeutic concentrations of drug in blood and tissues. Thus, different dosage schedules are provided for the first week of life and for the subsequent weeks of the neonatal period (Tables 248–11 and 248–12). With survival of very-low-birth-weight, premature infants, more data are needed on the use of antimicrobial agents in these infants with immature metabolic and physiologic mechanisms.[225] Dosages of antibiotics in these preterm infants, especially those weighing less than

TABLE 248–11 Dosage Schedules for Antimicrobial Agents Used in Neonates

		Dosage (mg/kg) and Interval of Administration				
		Weight < 1200 g	Weight 1200-2000 g		Weight > 2000 g	
Antibiotic	**Route**	**Age 0-4 wk**	**Age 0-7 Days**	**Age > 7 Days**	**Age 0-7 Days**	**Age > Days**
Penicillin G, crystalline (U)	IV	25,000-50,000 q12h	25,000-50,000 q12h	25,000-50,000 q8h	25,000-50,000 q8h	25,000-50,000 q6h
Penicillin G, procaine (U)	IM		50,000 q24h	50,000 q24h	50,000 q24h	50,000 q24h
Penicillin G, benzathine (U)	IM		50,000 once	50,000 once	50,000 once	50,000 once
Penicillinase-resistant penicillins						
Oxacillin	IV, IM	25 q12h	25-50 q12h	25-50 q8h	25-50 q8h	25-50 q6h
Nafcillin	IV, IM	25 q12h	25-50 q12h	25-50 q8h	25-50 q8h	25-50 q6h
Broad-spectrum penicillins						
Ampicillin	IV, IM					
Meningitis		50 q12h	50 q12h	50 q8h	50 q8h	50 q6h
Other infections		25 q12h	25 q12h	25 q8h	25 q8h	25 q6h
Ticarcillin	IV, IM	75 q12h	75 q12h	75 q8h	75 q8h	75 q6h
Meropenem	IV	20 q12	20 q12	20 q12	20 q12	20 q12 or q8
Cephalosporins						
Cefazolin	IV, IM	20 q12h	20 q12h	20 q12h	20 q12h	20 q8h
Cefotaxime	IV, IM	50 q12h	50 q12h	50 q8h	50 q12h	50 q6h or q8h
Ceftriaxone	IV, IM	50 q24h	50 q24h	50 q24h	50 q24h	75 q24h

TABLE 248–12 Dosage Schedule for Antibiotics Based on Postconceptual Age*

		Dosage (mg/kg) and Interval of Administration: Gestational Age plus Weeks of Life			
Antibiotic	**Route**	**≤26**	**27-34**	**35-41**	**≥42**
Amikacin	IV, IM	7.5 q24h	7.5 q18h	7.5 q12h	7.5 q8h
Gentamicin	IV, IM	2.5 q24h	2.5 q18h	2.5 q12h†	2.5 q8h†
Tobramycin	IV, IM	2.5 q24h	2.5 q18h	2.5 q12h	2.5 q8h
Vancomycin	IV	10-15 q24h	10-15 q18h‡	10-15 q12h‡	10-15 q8h‡ or q6h

**Dosages should be adjusted according to serum drug concentrations.*

†Single daily dosing is used commonly in neonates: 3-3.5 mg/kg (<35 wk) or 4 mg/kg (≥35 wk).

‡At 28 days of life, vancomycin is administered at 20 mg/kg per dose; the interval remains the same.

IM, intramuscularly; IV, intravenously.

1000 g, are uncertain for many agents, and measurement of serum concentrations should be considered for drugs such as vancomycin and the aminoglycosides.

SHOULD DOSAGES BE DETERMINED BY WEIGHT OR BY SURFACE AREA?

In most standard pediatric texts and in the package inserts prepared by manufacturers, dosages of antibiotics for children are based on body weight. Body surface area correlates more closely with extracellular fluid volume. Some investigators suggest that more predictable serum concentrations can be achieved by using calculations of dosages based on surface area than by using those based on weight.[120] This method may be more reliable for drugs that are distributed in extracellular fluid, such as aminoglycosides, especially when they are prescribed for obese or malnourished children. Currently, however, the convenience of calculating dosage on the basis of weight appears to be the more important consideration.

USE OF ORAL PREPARATIONS FOR SERIOUS INFECTIONS

Oral preparations of antimicrobial agents vary in their degree of absorption from individual to individual and within an individual, depending on the illness being treated and the formulation used. Because higher and more consistent serum concentrations of drug are achieved after parenteral administration, parenteral routes are preferable for serious infections. Sequential parenteral-oral antimicrobial therapy may be an option in patients with uncomplicated pneumonia, pyelonephritis, and intra-abdominal, skin and soft tissue, and suppurative skeletal infections.[185] Results of studies of orally administered antibiotics in children with skeletal infections indicate that this mode of administration can be used successfully for a portion of the therapeutic course.[205,264]

Specific guidelines for oral treatment of serious infections are recommended: (1) the patient should be able to swallow and retain the medication; (2) the dosage should be sufficiently large to provide adequate bactericidal concentrations of drug at the site of infection for at least 50 percent of the dosing interval for β-

lactams; and (3) when possible, it is advisable to have the hospital laboratory determine serum antimicrobial concentrations. When this is not possible, careful follow-up is mandatory, and measurements of inflammatory indices, such as the erythrocyte sedimentation rate and C-reactive protein, are very useful in determining resolution of the infection.

Oral therapy can be considered for patients with osteomyelitis and suppurative arthritis only after an initial period of parenteral therapy (≥5 to 7 days), after results are available from cultures and susceptibility tests, and after the patient shows definite signs of resolution of inflammation. Oral therapy should be initiated before discharge from the hospital to ascertain compliance, determine serum antimicrobial concentrations when available, and observe for significant side effects that would preclude use of the oral antibiotic.

FOOD INTERFERES WITH THE ABSORPTION OF SOME ORAL ANTIBIOTICS

The absorption of some oral antimicrobial agents is decreased significantly when the drug is taken with food or near mealtime. These drugs include unbuffered penicillin G, penicillinase-resistant penicillins (nafcillin, oxacillin, cloxacillin, and dicloxacillin), ampicillin, and lincomycin. Dairy products and other foods or medications containing calcium or magnesium salts interfere with the absorption of tetracyclines. Absorption of penicillin V, buffered penicillin G, amoxicillin, cephalexin, cefaclor, chloramphenicol, erythromycin, and clindamycin is affected only slightly by food. When absorption is affected by the concurrent ingestion of food, antibiotics should be taken 1 or more hours before or 2 or more hours after meals. A four-times-daily dosage schedule, rarely used for common infections, can be arranged for the drug to be given on arising, 1 hour before lunch and supper, and at bedtime. Most orally administered antibiotics can be administered twice or three times daily, a schedule that is accommodated easily by most parents.

INTRAVENOUS VERSUS INTRAMUSCULAR ADMINISTRATION

Although a brief period occurs when the serum antimicrobial concentration is higher after intravenous administration of an antimicrobial agent than after intramuscular administration, no therapeutic advantage of intravenous as opposed to intramuscular administration has been demonstrated. Intravenous administration should be used if the patient is in shock or is suffering from a bleeding diathesis. When prolonged parenteral therapy is anticipated, the pain of injection and the small muscle mass of infants and young children preclude the intramuscular route and render intravenous therapy preferable. The physician must be alert for thrombophlebitis, which can result from prolonged intravenous administration, and for sterile abscesses, which can develop after intramuscular administration.

Chloramphenicol, erythromycin, linezolid, tetracyclines, and vancomycin should be administered intravenously rather than intramuscularly. Chloramphenicol was thought to be absorbed poorly from intramuscular sites, although more recent data suggested that such is not the case. Intramuscular injection of parenteral tetracyclines and erythromycin causes local irritation and pain, and intramuscular injection of vancomycin causes tissue necrosis. Care should be given to the administration of intramuscular injections.[25,175] Sites that minimize the risk of local neural, vascular, or tissue injury should be selected. The preferred site varies with the age of the child: the upper anterolateral aspect of the thigh in infants, the ventrogluteal area in children older than 2 years of age, and the deltoid area for older children. Inadvertent intra-arterial injection of benzathine penicillin G can cause tissue damage.

"PUSH" VERSUS "STEADY" OR "CONTINUOUS DRIP" INTRAVENOUS ADMINISTRATION

Antimicrobial agents can be administered intravenously by the "push" method, in which case the drug is infused in 5 to 15 minutes; by "steady drip" in 1 to 2 hours; or by "continuous drip," whereby the drug is given throughout the period of administration. The push method results in high antibacterial activity in serum for short periods, whereas the steady and continuous drip methods produce lower but more sustained activity. The risk of development of adverse effects influences whether an antimicrobial agent should be administered by push or by steady drip. Pharmacodynamic studies suggest optimization of bactericidal activity when aminoglycosides are given by push once daily because these agents' activity is concentration-dependent. By contrast, β-lactams are given preferably in several doses or by a continuous drip to maintain concentrations of drug at the infection site that exceed the MIC of the pathogen for 50 percent or longer of the dosing interval (time-dependent pharmacodynamic principle). Rapid administration (<5 minutes) of large intravenous doses of penicillin should be avoided because of possible adverse CNS effects. Aminoglycosides given by the intravenous route should be infused in 20 to 60 minutes to obtain optimal peak concentrations. Antimicrobial activity, especially for penicillins, can deteriorate if drugs are kept in solution at room temperature for prolonged periods, as may occur with use of the continuous drip method. Fresh solutions of penicillins should be administered every 6 to 8 hours when the continuous drip method is used.

DIFFUSION OF ANTIMICROBIAL AGENTS ACROSS BIOLOGIC MEMBRANES

Diffusion of any drug across a biologic membrane depends on the molecular size of the drug, the degree of protein binding (only the unbound portion of the drug crosses), the degree of ionization at physiologic pH (only the un-ionized portion is available for equilibration), and solubility in lipids. Thus, the lipid solubility of the un-ionized and unbound fraction of an antimicrobial agent determines the capability of the drug to diffuse to the site of infection. Antibiotics usually are not distributed evenly throughout the body.[209,210]

Diffusion of antimicrobial agents from blood into a joint space, pleural and pericardial fluid, and middle ear fluid is relatively unimpeded, and high concentrations of many drugs are achieved in these sites after systemic administration. More than 60 percent of the peak serum concentration of various penicillins and cephalosporins is present in the inflamed joint space.[205] Loculations of fluid in the presence of fibrous adhesions may limit the passage of antimicrobial agents into infected areas.

Diffusion of antibiotics from blood into CSF or into the aqueous humor of the eye is limited. Drugs that are highly soluble in lipids, un-ionized, and minimally bound to proteins (e.g., chloramphenicol, isoniazid, rifampin, sulfonamides) pass into CSF in high concentrations, even in the absence of inflammation, whereas drugs such as the macrolides diffuse into CSF little, if at all. Fluoroquinolones pass readily into the CSF space but do not have an indication for use for meningitis in children. Penicillins, cephalosporins, and aminoglycosides pass more effectively into CSF when the membrane is inflamed; variable, but often low, concentrations of drug in CSF can be present even in the early stages of meningitis. The β-lactams are pumped actively out of

the CSF space by the choroid plexus, a process that is inhibited partially by inflammation.

DURATION OF THERAPY

Physicians must rely on empirically derived schedules of therapy for rapid and complete resolution of disease and minimal risk in terms of clinical or microbiologic failure or drug toxicity. Numerous studies evaluating the duration of therapy have been performed for streptococcal pharyngitis. The results are consistent in suggesting that the following are appropriate: 10 days of oral therapy with penicillins, cephalosporins, or macrolides; 5 days of azithromycin; or a single intramuscular dose of benzathine penicillin G. Opinions vary and data are conflicting regarding the duration of treatment for diseases such as osteomyelitis, suppurative arthritis, and infections of the urinary tract. Radetsky wrote an enlightening history of the recommendations for the duration of treatment in bacterial meningitis and pointed out: "Even in the absence of specific data certain numbers have an unaccountable power to satisfy and reassure .. 7, 10, 14 and 21 days have consistently appeared. Even in the trials performed at the dawn of the antimicrobial era, these numbers were chosen."[226]

DOSAGE SCHEDULES IN CHILDREN WITH RENAL OR HEPATIC INSUFFICIENCY

The kidneys are the major organs of excretion for most antimicrobial agents, including penicillins, cephalosporins, aminoglycosides, and tetracyclines (with the exception of doxycycline). Because impaired excretion can result in high and possibly toxic serum and tissue antimicrobial concentrations, alterations in dosage schedules should be considered in children with diminished renal function. Antibiotics that require careful dosage adjustment for renal impairment include aminoglycosides, ciprofloxacin, imipenem-cilastatin, meropenem, piperacillin, tetracyclines, ticarcillin, TMP-SMX, and vancomycin. Agents requiring dosage adjustments only when renal failure is severe include most penicillins, cephalosporins, and clindamycin. Drugs that are eliminated by nonrenal mechanisms and therefore do not require adjustment of the dosage schedule for renal impairment include chloramphenicol, cloxacillin, dicloxacillin, doxycycline, erythromycin (including the newer macrolides), metronidazole, linezolid, nafcillin, oxacillin, and rifampin.[277]

Dosage schedules for patients with renal insufficiency can be altered by administering the usual dosage for the initial dose and increasing the interval between doses or decreasing individual doses (or both, in the case of renal shutdown). Although numerous guidelines have been developed to assist the physician, these formulas have been generated from studies of adults with renal impairment, and pediatricians must be cautious in adapting the formulas for use in infants and young children.[277] Serum antimicrobial concentrations should be monitored when aminoglycosides, vancomycin, and other drugs of potential toxicity are administered to children with renal insufficiency. Serum specimens are obtained at the time of the anticipated peak and trough concentrations on the first day and repeated on subsequent days to ensure a safe and effective dosage schedule.

Hepatic disorders can alter plasma protein binding, tissue binding, hepatic metabolism, and the distribution of antimicrobials that are metabolized or excreted by the liver.[273] Few data exist regarding adjustment of dosage schedules for antibiotics that are metabolized by the liver in patients with hepatic insufficiency.[164] It would be prudent to avoid the use of tetracyclines and to exercise caution when prescribing chloramphenicol, clindamycin, metronidazole, macrolides, rifampin, and penicillinase-resistant penicillins to patients with underlying hepatic disease.

TOPICAL USE OF ANTIMICROBIAL AGENTS

Topical antimicrobial agents are used for a variety of indications: bacitracin or polymyxin ointments are available (in many cases without prescription) for first aid of minor cuts, abrasions, and burns; tetracycline, erythromycin, and clindamycin have been used for the treatment of pustular acne; and metronidazole is approved for the topical treatment of inflammatory lesions and erythema associated with rosacea. Erythromycin, chloramphenicol, sulfonamide, gentamicin, tobramycin, tetracycline, and a combination of TMP and polymyxin B ointment or drops are used for the treatment of conjunctivitis, styes, and other minor infections of the eye. Silver nitrate drops or either erythromycin or tetracycline ointment is used for the prevention of gonococcal ophthalmia in newborn infants. A controlled trial involving newborn infants in Africa demonstrated equivalent or superior efficacy of a 2.5 percent ophthalmic solution of povidone-iodine in comparison with topical silver nitrate or erythromycin for prophylaxis against ophthalmia neonatorum caused by *C. trachomatis*, *N. gonorrhoeae*, staphylococci, or gram-negative bacteria.[132] Ofloxacin drops (Floxin Otic) are approved for the treatment of otitis externa, chronic suppurative otitis media, and acute otitis media in children with tympanostomy tubes.[31] Ciprofloxacin and dexamethasone otic solution (Ciprodex) is approved for children 6 months of age and older who have tympanostomy tubes, to treat acute otitis media caused by *S. aureus*, *S. pneumoniae*, *H. influenzae*, *M. catarrhalis*, and *P. aeruginosa*, as well as acute otitis externa caused by *S. aureus* and *P. aeruginosa*. Mupirocin is effective in vitro against most *S. aureus* (including methicillin-resistant strains) and group A streptococci and is approved for the treatment of impetigo. At present, approximately 10 percent of CA-MRSA strains are resistant to mupirocin; in some areas, the rate is as high as 30 percent. Mupirocin applied to the anterior nares may be of value in eradicating nasal carriage of methicillin-resistant staphylococci. However, the few well-designed controlled studies that exist do not support the routine use of mupirocin, except possibly for patients undergoing dialysis, because prolonged use of mupirocin has been associated with resistance to this agent, and recolonization is a common occurrence.[60] Most antibiotics used topically, such as bacitracin, neomycin, and polymyxin B, are of limited use as systemic agents. Retapamulin ointment (Altabax), a pleuromutilin antibacterial, was approved by the FDA in 2007 for topical treatment of impetigo due to *S. aureus* (methicillin-susceptible isolates only) or *S. pyogenes* in patients aged 9 months or older. The dosage is twice daily applications for 5 days.

Absorption after application to the conjunctivae or large areas of denuded skin can be significant, but application to normal skin does not result in detectable concentrations of antimicrobial activity in blood or urine. Sensitization does not appear to be an important problem with most topical antibiotics, although some patients with chronic dermatoses may react to certain agents such as neomycin. Antimicrobial agents of value for systemic use should not be applied extensively to the surface of the body or used routinely in closed units (e.g., burn units) because of the risk of inducing resistance.

The Committee on Drugs of the American Academy of Pediatrics concluded that topical antimicrobial agents may prevent infection after minor cuts, abrasions, and burns, but in most instances, gentle cleansing of minor wounds and burns is sufficient antisepsis.[6] Systemic antibiotics, rather than topical drugs, are recommended for chronic pyoderma, including impetigo, especially when more than several lesions are present.

Intermittent administration of inhaled tobramycin (twice daily for 4 weeks followed by 4 drug-free weeks) is indicated for the management of children and adults with cystic fibrosis and *P. aeruginosa* infection. Clinical data from a large, randomized, placebo-controlled trial indicated that tobramycin treatment

improves pulmonary function, decreases the density of *P. aeruginosa* in sputum, reduces the risk of hospitalization, and is well tolerated. The diminished microbial reduction during the third cycle of treatment was not explained by the development of resistance to tobramycin.[229]

The use of antimicrobial-coated central venous catheters is not accepted practice in pediatrics, but limited evidence supports its potential usefulness, particularly if rates of catheter-related bloodstream infections exceed 3.3 per 1000 catheter days and if standard protective procedures already have been implemented.[214] Rates of bacterial colonization and bloodstream infections associated with the use of central venous catheters in high-risk adult patients were found to be lower in patients whose catheters were impregnated with minocycline and rifampin than in those impregnated with chlorhexidine and silver sulfadiazine.[75]

CURRENT USE OF ANTIMICROBIAL AGENTS FOR PROPHYLAXIS

Chemoprophylaxis refers to the use of drugs to prevent infection. *Antimicrobial treatment* refers to the use of drugs after infection has taken place or when early signs of infectious disease are present or infection is suspected. The use of antimicrobial agents for prophylaxis has proved to be of value in many circumstances (Table 248–13) and currently is considered to be of probable value or is investigational for the prevention of infections in many other situations. Prophylaxis is of greatest value when the following criteria are met: use of a single drug with a narrow spectrum of activity, use of a drug with limited side effects or toxicity, and prevention of colonization by an organism of known susceptibility and one that is unlikely to become resistant during the period of drug use.

USE OF ANTIMICROBIAL AGENTS FOR CHILDREN IN SCHOOL OR GROUP DAYCARE

Infants and children usually return to their school or daycare during a course of antimicrobial therapy. Because of problems with the administration of drugs outside the home, physicians should prescribe medications that are given infrequently, are relatively stable at ambient temperatures, and need only simple directions. Drugs that are administered in once- or twice-daily schedules are preferred. Chewable tablets, when available, may be of value in reducing the need for the school or daycare provider to measure specific amounts of liquid suspension and to refrigerate suspensions. Single-dose regimens, such as intramuscular benzathine penicillin G for group A streptococcal infections, may be advantageous. Guidelines for administration of medications in school have been published by the Committee of School Health of the American Academy of Pediatrics and should be useful to the physician for prescribing drugs to children who attend school.[8]

RESTRICTION ON USE OF ANTIMICROBIAL AGENTS FOR INFANTS AND CHILDREN

Many antimicrobial agents are approved for use in adults but have not been approved by the FDA for use in infants and children. The reasons for lack of approval include the following: drugs with insufficient experience in children, such as tigecycline (Tygacil); agents with real or suspected toxicity in children (e.g., damage to articular cartilage in juvenile animals associated with administration of the fluoroquinolones) that should be used only when necessary; and antibiotics for which the manufacturers have chosen not to submit data on use in children to the FDA, such as metronidazole (Flagyl), piperacillin (Pipracil), and cefotetan (Cefotan). These last three agents appear to be safe and effective in infants and children as a result of use by pediatricians, but no well-controlled studies of their efficacy or safety in this age group have been performed. Although a drug that has been approved for adults may be used in children at the discretion of the physician, the prudent physician chooses to use such a drug only when it is uniquely appropriate for the infectious illness and records the basis for choice of the unapproved drug.

Four antibiotics were approved for use in adults and have potential usefulness in the management of some pediatric patients with infections caused by multidrug-resistant pathogens. Daptomycin (Cubicin) is a cyclic lipopeptide that was approved by the FDA in 2003 for intravenous treatment of adults with compli-

TABLE 248–13 Antimicrobial Prophylaxis in Children

Prevention of Infection in Certain Patients	Antimicrobial Agent
Group A streptococcal infection in patients with a history of rheumatic fever	Benzathine penicillin G IM, penicillin V PO
Bacterial endocarditis in patients at risk during surgical procedures:	
Dental procedures, surgery on the upper respiratory tract	Amoxicillin PO; clindamycin, cephalexin, cefadroxil, azithromycin, or clarithromycin in penicillin-allergic patients
Gastrointestinal or genitourinary tract surgery or instrumentation	Amoxicillin PO, ampicillin IV, ampicillin plus gentamicin, or vancomycin plus gentamicin (for penicillin-allergic patients)
Neonatal sepsis caused by group B *Streptococcus*	Penicillin (preferred) or ampicillin IM or IV (intrapartum)
Gonococcal ophthalmia in newborn infants	Silver nitrate or erythromycin ophthalmic ointment
Meningococcal disease in contacts	Rifampin, ceftriaxone
Haemophilus influenzae type b disease in contacts	Rifampin
Recurrent episodes of acute otitis media	Amoxicillin, sulfisoxazole
Postoperative infections	Penicillinase-resistant penicillins or first- or second-generation cephalosporins
Tuberculosis infections in close contacts	Isoniazid
Recurrent urinary tract infections	Trimethoprim-sulfamethoxazole, nitrofurantoin
Sepsis in patients with functional asplenia	Penicillin, amoxicillin, trimethoprim-sulfamethoxazole

IM, Intramuscularly; IV, intravenously; PO, orally.

cated skin and skin structure infections caused by gram-positive infections, including MRSA, in a single daily dose of 4 mg/kg. Daptomycin was approved in 2006 for adults with methicillin-susceptible or methicillin-resistant bacteremia or right-sided endocarditis at a dose of 6 mg/kg daily for a minimum of 2 to 6 weeks. It has been shown to be inferior to comparator agents for community-acquired pneumonia, likely resulting from inactivation of daptomycin in the presence of pulmonary surfactant.[241] Although experience with daptomycin is meager in pediatrics, the drug does appear to be effective in the setting of persistent bacteremia in children with disseminated MRSA infection.

Quinupristin-dalfopristin (Synercid), a semisynthetic streptogramin, has synergistic activity against the same organisms as does linezolid and has been used extensively in adults in Europe. The dosage for children is 7.5 mg/kg, given intravenously three times daily. The drug has been well tolerated by children; diarrhea is the most common adverse effect. Telithromycin (Ketek) was approved in 2004 for use in adults. It is a semisynthetic ketolide antibacterial that differs chemically from the macrolide group by lack of α-L-cladinose at position 3 of the erythronolide A ring. Telithromycin is indicated for enteral treatment of adults with mild-to-moderate community-acquired pneumonia caused by common respiratory tract pathogens, including multidrug-resistant *S. pneumoniae* and atypical bacteria. In 2007, the FDA removed two previously approved indications, namely, acute exacerbations of chronic bronchitis and acute bacterial sinusitis because telithromycin has been associated with severe liver toxicity in adults. Its use is contraindicated in patients with myasthenia gravis. Safety and efficacy have not been established in children.

Tigecycline (Tygacil) is a glycylcycline related to minocycline that was approved by the FDA in 2005 for intravenous use in the treatment of adults with complicated intra-abdominal infections and complicated skin and skin structure infections caused by aerobic and anaerobic gram-positive and gram-negative bacteria, including MRSA.

HOME INTRAVENOUS ANTIBIOTIC THERAPY

Home intravenous antibiotic therapy is now available in most communities and permits discharge from the hospital earlier than in the past. The safety, effectiveness, and cost-efficiency of such a program have been proved, and these factors are of particular value for children who require 4 to 6 weeks of therapy for osteomyelitis or suppurative arthritis or who have chronic disease that can be managed in the home, such as cystic fibrosis or malignant disease. In many cases, home care enables the patient to resume normal activities, including return to school. The following are factors that are necessary before consideration of home care:

1. Availability of a team that includes the physician, the pharmacist, a vendor who will supply the drug and supplies, and an intravenous specialty nurse
2. A disease that is stable and requires only continued antimicrobial therapy
3. Unavailability of a suitable oral antibacterial agent (see the earlier section "Use of Oral Preparations for Serious Infections") and availability of a stable parenteral antibiotic with low toxicity that the patient can tolerate (as demonstrated in the hospital) and preferably with a long half-life to allow infrequent dosing
4. A member of the household who is able to administer the antibiotic and provide aseptic care of the venous access device
5. Appropriate follow-up that can be maintained for monitoring safety and effectiveness

If problems with venous access arise and ceftriaxone is appropriate therapy, the drug can be administered successfully at home by the intramuscular route once a day by a nurse.[104,240]

DRUG-DRUG INTERACTIONS

Drug-drug interactions can lead to therapeutic failure because of lack of effective activity of one or both drugs or serious adverse events resulting from toxic serum concentrations of one or both drugs.[105] Most children do not require daily medications for chronic diseases; thus, drug-drug interactions occur less commonly in pediatric than in geriatric patients, but the potential for interactions exists and must be considered when prescribing antibiotics. Because drug-drug interactions are not limited to prescription medications, inquiry into the use of over-the-counter medications should be made. Mechanisms for drug-drug interactions are classified as follows: physiochemical, whereby one drug is physically incompatible in solution with another; pharmacokinetic, whereby one drug interferes with the absorption, distribution, metabolism, or excretion of the other; and pharmacodynamic, whereby one drug affects the activity of a second drug. Examples of each mechanism include inactivation of aminoglycosides by extended-spectrum penicillins, decreased absorption of tetracyclines with co-administration of antacids, antagonism of sulfonamide activity by procaine as a result of competition for PABA-binding sites, and interference with the cytochrome P-450 oxidase enzyme system as observed with rifampin and macrolide drugs or with the azole antifungal agents and cyclosporine.

SUMMARY AND CONCLUSIONS

A summary of the information contained in this chapter is as questions that the physician must consider for appropriate use of antimicrobial agents in children.

1. Before the drug is administered:
   a. Have appropriate cultures been obtained for a specific microbiologic diagnosis?
   b. Has the patient received this drug or related compounds previously? If so, did the patient tolerate the drug? Were there any signs of toxicity or sensitization?
   c. Does the patient have a condition that requires exclusion of some drugs? For example, children with glucose-6-phosphate dehydrogenase deficiency may have induced hemolysis when a sulfonamide, nitrofurantoin, or primaquine is administered.
2. Factors to be considered when writing orders for the administration of antimicrobial agents in a hospital:
   a. If the drug is given by mouth, will co-administration with food interfere with absorption, or is diarrhea a risk?
   b. If a parenteral route is used, should the drug be administered by the intravenous or the intramuscular route?
   c. If the drug is administered by the intravenous route, is push, steady drip, or continuous drip preferred?
   d. Should the drug be instilled directly at the site of infection?
   e. Will the drug diffuse to the site of infection?
   f. Should incision and drainage of the infected area be performed before or after beginning therapy? Incision and drainage should be considered whenever a significant collection of pus is present. If a drainage procedure is performed, material should be obtained for culture and susceptibility testing.
   g. Does the patient have renal or hepatic insufficiency that requires alteration of the dosage schedule?
   h. Are any special precautions required for household contacts? Prophylaxis may be warranted in special circumstances of infection occurring in the household, daycare center, or nursery school.

3. Use of antimicrobial agents in children who are treated as outpatients:

a. Have the names and functions of the drugs been communicated to the patient and the parent? Do any of the drugs prescribed interact with each other?

b. Is the dosage schedule simple and satisfactory for the family circumstances (e.g., the child's school schedule, the schedule of the working parents)?

c. Does the child have an adequate supply of the drug until it can be purchased? If not, the use of starter packages is of value. Administration of the first dose in the clinic is advantageous because it provides knowledge of acceptance and tolerability of the drug by the child.

d. Are parents given instructions for reporting the clinical course by telephone? Is an appointment made for the next visit?

e. Does the patient or parent know how to assess adequacy of response to the drug? Does the parent know how to take the child's temperature?

f. Is the total amount of drug prescribed adequate for the course? Will refills of the prescription be needed?

g. Is the drug provided in a convenient dosage form? Will the package be provided with an adequate means of measuring the drug? Does the agent require refrigeration?

h. Has the patient or parent been informed of signs of side effects or toxicity?

i. Are generic equivalents of the drug adequate?

j. Will the patient be able to pay for the drug if it is purchased elsewhere (away from the clinic)? If applicable, will a third party pay for this prescription? (In some states, prescriptions by brand name may not be filled because reimbursement by the third-party payer, such as Medicaid, is insufficient.)

4. After the patient's course:

a. How long should the patient take the drug?

b. When should the initial choice of antimicrobial agents be reconsidered? When the results of cultures and appropriate susceptibility tests are available, should the initial choice be reevaluated and altered, if necessary?

c. What studies should be performed to monitor the safety and adequacy of the regimen? Hematologic indices must be measured during the administration of certain antibiotics to detect any adverse reaction. Vigilance is important to detect symptoms or signs attributable to adverse reactions.

d. Are repeat cultures necessary? In certain cases, the most appropriate criterion of efficacy is evaluation of the results of cultures.

e. What clinical and laboratory signs of efficacy should be monitored? Signs may differ for different diseases and various drugs but should be considered by the physician when the course of therapy is designed.

5. What factors should be considered if the patient fails to respond to the antimicrobial agent? If the patient does not respond appropriately to the course of therapy, various factors must be considered, including those related to the disease, host, drug, or organism (Table 248–14).

6. What steps can be taken to prevent re-infection? For example, in certain circumstances prophylactic antibiotics, immunizations, or surgical procedures may be warranted.

TABLE 248–14 Factors Contributing to Antimicrobial Failure

Host Related
Foreign body present
Anatomic defect
Defect in immune response to infection
Poor absorption of enteral antibiotic
Disease Related
Antibiotic inappropriate for the disease
Ancillary therapy not instituted (e.g., surgical drainage)
Sequestered focus of infection (undetected or inaccessible)
Organism Related
Acquired resistance to an antimicrobial agent
Superinfection with resistant bacteria
Drug Related
Inadequate adherence
Improper dosage schedule—route, dose, or duration
Inadequate diffusion to the site of infection
Drug-drug interactions—antibiotic inactivation or antagonism
Deterioration of drug during storage

Acknowledgments

We would like to acknowledge the contributions of Dr. Jerome Klein and Dr. Sheila Hickey, who were instrumental in preparation of this chapter in previous editions. Many of the sections have been modified to reflect more recently published information or the availability of new antimicrobial agents.

CHAPTER 249

Antimicrobial Prophylaxis

Gary D. Overturf

Antimicrobial prophylaxis is the provision of an antimicrobial agent or agents with the intent of preventing an infection. Prevention always is preferred, provided the means are available and the risk-benefit and cost-benefit ratios are acceptable. This chapter focuses on the prevention of morbidity and mortality from bacterial infections through the prophylactic and often empiric use of antimicrobial agents.

GENERAL PRINCIPLES OF PROPHYLAXIS

Several factors that influence the efficacy of prophylaxis are related to the potential pathogen, the prophylactic agent, the host, and the disease to be prevented (Table 249–1). Failure to consider all these factors will lead to ineffective prophylaxis, overuse of antimicrobial agents, promotion of resistant microorganisms, economic waste, and risk for development of toxicity or side effects.

TABLE 249–1 Factors Influencing Effective Prophylaxis

Single versus multiple potential pathogens
Time of exposure to the pathogen
Source of pathogens
Severity of the disease to be prevented
Targeted organs that could become infected
Spectrum of activity of the antimicrobial agent
Pharmacokinetics and the pharmacodynamics of the selected agent
Duration of chemoprophylaxis
Cost, toxicity, side effects, and acceptability of the agent
Likelihood and consequences of emerging resistance

THE BACTERIAL PATHOGEN

Prophylaxis is theoretically more effective when a single pathogen is targeted. In general, the greater the number of targeted pathogens, the less effective, the more toxic, and the more expensive the regimen becomes. Ideally, prophylaxis should be administered at the time of exposure to the potential pathogen. If exposure is prolonged or continuous, prophylaxis becomes less effective and less desirable. Bacteria that are not endogenous to the host (i.e., not part of the host's normal flora) generally are targeted more effectively if the exposure is known and identified.

THE DISEASE

The severity of the disease to be prevented is a major consideration. Potentially fatal infections (e.g., meningococcemia) or infections that result in high morbidity (e.g., endocarditis) are justifiably targeted. Prophylaxis usually is not required for minor illnesses (e.g., cuts, abrasions). The site of infection also is important. Adequate concentrations of antimicrobials are achieved

readily in organs that are highly vascular and have no barriers, whereas infections in restricted anatomic compartments (e.g., middle ear) or those that involve prosthetic materials may require special considerations.

THE ANTIMICROBIAL AGENT

The most desirable prophylactic agent is narrow spectrum, inexpensive, easily administered, and well tolerated and has minimal side effects. The less frequently an agent is given, the more reliable the adherence (compliance) of the patient.[64] When prophylaxis can be achieved effectively with a single administration of the antimicrobial agent, prophylaxis is likely to be ideal.

PROPHYLAXIS IN NEWBORN INFANTS

OPHTHALMIA NEONATORUM

The prophylaxis of ophthalmia neonatorum also is covered in the chapters on ocular infections and perinatal bacterial diseases (see Chapters 68 and 78). Prophylaxis targets *Neisseria gonorrhoeae* and *Chlamydia trachomatis.* Ideally, prophylaxis should be directed at infants who are exposed to these two pathogens; however, identification of this group with certainty is impossible. Routine prophylaxis has been discontinued in some countries (United Kingdom, Sweden)[28]; however, it is required in the United States.

Topical 1 percent silver nitrate solutions are available in single-dose ampules or single-dose tubes of an ophthalmic ointment containing 0.5 percent erythromycin or 1 percent tetracycline. All agents are effective and recommended for prophylaxis of gonococcal ophthalmia neonatorum.[58] Silver nitrate has been used for prophylaxis for more than 100 years. Because silver nitrate frequently causes chemical conjunctivitis, its use has been challenged, and alternative regimens have been sought. Erythromycin and tetracycline ophthalmic ointments appear to be as effective as silver nitrate solution for routine prophylaxis of gonococcal ophthalmia[76,120]; however, silver nitrate probably is the most effective agent against penicillinase-producing *N. gonorrhoeae.* The effectiveness of erythromycin or tetracycline in the prevention of ophthalmia caused by penicillinase-producing *N. gonorrhoea*e has not been established. No topical regimen has proven efficacy against *Chlamydia* conjunctivitis or prevention of invasive infections of the neonate, such as lower respiratory infection.[12,29,59] Furthermore, topical regimens do not eliminate *C. trachomatis* from the nasopharynx and do not prevent pneumonia.

Prophylaxis should be administered as soon as possible after birth. Each eyelid should be wiped gently with sterile cotton before local prophylaxis is administered. Care must be exercised to ensure that the solution or ointment is in the conjunctival sac and that it is not flushed from the eye after instillation.

GROUP B STREPTOCOCCAL INFECTIONS

Prophylaxis is aimed at prevention of early-onset neonatal group B streptococcal infections.[2,3,13,93,100,102] No recommendations for prophylaxis against late-onset infections exist. Prophylaxis of group B streptococcal infections also is covered in greater detail in Chapter 94.

In the past, several regimens have been used in attempts to reduce vertical transmission of group B streptococcus. Multiple studies involving the prepartum use of oral antimicrobial agents to eradicate group B streptococcus colonization of mothers (antepartum chemoprophylaxis) have not been successful, even when sexual partners were treated concurrently.[93] Prophylaxis of newborn infants with penicillin G or ampicillin soon after birth (postnatal chemoprophylaxis) is ineffective in preventing early-onset group B streptococcal disease, primarily because in most patients, infection occurs in utero and the infants are asymptomatic at or within a few hours after birth.

Current recommendations focus on treatment of all colonized women, who are tested universally at 35 to 37 weeks.[25] Previously, treatment of women in special-risk categories or the use of selective intrapartum maternal chemoprophylaxis was recommended.[1-3] The American Academy of Pediatrics as well as the current guidelines of the Centers for Disease Control and Prevention recommend that lower vaginal and anorectal (single swab) specimens for culture be obtained at 35 to 37 weeks' gestation, placed into selective broth medium, transported, and subcultured onto solid media.[3,25] Currently, both hybridization assays and DNA amplification techniques for detection of group B streptococci are available and serve as the only acceptable alternatives to culture.[10,63] Rapid amplification methods are available for testing women at the time of entry into labor and thus provide opportunities for treatment of women who may not have been tested at 35 to 37 weeks' gestation. Women who have no prenatal group B streptococcal culture results available and who begin labor with an identified risk factor (Table 249–2) thus may be tested for group B streptococcus by rapid tests or by culture. Maternal group B streptococcus carriers identified prepartum or those without culture or identification at the time of delivery with rapid testing but with one or more risk factors should be given intrapartum intravenous ampicillin (2 g initially, then 1 to 2 g every 4 to 6 hours) or penicillin G (5 million U every 6 hours) until delivery.[25] Penicillin-allergic women may be given clindamycin or erythromycin intravenously. Previous delivery of an infant with invasive group B streptococcal disease warrants intrapartum maternal chemoprophylaxis for each subsequent pregnancy, regardless of maternal colonization.

Intrapartum antibiotic prophylaxis prevents substantial numbers of but not all cases of early-onset neonatal group B streptococcal infection and will decrease the incidence of maternal group B streptococcal postpartum endometritis.[79,88] Since the institution of intrapartum antimicrobial prophylaxis, the rate of invasive group B streptococcal disease has declined approximately 65 percent. Administration of intravenous ampicillin reduces the risk for development of early-onset group B streptococcal infection by 36 percent in infants born to women with premature rupture of membranes.[9] Treatment of women with chorioamnionitis with ampicillin and gentamicin during labor reduces the

TABLE 249–2 Risk Factors for Early-Onset Group B Streptococcal Infection

Maternal Risk Factors
Premature onset of labor of <37 weeks' gestation
Premature rupture of membranes at <37 weeks' gestation
Rupture of membranes (>18 hr) at any gestation
Maternal fever during labor
Multiple births
High GBS genital inoculum
GBS bacteriuria
Low type-specific GBS capsular polysaccharide antibody
Maternal age <20 yr
Black race
Diabetes mellitus
Infant Risk Factors
Low birth weight
Prematurity

GBS, group B streptococcus.

likelihood for development of group B streptococcal infection by 86 percent. In some reports, the decrease in the rate of group B streptococcal disease was associated with an increased rate of disease caused by gram-negative pathogens. Although many obstetric care providers take some measures to prevent the development of group B streptococcal disease, reported practices often are inconsistent with the existing recommendations.[65] In the past, the most frequent deviation from accepted recommendations is timing of the antepartum screening cultures.[79]

Management of infants whose mothers received intrapartum chemoprophylaxis remains empiric and should be based on clinical manifestations and gestational age. If indicated, appropriate cultures should be performed and antimicrobial therapy initiated, pending culture results.[2]

NECROTIZING ENTEROCOLITIS

Neonatal necrotizing enterocolitis (NEC) is a multifactorial disease, with bowel wall necrosis of variable length and depth being the characteristic feature. Factors including ischemic stress, disruption of the bowel mucosal barrier, and resultant bacterial proliferation and invasion of the intestinal wall are part of the pathogenesis of NEC. Therefore, suppression of gastrointestinal flora with nonabsorbable oral antimicrobials has been used in an effort to prevent the development of NEC in premature infants. Administration of oral kanamycin or gentamicin prophylactically in the first few hours of life generated contradictory data. Furthermore, selective overgrowth of resistant organisms in the bowel and significant systemic absorption of aminoglycosides from the injured mucosa are potential risk factors. Currently, oral aminoglycosides are not recommended for the prophylaxis of NEC.

One report[92] suggests that oral vancomycin given for 48 hours before the introduction of oral feeding may be beneficial in preventing NEC. These observations have not been confirmed, and such prophylaxis is not practiced routinely or recommended.

Oral probiotics have been suggested to alter the bowel flora and to reduce the incidence or severity of NEC. Infants fed breast milk and products including *Lactobacillus acidophilus* and *Bifidobacterium infantis* had a reduced incidence and severity of NEC compared with infants fed breast milk alone.[81]

INTRAVASCULAR CATHETER INSERTION

Infection with coagulase-negative staphylococci, primarily *Staphylococcus epidermidis*, is likely to occur in premature infants or infants who have indwelling vascular catheters. Low-grade sepsis is the most common clinical manifestation; however, meningitis, endocarditis, omphalitis, cellulitis, and other focal infections may occur. Two randomized trials of low-dose vancomycin added to total parenteral nutrition fluids (25 μg of vancomycin per milliliter of fluid) suggested that such a prophylactic regimen significantly reduces coagulase-negative staphylococcal infections in small premature infants in neonatal intensive care units.[68,111] Widespread use of this regimen will not be recommended until more data are collected and the issue of emergence of vancomycin-resistant organisms is addressed adequately.[7] Currently, the American Academy of Pediatrics discourages the use of routine prophylaxis for infants of very low birth weight or the prevention of infection or colonization of indwelling central or peripheral intravascular catheters with either systemic or antibiotic lock administration techniques.[2]

Continuous administration of fluconazole has been studied in high-risk, low-birth-weight infants who are at risk for development of systemic infections caused by *Candida* spp. However, the American Academy of Pediatrics currently does not list the use of continuous fluconazole as an accepted procedure.[2]

DISEASE-TARGETED PROPHYLAXIS

RHEUMATIC FEVER

Group A streptococcal infections of the pharynx are the precipitating cause of rheumatic fever. Appropriate antibiotic treatment of streptococcal pharyngitis prevents the development of acute rheumatic fever in most cases.[38] Because at least one third of episodes of acute rheumatic fever result from inapparent streptococcal infections[32] and some symptomatic patients do not seek medical care, not all instances of rheumatic fever are preventable. Prevention of first attacks (primary prevention) is accomplished by proper identification, adequate antibiotic treatment, and eradication of this streptococcal infection. An individual who has suffered an attack of rheumatic fever is at very high risk for recurrence after subsequent group A streptococcal pharyngitis and needs continuous chemoprophylaxis to prevent such recurrence (secondary prevention).[34] The prophylaxis of rheumatic fever also is discussed in Chapter 35.

Primary Prevention

The primary treatment of episodic recurrent group A streptococcal infections is important in the prevention of rheumatic fevers and recurrent episodes. The diagnosis and treatment of group A streptococcal infections are discussed in Chapter 93, and the prevention of rheumatic fever and its prophylaxis are discussed in Chapter 35. The acceptable regimens for treatment of acute group A streptococcal infections (i.e., primary prevention) are provided in Table 249–3. Even when treatment is started as long as 9 days after the onset of acute illness, penicillin effectively prevents primary attacks of rheumatic fever.[24] Therefore, a brief delay (24 to 48 hours) for processing of the throat culture before initiation of antibiotic therapy does not increase the risk of development of rheumatic fever.

Intramuscular benzathine penicillin G is preferred to oral penicillin, particularly for patients who are unlikely to complete a 10-day course of oral therapy and patients with a personal or family history of rheumatic fever, rheumatic heart disease, or other factors that place them at substantial risk for development of rheumatic fever.[34]

Secondary Prevention

Continuous antibiotic administration is indicated in patients at risk for developing or recurrent disease after having infection with group A streptococcus or for those children with congenital or acquired cardiac disease who are at risk for development of endocarditis. Both the American Academy of Pediatrics and the American College of Cardiology provide recommendations for prophylaxis.

An individual in whom streptococcal pharyngitis develops after a previous attack of rheumatic fever is at high risk for having a recurrent attack of rheumatic fever, even after those infections that are asymptomatic or in those symptomatic infections that are treated optimally. Therefore, prevention of recurrent rheumatic fever requires continuous antimicrobial prophylaxis rather than recognition and treatment of acute episodes of streptococcal pharyngitis.[34] Continuous prophylaxis is recommended for patients with a well-documented history of rheumatic fever (including cases manifested solely by Sydenham chorea) and for those with definite evidence of rheumatic heart disease. Such prophylaxis should be initiated as soon as acute rheumatic fever or rheumatic heart disease is diagnosed. A full therapeutic course

TABLE 249–3 Prevention of Rheumatic Fever

From Dajani, A., Taubert, K., Ferrieri, P., et al.: Treatment of acute streptococcal pharyngitis and prevention of rheumatic fever: A statement for health professionals. Pediatrics 96:758-764, 1995. Copyright American Academy of Pediatrics 1995.

**Clarithromycin for 10 days or azithromycin for 5 days in recommended doses is also effective.*

of penicillin or other effective regimen should be given first to patients with acute rheumatic fever to eradicate residual group A streptococcus, even if a throat culture is negative at that time. Streptococcal infections occurring in family members of rheumatic patients should be treated promptly.

An injection of 1,200,000 U of benzathine penicillin G every 4 weeks is the recommended regimen for secondary prevention in most circumstances in the United States (see Table 249–3). In countries where the incidence of rheumatic fever is particularly high, in special circumstances, or in certain high-risk individuals, such as patients with residual rheumatic carditis, administration of benzathine penicillin G every 3 weeks is justified and recommended.[82,83] Long-acting penicillin is of particular value in patients with a high risk of having a recurrence of rheumatic fever, especially those with rheumatic heart disease, in whom recurrence is very serious. The advantages of giving benzathine penicillin G must be weighed against the inconvenience to the patient and the pain of injection, which causes some individuals to discontinue prophylaxis.

Successful oral prophylaxis (penicillin V or sulfadiazine, see Table 249–3) depends primarily on the patient's adherence to prescribed regimens.[33] Patients need to be given careful and repeated instructions about the importance of prophylaxis. Most failures of prophylaxis occur in nonadherent patients. Even with optimal adherence of the patient, the risk of having a recurrence is higher in individuals receiving oral prophylaxis than in those receiving intramuscular benzathine penicillin G.[47] Oral agents are more appropriate for patients at lower risk for having rheumatic recurrence. Accordingly, some physicians elect to switch therapy to oral prophylaxis when patients have reached late adolescence or young adulthood and have remained free of rheumatic attacks for at least 5 years.

Although sulfonamides are not effective in the eradication of group A streptococcus, they do prevent development of infection. Sulfonamide prophylaxis is contraindicated in late pregnancy because of transplacental passage of such drugs and potential competition with bilirubin for albumin-binding sites.

For patients who are allergic to penicillin and sulfisoxazole, erythromycin is recommended. No data have been published about the use of other penicillins, macrolides, or cephalosporins for the secondary prevention of rheumatic fever, but the American Academy of Pediatrics has stated that clarithromycin for 10 days or azithromycin for 5 days is adequate for secondary prevention.

The appropriate duration of prophylaxis must be determined for each situation.[34] Patients who have had rheumatic carditis are at relatively high risk for having recurrence of carditis and are likely to sustain increasingly severe cardiac involvement with each recurrence. Therefore, patients who have had rheumatic carditis should receive long-term antibiotic prophylaxis, perhaps for life. Prophylaxis should continue, even after valve surgery, including prosthetic valve replacement. Patients who have had rheumatic fever without rheumatic carditis are at considerably less risk of having cardiac involvement with a recurrence. Therefore, a physician may consider discontinuation of prophylaxis in these individuals after several years.[11] In general, prophylaxis should continue until 5 years has elapsed since the last rheumatic fever attack or the age of 21 years, whichever is longer.[34]

The decision to discontinue prophylaxis or to reinstate it should be made after discussion with the patient about the potential risks and benefits and careful consideration of various epidemiologic risk factors.[34] The risk of having a recurrence increases with multiple previous attacks, whereas the risk decreases as the interval since the most recent attack lengthens. In addition, the likelihood of acquiring a streptococcal upper respiratory tract infection is an important consideration. Individuals with increased exposure to streptococcal infections include children and adolescents, parents of young children, teachers, physicians, nurses and allied health personnel in contact with children, military recruits, and others living in crowded situations. A higher risk for recurrence has been demonstrated in economically disadvantaged populations.

BACTERIAL ENDOCARDITIS

In 2007,[117a] recommendations for antimicrobial prophylaxis were changed significantly from previous guidelines in 1997.[35] The rationale for these changes included three central concepts. First, endocarditis is much more likely to result from frequent exposure to random bacteremias associated with daily activities than from bacteremia caused by a dental, gastrointestinal tract, or genitourinary procedure. Second, prophylaxis may prevent an exceedingly small number of (if any) cases of endocarditis in individuals who undergo any procedure, and the risk of adverse reactions to antibiotics probably exceeds the benefit in any form of prophylactic treatment. Third, maintenance of optimal oral health and hygiene may reduce the incidence of bacteremia from daily activ-

ities and is more important than prophylactic antibiotics for a dental procedure to reduce the risk of endocarditis.

Therefore, recommendations for the use of antibiotic prophylaxis after 2007 were limited to the highest risk cardiac conditions. Cardiac conditions associated with the highest risk are listed in Table 249–4. Prophylaxis is no longer provide to all subjects who have the highest lifetime risk of endocarditis. For patients with high-risk conditions listed in Table 249–4, all dental procedures that involve manipulation of gingival tissues or the periapical region of teeth or perforation of the oral mucosa are reasonable for administration of dental prophylaxis. Events and procedures such as routine anesthetic injections through noninfected tissues, taking dental radiographs, placement or removal of prothodontic or orthodontic appliances, adjustment of orthodontic appliances, placement of orthodontic brackets, shedding of deciduous teeth, and bleeding from trauma to the lips or oral mucosa do not require prophylaxis. The recommendations for regimens for oral and parenteral antibiotics listed in Table 294–5 are for all dental procedures for which dental prophylaxis is reasonable for persons with high-risk conditions.

Recommendations for antimicrobial prophylaxis for respiratory procedures are only for procedures that involve the incision or incisional biopsy of the respiratory mucosa, such as tonsillectomy and adenoidectomy. Therefore, prophylaxis is not recommended for broncoscopy unless an incision of the respiratory tract will be made. An antimicrobial regimen that includes coverage of viridans group streptococci[35] can be selected from Table 249–5.

When using prophylaxis for high-risk procedures of the gastrointestinal or genitourinary tract, consideration of the possible involvement of enterococcal organisms must be considered as well as the inclusion of mixed infections with aerobic and anaerobic gram-negative and gram-positive organisms.[22,43] However, only enterococci are frequent causes of endocarditis. In the revised recommendations of 2007, the administration of prophylactic antibiotics solely to prevent endocarditis is not recommended for patients who undergo esophagogastroduodenosomy or colonoscopy, which is in contrast to previous recommendations made in 1997. For patients with infections of the gastrointestinal or genitourinary tract who may have intermittent or sustained enterococcal bacteremia or for those who receive antibiotic therapy to prevent wound infection or sepsis associated with a gastrointestinal or genitourinary tract procedure, it is reasonable to include an agent active against enterococci, such as penicillin, ampicillin, piperacillin, or vancomycin. Similarly for patients with high-risk conditions listed in Table 294–4 antibiotic therapy to eradicate the infection from the urine prior to surgery is reasonable for those who are scheduled for an elective cystoscopy or other urinary tract manipulation who have an enterococcal urinary tract infection or colonization. Amoxicillin or ampicillin is the preferred agent for enterococci, but vancomycin may be used in those intolerant of β-lactam antibiotics.

Incision of surgically scrubbed skin without an underlying or adjacent infection is not likely to cause bacteremia, and prophylaxis is not recommended. In contrast, procedures on infected skin, skin structure, or musculoskeletal tissues are likely to cause endocarditis. Therefore, for children with high-risk cardiac conditions, a therapeutic regimen administered for treatment of the infection should contain an agent active against staphylococci and β-hemolytic streptococci, such as an antistaphylococcal penicillin or cephalosporin. Vancomycin or clindamycin may be administered to children unable to tolerate β-lactam antibiotics or those who are known or suspected to be infected with a methicillin-resistant strain of staphylococcus (MRSA).

The 2007 changes in recommendations for prophylaxis for endocarditis represent substantial changes to all the recommendations before 1997. Therefore, a summary of those recommendations is listed in Table 249–6. In addition, the recommendations to withhold prophylaxis to subjects with a number of conditions have not changed, and those conditions or situations are listed in Table 249–7.

TABLE 249–4 Cardiac Conditions Associated with the Highest Risk of Adverse Outcomes from Endocarditis for Which Prophylaxis with Dental Procedures is Reasonable

Prosthetic cardiac valve or prosthetic material used for cardiac valve repair
A history of previous infectious endocarditis
Congenital heart disease • Unrepaired cyanotic CHD, including palliative shunts and conduits • Completely repaired congenital heart defect with prosthetic material or device inserted by surgery or catheter intervention during the first 6 months after the procedure • Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endotheliazation)
Cardiac transplantation recipients who develop valvulopathy

CHD, congenital heart disease.

RECURRENT OTITIS MEDIA

Acute otitis media is one of the most common infections in infants and children and has a tendency to recur, particularly during the first few years of life. In addition to tympanostomy tube placement and adenoidectomy, antimicrobial prophylaxis is

TABLE 249–5 Prophylactic Antimicrobial Regimens for Dental Procedures

		Regimen, Single Dose 30–60 Minutes before Procedure	
Situation	**Agent**	**Adults**	**Children**
Oral	Amoxicillin	2 g	50 mg/kg
Unable to take oral medications	Ampicillin	2 g IV or IM	50 mg/kg IV or IM
	OR		
	Cefazolin or ceftriaxone	1 g IV or IM	50 mg/kg IV or IM
Allergic to penicillins or ampicillin—oral	Cephalexin	2 g	50 mg/kg
	OR		
	Clindamycin	600 mg	20 mg/kg
	OR		
	Azithromycin or clarithromycin	500 mg	15 mg/kg
Allergic to penicillins or ampicillin and unable to take oral medications	Cefazolin or ceftriaxone	1 g IV or IM	50 mg/kg IV or IM
	OR		
	Clindamycin	600 mg IV or IM	20 mg/kg IV or IM

TABLE 249–6 Summary of Changes and New Recommendations for Antibiotic Prophylaxis for Bacterial Endocarditis

Concluded that bacteremia resulting from daily activities is much more likely to cause endocarditis than bacteremia associated with a dental procedure.
Only an extremely small number of cases of endocarditis might be prevented by antibiotic prophylaxis even if prophylaxis were 100% effective.
Prophylaxis is now recommended only for high-risk procedures (see Table 294–4), and prophylaxis is no longer recommended for any other form of congenital heart disease except for those listed in Table 294–5.
Prophylaxis is reasonable only for dental procedures that involve the manipulation of the gingival tissues or periapical region of teeth or perforation of the oral mucosa, and only for those with very high-risk conditions.
Antibiotic prophylaxis is reasonable for procedures on respiratory tract or infected skin or skin structures or musculoskeletal tissues only for patients with underlying cardiac conditions with the highest risk of adverse outcomes from endocarditis.
Antibiotic prophylaxis solely to prevent endocarditis is no longer recommended for genitourinary or gastrointestinal tract procedures.
Conditions previously listed as not requiring prophylaxis (1997) continue to not require prophylaxis and now include vaginal delivery, hysterectomy, and tattooing, although body piercing for patients with high-risk conditions for endocarditis should not be performed.

TABLE 249–7 Conditions for Which Antiobiotics Should Not Be Used Solely for Endocarditis Prophylaxis

Cardiac Conditions
Isolated secundum atrial septal defects
Surgical repair of atrial septal defect, ventricular septal defect, or patent ductus arteriosus (without residual and beyond 6 months of age)
Previous coronary artery bypass graft surgery
Mitral valve prolapse without valvular regurgitation
Physiologic, functional, or innocent heart murmurs
Previous Kawasaki disease without valvular dysfunction
Previous rheumatic fever with valvular dysfunction
Cardiac pacemakers (intravascular and epicardial and implanted defibrillators)
Respiratory Tract
Endotracheal intubation
Bronchoscopy with a flexible bronchoscope, with or without biopsy
Tympanostomy tube insertion
Gastrointestinal Tract
Endoscopy with or without gastrointestinal biopsy
Genitourinary Tract
Vaginal hysterectomy
Vaginal delivery
Caesarean section
In uninfected tissue:
Urethral catheterization
Uterine dilation and curettage
Therapeutic abortion
Sterilization procudures
Insertion or removal of intrauterine devices
Other
Cardiac catheterization, including balloon angioplasty
Implanted cardiac pacemakers, implanted defibrillators, and coronary stents
Incision or biopsy of surgically scrubbed skin
Circumcision

one of the options recommended for the management of recurrent otitis media.[23,42,99] Chemoprophylaxis of otitis media is discussed also in Chapter 19.

Antimicrobial prophylaxis currently is recommended for a child who has had three or more episodes of acute otitis media in 6 months or four episodes within a year, with the last episode occurring during the previous 6 months.[53,95] Patients who are most likely to benefit from prophylaxis include those younger than 2 years, those in out-of-home childcare, and Native American children.[72,95] Prophylaxis is directed against the most common potential pathogens that cause otitis media: *Streptococcus pneumoniae*, *Moraxella catarrhalis*, and nontypeable *Haemophilus influenzae*. Amoxicillin, at a dose of 20 mg/kg, or sulfisoxazole, at a dose of 50 mg/kg, may be given orally each evening for a period of 3 to 6 months or during the winter months. Although many other antimicrobial agents are used for the treatment of otitis media, only amoxicillin and sulfisoxazole currently are recommended as prophylactic agents because only these two agents have undergone critical analysis in prospective trials. Antimicrobial prophylaxis must be used with great caution and balanced against the potential for increasing the emergence of resistant organisms, particularly *S. pneumoniae*, and the possible occurrence of drug-associated toxicity (e.g., neutropenia, rash, or other). Other measures that may decrease the incidence of recurrent acute otitis media include eliminating smoking in the home, reducing daycare attendance, eliminating pacifiers, and administering influenza and the heptavalent conjugated pneumococcal vaccines. If these measures do not prevent recurrent infections, referral to an otolaryngologist is recommended for evaluation and possible tympanostomy tube placement or adenoidectomy, or both procedures.

RECURRENT URINARY TRACT INFECTION

Urinary tract infection (UTI) occurs in approximately 5 percent of girls and 1 to 2 percent of boys.[123] Recurrent UTIs are noted in roughly 30 to 50 percent of children with UTIs, with most recurrences taking place within 3 months after the initial episode. Eighty percent of recurrences are new infections caused by different colonic bacterial species that have become resistant to recently administered antibiotics. The recurrence rate is not altered by extending the duration of treatment.

Renal parenchymal infections and renal scarring are well-recognized complications of UTIs in children.[62,87,107] Parenchymal scarring is found in 10 to 15 percent of children with UTIs,[110,123] hypertension will develop in an estimated 10 percent of children with this complication, and renal insufficiency may develop in a smaller number.[66] Vesicoureteral reflux is noted in 30 to 50 percent of children with UTIs,[87] the frequency being related directly to the number of UTI episodes and inversely to age. Children with reflux have a much higher incidence (30% to 60%) of pyelonephritic scarring than do children without reflux. More than 90 percent of children with renal parenchymal scarring have had vesicoureteral reflux and a history of UTI.[110,123]

Children who have three or more UTIs in a 12-month period may benefit from suppressive antibiotic therapy for as long as 6 months to allow repair of intrinsic bladder defense mechanisms.[123] In children with anatomic defects or reflux, suppressive therapy may be needed for as long as the underlying defect exists.

Appropriate prophylactic agents should result in low serum but high urinary levels of the medication, have minimal effect on fecal flora, be well tolerated, and be inexpensive.[86] Methenamine mandelate (75 mg/kg divided every 12 hours) is a suitable agent for prophylaxis because it releases formaldehyde in an acid medium. A pH of 5.5 or lower must be maintained in the urine to obtain optimal results. Ascorbic acid or other acidifying agents should be used to achieve the desired urine acidity. Other useful agents for prophylaxis in children with normal renal function are trimethoprim-sulfamethoxazole (TMP-SMX), nitrofurantoin, and nalidixic acid.[17,60,66,87,105] TMP-SMX can be given at 2 mg of TMP and 10 mg of SMX per kilogram in a single daily dose or

at 5 mg of TMP and 25 mg of SMX per kilogram twice a week. TMP has the additional unique characteristic of diffusing into vaginal and urethral fluids, thereby decreasing bacterial colonization with members of the Enterobacteriaceae and diminishing ascending re-infection.[60,112] Nitrofurantoin is recommended at 1 to 2 mg/kg, taken each night. It has been used effectively as prophylaxis for recurrent UTIs in infants and children. Pulmonary, neurologic, and hepatic adverse effects have been reported but are rare occurrences.[87] Nalidixic acid (not recommended for children) is administered at 30 mg/kg divided every 12 hours. It is a bactericidal agent for most of the common gram-negative uropathogens. More recently, various cephalosporins and amoxicillin–clavulanic acid have been used as prophylactic agents with good results.[86] Prophylactic agents are best administered as a single dose at bedtime.

Prophylaxis for UTIs may reduce the incidence of UTIs by up to 50 percent in children with nocturnal continence. No studies of prophylaxis in children without nocturnal continence have shown efficacy, and prophylactic regimens employing broad-spectrum antibiotics (e.g., amoxicillin, cephalexin) are associated with the emergence of recurrent infections caused by antibiotic-resistant organisms such as *Pseudomonas aeruginosa*.

POSTEXPOSURE PROPHYLAXIS

Prophylaxis targeted against specific organisms after an individual is exposed is discussed in this section.

PERTUSSIS

Prompt administration of erythromycin or other approved macrolide drug to those in close contact with a case of pertussis is effective in limiting secondary transmission. Close contacts are household members, attendees of childcare facilities, and other individuals who are in contact with the index case for 4 hours or more a day. Chemoprophylaxis is recommended irrespective of age or vaccination status because immunity after receiving pertussis immunization is not absolute and may not prevent development of infection.[2] The recommended dose of erythromycin is 40 to 50 mg/kg/day (maximum, 2 g/day) to be given orally in four divided doses for 14 days. Both clarithromycin, 15 mg/kg, up to a maximum of 1.0 g, divided twice daily for 7 days, and azithromycin at standard doses (10 mg/kg the first day, up to a maximum of 500 mg, followed by 5 mg/kg, up to a maximum of 250 mg, each of the days 2 through 4) have been shown to be as effective as erythromycin and are much better tolerated than is erythromycin [26] Individuals who are allergic to erythromycin or macrolides or those who cannot tolerate their side effects may be given TMP-SMX, although the efficacy of this regimen has not been documented. The dose is 8 mg/kg/day (TMP) and 40 mg/kg/day (SMX) orally in two divided doses for 14 days.[26]

Persons who have been in contact with an infected individual should be monitored closely for respiratory symptoms for 2 weeks after the last contact with the index case. The risk of contracting pertussis in adults providing medical care to children should be recognized. Symptoms may be mild and not readily recognized as pertussis; however, such individuals can transmit the infection.

MENINGOCOCCAL INFECTIONS

Close contacts of patients with invasive disease caused by *Neisseria meningitidis* (meningococcemia, meningitis, or both) are at higher risk for acquisition of infection than is the general population. Secondary cases and outbreaks may occur in households, childcare centers, nursery schools, colleges, and military camps.[2] The attack rate for household contacts is 0.3 to 1.0 percent (300 to 1000 times the rate in the general population). Spread from patients to medical care providers occurs infrequently unless intimate contact (e.g., mouth-to-mouth resuscitation, intubation, suctioning) occurs. Respiratory tract cultures are not recommended and are not of value in deciding who should receive prophylaxis.[2]

Chemoprophylaxis should be administered as soon as possible, preferably within 24 hours of identification of the index case.[2] Treatment with penicillin G, ampicillin, or sulfonamides for meningococcal disease does not eradicate nasopharyngeal carriage of *N. meningitidis* reliably, whereas treatment with extended-spectrum cephalosporins (e.g., ceftriaxone and cefotaxime) does eliminate carriage. Therefore, antimicrobial chemoprophylaxis should be administered to the index patient before discharge from the hospital if the patient has been treated with the first three antibiotics.

The antibiotic of choice in most instances is rifampin. The recommended regimen is 10 mg/kg (maximum, 600 mg) every 12 hours for a total of four doses in 2 days. A liquid preparation can be formulated, or the powder can be mixed with applesauce or a similar vehicle. The rifampin prophylaxis regimen recommended for *Haemophilus influenzae* type b disease (see later) also is effective for meningococcal prophylaxis.

Rifampin prophylaxis has several shortcomings.[103] It fails to eradicate *N. meningitidis* in 10 to 20 percent of pharyngeal carriers.[90] It is not recommended for pregnant women. Side effects occur frequently and include headache, dizziness, gastrointestinal symptoms, discoloration of body secretions (saliva, tears, urine), staining of contact lenses, and hepatotoxicity. Finally, several studies have documented the emergence of resistant meningococcal strains after the administration of rifampin prophylaxis.[103]

If the meningococcal isolate is known to be susceptible to sulfonamides, sulfisoxazole may be recommended, but currently it is difficult to obtain. The dose is 500 mg/day for infants, 500 mg every 12 hours for children 1 to 12 years of age, and 1 g every 12 hours for children older than 12 years and adults. The duration of prophylaxis is 2 days.

During an outbreak, a single intramuscular injection of ceftriaxone was significantly more effective than rifampin in eradicating meningococci at 1 week (97% versus 75%) and at 2 weeks (97% versus 81%) after prophylaxis.[103] Ceftriaxone administered as a single intramuscular dose (125 mg for children younger than 15 years and 250 mg for adults) now is recommended as an acceptable alternative for prophylaxis. Ceftriaxone has the advantages of ease of administration, possibly greater efficacy, and safety in pregnancy. For high-risk contacts 18 years of age or older, a single 500-mg oral dose of ciprofloxacin is a third option for meningococcal prophylaxis.

HAEMOPHILUS INFLUENZAE TYPE b INFECTIONS

The risk for development of secondary invasive disease with *H. influenzae* type b is age dependent.[6] The risk incidence of disease has declined dramatically with the routine use of *Haemophilus* conjugate vaccines. However, in the era when *H. influenzae* type b infections occurred frequently, household contacts younger than 1 year had the highest risk (6%) for acquisition of secondary illness; the risk in children 4 years or younger also was high (2.1%). Children older than 6 years and adults are at little or no risk. The risk for children attending childcare centers may be increased but appears to be less than that for household contacts.[19,48,85,91,94] Exposed hospital personnel do not require antimicrobial prophylaxis. Data on the risk of spread with invasive disease due to other *Haemophilus* serotypes, such as a or f, are unknown, and currently prophylaxis is not recommended for serotypes other than type b.

In addition to protecting vaccinated children against invasive disease, conjugate vaccines appear to decrease pharyngeal colonization, which further reduces *H. influenzae* type b transmission to unvaccinated children. Prophylaxis currently is recommended

for all household contacts, regardless of age, if at least one of the contacts is younger than 4 years and not immunized completely.[2] Complete immunization is defined as having received a conjugate vaccine: (1) at least one dose at 15 months or older, (2) two doses between 12 and 14 months of age, or (3) two or more doses before 12 months of age with a booster at 12 months or older.

Prophylaxis for nursery and daycare center contacts is less well defined, and definitive recommendations are lacking. In general, prophylaxis is recommended for childcare centers with the same regimen as that recommended for households if (1) the center is attended by unvaccinated or incompletely vaccinated children younger than 2 years where contact is 25 hours per week or more or (2) two or more cases of invasive *H. influenzae* type b disease occur among attendees within 60 days and unvaccinated or incompletely vaccinated children attend the facility.[2] In facilities where all contacts are older than 2 years, prophylaxis need not be given, regardless of vaccination status.

Rifampin in a single dose of 20 mg/kg/day (maximum, 600 mg) for 4 days effectively eliminates oropharyngeal carriage of *H. influenzae* type b in 95 percent of treated individuals.[2] This regimen has been shown to be effective in preventing secondary cases of invasive *H. influenzae* type b disease in household members, daycare settings, and classroom contacts.[6,19] Prophylaxis should be initiated as soon as possible because most secondary cases occur during the first week after identification of the index case.[6] The index case also should receive rifampin prophylaxis, usually initiated during hospitalization and just before discharge.

If prophylaxis is given to limit secondary spread to a cohort (household or daycare), children vaccinated with any *H. influenzae* type b vaccine and unvaccinated susceptible children should receive prophylaxis.[2] Prophylaxis is not recommended for pregnant women.

TUBERCULOSIS

The three goals of preventive therapy for tuberculosis are (1) to prevent asymptomatic (latent) infection from progressing to clinical (active) disease, (2) to prevent recurrence of past disease, and (3) to prevent initial infection in individuals who have negative tuberculin skin test results. The first two goals are covered in detail elsewhere (see Chapter 107); prevention of initial infection is addressed herein. Chemoprophylaxis is given in an attempt to prevent the establishment of infection, and the recipient is protected only as long as antituberculous therapy is continued.

In the United States, isoniazid administered for 9 months is the preferred drug for children for chemoprophylaxis against *Mycobacterium tuberculosis.* The recommended dose is 10 to 15 mg/kg/day (maximum, 300 mg/day) to be given as a single dose. However, alternative regimens, including a 6-month regimen or daily or weekly isoniazid, are recommended for children who cannot comply with a 9-month regimen. For both the 9- and 6-month regimens, twice-weekly, directly observed therapy regimens are equal in efficacy to the daily regimens. Similarly, a daily or biweekly regimen of rifampin-pyrazinamide given for 2 weeks or rifampin given daily is recommended for children exposed to individuals with isoniazid-resistant isolates.[27]

Persons exposed to an infectious case of tuberculosis should undergo tuberculin skin testing, have a chest radiograph, and receive isoniazid prophylaxis or another appropriate and approved regimen.[2] If the tuberculin test result is negative and the chest radiograph is normal and the individual is not anergic, isoniazid or another appropriate regimen should be administered for 12 weeks and contact with the index case should be broken. Isoniazid may be discontinued if the result of a repeated skin test after 12 weeks of prophylaxis remains negative. If the skin test result becomes positive, isoniazid is continued for a total of 9 months. Candidates for prophylaxis include persons with impaired immunity; household contacts, particularly children younger than 4 years; recent contacts, especially human immunodeficiency virus–positive contacts; and persons known to be anergic from populations with a high prevalence of tuberculosis.

Management of a newborn infant whose mother or other household contact has tuberculosis should be based on individual considerations.

HOST-TARGETED PROPHYLAXIS

HUMAN AND ANIMAL BITES

Human and animal bites are relatively common occurrences. According to the Centers for Disease Control and Prevention, more than 1 million animal bites that occur each year require medical attention.[116] Human bites accounted for 1 in 600 pediatric emergency visits and dog bites for 1 percent of all such visits.[104] Dog bites account for 80 to 90 percent of animal bites that require medical care.[18] The organisms most frequently isolated in human bites are *S. aureus*, gamma-hemolytic streptococci, *Bacteroides* spp., *Eikenella corrodens*, and *Fusobacterium* spp.[114] In animal bites, *Pasteurella multocida*, *S. aureus*, and anaerobic cocci are the main pathogens.[113]

Data on the use of prophylactic antimicrobial agents after bites are sparse, and the role of prophylaxis in patients who seek medical care early for bite wounds is uncertain.[5,40,104,109] However, because these wounds usually are contaminated with potential pathogens, the administration of prophylaxis should be considered for patients who have the following risk factors: delay of 18 hours or more between the time of injury and the time of initial physician assessment, facial and hand bites, deep puncture wounds, bites that are difficult to irrigate and cleanse adequately before repair, delay in primary closure of wounds, and wounds in immunocompromised individuals.[5,18,39,84,104,124] For many of these indications, the use of antibiotics is in effect early treatment rather than prophylaxis because contamination of the wound occurs at the time of the bite.

Because most human and animal bites result in polymicrobial aerobic and anaerobic infections, prophylaxis should target these organisms. For initial prophylaxis, amoxicillin–clavulanic acid (30 to 50 mg/kg/day) probably is optimal therapy.[14,18,46,109] Prophylaxis is recommended for 3 to 5 days. Combination therapy with penicillin and cephalexin or dicloxacillin has been suggested by some authorities. Although they are only moderately active against *P. multocida*, erythromycin (30 to 50 mg/kg/day) and standard doses of clarithromycin or azithromycin are accepted alternatives in penicillin-allergic children. Some experts recommend clindamycin (30 mg/kg/day divided into three doses) as an alternative in children allergic to penicillins or cephalosporins.

ASPLENIA

The spleen constitutes approximately 25 percent of the lymphoid mass. It filters blood at a rate of 150 mL/min and plays an important role in the primary defense against bacteria that gain access to the circulation.[115] The spleen has an active role in phagocytosis, is a major source of T lymphocytes, and produces IgM antibodies, complement, opsonins, and tuftsin (a phagocytosis-promoting tetrapeptide).

Asplenia may be congenital or acquired. Splenectomy is performed frequently and is done for a variety of indications. Overwhelming and often fatal septicemia and meningitis occur with increased frequency in asplenic individuals.[122] The frequency of sepsis is 60 times greater in children who undergo splenectomy than in normal children. The risk of sepsis or severe outcome from sepsis is greater in children who lose splenic function by disease or trauma before 2 years of age or in those who have

congenital absence of the spleen. Numerous congenital cardiac conditions carry high risk for development of congenital asplenia. Fatality from sepsis in splenectomized individuals is 200 times more common than that in the normal population.[115] The risk for development of sepsis is greatest in patients who have undergone splenectomies for underlying immunologic or reticuloendothelial disorders, and the risk is lowest in children after splenectomy for trauma.[73] In all categories, the risk is highest in young infants and children, but it extends to teenagers and adults as well. The period of heightened susceptibility to infection is the initial 1 to 2 years after splenectomy; however, fulminant infection has been reported as long as 25 years after splenectomy.

S. pneumoniae is the most common cause of septicemia in splenectomized individuals. Despite prompt diagnosis and treatment, pneumococcal septicemia is associated with a fatality rate as high as 50 percent. Overall, 80 percent of post-splenectomy infections are caused by bacteria with capsular polysaccharides, particularly *S. pneumoniae* and *H. influenzae*.[108,115] Although *N. meningitidis* also has a polysaccharide capsule, lack of terminal components of complement constitute the greatest risk for development of infection, and whether the incidence of sepsis is higher in persons with asplenia is unclear. However, because overwhelming meningococcal sepsis has been reported in patients with asplenia, it is reasonable to include these patients at risk.

To reduce the likelihood of serious infections after splenectomy, several measures are advisable. Splenectomy should be performed only when it is absolutely indicated. If possible, the best approach is to delay the surgical intervention until the child is 5 or 6 years of age. For children with congenital high-risk conditions, pneumococcal polysaccharide protein conjugate vaccines should be provided in the recommended schedules. Although multivalent pneumococcal polysaccharide vaccine provides incomplete protection for patients undergoing splenectomy, especially infants and young children, it should be administered to all patients who are older than 2 years, ideally 2 weeks before the splenectomy is performed.[111] Vaccination against *H. influenzae* type b and *N. meningitidis* types A, C, Y, and W-135 with the appropriate polysaccharide or polysaccharide-protein conjugate vaccine recommended for use in children should be provided.

For antibiotic prophylaxis, penicillin is the agent of choice. Penicillin V given twice daily (125 mg twice daily for children younger than 5 years; 250 mg twice daily for children older than 5 years) significantly decreases the frequency of invasive pneumococcal infection. Erythromycin and TMP-SMX are alternative options in patients with documented hypersensitivity to penicillin. The duration of prophylactic coverage remains controversial; current practice is to provide penicillin prophylaxis indefinitely in immunocompromised patients.[108]

HEMOGLOBINOPATHIES

Functional asplenia is the primary reason for susceptibility to pneumococcal infection in children with sickle-cell anemia. Serum immunoglobulins are normal or increased in these children; however, they have a dysfunctional alternative complement pathway and decreased opsonic activity (which is mediated by both the alternative and the classic components) against *S. pneumoniae*. Leukocyte function also is defective in patients with sickle-cell anemia; intracellular production of hydrogen peroxide, respiratory stimulation, and hexose monophosphate shunt activity are inadequate during phagocytosis. In contrast, leukocytes from splenectomized patients without sickle-cell anemia exhibit normal phagocytic function accompanied by adequate metabolic stimulation. Immunologic dysfunction occurs less rapidly and less commonly in children with hemoglobin C sickle-cell anemia and hemoglobin C beta-thalassemia.[77]

Patients with sickle-cell disease are at risk for development of overwhelming infection (septicemia and meningitis) by encapsulated bacteria, including *S. pneumoniae*, *H. influenzae* type b, and, rarely, *N. meningitidis*. *S. pneumoniae* is the most important and frequent cause of septicemia and meningitis in these patients.[118] The risk is particularly high in children younger than 3 years.[51] A trend toward increased frequency of invasive disease in the first 2 to 5 years after splenectomy also has been noted. Unlike very young children, school-age children appear to be less vulnerable to pneumococcal invasive infection, even though they remain functionally asplenic.[52,118,121]

The efficacy of penicillin prophylaxis in preventing pneumococcal infection in infants and young children with sickle-cell disease has been well documented in several reports.[44,51,52,96,121] The recommended dose of penicillin V is 125 mg twice daily in children younger than 3 years and 250 mg twice daily in children 3 years or older. Some physicians recommend use of amoxicillin (20 mg/kg/day) or TMP-SMX (4 mg TMP plus 20 mg SMX per kilogram daily) in children younger than 5 years to include coverage against *Haemophilus* organisms, which are less likely to be a concern in patients who are immunized adequately.

Because overwhelming infection can occur in infants as young as 3 months, detection of sickle-cell anemia should be accomplished in the neonatal period. Babies in whom sickle-cell anemia is diagnosed should start a prophylactic antibiotic regimen no later than 3 to 4 months of age.[52] The optimal duration of prophylaxis is not defined clearly, and the age at which prophylactic penicillin can be discontinued safely is determined arbitrarily. A concern is that penicillin prophylaxis may decrease the development of natural immunity against pneumococcal infection in children receiving prophylaxis, thereby rendering them more susceptible to development of infection after prophylaxis is discontinued.[20] Another concern is the accelerated development of penicillin-resistant strains of *S. pneumoniae*.[45,118] A multicenter study by the Prophylactic Penicillin Study II group suggests that in children with sickle-cell anemia who have not had a previous severe pneumococcal infection or surgical splenectomy and are receiving comprehensive care, prophylaxis may be stopped safely at 5 years of age.[45] Continuous prophylaxis has limitations, and serious overwhelming infection can occur while patients are receiving prophylaxis. Patients or parents (or both) should be aware that any febrile illness is potentially serious, and immediate medical attention should be sought.[31,96]

CEREBROSPINAL FLUID LEAKAGE

The value of antibiotic prophylaxis in patients with cerebrospinal fluid leakage has not been proved.[49,89] In the absence of meningeal inflammation, many antibiotics do not penetrate the blood-brain barrier and do not attain adequate levels in cerebrospinal fluid. Antibiotic prophylaxis often fails and frequently alters the normal flora of the respiratory tract, thereby resulting in colonization with resistant bacteria. Prophylaxis may be considered for a short duration while surgical repair is being planned.[89]

SURGICAL PROPHYLAXIS

GENERAL SURGICAL PROCEDURES

Postoperative infection always has been a feared complication of surgical procedures. Skin incision, organ manipulation, and surgical trauma increase the likelihood for development of local infection. Surgical procedures traditionally are classified as clean, clean-contaminated, and contaminated (Table 249–8). Prophylactic antibiotics are effective in reducing postoperative infections after contaminated and clean-contaminated surgical procedures, whereas their efficacy is more controversial for clean surgical procedures. Clean surgical procedures generally carry a risk for development of postoperative wound infection that is less than 5 percent and, in many hospitals, less than 1 percent.

TABLE 249–8 Surgical Procedures and Probable Pathogens

Surgical Category	Most Likely Pathogens
Clean	
Neurosurgical	CNS, *Staphylococcus aureus*
Cardiovascular	CNS, *S. aureus*
Orthopedic	CNS, *S. aureus*
Clean-Contaminated	
Burn	Group A streptococci, *S. aureus*, GNB
Gastrointestinal	GNB, anaerobes, enterococci
Urogenital	GNB, enterococci
Respiratory	Alpha-hemolytic streptococci, anaerobes
Contaminated	
Ruptured viscera	GNB, anaerobes, enterococci
Traumatic wounds	*S. aureus*, group A streptococci, clostridia

CNS, coagulase-negative staphylococci; GNB, gram-negative bacilli.

The critical period for development of infection is short, and optimal prophylaxis should be restricted to the perioperative period. Antibiotic prophylaxis of less than 24 hours' duration is effective both clinically and experimentally. Administration of antibiotics should be started at the time of induction of anesthesia or immediately before the surgical incision is made and discontinued within 24 hours.

Addressing all situations of surgical prophylaxis is beyond the scope of this chapter, and the reader is referred to several publications and reviews on the subject.[36,61,67,69,97,117] Nationwide standards and goals for surgical prophylaxis have been established.[15,16] The consensus of these statements is that effective surgical prophylaxis must include the first dose of antimicrobial agents within 60 minutes before the surgical procedure and that dosing should be discontinued within 24 hours after the end of surgery. These documents and others provide the routine basis and evidence base for all current guidelines on surgical prophylaxis, including the recommended regimens and dosing for cardiothoracic, vascular, and abdominal or colonic surgery as well as hip or knee arthroplasty, vaginal or abdominal hysterectomy, and neurosurgical procedures.[4]

NEUROSURGICAL PROCEDURES

The use of prophylactic antibiotics for clean neurosurgical procedures remains controversial.[50,56,89,99] However, because of the suggested benefit of prophylactic antibiotics in uncontrolled trials involving a large number of patients, of whom adults were the majority, and in view of the scarcity of definitive studies, the literature supports the use of a short-course prophylactic regimen.[21,41,54,98,119] Prophylaxis for clean neurosurgical procedures is particularly valuable for high-risk groups (e.g., patients undergoing operative procedures in excess of 4 hours, operations in which craniotomies are performed, or patients with major underlying disease).[37,106]

Placement of cerebrospinal fluid shunts is one of the most common neurosurgical procedures in pediatric patients. An estimated 10,000 new shunt insertions and 6000 revisions are performed annually in the United States. The frequency of shunt infection varies from 1.5 to 39 percent (average, 10% to 15%).[74,101] The major route of infection is colonization of the device or the operative wounds during placement.[54] Retrograde spread from the distal end of the catheter or hematogenous seeding accounts for some instances of infection.

Most infections are noted within 15 days to 2 months of shunt placement.[78,101] Commensal skin flora are the predominant pathogens. Coagulase-negative staphylococci are the most common pathogens and account for approximately 70 percent of shunt infections. *S. aureus* is less common. Gram-negative bacilli are the least common and often are the result of retrograde infection from the peritoneum.[74,101]

The role of prophylactic antibiotics for placement of cerebrospinal fluid shunts has been controversial.[55] A meta-analysis of 1359 patients in 12 randomized, controlled trials indicated that short-term perioperative antimicrobial prophylaxis at the time of placement of a cerebrospinal fluid shunt significantly decreases the risk for subsequent development of device-related infection.[78] Various antimicrobial regimens, including antistaphylococcal penicillins, cephalosporins, TMP-SMX, vancomycin, gentamicin, and combinations, were used in these trials. The choice of an appropriate prophylactic regimen in a particular setting should be based on the local epidemiology of suspected pathogens, local patterns of antimicrobial susceptibility, cost, and expected toxicity. The duration of perioperative prophylaxis should not exceed 48 hours.[71,78] A longer duration of prophylaxis increases cost and the risk for development of adverse reactions and promotes alteration of the normal flora and the emergence of resistant bacteria.

CARDIOVASCULAR SURGERY

Infectious complications of cardiovascular surgery can be very serious and life-threatening, and antimicrobial prophylaxis is used commonly in most medical centers.[70,75] Most available data are based on reports from adult patients,[30,57] with little specific information available on prophylactic antibiotic use in pediatric patients. The goal of prophylactic therapy is prevention of wound infection, mediastinitis, and endocarditis. A survey of 43 North American academic centers with pediatric cardiovascular surgery programs indicated that all centers use prophylactic antibiotics for all operative procedures.[80] Monotherapy prophylaxis was used by 91 percent of respondents and consisted almost exclusively of a first- or second-generation cephalosporin. In 95 percent of centers, prophylaxis was started just before surgery or intraoperatively. Prophylaxis was continued for 48 hours or less in most (68%) instances. Prophylactic antibiotics often were continued while thoracostomy tubes, mediastinal tubes, or transthoracic vascular catheters were in place but usually not for endotracheal tubes, arterial or percutaneous central venous catheters, or temporary pacing wires.

CHAPTER 250

Outpatient Intravenous Antimicrobial Therapy for Serious Infections

John S. Bradley

Outpatient parenteral antimicrobial therapy (OPAT) is the means by which children can receive the benefits of parenteral (intravenous or intramuscular) therapy in an outpatient setting, usually the home, avoiding hospitalization with the associated exposure to nosocomial pathogens, inpatient costs, and psychological stress for child and family. The widespread acceptance of OPAT by physicians, families, and insurers has led to a tremendous increase in the outpatient treatment of serious infectious diseases.[3,13,19,21,22,29,32,36,37] The standard of care provided to children through OPAT should equal or surpass that provided to hospitalized children. National guidelines for OPAT in adults and children have been published by the Infectious Diseases Society of America and define both benefits and risks.[46] This chapter explains the basic concepts behind OPAT for children. The OPAT team, which includes the physician, OPAT coordinator, nurse, pharmacist, parent or caregiver, and third-party payer, needs to work closely to ensure a successful outcome for the child. Defined patient care outcomes in OPAT for adults and children currently are being addressed by a joint task force of the Infectious Diseases Society of America and the American Medical Association.

EVALUATING A CHILD AND PARENTS FOR OUTPATIENT PARENTERAL ANTIMICROBIAL THERAPY

Broad criteria are used to determine the medical feasibility of using OPAT (Table 250–1). The most important aspect in the

assessment of a newborn, infant, or child for OPAT is a determination that ongoing parenteral therapy is required to treat the infection appropriately and that continuous skilled nursing observation and care are not required for management. Development of complications of the infection in the child should be considered highly unlikely by the time OPAT is undertaken; unskilled clinical observations by the parents or caregivers should be considered adequate for care. No additional significant risk should be placed on the child's recovery by enrollment in an OPAT program. Whenever possible, oral antibiotic therapy should be used instead of parenteral therapy; recent options for oral therapy include fluoroquinolones (ciprofloxacin, levofloxacin) and oxazolidinones (linezolid).

A child usually is prescribed an OPAT regimen from either a hospital setting, after inpatient intravenous therapy, or an outpatient setting such as a clinic or emergency department. For a child being discharged from the hospital, an unequivocal response to parenteral anti-infective therapy should be demonstrated. Most often, appropriate cultures will have directed the use of anti-infective therapy active against the isolated pathogens. For children with no positive cultures, the signs and symptoms of the infection should be resolving with empiric therapy, as demonstrated by decreasing fever and improving function. The child's infection should be judged by the clinician to be unlikely to progress or to result in complications. No further surgical or medical interventions should be anticipated during the remainder of the parenteral antimicrobial therapy course.

The child's clinical course during receipt of OPAT needs to be monitored to be certain that the anticipated response continues to occur. An outpatient visit usually is scheduled for the day after discharge.

Before a child is enrolled in OPAT, an assessment of the parents or caregivers also is required (see Table 250–1). Because the parents are responsible for the nursing care of their child in the home, they must be willing and capable participants. Although most parents are very interested and highly motivated to return home with their child, not all are willing to perform or are capable of performing the required nursing functions. Although most parents are capable of providing limited medical assessment of their children, some are not. In addition, the home environment should have the resources required for the proposed medical care. For example, intravenous therapy administered to a child through a tunneled, central catheter requires local sterile conditions for anti-infective drug infusions and dressing changes, which will require the availability of a clean room with running water, and a refrigerator if storage of antimicrobials and diluents is necessary. Less stringent criteria clearly would apply for a child visiting the outpatient clinic daily to receive intramuscular antibiotic injections. Communication between the parents and medical personnel is essential. For parents or caregivers, telephone access to nurses and clinicians is critical. In addition, the parents should be able to bring their child back to the hospital or clinic for reevaluation if complications arise either from the infection or from therapy. Hence, access to adequate transportation within a medically appropriate time frame is required. Families with no available transportation, families who live in rural areas located several hours' travel from a medical facility, and weather conditions that may severely limit travel all should be considered before OPAT is started. In addition to observing their child and communicating information to medical providers, some parents may be asked to infuse anti-infective agents into their children. Doing so requires an additional level of skill in the parent or caregiver and further assessment of parental competence by the OPAT nursing and medical personnel.

TABLE 250–1 Medical and Social Criteria for OPAT

Medical Criteria for OPAT
Medical diagnosis of infection with a suspected or documented pathogen
Clinical response to anti-infective therapy (if therapy is started in the hospital)
No assessed need for urgent medical, surgical, or laboratory interventions to achieve a clinical response to anti-infective therapy
No significant risk of complications of the infection
No requirement for continuous skilled nursing care
Social Criteria for OPAT
Parents interested and motivated
Parents capable of assessing the child for complications of infection and therapy
24-hour telephone access to the OPAT team
Transportation for timely return to the clinic or hospital, if needed
Home environment acceptable and resources available
Parents documented to be capable of administering parenteral anti-infective agents, if required, before OPAT begins

OPAT, outpatient parenteral antimicrobial therapy.

THE OUTPATIENT PARENTERAL ANTIMICROBIAL THERAPY PROGRAM

The roles of physicians, OPAT coordinators, nurses, pharmacists, and parents or patients have been defined previously (Table 250–2).[46] Once the clinician considers that the child's condition is sufficiently stable to pursue outpatient therapy from a hospi-

OPAT, outpatient parenteral antimicrobial therapy.

tal ward, a clinic, or an emergency department setting, the coordinator of the outpatient treatment program is notified. This person is capable of assessing the feasibility of implementing OPAT for that particular child and family. The OPAT coordinator interviews parents and medical staff to determine the parents' willingness and their abilities and to assess the home environment. After the clinician prescribes the anti-infective agents, required nursing visits, ongoing laboratory and imaging tests, and follow-up clinic visits, the OPAT coordinator puts together the resources required for successful therapy. With knowledge of the parents' abilities and resources, the medication and equipment requirements, and the home nursing visits required, the coordinator makes the final determination about the feasibility of the program. The coordinator also determines who is required to pay the costs of OPAT among the family, the third-party payer (private or government) if one exists, and the hospital. Authorization from third-party payers may be required before OPAT can begin; many insurance companies require a much greater financial contribution by families for the cost of care once a child is discharged. An example of an OPAT physician's order form that includes catheter management and medication orders, laboratory and imaging test orders, and clinic visits is reproduced in Figure 250–1. The coordinator of the OPAT program, whether it is clinic or hospital based, should ensure that open lines of communication exist among the clinician, the home visiting nurse, the pharmacist, and the parents. A defined, written plan for medical and nursing care should be established. All members of the OPAT team should be aware of their responsibilities before outpatient therapy is implemented.

The frequency of the required home pediatric nursing visits needs to be individualized for each child and depends on many factors: the clinical course while the child is receiving therapy, the seriousness of the infection, the ability of the parents to effectively examine the child, and the risk for development of complications that can be related to either the infection or therapy. For most children, the frequency of home nursing visits will be greatest at the beginning of OPAT, often once daily. After treatment at home has been delivered as anticipated and recovery from infection is proceeding as expected, visits may be decreased to two or three times each week, particularly if the parents have demonstrated competency in providing nursing care, including managing an intravenous catheter, changing wound dressings, and providing clinical assessment. The home visiting nurse also may have the opportunity to establish ongoing assessment of the parents' ability to administer anti-infective agents in the home. Physical assessment of neonates receiving OPAT may be particularly difficult for parents to determine, and daily visits throughout the entire course of therapy by skilled pediatric home visiting nurses may be required. Daily visits also are important for children with less stable infections, such as central nervous system infections, because subtleties in the neurologic examination findings may not be appreciated by parents or caregivers and may provide clues to impending problems. Nursing aspects of pediatric OPAT have been outlined by successful programs.[22,29,44]

Pediatric competency in nursing is not standardized. Each state government in the United States licenses nurses on the basis of criteria specific for that state. However, just as for inpatient pediatric care, pediatric experience is an important qualification for the home visiting nurse. Unfortunately, home nursing agencies providing care to children are not required to have expertise in pediatric nursing. Therefore, considerable discrepancy exists in pediatric competency among nursing agencies. Given the importance of pediatric expertise in evaluation and management of infected children in the home, the home nursing agency contracted to provide care is expected to have personnel with training and experience equivalent to that of nurses providing care in a pediatric inpatient setting. The home nursing agency should be able to document proficiency in delivering care to newborns, infants, and children to the clinician and the OPAT coordinator.

In many states, only licensed nurses (RN, LVN) may infuse anti-infective agents. However, most states have no rules prohibiting parents from administering drugs. Accordingly, parents may be expected to infuse medications to their children if licensed nurses are not deemed by the home care agency and the physician to be necessary to provide this function. The physician should be aware of the qualifications of the personnel responsible for the intravenous infusion of anti-infective agents.

The home visiting nurse should communicate with the physician about the status of the child as determined by the physician before OPAT is started. Analogous to inpatient care, the nurses and physicians are expected to be on-call 24 hours each day.

Similarly, the pharmacist providing anti-infective therapy for OPAT should be familiar with the dosages and side effects of therapy provided to all pediatric age groups, from newborns to adolescents. Dosing errors in infants and children are not uncommon occurrences, given the broad range of doses administered.[26]

The parents should have written instructions for the tasks that they are required to perform in the home, including information on sterile technique, administration of antimicrobials, flushing of catheters, and dressing changes. Their proficiency in management of the catheter and infusion of anti-infective agents should be demonstrated before the child is discharged from the hospital, emergency department, or clinic. Telephone numbers should be provided for the 24-hour on-call nursing and physician personnel. A list of complications of the medications and procedures and information on clinical assessment of the child's infection should be provided, along with a set of parameters requiring immediate notification of medical personnel. Plans for disposal of needles, dressings, and other medical waste also should be made before the child is sent home.

Visits to clinicians (primary care providers, surgeons, subspecialists) are scheduled as necessary according to the clinical status of the child and the degree of expertise required by the examiner. If the child is stable in an outpatient setting, once-weekly visits to a physician usually are sufficient unless the home visiting nurse or parent observes problems requiring more immediate attention. For any high-risk, relatively unstable child, daily physician visits may be important, particularly if skilled pediatric home nursing is not available.

Although abuse of intravenous access seldom occurs, for an adolescent who may have a history of alcohol or drug dependence, the clinician should be particularly cautious in approving OPAT. For younger children with indwelling catheters, Münchausen syndrome by proxy may be a concern for infants and children who do not recover clinically as anticipated.

INFECTIONS SUITABLE FOR OUTPATIENT PARENTERAL ANTIMICROBIAL THERAPY

Virtually any infection can be treated by OPAT at some point in the course of therapy by following the criteria listed in Table 250–1. For each child, a thorough assessment of the risks for development of complications of the infection must be made before outpatient therapy is considered. A partial list of infections treated with OPAT is given in Table 250–3; most of the studies are not prospective, randomized investigations comparing children receiving therapy in the hospital with those receiving therapy outside the hospital. The variety of infections that have been treated with OPAT at some point include bloodstream infections, such as bacteremia, catheter sepsis, and endocarditis; central nervous system infections, including meningitis, epidural abscess, subdural empyema, and brain abscess; osteomyelitis and septic arthritis; urinary tract infections; upper respiratory tract infections, including severe acute otitis media, chronic suppura-

tive otitis, and mastoiditis; lower respiratory tract infections; fever with or without neutropenia in low-risk immunocompromised children; neonatal bacterial sepsis; intra-abdominal infections; and postoperative wound infections.

DELIVERY OF ANTIMICROBIAL THERAPY

SELECTION OF AN ANTIMICROBIAL AGENT

Selection of antimicrobial therapy for OPAT is similar to selection of therapy for any child in that the primary goal is to achieve clinical and microbiologic cure with the most efficacious, least toxic, and most cost-effective agents. Selection of an agent that is more convenient to administer but that may not be as effective is not appropriate. However, of the agents that demonstrate equivalent activity against the child's pathogen, the preferred agent is the one that is given least frequently, is nontoxic, and requires the least frequent monitoring for adverse events. Preferred agents for the most common community-acquired pathogens are given in Table 250–4. Almost any pathogen, community acquired or nosocomial, bacterial, fungal, or viral, can be treated in the home if the medical and social criteria for OPAT can be met.

In general, β-lactam agents (penicillins, cephalosporins, carbapenems) require less frequent monitoring than do aminoglycosides (gentamicin, tobramycin, amikacin), glycopeptides (vancomycin or teicoplanin), or oxazolidinones (linezolid). Agents that can be given intravenously during the course of a short period (15 minutes), such as β-lactam agents, are preferred to those that require up to an hour with each infusion (aminoglycosides and glycopeptides). Agents that can be given intramuscularly if intravenous access is temporarily lost are preferred to those that may be given only intravenously. Not only are these parameters designed to provide the optimal clinical outcome with minimal toxicity, they also are designed to facilitate therapy in the home. Dosing more frequently than every 8 hours poses a formidable challenge to many families, particularly those without extensive support. Administration of two or three antibiotics that each require dosing three or four times each day is virtually impossible for most families to accomplish. These parameters are designed to maximize the potential for parents to be able to provide care at home with minimal risk. Although more frequent nursing visits may provide relief to parents, the charges for home nursing visits to administer therapy and to provide nursing care (e.g., wound dressing changes) are substantial; the charge for three nursing visits each day approaches the cost of a day in the hospital for a stable child, and most agencies do not have sufficient staff to provide more than one visit each day to a family. Depending on the agent used, monitoring for antimicrobial toxicity in the outpatient setting should occur with the same frequency as that in the inpatient setting. Monitoring of renal function and serum antibiotic concentrations is important for children being treated with aminoglycosides or vancomycin. For children receiving long-term β-lactam therapy, periodic monitoring of the peripheral white blood cell count and renal and hepatic function every 2 to 4 weeks may detect the uncommon but well-described antibiotic-mediated toxicities of this class of antibiotics before any clinical manifestations occur.

DELIVERY OF ANTIMICROBIAL AGENTS

OPAT can be delivered by intramuscular or intravenous injection. In general, the need for more than two or three injections necessitates intravenous therapy. However, once-daily intramuscular therapy lasting 1 week or longer has not been associated with short-term complications in anecdotal reports.[5,6] Short polyethylene catheters normally used for inpatient intravenous therapy may be used for short-term therapy lasting less than 5 to 7 days. On occasion, intravenous access will be lost and the child will need to be reevaluated for ongoing parenteral therapy; if clinical improvement exceeds expectations, an early switch to oral convalescent therapy may be possible. If not, intravenous access may need to be reestablished. It may be performed in the home but more often will require the child and parent to return to the clinic or hospital. An intramuscular injection or injections may be given temporarily in the home, clinic, or emergency department until the intravenous catheter can be replaced.

For therapy lasting longer than 5 to 7 days, central catheters are preferred. Peripherally inserted silicone rubber elastomer (Silastic) central catheters (PICC lines) are practical and cost-effective and have become the intravenous access of choice for extended therapy.[45] These catheters may be inserted through many different peripheral sites (usually the antecubital vein) by physicians or nurses with training in the placement of central catheters. Sedation usually is required for younger infants and children. Alternatively, more traditional subcutaneously tunneled central catheters with multiple ports (e.g., Hickman, Groshong) may be placed by a surgeon in the operating room with the child under general anesthesia. These tunneled catheters, which also may be used for blood sampling, are preferred for children requiring several weeks of therapy with agents that require periodic blood tests for assessment of organ function and serum antibiotic concentrations. Each type of central catheter requires sterile techniques for accessing the catheter and close monitoring of the catheter exit site during administration of therapy. The home visiting nurse agency should have written protocols for the care and use of central catheters that are consistent with standards set by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) for both inpatients and outpatients.[23]

Anti-infective agents may be infused directly into the catheter by the caregiver by way of an antibiotic-containing syringe simply attached to the catheter hub ("IV push"), followed by flushing of the catheter with saline or a heparin-containing solution. Alternatively, particularly for agents that cannot be infused quickly, an intravenous drip system must be used, or the agent must be infused by a pump. Pumps come in three basic designs: those with

TABLE 250–4 Selection of Antimicrobial Agents for Common Pathogens in Community-Acquired Infections

Pathogen	Antimicrobial Agent	Dosing Frequency (hr)	Toxicity
Gram-Positive Bacteria			
Streptococcus pneumoniae	Penicillin G*	6	
	Ampicillin*	6-8	
	Cefuroxime*	8	
	Cefotaxime*	6-8

	Cefotaxime* or ceftriaxone plus an aminoglycoside‡ (gentamicin, tobramycin, amikacin)	Cefotaxime: 6-8 Ceftriaxone: 24 Gentamicin and tobramycin: 8-24 Amikacin: 24	Renal toxicity, ototoxicity (aminoglycoside)
Pseudomonas aeruginosa	Meropenem†	8	
	Cefepime	8	
	Ceftazidime* plus an aminoglycoside‡	Ceftazidime: 8 Aminoglycoside: see above	Renal toxicity, ototoxicity (aminoglycoside)
	Imipenem-cilastatin	6-8	Central nervous system irritability in children with underlying central nervous system inflammation
	Ticarcillin-clavulanate* plus an aminoglycoside‡	Ticarcillin-clavulanate: 6 Aminoglycoside: see above	Renal toxicity, ototoxicity(aminoglycoside)
	Piperacillin-tazobactam* plus an aminoglycoside‡	Piperacillin-tazobactam: 6 Aminoglycoside: see above	Renal toxicity (aminoglycoside)
	Ciprofloxacin§	8-12	Possible arthropathy
Neisseria meningitidis	Ceftriaxone†	24	
	Penicillin G	6	
Fungal Pathogens			
Candida	Fluconazole IV†	24	
	Amphotericin B (lipid preparations are better tolerated)	24, or every other day; may return to infusion center for each injection to manage side effects	Fever, chills, anemia, hypokalemia, decreased glomerular function
	Caspofungin or micafungin	24	
Viral Pathogens			
Herpes simplex virus	Acyclovir	8	Neutropenia, renal toxicity
Cytomegalovirus	Ganciclovir	12-24	Neutropenia

**If organisms are documented to be susceptible.*
†Preferred agents based on dosing frequency and side effects.
‡Requires monitoring of renal function and serum concentrations.
§Not indicated for therapy unless no other therapy options exist.

no electronic or moving parts; syringe pumps, in which the syringe containing the anti-infective agent is placed in a motorized pump designed to administer the dose during the course of a certain period; and electronic programmable pumps, which may have a variety of pump mechanisms and are programmed to control infusions of one or more agents administered during the course of different periods.

The least expensive pumps are those with no moving parts. One type of pump requires injection of the antibiotic solution, under some pressure, into a thick elastomeric "balloon." The pressure used to inject the antibiotic into the balloon then pushes the antibiotic through an infusion rate–limiting valve into the intravenous line and subsequently into the child. Other types of pumps are designed to place the antibiotic solution into a bag that then is placed into a device in which spring-loaded plates press on the solution contained in the bag, again pushing the antibiotic into the child through an infusion rate–limiting valve. These pumps generally use disposable infusion containers and are adequate for treatment with a single antibiotic administered up to a few times each day.

New tools for OPAT are becoming available each year. Resource guides to the equipment used for OPAT are available on the Internet.[35] Unfortunately for children, most of the equipment and resources available are designed for adults.

OUTCOME ANALYSIS

The anticipated outcome in the treatment of an infection is clinical and microbiologic cure with no complications of therapy. Although the psychosocial benefits of OPAT for children from a secure home environment were the original impetus for the establishment of pediatric programs, the economic benefits of outpatient therapy have been easier to document for both adults and children.[3,17,18,25,31,48,52-54] The cost of treatment is substantially less for outpatient therapy when neither hospital facilities nor 24-hour skilled nursing care is necessary. With shorter periods of hospitalization, the risk of acquiring a nosocomial viral or bacterial infection should diminish and further decrease the overall cost of care.

However, complications may occur in children receiving OPAT, just as they occur in inpatients.[16] The infection being treated may not be under control or may relapse while the child is being monitored by parents or home nursing personnel. Errors in antibiotic dosing and administration may occur,[26] particularly if parents are given the responsibility of preparing and administering antibiotics in the home. Complications of anti-infective therapy may increase when the number of anti-infective agents and doses administered to a child increases. Catheter- and pump-related complications may arise during therapy.[39] Parents may not be compliant with clinic visits and may not be in the home when the home nursing agency has scheduled a visit. Family members other than those trained to care for the child may provide care without the knowledge of the home nursing agency or physician. The clinician may need to rehospitalize the child if doing so is required to complete parenteral therapy safely.

JCAHO publishes standards[24] and reviews home care outcomes by evaluating specified parameters, including unscheduled inpatient admissions, early discontinuation of parenteral therapy, interruptions in parenteral therapy, catheter-related infections, and adverse drug reactions. Until recently, data on outcomes from various home nursing agencies were not made available to contracting physicians, hospitals, or payers. Outcome data now are required to be collected by home health organizations, which eventually will help standardize the assessment of OPAT programs. The physician or OPAT coordinator should request outcomes data from any home nursing agency proposing to care for a child by OPAT.

SUMMARY

Successful use of OPAT requires integrated delivery of care for children who are assessed to be at low risk for development of complications from their infections and therapy. Parents fulfill the role of the skilled pediatric nurse in the hospital and should be capable of providing a focused, limited assessment of their child and communicating any changes in the child's medical condition to the appropriate medical personnel. The anti-infective agents, infusion equipment, and medical follow-up all should be designed for the outpatient setting compatible with the training and resources available to parents or caregivers in the home. Outcomes of pediatric OPAT should be equivalent to or better than those achieved in an inpatient setting.

Antiviral Agents

Gail J. Demmler-Harrison

HISTORY AND BACKGROUND

The age of modern antiviral therapy began in the early 1950s, when methisazone, a derivative of the thiosemicarbazones (early antituberculosis compounds), was found to also have activity against vaccinia and variola viruses.[26,27,184,371,453,479] In 1959, the first antiherpes compound, idoxuridine, was synthesized; in 1962, it was approved for the topical treatment of herpetic keratitis.[244,358] Shortly thereafter, in 1964, trifluridine also was used to treat herpetic keratitis.[245,246] Also in 1964, the first description of vidarabine as an antiviral agent active against herpes simplex virus (HSV) was published, and amantadine was shown to have activity against influenza virus.[104,396] Two years later, amantadine was approved first for the prophylaxis and subsequently for the treatment of influenza A virus infection.[481] Shortly thereafter, in 1972, vidarabine was approved for the treatment of herpes encephalitis.[471] The year 1972 also marked the first description of ribavirin as a broad-spectrum antiviral agent, with activity against both DNA and RNA viruses, and in 1985, the aerosolized form of the drug was approved for the treatment of respiratory syncytial virus (RSV) bronchiolitis.[107,405] In 1977, acyclovir was reported to be a potent and selective inhibitor of the replication of both HSV and varicella-zoster virus (VZV) and boasted the added advantage of a favorable safety profile.[106,127,392] Subsequently, several structural analogues of acyclovir led to the development of antiviral agents with expanded antiviral spectra, such as ganciclovir, and agents with more favorable bioavailability, such as with the prodrugs valacyclovir and valganciclovir.[97,297] In the 1990s, the introduction of cidofovir, a broad-spectrum, long-lasting antiviral agent, and the neuraminidase inhibitors zanamivir and oseltamivir, which treat both influenza A and influenza B viruses, added new dimensions to antiviral therapy.[94,274,418] The research now being conducted no doubt will expand our antiviral armamentarium to combat viruses that may be used as biologic weapons as well as to prevent the emergence of resistant viruses and spawn creative strategies such as multidrug therapy and targeted delivery systems.[162,194]

Even though diseases caused by viruses (Table 251–1) now may be treated with a variety of antiviral agents, the close relationship between the viral replicative cycle and its host-cell metabolism unfortunately has caused the development of safe and effective antiviral agents to lag behind the development of other antimicrobials, such as antibiotics and antifungals. Clinically successful antiviral agents target and inhibit virus-specific functions while keeping cellular toxicity to a minimum. In addition, as a further testament to the codependency between

viruses and host cells, some antiviral agents actually require cellular metabolism for antiviral activity, such as the terminal phosphorylation of acyclovir monophosphate to the active triphosphate form.

Antiviral agents can be categorized as virucidals, antiviral chemotherapeutic agents or drugs, and immunomodulators. Virucidal agents inactivate the virus on contact and include detergents, solvents, and ultraviolet light. These agents are not useful for treating human viral disease because healthy tissue also is destroyed. They may, however, be used to inactivate viruses on the surface of the skin or inanimate objects. Antiviral treatments that physically destroy both virus and the tissues infected or transformed by them include cryotherapy, laser therapy, and podophyllin and are used primarily to treat recalcitrant or life-threatening warts on mucocutaneous or laryngeotracheal tissue. These agents are discussed elsewhere. The host immune response also is important and in many cases essential for recovery from viral disease or even maintenance of a latent or inactivated state of the virus. Therefore, successful antiviral treatment may necessitate relief from immunosuppression when it is feasible, such as for patients with Epstein-Barr virus (EBV)–induced lymphoproliferative disease who are undergoing cancer chemotherapy or organ transplantation. It also may include the use of biologic response modifiers, or immunomodulators, that manipulate the immune system to enhance its ability to contain viral infection. Examples of immune modulators include immune globulin and monoclonal antibody preparations, cytokines such as interferons, and even novel approaches such as virus-specific cytotoxic T-cell lines designed to reconstitute host immunity.[15,24] Finally, updated knowledge about specific antiretroviral therapy is reviewed in Chapter 204.

Antiviral chemotherapeutic agents usually inhibit virus-specific events (Fig. 251–1), such as adsorption or attachment to the host cell (pleconaril), penetration and uncoating of the viral genome (amantadine), viral gene expression and nucleic acid synthesis (acyclovir, ganciclovir), and even viral assembly of intact, infectious viral particles (interferons). Therefore, antiviral agents exhibit their "antiviral effect" primarily while viral replication is active at the host-cell level. If the antiviral compound is withdrawn or discontinued, viral replication resumes. Furthermore, the currently available antiviral agents do not appear to eliminate viruses that are latent or in other dormant or nonreplicative states. The goal of antiviral therapy, for the most part, is to inhibit active viral replication to such a degree that the host immune response is able to contain or in some instances even eliminate the infection.

Antiviral agents usually have a narrow range of activity that can be predicted by their molecular mechanism of action. For example, rimantadine and amantadine have high activity against the RNA-containing influenza A virus, very limited activity against influenza B virus, and virtually no activity against the DNA herpesviruses,[94,104] whereas acyclovir, a deoxyguanosine analogue that requires monophosphorylation by the viral enzyme thymidine kinase (TK) for activation, has significant activity against DNA viruses (HSV), which carry TK, but no activity against RNA viruses such as influenza virus. Viruses infecting a host also may become resistant to a specific agent to which they originally were susceptible, usually by induced or selected mutations. Resistance is therefore most likely to occur in viruses that infect the host with a high viral load and that have a high intrinsic viral mutation rate as well as hosts who are exposed to selective drug pressure during chronic, low-dose, or repeated treatment with an antiviral agent.[213] Both resistant and sensitive viruses are capable of causing serious disease, especially in an immunocompromised host. Currently, most antiviral agents are administered alone. However, in the future, combination antiviral therapy, now a routine therapy in modern antiretroviral regimens, may someday be evaluated in clinical trials.[189,194] Such a strategy may

increase antiviral effectiveness, prevent the emergence of drug resistance, and allow the administration of lower, less toxic dosages.

ANTIVIRAL AGENTS ACTIVE AGAINST RNA VIRUSES (Table 251–2)

AMANTADINE AND RIMANTADINE

Spectrum of Activity

Amantadine (1-adamantanamine hydrochloride) and rimantadine (α-methyl-1-adamantane methylamine hydrochloride) are tricyclic amines with specific activity against influenza A viruses (Fig. 251–2). Mean inhibitory concentrations of 0.1 to 0.4 μg/mL for amantadine have been reported, and rimantadine is 4 to 10 times more active than amantadine against influenza A virus.[56,192] Amantadine also has in vitro activity against rubella virus, but efficacy was not confirmed in animal models.[341,342,432] Much higher concentrations (10 to 50 μg/mL) appear to inhibit influenza B virus and parainfluenza viruses, but these high concentrations cannot be achieved safely in humans.[432] These agents also have activity against hepatitis C virus (HCV).[415]

Mechanism of Action and Resistance

The mechanism of action of both amantadine and rimantadine against influenza A virus appears to be primarily inhibition of the ion channel function of the M2 protein in the membrane of the virus, possibly affecting two stages of viral replication, uncoating and, to a lesser extent, assembly.[94,188] Amantadine and rimantadine resistance occurs when mutations cause an amino acid change in one of four critical sites (amino acids 26, 27, 30, or 31) in the transmembrane channel or domain of the M2 viral protein.[262] Such mutations occur frequently and rapidly during therapy because approximately 30 percent of adults and children who receive amantadine or rimantadine therapy for at least 5 days shed resistant influenza virus.[190,193] These resistant strains are genetically stable, may be transmitted to close contacts, and can produce disease.[31,190,489] Immunocompromised patients may shed drug-resistant influenza viruses for prolonged periods, and resistant strains can persist even after drug administration has been discontinued.[262] Resistant strains of influenza A subtype H3N2 have now produced community outbreaks and epidemics at this time.[31,190,202a,489] However, debate has begun among experts concerning whether patients in whom a resistant strain is identified should be isolated somehow until viral shedding has ceased.[180] Strains of influenza A virus resistant to amantadine also are resistant to rimantadine, and vice versa, but they are usually susceptible to ribavirin and neuraminidase inhibitors.

Pharmacokinetics

Amantadine is absorbed rapidly and nearly completely after oral administration, with peak plasma concentrations of 0.5 to 0.8 μg/mL attained within 2 hours of administration.[39,198] It is excreted almost unchanged in urine. Nasal and salivary secretions also contain high levels of amantadine, and the drug is present in cerebrospinal fluid (CSF) as well, at approximately half the plasma

TABLE 251–2 Clinical Indications and Usual Treatment Dosages for Antiviral Agents Active Against RNA Viruses

Agent	Indication	Dosage
Amantadine	Influenza A	2.2-4.4 mg/kg/dose PO bid (max, 100-200 mg daily)
Rimantadine	Influenza A	2.5 mg/kg/dose PO bid (max, 150 mg daily)
Oseltamivir	Influenza A and B	2 mg/kg/dose PO bid (max, 150 mg daily)
Zanamivir	Influenza A and B	5 mg/dose inhaled bid
Ribavirin	Respiratory syncytial virus	6 g/300 mL inhaled daily in an 18-hr period *or* 2-6 g/100 mL inhaled in a 2-hr period tid
	Hepatitis C	600 mg PO bid (with interferon-α)

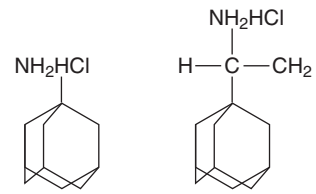

Figure 251–2 Structure of amantadine and rimantadine.

level. Dose reductions, adjusted according to creatinine clearance, are required in patients with renal insufficiency and renal failure.[222,423,481] Rimantadine, on the other hand, is more slowly absorbed than amantadine, with peak plasma levels of 0.4 to 0.6 μg/mL achieved within 2 to 4 hours of administration.[9,198,330] Rimantadine is also present in high concentration in nasal secretions. It is excreted in urine, but only after extensive metabolism by the liver. Dose reduction is therefore recommended in patients with renal or hepatic disease.[63,474] Hemodialysis does not appear to clear either drug, so supplemental doses usually are not recommended after dialysis.[423] When they are administered to chronically ill, institutionalized elderly patients, dosages also may need to be adjusted.[322,347] In addition, aerosolized forms of amantadine and rimantadine have been evaluated in human volunteers.[196,202]

Clinical Indications, Dosage, and Adverse Effects

CLINICAL INDICATIONS

Amantadine and rimantadine are equally effective for the treatment of disease caused by influenza A virus.[94,262,475] If they are administered within the first 48 hours of symptoms, both agents significantly reduce the signs and symptoms of influenza in both adults and children by significantly shortening the duration of fever and respiratory and systemic symptoms by 1 day.[94,109,287,454,475,484] The duration and amount of viral shedding from the nasopharyngeal tract also are decreased, and otologic complications may be reduced.[118] Both agents are effective for prophylaxis against influenza A virus infection and disease, with approximately 50 percent overall effectiveness in preventing infection with the virus and approximately 60 to 70 percent overall effectiveness (up to 90% in some studies) in preventing clinical disease and, in individuals with breakthrough clinical disease, in reducing the severity of the disease.* The spontaneous emergence of resistant strains during rimantadine or amantadine therapy and subsequent transmission of these resistant strains may lessen the effectiveness of prophylaxis in some families and nursing homes.[190,303] Amantadine and rimantadine are both available as tablets (100 mg) and syrup (50 mg/5 mL) for oral administration.

DOSAGE

The usual dose of amantadine for children is 4.4 to 8.8 mg/kg/day divided twice daily (many experts recommend 5 mg/kg/day), with a maximal recommended daily dose of 200 mg. The usual dose of rimantadine for children is 5 mg/kg/day divided twice daily, with a maximal recommended daily dose of 150 mg.[9,180,330,474] Older children and adolescents may take the usual adult dose for each drug, which is 200 mg/day given once daily or, for better tolerance, divided into two 100-mg doses daily.[9] Elderly patients should receive 100 mg daily or less if renal insufficiency is present. To be effective, these agents should be given as soon as possible after the onset of symptoms.[94,95] The duration of treatment of established influenza should be 3 to 7 days, or at least 2 days after the cessation of systemic signs and symptoms.[94] Prevention of influenza is accomplished best through annual vaccination; however, rimantadine and amantadine may be used to prevent or to lessen influenza symptoms in both adults and children.[83,94,96] Prophylaxis should be administered during the period of risk, whether exposure is in the family, community, or nosocomial setting. In general, prophylaxis should continue for at least 10 days after a known exposure occurs in an unprotected individual. For patients who receive the combination of inactivated vaccine and oral prophylaxis, rimantadine or amantadine should be continued for at least 2 to 4 weeks after vaccination, when maximal antibody response from the vaccine is expected to occur. For patients who are at high risk but did not receive the vaccine, oral prophylaxis should be continued for as long as the period of risk is anticipated and may be extended to the end of the community's influenza season. Doses of both drugs should be adjusted for patients with renal disease, and doses of rimantadine should be adjusted for patients with hepatic disease.[63,222,423,474] Prolonged treatment may be associated with side effects, especially in the elderly.[347] If side effects occur, the daily dose may be reduced to 100 mg and still be effective in most cases. The emergence of resistant strains during the period of drug administration may lessen the effectiveness of prophylaxis in some patients.[190,303] Combination with aerosolized ribavirin may enhance the antiviral effect of amantadine or rimantadine against influenza A virus.[189,194]

ADVERSE EFFECTS

The adverse effects of both amantadine and rimantadine include central nervous system (CNS) effects such as anxiety, depression, insomnia, dizziness, and impaired concentration; in children, these side effects appear to be rare, but they may be manifested as behavioral changes.[83,94,116,421] Rimantadine reportedly has fewer CNS side effects than amantadine does.[94,116,197,318] Hallucinations,

*See references 94, 110, 116, 156, 231, 232, 323, 338, 380, 467, 490.

tremors, and seizures also may occur, especially in patients with renal failure who have high plasma levels of amantadine. In addition, rare cases of coma and fatal cardiac dysrhythmia have been reported.[352,388] A prudent procedure is to administer amantadine and rimantadine with caution to individuals being treated for seizures or neuropsychiatric disorders or to patients also receiving other medications that affect the nervous system, such as antihistamines.[318] Furthermore, the institutionalized elderly may have increased plasma levels and experience side effects more often than younger patients do.[347] On occasion, gastrointestinal symptoms such as nausea and vomiting may accompany the oral administration of these agents in all age groups. Most reported adverse effects of these two agents have been reversible, with significant long-term complications being exceedingly rare. Of note, amantadine also is used to treat parkinsonism and drug-induced extrapyramidal reactions.[398]

NEURAMINIDASE INHIBITORS (ZANAMIVIR AND OSELTAMIVIR)

Spectrum of Activity

Zanamivir, (5-[acetylamino]-4-[(aminoiminomethyl)-amino]-2,6-anhydro-3,4,5-trideoxy-D-glycero-D-galacto-non-2-enoic acid) and oseltamivir, ([3*R*,4*R*,5*S*]-4-acetylamino-5-amino-3[1-ethylpropoxy]-1-cyclohexene-1-carboxylic acid ethyl ester phosphate [1 : 1]), are both analogues of *N*-acetylneuraminic acid, the cell surface receptor for influenza viruses, and were designed to inhibit the viral neuraminidase of influenza viruses (Fig. 251–3). Both agents are potent and specific inhibitors of the neuraminidases of influenza A and B viruses, with 90 percent of the strains inhibited at concentrations of 0.05 to 100 μmol/L.[254,456] The compounds also are capable of inhibiting neuraminidases from other pathogens and mammalian cells, but only at extremely high concentrations.

Mechanism of Action and Resistance

Neuraminidase permits influenza virus to penetrate through the mucoproteins present in respiratory secretions to the surfaces of cells, and inhibition of this enzyme prevents viral access and infection of cells. Neuraminidase also destroys receptors recognized by viral hemagglutinin and is therefore necessary for optimal release of influenza virus particles from infected cells. Inhibition prevents cell-to-cell spread of virus within the respiratory tract and lessens the intensity of the initial infection.[87,94,254,332,456] Mutations that induce amino acid changes in viral neuraminidase alter enzyme stability or activity, mutations in hemagglutinin produce a reduced affinity for cell receptors, and mutations in both produce resistant influenza viruses.[94,172-175] Cross-resistance to both zanamivir and oseltamivir also can occur, especially if the mutation is in the hemagglutinin portion.[313] Resistance has been documented not only by in vitro passage of the virus in increasing concentrations of the agents but also in patients receiving these agents. Emergence of influenza A H1N1 subtypes resistant to oseltamivir is also a concern, and clinicians should monitor antiviral resistance trends (www.cdc.gov/flu/).[202a] Clinical trials of oral oseltamivir for the treatment of naturally occurring influenza detected resistance in 1 to 2 percent of post-treatment isolates from adults and adolescents and in 5 to 8 percent of isolates from younger children.[94,174,222,486] Zanamivir resistance has been documented in one immunocompromised child receiving the drug for 2 weeks, but not in large, randomized trials of healthy individuals.[172,195,199,203,320] Preliminary evidence suggested mutant resistant strains may have reduced infectivity or virulence in comparison to susceptible strains,[442] but some resistant strains have caused outbreaks and epidemics.[202a]

Pharmacokinetics

Zanamivir is administered topically as an inhaled dry powder and is deposited in the oropharynx and, to a lesser extent, in the tracheobronchial tree and lungs.[94] Approximately 4 to 17 percent of inhaled drug is absorbed systemically, and levels of 17 to 142 ng/mL can be detected in serum 1 to 2 hours after administration of a typical inhaled dose of 10 mg to adults.[64] Serum levels in pediatric patients who received an inhaled dose were extremely low (<10 ng/mL) or undetectable, which may be related to the ability of the patient to cooperate with the inhaled drug delivery system. The oral bioavailability of zanamivir is extremely low, with less than 5 percent of the administered dose absorbed, and therefore it is not administered in this form. Intravenous and intramuscular preparations of zanamivir also have been tested in clinical trials, but this form is not available clinically at this time.[62,64,153,202a] The drug is excreted unchanged in urine.

Oseltamivir, in contrast, has good oral bioavailability. The prodrug compound oseltamivir phosphate is metabolized by hepatic esterases to the parent active compound oseltamivir carboxylate.[94] Approximately 75 to 80 percent of the administered dose is absorbed, and peak plasma concentrations are reached within 3 to 4 hours but may be delayed, but not reduced, if the drug is given with food. A typical 75-mg dose will provide plasma concentrations of 0.3 to 0.5 μg/mL. Both the prodrug and the active form are eliminated unchanged through the kidneys, and dosages should be adjusted for patients with renal insufficiency or renal failure. Whether the drug dosage should be adjusted for patients with hepatic disease or liver failure is unclear from the available evidence. Information from a small number of pediatric patients suggests that the drug may be eliminated faster in younger children. Elderly, geriatric patients, however, appear to metabolize the drug similar to young adults.

Clinical Indications, Dosage, and Adverse Effects

CLINICAL INDICATIONS

Zanamivir and oseltamivir have been shown to be effective in treating both influenza A and influenza B infection.[303a] However,

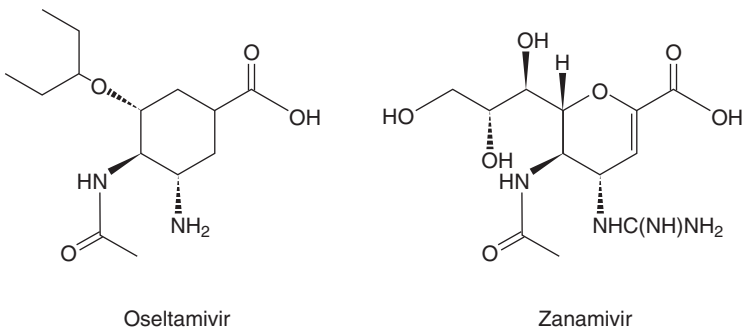

Figure 251–3 Structure of the neuraminidase inhibitors oseltamivir and zanamivir.

susceptibility of type B and HSNI and H1N1 subtypes of type A influenza may be reduced for oseltaminivir.[439a] When they are administered within the first 2 days of illness, they provide relief from symptoms up to 1.5 days earlier than placebo does and reduce the quantity and duration of viral shedding.* In some studies, the frequency of secondary complications such as sinusitis, bronchitis, and otitis media with effusion (but not pneumonia) also was reduced.[94,461] Both antiviral agents are effective for the prophylaxis of influenza A and influenza B infection in both adults and children in family, community, and nursing home situations. They appear to be 30 to 50 percent effective in preventing viral infection and 64 to 84 percent effective in preventing disease.[94,195,201,305,324,461] However, up to 89 percent efficacy in preventing disease in families has been reported, and in elderly patients in nursing homes, 92 percent of cases of influenza may be prevented if the agents are administered to those who also have received influenza vaccine.[94,195,305]

DOSAGE

Zanamivir is administered by oral inhalation with an inhalation device provided with the product. Each inhalation dose is 5 mg, and two inhalations twice daily for 5 days is the usual recommended dosage for all age groups. Use of this drug and device is dependent on the understanding and cooperation of the patient; therefore, it is not indicated for use in children younger than 7 years and may be of limited use in older children and adults who are unable to cooperate with the delivery system. No reduction in dosage is needed for patients with impaired renal function because very little of the inhaled drug is absorbed systemically. Oseltamivir is administered orally and is available in 75-mg capsules and a 12-mg/mL suspension. The usual adult dosage is 75 mg twice daily for treatment and once or twice daily for as long as 6 weeks for prophylaxis. The pediatric dose is 2 mg/kg per dose given twice daily (4 mg/kg/day divided twice daily).[94]

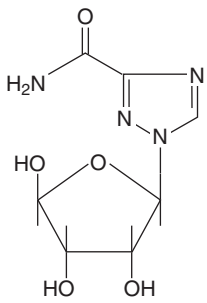
ADVERSE EFFECTS

Both neuraminidase inhibitors are generally well tolerated, with very few if any serious adverse effects observed in clinical trials. Zanamivir inhalation, however, may produce local irritation or bronchospasm in some patients, and oseltamivir has been associated with nausea and vomiting, which may be lessened by administration of the drug with food.[94]

RIBAVIRIN

Spectrum of Activity

Ribavirin (1-β-D-ribofuranosyl-1,2,4-triazole-3-carboxamide) is a synthetic guanosine analogue with broad-spectrum antiviral activity[412] (Fig. 251–4). It inhibits the in vitro replication of a wide variety of RNA viruses, including orthomyxoviruses such as influenza A and B viruses; paramyxoviruses, such as RSV, parainfluenza viruses, and measles virus; arenaviruses, such as Lassa fever virus; bunyaviruses that cause viral encephalitis; togaviruses, such as HCV; enteroviruses, such as polioviruses and coxsackie B virus; and retroviruses, including human immunodeficiency virus (HIV) type 1.[136,225,252,275,277,340,405] Also inhibited by ribavirin are many DNA viruses, such as adenoviruses, hepatitis A virus, cytomegalovirus (CMV); and poxviruses, such as vaccinia virus.[117] It inhibits most orthomyxoviruses and paramyxoviruses at concentrations of 3 to 10 μg/mL and Lassa fever virus at 4 to 40 μmol/L.[224] Because most of its clinical use has been for the treatment of RNA viruses, especially RSV, ribavirin is included in this section of the chapter.



Ribavirin

Figure 251–4 Structure of ribavirin.

Mechanism of Action and Resistance

Ribavirin most likely exerts it antiviral effects by altering the cellular nucleotide pools and by interfering with viral mRNA formation.[55,136,434] The compound is phosphorylated by host-cell enzymes to monophosphate, diphosphate, and triphosphate active forms, each with specific antiviral actions.[410] For example, ribavirin monophosphate competitively interferes with the synthesis of guanosine triphosphate and, subsequently, with viral nucleic acid synthesis. Ribavirin triphosphate inhibits the RNA polymerase of influenza virus and also interferes with the capping of its viral mRNA.[136,252,340,480] In addition, the diphosphate and triphosphate forms of ribavirin appear to inhibit the reverse transcriptase activity of HIV-1.[140] The mechanism of action of ribavirin against HCV and other viruses, however, is not well understood. Ribavirin also exerts an effect on the host immune system by inhibiting mast cell secretory responses and diminishing IgE responses.[298] Antiviral resistance is not well characterized and appears to be a rare occurrence. No ribavirin-resistant RSV isolates have been identified during clinical trials, and information is scant regarding the resistance of other viruses to ribavirin.[182,293,393]

Pharmacokinetics

Ribavirin can be administered topically by aerosol, orally, and intravenously. Aerosol administration of ribavirin with a small-particle aerosol generator delivers very high concentrations (>1000 μg/mL) of the drug to the respiratory tract.[264] The aerosolized drug also is absorbed systemically, and peak plasma levels after 8 hours of continuous aerosol administration range from 0.5 to 2.2 μg/mL; after 20 hours, they reach 0.8 to 3.3 μg/mL. After oral administration, bioavailability is 33 to 45 percent, and peak plasma levels of 1.3 to 3.2 μg/mL have been observed 1 to 2 hours after administration. Intravenous administration of ribavirin produces 10-fold higher plasma levels in less than 1 hour than after the administration of equivalent doses by different routes.[345] The higher doses used to treat Lassa fever produce plasma levels of up to 24 μg/mL. Ribavirin also crosses the blood-brain barrier and is present in CSF at approximately 70 percent of the plasma level.[91,223] The drug is metabolized by the liver, and approximately 40 percent of the dose is excreted by the kidneys.[345] The triphosphate form also concentrates in erythrocytes at an erythrocyte-to-plasma ratio of 40 : 1 and is slowly eliminated with a half-life of 40 days or longer. Hemodialysis and hemofiltration do not remove significant amounts of ribavirin from the body.[267]

*See references 61, 94, 199, 262, 305, 320, 325, 355, 450, 473.

Clinical Indications, Dosage, and Adverse Effects

CLINICAL INDICATIONS

Ribavirin aerosol is licensed for the treatment of RSV bronchiolitis and pneumonia in children.[179] Treatment shortens the duration of viral shedding and improves the fever, respiratory rate, arterial oxygen saturation, and lower respiratory tract signs on physical examination in severely ill patients who receive the antiviral agent early in the course of their illness.*

No clear benefit has been observed in patients with mild disease or in those who receive treatment late in the course of the disease. Studies of infants receiving mechanical ventilation have reported conflicting results in clinical benefit.[310,321,413] However, despite numerous clinical studies, indications for treatment remain controversial because efficacy has not been documented convincingly in all studies and the benefits observed generally have been mild and difficult to quantitate objectively.[179] Nonetheless, because antiviral treatment clearly appeared to provide benefit to some children, in 1996, the American Academy of Pediatrics recommended that ribavirin be considered for the treatment of hospitalized infants and children with severe lower respiratory tract infection caused by RSV, and these recommendations remain in effect.

Patients thought to potentially benefit the most from treatment are those younger than 6 weeks; those with chronic illnesses, such as congenital heart disease and chronic lung disease; premature infants; immunosuppressed children; and those with neurologic or neuromuscular disorders. Treatment with ribavirin also appears to decrease nasopharyngeal secretion of RSV-specific IgE and IgA responses.[378] Long-term follow-up of treated patients suggests no adverse effects but possible improvement in pulmonary function.[206,238,290] Treatment may benefit immunocompromised children who have serious or prolonged RSV infection, such as those with congenital severe combined immunodeficiency.[308] Aerosolized or intravenous ribavirin, especially combined with intravenous immune globulin or hyperimmune globulin, also may be of benefit to bone marrow transplant recipients with RSV lower tract disease.[290,292,470] Anecdotal reports suggest that early administration of ribavirin to immunocompromised patients during upper respiratory tract disease may be more efficacious than supportive care alone in preventing progression to lower tract disease or pneumonia.[132,308] Laboratory confirmation of RSV infection by viral culture or rapid diagnostic tests that detect viral antigen in respiratory secretions is recommended for all patients before treatment with ribavirin is initiated or continued beyond 12 to 24 hours. Ribavirin also is licensed in capsule form for the treatment of chronic hepatitis caused by HCV, and in combination with interferon-α, it produces a sustained decrease in HCV RNA levels, improvement in systemic symptoms such as fatigue, reduction in transaminases, and improvement in liver histologic features. These clinical benefits have been observed during initial treatment in previously untreated patients, in individuals initially unresponsive to interferon alone, and in patients treated for relapse.[38,41,105,114,152,221,307,365] Treatment with high doses of orally or intravenously administered ribavirin significantly reduces mortality rates in patients with Lassa fever.[237,306] Ribavirin also appears to benefit patients suffering from other hemorrhagic fever syndromes, including Argentine, Sabia, Bolivian, and Crimean-Congo hemorrhagic fevers, as well as those who have hemorrhagic fever with renal failure syndrome.[134,143,226,227,253] In addition, ribavirin may benefit patients with viral encephalitis, but clinical trials have not been performed.[65] Oral ribavirin also may be of benefit prophylactically in individuals who are exposed to hemorrhagic fever syndromes, including Lassa fever.[220] Treatment of hantavirus pulmonary syndrome with intravenously administered ribavirin is being evaluated in clinical trials. Ribavirin also may benefit individuals with influenza A or B virus infection. In one randomized study of young adults suffering from influenza, aerosol treatment significantly reduced fever, systemic signs and symptoms, and virus titer in respiratory secretions.[412] Another study showed clinical benefit with high-dose oral ribavirin, but other studies have not confirmed a measurable clinical benefit or virologic response consistently with aerosolized or oral ribavirin.[34,263,412,431] Intravenous ribavirin also has been used anecdotally to treat serious, life-threatening influenza.[200,361] Early treatment with aerosolized or intravenous ribavirin in bone marrow and stem cell transplant recipients infected with parainfluenza virus may help prevent progression to lower tract disease and pneumonia, but controlled trials documenting efficacy and effect on overall mortality rates have not been published.[128,200,468] Ribavirin also has been used to treat measles pneumonia in immunocompetent and immunocompromised patients, with clinical benefit reported in some.[146,176,242]

Clinical benefit, but not cure, also has been documented in case reports of children with subacute sclerosing panencephalitis caused by measles virus.[223,224,329,443] In these reports, repeated courses of large doses of ribavirin administered intravenously, combined with interferon-α, provided serum and CSF levels that exceeded the minimal inhibitory concentrations needed to inhibit the virus in vitro and improved or stabilized seizures and neurologic status in treated patients.[223] Case reports and small series using ribavirin to treat serious adenoviral disease, including pneumonia and disseminated adenoviral disease, have been published, but no controlled trials documenting clinical benefit have been published.[22,46,69,160,302,327] Despite documented antiretroviral activity, treatment of HIV-infected patients with oral ribavirin has not shown clinical, virologic, or immunologic benefits consistently.[91,140,239]

DOSAGE

A number of different dosages and routes of administration have been used to administer ribavirin to a variety of patients experiencing various infections. In normal and immunocompromised patients of all ages, the usual dosage of ribavirin, when it is administered topically by aerosol to the respiratory tract for treatment of influenza and lower respiratory tract disease caused by RSV, parainfluenza virus, and measles virus, is 6 g of drug reconstituted in a final volume of 300 mL of sterile water (final concentration, 20 mg/mL); a small-particle aerosol generator (SPAG-2 unit) is used to administer the drug continuously during a period of 12 to 18 hours for 3 to 7 days.* The drug may be delivered to an infant oxygen hood or tent, by facemask, or through pressure- or volume-cycled ventilators, provided ventilatory pressure is monitored and the device is checked for precipitation, which may cause ventilator dysfunction.[151,339]

Intermittent high-dose therapy, with drug administered at 60 mg/mL for 2 hours three times daily for 5 days, also appears to be effective and may be better tolerated in some older patients.[131] Longer courses of aerosolized therapy for up to 14 days have been used in severely immunocompromised patients with prolonged viral shedding and severe disease.[285] Oral doses of up to 600 mg twice daily for 24 to 48 weeks, usually combined with interferon-α, are used to treat HCV in adults.[38,41,105,114,221,307,365] High doses of oral ribavirin also appear to be effective in treating influenza in normal hosts.[432] Even higher doses of oral ribavirin (2-g loading dose, followed by 2 g/day divided every 8 hours for 10 days)

*See references 171, 181, 206, 238, 310, 321, 359, 413, 441, 469.

*See references 34, 128, 171, 181, 182, 242, 263, 285, 302, 310, 321, 327, 412, 413, 441, 470.

have been used for the treatment of Lassa fever and other hemorrhagic fever syndromes in adults.[134,143,220,227,237,253,306] The intravenous dose of ribavirin used to treat Lassa fever is a 2-g loading dose (25 to 33 mg/kg estimated pediatric dose), followed by 1-g doses (16 mg/kg estimated pediatric dose) every 6 hours for 4 days and then 500-mg doses (8 mg/kg estimated pediatric dose) every 8 hours for 3 days to complete a 7- to 10-day course of treatment.[237,306] This intravenous dosage regimen also has been used to treat measles pneumonia, severe influenza with complications, pneumonia caused by parainfluenza virus in immunocompromised patients, and disseminated adenovirus disease.[146,176,292,361] Continuous intravenous infusions of ribavirin have been used in patients with severe disease caused by influenza and parainfluenza viruses.[200] Doses used to treat subacute sclerosing panencephalitis in children have been considerably higher and administered for longer periods.[223,329] In one report, pediatric patients received interferon-α combined with 10 mg/kg of ribavirin administered intravenously every 8 hours daily for 7 days. Escalating doses of 20 and then 30 mg/kg given every 8 hours daily for 7 days at 7-day intervals then were administered.[223] The highest dose tolerated was given for 7 days, repeated in 7-day intervals, and administered for a period of 6 months.

ADVERSE EFFECTS

Adverse effects of aerosolized ribavirin are unusual but include local irritation causing facial rash and conjunctivitis. Abnormalities in pulmonary function, including worsening of respiratory distress and bronchospasm, also have been reported.[165,182,441] In addition, one case of water intoxication associated with aerosolized ribavirin administration has been reported.[447] Older children, adolescents, and adults may be noncompliant with treatment or may even have anxiety attacks or experience other forms of psychological stress as they are being confined for continuous treatment for a 12- to 18-hour period. In these cases, intermittent, high-dose regimens may be better tolerated and might enhance compliance of the patient.[131] Precipitation of the drug in ventilator tubing systems and on filtering devices may cause ventilator dysfunction and respiratory distress or failure in mechanically ventilated patients, especially those receiving high-dose intermittent administration, but such events may be minimized by frequent monitoring of ventilator pressure and changing of the filters.[151,310,321,339] Adverse hematologic effects such as anemia have not been documented consistently in patients who received aerosolized ribavirin. The environmental exposure to aerosolized ribavirin by health care workers providing direct care to a virus-infected patient may, in some instances, cause headache, conjunctivitis, contact lens damage, watery eyes, and bronchospasm in those with underlying reactive airway disease.[49,165,372,404] These potential adverse effects are probably more likely to be seen in instances in which ribavirin is administered by hood, tent, or facemask than when it is administered to mechanically ventilated patients.[50] Environmental exposure of health care workers and family members may be reduced by providing routine patient care during periods when the aerosol generator has been turned off, by turning off the aerosol generator during periods of more urgent care, and by using protective equipment such as masks and goggles. Dose-related, reversible, usually mild anemia occurs frequently during and after long-term oral therapy and intravenous administration of ribavirin.[221,239] Rarely, severe anemia may occur and necessitate dose reduction or cessation of therapy. Reversible increases in serum bilirubin, serum iron, and uric acid concentrations also have been documented during oral therapy. On rare occasion, intravenous administration of ribavirin has produced chills and rigors.[142,165] Ribavirin has shown teratogenic, mutagenic, and embryotoxic effects in preclinical animal models.[211] Therefore, investigators recommend that exposure of pregnant women to ribavirin, either therapeutically or through environmental exposure, be minimized or prevented whenever possible or practical.

PLECONARIL

Spectrum of Activity

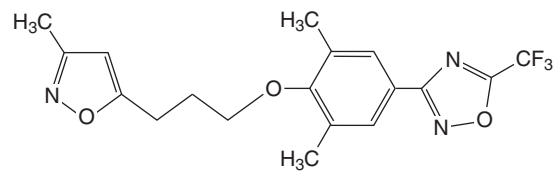
Pleconaril (3-[3,5-dimethyl-4[[3-(3-methyl-5-isoxazolyl)propyl]oly]phenyl]-5-(trifluoromethyl)-1,2,4-oxadiazole) is an antiviral agent with significant and specific activity against picornaviruses, both enteroviruses and rhinoviruses (Fig. 251–5). In vitro, pleconaril inhibits the replication of most serotypes of enteroviruses at concentrations between 0.01 and 0.1 μg/mL.[351] Echovirus 11, a commonly isolated enterovirus in the United States, appears to be the most sensitive enterovirus tested to date (inhibited at a mean concentration of 0.006 μg/mL). Most rhinovirus serotypes are inhibited at slightly higher concentrations of 0.21 to 0.78 mg/mL but still within ranges safely achievable in patients.

Mechanism of Action and Resistance

Pleconaril binds efficiently to a specific hydrophobic pocket within the viral capsid of picornaviruses and exhibits an antiviral effect by interfering with uncoating, attachment, and cell-to-cell transmission of infectious viral particles.[379] The drug induces a more rigid structure within the viral capsid, which then interferes with viral uncoating and release of viral RNA.[148,309,350,351,373,379] Pleconaril also appears to change the conformation of the canyon floor of the virus capsid when it integrates with the underlying pocket, thereby interfering with attachment of the virus to host-cell receptors.[350,379] Resistance of picornaviruses to pleconaril has not been reported.

Pharmacokinetics

The pharmacokinetics of pleconaril varies with the age of the group tested. After oral administration of single doses of 200 to 400 mg to adults, peak plasma concentrations of 1.1 to 2.4 μg/mL are achieved in 1.5 to 5 hours, with an average elimination half-life of 25 hours.[2] Repeated dosing for a 7-day period increases plasma concentrations to 1.33 to 3.4 μg/mL. When it is taken with food, especially a meal high in fat, absorption of pleconaril is enhanced significantly.[1,248] Single oral doses of 5 mg/kg in children provide plasma concentrations of approximately 1.3 μg/mL with a more rapid elimination half-life of approximately 6 hours.[247] Neonates also absorb pleconaril well, but they do not exhibit dose-proportionate pharmacokinetics as adults do.[248] The drug also has a large volume of distribution and concentrates in tissues such as the liver, brain, and nasal epithelium, where viral replication and virus-induced disease are likely to occur.[248] Pleconaril appears to be excreted in feces and urine.



Pleconaril

Figure 251–5 Structure of pleconaril.

Clinical Indications, Dosage, and Adverse Effects

CLINICAL INDICATIONS

Pleconaril currently is not licensed for therapeutic use. Pleconaril has shown efficacy in early clinical trials against picornavirus infections in adults, children, and neonates. In pretreated adults experimentally infected with coxsackie A21 virus, pleconaril significantly reduced viral titers as well as the clinical parameters of fever, nasal mucus production, and systemic symptoms compared with placebo.[191,379,394] In another trial, pleconaril resolved the symptoms of illness 2 days earlier than placebo did, and patients who received pleconaril did not require as much concomitant medication for symptomatic relief as did those who received placebo.[379] In two placebo-controlled trials in adults with aseptic meningitis caused by enterovirus, pleconaril treatment reduced the duration of headache and other symptoms of meningitis by 2 to 3 days and allowed treated patients to return to work and routine daily activities 2 days earlier than patients who received placebo.[379,394] In a placebo-controlled trial in pediatric patients with aseptic meningitis caused by enterovirus, pleconaril significantly improved illness scores and reduced the duration of headache in older children, but clinical efficacy was difficult to assess in infants and younger children.[2a] Viral shedding from the throat also was reduced in the treatment group.[389] In addition to treatment for the "common cold" and for "viral meningitis," another potential use for pleconaril is for the treatment of serious, persistent, or life-threatening illness caused by enteroviruses. More than 90 patients with unusual or life-threatening infections with enterovirus have received pleconaril on a compassionate-use basis.[148] These patients included immunocompromised patients with chronic meningitis, neonates with disseminated disease, patients with myocarditis,[374] and individuals with poliomyelitis associated with vaccine or wild-type poliovirus. In all groups, most of the patients showed clinical and virologic responses.

DOSAGE

Pleconaril is manufactured as a hard gelatin capsule and an oral solution. The capsule contains 200 mg of drug, and doses used in adults and older children have been 200 to 400 mg every 8 hours for 7 days (21 doses). An oral solution also has been prepared for pediatric use. It contains 40 mg/mL of pleconaril, medium-chain triglycerides, two surfactants (Tween 80 and Arlacel), 1.5% saccharin, and cherry-peppermint flavoring. Doses of 5 to 7.5 mg/kg of the oral solution administered every 8 to 12 hours for 7 days (14 to 21 doses) have been used in clinical trials of young children, infants, and neonates.[379] Oral pleconaril is generally well tolerated by all age groups.

ADVERSE EFFECTS

Adverse effects associated with pleconaril treatment include nausea, diarrhea, stomach upset or discomfort, and headache. Serious toxicities have not been documented to date, and preclinical studies did not show teratogenicity or fetal toxicity.

ANTIVIRAL AGENTS ACTIVE AGAINST DNA VIRUSES (Table 251–3)

ACYCLOVIR

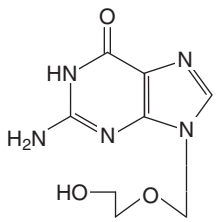
Spectrum of Activity

Acyclovir, 9-[(2-hydroxyethoxy)methyl]-9H-guanine (also known as acycloguanosine), is an analogue of the nucleoside deoxyguanosine that has selective activity against the herpes family of viruses[101,127] (Fig. 251–6). It has the most potent antiviral activity against HSV type 1 and inhibits the virus at concentrations of

TABLE 251–3 Clinical Indications and Usual Treatment Dosages for Antiviral Agents Active Against DNA Viruses

Agent	Indication	Dosage
Acyclovir	HSV, mucocutaneous	5% ointment 6× daily 15 mg/kg/dose PO 5× daily (max, 200 mg/dose) 5-10 mg/kg/dose IV q8h
	HSV, encephalitis	10-20 mg/kg/dose IV q8h
	HSV, neonatal	20 mg/kg/dose IV q8h
	VZV, chickenpox and zoster	20 mg/kg/dose (max, 800 mg) PO q6h 10-20 mg/kg/dose (500 mg/m^2/dose) IV q8h
Valacyclovir	HSV	500-1000 mg/dose PO bid*
	VZV, zoster	1000 mg/dose PO bid*
Penciclovir	HSV, mucocutaneous	1% cream q2h
Famciclovir	HSV, mucocutaneous	125-500 mg PO bid*
	VZV, zoster	500 mg PO tid*
Ganciclovir	CMV	5-6 mg/kg/dose IV q12h—induction 5 mg/kg/dose qd 5 days/wk *or* 1000 mg PO tid* *or* 500 mg PO 6× daily*—maintenance
Valganciclovir	CMV	900 mg PO bid*—induction 900 mg PO qd*—maintenance
Foscarnet	CMV	60 mg/kg/dose IV q8h—induction 90-120 mg/kg/dose daily—maintenance
Cidofovir	CMV	5 mg/kg/dose IV weekly *or* 1 mg/kg/dose IV 3×/wk—induction 5 mg/kg q2wk—maintenance

**Only adult dosages are available at this time.*
CMV, cytomegalovirus; HSV, herpes simplex virus; VZV, varicella-zoster virus.



Acyclovir

Figure 251–6 Structure of acyclovir.

0.02 to 0.9 μg/mL.[459,472] Inhibitory concentrations of HSV type 2 and VZV are also high, at 0.3 to 2.2 μg/mL and 0.8 to 4.0 μg/mL, respectively.[37,392,459,472] In addition, EBV replication is inhibited by acyclovir at a mean concentration of 1.6 μg/mL, but the drug has no effect on cells latently infected with EBV.[85,286] CMV also is inhibited by very high concentrations of acyclovir (2 to 57 μg/mL).[37] Acyclovir has in vitro activity against simian herpesvirus B and hepatitis B virus (HBV).[33,219,459]

Mechanism of Action and Resistance

Acyclovir is phosphorylated to acyclovir monophosphate by viral TK. Cellular enzymes then convert the monophosphate form to acyclovir triphosphate, the active form of the drug.[472] Acyclovir triphosphate is present in HSV-infected cells at 40 to 100 times the concentration found in uninfected cells, and it competitively inhibits viral DNA polymerase in infected cells. Acyclovir triphosphate also is incorporated into viral DNA and, because it lacks the 3′-hydroxyl group, acts as a chain terminator during viral DNA synthesis. The DNA polymerase enzymes of the various herpesviruses differ in their degree of inhibition by acyclovir triphosphate, and for EBV and CMV, which do not contain viral TK, this inhibition accounts for most of the antiviral effect of the drug.[111,154] Host cellular growth also can be inhibited by acyclovir, but only at levels thousands of times higher than those that inhibit viral replication. This relatively selective mechanism of antiviral action provides a uniquely high therapeutic index.

Three basic mechanisms of resistance have been identified for herpesviruses to become resistant to acyclovir: deficient TK activity caused by absent or low production of viral TK, altered TK activity caused by abnormal substrate specificity so that the enzyme is present and able to phosphorylate but just does not phosphorylate acyclovir, and altered DNA polymerase.[70] Most clinical isolates of HSV that are resistant to acyclovir have deficient TK activity, and most resistant VZV isolates have altered TK activity or altered DNA polymerase.[346] The prevalence of acyclovir-resistant HSV isolates in normal hosts is less than 1 percent, but it can be as high as 10 to 20 percent in immunocompromised hosts receiving acyclovir therapy for 2 weeks or longer.[79,100,133,159,208] Resistant strains of VZV, on the other hand, are unusual.[86] Resistant HSV and VZV isolates retain virulence and can cause disease, especially extensive mucocutaneous lesions in immunocompromised hosts, but invasive diseases such as keratitis, uveitis, meningoencephalitis, and pneumonia also have occurred with resistant strains of HSV.[79,133,159,208,233,417] Immunocompromised hosts may shed resistant strains of HSV for prolonged periods and may experience recurrent disease with either sensitive or resistant strains. Such mutants are also cross-resistant to other antiviral agents that require viral TK for phosphorylation and activation (e.g., penciclovir and ganciclovir), but they are inhibited by antiviral agents that have different mechanisms of action (e.g., foscarnet, cidofovir, and trifluridine).

Pharmacokinetics

Acyclovir is available for topical, oral, and intravenous administration. Systemic absorption of acyclovir after topical application to intact skin is minimal (<0.01 μg/mL), and in one study in which acyclovir ointment was applied to zoster lesions in immunocompromised patients, plasma concentrations of less than 0.1 to 0.78 μg/mL were observed, thus suggesting some degree of percutaneous absorption.[93,459] The bioavailability of oral acyclovir is low (15-21%), with peak plasma concentrations of 0.4 to 0.8 μg/mL observed after the intake of one 200-mg capsule and concentrations of up to 1.6 μg/mL observed after an 800-mg dose.[40] When an equivalent dose in liquid suspension is administered to children, slightly lower peak plasma levels of 1.0 μg/mL were observed.[438] Intravenous infusion of 5 mg/kg for 1 hour provides peak plasma levels of 9.8 μg/mL, whereas plasma levels of 20.7 μg/mL are produced after a 10-mg/kg infusion. Most of the administered dose of acyclovir is excreted unchanged in urine.[459] The elimination half-life of acyclovir is 2.5 to 3 hours in adult patients with normal renal function, slightly longer (3.8 hours) in neonates, and up to 20 hours in anuric patients.[40,150,212] Therefore, dose adjustment, according to creatinine clearance, is needed in patients with renal insufficiency or renal failure.[278] Probenecid administration decreases renal clearance and prolongs the half-life of acyclovir. Acyclovir is distributed widely into a variety of body fluids, including saliva (13% of plasma levels), vaginal secretions (15-170% of plasma levels), zoster vesicular fluid (90-100% of plasma levels), aqueous humor (37% of plasma levels), breast milk (>300% of plasma levels), amniotic fluid and placenta (>200% of plasma levels), and CSF (50% of plasma levels).[150,229,259,279,316] More than half the drug is removed by hemodialysis but very little after peritoneal dialysis.[268,278]

Clinical Indications, Dosage, and Adverse Effects

CLINICAL INDICATIONS

Topical acyclovir may decrease healing time and viral shedding slightly in mucocutaneous lesions of patients experiencing primary infection with HSV.[93] Little if any clinical benefit has been documented in patients with recurrent herpes simplex lesions; however, some patients report a soothing sensation after application of ointment to the lesions. Topical therapy also may produce a mild clinical benefit in immunocompromised patients with zoster lesions.[459] Oral acyclovir significantly reduces viral shedding, clinical symptoms, and time until lesion healing in normal and immunocompromised patients with a variety of mucocutaneous lesions (e.g., orolabial, pharyngeal, genital, rectal, gingivostomatitis, whitlow, skin) associated with primary HSV infection.[8,375,472] It also has been used to treat eye disease, including dendritic corneal ulcers.[90,205]

Oral acyclovir provides benefit to normal and immunocompromised children, adolescents, and adults with primary infection with VZV (varicella or chickenpox). Treatment reduces the duration of fever by 24 hours, the mean number of skin lesions, and the time to total crusting of lesions by 2 days. Postexposure prophylaxis with oral acyclovir also may reduce the risk of acquiring varicella by close and household contacts of patients with varicella. Administration of oral acyclovir during pregnancy is likely to clinically benefit a mother with varicella, but whether it reduces the risk of congenital or neonatal disease is not clear at this time. Recurrent HSV disease also is improved with oral acyclovir therapy. When it is administered during the prodrome or at the very first sign of lesions, treatment reduces viral shedding and time to lesion healing by 1.5 to 2 days.[366,460] Long-term, continuous suppressive therapy with oral acyclovir may be of benefit in some patients with frequent episodes of recurrent mucocutaneous disease, but asymptomatic shedding and person-to-person

transmission still may occur.[166,376] Patients with recurrent skin disease, whitlow, or erythema multiforme may benefit from long-term suppressive therapy with oral acyclovir. Oral acyclovir suppression also reduces recurrences of genital herpes simplex during the last trimester of pregnancy and decreases the need for cesarean section delivery.[53,397,399-401] Short-term prophylaxis administered during a period of risk for recurrence (sunlight exposure, for example) may reduce the clinical recurrence of mucocutaneous disease. Oral acyclovir reduces virus shedding, time to skin lesion healing, and the duration of zoster-associated pain.[29,84] Treatment combined with steroids also appears to decrease the frequency and severity of postherpetic neuralgia in older patients and the elderly, but specific trials conducted in children have not been performed because children seldom experience postherpetic neuralgia. Oral acyclovir also may reduce recurrences of HSV and VZV in bone marrow and solid organ transplant recipients. Its effect on CMV and EBV disease in these patients, however, is minimal, if any. Continuous suppressive therapy with oral acyclovir reduces cutaneous recurrences after neonatal infection when it is administered after a 14- to 21-day course of intravenous therapy has been completed.[258] Whether long-term oral suppressive therapy in neonates also prevents CNS recurrence is unclear at this time. Bell palsy associated with HSV infection may be treated with a combination of acyclovir and prednisone.[4] EBV-associated diseases have been treated with acyclovir, with variable clinical benefit.[397,439] Oral hairy leukoplakia, however, appears to respond to oral acyclovir treatment.[368] Treatment of patients with infectious mononucleosis reduces viral shedding but does not alter the disease course.[451] No clinical benefit has been documented when acyclovir was used to treat chronic hepatitis B.[33]

Intravenous acyclovir is used to treat all severe or life-threatening diseases caused by HSV and VZV, including encephalitis, hepatitis, neonatal disease, acute retinal necrosis syndrome, mucocutaneous disease, and zoster, with or without visceral dissemination, in both normal and immunocompromised patients.[177,256,261,270,344,458,483] Pediatric patients suffering from severe herpetic gingivostomatitis may benefit as well.[8] Early clinical trials also showed efficacy in the treatment of primary genital HSV infection.[92] In addition, normal patients with complications of varicella, including pneumonitis, encephalitis, and hepatitis, should receive intravenous acyclovir.[177] Other diseases associated with VZV in which acyclovir treatment is beneficial include zoster ophthalmicus with complications such as keratitis, anterior uveitis, and contralateral hemiplegia as well as acute retinal necrosis syndrome.[344,417] Intravenous acyclovir is also highly effective in reducing the incidence of disease associated with HSV and VZV in marrow and solid organ transplant recipients. Moreover, it may help reduce serious CMV disease in selected marrow and solid organ transplant recipients, although it clearly is not as effective as ganciclovir or other antiviral agents with specific activity against CMV.[18,19,43,317,455] Treatment of human herpes infection with simian virus B requires high doses of intravenous acyclovir administered for a prolonged period, followed by suppressive therapy.[219] Despite in vitro activity, clinical benefit has not been documented in patients with hepatitis B.[33]

DOSAGE

Topical acyclovir as a 5 percent ointment can be applied to local lesions every 3 to 4 hours five to six times daily for 7 days.[93] If the disease is unresponsive or severe, systemic therapy with oral or intravenous acyclovir should be initiated.

Oral acyclovir is formulated as 200-mg capsules, 800-mg tablets, and a 200-mg/5 mL banana-flavored suspension. The usual dose used to treat mucocutaneous lesions caused by primary infection with HSV in adults and adolescents is 200 mg administered five times daily for 10 days. The usual pediatric oral dose is 15 mg/kg per dose (maximum, 200 mg per dose) administered five times daily for 10 days. Recurrent HSV disease in adults and adolescents may be treated with a variety of different regimens: 800 mg three times daily for 2 days, 400 mg three times daily for 5 days, or 200 mg five times daily for 5 days.[244,245,460] Suppressive doses of 400 mg administered twice daily, often for many years, seem to be safe and effective.[166] This dose, administered to pregnant women with recent primary or recurrent genital herpes, also appears to decrease recurrences at or near delivery and diminish the need for cesarean section delivery.[53,259,401] After intravenous therapy has been completed, the usual dose for neonatal suppressive therapy is 300 mg/m^2 per dose administered three times daily for 6 months.[258] Because neonatal prophylaxis decreases but does not eliminate the risk for CNS recurrence and because the emergence of resistant strains has been documented, all early cutaneous recurrences that occur despite compliance with oral prophylaxis, as well as other signs and symptoms suggestive of recurrent visceral or CNS disease, should be evaluated carefully in young infants, and the need for systemic therapy should be considered.[258] Oral acyclovir must be administered in higher doses to treat varicella and other VZV-associated diseases.[472] Adults and adolescents require 800-mg doses administered five times daily for 7 to 10 days or until lesions have crusted over.[23,462] The pediatric dose of acyclovir to treat varicella or chickenpox is 20 mg/kg (up to 800 mg maximum) per dose (80 mg/kg/day) administered four times daily for 5 days or until lesions have crusted.[7,124]

The usual dose for intravenous administration of acyclovir to treat serious disease associated with HSV is 5 to 10 mg/kg per dose administered as a 1-hour infusion every 8 hours.[357,459,472] Treatment for a duration of 7 days is usually sufficient for mucocutaneous disease, but it should be continued until all lesions are healed. Herpes encephalitis should be treated for at least 10 to 14 days or longer, depending on clinical response and clearance of HSV DNA from the CSF.[255,256,271,471] The usual recommended dose to treat neonatal HSV disease with disseminated visceral involvement or encephalitis is a high-dose regimen of 20 mg/kg per dose administered every 8 hours (60 mg/kg/day) for at least 21 days or until HSV DNA has cleared from the CSF, whichever is longer.[255,256] Some experts use a slightly lower dose (15 mg/kg per dose or 45 mg/kg/day) and a slightly shorter duration of therapy (14 days) for neonates with proven skin, eye, or mouth disease without clinical and laboratory evidence of visceral or CNS involvement. Clinical studies have documented that these higher doses are safe in neonates, but it has not been established clearly that they have superior efficacy over lower doses. Treatment of VZV-associated disease requires higher doses of acyclovir: 500 mg/m^2 per dose (10 to 20 mg/kg per dose) administered every 8 hours (total, 1500 mg/m^2/day) for at least 5 to 7 days or until all lesions have been crusted over for 24 to 48 hours.[459,472] In all clinical indications, the dosage of intravenously administered acyclovir should be adjusted according to creatinine clearance in patients with renal insufficiency and renal failure.

ADVERSE EFFECTS

Adverse effects of acyclovir are unusual.[250] Topical application of the ointment may cause pain or local irritation, usually caused by the polyethylene glycol base.[93,459] Handwashing must be performed after each local application to lesions to avoid autoinoculation or person-to-person transmission. Oral acyclovir may cause nausea and diarrhea, rash, or headache.[459] Long-term oral acyclovir appears to be safe in adults but may be associated with neutropenia in 46 percent of infants who receive suppression after treatment of neonatal HSV infection.[258,319] Intravenous acyclovir is generally well tolerated. However, extravasation of the drug (pH 9 to 11) can cause inflammation, ulceration, and necrosis of surrounding tissue.[250,440] Phlebitis also can develop.

Neurotoxicity occurs rarely, usually in patients with renal insufficiency who have high serum concentrations.[28,139,178,457] Neurotoxicity associated with acyclovir is characterized by lethargy, confusion, tremor, and rarely seizures and coma. Renal tubular damage, crystalline nephropathy, or interstitial nephritis may occur in approximately 5 percent of patients.[360,390] These renal complications are more likely to develop in patients who are not adequately hydrated or in whom the drug has been infused at a rate faster than the recommended infusion time of 1 hour. No excess frequency of adverse events has been reported to date in pregnant women who receive acyclovir or in their fetuses or newborns.[53,67,259,397,401,483] Therefore, on the basis of available information, acyclovir seems to be safe when it is administered during pregnancy, especially during the last trimester, and does not appear to have any significant adverse effects.

VALACYCLOVIR

Spectrum of Activity

Valacyclovir (L-valine, 2-[(2-amino-1,6-dihydro-6-oxo-9H-purin-9-yl)methoxy]ethyl ester monohydrochloride) (also known as valacyclovir hydrochloride) is the hydrochloride salt of the L-valine ester of acyclovir.[30] It has essentially the same selective spectrum of antiviral activity against the herpesviruses as acyclovir does.[35]

Mechanism of Action and Resistance

Valacyclovir is converted rapidly to acyclovir and therefore has the same mechanisms of action and resistance as acyclovir does.[35] Viral isolates that are resistant to acyclovir will be resistant to valacyclovir.

Pharmacokinetics

The pharmacokinetics of valacyclovir has not been studied in the pediatric population, but information gained from adults can be applied, in many ways, to pediatric patients. After oral administration, valacyclovir is absorbed rapidly from the gastrointestinal tract. It is metabolized by first pass through the intestinal tract and also by the liver into acyclovir and L-valine.[35] It has the advantage over acyclovir of having 54 percent bioavailability (versus 20% for acyclovir), which is not altered by food.[422] A single dose of 1 g of valacyclovir administered to an adult produces plasma levels of 0.4 to 0.8 μg/mL. The half-life is 2.5 to 3 hours, similar to that of acyclovir, and is prolonged in patients with renal insufficiency or renal failure.[464,466] The drug is removed by hemodialysis. The rate but not the extent of conversion of valacyclovir to acyclovir is prolonged in patients with liver disease.

Clinical Indications, Dosage, and Adverse Effects

CLINICAL INDICATIONS

Valacyclovir has been reported to be effective in treatment of primary and recurrent mucocutaneous disease caused by HSV-1, HSV-2, and VZV.[35,36,42,284,367,429] Randomized clinical trials conducted in adult patients showed valacyclovir to be superior to placebo and comparable to acyclovir in reducing the number and duration of lesions, pain, and time to healing in patients with primary and recurrent genital herpes and zoster.[42,367,429] It is also comparable to acyclovir for suppression of genital herpes recurrences. Furthermore, in a study of 27 CMV-seropositive heart transplant recipients, valacyclovir appeared to be equal or superior to oral acyclovir in preventing both laboratory and clinical parameters of CMV reactivation.[126] Because valacyclovir is converted to acyclovir, it is likely to be effective for all the clinical indications for which acyclovir has been shown to be effective.

DOSAGE

Valacyclovir is available only in 500-mg caplets; therefore, a pediatric liquid formulation is not available at this time. The usual dose is 1 g twice daily for 10 days for primary genital herpes and 500 mg twice daily for 3 to 5 days for recurrent disease.[35,42,284,429] A daily dose of 500 mg has been used safely for longer than a year to suppress recurrences of HSV disease.[298] The dose to treat VZV-associated disease is higher than that for HSV-associated disease. A dose of 1 g three times a day for at least 7 days is usually necessary to treat zoster, and therapy should be continued until the lesions have dried.[36] The dose of valacyclovir should be adjusted according to creatinine clearance in patients with renal insufficiency or renal failure.

ADVERSE EFFECTS

The adverse effects of oral valacyclovir are similar to those of oral acyclovir and include gastrointestinal disturbances such as nausea, vomiting, and diarrhea.[35] Headache and behavioral changes also have been observed. Overdosage may produce precipitation of acyclovir in the renal tubules as well as CNS toxicity.

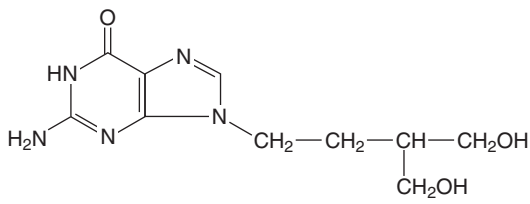
PENCICLOVIR

Spectrum of Activity

Penciclovir (9-[4-hydroxy-3-hydroxymethylbut-1-yl]guanine) is an acyclic guanosine analogue with a selective spectrum of activity against the herpesviruses similar to that of acyclovir[48] (Fig. 251–7). This compound inhibits HSV-1 at very low concentrations (0.2 to 0.6 μg/mL) and HSV-2 at slightly higher concentrations (0.3 to 2.4 μg/mL).[16,48,167,465] At even higher concentrations (0.9 to 4.0 μg/mL), it inhibits VZV.[16,17] The compound has very little activity against CMV, with concentrations greater than 50 μg/mL required to inhibit CMV. However, penciclovir does have activity against hepatitis B virus.[89,266,403]

Mechanism of Action and Resistance

Like acyclovir, penciclovir is preferentially phosphorylated by viral TK in virus-infected cells to penciclovir monophosphate and by cellular enzymes to penciclovir triphosphate, which is the active form of the drug.[125] Penciclovir triphosphate competitively inhibits viral DNA polymerase. It is approximately 100 times less potent than acyclovir triphosphate in inhibiting viral DNA polymerase, but an antiviral effect is achieved because it is present in high concentrations for a prolonged period (7 to 20 hours) in virus-infected cells. However, unlike acyclovir, penciclovir is not a chain terminator during DNA synthesis. Penciclovir triphos-



Penciclovir

Figure 251–7 Structure of penciclovir.

phate also inhibits the DNA polymerase of HBV. Emergence of HSV strains resistant to penciclovir has been minimal.[282] Similar to HSV isolates resistant to acyclovir, isolates resistant to penciclovir may have viral TK gene mutations that produce mutants with deficient or altered TK activity, or they may have mutations in DNA polymerase genes.[74] Strains of acyclovir-resistant HSV that are TK-deficient mutants also will be resistant to penciclovir, but strains of acyclovir-resistant HSV that are TK altered may be susceptible to penciclovir.[49,348]

Pharmacokinetics

Penciclovir is poorly absorbed after oral administration.[147] Adults who received a 10-mg/kg intravenous infusion of penciclovir had plasma levels of 12 μg/mL, but no pediatric information is available. Penciclovir 1 percent cream is not absorbed systemically. The systemic pharmacokinetics of penciclovir is discussed under famciclovir.

Clinical Indications, Dosage, and Adverse Effects

Penciclovir is available in the United States as a 1 percent cream in a propylene glycol base and is licensed for the treatment of herpes labialis lesions on the lips and face. Maximal clinical benefit occurs when the cream is applied to the lesions early, at the first clinical sign of disease, every 2 hours while awake for 3 to 5 days.[428] Application of penciclovir cream may be associated with local skin reactions, most likely caused by the propylene glycol base. An intravenous form of penciclovir has been tested in Europe, but it is not available in the United States. Penciclovir is not absorbed orally, but it is available as the oral prodrug famciclovir, which is converted rapidly to penciclovir. Dosages and systemic adverse effects of penciclovir are discussed under famciclovir.

FAMCICLOVIR

Spectrum of Activity

Famciclovir, 2-[(2-amino-9H-purin-9-yl)]-1,3-propanedial diacetate, is the prodrug of the antiviral agent penciclovir, which has selective activity against HSV-1, HSV-2, VZV, and HBV.

Mechanism of Action and Resistance

Famciclovir undergoes rapid transformation to penciclovir, which is monophosphorylated by viral TK to penciclovir monophosphate; the monophosphate, in turn, is converted by cellular enzymes to penciclovir triphosphate, the active form of the antiviral compound. Penciclovir then competitively inhibits viral DNA polymerase and, thereby, viral replication. The prolonged intracellular half-life observed with penciclovir also is observed with famciclovir. Penciclovir-resistant strains of HSV and VZV occur when mutations produce deficient or altered TK or altered DNA polymerase. Most TK-deficient acyclovir-resistant strains of HSV are also resistant to penciclovir.

Pharmacokinetics

Famciclovir is the diacetyl-6-deoxy analogue of the antiviral compound penciclovir. After oral administration, famciclovir is absorbed rapidly from the gastrointestinal tract with excellent (77%) bioavailability, and then it is metabolized in the liver by deacetylation and oxidation to form penciclovir. Single oral doses of 250 and 500 mg of famciclovir administered to adults produce peak plasma penciclovir levels of 1.6 to 1.9 μg/mL and 2.7 to 4.0 μg/mL, respectively. Administration of famciclovir with food reduces peak plasma concentrations by slowing the absorption time but does not alter the overall bioavailability of the drug. The half-life for penciclovir is 2 to 3 hours, after which it is excreted by filtration and active tubular secretion by the kidneys. Nonrenal clearance by fecal excretion also occurs for as much as one third of the oral dose. Excretion of penciclovir is decreased in patients with renal insufficiency and renal failure, and in patients with liver disease, peak plasma levels may be reduced.[44] Penciclovir is removed from the body by hemodialysis. After oral administration of famciclovir to rats, penciclovir is concentrated in breast milk; however, no studies have been performed in lactating mothers to confirm such concentration in humans.

Clinical Indications, Dosage, and Adverse Effects

CLINICAL INDICATIONS

In adult clinical trials, oral famciclovir was as effective as oral acyclovir and superior to placebo in treatment of recurrent mucocutaneous infections with HSV and VZV in both normal and immunocompromised patients.[82,299,381,452] When given early in the course of illness, time to lesion crusting and healing, duration of viral shedding, and length of acute pain all were shortened by treatment with famciclovir. In some studies, the duration of postherpetic neuralgia in elderly patients with zoster also was shortened.[452] Although to date it has not been studied specifically in clinical trials of patients with primary HSV and VZV infection, famciclovir probably also will provide clinical benefit in these conditions.[291] In addition, famciclovir is effective as suppressive therapy to reduce HSV recurrences and viral shedding.[113,315] Famciclovir also has been used to treat chronic HBV infection and for prophylaxis against recurrent HBV infection in liver transplant recipients.[183,299,406] No clinical trials in pediatric patients have been conducted.

DOSAGE

Famciclovir is available in 125-, 250-, and 500-mg tablets. An oral suspension for pediatric use is not available. The usual recommended oral dose of famciclovir to treat primary and recurrent mucocutaneous HSV disease is 125 mg twice daily for 5 days.[381] Dosages of suppressive therapy are slightly higher, 250 mg twice daily for as long as 1 year. Of note is that clinical trials showed that single daily doses of 250 mg were not as effective as the twice-daily regimen in suppressing recurrences. For immunocompromised patients, especially those infected with HIV, even higher doses (500 mg twice daily for 7 days) may be necessary.[391] Treatment of VZV-associated disease such as zoster also requires higher doses, 500 mg twice or three times daily for 10 days.[452] All dosage regimens should be reduced, according to creatinine clearance, in patients with renal insufficiency or renal failure.

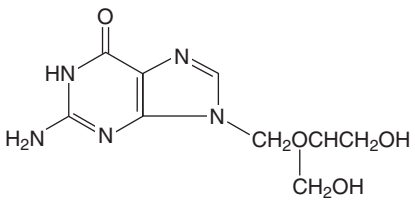
ADVERSE EFFECTS

Adverse effects of treatment with oral famciclovir are unusual and include gastrointestinal disturbances, such as nausea and diarrhea; rash; CNS complaints, such as confusion, hallucinations, and disorientation; neutropenia; and elevated liver transaminases.[82,103,386]

GANCICLOVIR

Spectrum of Activity

Ganciclovir (9-(1,3-dihydroxy-2-propoxymethyl)guanine) (also known as DHPG) is an analogue of deoxyguanosine, similar to



Ganciclovir

Figure 251–8 Structure of ganciclovir.

acyclovir, yet different in that it has an additional hydroxymethyl group on the acyclic side chain[138,141,354,409] (Fig. 251–8). This antiviral compound has selective activity against the herpesviruses, with uniquely potent antiviral activity against CMV. Ganciclovir inhibits HSV-1 and HSV-2 at 0.05 to 0.6 μg/mL, VZV at 0.4 to 10 μg/mL, CMV at 0.02 to 3.4 μg/mL, and EBV at 1.5 μg/mL. Human herpesvirus types 6 (HHV-6), 7 (HHV-7), and 8 (HHV-8) also may be inhibited by ganciclovir.[249] It has in vitro activity against adenoviruses and HBV as well.[138,164,327,446] High concentrations (30 to >700 μg/mL) of ganciclovir will inhibit the growth of most uninfected mammalian cells; bone marrow–derived cells, however, appear to be uniquely sensitive and can be inhibited at much lower concentrations (<0.7 μg/mL).

Mechanism of Action and Resistance

Ganciclovir is monophosphorylated in infected cells by virus-induced enzymes: TK in HSV-infected cells and protein kinases that are encoded by the UL97 phosphotransferase gene in CMV-infected cells.[37,138,288,409] Cellular enzymes complete the phosphorylation to ganciclovir triphosphate, the active form of the compound, which is concentrated in infected cells. Ganciclovir triphosphate competitively inhibits the incorporation of deoxyguanosine triphosphate into viral DNA, where it slows and stops viral DNA chain elongation and produces short, non-infectious viral DNA fragments.[185] Ganciclovir also preferentially inhibits viral DNA polymerase.[294] Ganciclovir resistance has been detected in 8 to 38 percent of immunocompromised adult and pediatric patients who have received prolonged administration of ganciclovir, and such resistance is an important clinical problem.[76,121,163,430]

Patients may be infected with single or multiple strains of CMV, with both drug-sensitive and drug-resistant strains mixed in the population.[135] Resistant strains may be induced or infect a patient primarily, emerge quickly after only weeks of therapy, or evolve more slowly and emerge sequentially after several months of antiviral prophylaxis or therapy.[77,135,230,377,478] These resistant mutants also retain virulence and are capable of producing serious and progressive disease.[45,135,230,420,448] Ganciclovir resistance in CMV strains occurs by at least two mechanisms: (1) point mutations or deletions in the UL97 gene that reduce intracellular phosphorylation of ganciclovir and (2) point mutations in the viral DNA polymerase UL54 (pol) gene that alter the function of the polymerase.[76,294,414,430] Most strains of CMV that are resistant to ganciclovir have UL97 mutations (most commonly at codons 460, 520, 594, and 595) and reduced phosphorylation, but they remain susceptible to foscarnet and cidofovir.[75,76,430] However, CMV strains that are resistant to ganciclovir because of a mutation in the UL54 DNA polymerase gene also may be resistant to foscarnet or cidofovir, or to both.[294,387] Moreover, multiple highly resistant strains of CMV may occur if both UL97 phosphotransferase and UL54 DNA polymerase gene mutations are present.[77,414] Resistance conferred by UL54 mutations usually emerges after UL97 mutations have occurred.[163,414] Ganciclovir resistance in HSV occurs in TK-deficient, acyclovir-resistant strains of the virus.

Pharmacokinetics

Intravenous administration of a 5-mg/kg dose of ganciclovir in adults produces peak plasma levels of 8 to 11 μg/mL.[138,144] Similar pharmacokinetics in 10 pediatric patients aged 9 months to 12 years has been observed.[155] A study of the pharmacokinetics of ganciclovir in 27 neonates aged 2 to 49 days who were administered intravenous ganciclovir for treatment of congenital CMV disease showed a dose of 6 mg/kg to be the most appropriate dose for that age group.[449,488] After intravenous administration, ganciclovir is distributed in CSF at 24 to 70 percent of plasma levels, and 38 percent of plasma levels enter brain tissue.[82] Drug levels in aqueous, vitreous, and subretinal fluid in the eye are comparable to serum levels, and even higher levels can be achieved with intravitreal implants.[13,144,269,301,328] Ganciclovir also accumulates in breast milk in animal models.[5] The plasma half-life is 2 to 4 hours in adults with normal renal function and longer than 24 hours in patients with renal insufficiency and renal failure.[419] The drug is eliminated by renal excretion, and dose reduction is required for patients with impaired creatinine clearance. Hydration will enhance elimination of the drug, and hemodialysis removes 60 percent of ganciclovir in plasma.[419] Ganciclovir also can be administered orally. Its oral bioavailability is rather poor: 5 percent under fasting conditions and 6 to 9 percent if it is administered with food.[10,280] Oral doses of 1000 mg administered to adults every 8 hours produce plasma levels of 0.9 to 1.2 μg/mL.[10,424] A recently licensed valine ester prodrug of ganciclovir, valganciclovir, has high oral bioavailability.[300]

Clinical Indications, Dosage, and Adverse Effects

CLINICAL INDICATIONS

Ganciclovir is used for the treatment of established CMV disease, for early or preemptive therapy in immunocompromised patients with virologic markers of active infection that are predictive of CMV disease, and for prophylaxis of high-risk patients such as those who are CMV seropositive or who have received transplants from CMV-seropositive donors. Ganciclovir is licensed for treatment and chronic suppression of sight-threatening CMV retinitis in immunocompromised patients and for prevention of CMV disease in transplant recipients. Clinical trials have demonstrated efficacy in these conditions.* Treatment with ganciclovir also is beneficial in immunocompromised individuals with other forms of invasive CMV disease, including pneumonia, colitis, esophagitis, myocarditis, encephalitis, persistent fever and leukopenia syndrome, and viral sepsis syndrome.† Treatment of established CMV pneumonia in bone marrow and stem cell transplant recipients is difficult, and the disease may not respond to ganciclovir treatment, with or without immune modulators or globulins. Most clinical trials have been performed in adults, but children and infants with CMV disease benefit from treatment as well. Ganciclovir treatment also has been evaluated in newborns congenitally infected with CMV with CNS involvement.[257,449,488] In addition, ganciclovir is used for preemptive therapy for patients (primarily recipients of solid organ, marrow, and stem cell transplants) with virologic markers that are predictive of serious CMV disease.[52,169,207,426] Prophylaxis with ganciclovir to prevent CMV infection and disease in immunocompromised patients, including solid organ and bone marrow transplant recipients and patients with acquired immunodeficiency

*See references 52, 99, 123, 168, 169, 207, 218, 314, 395, 476.
†See references 60, 80, 88, 115, 119, 129, 363, 364, 424, 426, 427.

syndrome (AIDS), also has been beneficial in most groups studied.[52,123,168,426,476,477] Prophylaxis reduces the risk for the acquisition of serious CMV disease or, in some groups, prolongs the incubation period, but it does not eliminate the risk.[123,168,395,476] Ganciclovir prophylaxis is also effective in preventing HSV infection in immunocompromised patients.[168] Ganciclovir appears to decrease HBV DNA levels and to improve hepatic enzymes in patients with post-transplantation infection or reactivation with HBV.[164] In addition, ganciclovir has been used to treat patients with serious disease associated with adenovirus infection, but clinical trials proving efficacy have not been performed.[446]

DOSAGE

Ganciclovir is supplied as a solution for intravenous infusion and as 250- and 500-mg capsules for oral administration. The intravenous infusions are delivered best in a concentration of 10 mg/mL or less and administered during a 1-hour period. Intravitreal implants are also available and are designed to slowly release relatively large doses of ganciclovir locally into the eye during a period of many months. Ganciclovir therapy for serious CMV disease usually is administered in two phases, induction and maintenance. The recommended dose for induction therapy for serious CMV disease in adults and children with normal renal function is 5 mg/kg per dose administered intravenously every 12 hours for 2 to 3 weeks. Successful induction therapy is accompanied by clinical and virologic response. Maintenance therapy at doses of 5 mg/kg/dose administered intravenously every 12 to 24 hours should be continued in severely immunocompromised patients who are at risk for relapse. Selected patients may receive oral ganciclovir for maintenance therapy. The usual recommended dose for adults is 1000 mg three times daily or, alternatively, 500 mg administered six times daily. The pediatric dose for maintenance oral therapy has not been established. The duration of maintenance therapy should be individualized for each patient, but such therapy usually lasts through the period of greatest risk, such as rejection or immune suppression, or may be lifelong, as in patients with AIDS. Some patients who experience CMV disease, such as solid organ transplant recipients with minimal immune suppression and minimal or no rejection, will respond dramatically to induction therapy and will not require long-term maintenance therapy. A dose of 6 mg/kg administered every 12 hours for 6 weeks has been used to treat newborns with congenital CMV disease.[257,276,488] This dose appears to be adequate for term newborns and premature newborns as young as 32 weeks' gestation, provided renal function seems to be normal for age. The dose for extremely premature newborns is not known and should be individualized according to the clinical judgment of the infectious diseases specialist. Preemptive therapy, 5 mg/kg per dose administered every 12 hours, is initiated when virologic markers for active, invasive infection, such as positive cultures for CMV from bronchoalveolar lavage samples or the presence of CMV DNAemia or antigenemia, are identified by routine virologic surveillance.[395,425] After an induction period of 7 to 14 days, maintenance therapy usually is continued for 100 to 120 days after transplantation or longer if the patient remains at high risk for relapse of CMV disease. Prophylaxis with ganciclovir is administered immediately before transplantation and for a defined period after transplantation in patients who are at high risk, such as those who are CMV seropositive before transplantation and those who receive marrow or solid organ transplants from a CMV-seropositive donor.[51,123,157,168,395,426,476,477] Patients who do not respond to induction therapy or who relapse or progress during maintenance therapy with ganciclovir may have a resistant strain of CMV. The addition of another antiviral with different mechanisms of action, such as foscarnet or cidofovir, may be beneficial. If clinical or virologic responses still are not maintained, the possibility of a multiply resistant CMV strain should be considered. Patients with disseminated adenovirus disease have received doses of 5 mg/kg every 12 hours for 14 or more days, but clinical benefit has not been proved.[327]

ADVERSE EFFECTS

Adverse effects of ganciclovir can be both local and systemic. Local reactions such as phlebitis, irritation, blistering, or ulceration at or around the infusion site can occur and usually are attributed to the alkaline pH (pH 11) of the intravenous solution. Local reactions can be minimized by paying careful attention to the infusion site or by administering the antiviral agent through a central venous catheter. The most common systemic toxicity associated with ganciclovir administration is dose-dependent, reversible neutropenia, which occurs in a third to a half of patients (adults, children, and newborns) who receive this antiviral for longer than 2 weeks.[99,138] Thrombocytopenia also can occur, most often in patients with AIDS who are receiving other antiviral agents, including antiretrovirals.[216] If the neutropenia is severe (absolute neutrophil count <500/mm^3), ganciclovir administration should be halted temporarily until the neutrophil count recovers. Ganciclovir then may be readministered, if it is still clinically indicated, at the same or half the original dose while the patient is carefully monitored for recurrence of the neutropenia. Some experts have used recombinant granulocyte-macrophage colony-stimulating factor successfully to treat ganciclovir-induced neutropenia.[187] Anemia associated with ganciclovir administration is an unusual occurrence. Other adverse effects associated with ganciclovir include CNS disturbances, such as headache, behavioral changes, psychosis, seizures, and coma; mild nephrotoxicity with azotemia; liver dysfunction with elevated transaminases; and rash. Ganciclovir also is mutagenic, carcinogenic, and immunosuppressive. In addition, preclinical animal studies showed reproductive toxicity, with teratogenicity, embryotoxicity, and testicular atrophy.[138] Long-term studies in children who received ganciclovir as newborns are being conducted to determine the long-term effects of ganciclovir administration, if any. Also, caretakers who prepare and administer ganciclovir to patients should take precautions to minimize direct exposure to the antiviral agent.

VALGANCICLOVIR

Spectrum of Activity

Valganciclovir (L-valine, 2-[(2-amino-1,6-dihydro-6-oxy-9H-purin-9-yl)methoxy]-3-hydroxypropyl ester) is a prodrug of ganciclovir and therefore has the same selective spectrum of activity as ganciclovir against herpesviruses, especially CMV, as well as limited activity against adenoviruses and HBV.

Mechanism of Action and Resistance

Valganciclovir is the L-valyl ester (prodrug) of ganciclovir.[300] It is metabolized rapidly in the body to ganciclovir. Ganciclovir then is monophosphorylated by viral protein kinase (coded for by UL97 genes) in CMV-infected cells and further phosphorylated to the active form ganciclovir triphosphate by cellular kinases. Viral DNA synthesis is inhibited by ganciclovir triphosphate (see ganciclovir for details). Isolates of CMV become resistant to valganciclovir by mutations in UL97, the viral kinase gene, or in UL54, the viral DNA polymerase gene. Mutations in UL97 confer resistance to ganciclovir and therefore to valganciclovir, whereas mutations in UL54 confer double or triple resistance to ganciclovir, foscarnet, and cidofovir. Mutations in both genes can produce highly resistant strains of CMV.

Pharmacokinetics

Valganciclovir is well absorbed after oral administration and is rapidly hydrolyzed in the intestine and liver to ganciclovir.[349] The bioavailability of valganciclovir is high, approximately 60 percent (versus 6% to 9% for ganciclovir), and an oral dose of 900 mg administered to adults produces ganciclovir blood levels equivalent to a 5-mg/kg dose administered intravenously.[54,241,300] Absorption is enhanced significantly with the ingestion of food, so physicians recommend that valganciclovir be taken with food or meals. The drug is excreted by the kidneys, and renal insufficiency produces prolonged excretion and a longer half-life (see ganciclovir). Oral valganciclovir solution administered to neonates and infants up to 6 weeks of age, at a dosage of 16 mg/kg/dose, is 41% bioavailable and provides plasma concentrations comparable to intravenously administered ganciclovir.[259a]

Clinical Indications, Dosage, and Adverse Effects

Valganciclovir is available in 450-mg tablets, and the usual adult dose is 900 mg (two 450-mg tablets) twice daily for 14 days (induction therapy), followed by a maintenance dose of 900 mg administered once daily.[300] Special oral solutions are still investigational.[259a] Valganciclovir is licensed for induction and maintenance treatment of CMV retinitis in immunocompromised patients, but clinical trials are likely to show that valganciclovir is beneficial to a variety of patients with a number of different CMV infections.[300] A liquid, pediatric formulation is not available at this time. As with ganciclovir, if a patient treated with valganciclovir experiences progression of disease or recurrence during maintenance therapy, a resistant strain of CMV should be considered a possibility. Adverse effects associated with the oral administration of valganciclovir are similar to those with oral ganciclovir and include diarrhea and dose-dependent, reversible neutropenia.[300]

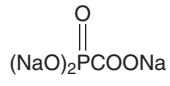
FOSCARNET

Spectrum of Activity

Foscarnet (phosphonoformic acid or trisodium phosphonoformate hexahydrate) is a pyrophosphate analogue that selectively inhibits herpesviruses[337] (Fig. 251–9). It also has activity against HIV and HBV.[20,137] At concentrations of 100 to 300 µmol/L, CMV is inhibited; whereas slightly lower concentrations (80 to 200 µmol/L) inhibit HSV types 1 and 2, VZV, EBV, and HHV-8.[337] Concentrations between 20 and 200 µmol/L appear to inhibit HBV. Foscarnet also inhibits most but not all acyclovir-resistant HSV and VZV strains and most but not all ganciclovir-resistant CMV strains.[149,296,382] Combinations of ganciclovir and foscarnet are synergistic against CMV, and combinations of zidovudine and foscarnet appear to be synergistic against HIV.[137,296] At high concentrations (500 to 1000 µmol/L), foscarnet inhibits cellular DNA synthesis in uninfected cells.[78]

Mechanism of Action and Resistance

Foscarnet is not a nucleoside analogue, and it does not require phosphorylation or any other form of intracellular metabolism to be activated. Rather, it is a pyrophosphate analogue that directly inhibits viral and cellular DNA polymerase.[98,112] Selective viral inhibition is accomplished by noncompetitive and reversible blocking of the pyrophosphate binding site of the viral polymerase, in much lower concentrations than it inhibits cellular DNA polymerases. Because foscarnet does not require phosphorylation by viral TK or other kinases, it inhibits TK-deficient and altered strains of HSV and VZV that are resistant to acyclovir as well as UL97 phosphotransferase mutants of CMV that are resistant to ganciclovir. However, strains of herpesviruses of all types that are resistant to acyclovir or ganciclovir by mutation of the viral DNA polymerase gene are also resistant to foscarnet.[21,384]



Foscarnet

Figure 251–9 Structure of foscarnet.

Pharmacokinetics

Intravenous administration of 60 mg of foscarnet every 8 hours to adults produces plasma levels of 450 to 575 µmol/L; 90 mg administered every 12 hours produces plasma levels of 420 to 746 µmol/L.[112,382] CSF levels are usually approximately 60 percent of plasma levels, and vitreous concentrations in the eye are the same or slightly higher than plasma levels.[204] Most (80%) of the dose of foscarnet is eliminated unmetabolized from the body through the kidneys, and plasma clearance decreases if renal function is impaired. The remaining 20 percent appears to be deposited in teeth and bone, where it accumulates and remains for months. The drug is removed by hemodialysis, but not appreciably by peritoneal dialysis.[6,295] Oral foscarnet has poor bioavailability (less than 10%) and causes diarrhea, and it is unlikely to be available for patient use.[336] Pharmacokinetic data in infants and children have not been published. However, preclinical studies showed that deposition of foscarnet in teeth and bones is greater in younger than in older animals.

Clinical Indications, Dosage, and Adverse Effects

CLINICAL INDICATIONS

Foscarnet is licensed for both induction and maintenance treatment of CMV retinitis in immunocompromised patients and for treatment of mucocutaneous disease caused by acyclovir-resistant HSV.* Foscarnet also may be of benefit in patients with zoster caused by acyclovir-resistant VZV.[382] Because the combination of foscarnet and ganciclovir appears to be synergistic in vitro, immunocompromised patients who experience progression or relapse of CMV disease while receiving therapy with one or the other antiviral agent may benefit from combination therapy in some instances.[122,149,234] Foscarnet also may be used for the treatment or prophylaxis of serious or life-threatening CMV disease when ganciclovir is contraindicated or otherwise deemed clinically undesirable because of its myelosuppressive effects.[369,482] The antiretroviral properties of foscarnet, when it is combined with other antiviral agents, also may be beneficial in patients with HIV infection or AIDS.[32,236,343]

DOSAGE

Treatment with foscarnet usually is divided into two phases, induction and maintenance. The usual dosage of foscarnet for induction therapy is 60 mg/kg per dose administered intravenously every 8 hours for 3 weeks; maintenance therapy is 90 to 120 mg/kg/day administered indefinitely or through the period of risk.[243] The dose of foscarnet should be given slowly, during the course of 2 hours (or no faster than 1 mg/kg/min), to reduce renal toxicity. Creatinine clearance should be used to adjust

*See references 112, 122, 234, 281, 295, 343, 384, 435, 436, 463.

dosage regimens in patients with renal insufficiency or renal failure. Published experience on the use of foscarnet in pediatric patients is limited, but undoubtedly, certain pediatric patients benefit from receiving foscarnet therapy.[463] In these cases, the same per-kilogram dosage regimens can be used for most patients.

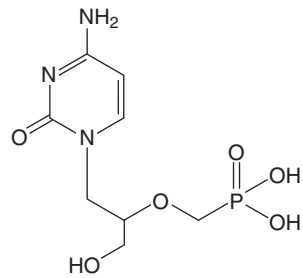
ADVERSE EFFECTS

Foscarnet is associated with serious adverse effects and should be used only after thorough consideration of the risks and benefits involved.[78,112] Renal toxicity with azotemia, proteinuria, crystalluria, renal tubular acidosis or necrosis, and interstitial nephritis can occur in as many as a third of patients who receive foscarnet.[110,240] Renal toxicity generally occurs after the first week of therapy and usually is reversible. The risk for the development of renal toxicity is increased if the drug is given by rapid infusion or administered in high doses, if the patient is dehydrated, or if other nephrotoxic drugs are administered concomitantly with foscarnet.[333] Hydration, including saline loading, and administration of each dose during the course of at least 2 hours appear to reduce the risk for development of renal toxicity. Foscarnet binds divalent metal ions such as calcium in the body, and metabolic abnormalities, including hypocalcemia and hypercalcemia (total or ionized), hypophosphatemia and hyperphosphatemia, hypomagnesemia, and hypokalemia, may occur in approximately a third of patients who receive foscarnet.[235] Symptoms of these acute metabolic abnormalities include perioral tingling, numbness or paresthesias of the limbs, and, if severe, seizures, tetany, and cardiac dysrhythmias. Administration of the dose during the course of at least 2 hours also reduces the risk for development of metabolic abnormalities. Foscarnet also can be deposited and concentrate in bone, with as yet unclear long-term consequences.[112] CNS side effects also occur in approximately a fourth of patients and include headache, tremor, seizures, and behavioral changes. Abnormal liver function test results have been noted, and high urinary concentrations of foscarnet may produce painful genital ulcerations and rash in some patients.[417] Preclinical studies showed foscarnet to be mutagenic and associated with anomalies of skeletal development in young animals.[109]

CIDOFOVIR

Spectrum of Activity

Cidofovir (*S*)-1-3-hydroxy-2-[phosphonomethoxypropyl])cytosine dihydrate (also known as HPMPC) is an acyclic phosphonate nucleotide analogue of deoxycytidine monophosphate with broad-spectrum in vitro antiviral activity against all DNA viruses, including herpesviruses (HSV types 1 and 2; CMV, EBV, and VZV; and HHV types 6, 7, and 8), adenoviruses, polyomaviruses (JC and BK viruses), papillomaviruses, and poxviruses (vaccinia, variola or smallpox, cowpox, monkeypox, camelpox, and molluscum contagiosum and orf viruses) (Fig. 251–10).* Cidofovir exhibits its most specific and potent antiviral activity against CMV (minimal inhibitory concentration, 0.25 μmol/L).[71,72,120,130] The compound also is very active against VZV (0.79 μmol/L), HSV-1 (12.7 μmol/L), and acyclovir-resistant, TK-deficient HSV-1 strains (6.24 μmol/L).[214,312,418] Cidofovir inhibits HSV-2 at concentrations of 31.7 μmol/L, adenoviruses at 10.8 μmol/L, and vaccinia virus at 12.7 μmol/L.[108,170,411] Strains of CMV UL97 mutants that are resistant to ganciclovir are inhibited by cidofovir, and cidofovir in combination with ganciclovir or foscarnet shows synergistic inhibition of CMV in vitro.[383]



Cidofovir

Figure 251–10 Structure of cidofovir.

Mechanisms of Action and Resistance

Cidofovir inhibits the replication of CMV and other viruses by selective inhibition of viral DNA polymerase.[72,214,312] The compound is phosphorylated by cellular enzymes to the active form cidofovir diphosphate. Cidofovir diphosphate inhibits both viral and cellular DNA polymerase; however, because the concentration necessary to inhibit cellular DNA synthesis is hundreds of times higher than that needed to inhibit viral DNA synthesis, cidofovir appears to selectively inhibit viral DNA synthesis at concentrations safely administered to humans. Cidofovir diphosphate has a long intracellular half-life that provides prolonged and persistent antiviral activity and allows infrequent dosing regimens in humans.[145,215,418] Because the compound does not require TK for initial phosphorylation, it is active against TK-deficient and TK-altered acyclovir-resistant HSV strains.[312] Resistance to cidofovir is unusual but can occur by mutations in viral DNA polymerase genes (codons 375 to 540 and possibly 978 to 988), most likely in patients who have received prolonged or repeated periods of treatment with ganciclovir or foscarnet. Strains of CMV that are resistant to cidofovir are also usually resistant to ganciclovir, and occasionally, triple mutants resistant to ganciclovir, foscarnet, and cidofovir occur.[120,445]

Pharmacokinetics

After an intravenous infusion of 5 mg/kg of cidofovir, peak plasma levels range from 11.6 to 26.1 μg/mL, with the latter occurring after administration of probenicid.[102,383,445] The plasma half-life is 2 to 3 hours, but the intracellular half-life is very prolonged (between 17 and 65 hours).[418] CSF penetration by cidofovir is not well studied, but in at least one patient, the drug did not appear to cross the blood-brain barrier in detectable amounts. After topical administration to the eye or intact skin, systemic absorption is low, with peak plasma levels usually less than 0.5 μg/mL.[273,274] However, patients with abraded or denuded skin may have significant absorption.[36] The systemic absorption that occurs after intralesional or subcutaneous administration is not well characterized at this time. Intravitreal administration produces sustained antiviral effects in animal models.[145] Cidofovir is not well absorbed orally, with less than 5 percent bioavailability. However, bioavailable alkoxyalkyl esters of cidofovir are in development and may lead to an oral compound in the near future.[251] Aerosolized cidofovir also is being studied in animal models and appears to deliver high concentrations of antiviral to the lungs.[51] Cidofovir is eliminated through the kidney by glomerular filtration and active tubular secretion, and more than 90 percent of the original dose can be recovered unchanged in urine.

Clinical Indications, Dosage, and Adverse Effects

CLINICAL INDICATIONS

Cidofovir is licensed for induction and maintenance treatment of CMV retinitis in immunocompromised adults with AIDS.[383] Clinical trials have shown that cidofovir significantly delays progression of CMV retinitis in previously untreated patients as well as in those who previously failed or were intolerant of foscarnet or ganciclovir therapy.[273,274,356,437] Cidofovir also has been shown to be effective for the treatment of CMV infection and disease in marrow and stem cell transplant recipients. In addition, it has been used, in selected patients, for preemptive treatment of CMV infection after marrow and stem cell transplantation.[68,289,353] One study also showed that cidofovir helped prevent post-transplantation CMV-associated atherosclerosis in rats.[57] Patients infected with CMV strains resistant to ganciclovir or foscarnet, or both, may benefit from receiving cidofovir treatment.[120] Cidofovir is used by clinicians to treat immunocompromised children with serious CMV disease despite the lack of published experience in children.[59,66] Cidofovir has broad-spectrum antiviral activity, and published case reports show that it has been used to treat patients with serious infections caused by a wide variety of DNA viruses. For example, patients with acyclovir- and foscarnet-resistant HSV infection have been treated successfully with topical and systemic cidofovir.[58,265,272,274] It also may be effective in treatment of selected patients with acyclovir-resistant VZV infections.[444] Moreover, one report showed that treatment with cidofovir and anti-CD20 monoclonal antibody was associated with remission and regression of post-transplantation EBV-associated lymphoproliferative disease.[186] The use of cidofovir to treat patients with AIDS and HHV-8 viremia and disease also has been reported.[47,304] Human papillomavirus–induced epithelial cell proliferation may be responsive to treatment with topical and intralesional administration of cidofovir. Several small, uncontrolled case series have described the successful use of cidofovir to treat juvenile laryngeal papillomatosis, hypopharyngeal and esophageal papillomatous lesions, anogenital condylomas, and cervical intraepithelial neoplasia.[14,73,416,433,485] Furthermore, intravenous and intralesional therapy with cidofovir has been used to treat individual patients, including children, with refractory disseminated respiratory papillomatosis of the lung.[14,296a] Human BK polyomavirus–associated acute hemorrhagic cystitis in immunocompromised patients has been treated with cidofovir, with varying results.[25,137a] Case reports and small clinical trials evaluating cidofovir treatment in patients with progressive multifocal leukoencephalopathy who have AIDS or other immunocompromising conditions have not shown consistent benefit in survival or sustained improvement in neurologic status.[12,81,158,228,326,362,385,402] Successful cidofovir treatment of adenovirus disease in marrow and stem cell transplant recipients has been published in reports of case series, with the best results noted in patients in whom the disease was localized and treatment was initiated early.[46,160,217,283,370] Controlled clinical trials evaluating eyedrops containing an investigational topical solution of cidofovir to treat patients with acute keratoconjunctivitis caused by adenovirus have not shown consistent benefit in the doses used.[209,210] Poxviruses are inhibited by cidofovir in concentrations safely achievable in humans, and at least one case report of successful treatment of orf (ecthyma contagiosum) has been published.[161] In addition, in vitro and animal model data suggest that cidofovir may be effective in the treatment and short-term, postexposure prophylaxis of smallpox and other related poxvirus infections in humans as well as in the treatment of complications that may occur after inoculation with smallpox (vaccinia-like) vaccine.[11,71,72,108,120,383,411] However, no clinical trials in humans to evaluate the efficacy of cidofovir for the treatment of poxvirus infections have been published.

DOSAGE

The usually recommended dose for induction therapy with cidofovir is 5 mg/kg given as an intravenous infusion during the course of 1 hour administered once weekly for 2 consecutive weeks. Some clinicians suggest a reduced dosage regimen of 1 mg/kg administered three times weekly to reduce the risk of renal toxicity.[217] Maintenance therapy usually is administered as 1-hour infusions of 5 mg/kg once every 2 weeks to complete a total of at least five doses. These doses should be decreased to 1 to 3 mg/kg if renal insufficiency is present and discontinued if significant elevation of serum creatinine concentration or proteinuria occurs. Probenecid must be administered orally with each dose of cidofovir, 3 hours before and then 2 and 8 hours after completion of the intravenous infusion. Prehydration with normal saline before each infusion also is recommended. Investigational topical preparations of eyedrops containing 0.2 to 1 percent cidofovir and creams containing 1 percent cidofovir are being investigated.[209,210] The usual concentration used for intralesional injection is 2.5 mg/mL.[433]

ADVERSE EFFECTS

Cidofovir is nephrotoxic and produces clinically apparent proximal tubular dysfunction, including Fanconi syndrome and acute renal failure, in as many as half the patients who receive the drug.[311,383] Early laboratory signs of renal toxicity include proteinuria, glycosuria, azotemia, and metabolic acidosis. Therefore, patients receiving cidofovir should have a urinalysis and serum tests for renal function performed before taking each dose. The risk for development of renal toxicity can be reduced but not eliminated by probenecid and saline prehydration. Moreover, renal toxicity is more likely to occur if other nephrotoxic agents, such as aminoglycosides, amphotericin B, or foscarnet, are administered concurrently with cidofovir.[487] In clinical trials of patients with AIDS, administration of cidofovir also was associated with neutropenia. Ocular toxicity, including ocular hypotony (decreased intraocular pressure) and anterior uveitis and iritis, also has been reported in patients receiving cidofovir therapy.[3] Therefore, frequent monitoring by an ophthalmologist, including measurement of intraocular pressure, is recommended for patients receiving cidofovir therapy. Intravitreal administration of cidofovir has produced uveitis, vitreitis, reduced intraocular pressure, and loss of vision.[260,331] Local or topical treatment with cidofovir may produce local reactions in the skin.

CHAPTER 252

Antifungal Agents

Andreas H. Groll ❁ Thomas J. Walsh

Invasive fungal infections are important causes of morbidity and mortality in children with severe underlying illnesses. These infections remain difficult to diagnose and can be rapidly fatal. As a consequence, early and aggressive antifungal chemotherapy is pivotal for successful management and survival. For a long time, options for antifungal chemotherapy were limited to amphotericin B deoxycholate with or without the addition of flucytosine. The 1990s, however, witnessed major progress through the introduction of fluconazole and itraconazole and the development of less toxic formulations of amphotericin B. More recent advances include the advent of novel, potent, and broad-spectrum antifungal triazoles and the clinical development of echinocandins, an entirely new class of antifungal agents that target the fungal cell wall (Fig. 252–1). This chapter is devoted to the clinical pharmacology of systemic antifungal agents; emphasis is placed on pharmacokinetics, dosing, and safety in pediatric age groups.

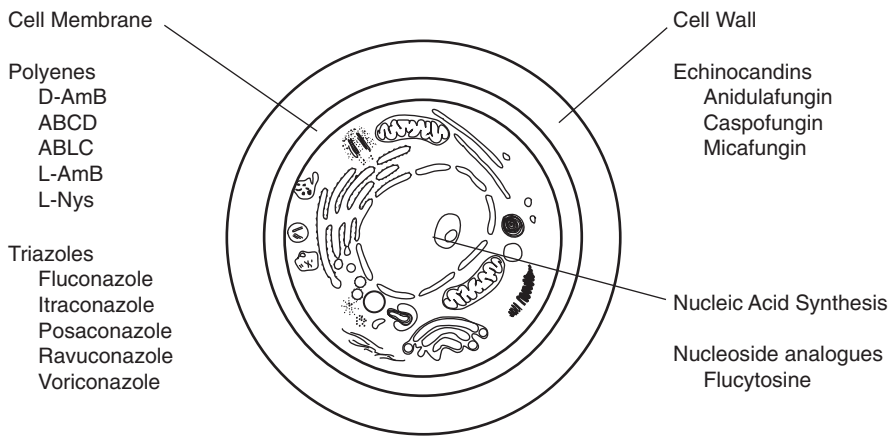

Figure 252–1 Cellular targets of approved and investigational antifungal agents for treatment of invasive mycoses at the beginning of the 21st century. *(Modified from Groll, A. H., Piscitelli, S. C., and Walsh, T. J.: Antifungal pharmacodynamics: Concentration-effect relationships in vitro and in vivo. Pharmacotherapy 21[Suppl. 8]:133-148, 2001.)*

AGENTS FOR TREATMENT OF INVASIVE MYCOSES

POLYENE ANTIBIOTICS

Amphotericin B Deoxycholate

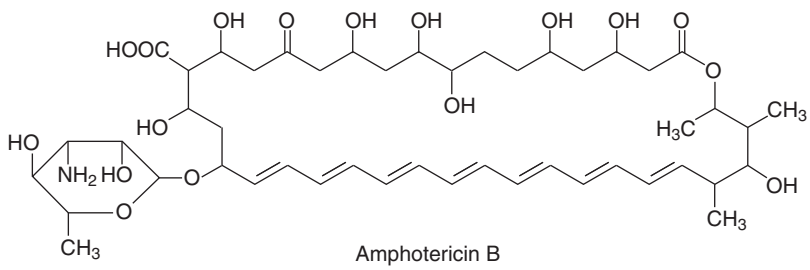
Despite an expanded antifungal armamentarium, amphotericin B deoxycholate still has a role in the treatment of selected invasive fungal infections. First isolated in the 1950s as a natural product of a soil actinomycete,[161] amphotericin B belongs to a family of approximately 200 polyene macrolide antibiotics and consists of 7 conjugated double bonds, an internal ester, a free carboxyl group, and a glycoside side chain with a primary amino group (Fig. 252–2). The compound is amphoteric, not orally or intramuscularly absorbed, and virtually insoluble in water. For parenteral use, amphotericin B has been solubilized with deoxycholate as micellar suspension, and this formulation has been available for more than 50 years.[38]

MECHANISM OF ACTION. Amphotericin B, similar to other polyenes, acts primarily by binding to ergosterol, the principal sterol in the cell membrane of most fungi. This interaction with ergosterol results in the formation of ion channels, loss of protons and monovalent cations, depolarization, and concentration-dependent cell death. Although with less avidity, the compound also binds to cholesterol, the main sterol of mammalian cell membranes; this action accounts for most of the toxicities associated with this drug. A second mechanism of action of amphotericin B may involve oxidative damage of the cell through a cascade of oxidative reactions linked to its own oxidation, with formation of free radicals or an increase in membrane permeability. In addition to its antifungal activity, amphotericin B has stimulatory effects on phagocytic cells that also are related to oxidation-dependent events.[63,185]

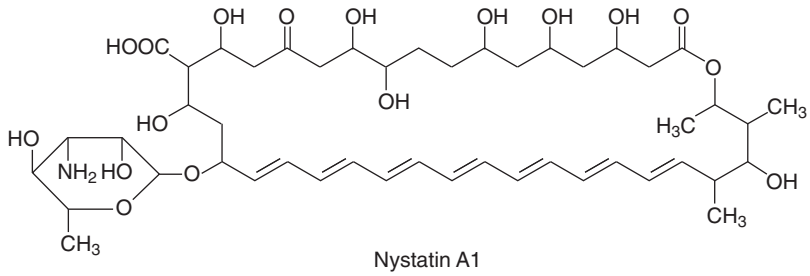
ANTIFUNGAL ACTIVITY. Amphotericin B has a broad spectrum of antifungal activity that includes most fungi pathogenic in humans. This characteristic maintains amphotericin B as the gold standard in the development of other antifungal agents. True microbiologic resistance to antifungal polyenes has been associated with qualitative or quantitative differences in the sterol composition of the cell membrane, but this resistance may also be related to increased catalase activity with decreased susceptibility to oxidative damage.[185] Resistance to amphotericin B remains rare in *Candida* spp. other than *Candida lusitaniae*, although the compound appears somewhat less active against *Candida guilliermondii*, *Candida parapsilosis*, and *Candida tropicalis*.[471,486,514] *Aspergillus* spp. and other opportunistic molds, but not the dimorphic molds, tend to have more variable susceptibility to amphotericin B; *Aspergillus terreus*[223,442] and some of the emerging pathogens such as *Trichosporon asahii*,[11,491,492] *Fusarium* spp.,[61,380] *Scedosporium apiospermum*,[453,494] *Scedosporium prolificans*,[46,286] and certain dematiaceous fungi[171] may be completely resistant to amphotericin B at concentrations achievable in patients by maximum tolerated dosages. Acquisition of secondary resistance is an uncommon occurrence and has not been a clinical problem.[184]

PHARMACODYNAMICS. In time-kill studies, amphotericin B displays concentration-dependent fungicidal activity against susceptible *Candida albicans*, *Cryptococcus neoformans*, and *Aspergillus fumigatus*.[245,246,375] In addition to its concentration-dependent fungicidal dynamics, a prolonged post-antifungal effect (PAFE) of amphotericin B of up to 12 hours' duration has been demonstrated in *C. albicans* and *C. neoformans*.[130,461] Studies in laboratory animals support the concentration-dependent kill kinetics of amphotericin B in vitro. In neutropenic pharmacokinetic/pharmacodynamic mouse models of disseminated candidiasis and pulmonary aspergillosis, peak plasma concentration (C_{max})/minimal inhibitory concentration (MIC) was the parameter that provided the best correlation with outcome as measured by the residual organismal burden in tissue.[22,512] These laboratory findings indicate that large doses will be most effective and that achievement of optimal peak concentrations is important. Therefore, the dosage of amphotericin B should not be uncritically reduced, and infusion for durations longer than that recommended by the manufacturer should be avoided.

PHARMACOKINETICS. After intravenous administration, amphotericin B rapidly dissociates from its vehicle and becomes highly protein-bound before distributing into tissues.[86] The dis-



Amphotericin B



Nystatin A1

Figure 252–2 Structural formulas of antifungal polyenes: amphotericin B and nystatin A1.

position of the compound follows a three-compartment model, with rapid initial clearance from plasma followed by a biphasic pattern of elimination with a beta half-life of 24 to 48 hours and a prolonged terminal (gamma) half-life of 15 days or more.[28] Tissue levels of amphotericin B in laboratory animals are highest in liver, spleen, bone marrow, kidney, and lung; concentrations in body fluids other than plasma are generally low.[225,270] However, despite mostly undetectable concentrations in the cerebrospinal fluid (CSF) and comparatively low concentrations in brain tissue across all species, amphotericin B is effective in the treatment of fungal infections of the central nervous system (CNS). Although no metabolites of amphotericin B have been identified, only small quantities of parent compound are excreted into urine and bile, a finding suggesting that tissue accumulation accounts for most of the disposition of drug.[39,40,98,385] Accordingly, adjustment of dose is not necessary in patients with unrelated renal or hepatic dysfunction. Because of the high protein binding of amphotericin B, hemodialysis usually does not affect plasma concentrations.[99]

Reported pharmacokinetic data in pediatric age groups are characterized by a high interindividual variability, which may be related to differences in underlying diseases and modes of administration (Table 252–1).[31,44,253,327,437] However, infants and children appear to clear the drug from plasma more rapidly than do adults, as indicated by a significant negative correlation between age and clearance in two separate studies.[44,253] Because distribution into tissues appears to be the main route of clearance from plasma, the faster clearance in individuals of younger age may be explained by the larger relative volume of parenchymatous organs in comparison with adults.[316] Whether the enhanced clearance from the bloodstream has implications for dosing remains unknown. Currently, dosage recommendations for all pediatric age groups do not differ from those in adult patients.

ADVERSE EFFECTS. Infusion-related reactions and nephrotoxicity are major problems associated with the use of conventional amphotericin B and often limit successful therapy. Infusion-related reactions (fever, rigors, chills, myalgias, arthralgias, nausea, vomiting, and headaches) are thought to be mediated by the release of cytokines from monocytes in response to the drug.[24] These reactions can be noted in as many as 73 percent of patients prospectively monitored at the bedside.[485] In a more recent prospective interventional study of pediatric patients with cancer, investigators observed fever or rigors, or both, associated with the infusion of conventional amphotericin B in 19 of 78 treatment courses (24%).[327] However, these characteristic adverse effects of amphotericin B are observed only rarely in the neonatal setting.[242] In clinical practice, infusion-related reactions associated with amphotericin B therapy may be blunted by slowing the infusion rate but often require premedication with acetaminophen (10 to 15 mg/kg), hydrocortisone (0.5 to 1.0 mg/kg), or meperidine (0.2 to 0.5 mg/kg).[486] Less common acute adverse effects are hypotension, hypertension, flushing, and vestibular disturbances; bronchospasm and true anaphylaxis are rare occurrences.[184] Cardiac arrhythmias and cardiac arrest resulting from acute potassium release may occur with rapid infusion (<60 minutes), especially if the patient has preexisting hyperkalemia or renal impairment.[73,166,313]

The hallmarks of amphotericin B–associated nephrotoxicity are azotemia, wasting of potassium and magnesium; tubular acidosis and impaired urinary concentration ability rarely are of clinical significance.[163,411] Relevant electrolyte wasting occurs in approximately 12 percent of prospectively monitored patients.[485] Hypokalemia can be quite refractory to replacement until hypomagnesemia is corrected.[411] Azotemia is a common occurrence: In a large prospective clinical trial, the baseline serum creatinine rose by more than 100 percent in 34 percent of 344 unstratified pediatric and adult patients receiving conventional amphotericin B for empiric therapy of fever and neutropenia.[485] Azotemia can be exacerbated by concomitant nephrotoxic agents, in particular by cyclosporine and tacrolimus: in a more recent clinical trial in persistently febrile neutropenic patients, renal toxicity occurred in 67 percent of patients receiving these drugs as compared with 31 percent in patients not receiving them concurrently with amphotericin B.[509] Data from another clinical trial suggested a somewhat lower rate of azotemia in children as compared with adults,[370] but this observation does not appear to be consistent.[509] A frequency of amphotericin B–associated azotemia of only 2 percent was reported for pediatric patients with cancer who were receiving the drug at 1 mg/kg/day for empiric antifungal therapy.[327] In contemporary series reporting safety data of conventional amphotericin B (0.5 to 1.0 mg/kg) in premature neonates, the incidence of azotemia ranged from zero to 15 percent,[72,159,242,373] a finding indicating that the compound is much better tolerated in this setting than reported early during its use.[30]

Renal toxicity associated with the use of conventional amphotericin B has the potential to lead to renal failure and dialysis,[515] but azotemia often stabilizes with therapy and usually is reversible after discontinuation of the drug.[486] Avoiding concomitant nephrotoxic agents, appropriate hydration and normal saline loading (10 to 15 mL NaCl/kg/day)[25,201] may greatly lessen the likelihood and severity of azotemia associated with amphotericin B therapy.

Children/adults[9] (*n* = 20, 4-66 yr)	1.0/md	2.9	36	1.1	0.028	39

**All values are given as means.*

$AUC_{0-\infty}$, area under the concentration versus time curve from time zero to infinity; Cl, plasma clearance; C_{max}, peak plasma concentration; md, multiple-dose data; N/A, not assessed; sd, single-dose data; $t_{1/2}$, elimination half-life; Vd_{ss}, apparent volume of distribution at steady state.

Other, potentially relevant adverse effects of amphotericin B include demyelinizing encephalopathy in bone marrow transplant recipients conditioned with total body irradiation and/or receiving cyclosporine and concomitant high-dose amphotericin B therapy,[319] and normocytic, normochromic anemia associated with low erythropoietin levels after long-term administration.[99] Amphotericin B deoxycholate is topically irritating; therefore, a central line should be used for infusion, and local instillation of amphotericin B should be considered only in conjunction with expert consultation.

THERAPEUTIC MONITORING. Historically, 1-hour postinfusion plasma concentrations of twice the MIC of the fungal isolate have been proposed as targets for treatment of yeast infections.[123] However, monitoring of amphotericin B concentrations in plasma or CSF appears to be of little value because relationships between plasma and tissue concentrations and clinical efficacy or toxicity have not been adequately characterized.[184]

The toxicity of amphotericin B and the practice of normal saline loading implicate close monitoring of related laboratory parameters. The drug must not be infused in less than 60 minutes and only under particularly careful cardiac monitoring in newborns and in patients with hyperkalemia and renal impairment, circumstances in which arrhythmias resulting from acute potassium release have been observed.[73,179]

DRUG INTERACTIONS. Drug-drug interactions caused by shared metabolic pathways are unknown for amphotericin B. Hypokalemia may be aggravated by corticosteroids, and, in turn, can potentiate digoxin toxicity, cause rhabdomyolysis, and enhance the effects of nonpolarizing muscle relaxants. Similarly, hypomagnesemia may become especially profound in patients with cancer and platinum-associated nephropathy. Impairment of glomerular filtration by amphotericin B may enhance plasma levels and, thereby, toxicity of many renally cleared drugs, including aminoglycosides, vancomycin, fluorocytosine, and cyclosporine.[184] Finally, the simultaneous infusion of granulocytes has been associated with acute pulmonary reactions[521] and therefore should be avoided.

INDICATIONS. With the advent of newer antifungal agents and after the completion of pivotal phase III clinical trials, few indications are left for antifungal treatment of opportunistic mycoses with conventional amphotericin B deoxycholate. These indications include candidemia and acute tissue invasive candidiasis, particularly in neonates, and induction therapy for cryptococcal meningitis; however, in the absence of adequate clinical trials, amphotericin B deoxycholate is still a valid option for treatment of severe forms of the endemic mycoses (Tables 252–2 to 252–4). Depending on both the type of infection and the host, the recommended daily dosage ranges from 0.7 to 1.0 mg/kg/day administered over 2 to 4 hours as tolerated.[184]

For empiric antifungal therapy in the persistently febrile neutropenic host, the historical standard dosage is 0.5 to 0.6 mg/kg/day.[126,366] Efficacy of prophylactic intravenous amphotericin B in the setting of anticancer therapy has not been documented,[186] and a large, randomized, multicenter study failed to show any preventive benefit of aerosolized amphotericin B in neutropenic patients at high risk for developing invasive mold infections.[420] However, aerosolized amphotericin B deoxycholate may have a preventive role in patients who have undergone lung transplantation.[120]

On principle, treatment should be started at the full target dose, with careful bedside monitoring during the first hour of infusion to allow for prompt intervention for infusion-related reactions.[486] With the exception of uncomplicated candidemia and induction therapy of cryptococcal meningoencephalitis, the duration of treatment is ill defined for most infections. Prolonged and individualized therapy often is required until complete resolution of the individual disease process, including the use of lipid formulations of amphotericin B, triazoles, and echinocandins for salvage or consolidation therapy.

TABLE 252–2 Medical Management of Invasive Infections by Opportunistic Yeast

Fungal Disease	Management
Esophageal candidiasis	Fluconazole (8-12 mg/kg QD; max, 800 mg QD PO/IV) Itraconazole (2.5 mg/kg BID PO) Voriconazole (4 mg/kg BID PO/IV)* Amphotericin B deoxycholate (0.5-1.0 mg/kg QD) Echinocandin lipopeptides‡
Uncomplicated candidemia or invasive candidiasis	Amphotericin B deoxycholate (0.6-1.0 mg/kg QD IV) Fluconazole (8-12 mg/kg QD; max, 800 mg QD IV) Fluconazole (16 mg/kg QD) plus amphotericin B deoxycholate (0.7 mg/kg QD for day 1 to 5 IV) Voriconazole (4 mg/kg BID IV; day 1:12 mg/kg IV)* Liposomal amphotericin B (3 mg/kg QD IV) Echinocandin lipopeptides‡
Second-line therapy for • Refractory infections • Limiting toxicity	Liposomal amphotericin B (3-5 mg/kg QD IV) Amphotericin B Lipid Complex (5 mg/kg QD IV) Voriconazole (4 mg/kg BID IV; day 1:12 mg/kg)* Amphotericin B deoxycholate (0.7-1.0 mg/kg QD) plus flucytosine† (100 mg/kg/day in 3 to 4 dosages) Echinocandin lipopeptides‡
Cerebral cryptococcosis	Amphotericin B deoxycholate (0.7 mg/kg QD IV) plus flucytosine† (100 mg/kg/d in 3-4 dosages) for ≥2 weeks (induction), followed by fluconazole (8-12 mg/kg QD PO) (consolidation/maintenance) "Second line" for intolerance of amphotericin B deoxycholate: Liposomal amphotericin B (5 mg/kg QD IV); in case of polyen intolerance: fluconazole (8-12 mg/kg QD) plus flucytosine†
Extracerebral manifestations	Amphotericin B deoxycholate (0.7-1.0 mg/kg QD IV) Fluconazole (8-12 mg/kg QD) Amphotericin B deoxycholate (0.7 mg/kg QD) plus flucytosine‡ (100 mg/kg/d in 3-4 dosages)

**IV dosage for patients > 11 years; IV dosage for children from 2 to 11 years: 7 mg/kg QD without loading dose. PO dosage from 2 to 18 years: 200 mg BID.*
†Monitoring of plasma concentrations recommended (>40 bis < 100 μg/mL).
‡For details of pediatric approval status of the three compounds please see text.

§Not approved in pediatric patients; 800 mg/day safely given to children >12 years of age.
¶Proposed pediatric dosage; monitoring of trough concentrations recommended (target: >0.5 μg/mL).

Amphotericin B Lipid Formulations

During the late 1990s, three novel formulations of amphotericin B were approved in the United States and most of Europe: AmB colloidal dispersion (ABCD, Amphocil, or Amphotec), AmB lipid complex (ABLC or Abelcet), and a small unilamellar vesicle (SUV) liposomal formulation (L-AmB, AmBisome). Because of their reduced nephrotoxicity in comparison with deoxycholate amphotericin B, these compounds allow for the safe delivery of higher dosages of the parent. However, data from animal models also suggest that higher dosages are required for equivalent antifungal efficacy.[207,520]

PHYSICOCHEMICAL PROPERTIES AND PHARMACOKINETICS. The carriers of the lipid formulations are composed of biodegradable, amphiphilic bilayered membranes in which the hydrophilic heads of the lipid molecules face outward to shield the hydrophobic tails. The membranes may form either spherical vesicles called liposomes or bilayered complexes or dispersions with no specific vesicular structure. Incorporated into these water-soluble carriers, amphotericin B becomes soluble in plasma and available for distribution. Each of the lipid formulations of amphotericin B possesses distinct physicochemical and pharmacokinetic properties. All three, however, preferentially distribute to organs of the mononuclear phagocytic system (MPS) and functionally spare the kidney. Although the micellar dispersion of ABCD behaves kinetically very similarly to amphotericin B deoxycholate, the small unilamellar liposomal preparation has a prolonged circulation time in plasma, achieves strikingly high C_{max} and area under the concentration versus time curve (AUC) values, and is only slowly taken up by the MPS. In contrast, the large, ribbon-like aggregates of ABLC are efficiently opsonized by plasma proteins and rapidly taken up by the MPS, thus resulting in lower peak plasma and AUC values (Table 252–5).[182,207] Whether and how the distinct physicochemical and pharmacokinetic features of each formulation translate into different pharmacodynamic properties in vivo are largely unknown. However, experimental head-to-head comparisons of all four formulations of amphotericin B against defined invasive mycoses suggest that important differences exist in antifungal efficacy depending on the agent, dose, type, and site of infection.[88,176,340]

SAFETY AND ANTIFUNGAL EFFICACY. Safety and antifungal efficacy of ABCD, ABLC, and L-AmB were demonstrated in an array of phase II and III clinical trials in immunocompromised, mostly adult patients with a wide spectrum of underlying disorders.[92,386,394,488,509] The overall response rates in these trials ranged from 53 to 84 percent in patients with invasive candidiasis and 34 to 59 percent, respectively, in patients with presumed or documented invasive aspergillosis.[182,207] A few randomized, controlled trials were completed in which one of the newer formulations was compared with amphotericin B deoxycholate. These studies consistently showed at least equivalent therapeutic efficacy and reduced nephrotoxicity of the investigated lipid formulation. Infusion-related side effects of fever, chills, and rigor appeared to be less frequent with L-AmB only.[16,485,508,509] Several individual cases of substernal chest discomfort, respiratory distress, and sharp flank pain were noted during infusion of L-AmB,[230,389] and in comparative studies, hypoxic episodes associated with fever and chills occurred more frequently in ABCD recipients than in recipients of the deoxycholate formulation.[62,508] Mild increases in serum bilirubin and alkaline phosphatase have been observed with all three formulations, as well as mild increases in serum transaminases with L-AmB. However, no case of fatal liver disease has occurred.[182,207,520]

EXPERIENCE IN PEDIATRIC PATIENTS. Considerable numbers of pediatric patients have been treated with ABCD,

ABLC, or L-AmB on protocols in the clinical trials cited earlier. Separately published pediatric data are discussed in the following subsections.

ABCD. ABCD is a complex of amphotericin B and sodium cholesteryl sulfate in an approximate 1:1 molar ratio that forms disklike colloidal structures on dissolution.[182] Population-based, multiple-dose pharmacokinetic studies with ABCD in bone marrow transplant recipients with systemic fungal infections included the compartmental analysis of five children younger than 13 years of age who received the compound at 7.0 and 7.5 mg/kg/day. Estimated pharmacokinetic parameters in these children were not significantly different from those obtained in a dose-matched cohort of adult patients: under conditions of steady state, the mean AUC from 0 to 24 hours ($AUC_{0\text{-}24}$) was 7.10 μg/mL/hour (normalized to a 1-mg/kg/day dose), the mean volume of distribution was 4.57 L/kg, and the mean total clearance was 0.144 L/hour/kg.[9]

A double-blind, randomized trial comparing ABCD (4 mg/kg/day) with D-AmB (0.8 mg/kg/day) for empiric antifungal therapy of febrile neutropenic patients separately reported safety data from 46 children (≥2 to <16 years of age) either randomized to ABCD (n = 25) or D-AmB (n = 21). ABCD was overall significantly less nephrotoxic than was D-AmB, and no differences in adverse events and efficacy were reported as compared with the (much larger) adult study population.[508] An additional 70 children (0 to 15 years; mean, 8.8 years) with presumed or proven invasive fungal infections refractory to or intolerant of amphotericin B were treated on five different open-label studies of ABCD. The dosages ranged from 0.8 to 7.5 mg/kg (mean, 4.5 mg/kg), administered for a mean of 30 days (range, 1 to 192). Although 67 percent of patients reported infusion-related reactions, nephrotoxicity, defined as an increase in serum creatinine to two times or greater the baseline value, was reported in only 12 percent. Other unexpected toxicities were not observed.[406]

The published experience in the neonatal setting is limited to 16 very-low-birth-weight infants (779 ± 170 g; 25 ± 2 weeks) with invasive candidiasis and a serum creatinine concentration of 1.2 mg/dL or greater.[278] Infants received 3 mg/kg ABCD on day 1, followed by 5 mg/kg/day thereafter; a second agent was permitted for candidemia that persisted for 7 or more days. Thirteen of 14 evaluable patients cleared the organism after therapy with ABCD alone (n = 8) or in combination with another agent (n = 5), and overall survival was 75 percent. ABCD was well tolerated without infusion-related reactions, increases in serum creatinine, hepatotoxicity, or hepatotoxicity.

These data overall indicate no fundamental differences in disposition, safety, and antifungal efficacy of ABCD in comparison with adult populations. The U.S. Food and Drug Administration (FDA)–approved indication is treatment of probable or proven invasive aspergillosis refractory to or intolerant of ampho-

Modified from Groll, A. H., Muller, F. M., Piscitelli, S. C., and Walsh, T. J.: Lipid formulations of amphotericin B: Clinical perspectives for the management of invasive fungal infections in children with cancer. Klin. Padiatr. 210:*264-273, 1998.*

tericin B deoxycholate, and the approved dosage is 3 to 4 mg/kg/day, administered over the course of 2 hours.

ABLC. ABLC is composed of dimyristoyl phosphatidylcholine/dimyristoyl phosphatidylglycerol (DMPC/DMPG) in a 1:1 molar ratio of lipid to amphotericin B and forms large, ribbon-like structures. The pharmacokinetic properties of ABLC were studied in whole blood in three pediatric patients with cancer who received the compound at 2.5 mg/kg over the course of 6 weeks for hepatosplenic candidiasis.[498] Steady state was achieved by day 7 of therapy; following the final dose, the mean $AUC_{0\text{-}24}$ was 11.9 ± 2.6 μg/mL/hour, the mean C_{max} was 1.69 ± 0.75, and clearance was 0.218 L/kg/hour. In the six patients evaluable for safety assessment, mean serum creatinine levels were stable at the end of therapy and at 1-month follow-up, and no increase in hepatic transaminases occurred. Five of the patients had infusion-related reactions to the first dose, which was prospectively monitored without prior premedication; however, infusion-related adverse reactions were well controlled thereafter by conventional premedications. All evaluable patients responded to therapy.

Safety and antifungal efficacy of ABLC were studied in 111 treatment episodes in pediatric patients (21 days to 16 years of age) refractory of or intolerant to conventional antifungal agents through an open-label, emergency-use protocol in the United States.[496] ABLC was administered at a mean daily dosage of 4.85 mg/kg (range, 1.1 to 9.5 mg/kg/day) for a mean duration of 38.9 days (range, 1 to 198 days). The mean serum creatinine for the entire study population did not significantly change between baseline (1.23 ± 0.11 mg/dL) and cessation of ABLC therapy (1.32 ± 0.12 mg/dL) during 6 weeks. No significant differences were observed between baseline and end-of-therapy levels of serum potassium, magnesium, hepatic transaminases, alkaline phosphatase, and hemoglobin. However, an increase in the mean total bilirubin (3.66 ± 0.73 to 5.13 ± 1.09 mg/dL) occurred at the end of therapy ($p = .054$). In 7 patients (6%), ABLC therapy was discontinued because of one or more adverse effects, and in 6 patients (5%), ABLC was discontinued because of progression of disease. Among 54 cases fulfilling criteria for evaluation of antifungal efficacy, a complete or partial therapeutic response was obtained in 38 patients (70%).

The safety and efficacy of ABLC also were assessed in 548 children and adolescents who were enrolled in the Collaborative Exchange of Antifungal Research (CLEAR) registry of the manufacturer between 1996 and 2000. Most patients were either intolerant of or refractory to conventional antifungal therapy. Response data were evaluable for 255 of the 285 patients with documented single or multiple pathogens. A complete (cured) or partial (improved) response was achieved in 54.9 percent of patients. No significant difference was noted between the rates of new hemodialysis versus baseline hemodialysis. Elevations in serum creatinine of greater than 1.5 times baseline and greater than 2.5 times baseline values were seen in 24.8 and 8.8 percent of all patients, respectively. The overall response rate and safety profile in pediatric patients were consistent with earlier reported findings of smaller trials.[513]

Eleven infants aged 6 months and younger with candidemia were enrolled on the U.S. open-label, emergency-use protocol[496] and received 5 to 41 daily doses of ABLC; these infants were between 3 and 13 weeks of age and weighed between 0.8 and 5 kg. Seven of the 11 patients maintained a stable mean serum creatinine; in 4 patients, a rise in serum creatinine was observed, but in each case, the increase was less than 40 percent of the baseline value. No differences were observed between baseline and end-of-therapy mean bilirubin levels. Among the 8 evaluable infants, a complete response was observed in 6 (75%).[496]

A population pharmacokinetic study in 28 mostly immature neonates with invasive *Candida* infections demonstrated that the disposition of ABLC in neonates is similar to that observed in other age groups: weight was the only factor that influenced clearance. Based on the results of this study and a cure rate of greater than 80 percent, a dosage of 2.5 to 5.0 mg/kg is recommended for treatment of neonatal candidiasis.[522]

The current data suggest no fundamental differences in disposition, safety, and antifungal efficacy of ABLC as compared with adults. The FDA-approved indication is treatment of invasive fungal infections refractory to or intolerant of amphotericin B deoxycholate, and the approved dosage is 5 mg/kg/day administered over the course of 2 hours.

L-AmB. L-AmB consists of small, unilamellar spherical vesicles (true liposomes) composed of hydrogenated soy phosphatidylcholine and distearoyl phosphatidylglycerol stabilized by cholesterol and combined with amphotericin B in a 2:0.8:1:0.4 molar ratio.[173] The pharmacokinetic properties of L-AmB in pediatric patients beyond the neonatal period were investigated in a formal phase II, dose-escalation trial investigating dosages of 2.5, 5.0, and 7.5 mg/kg in immunocompromised patients, as well as by using a population-based approach. The results of these studies indicate that the disposition of L-AmB in pediatric patients is not substantially different from that in adults and that weight is a covariate that determines clearance and volume of distribution.[211,424] A pharmacokinetic pilot study was conducted in 12 children at risk for developing invasive fungal infections who received once-weekly, high-dose L-AmB (10 mg/kg over 2 hours) as prophylaxis. L-AmB was well tolerated and showed measurable amphotericin B plasma concentrations 7 days after the dose, a finding suggesting that once-weekly administration may provide useful protection against fungal infections.[303]

Many pediatric patients have been enrolled on clinical trials with L-AmB but have not been reported separately.[307,485] Two hundred four children (mean age, 7 years) with neutropenia and fever of unknown origin were randomized in an open-label, multicenter trial to receive conventional amphotericin B deoxycholate at 1 mg/kg/day ($n = 63$), L-AmB at 1 mg/kg/day ($n = 70$), or L-AmB at 3 mg/kg/day ($n = 71$) for empiric antifungal therapy.[370] Twenty-nine percent of patients treated with L-AmB 1, 39 percent of patients treated with L-AmB 3, and 54 percent of patients treated with AMBD experienced adverse effects ($p = .01$); nephrotoxicity, defined as 100 percent or more increase in serum creatinine from baseline, was noted in 8, 11, and 21 percent, respectively (NS). Hypokalemia (<2.5 mmol/L) occurred in 10, 11, and 26 percent of patients, respectively ($p = .02$); increases in serum transaminase levels (≥110 U/L) occurred in 17, 23, and 17 percent, respectively (NS); and increases in serum bilirubin (≥35 μmol/L) occurred in 11, 12, and 10 percent of patients, respectively. Efficacy assessment by intent-to-treat analysis indicated successful therapy in 51 percent of children treated with AMBD and 64 or 63 percent in children treated with L-AmB at either 1 or 3 mg/kg/day ($p = .22$), respectively. L-AmB at either 1 or 3 mg/kg/day was significantly safer and at least equivalent to AMBD with regard to resolution of fever of unknown origin. L-AmB was well tolerated and effective in cohorts of immunocompromised children requiring antifungal therapy for proven or suspected infections, including patients with bone marrow transplants for primary immunodeficiencies[352] and patients with cancer.[387] A phase IV analysis of 141 courses of L-AmB administered for a mean of 17 days' duration at a mean maximum dosage of 2.5 mg/kg for various indications to pediatric patients with cancer and hematopoietic stem cell transplantation (HSCT) revealed a low rate of adverse events (4%), necessitating discontinuation. Whereas mean aspartate aminotransferase, alanine aminotransferase, alkaline phosphatase, and bilirubin values were slightly higher at the end of treatment ($p < .01$), bilirubin and creatinine values were not different from baseline. L-AmB had acceptable safety and tolerance and displayed efficacy in prevention and treatment of invasive fungal infections.[250]

L-AmB (2.5 to 7 mg/kg/day) was evaluated prospectively in 24 very-low-birth-weight infants (mean birth weight, 847 ± 244 g; mean gestational age, 26 weeks) with systemic candidiasis. In 13 infants, previous antifungal therapy with amphotericin B (with or without 5-flucytosine) had failed. *Candida* spp. were isolated from the blood in all 25 episodes and from skin abscesses and urine in 4 infants each, respectively. The mean duration of therapy was 21 days; the cumulative L-AmB dose was 94 mg/kg. Fungal eradication was achieved in 92 percent of the episodes; 20 (83%) infants were considered clinically cured at the end of treatment. No major adverse effects were recorded. One infant developed increased bilirubin and hepatic transaminase levels during therapy. Four (17%) infants died; in 2 of them (8%), the cause of death was attributed directly to systemic candidiasis.[233] In a second study undertaken by the same investigators, high-dose (5 to 7 mg/kg/day) L-AmB was evaluated prospectively in 41 episodes of systemic candidiasis occurring in 37 neonates (36 of the 37 were premature infants with very low birth weights). *Candida* spp. were isolated from blood in all patients and from urine, skin abscesses, and peritoneal fluid in 6, 5, and 1 neonates, respectively. Twenty-eight, 5, and 8 infants received 7, 6 to 6.5, and 5 mg/kg/day, respectively. Median duration of therapy was 18 days; median cumulative dose was 94 mg/kg. Fungal eradication was achieved in 39 of 41 (95%) episodes. One patient died of systemic candidiasis on day 12 of therapy. High-dose L-AmB was effective and safe in the treatment of neonatal candidiasis. Fungal eradication was achieved more rapidly in patients treated early with high doses and in patients who received high-dose L-AmB as first-line therapy.[232]

Current data indicate no substantial differences in pharmacokinetics and pharmacodynamics of L-AmB between pediatric and adult patients. The FDA-approved dosages are 3 mg/kg/day (empiric antifungal therapy in febrile neutropenic patients), 3 to 5 mg/kg/day (therapy of invasive infections intolerant or refractory to amphotericin B deoxycholate), and 6 mg/kg/day for cryptococcal meningitis, administered over the course of 2 hours.

INDICATIONS. The lipid formulations of AmB represent an important therapeutic advance in the management of invasive opportunistic fungal infections in immunocompromised patients. All three compounds have less renal toxicity than does conventional amphotericin B as defined by development of azotemia; distal tubular toxicity also may be somewhat reduced. Infusion-related reactions of fever, chills, and rigor appear to occur substantially less frequently only with L-AmB, and no new toxicities have been noted. The available pharmacokinetic and safety data from children so far indicate no fundamental differences from data obtained in the adult population.

Therapeutically, the lipid formulations are at least as effective as is conventional amphotericin B for treatment of most opportunistic human mycoses, and these formulations can be effective if conventional amphotericin B has failed. They may be indicated when toxicity prohibits the administration of effective dosages of AMBD and when standard therapies fail to induce a therapeutic response against an organism susceptible to amphotericin B. The experience with life-threatening endemic mycoses, however, is limited. The lipid formulations currently are approved for the treatment of patients with invasive mycoses refractory of or intolerant to AMBD, and, limited to L-AmB, for empiric therapy of persistently neutropenic patients (see Tables 252–2 to 252–4).

FLUCYTOSINE

Flucytosine (5-fluorocytosine) is a low-molecular-weight, water-soluble, synthetic fluorinated pyrimidine analogue (Fig. 252–3). It is taken up into the fungal cell by the fungus-specific enzyme cytosine permease and is converted in the cytoplasm by cytosine deaminase to 5-fluorouracil, a potent antimetabolite that causes RNA miscoding and inhibits DNA synthesis (Fig. 252–4).[119] Flucytosine is relatively nontoxic to mammalian cells because of the absence or very low level of activity of cytosine deaminase. In the United States, flucytosine is available only as oral formulation; an intravenous formulation is available outside the United States in select countries.

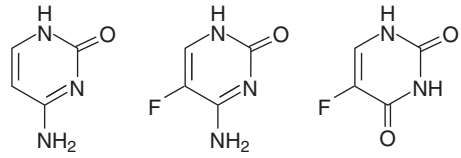

Figure 252–3 Structural formulas of cytosine, flucytosine, and fluorouracil.

ANTIFUNGAL ACTIVITY. The antifungal activity of flucytosine in vitro is essentially limited to *Candida* spp., *C. neoformans*, *Cryptococcus gattii*, *Saccharomyces cerevisiae*, *Rhodotorula* spp. and some dematiaceous molds.[114,140,209,360,362,456] Flucytosine generally is thought to have no or weak activity against *Aspergillus* spp. and other hyaline molds,[153,295] although this lack of activity in vitro may be pH-dependent[444] and does not correlate with the documented efficacy in animal models.[446] Notably, whereas *Candida krusei* appears to be less susceptible to flucytosine, the compound is highly active against *Candida glabrata*.[119,140,360] Synergistic or additive effects in combination with amphotericin B have been observed against *Candida*[302,314] and *Aspergillus* spp.[445] and in combination with amphotericin B, fluconazole, voriconazole, and posaconazole against *C. neoformans*.[34,194,302,332,422] Combination with echinocandins was additive or indifferent in vitro against *Candida* spp.[235]

Two mechanisms of resistance have been reported: (1) mutations in enzymes necessary for cellular uptake and transport of flucytosine or its metabolism and (2) increased synthesis of pyrimidine that competes with the fluorinated antimetabolites of the compound.[117,477] In pretreatment isolates, intrinsically resistant strains have been found in 3 to 8 percent of *C. albicans*, in 0 to 8 percent of non-*albicans Candida* spp., and in 2 percent or less of *C. neoformans* isolates.[301,360] In an analysis of 8803 clinical isolates of *Candida* spp. (18 species) obtained from more than 200 medical centers worldwide between 1992 and 2001 that used the broth microdilution test according to National Committee on Clinical Laboratory Standards guidelines, primary resistance to flucytosine was an uncommon occurrence among *Candida* spp. (95% sensitive, 2% intermediate, and 3% resistant), with the exception of *C. krusei* (5% sensitive, 67% intermediate, and 28% resistant).[360] Development of resistance to flucytosine can be observed during treatment,[140] and it is thought to be caused predominantly by selection of resistant clones.[477] As a consequence, flucytosine is rarely given alone but instead is given in combination with amphotericin B or fluconazole.

PHARMACODYNAMICS. Time-kill assays against *Candida* spp. and *C. neoformans* demonstrated a predominantly concentration-independent fungistatic (99% reduction in colony-forming units) activity of flucytosine at concentrations exceeding the MIC of the investigated isolates.[275,467] A prolonged PAFE against these organisms was noted consistently that was dependent on concentration and duration of exposure and ranged from 0.8 to 10 hours.[413,526] In addition, synergistic PAFEs were demonstrated with flucytosine in combination with fluconazole and amphotericin B, respectively, against *C. albicans*.[309,413,414] Investigation of pharmacokinetic and pharmacodynamic relationships in a neutropenic mouse

model of disseminated candidiasis that used the residual fungal burden in kidney tissue as the end-point of antifungal efficacy revealed that both the time above the MIC and the AUC/MIC ratio were important in predicting efficacy; the peak level/MIC ratio was the least important parameter. Maximal efficacy was observed when levels exceeded the MIC for only 20 to 25 percent of the 24-hour dosing interval.[18] In experiments that used a pharmacodynamic model of disseminated candidiasis and bridging to humans by population pharmacokinetics and Monte Carlo simulation, an in vivo drug exposure breakpoint for flucytosine was apparent when serum levels were greater than the MIC for 45 percent of the dosing interval. The Monte Carlo simulations suggested that, using a human dose of 100 mg/kg/day in four divided doses, flucytosine resistance was defined at an MIC of 32 mg/L. Target attainment rates after administration of 25, 50, and 100 mg/kg/day were similar.[213] These data collectively suggest that lower dosages or less frequent dosing may yield identical antifungal efficacy while further reducing potential toxicities of flucytosine that are thought to be concentration-dependent.[140]

PHARMACOKINETICS. Flucytosine is absorbed readily from the gastrointestinal tract, and oral bioavailability exceeds 80 percent (Table 252–6). C_{max} occurs 1 to 2 hours after administration. As a water-soluble compound, flucytosine has negligible protein binding (4%) and is widely distributed in the body, with a volume of distribution that approximates that of total body water. Mean CSF concentrations usually are 65 to 90 percent of simultaneous plasma concentrations. The drug penetrates well into peritoneal fluid, inflamed joints, and other fluid compartments, including the eye.[99,184]

In humans, less than 1 percent of a given dose of flucytosine is thought to undergo hepatic metabolism. In addition to 5-fluorouracil, several other metabolites of yet unclear toxic potential have been identified.[289] Some evidence suggests that bacteria of the gastrointestinal flora deaminate flucytosine to resorbable 5-fluorouracil,[196,289] a finding that may account for some of the toxicities observed after oral administration of the drug. Approximately 95 percent of a given dose of flucytosine is excreted into the urine in unchanged, active form by simple glomerular filtration, and the plasma elimination half-life is 3 to 6 hours in adult patients with normal renal function.[184] Because the compound's elimination parallels the glomerular filtration rate, adjustment of the dosage is necessary in patients with impaired renal function.[99] In patients undergoing hemodialysis, a dose of 37.5 mg/kg is recommended following dialysis,[51] and in those undergoing hemofiltration, the dosage needs to be adjusted to the individual filtration rate.[222,268] In peritoneal dialysis, the compound can be administered systemically or intraperitoneally.[308] Although the data are limited, impaired liver function does not appear to alter the disposition of flucytosine.[99]

In infants and children, the pharmacokinetic properties of flucytosine have not been systematically characterized thus

TABLE 252–6 Pharmacokinetics of Flucytosine in Adults

Parameter or Characteristic	Value
Oral bioavailability	≥80%
C_{max}	50-120 μg/mL*
T_{max}	1-2 hr
Protein binding	4%
Vd_{ss}	0.6-0.7 L/kg
$t_{1/2}$beta	3-6 hr
Clearance	≥95% renal
Unchanged drug in urine	≥95%
Relative cerebrospinal fluid levels	65%-90%

**At steady state in patients with cryptococcal meningitis receiving 4 × 2 g/day PO.*
C_{max}, peak plasma concentration; T_{max}, time until occurrence of peak plasma concentration; Vd_{ss}, volume of distribution at steady state.
Modified from Groll, A. H., Piscitelli, S. C., and Walsh, T. J.: Antifungal pharmacodynamics: Concentration-effect relationships in vitro and in vivo. Pharmacotherapy 21(Suppl. 8):133-148, 2001.

far. However, because of very similar physicochemical and pharmacokinetic properties, developmental changes in disposition similar to those found with fluconazole can be anticipated. Indeed, a similarly marked interindividual variability in clearance and volume of distribution has been reported in neonates[31] that renders uniform dosing recommendations in this population impossible.

A starting dosage for both adults and children of 100 mg/kg daily divided into three or four doses is recommended currently. Monitoring of plasma concentrations is essential to adjust dosage to changing renal function and to avoid toxicity. After oral administration, near peak levels 2 hours after dosing overlap with trough levels as patients reach steady state, and thus these levels are sufficient for therapeutic monitoring.[140] In practice, plasma levels between 40 (trough) and less than 100 μg/mL (peak) correlate with antifungal efficacy and seldom are associated with hematologic adverse effects.[140,478] However, retrospective evaluations in the United Kingdom revealed that only a fraction of plasma levels ordered for therapeutic monitoring were in this concentration range.[353,435]

ADVERSE EFFECTS. Common adverse effects associated with flucytosine, effects that occur in 5 to 6 percent of patients, include gastrointestinal intolerance and reversible elevations of hepatic transaminases and alkaline phosphatase. Rarer side effects are skin rashes, blood eosinophilia, and crystalluria.[184]

Hematologic adverse effects have been reported in overall 6 percent of patients receiving oral flucytosine and may include neutropenia, thrombocytopenia, or pancytopenia. Although these effects usually are reversible after discontinuation of the drug or dosage reduction, fatal outcomes have been reported.[140,184] Some of the adverse effects of flucytosine may result either from conversion of the compound to 5-fluorouracil by the gastrointestinal bacterial flora[196,289] or from toxic effects of endogenously produced metabolites. Notably, hematologic adverse effects occur less frequently if plasma levels of flucytosine do not exceed 100 μg/mL.[140,278] However, this relationship is not absolute, and hematologic toxicity may occur at levels much lower than threshold.

DRUG INTERACTIONS. Orally administered, nonresorbable antibiotics and administration of aluminum/magnesium hydroxide–based antacids may delay but do not impair absorption of the compound from the gastrointestinal tract.[184] Flucytosine undergoes only minor hepatic metabolism, and it is not known to interfere with the cytochrome P-450 enzyme system. However, any drug that can cause a reduction in the glomerular filtration rate may lead to increased flucytosine serum levels and thereby has the potential to enhance flucytosine-associated toxicity. This phenomenon almost invariably is encountered with concomitant administration of amphotericin B, but it can occur similarly with numerous antimicrobial agents, anticancer drugs, and cyclosporine, to name only the most common examples.[99] The anticancer drug cytosine arabinoside competitively inhibits the action of flucytosine, and these drugs should not be given concomitantly.[77]

CLINICAL INDICATIONS. Because of the propensity of susceptible organisms to develop resistance in vitro,[367] flucytosine traditionally is not administered as a single agent. Ample laboratory and clinical experience exists regarding the combination of conventional amphotericin B and flucytosine (see Table 252–2).[119,184,477] Randomized clinical trials established the use of amphotericin B in combination with flucytosine as standard for induction therapy of cryptococcal meningitis in non–human immunodeficiency virus (HIV)-infected and HIV-infected patients.[43,468] Indeed, a small but well-designed trial demonstrated that the clearance of cryptococci from the CSF was significantly faster with amphotericin B in combination with flucytosine than with amphotericin B alone, amphotericin B in combination with fluconazole, or triple therapy, a finding confirming that the combination is the most rapidly fungicidal regimen.[66]

Although no comparative trials have been performed, the cumulative clinical experience supports the combination of amphotericin B with flucytosine for the treatment of *Candida* infections involving deep tissues, particularly in critically ill patients and when non-*albicans Candida* spp. are involved.[140,215,296,448] This includes *Candida* meningitis, endophthalmitis, endocarditis, vasculitis, and peritonitis, as well as osteoarticular, renal, and disseminated candidiasis.[184,486] Susceptibility of *Aspergillus* spp. to flucytosine in vitro is controversial,[153,295,444] and high-dose amphotericin B in combination with flucytosine compared with high-dose amphotericin B alone in the treatment of invasive aspergillosis has not been investigated. Although the combination has been employed in cases of successful treatment of invasive aspergillosis,[69,106,236] its role remains unclear.

Investigators also have begun to explore combinations of flucytosine with fluconazole.[184] The combination of flucytosine with fluconazole has been studied in a prospective study in 32 patients with acquired immunodeficiency syndrome (AIDS) and cryptococcal meningitis. Clinical and microbiologic responses were superior to those reported with either amphotericin B or fluconazole alone but not as favorable as those documented for the combination of amphotericin B and flucytosine.[267] Thus, flucytosine in combination with fluconazole may be used for cryptococcal meningitis, when treatment with conventional or liposomal amphotericin B is not feasible. In addition, this combination also may be useful as second-line therapy for individual patients with invasive *Candida* infections involving aqueous body compartments.

Flucytosine has demonstrated impressive therapeutic efficacy against chromoblastomycosis[281] and significant activity in murine models of phaeohyphomycosis.[52,116] Given the high case-fatality rate of invasive phaeohyphomycoses in humans, further investigation of flucytosine in combination with other antifungal compounds against these infections appears warranted.

ANTIFUNGAL TRIAZOLES

The antifungal azoles are a class of synthetic compounds that have one or more azole rings and—attached to one of the nitrogen atoms—a more or less complex side chain. Whereas the imidazoles have two, the triazoles have three nitrogen atoms in the five-member ring. The triazole ring confers improved resistance to metabolic degradation, greater target specificity, and an expanded spectrum of activity.[167,168] The imidazoles miconazole and ketoconazole (Fig. 252–5) were the first azole compounds developed for systemic treatment of human mycoses. Severe toxicities associated with the drug carrier (miconazole) and erratic absorption and significant interference with the human cytochrome P-450 system (ketoconazole), however, have limited their clinical usefulness.[184] The triazoles fluconazole and itraconazole (Fig. 252–6), in contrast, have become extremely useful components of the antifungal armamentarium. Overall, they are well tolerated and possess a broad spectrum of activity. Whereas fluconazole and itraconazole have been available since the 1990s, a new generation of antifungal triazoles has entered clinical practice more recently; these so-called second-generation triazoles include voriconazole and posaconazole (Fig. 252–7).

MECHANISM OF ACTION. The antifungal azoles, as a class, target ergosterol biosynthesis by inhibiting the fungal cytochrome P-450–dependent enzyme lanosterol 14α-demethylase. This inhibition interrupts the conversion of lanosterol to ergosterol and thus leads to accumulation of aberrant 14α-methylsterols and depletion of ergosterol in the fungal cell mem-

brane (Fig. 252–8). These effects alter cell membrane properties and function and, depending on organism and compound, may lead to cell death or inhibition of cell growth and replication. In addition, the azoles also inhibit cytochrome P-450–dependent enzymes of the fungal respiration chain, but the contribution of this action to their overall activity is unclear. Interaction with structurally similar mammalian cytochrome P-450–dependent enzyme systems is responsible for most toxicities and drug interactions of this class of compounds.[184,470]

ANTIFUNGAL ACTIVITY. Fluconazole and itraconazole are active principally against dermatophytes, *Candida* spp., *C. neoformans*, *C. gattii*, *T. asahii*, and other uncommon yeast organisms, as well as against dimorphic fungi such as *Histoplasma capsulatum*, *Coccidioides immitis*, *Blastomyces dermatitidis*, *Paracoccidioides brasiliensis*, and *Sporothrix schenkii*.[167,168,456] These drugs have less activity against *C. glabrata* and none against *C. krusei*.[184,383] Clinically useful activity against *Aspergillus* spp. and dematiaceous molds is restricted to itraconazole, and both itraconazole and fluconazole are considered inactive against *Fusarium* spp. and the Zygomycetes.[184] The second-generation triazoles voriconazole and posaconazole have enhanced target activity and are active against a wide spectrum of clinically important fungi, including *Candida* spp., *T. asahii*, *C. neoformans*, *Aspergillus* spp., *Fusarium* spp. and other hyaline molds, as well as dematiaceous and dimorphic molds.[5,81,84,87,184] In contrast to fluconazole and itraconazole, both agents are active against *C. glabrata* and *C. krusei*; posaconazole also is active against Zygomycetes, a feature that distinguishes it from all current azole compounds.[172]

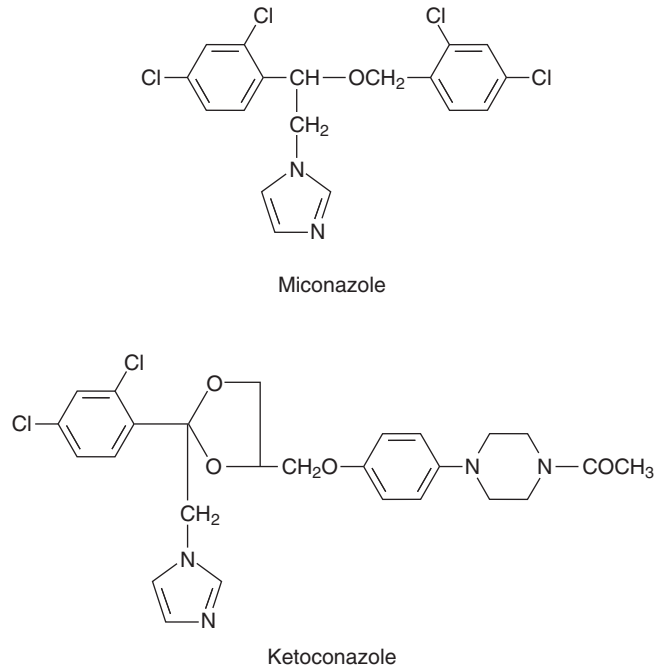

Figure 252–5 Structural formulas of systemic antifungal imidazoles: miconazole and ketoconazole.

RESISTANCE. Selection and nosocomial spread of azole-resistant *Candida* spp. have become matters of concern in hospitalized or persistently immunocompromised patients. Several mechanisms of resistance have been identified and include, but are not limited to, molecular alterations at the target binding site, increased target expression, and induction of cellular efflux pumps.[407,510] In contrast to pathogenic bacteria, genetic exchange mechanisms are largely unknown in fungi. Exposure-induced cumulative molecular events that lead to stable azole resistance have been reported; however, in the clinical setting, resistance is encountered most commonly in the form of a primarily resistant species or through selection of resistant subclones during exposure to azoles.[383,510]

Acquisition of microbiologic and clinical azole resistance was reported first in patients with chronic mucocutaneous candidiasis who were receiving long-term therapy with ketoconazole.[216] In the 1990s, before the advent of highly active antiretroviral therapy (HAART), azole-resistant oropharyngeal and esophageal candidiasis became a major clinical conundrum in patients with advanced HIV infection.[377,393] Emergence of *C. glabrata* and *C. krusei* infections in association with fluconazole prophylaxis has been observed in several bone marrow transplant centers[226,300,516,517] and in large cancer centers.[252] However, a large prospective series from Seattle showed an altogether low incidence of breakthrough candidemia (4.6%; in two thirds caused by *C. glabrata* or *C. krusei*)

and a low attributable mortality (20%) in patients receiving fluconazole prophylaxis despite frequent colonization with fluconazole-resistant *Candida* spp.[300] Although cross-resistance of *Candida* spp. to antifungal azoles is a common occurrence,[36,162,320,355] it is not obligate: for example, patients with microbiologic and clinical fluconazole-resistant mucosal candidiasis may respond to itraconazole or second-generation triazoles.[200,400] Nonetheless, patients who have been exposed to azoles and who have breakthrough candidemia or an azole-resistant *Candida* isolate have a high likelihood of cross-resistance, and treatment with alternative agents is advised.[288,347] Acquired resistance to azoles was documented in a few patients with *C. neoformans* meningitis who were receiving maintenance therapy, but little is known about the frequency and mechanisms of secondary azole resistance and cross-resistance in filamentous fungi.[80,184,312]

Fluconazole

Fluconazole is a synthetic, low-molecular-weight, water-soluble *bis*-triazole (see Fig. 252–6). In comparison with ketoconazole, the compound has similar potency at the target enzyme but is much more specific and therefore is better tolerated. Fluconazole is active against *Candida* spp., *C. neoformans*, *C. gattii*, *T. asahii*, and endemic dimorphic fungi, but not against *Aspergillus* spp. and other hyaline or dematiaceous molds. Fluconazole has intermediate activity against *C. glabrata* and is inactive against *C. krusei*.[160,168,361,456]

PHARMACODYNAMICS. Fluconazole generally is considered to be a fungistatic agent.[185] Time-kill assays performed over incubation periods of 24 to 48 hours in susceptible *Candida* spp. and *C. neoformans* showed fungistatic activity of fluconazole with variable concentration-related growth effects.[70,71,112,245,246] However, time-kill studies that used extended periods of incubation up to 14 days and nonproliferating growth conditions demonstrated direct fungicidal activity of fluconazole against *C. albicans*.[434] These observations raise the possibility that fluconazole may ultimately be able to eliminate *Candida* spp. without help from host defenses. In serum-free growth media, fluconazole displays no measurable PAFE against *C. albicans* and *C. neoformans*, but concentration-dependent PAFEs of 1 to 3.6 hours were observed in the presence of fresh serum. Finally, pretreatment of *C. albicans* with fluconazole increased its vulnerability to killing by polymorphonuclear leukocytes.[130,310]

In vivo pharmacodynamic studies of fluconazole in murine models of disseminated *C. albicans* candidiasis using the fungal burden in kidney tissue as an end-point for antifungal efficacy collectively suggested that the AUC/MIC ratio is the pharmacodynamic parameter that best predicts antifungal efficacy of fluconazole[17,284,436] and that dosing regimens that produce prolonged sub-MIC concentrations are associated with development of

resistance.[19] Pharmacodynamic studies of fluconazole in patients with fungal infections have not been presented to date. The dose-independent pharmacokinetics and the available experimental and clinical data are in support of once-daily dosing regimens. Current susceptibility breakpoints and dosing recommendations for fluconazole against *Candida* spp. have been derived from MIC and outcome information of patients with mostly superficial *Candida* infections.[382] The feasibility of this approach is supported not only by the pharmacodynamic models discussed earlier and several animal studies that have demonstrated a correlation between MIC and antifungal efficacy[13,33,390,487] but also by an analysis of 1295 patient-episode-isolate events from 12 published clinical studies that demonstrated success rates of 85 percent for those episodes in which the fluconazole MIC was 8 μg/mL or less, 67 percent for those episodes in which the MIC was 16 to 32 μg/mL, and 42 percent for those episodes with resistant (MIC = 64 μg/mL) isolates.[359] However, in view of the availability of alternative agents, treatment of serious invasive mycoses caused by organisms in the susceptible-dose dependent MIC range by dose escalation remains controversial.

PHARMACOKINETICS. Fluconazole has favorable pharmacokinetic properties. It is available for oral and parenteral use, and its disposition is independent of route and formulation. Fluconazole exhibits linear plasma pharmacokinetics that fit best into a two-compartment open model.[65]

Independent of food or intragastric pH, the oral bioavailability of fluconazole is greater than 90 percent. C_{max} occurs 1 to 2 hours after ingestion. Multiple dosing increases C_{max} approximately 2.5-fold. Steady state generally is reached within 4 to 7 days after once-daily dosing, but it can be achieved rapidly by doubling the dose on the first day.[160,168] Because of the free solubility in water of this drug, protein binding is low. Fluconazole distributes well into virtually all tissue sites and body fluids. The ratio of CSF and serum concentrations ranges from 0.5 to 0.9 during the dosing interval, and penetration into brain tissue and the different compartments of the eye is excellent. Fluconazole is relatively stable to metabolic conversion; more than 90 percent of a dose is excreted by the kidney, with approximately 80 percent recovered as unchanged, active drug and 11 percent recovered as inactive metabolites.[65,160,168] Because excretion of fluconazole parallels the glomerular filtration rate, the dosage must be adjusted in patients with renal failure. A 50 percent reduction is required in patients with a creatinine clearance of 50 mL/minute or less, and a 75 percent reduction is required in patients with a creatinine clearance of less than 21 mL/minute; the initial loading dose need not be adjusted.[48,168] Fluconazole is dialyzable; in patients undergoing hemodialysis, 100 percent of the target dose is given after each dialysis session. In continuous venovenous hemofiltration and hemodiafiltration, dosing at the higher end of the dosing range (i.e., 800 mg/day in adults) is suggested. A dose of 150 mg in a single 2-L dialysate bag has been used for continuous ambulatory peritoneal dialysis.[147,160,321,333,418,453] Hepatic insufficiency per se does not require adjustments of dosing, but careful monitoring of additional hepatic toxicity is required.[395]

The plasma pharmacokinetic properties of fluconazole in pediatric age groups reflect developmental changes in the volume of distribution and clearance that are characteristic for a highly water-soluble drug with minor metabolism and predominantly renal elimination (Table 252–7). Except for premature neonates, in whom clearance initially is decreased, pediatric patients tend to have an increased weight-normalized clearance rate from plasma that leads to a shorter half-life in comparison with that in adults.[64,262,272,412,423,451] As a consequence, dosages at the high end of the recommended dosage range are necessary for the treatment of invasive mycoses in children. Because exposure over the course of time appears to be the most predictive pharmacodynamic parameter,[17,284] fractionating the dose is not required in infants and children, despite the shorter half-life in these age groups.

TABLE 252–7 Pharmacokinetic Parameters of Fluconazole in Pediatric Patients*

Age Group	Vd_{ss} (L/kg)	Cl (L/hr/kg)	$t_{1/2}$beta (hr)
Preterm <1500 g			
Day 1	1.18	0.010	88
Day 6	1.84	0.019	67
Day 12	2.25	0.031	55
Term neonates	1.43	0.036	28
Infants >1-6 mo	1.02	0.037	19
Children, 5-15 yr	0.84	0.031	18
Adult volunteers	0.65	0.015	30

**Data represent mean values.*
Cl, total plasma clearance; $t_{1/2}$beta, elimination half-life; Vd_{ss}, apparent volume of distribution at steady state.
Data from references 64, 262, 272, 323, 412, and 423.

ADVERSE EFFECTS. In adults, fluconazole has been administered safely over prolonged periods of time at dosages of up to 1200 mg/kg/day; dose-escalation to 1600 mg/day resulted mainly in increased hepatotoxicity, and dose-limiting neurotoxicity was observed at 2000 mg/day.[14] Compiled data from adult patients who received the drug at dosages of 100 to 400 mg/day over the course of at least 7 days indicate an overall incidence of possibly related adverse effects of 16 percent; significant adverse effects or laboratory abnormalities leading to the discontinuation of the drug were noted in overall 2.8 percent.[168] Nausea, vomiting, and other gastrointestinal symptoms are seen in fewer than 5 percent, skin rashes and headaches in fewer than 2 percent, and usually reversible, asymptomatic hepatic transaminase elevations were reported in as many as 7 percent of adult patients.[89,168]

In pediatric patients of all age groups, at dosages up to 12 mg/kg/day, fluconazole generally is well tolerated. The most common reported side effects in pediatric patients include gastrointestinal disturbances (8%), increases in hepatic transaminases (5%), and skin reactions (1%); toxicity-related discontinuation of therapy with fluconazole occurs in approximately 3 percent of patients.[355] Severe side effects, including severe hepatotoxicity and exfoliative skin reactions, have been reported anecdotally in association with fluconazole therapy; fluconazole does not appear to affect the synthesis of human steroid hormones at the dosages currently used.[89,178]

DRUG INTERACTIONS. Fluconazole undergoes minimal cytochrome P-450–mediated metabolism; it inhibits CYP3A4 and several other cytochrome P-450 isoforms in vitro and interacts with enzymes involved in glucuronidation, thus leading to certain significant drug-drug interactions.[89,174,188,365] Most important, concurrent therapy with cisapride and newer antihistamines results in inhibition of the metabolic pathways of these drugs and potentially serious cardiac arrhythmias and is therefore strictly contraindicated.[184] By similar mechanisms, fluconazole can precipitate phenytoin toxicity,[311] may lead to increased plasma concentrations of cyclosporine and tacrolimus,[271,344] and may potentiate the effects of warfarin, sulfonylurea drugs, rifabutin (in particular short-acting benzodiazepines, carbamazepine), and nifedipine.[271,324,339] At a small magnitude, fluconazole can decrease the plasma clearance of theophylline and zidovudine.[251,404] Fluconazole also may interfere with the plasma clearance of cyclophosphamide, a widely used anticancer agent that must be metabolized by cytochrome P-450 enzymes to produce alkylating species. This interaction may potentially result in a relevant reduction in the therapeutic efficacy of cyclophosphamide.[525]

Further potential interactions with anticancer drugs have been observed with busulfan[68] and all-*trans*-retinoic acid.[419]

Conversely, drugs notorious for hepatic enzyme induction may lead to decreased fluconazole levels and therapeutic failure as the ultimate consequence.[89,168] In addition, the potential for added hepatotoxicity must be monitored when fluconazole is given in combination with these compounds.[168,324]

The clinical indications for fluconazole are summarized in Tables 252–2, 252–4, 252–15, and 252–16. Fluconazole is highly effective against superficial infections caused by dermatophytes and *Pityrosporum* spp.,[143,192] and it has excellent activity in the treatment of mucosal candidiasis, including vaginal, oropharyngeal, esophageal, and chronic mucocutaneous candidiasis.[136,183,205,294]

Several controlled studies including both neutropenic and non-neutropenic adult patients indicated that intravenous fluconazole (400 to 800 mg/day) is as effective as is D-AmB (0.5 to 1.0 mg/kg/day) against candidemia and other forms of invasive candidiasis, but it is better tolerated.[11,15,363,381] Fluconazole thus can be used for invasive *Candida* infections caused by susceptible organisms in patients who are in stable condition.[350,383] In patients who have received antifungal azoles for prophylaxis, the role of fluconazole as a therapeutic agent is very limited; breakthrough infections in this setting are likely to be caused by fluconazole-resistant *Candida* spp.,[252,300] and alternative agents are recommended.

Fluconazole is a useful agent for treatment of invasive *Candida* infections in the neonatal setting: in 6 published series including 10 or more patients with proven invasive *Candida* infections, treatment with fluconazole at a daily dosage of mostly 5 to 6 mg/kg was successful in 83 to 97 percent, and crude mortality ranged from 10 to 33 percent. In none of the altogether 125 patients was fluconazole discontinued because of toxicity.[50,60,121,122,133,221,482] The recommended dosage range for pediatric patients of all age groups is 6 to 12 mg/kg/day. However, in view of the faster clearance rate, the larger volume of distribution, and the safety profile of fluconazole, 12 mg/kg/day may be the more appropriate dosage for treatment of serious infections in term neonates, infants, and children. A dosing regimen of 6 to 12 mg/kg once every 72 hours has been advocated during the first week of life in preterm neonates who weigh less than 1500 g, based on an initially decreased clearance of fluconazole.[412] However, this dosage regimen has not been validated in the therapeutic setting; given the extreme variability in extravascular water content and renal function in may of these children, predictably effective and safe treatment with fluconazole may not be possible in the early postnatal period.

Fluconazole has been useful in the treatment of focal *Candida* urinary tract infections and uncomplicated funguria, and it has been used successfully in *Candida* peritonitis, endocarditis, osteomyelitis, meningitis, and endophthalmitis.[184,274] Further potential indications for fluconazole beyond the treatment of acute invasive *Candida* infections include consolidation therapy for chronic disseminated candidiasis[10,239] and cryptococcal meningitis.[399,468] High-dose fluconazole is an option for systemic infections caused by the yeast *T. asahii* in non-neutropenic hosts.[12,171] Fluconazole is the current drug of choice for treatment of coccidioidal meningitis,[148,405] and it has proven effectiveness in nonmeningeal coccidioidal infections.[79,178] Fluconazole appears comparatively less active than is itraconazole in the treatment of paracoccidioidomycosis, blastomycosis, histoplasmosis, and sporotrichosis.[113,193,240,241,348,349,506]

Fluconazole can prevent mucosal candidiasis in patients with HIV infection or cancer,[177,334,368] and it has proven efficacy in preventing invasive *Candida* infections in high-risk patients with acute leukemia or with bone marrow or liver transplants.[165,391,519] Fluconazole, given at 400 mg once daily from the start of the conditioning regimen until day 75, can reduce the frequency of invasive *Candida* infections and lower mortality at day 110 following allogeneic bone marrow transplantation,[432] and it also may provide persistent protection against invasive candidiasis and *Candida*-related death. Fluconazole can decrease the frequency of severe, gut-related graft-versus-host disease (GVHD), and it has an independent overall survival benefit of 17 percent at 8 years after the end of treatment.[299] Fluconazole also has been shown to reduce the incidence of *Candida* infections in low-birth-weight infants.[49,197,237,238,293,462] Thus, fluconazole prophylaxis is a valid option for centers with a high frequency (>10%) of invasive *Candida* infections in premature infants of less than 1000 g birth weight or in the setting of a nosocomial outbreak by a fluconazole-susceptible *Candida* spp. Fluconazole is approved by the FDA for treatment of vaginal, oropharyngeal, and esophageal candidiasis, invasive *Candida* infections, and cryptococcal meningitis, as well as for prophylaxis of candidiasis in patients undergoing bone marrow transplantation.

Itraconazole

Itraconazole is a high-molecular-weight, highly lipophilic *bis*-triazole (see Fig. 252–6). Structurally closely related to ketoconazole, it has a broader spectrum of antifungal activity that includes dermatophytes, *Candida* spp. (*C. krusei* excluded), *C. neoformans* and *C. gattii*, *Aspergillus* spp., various dematiaceous molds, and the dimorphic fungi. Itraconazole binds more avidly to its fungal target than does ketoconazole, but only weakly to human cytochrome P-450, thus leading to comparatively fewer mechanism-associated adverse effects.[167]

PHARMACODYNAMICS. In vitro, itraconazole exerts species- and strain-dependent fungistatic or fungicidal pharmacodynamics. Time-kill experiments in serum-free and serum-containing media demonstrated the concentration-independent, fungistatic activity of itraconazole against *Candida* spp. and *C. neoformans*.[70,71,146,526] Against *Aspergillus* spp., however, itraconazole displayed time- and concentration-dependent fungicidal activity with 87 to greater than 97 percent killing within 24 hours of exposure to the drug.[290] Persistent effects have not been reported thus far.

The principal feasibility of a correlation between in vitro susceptibility and outcome was demonstrated in mice with experimental disseminated aspergillosis.[108] Relationships between drug concentrations and antifungal efficacy of itraconazole were assessed in a model of invasive pulmonary aspergillosis in methylprednisolone/cyclosporine-immunosuppressed rabbits. In this model, an inhibitory sigmoid maximum effect model predicted a significant pharmacodynamic relationship ($r = .87$, $p < .001$) between itraconazole concentrations in plasma and antifungal efficacy as a function of the burden of *A. fumigatus* in lung tissue.[45]

In patients, however, the main rationale for monitoring plasma levels has been the erratic oral bioavailability of itraconazole, particularly in neutropenic patients. Historically, the target plasma level for itraconazole has been estimated at 0.25 μg/mL (high-performance liquid chromatography [HPLC]) at trough, based on the concentration that inhibits 90 percent of a large set of clinical isolates.[58,101] More recently, the predictive value of threshold concentrations of prophylactic itraconazole was analyzed in a large cohort of patients undergoing intensive chemotherapy for acute leukemia. The median itraconazole trough concentration after the first week of prophylaxis was significantly lower in patients who developed invasive fungal infections (0.46 versus 0.82 μg/mL; $p = .008$). Multivariate logistic regression analysis demonstrated a significant ($p = .028$) statistical association of trough concentrations less than 0.5 μg/mL with the occurrence of invasive fungal infections. A threshold of 0.25 μg/mL did not influence the occurrence of invasive mycoses in univariate and multivariate analyses.[157]

In a phase I/II clinical trial of oral cyclodextrin-itraconazole in HIV-infected children with oropharyngeal candidiasis, the relationships between pharmacodynamic parameters and therapeutic response as assessed by standardized scoring of mucosal disease after 14 days of therapy fitted to inhibitory maximum effect pharmacodynamic models. Best fits were observed for area under the curve (AUC), AUC/MIC, C_{max}, and C_{max}/MIC ($r = .483$ to $.595$; $p < .01$). In this study, no significant correlations were found between the MIC values of itraconazole for the fungal isolates at baseline and the therapeutic response.[179]

PHARMACOKINETICS. Itraconazole is available as capsules, as oral solution in hydroxypropyl-β-cyclodextrin (HP-β-CD), and as parenteral solution that also uses HP-β-CD as solubilizer. Absorption of itraconazole from the capsule form is dependent on a low intragastric pH and is compromised in the fasting state, and it becomes erratic in patients with granulocytopenic cancer or hypochlorhydria.[89,178,184] Absorption can be somewhat improved when the capsules are taken with food or an acidic cola beverage.[100,178] The oral solution of itraconazole in HP-β-CD, however, leads to an improved oral bioavailability of the parent compound that is further enhanced in the fasting state.[36,384]

After oral administration, C_{max} is measured within 1 to 4 hours; following once-daily dosing, steady state is achieved after 7 to 14 days.[167,178] Steady state can be reached more rapidly by doubling the dose during the first 2 to 3 days. In adult patients with cancer who were receiving the standard regimen of 2.5 mg/kg of HP-β-CD itraconazole twice daily, mean trough levels were 0.8 μg/mL under conditions of steady state[369]; systemic absorption of the carrier was negligible.[101] After administration of intravenous HP-β-CD itraconazole, drug and carrier rapidly dissociated and followed their own disposition. After administration of 200 mg twice daily for 2 days followed by 200 mg daily for 5 days to patients with hematologic malignancies, mean trough levels 24 hours after the last dose were 0.53 μg/mL.[57] The carrier HP-β-CD is not significantly metabolized, and virtually 100 percent is eliminated from plasma within 24 hours in unchanged form through glomerular filtration.[527]

Itraconazole exhibits dose-dependent pharmacokinetics with hyperproportional increases in the AUC with increasing and split dosages.[167,179,369] Itraconazole is highly (95%) protein-bound; only 0.2 percent circulates as free drug, whereas the remainder is bound to blood cells.[206] The compound is distributed extensively throughout the body. Although concentrations in nonproteinaceous body fluids are negligible, tissue concentrations in many organs, including the brain, exceed corresponding plasma levels by 2 to 10 times.[100,206]

Itraconazole is metabolized extensively in the liver by numerous pathways to more than 30 metabolites and is excreted in metabolized form into bile and urine. The major metabolite, hydroxyitraconazole, possesses antifungal activity similar to that of itraconazole. It is eliminated more rapidly, but its plasma concentrations at steady state are 1.5 to 2 times higher than those of the parent compound.[100,178] As a consequence, plasma concentrations of itraconazole measured by bioassay are approximately 3.5 times higher than those determined by HPLC.[500] The elimination from plasma follows a biphasic pattern. In healthy adult volunteers, the elimination half-life of the compound is 20 to 24 hours after single dosing and 35 to 40 hours under terms of steady state, a finding reflecting saturable excretion mechanisms.[195] The dosage of oral itraconazole does not need to be adjusted in patients with renal insufficiency or dialysis. Because the elimination of HP-β-CD parallels the glomerular filtration rate, intravenous itraconazole is contraindicated in patients with a creatinine clearance of less than 30 mL/minute. In patients undergoing hemodialysis, administration just before dialysis appears to produce adequate systemic exposure while allowing dialysis clearance of the carrier.[312] No data are available for continuous hemofiltration methods. In patients with severe hepatic insufficiency, the elimination half-life of itraconazole can be prolonged, and additional hepatic toxicity or possible drug interactions should be monitored carefully.

Data on the plasma pharmacokinetics of itraconazole in pediatric patients are limited to the oral HP-β-CD solution (Table 252–8).[111,179,415] In 26 infants and children aged 6 months to 12 years with cancer ($n = 20$) or liver transplantation who received

†Data from de Repentigny, L., Ratelle, J., Leclerc, J. M., et al.: Repeated-dose pharmacokinetics of an oral solution of itraconazole in infants and children. Antimicrob. Agents Chemother. 42:404-408, 1998.

‡Data from Schmitt, C., Perel, Y., Harousseau, J., et al.: Pharmacokinetics of itraconazole oral solution in neutropenic children during long-term prophylaxis. Antimicrob. Agents Chemother. 45:1561-1564, 2001.

Accumulation factor; AUC_{0-24} day 14/$AUC_{0-\infty}$ day 1; $AUC_{0-\infty}$, area under the concentration versus time curve from zero to infinity; C_{max}, peak plasma levels; C_{min}, minimum plasma levels; N/A, not assessed; $t_{1/2}$beta, elimination half-life; T_{max}, time until occurrence of peak plasma concentration.

the compound at 5 mg/kg once daily, plasma concentrations were substantially lower than those reported in adult patients with cancer, particularly in children younger than 2 years of age.[111,369] In contrast, in a pharmacokinetic study in 16 neutropenic children (1.7 to 14.3 years of age) who received cyclodextrin itraconazole for antifungal prophylaxis in a split dosing regimen of 2.5 mg/kg twice daily, peak and trough levels of itraconazole were substantially higher; nonetheless, a similar trend toward lower plasma concentrations occurred in the group of children 5 years of age and younger.[415] Finally, in a cohort of 26 HIV-infected children and adolescents (1.25 to 18 years), cyclodextrin itraconazole was safe and effective for treatment of oropharyngeal candidiasis at dosages of 2.5 mg once a day or 2.5 mg twice daily given for at least 14 days.[179] Many (77%) of the patients were receiving concomitant therapy with protease inhibitors or clarithromycin, drugs that are strong inhibitors of the CYP3A4-dependent metabolism of itraconazole.[365] Peak and trough levels measured after administration of the split-dosage regimen were similar to those observed in patients with cancer who were receiving the same dosage regimen.[415]

Despite the tremendous interpatient variability that results from both variable absorption and hepatic metabolism, the pharmacokinetic properties of itraconazole in pediatric patients appear not to be fundamentally different from those of adults. Although oral cyclodextrin itraconazole is not approved for pediatric age groups, a starting dosage of 2.5 mg/kg twice daily can be advocated, based on the available pharmacokinetic data.[111,179,415] Data on the use of intravenous itraconazole in pediatric patients are currently lacking; the dosage regimen used in the published adult studies is 200 mg twice daily for 2 days, followed by 200 mg once a day for a maximum of 12 days.[57,75] Because some evidence suggests that a relationship exists between trough concentrations and antifungal efficacy,[157] trough levels should be monitored, and dosing should be adjusted to maintain plasma concentrations of the parent itraconazole higher than 0.5 μg/mL. Only anecdotal reports have been published on the use of itraconazole in the neonatal setting.

ADVERSE EFFECTS. Itraconazole usually is well tolerated, with a pattern similar to that of fluconazole and a frequency of adverse effects approximately identical to that seen with fluconazole.[89] In 189 patients treated for systemic fungal infections at dosages of 50 to 400 mg/day for a median of 5 months, the rate of possibly or definitely related adverse effects was 39 percent.[460] Most of the observed reactions were transient and included nausea and vomiting (<10%), hypertriglyceridemia (9%), hypokalemia (6%), elevated hepatic transaminases (5%), rash or pruritus (2%), headaches or dizziness (<2%), and pedal edema (1%). Four percent of patients discontinued itraconazole treatment because of adverse effects. Gastrointestinal intolerance appears to be the dose-limiting toxicity of the oral cyclodextrin formulation. In a comparative study in adult patients with acute leukemia, 46 percent of patients receiving a daily dose of 800 mg stopped treatment early because of severe nausea and vomiting. Crossover to the identical dose of the capsule formulation was well tolerated by all patients; patients receiving 400 mg/day of the solution had no gastrointestinal adverse effects.[156] Only a few cases of more severe hepatic injury or hepatitis have been described.[269] Itraconazole can have negative inotropic effects; because of a low but possible risk of cardiac toxicity, itraconazole should not be administered to patients with ventricular dysfunction.[6]

Cyclodextrin itraconazole solution was safe and well tolerated for at least 14 days in reported phase I/II pharmacokinetic studies in immunocompromised pediatric patients.[111,179,415] Vomiting (12%), abnormal liver function tests (5%), and abdominal pain (3%) were the most common adverse effects considered definitely or possibly related to cyclodextrin itraconazole solution in an open study in 103 neutropenic pediatric patients with cancer who received the drug at 5 mg/kg daily or 2.5 mg/kg twice daily for antifungal prophylaxis for a median duration of 37 days; 18 percent of patients withdrew from the study because of adverse events.[138] In another report on pediatric patients with cancer who were receiving prophylactic oral itraconazole, adverse effects that led to the cessation of the itraconazole prophylaxis occurred in 11 percent of all 44 courses.[430]

DRUG INTERACTIONS. In comparison with fluconazole, both the propensity to and the extent of drug-drug interactions are greater.[175,178] Itraconazole is a substrate of CYP3A4, but it also interacts with the heme moiety of CYP3A, thus resulting in noncompetitive inhibition of oxidative metabolism of many CYP3A substrates. An interaction also can result from inhibition of P-glycoprotein–mediated efflux; P-glycoprotein is extensively co-localized and exhibits overlapping substrate specificity with CYP3A.[174,188] Inhibition of hepatic cytochrome P-450 enzyme systems may lead to increased and potentially toxic concentrations of co-administered drugs. Most important, the co-administration of cisapride, pimozide, terfenadine, astemizole, oral midazolam, quinidine, dofetilide, triazolam, and levacetylmethadol with itraconazole can lead to serious cardiac arrhythmias and is thus strictly contraindicated.[212,365] Similarly contraindicated is the co-administration of cholesterol-lowering agents such as lovastatin and simvastatin, which are associated with rhabdomyolysis,[331] and that of ergot alkaloids metabolized by CYP3A4, which may result in ergotism. Potentially toxic levels of the co-administered drug also can be reached when itraconazole is given along with phenytoin, carbamazepine, benzodiazepines, cyclosporine, tacrolimus, sirolimus, methylprednisolone, budesonide, atorvastatin, cerivastatin, digoxin, warfarin, sulfonylurea compounds, rifampin, rifabutin, ritonavir, indinavir, haloperidol, clarithromycin, verapamil, felodipine, busulfan, and vinca alcaloids.[55,257,339,365,403,472] Increased metabolism of itraconazole resulting in decreased plasma levels can be induced by rifampin, rifabutin, isoniazid, carbamazepine, phenobarbital, and phenytoin.[178,365,459] As a consequence, patients who receive itraconazole along with one of the listed drugs should be followed closely, and plasma concentrations of ideally both compounds as well as hepatic function should be monitored carefully.

CLINICAL INDICATIONS. The clinical indications for itraconazole are summarized in Tables 252–2, 252–3, 252–4, 252–15 and 252–16. Itraconazole is a useful agent for dermatophytic infections, pityriasis versicolor,[4,142,167,191] and vaginal candidiasis.[438] It is effective in treating patients with oropharyngeal and esophageal candidiasis, including adult and pediatric patients who have developed resistance to fluconazole.[1,111,179,400] The clinical efficacy of itraconazole in candidemia and other deeply invasive *Candida* infections has not been evaluated systematically. Although the experience with itraconazole in the primary treatment of cryptococcal meningitis is scant, itraconazole has been used with success for long-term treatment of cryptococcal meningitis in patients with HIV infection.[399,468]

Itraconazole may be a second-line option for treatment of invasive *Aspergillus* infections, in particular as maintenance or consolidation therapy in non-neutropenic patients. Two separate uncontrolled studies investigated oral itraconazole for treatment of proven or probable invasive aspergillosis; the results suggest a response rate comparable to that of conventional amphotericin B.[110,439] The published experience with the intravenous formulation for this indication is limited.[75] Beyond invasive aspergillosis, itraconazole may be useful in the management of infections by certain dematiaceous molds.[171,418] However, the compound has no well-documented clinical efficacy against zygomycosis and fusariosis.

Itraconazole is the current treatment of choice for lymphocutaneous sporotrichosis[240,379] and non–life-threatening, nonmenin-

geal paracoccidioidomycosis, blastomycosis, and histoplasmosis in non-immunocompromised patients.[82,115,325,329,450,507] It also has established efficacy in both induction and maintenance therapy of mild to moderate, nonmeningeal histoplasmosis in HIV-infected patients.[504,505,507] Although earlier uncontrolled clinical trials suggested a somewhat inferior efficacy against nonmeningeal and meningeal coccidioidomycosis in comparison with fluconazole,[169,457,458] a more recent randomized, double-blind comparative study in patients with progressive, nonmeningeal coccidioidomycosis showed a trend toward slightly greater efficacy when both drugs were given at a daily dosage of 400 mg.[149] However, amphotericin B remains the treatment of choice for most immunocompromised patients and for those with life-threatening forms of endemic mycoses.[184]

Prophylactic itraconazole may reduce the incidence of proven or suspected invasive fungal infections in patients with hematologic malignancies[306] and those who have undergone HSCT.[297,518] Efficacy in the prevention of invasive aspergillosis is supported by a large meta-analysis,[158] but not by a randomized, comparative trial. Finally, itraconazole was at least as effective as is conventional amphotericin B and was superior with respect to its safety profile when it was investigated as empiric antifungal therapy in persistently neutropenic patients with cancer.[59]

Posaconazole

Posaconazole (see Fig. 252–7) is a novel lipophilic antifungal triazole with potent and broad-spectrum activity against opportunistic, endemic, and dermatophytic fungi in vitro. This activity extends to organisms that often are refractory to existing triazoles or amphotericin B or to echinocandins such as *C. glabrata*, *C. krusei*, *A. terreus*, and *Fusarium* spp. Posaconazole also possesses activity against Zygomycetes both in vitro and in vivo, a feature that distinguishes it from all other available azoles.[172,402,452]

PHARMACODYNAMICS. Posaconazole is considered fungistatic against *Candida* and fungicidal against *Aspergillus* spp.[172] In time-kill assays, posaconazole showed concentration- and time-dependent fungicidal activity against *A. fumigatus*.[180,291,292] In vivo, in a neutropenic kidney target murine model of *C. albicans* infection, the AUC/MIC ratio was the parameter that was most predictive of antifungal efficacy.[20]

PHARMACOKINETICS. Posaconazole is available as oral suspension only and achieves optimal exposure when it is administered in two to four divided doses given with food or a nutritional supplement. The compound has dose-proportional pharmacokinetics in the 50- and 800-mg dose range, with saturation of absorption occurring at doses higher than 800 mg; after repeat dosing, steady state is achieved after 7 to 10 days with a 6- to 8-fold accumulation of plasma concentrations.[95] Posaconazole has a large volume of distribution in the order of 5 L/kg and a prolonged elimination half-life of approximately 20 hours. It is not significantly metabolized through the cytochrome P-450 enzyme system but is primarily excreted in unchanged form in the feces. The drug is inhibitory against cytochrome P3A4 but has no effects on 1A2, 2C8, 2C9, 2D6, and 2E1 isoenzymes, and therefore, a limited spectrum of drug-drug interactions can be expected (Table 252–9).[172,260,503] Posaconazole is a substrate and inhibitor of P-glycoprotein. However, investigation of the relationship between MDR1 mRNA expression and posaconazole exposure showed no correlation. Thus, the moderate variability in the compound's pharmacokinetics is unlikely to be caused by interindividual differences in P-glycoprotein expression.[96]

ADVERSE EFFECTS. The overall safety of posaconazole was assessed in two open-label clinical trials of more than 400 patients with invasive fungal infections who received posaconazole suspension (800 mg/day in divided doses). Treatment-related adverse events occurred in 38 percent of patients (164/428); the most common were nausea (8%), vomiting (6%), headache (5%), abdominal pain (4%), and diarrhea (4%). Treatment-related abnormal liver function test results were observed in as many as 3 percent of patients. No clinically significant differences occurred in mean QTc interval change from baseline. Serious adverse events considered possibly or probably related to posaconazole occurred in 35 (8%) patients. The most common severe adverse events were altered drug level, increased hepatic enzymes, nausea, rash, and vomiting (1% each). No significant trends related to age, sex, or race were observed, and no unique treatment-related adverse events were identified in patients during long-term exposure (>6 months) compared with those identified during shorter-duration therapy.[354,373] In two large, prospective, randomized comparative clinical trials investigating posaconazole for prevention of invasive fungal infections in high-risk patients with leukemia or HSCT, posaconazole was well tolerated, and the rate of study drug discontinuations in posaconazole-treated subjects was not different from that in subjects in the control cohort receiving fluconazole or itraconazole.[93,463]

INTERACTIONS. Posaconazole is not significantly metabolized through the cytochrome P-450 enzyme system, and cytochrome P-450–mediated drug-drug interactions will have limited potential to affect posaconazole pharmacokinetics.[260] Posaconazole is inhibitory against cytochrome P3A4, but it has no effect on 1A2, 2C8, 2C9, 2D6, or 2E1 isoenzymes.[503] The drug-drug interaction potential of posaconazole was investigated in seven open-label, crossover drug interaction studies. No adjustments of doses are needed when posaconazole is co-administered with glipizide, zidovudine, and lamivudine, whereas dosages of ritonavir and indinavir may need to be lowered. Monitoring of cyclosporine and tacrolimus blood concentrations is mandatory, and adjustments of doses should be made accordingly. Because of a relevant decrease in posaconazole concentrations, concomitant use with rifabutin, phenytoin, or cimetidine should be avoided. As with other azoles, caution is advised when posaconazole is co-administered with CYP3A4 substrates that have the potential to prolong the QTc interval.[408,409]

CLINICAL EFFICACY. Posaconazole has been targeted for prevention and treatment of serious infections caused by opportunistic and endemic fungal organisms. Posaconazole has demonstrated strong antifungal efficacy in phase II clinical trials in immunocompromised patients with primary or refractory oropharyngeal and esophageal candidiasis.[431,474] In a randomized, comparative phase III trial, posaconazole (100 mg daily; day 1: 200 mg) was as effective as was fluconazole (100 mg daily; day 1: 200 mg) in the primary treatment of HIV-associated

oropharyngeal candidiasis: 155 of 169 (91.7%) patients receiving posaconazole compared with 148 of 160 (92.5%) of patients receiving fluconazole achieved a complete clinical response (cure). The relapse rate at day 42 was greater in fluconazole recipients than in posaconazole-treated subjects (38.2% versus 31.5%; $p = .038$).[475] Posaconazole (800 mg in divided doses) also was investigated as salvage therapy in a large phase II study including 330 patients with invasive fungal infections intolerant to or refractory to standard therapies and a contemporaneous external control of 279 patients.[372] Most patients (86%) were refractory to previous therapy. Successful outcomes at the end of treatment in the posaconazole cohort and in the contemporaneous external control cohort were 42 versus 26 percent in aspergillosis (107 and 86 patients; separately published[495]), 39 versus 50 percent in fusariosis (18 versus 4 patients), 56 versus 50 percent in zygomycoses (11 versus 8 patients), 69 versus 43 percent (16 versus 7 patients) in coccidioidomycosis, 52 versus 53 percent in candidiasis (23 versus 30 patients), 48 versus 58 percent in cryptococcosis (31 versus 64 patients), 81 versus 0 percent in chromoblastomycosis (11 versus 2 patients), and 64 versus 60 percent in other invasive fungal infections (30 versus 20 patients). In a subset analysis of 39 patients with mostly refractory proven or probable CNS infections, posaconazole proved efficacious against cryptococcal meningitis (success rate in 29 patients, 48%) and against infections caused by opportunistic or endemic molds (5 of 10 patients, 50%).[364] These data are in agreement with the compound's extended spectrum of activity in vitro and demonstrate efficacy for treatment of refractory invasive opportunistic and endemic mycoses. A retrospective analysis of the manufacturer's compassionate-use program including 91 patients with proven or probable zygomycosis refractory or intolerant to prior antifungal therapy revealed a 60 percent success rate (complete and partial responses) at 12 weeks after initiation of therapy, thus providing first evidence for the clinical utility of posaconazole as second-line or consolidation therapy of zygomycosis.[465]

Two pivotal preventive randomized phase III studies in high-risk patients with HSCT and GVHD[463] and acute leukemias[93] have been completed. In the first study, patients received either posaconazole 200 mg three times a day or fluconazole 400 mg daily, respectively, with the start of immunosuppression for a total of 16 weeks. Treatment with posaconazole led to a decreased incidence of invasive fungal infections at 16 weeks (5% versus 9%; $p = .07$), with a statistically significant decrease in invasive *Aspergillus* infections (2% versus 7%; $p = .006$). Seven days after end of treatment, fewer patients had invasive fungal disease (2% versus 8%; $p = .004$), and fewer patients had invasive aspergillosis (1% versus 6%; $p = .001$). No differences in overall mortality rates occurred at 12 weeks.[463] In the second study, patients received either posaconazole 200 mg three times a day and either fluconazole 400 mg daily or itraconazole 200 mg twice a day, respectively. Treatment was started with each cycle following a drop of the absolute neutrophil count (ANC) to 500 μL or less for up to 12 weeks. Significantly fewer patients enrolled in the posaconazole arm of the trial developed an invasive fungal infection at day 7 after the end of treatment as compared with the comparator arm (2% versus 8%; $p < .01$); most important, treatment with posaconazole resulted in a significant decrease in the rate of invasive aspergillosis (1% versus 7%; $p < .001$). At day +100 after randomization, the rate of invasive fungal infections was 5 and 11 percent ($p < .01$), respectively, and patients treated with posaconazole had a significantly improved survival probability ($p = .035$).[93] These two important studies demonstrate the preventive efficacy of posaconazole, in particular against invasive *Aspergillus* infections in high-risk patients, and a statistically significant survival benefit in patients with acute myeloblastic leukemia/myelodysplastic syndrome who are undergoing remission induction chemotherapy.

APPROVAL STATUS AND DOSING. In the United States, posaconazole is approved for treatment of oropharyngeal candidiasis, including disease refractory to itraconazole or fluconazole, and for prophylaxis of invasive *Candida* and *Aspergillus* infections in high-risk patients 13 years of age and older with HSCT and GVHD or those with hematologic malignancies and prolonged neutropenia. In the European Union, the compound also is approved for treatment of aspergillosis, fusariosis, chromoblastomycosis, and coccidioidomycosis refractory to or intolerant of standard therapies in subjects 18 years of age and older (see Tables 252–3, 252–4, and 252–16).

The recommended dose for primary treatment of oropharyngeal candidiasis is 100 mg/day (day 1: 100 mg twice daily) and 400 mg twice a day for refractory disease; for prophylaxis of invasive *Candida* and *Aspergillus* infections, the recommended dose is 200 mg three times a day. The dose for salvage treatment is 400 mg twice a day given with food; for patients not tolerating solid food, a dose of 200 mg four times a day is recommended, preferentially together with a nutritional supplement.

Current data indicate no need for adjustments to dosage based on differences in age, gender, race,[410] or renal or hepatic function.[94,97] The pharmacokinetic properties of posaconazole in pediatric patients (<18 years of age) have not been studied. Limited data obtained in 12 pediatric subjects 8 years of age and older indicated no fundamental differences in trough plasma concentrations as compared with adults.[261] Salvage treatment with posaconazole resulted in successful outcomes in 5 of 11 pediatric subjects (8 to 17 years of age), a result that resembles the outcome in the adult population.[54]

Voriconazole

Voriconazole (see Fig. 252–7) is a synthetic antifungal triazole with activity against a wide spectrum of clinically important yeasts and molds, including *Candida* spp., *C. neoformans*, *Aspergillus*, and other hyaline molds, dematiaceous molds as well as dimorphic molds, both in vitro and in animal models. A notable exemption are the Zygomycetes, against which voriconazole is intrinsically inactive.[175,228,229,317]

PHARMACODYNAMICS. Against *Candida* spp. and *C. neoformans*, voriconazole exhibited non-concentration against *A. fumigatus*, and displayed time-dependent fungicidal activity.[244,290] A concentration-dependent PAFE of 0.2 to 4.1 hours has been observed in the presence of serum against *C. albicans*.[150] In a murine kidney target model of disseminated candidiasis, the AUC/MIC ratio was the pharmacodynamic parameter that correlated best with efficacy. Using 10 *C. albicans* isolates of different voriconazole susceptibilities, the free drug AUC/MIC ratios were similar to all the organisms studied and similar to those observed for other azoles.[21] Because voriconazole has nonlinear pharmacokinetics and underlies considerable interindividual variability in metabolism, assessment of concentration-effect relationships continues to be a challenge.[185]

PHARMACOKINETICS. Voriconazole is available in oral and intravenous formulations; oral bioavailability exceeds 90 percent in the fasted state. In adults, the compound has nonlinear pharmacokinetics. Plasma protein binding is 58 percent, and the mean volume of distribution accounts for 2 L/kg. Tissue and CSF levels exceed those of trough plasma levels severalfold. The plasma half-life is 6 hours, with elimination occurring primarily by oxidative hepatic metabolism to at least eight metabolites that are eliminated through the urine; less than 2 percent of a dose of voriconazole is excreted unchanged in urine. The major isoenzyme involved in voriconazole metabolism is CYP2C19, but CYP2C9 and CYP3A4 also contribute (see Table 252–9). Wide between-subject variability exists in the

disposition of voriconazole that is related to genetic CYP2C19 polymorphism.[175,371]

SAFETY. Voriconazole has an acceptable safety profile. The accrued clinical data indicate that side effects include four distinct clinical categories: transient liver enzyme abnormalities (10% to 20%), skin reactions (<10%), hallucinations or confusion (<10%), and transient, dose-related visual disturbances (altered or enhanced perception of light, blurred vision; 25% to 45%).[175] With regard to the visual disturbances, no morphologic correlation was noted in animal models, and the underlying mechanism remains to be elucidated.[229] Drug-related adverse effects requiring the discontinuation of voriconazole were infrequent in comparative clinical trials and ranged from 2 to 13 percent.[8,203,493]

Serious hepatic reactions including hepatic failure have been observed during treatment with voriconazole; therefore, evaluation of liver function tests before and during treatment with voriconazole is advised. Azole therapy has been associated with QTc prolongation; for this reason, voriconazole should be administered with caution to patients with proarrhythmic conditions. Voriconazole is teratogenic in animals and may cause fetal harm when it is administered to a pregnant woman.[175]

INTERACTIONS. Voriconazole is both substrate and inhibitor of CYP2C19, CYP2C9, and CYP3A4, and therefore, numerous clinically relevant and potentially hazardous drug-drug interactions need to be considered.[175] Voriconazole significantly increases exposure to cyclosporin, tacrolimus, benzodiazepines, methadone, vinca alkaloids, the statins, omeprazole, warfarin, sulfonylurea drugs, phenytoin, protease inhibitors other than indinavir, and non-nucleoside reverse transcriptase inhibitors, thus requiring dosage adjustment or monitoring. Voriconazole exposure is significantly decreased by phenytoin, ritonavir, efavirenz, rifabutin, carbamazepine, rifampin, and phenobarbital. Concurrent use of the last three enzyme inducers with voriconazole is contraindicated (risk of subtherapeutic levels of voriconazole), as is the concurrent use of terfenadine, astemizole, cisapride, quinidine, pimozide (risk of QTc prolongation resulting from increased exposure to these agents), ergotamine (risk of ergotism resulting from increased exposure), and sirolimus (increased exposure). Dosage adjustments of voriconazole are necessary when the drug must be used concurrently with phenytoin or rifabutin.[175,229,247]

CLINICAL EFFICACY. Voriconazole has demonstrated excellent clinical efficacy in phase II and III clinical trials in patients with oropharyngeal candidiasis and esophageal candidiasis.[8,200] In salvage studies in patients with fungal infections refractory or intolerant to treatment, complete and partial responses were seen in 43 and 48 percent of patients with invasive aspergillosis,[109,356,490] in 45 to 52 percent of patients with invasive candidiasis,[356] in 30 to 63 percent of patients with scedosporiosis,[356,490] in 45 percent of patients with fusariosis,[356] and in 38 percent of patients with cryptococcosis.[356]

A large, multinational, randomized phase III clinical trial of voriconazole and conventional amphotericin B followed by other licensed antifungal therapeutic agents for primary therapy of invasive aspergillosis revealed superior outcomes in voriconazole-treated patients[203]: At week 12, successful outcomes were noted in 52.8 percent of the patients in the voriconazole group and in 31.6 percent of those in the amphotericin B group (absolute difference, 21.2 percentage points; 95% confidence interval (CI), 10.4 to 32.9). The survival rate at 12 weeks was 70.8 percent in the voriconazole group and 57.9 percent in the amphotericin B group (hazard ratio, 0.59; 95% CI, 0.40 to 0.88). Voriconazole-treated patients had significantly fewer severe drug-related adverse events. A randomized comparative study of voriconazole versus conventional amphotericin B followed by fluconazole for treatment of candidemia in non-neutropenic patients showed similar response rates and end-of-treatment and similar survival rates at 3 months.[263] Twelve weeks after the end of treatment, successful outcomes were observed in 41 percent of patients in both treatment groups (95% CI for difference, –10.6% to 10.6%). Voriconazole cleared blood cultures as quickly as did amphotericin B/fluconazole, and significantly fewer serious adverse events and cases of renal toxicity occurred than in the group treated with amphotericin B/fluconazole. In a large, international collaborative study of voriconazole versus liposomal amphotericin B for empiric therapy, voriconazole did not meet the prespecified statistical end-point for non-inferiority in a composite end-point but was associated with significantly fewer breakthrough invasive fungal infections, particularly those caused by invasive aspergillosis.[493] Finally, several reports also suggested the potential usefulness of voriconazole for treatment of infections by unusual hyaline and dematiaceous fungi,[356] as well as for treatment of cerebral mold infections.[421]

APPROVAL STATUS AND DOSING. Voriconazole is approved for treatment of the following: invasive aspergillosis, fusariosis, and scedosporiosis; esophageal candidiasis; and primary treatment of candidemia and certain forms of invasive candidiasis in non-neutropenic patients (see Table 252–2 and 252–3). The recommended intravenous dosages for patients 12 years and older are 6 mg/kg twice a day on day 1, followed by 4 mg/kg twice a day. Oral doses in adults are 400 mg twice a day on day 1 (<40 kg: 200 mg twice daily), followed by 200 mg twice a day (<40 kg: 100 mg twice daily). In patients with renal insufficiency, no adjustment of dosage is needed for the oral formulation; because of the renal clearance of the intravenous carrier, patients with a creatinine clearance of less than 50 mL/minute should receive voriconazole by the oral route. In patients with mild to moderate hepatic function abnormalities, half of the daily maintenance dosage is recommended after the initial loading dose. Recommendations for severe liver failure are lacking.[175,229]

Pediatric patients 2 to 12 years have a higher capacity for elimination of voriconazole per kilogram of body weight than do adult healthy volunteers; the result is lower, potentially nontherapeutic exposure at similar dosages (Table 252–10).[489] An intraindividual dosage escalation study exploring pharmacokinetics and safety of higher dosage regimens of voriconazole in this patient population has been completed; based on the population-based

TABLE 252–10 Simulated Plasma Concentrations of Voriconazole following Multiple Doses of 3 and 4 mg/kg in Pediatric versus Adult Patients

	Value*			
	Pediatric Patients 2-11 yr		Adult Patients	
Parameter	3 mg/kg	4 mg/kg	3 mg/kg	4 mg/kg
AUC_{tau} (ng/hr/mL)	10,670	14,227	13,855	38,605
$C_{average}$ (ng/mL)	889	1,186	1,155	3,217

**Data are reported as medians following 6 mg/kg every 12 hours on day 1 and maintenance dose 3.*

Whereas in pediatric patients, an increase in dosage by a factor of 1.3 leads to proportional increase in the mean average plasma concentration ($C_{average}$) and in the mean area under the concentration versus time curve (AUC_{tau}), adult patients display a 2.8-fold, hyperproportional increase in exposure, indicating nonlinear disposition. As a consequence, pediatric patients given 4 mg/kg do not achieve the same exposure as adults given 4 mg/kg, the dosage that has led to the approval of voriconazole for first-line treatment of invasive aspergillosis.

Modified from Walsh, T. J., Karlsson, M. O., Driscoll, T., et al.: Pharmacokinetics and safety of intravenous voriconazole in children after single- or multiple-dose administration. Antimicrob. Agents Chemother. 48*:2166-2172, 2004.*

analysis of the data set of that study, an intravenous dosage of 7 mg/kg twice a day and an oral dose of 200 mg twice a day (oral suspension) without loading doses is currently suggested and approved by the European Medicine Agency for children between the ages of 2 and 12 years.[484] Voriconazole has been administered safely and with success to children younger than 12 years of age who had no therapeutic alternative. Of 58 immunocompromised children with proven or probable invasive fungal infection refractory to or intolerant of conventional antifungal therapy, 26 patients (45%) had a complete or partial response. Four patients (7%) discontinued therapy because of intolerance. A total of 23 patients had voriconazole-related adverse events, most commonly elevation in hepatic transaminases or bilirubin ($n = 8$), skin rash ($n = 8$), abnormal vision ($n = 3$), and photosensitivity reactions ($n = 3$).[490] The safety and tolerance of voriconazole were further analyzed in a retrospective cohort study of 37 immunocompromised children and adolescents who required therapy for various indications. Voriconazole was administered intravenously or orally at dosages ranging from 2 to 8 mg/kg twice daily for a mean duration of 174 days (range, 5 to 998 days). Grade I or II adverse events were observed in 19 patients (51%); the most frequent events included transient increases in hepatic transaminases (19) and transient visual disturbances (5). Four patients (10%) experienced grade III/IV adverse events, and three (8%) permanently discontinued therapy. Voriconazole showed promising efficacy as a preventive and therapeutic modality, although these outcomes were not primary end-points of the analysis.[249] Voriconazole also has been used with success and acceptable tolerance in many patients with cystic fibrosis and allergic bronchopulmonary aspergillosis.[208]

ECHINOCANDIN LIPOPEPTIDES

The echinocandins are a novel class of semisynthetic amphiphilic lipopeptides that are composed of a cyclic hexapeptide core linked to a variably configured lipid side chain. The first compound of this class undergoing preclinical evaluation was cilofungin (LY 121019), a semisynthetic echinocandin B derivative with activity limited to *Candida* spp. However, clinical development was abandoned in early stages because of concerns regarding toxicity associated with the intravenous polyethylene glycol formulation vehicle.[184] Since the 1990s, a second generation of semisynthetic echinocandins with extended antifungal spectrum against *Candida* and *Aspergillus* spp., a favorable safety profile and pharmacokinetic characteristics, has been developed: anidulafungin (Eraxis), caspofungin (Cancidas), and micafungin (Mycamine) (Fig. 252–9). The data accumulated thus far indicate that these agents are not fundamentally different with respect to spectrum, pharmacokinetics, safety, and antifungal efficacy.

MECHANISM OF ACTION. The echinocandins act by noncompetitive inhibition of the synthesis of 1,3-β-D-glucan, a polysaccharide in the cell wall of many pathogenic fungi (Fig. 252–10). Together with chitin, the ropelike glucan fibrils are responsible for the cell wall's strength and shape. They are important in maintaining the osmotic integrity of the fungal cell and play a key role in cell division and cell growth.[104,105,199] The proposed molecular target of the echinocandins, glucan synthase, is a heteromeric enzyme complex composed of at least one large integral membrane protein encoded by the *FKS* gene that binds the substrate (uridine diphosphate glucose), and one small regulatory subunit, Rho1p, a guanosine triphosphate–binding protein; additional, yet unidentified, components also may be involved.[264,449]

ANTIFUNGAL ACTIVITY. All three compounds have potent and broad-spectrum fungicidal in vitro activity against *Candida* spp. and potent inhibitory activity against *Aspergillus* spp.; their antifungal efficacy against these organisms in vivo has been demonstrated in various animal models. The current echinocandins have variable activity against dematiaceous and endemic mold and are considered inactive against most Hyalohyphomycetes, Zygomycetes, *C. neoformans*, and *T. asahii*. All echinocandins have demonstrated preventive and therapeutic activity in animal models of *Pneumocystis carinii* (now *Pneumocystis jiroveci*) pneumonitis.[145,147,473]

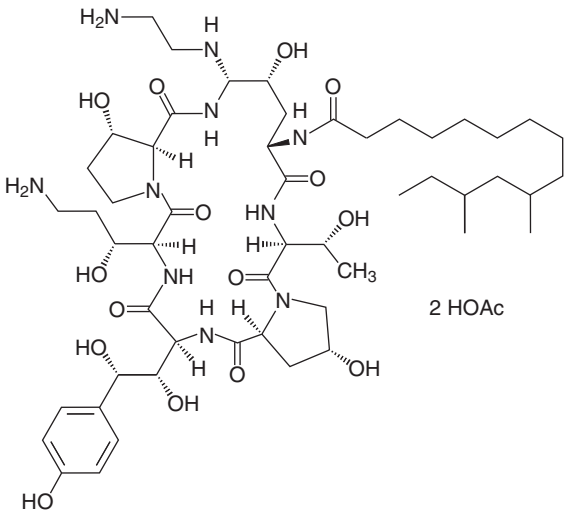
As expected from their mechanism of action, the echinocandins show no cross-resistance to amphotericin B and fluconazole-resistant *Candida* isolates. Resistance to echinocandins in otherwise susceptible fungal yeast species is rare; most mutations conferring resistance have been mapped to the *FKS* gene.[264,351] Little is known thus far about potential mechanisms of echinocandin resistance among *Aspergillus* spp.[152]

PHARMACODYNAMICS. The echinocandins demonstrate a species-dependent mode of antifungal activity. Whole-cell in vitro assays reveal fungicidal activity against most *Candida* spp. but not against *Aspergillus* spp.[37,443] Microscopical examination of drug-exposed *A. fumigatus* shows a dose-dependent formation of microcolonies with progressively truncated, swollen hyphal elements that appear to be cell wall deficient but are able to regain their cell walls on subculture in the absence of drug.[118,265,336,378] These observations demonstrate differences in functional target sensitivity that are not fully understood. Time-kill studies in *Candida* spp. demonstrated predominantly concentration-dependent fungicidal activity and rate-of-kill at concentrations greater than the MIC for all three compounds.[129,131,357] In addition, PAFEs between 5 and 12 hours at concentrations greater than the MIC have been demonstrated.[130,292]

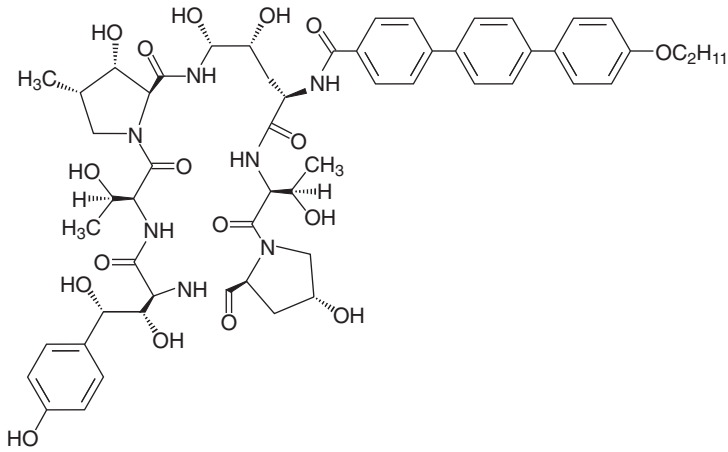
In persistently neutropenic rabbit models, anidulafungin showed highly predictable concentration-effect relationships in experimental disseminated candidiasis; however, no concentration-effect relationships were observed in experimental pulmonary aspergillosis, despite full exploration of the dosage range.[181] Pharmacodynamic studies in murine kidney target models of disseminated candidiasis showed prolonged in vivo antifungal effects and indicated that the AUC/MIC ratio is the pharmacodynamic parameter that predicts caspofungin efficacy.[283] In a murine model of invasive pulmonary aspergillosis, the C_{max}/MEC ratio appeared to be the parameter most closely associated with efficacy.[511]

PHARMACOKINETICS. At present, all current echinocandins are available only for intravenous administration. They exhibit dose-proportional plasma pharmacokinetics with a triexponential elimination pattern. Their beta half-life is between 10 and 15 hours, thus allowing for once-daily dosing without major accumulation after multiple dosing. All echinocandins are highly (>95%) protein-bound and distribute into all major organ sites including the brain; however, concentrations in uninfected CSF are low. The echinocandins are chemically degraded or metabolized by the liver and slowly excreted into urine and feces; only small fractions (<2%) of a dose are excreted into urine in unchanged form (Table 252–11).[145,147,473] The current echinocandins are not dialyzable, and no adjustment in dose is required for patients with renal insufficiency or renal failure. Similarly, no adjustment in dose is necessary for patients with mild to moderate (all) or severe (anidulafungin) hepatic failure. Whether the minor differences in individual pharmacokinetic parameters such as AUC, peak plasma levels, volume of distribution, and clearance of the echinocandins are of clinical significance remains to be elucidated.

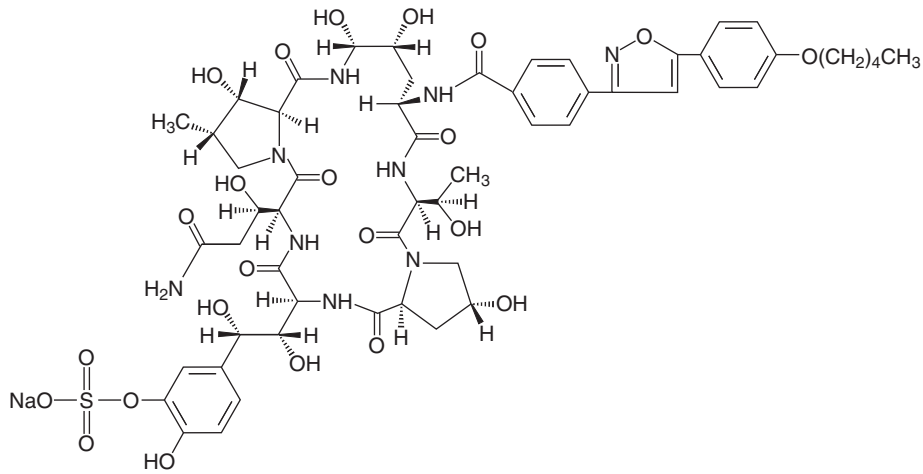
ADVERSE EFFECTS. At current dosages, anidulafungin, caspofungin, and micafungin generally are well tolerated. Fewer than 10 percent of patients enrolled on the various randomized



Caspofungin (MK0991)



Anidulafungin (LY303366)



Micafungin (FK463)

Figure 252–9 Structural formulas of echinocandin lipopeptides: anidulafungin, caspofungin, and micafungin.

comparative clinical trials discontinued echinocandin therapy because of drug-related adverse events.[103,259,315,376,466,497] Increased liver transaminases, gastrointestinal symptoms, skin rash, and headache probably or definitely associated with echinocandin treatment have been reported to occur at a frequency of less than 5 percent each. Like other basic polypeptides, the echinocandins have the theoretical potential to cause release of histamine. Symptoms such as rash, facial swelling, pruritus, or sensation of warmth and anaphylactic reactions have been reported in isolated cases.[103,259,315,376,466,497] Because of transient elevations of hepatic transaminases in interaction studies in healthy volunteers,[170] the concomitant use of caspofungin and cyclosporine currently is not recommended; clinical experience, however, indicates that both drugs can be given safely under careful monitoring.[173,298,454]

DRUG INTERACTIONS. In vitro studies showed that anidulafungin does not significantly inhibit the activities of clinically important human cytochrome P-450 isoforms at clinically relevant concentrations and that it is not an inhibitor of P-glycoprotein. Interaction studies demonstrated that no adjustment of dosage of either drug is warranted when anidulafungin is co-administered with cyclosporine, tacrolimus, voriconazole, liposomal amphotericin B, or rifampin.[76]

Caspofungin is not a substrate of P-glycoprotein and is a poor substrate and a weak inhibitor of cytochrome P-450 enzymes.[29,523] Clinical studies showed that the pharmacokinetic properties of caspofungin are not altered by itraconazole, amphotericin B, mycophenolate, nelfinavir, or tacrolimus. Caspofungin has no effect on the pharmacokinetics of itraconazole, amphotericin B, or the active metabolite of mycophenolate.[76,346,440] Caspofungin can reduce the AUC of tacrolimus by approximately 20 percent, but it has no effect on cyclosporine levels. Inducers of drug clearance or mixed inducer/inhibitors, namely efavirenz, nelfinavir, nevirapine, phenytoin, rifampin, dexamethasone, and carbamazepine, may reduce caspofungin concentrations, and dose adjustment to a daily dose of 70 mg of caspofungin should be considered.[76,170]

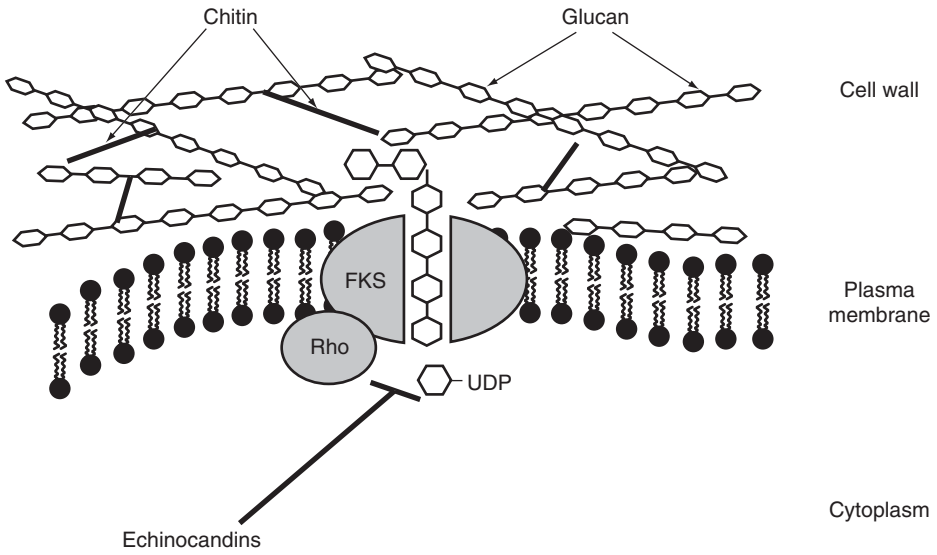


Figure 252–10 Schematic of the proposed mechanism of action of echinocandin lipopeptides. Echinocandins inhibit the synthesis of cell wall 1,3-β-glucan at the level of the cell membrane. Fks is the proposed catalytic subunit, and Rho the proposed regulatory subunit of the glucan synthase complex. *(Modified from Kurtz, M. B., and Douglas, C. M.: Lipopeptide inhibitors of fungal glucan synthase. J. Med. Vet. Mycol. 35:79-86, 1997.)*

Micafungin is a weak inhibitor of CYP3A in vitro, but it is neither a P-glycoprotein substrate nor inhibitor in vitro. In clinical studies, micafungin had no effect on mycophenolate mofetil, cyclosporine, tacrolimus, prednisolone, and fluconazole pharmacokinetics, but it increased the AUC of sirolimus and nifedipine by approximately 20 percent. Patients receiving sirolimus or nifedipine in combination with micafungin should be monitored for sirolimus or nifedipine toxicity, and sirolimus or nifedipine dosage should be reduced if necessary.[187,322]

Caspofungin

CLINICAL EFFICACY. The clinical efficacy of caspofungin against *Candida* spp. was demonstrated first in phase II and III studies in immunocompromised patients with esophageal candidiasis.[23,480,481] A multicenter, randomized, double-blind phase III clinical trial investigated the efficacy of caspofungin for primary treatment of invasive *Candida* infections in 224 mostly non-neutropenic patients with amphotericin B deoxycholate (0.6 to 1.0 mg/kg) as comparator agent. Among patients receiving at least one dose of the study drug, 73 percent of patients in the caspofungin cohort and 61.7 percent of patients in the amphotericin B deoxycholate cohort had therapeutic success at the end of intravenous therapy. Among patients who received five or more doses, the response rates were 80.7 and 64.9 percent, respectively. No difference occurred in relapse or survival, but caspofungin was better tolerated.[315] A multicenter phase II salvage trial of caspofungin was completed in 83 patients with definite or probable invasive aspergillosis refractory to or intolerant of standard therapies. As determined by an independent expert panel, a complete or partial response was observed in 45 percent of patients receiving at least one dose of caspofungin; in patients receiving the drug for more than 7 days, the response rate was 56 percent.[287] Finally, in a large, randomized, double-blind clinical trial including 1095 patients, caspofungin was as effective as was liposomal amphotericin B for empiric antifungal therapy in persistently febrile granulocytopenic patients, but it was better tolerated. The proportion of patients who survived at least 7 days after therapy was greater in the caspofungin group (92.6% versus 89.2%).[497]

APPROVAL STATUS AND DOSING. Caspofungin is licensed in both the United States and Europe in patients 3 months of age or older with candidemia and certain forms of invasive *Candida* infections in non-neutropenic patients, as second line therapy for invasive aspergillosis, and for empirical antifungal therapy in granulocytopenic patients. In the United States, caspofungin also is approved for treatment of esophageal candidiasis (see Tables 252–2, 252–3 and 252–16).[76] The adult dose regimen is 50 mg daily with a single 70-mg loading dose on day 1, administered over 1 hour. No dosage adjustment is required in patients with renal insufficiency and mild hepatic insufficiency. In patients with moderate hepatic insufficiency (Child-Pugh category B), a maintenance dose of 35 mg/day is recommended after the loading dose of 70 mg. No recommendations exist for patients with severe hepatic insufficiency (Child-Pugh category C).[186]

In children and adolescents 2 to 17 years of age, the pharmacokinetics and safety of caspofungin was investigated using either a weight-based or a body surface area regimen. Although a maintenance dosage of 1 mg/kg/day achieved suboptimal exposure,

TABLE 252–12 Single-Dose Caspofungin Pharmacokinetics in Pediatric versus Adult Patients*

Dosage	Children (2-11 yr) 1 mg/kg	Children (2-11 yr) 50 mg/m^2	Adolescents (12-17 yr) 50 mg/m^2	Adults 50 mg
$AUC_{0\text{-}24\ hr}$ (μg/hr/mL)	41.5	96.4	77.6	70.6
C1 (μg/mL)	6.59	13.9	7.67	7.67
C24 (μg/mL)	0.45	1.09	1.35	1.35
$t_{1/2}$beta (hr)	7.2	7.6	11.7	11.7
Cl (mL/min/m^2)	8.57	7.78	6.07	6.07

**Least square means are reported for AUC, C1 (peak plasma concentration [C_{max}]), and C24 (minimum plasma concentration [C_{min}]), and harmonic means for $t_{1/2}$beta. Data were obtained in groups of 6 to 10. Data in pediatric patients were compared with those obtained in 32 adult patients with mucosal candidiasis. In comparison with adult values, a 1-mg/kg dosage does not achieve the target trough concentration of caspofungin of 1 μg/mL and leads to a lower exposure as measured by the $AUC_{0\text{-}24\ hr}$; the dosage regimen of 50 mg/m^2 leads to similar or slightly higher trough concentrations and similar or slightly higher exposure ($AUC_{0\text{-}24\ hr}$) and has been selected for the further development program in pediatric patients.*

AUC, area under the concentration versus time curve from 0 to 24 hours; Cl, clearance; $t_{1/2}$beta, elimination half-life.

Modified from Walsh, T. J., Adamson, P. C., Seibel, N. L., et al.: Pharmacokinetics, safety, and tolerability of caspofungin in children and adolescents. Antimicrob. Agents Chemother. 49:4536-4545, 2005.

dosing with 50 mg/m^2/day provided similar or slightly higher exposure relative to adults (Table 252–12).[483] As a consequence, in conjunction with pharmacokinetic data obtained in small children,[328a] the dosage of 50 mg/m^2/day (day 1: 70 mg/m^2/day; maximum daily dose; 70 mg) has been selected for pediatric patients between 3 months and 17 years of age. In neonates up to 3 months of postnatal age, limited pharmacokinetic data suggest a dosage of 25 mg/m^2/day.[338,403a]

Caspofungin appears to be well-tolerated in pediatric patients. In the above-mentioned phase I/II dose-finding study, none of the patients developed a serious drug-related adverse event or discontinued because of toxicity.[483] In a phase III estimation trial with safety as the primary objective, 82 patients between the ages of 2 and 17 years with persistent fever and neutropenia were randomly assigned to receive caspofungin or liposomal amphotericin B (3 mg/kg daily) in a 2:1 ratio. Rates of drug-related adverse events were similar (clinical 48.2% vs. 46.2%; laboratory 10.7% vs. 19.2%); serious drug-related adverse events occurred in 1.8% of caspofungin-treated and in 11.5% of amphotericin B-treated patients. Overall success rates were not different. The interim analysis of the first 28 patients enrolled on a phase II trial in patients with invasive infections revealed no serious drug-related adverse events and an overall response rate of 75%.[224] Similarly favorable safety experiences have been reported in immunocompromised pediatric patients who received the compound for various indications, mostly in combination with other antifungal agents,[141,170] and in neonates with refractory invasive candidiasis.[326,337,338]

Anidulafungin

CLINICAL EFFICACY. The clinical efficacy of anidulafungin against *Candida* spp. was demonstrated in phase II or phase III studies in immunocompromised patients with esophageal candidiasis and candidemia. Anidulafungin had equivalent efficacy to fluconazole in esophageal candidiasis in a randomized, double-blind, international multicenter study; success was documented in 242 of 249 evaluable anidulafungin-treated patients (97.2%) and in 252 of 255 fluconazole-treated patients (98.8%). Adverse events leading to discontinuation were reported in 29 anidulafungin-treated patients (10%) versus 23 fluconazole-treated patients (8%).[258] In a noncomparative dose-ranging study in 123 patients with invasive candidiasis randomized to one of three intravenous regimens, 50, 75, or 100 mg once daily continued for 2 weeks beyond resolution or improvement of signs and symptoms, success rates at end of therapy were 84, 90, and 89 percent in the 50-, 75-, and 100-mg groups, respectively.[259] This study was followed by a randomized, double-blind phase III study that compared anidulafungin (100 mg once daily) with fluconazole (400 mg once daily) in a total of 245 mostly non-neutropenic patients with invasive candidiasis.[376] The preliminarily presented data indicate that more patients receiving anidulafungin had clinical and microbiologic success at the end of intravenous therapy (75.6% versus 60.2%); similar superiority was found at the 2- and 6-week follow-ups after end of all therapy (64.6% versus 49.2% and 55.9% versus 44.1%, respectively). Survival at end of therapy was higher in the anidulafungin-treated group (74% versus 69%).

APPROVAL STATUS AND DOSING. Anidulafungin is licensed in both the United States and Europe for patients 18 years of age or older for candidemia and certain forms of invasive *Candida* infections in non-neutropenic patients. In the United States, the compound is also licensed for esophageal candidiasis (see Table 252–2).[128] The recommended dose regimen consists of 100 mg (day 1: 200 mg) for invasive candidiasis and 50 mg QD (day 1: 100 mg) for esophageal candidiasis, administered at a rate of 1.1 mg/minute or higher. No dosage adjustment is needed in subjects with renal impairment, those undergoing hemodialysis, and patients with hepatic impairment (Child-Pugh class A, B and C).[128,475]

A pediatric phase I/II multicenter study of the pharmacokinetics and safety of anidulafungin has been completed in 19 granulocytopenic children with cancer. Patients were divided into two age cohorts (2-11 and 12-17 years) and were enrolled into sequential groups to receive 0.75 or 1.5 mg/kg/day[41] (Table 252–13). No drug-related serious adverse events were recorded. Pharmacokinetic parameters were similar across age groups and dosage cohorts and similar relative to adult subjects. Following single and multiple daily doses of 0.75 mg/kg and 1.5 mg/kg, plasma concentration data corresponded to those in adults following a daily 50 and 100 mg dose, respectively.[41] The pediatric development program of the compound is in advanced stages.

Micafungin

CLINICAL EFFICACY. Micafungin was studied in open-label dose-ranging trials of endoscopically proven esophageal candidiasis in patients with HIV infection.[358,441] A double-blind comparative study investigating 50, 100, and 150 mg/day versus fluconazole 200 mg/day for HIV-associated esophageal candidiasis showed similar endoscopic cure rates and safety profiles for micafungin at doses of 100 and 150 mg/day and fluconazole.[103] A further randomized, double-blind comparative trial in 523 patients 16 years old and older with esophageal candidiasis investigated micafungin (150 mg/day) versus fluconazole (200 mg/day).[102] For the primary end-point of endoscopic cure, treatment difference was –0.3 percent (micafungin, 87.7%; fluconazole, 88.0%). A large, phase III, 1:1 randomized, double-blind non-inferiority trial was completed that compared micafungin (100 mg

Modified from Seibel, N. L., Schwartz, C., Arrieta, A., et al.: Safety, tolerability, and pharmacokinetics of Micafungin (FK463) in febrile neutropenic pediatric patients. Antimicrob. Agents Chemother. 49:3317-3324, 2005; and Groll, A. H., Stergiopoulou, T., Roilides, E., and Walsh, T. J.: Micafungin: Pharmacology, experimental therapeutics and clinical applications. Expert Opin. Investig. Drugs 14:489-509, 2005.

once daily) and liposomal amphotericin B (3 mg/kg once daily) for first-line therapy of invasive *Candida* infections in a total of 531 adult patients. The overall success rate in both treatment arms of the trial was similar (89.6% versus 89.5%). No difference in survival occurred. Predefined safety parameters showed micafungin to have advantages over liposomal amphotericin B in renal function.[394] In another large, phase III, randomized clinical trial of a total of 593 patients with invasive candidiasis, micafungin at 100 mg/day, micafungin at 150 mg/day, and caspofungin at 50 mg/day (day 1: 70 mg) were equivalent in terms of efficacy, adverse events, and mortality.[124] A multinational, noncomparative open-label clinical trial investigated micafungin for proven or probable invasive aspergillosis alone or in combination with another systemic antifungal agent. A favorable response rate at the end of therapy was seen in 35.6 percent (80/225) of patients. Of those treated with only micafungin, favorable responses were seen in 6 of 12 (50%) of the primary and 9 of 22 (40.9%) of the salvage therapy group, with corresponding numbers in the combination treatment groups of 5 of 17 (29.4%) and 60 of 174 (34.5%) of the primary and salvage treatment groups, respectively.[106] Finally, micafungin (50 mg/day; 1 mg/kg for patients <50 kg) versus fluconazole (400 mg/day; 8 mg/kg for patients <50 kg) was investigated for prophylaxis of invasive fungal infections in 882 patients undergoing HSCT. Prophylaxis was given from the start of the conditioning regimen until 5 days after engraftment. The overall success rate was significantly higher for patients randomized to receive micafungin (80.0% versus 73.5%; $p = .03$). Drug-related adverse events were comparable.[466]

APPROVAL STATUS AND DOSING. In the United States, micafungin is licensed in adults for prevention of *Candida* infections in patients undergoing hematopoietic stem cell transplantation (HSCT), for treatment of candidemia and defined forms of invasive candidiasis, and for treatment of esophageal candidiasis (see Table 252–2). In Europe, the compound is licensed for use in neonates, children, and adults for treatment of invasive candidiasis and as prophylaxis of *Candida* infections in patients with allogeneic HSCT and those with prolonged neutropenia; it is also licensed for treatment of esophageal candidiasis in individuals 16 years and older. The recommended dosage is 100 mg/day for invasive candidiasis (≤40 kg body weight: 2 mg/kg), 150 mg/day for esophageal candidiasis (≤40 kg: 3 mg/kg), and 50 mg/day (≤40 kg: 1 mg/kg) for the preventive indication. Renal dysfunction, dialysis, or mild-to-moderate hepatic dysfunction (Child-Pugh class A and B) does not alter the pharmacokinetics of micafungin.[198,322]

The pharmacokinetics and safety of micafungin have been studied in 70 febrile granulocytopenic children aged 2 to 17 years. Micafungin was well tolerated at dosages of 0.5 to 3.0 mg/kg/day; pharmacokinetics were linear and similar to those observed in adults[424] (Table 252–14). A phase I trial investigated the safety and pharmacokinetics of micafungin (0.75 mg/kg, 1.5 mg/kg, and 3.0 mg/kg) in 18 premature infants weighing more than 1000 g. Micafungin pharmacokinetics were linear, but clearance rates were more rapid compared with those of older children and adults. No serious drug-related adverse events were observed.[204] A noncomparative phase II study investigated the activity of micafungin alone or in combination with other agents in 58 pediatric patients with mostly refractory invasive aspergillosis. Most patients ($n = 56$) received micafungin in combination with another agent, primarily liposomal amphotericin B ($n = 47$). The mean daily dose was 2.0 ± 1.2 mg/kg/day, and the mean duration of dosing was 67 ± 85 days. Overall response was 26/58 (45%). Thirteen patients (22%) discontinued micafungin, primarily because of a progression of underlying disease or invasive aspergillosis.[137] Micafungin was further investigated in the pediatric subpopulation of a double-blind, phase III trial in patients with invasive candidiasis or candidemia. Patients were randomized to receive intravenous micafungin (2 mg/kg/day) or liposomal amphotericin B (3 mg/kg/day) for a minimum of 14 days. There was no difference in the success rates (69.2% vs. 74.1%). The incidence of serious adverse events (3.8% vs. 9.3%) and the rate of patients discontinuing therapy because of an adverse event (3.8% vs. 16.7%) were lower in micafungin-treated patients.[26,371a] In a pooled analysis of adverse events data from six clinical trials that included close to 300 patients, 26.7 percent of patients had a treatment-related adverse event and 2.4 percent had a treatment-related adverse event that led to treatment discontinuation. No trends were seen with respect to dose or duration of treatment, and the types and rates of events wre similar to those observed in adults.[23a]

In Europe, the Summary of Product Characteristics for micafungin recommends careful monitoring of liver function and early discontinuation in the presence of significant and persistent elevation of ALT/AST values. It also recommends that micafungin treatment be conducted on a careful risk-benefit assessment,

particularly in patients with liver diseases or concomitant hepatotoxic-genotoxic therapies.[27a] This recommendation is based on preclinical data from a high-dose, long-term exposure model in rats treated with micafungin for either 3 or 6 months (equivalent to 12.5% or 25% of the total life span of the rat, respectively). The observed development of foci of altered hepatocytes and liver tumors in this species was dependent on both dose and duration of micafungin treatment. The human relevance of this finding is presently not known.

AGENTS FOR SYSTEMIC TREATMENT OF MYCOSES OF THE SKIN AND ITS APPENDAGES

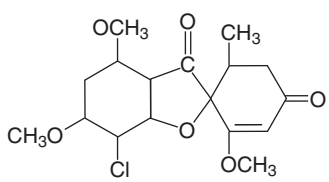
GRISEOFULVIN

Griseofulvin (Fig. 252–11) was isolated originally in 1939 as a natural product of *Penicillium griseofulvum*.[346] However, only in the late 1950s was it was reported to be effective as an antifungal agent.[154] Griseofulvin has been used since extensively for the systemic treatment of superficial dermatophyte infections in both adults and children.

MECHANISM OF ACTION. Griseofulvin interferes with fungal microtubule formation. It disrupts the cell's mitotic spindle formation and thus arrests the metaphase of cell division.[189] Several additional mechanisms of action have been proposed, including inhibition of nucleic acid synthesis, interference with the synthesis of cell wall chitin, and anti-inflammatory properties.[192] Griseofulvin is deposited in keratin precursor cells and produces an unfavorable environment for fungal invasion; infected skin, hair, and nails are replaced with tissue not infected by the dermatophyte.

ANTIFUNGAL ACTIVITY. As evident from its mechanism of action, griseofulvin is a fungistatic compound. It is active against *Trichophyton*, *Microsporon*, and *Epidermophyton* spp. The drug has no activity against yeastlike organisms such as *Candida* spp., *Pityrosporum* spp., and *C. neoformans*. It also is inactive against opportunistic hyaline and dematiaceous molds and the dimorphic (endemic) molds.[142]

PHARMACOKINETICS. Griseofulvin is commercially available for oral administration only as griseofulvin microsize and griseofulvin ultramicrosize. Microsize griseofulvin contains predominantly particles in the order of 4 μm in diameter, and ultramicrosize griseofulvin contains predominantly particles of less than 1 μm in diameter. Griseofulvin is weakly water soluble and poorly absorbed from the gastrointestinal tract. In comparison with nonmicronized drug preparations, micronized and ultramicronized formulations display enhanced absorption, particularly when polyethylene glycol is used as dispersion carrier in the ultramicronized formulations. Oral bioavailability of the micronized formulation is variable and ranges from 25 to 70 percent; ultramicronized griseofulvin, in contrast, is almost completely absorbed.[53,192]



Griseofulvin

Figure 252–11 Structural formula of griseofulvin.

After oral administration, C_{max} occurs approximately 4 hours after dosing. Griseofulvin distributes to keratin precursor cells and is concentrated in skin, hair, nails, liver, adipose tissue, and skeletal muscles. In skin, over time, a concentration gradient is established, with the highest concentrations found in the outermost stratum corneum.[127,427] Non–protein-bound drug is carried in the extracellular fluid, in sweat, and through transepidermal fluid loss; in addition, reversible protein binding and high lipid solubility cause griseofulvin to partition into the stratum corneum, where its concentrations exceed that of serum. Within 48 to 72 hours after discontinuation of the drug, plasma concentrations of griseofulvin are markedly reduced, and the compound no longer is detectable in the stratum corneum.[53,192]

Griseofulvin is oxidatively demethylated and conjugated with glucuronic acid primarily in the liver; its major metabolite, 6-desmethylgriseofulvin, is microbiologically inactive.[276] The elimination of the compound from plasma is bi-exponential, with a terminal elimination half-life of 9 to 21 hours.[392] Approximately one third of a single dose of micronized griseofulvin is excreted in feces, and 50 percent is excreted in urine within 5 days. In urine, the drug is excreted mainly as free and glucuronized 6-desmethylgriseofulvin. Unchanged drug in the urine accounts for less than 1 percent of the dose.[276,277]

Separate pharmacokinetic data for pediatric patients have not been published; however, the compound is approved for children older than 2 years of age. The recommended pediatric dosage of microsize griseofulvin is 10 to 20 mg/kg/day (maximum, 1 g) administered in two divided doses; the recommended pediatric dosage of ultramicronized griseofulvin is 5 to 10 mg/kg/day (maximum, 750 mg), also given in two divided doses.[125,143]

ADVERSE EFFECTS. Griseofulvin has an acceptable safety profile. More common adverse effects include headaches and a variety of gastrointestinal symptoms. Griseofulvin can cause photosensitivity and can exacerbate lupus and porphyria. Cases of erythema multiforme–like reactions, toxic epidermal necrolysis, and a reaction resembling serum sickness have been reported. Proteinuria, nephrosis, hepatotoxicity, leukopenia, and menstrual irregularities have been reported rarely in association with griseofulvin therapy. Griseofulvin has been noted to produce estrogen-like effects in children and reversible diminution of hearing.[53,142,192] Griseofulvin is contraindicated in patients with porphyria or hepatocellular failure. The compound has been shown to be teratogenic in animals and should not be administered to pregnant women. Griseofulvin also has mutagenic and carcinogenic potential; the significance of these observations for humans, however, is unclear.[142]

DRUG INTERACTIONS. Griseofulvin has been noted to enhance the clearance of oral contraceptives, cyclosporine, theophylline, aspirin, and warfarin. Concurrent use of phenobarbital may lead to decreased levels of griseofulvin. Finally, concurrent ingestion of alcohol may lead to a disulfiram-like reaction.[142]

INDICATIONS. Griseofulvin remains an important agent for the treatment of tinea capitis and refractory tinea corporis (Table 252–15).[135] For tinea capitis, 6 to 8 weeks of treatment usually are required.[125,217] The usual duration of therapy for refractory tinea corporis is 4 weeks.[125,144] Nail infections, which are rare occurrences in the pediatric population, usually fail to respond to therapy with griseofulvin and are better treated with itraconazole or terbinafine. Because griseofulvin is not effective against other fungal infections (Table 252–16), the infecting organism always should be identified as a dermatophyte before therapy is initiated. In vitro resistance of dermatophytes to griseofulvin has been reported and may be the cause of therapeutic failure.[27]

TABLE 252–15 Medical Management of Superficial Infections by Dermatophytes

Fungal Disease	Management
Tinea capitis	Griseofulvin (micronized: 5-10 mg/kg bid; ultramicronized: 2.5-5 mg/kg bid) for a total of 6 to 8 wk
	Fluconazole (6 mg/kg qd) for 4 wk
	Itraconazole (2.5 mg/kg bid) for 4 wk*
	Terbinafine (<20 kg: 62.5 mg qd; 20-40 mg: 125 mg qd; >40 mg: 250 mg qd) for 4 wk*
Tinea unguium	Itraconazole (2.5 mg/kg bid 1 wk/mo) for 3 to 4 mo*
	Terbinafine (<20 kg: 62.5 mg qd; 20-40 mg: 125 mg qd; >40 mg: 250 mg qd) for 6 wk (fingernail) or 12 wk (toenail)*
Tinea corporis	Topical antifungal azoles:
Tinea facialis	Miconazole, clotrimazole, econazole,
Tinea pedis	ketoconazole, sulconazole, oxiconazole bid for 2-4 wk
	Topical allyl/benzylamines, thiocarbamates:
	Terbinafine, naftifine, butenafine, tolnaftate qd/bid for 2-4 wk
	Other topical agents:
	Ciclopirox olamine bid for 2 to 4 wk
	Refractory infections/immunocompromised patients:
	Griseofulvin (micronized: 5-10 mg/kg bid; ultramicronized: 2.5-5 mg/kg bid) for 2-4 wk
	Fluconazole (3-6 mg/kg qd) for 2-4 wk
	Itraconazole (2.5 mg/kg bid) for 2-4 wk*
	Terbinafine (<20 kg: 62.5 mg qd; 20-40 mg: 125 mg qd; >40 mg: 250 mg qd) for 2-4 wk*

**Not approved by the U.S. Food and Drug Administration in individuals <18 years of age.*

TABLE 252–16 Medical Management of Superficial Infections by Yeastlike Fungi

Fungal Disease	Management
Candida dermatitis	Topical antifungal azoles:
Tinea versicolor	Miconazole, sulconazole, econazole, oxiconazole, clotrimazole bid for 2-4 wk
	Topical polyenes:
	Amphotericin B or nystatin bid/qid for 2-4 wk
	Other topical agents:
	Ciclopirox olamine bid for 2-4 wk
	Refractory infections/immunocompromised patients:
	Fluconazole (3-6 mg/kg qd) for 2-4 wk
	Itraconazole (2.5 mg/kg bid) for 2-4 wk*
Oropharyngeal candidiasis	Topical polyenes:
	Nystatin (200-600.000 U) or amphotericin B (100 mg) four times daily for ≥2 wk
	Topical antifungal azoles:
	Clotrimazole lozenges (10 mg) five times daily for ≥2 wk
	Refractory infections/immunocompromised patients:
	Fluconazole (3-6 mg/kg qd) for ≥2 wk
	Itraconazole (2.5 mg/kg bid) for ≥2 wk*
	Voriconazole (200 mg bid PO)
	Posaconazole (100-400 mg bid PO)*
	Amphotericin B deoxycholate (0.5-1 mg/kg qd)
	Echinocandin lipopeptides
Vulvovaginal candidiasis	Topical antifungal azoles:
	Miconazole, clotrimazole, butoconazole, terconazole, tioconazole qhs for ≤7 days
	Topical polyenes:
	Nystatin qhs for 14 days
	Systemic antifungal azoles:
	Fluconazole 150 mg PO × 1day/50 mg PO × 3days
	Refractory infections/immunocompromised patients:
	Fluconazole (3-6 mg/kg qd) for ≥2 wk
	Itraconazole (2.5 mg/kg bid) for ≥2 wk*
	Amphotericin B deoxycholate (0.5-1 mg/kg qd)

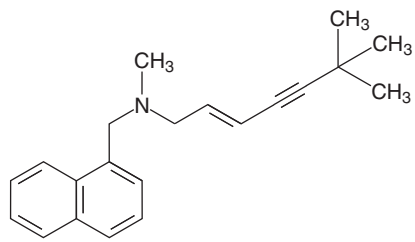
**Not approved by the U.S. Food and Drug Administration in individuals of <18 years of age.*

Data from Bennett, J. E.: Antifungal agents. In *Mandell, G. L., Bennett, J. E., and Dolin, R. (eds.): Principles and Practice of Infectious Diseases. 4th ed. New York, Churchill Livingstone, 1995, pp. 401-410; and Walsh, T. J., Gonzalez, C., Lyman, C. A., et al.: Invasive fungal infections in children: Recent advances in diagnosis and treatment. Adv. Pediatr. Infect. Dis. 11:187-290, 1996.*

TERBINAFINE

The synthetic allylamine terbinafine (Fig. 252–12) is a relatively novel antifungal agent that is useful for topical and systemic (oral) treatment of superficial infections of the skin and its appendages by dermatophytes and yeasts, as well as possibly for treatment of cutaneous sporotrichosis. Terbinafine acts by inhibiting the biosynthesis of fungal ergosterol at the level of squalene epoxidase (see Fig. 252–8), thus leading to depletion of ergosterol and accumulation of toxic squalenes in the fungal cell membrane.[32]

ANTIFUNGAL ACTIVITY. Terbinafine has exceptionally potent and fungicidal in vitro activity against dermatophytes.[134] It also is highly active against *Aspergillus* spp., certain Hyalohyphomycetes, dematiaceous and dimorphic fungi, and *P. jiroveci* (formerly *P. carinii*). Its in vitro activity against yeasts appears more variable.[151,184,227,397] Comparative studies have indicated that terbinafine may be more active against *Aspergillus* spp. than is itraconazole[426] or amphotericin B,[416] more active than is itraconazole against *S. schenkii*,[248] and less or comparably active than are the azoles against yeasts.[426] Synergy with triazoles against *C. albicans*,[139,501] *C. glabrata*,[35] *C. neoformans*,[139] *A. fumigatus*,[318,396] non-*Aspergillus* Hyalohyphomycetes[304,305,342,397] and Zygomycetes[164] has been reported. Although more variable, synergy with amphotericin B also has been demonstrated for filamentous and yeastlike fungi.[397] Terbinafine resistance in clinical dermatophyte isolates is a rare occurrence; only two cases have been documented in which the resistance mechanism was identified as a single amino acid substitution in squalene epoxidase.[343]



Terbinafine

Figure 252–12 Structural formula of terbinafine.

PHARMACOKINETICS. The pharmacokinetic properties of terbinafine in adults are well characterized.[32] Independent of food, oral bioavailability is 70 to 80 percent. Over the adult

dosage range of 125 to 750 mg once daily, terbinafine displays linear plasma pharmacokinetics. C_{max} of 0.5 to 2.7 μg/mL is measured within 2 hours,[254] and steady state is reached after 10 to 14 days after only twofold accumulation.[32] As a lipophilic drug, terbinafine is strongly bound to plasma proteins. The compound is distributed extensively to tissues and accumulates throughout adipose tissues, dermis, epidermis, and nail. It exhibits a triphasic distribution pattern in plasma, with a terminal half-life up to 3 weeks; microbiologically active concentrations can be measured in plasma for weeks to months after the last dose, a finding consistent with a slow redistribution from peripheral tissue and adipose tissue sites.[32,254,328]

Terbinafine undergoes extensive and complex hepatic biotransformation that involves at least seven cytochrome P-450 enzymes.[479] Fifteen metabolites have been identified, mainly in urine; none has been shown to be mycologically active.[255] Studies employing radiolabeled drug demonstrated that urinary excretion accounts for more than 70 percent and fecal elimination for 10 percent of radioactivity; the extent of enterohepatic recycling is unknown.[219,220] As a consequence of the compound's extensive hepatic metabolism and urinary excretion, caution is warranted in treating patients with severe hepatic and renal impairment.[32]

Several studies were conducted to evaluate the safety, pharmacokinetics, and antifungal efficacy in the pediatric population.[2,67,144,220,231,256,279,330] The pharmacokinetic properties of terbinafine and five known major metabolites in plasma and urine were investigated carefully after single and repeated oral administration of 125 mg/day to 12 pediatric patients for up to 56 days (mean age, 8 years; age range, 5 to 11 years; weight range, 17 to 34 kg) (Table 252–17). No differences were found regarding the metabolism of terbinafine in comparison with healthy adults. Steady state was reached at least on day 21, and no further accumulation occurred between days 21 and 56.[219,330] Comparison of the kinetic parameters of terbinafine after single administration of 125 mg showed comparable C_{max} and T_{max} (time until occurrence of C_{max}) values, and a 40 percent higher AUC; when dose was calculated as milligrams per kilogram or milligrams per square meter, children showed a lower AUC (range, –29% to –45%) as compared with adults, a finding indicating a higher, weight-normalized volume of distribution into lipophilic tissue. Children had shorter beta-phase elimination half-lives, but the gamma-phase, terminal half-life determined after multiple dosing during washout was similar to that in adults. Thus, in children weighing 17 to 34 kg, a dose of 125 mg terbinafine yields pharmacokinetic properties similar to those in adults without drug accumulation, and use of a calculation of milligrams per kilogram or milligrams per square meter would lead to lower drug levels than those recorded in adults.[2,220,231,330] Exploration of lower doses (62.5 mg/day) in eight children weighing 19 to 35 kg revealed an approximate reduction in trough level of 50 percent, a finding indicating linearity of plasma pharmacokinetics in children.[231]

Based on the experience with dosages of 10 mg/kg and less in adults and the described pharmacokinetic profile of the compound in children, a dose of 250 mg/day has been proposed for children weighing more than 40 kg, a dose of 125 mg/day for children weighing 20 to 40 kg, and 62.5 mg/day for children weighing less than 20 kg.[231]

TABLE 252–17 Pharmacokinetic Parameters of Terbinafine in Children after a Single Dose of 125 mg Compared with Similar Parameters in Healthy Adults*

	Children with Tinea Capitis (n = 12)	Healthy Adults (n = 16)	Statistical Comparison
Age (yr)	8 ± 2 (5-11)	26 ± 4 (21-34)	—
Weight (kg)	26 ± 5 (17-34)	64 ± 6 (54-80)	—
C_{max} (μg/mL)	0.706 ± 0.277 (0.333-1.212)	0.565 ± 0.329 (0.196-1.172)	NS
T_{max} (hr)	2.1 ± 1.1 (1.0-4.0)	5 ± 0.7 (0.7-2.5)	NS
$AUC_{0-\infty}$ (μg/mL/hr)	2.967 ± 0.965 (1.474-4.841)	2.135 ± 1.131 (0.758-4.435)	$p < .05$
$t_{1/2}$beta (hr)	14.7 ± 4.3 (10-26)	27 ± 12 (12-58)	$p < .001$

**Mean values ± SD (range).*

$AUC_{0-\infty}$, area under the concentration versus time curve from zero to infinity; C_{max}, peak plasma concentration; NS, not significant; $t_{1/2}$beta, elimination half-life; T_{max}, time until occurrence of peak plasma concentration.

Modified from Jones, T. C.: Overview of the use of terbinafine (Lamisil) in children. Br. J. Dermatol. 132:683-689, 1995.

ADVERSE EFFECTS. In adults, terbinafine usually is well tolerated at doses of up to 500 mg/day, and it has a relatively low incidence of adverse effects. The primary adverse effects associated with terbinafine include gastrointestinal upsets and skin reactions in 2 to 7 percent of patients. Terbinafine can cause hepatitis and liver failure. Potentially severe hepatotoxicity is estimated to occur in 1 of 120,00 patients, and asymptomatic rises in liver enzyme activities are likely to occur at a frequency of 1 per 200. Although hepatotoxicity may occur in patients with or without chronic or active liver disease, the drug should not be administered in patients with an underlying liver problem, and liver function tests should be obtained before terbinafine is prescribed. Less common significant adverse effects have included reversible loss of taste, severe skin eruptions including generalized erythematous pustulosis and drug-induced lupus erythematosus, Stevens-Johnson syndrome, and blood dyscrasias.[3] No evidence indicates that these idiosyncratic effects are increasing in incidence with the increasing use of terbinafine.[345]

Several clinical studies documented the safety of terbinafine in pediatric patients.[67,74,144,145,231,256,279,330,429] Terbinafine, administered for a median duration of 4 weeks (range, 1 to 28 weeks) was safe in children between 2 and 17 years of age who received the drug for various dermatophyte and yeast infections of the skin: of a total of 196 patients enrolled in 6 studies, 22 adverse events were observed in 15 patients. Adverse events probably associated with the use of terbinafine occurred in 6 of these patients (3%), but in none of these patients did terbinafine therapy have to be discontinued.[231] Terbinafine was similarly well tolerated in two double-blind, randomized trials in children with tinea capitis.[144,279]

DRUG INTERACTIONS. Multiple cytochrome P-450 enzymes are involved in the metabolism of terbinafine. However, with the possible exception of CYP2D6 substrates, in vitro studies revealed little or no effect on the metabolism of many characteristic CYP substrates.[479] Inhibition of CYP2D6-mediated metabolism may be relevant with the concomitant use of tricyclic antidepressants, beta blockers, selective serotonin reuptake inhibitors, and type B monoamine oxidase inhibitors.

In clinical interaction studies, no pharmacokinetic or pharmacodynamic interactions were observed with the concomitant administration of terfenadine,[388] midazolam,[7] and alfentanil.[401] Terbinafine can (1) reduce the clearance of theophylline[455]; (2) increase levels of nortryptiline,[469] amitryptiline,[78] desipramine,[285] imipramine,[447] and paroxetine[524]; (3) increase or reduce warfarin exposure[190,501]; and (4) reduce the trough cyclosporine concentration in patients with transplants.[280] The metabolism of terbinafine may be decreased by cimetidine and increased by rifampin.[184]

CLINICAL INDICATIONS. Terbinafine is approved by the FDA in subjects older than18 years of age for the treatment of

onychomycosis of toenails and fingernails caused by dermatophytes. It may be indicated for treatment of other superficial infections of the skin and its appendages caused by dermatophytes,[3,32,143] for cutaneous and lymphocutaneous sporotrichosis[83,218] subcutaneous phaeohyphomycosis[56,374] (see Tables 252–4 and 252–15), and, investigationally, for seborrhoic dermatitis.[476] Recommended durations of treatment for tinea capitis, tinea corporis and pedis, fingernail onychomycosis, and toenail onychomycosis in adults are 4, 2, 6, and 12 weeks, respectively.[231]

Several studies investigated the safety and clinical efficacy of terbinafine in the pediatric population.[67,74,144,145,231,256,279,330,429] The overall mycologic and clinical efficacy for 152 children aged 2 to 17 years with various dermatophyte and yeast infections of the skin exceeded 95 percent.[231] In a prospective, randomized clinical trial in 210 children comparing treatment with 4 weeks of terbinafine versus 8 weeks of griseofulvin for *Trichophyton* tinea capitis, both regimens showed overall similar efficacy.[145] In a subsequent study of the duration of treatment in 176 patients, both 2 and 4 weeks of treatment were clinically superior to a 1-week regimen and had similar treatment efficacy, a finding suggesting that a 2-week course may be sufficient for patients with *Trichophyton* tinea capitis.[144] A similar study performed in 134 patients with *Microsporon* tinea capitis investigating 6, 8, 10, or 12 weeks of therapy demonstrated that 6 weeks of therapy were equivalent to griseofulvin.[279] Finally, a meta-analysis of 6 randomized, comparative clinical trials indicated that a 2- to 4-week course of terbinafine was at least as effective as a 6- to 8-week course of griseofulvin for the treatment of tinea capitis caused by *Trichophyton* spp.[135]

The broad-spectrum fungicidal in vitro activity, systemic availability, and lack of significant side effects suggested potential usefulness of terbinafine against deep-seated fungal infections. However, terbinafine was ineffective in animal models of pulmonary and disseminated aspergillosis,[243,417] systemic sporotrichosis,[234] cerebral phaeohyphomycosis,[116] disseminated candidiasis, and pulmonary cryptococcosis,[396] findings explained by nonsaturable protein-binding kinetics.[417] Against experimental pulmonary pneumocystosis, terbinafine was active in some,[90,91] but not all,[499] models.

TOPICAL ANTIFUNGAL AGENTS

Apart from fungal keratitis, the use of topical antifungal agents is confined to superficial infections of the skin and mucosal surfaces. The decision to treat superficial infections of the skin and mucosal surfaces with a topical or systemic agent depends mainly on the site and extent of the infection. Immunocompromised children, however, usually require systemic therapies, as do patients with tinea capitis and onychomycosis (see Tables 252–15 and 252–16).[125]

TOPICAL THERAPEUTICS FOR SUPERFICIAL SKIN INFECTIONS

Dermatophytosis is caused by the filamentous fungi *Microsporon* spp., *Trichophyton* spp., and *Epidermophyton floccosum*. Many different agents and formulations are available for topical treatment of dermatophytic skin infections (tinea corporis, facialis, or pedis), including allylamines and azoles. Agents for treatment of *Candida* dermatitis and tinea (pityriasis) versicolor (caused by *Malassezia furfur* or *Malassezia pachydermatidis*) include various topical azoles and topical polyenes. Most topical agents are applied twice daily well beyond the clinical resolution of the infection. A detailed review of the pharmacologic properties of these topical drugs and of the treatment of cutaneous mycoses is beyond the scope of this chapter and can be found elsewhere.[125,143,217]

TOPICAL THERAPEUTICS FOR MUCOSAL CANDIDIASIS

Agents for the topical treatment of vulvovaginal candidiasis include a large variety of antifungal azoles and the polyene nystatin.[42,433] Azole agents may be absorbed to a minor extent and potentially can interfere with the metabolism of concomitant drugs. For example, potentiation of the anticoagulatory effects of acenocoumarol was noted after vaginal administration of miconazole capsules to two postmenopausal patients[266] and after oral administration of miconazole gel in three elderly patients with oral candidiasis.[341]

Antifungal azoles such as clotrimazole and miconazole and antifungal polyenes such as amphotericin B and nystatin are effective in the treatment of oropharyngeal candidiasis. Many clinical trials evaluated the usefulness of these agents for prevention of fungal infections in immunocompromised patients with cancer or HSCT. Although most agents have documented efficacy in the prevention of oropharyngeal candidiasis, they are not effective in preventing invasive mycoses and in improving infection-related and overall mortality in this setting.[186,214,282,464]

FUTURE DIRECTIONS

Pediatric age groups display important differences in host biology, predisposing conditions, epidemiology, and presentation of fungal infections relative to the adult population. Since the late 1990s, major advances have been made in the field of medical mycology. Most importantly, an array of new antifungal agents has entered the clinical arena. Although the final pediatric approval of several of these agents remains to be established, the development of pediatric therapies is moving forward at a steady pace. Invasive fungal infections will remain important causes of morbidity and mortality in immunocompromised pediatric patients. The availability of alternative therapeutic options is an important advance; at the same time, however, antifungal therapy has become increasingly complex. In addition to information on prior antifungal therapies, microbiologic data, existing comorbidities, and concurrent medications, detailed knowledge of the available antifungal armamentarium and contemporary clinical trials are needed more than ever in the management of the individual patient.[85]

CHAPTER 253

Drugs for Parasitic Infections

The Medical Letter (Peter J. Hotez)

With increasing travel, immigration, and use of immunosuppressive drugs and the spread of acquired immunodeficiency syndrome (AIDS), physicians anywhere may see infections caused by parasites. The table below lists first-choice and alternative drugs for most parasitic infections. A later table summarizes the known prenatal risks of antiparasitic drugs. The brand names and manufacturers of the drugs are listed at the end of the chapter. The table was modified from *The Medical Letter*, Vol. 5 (Suppl), last modified August 2008.

Infection		Drug	Adult Dosage	Pediatric Dosage
ACANTHAMOEBA keratitis				
Drug of choice:		See footnote 1		
AMEBIASIS *(Entamoeba histolytica)*				
Asymptomatic				
Drug of choice:		Iodoquinol[2]	650 mg PO tid × 20 d	30-40 mg/kg/d (max. 2 g) PO in 3 doses × 20 d
	OR	Paromomycin[3]	23-35 mg/kg/d PO in 3 doses × 7 d	25-35 mg/kg/d PO in 3 doses × 7 d
	OR	Diloxanide furoate[4]*	500 mg PO tid × 10 d	20 mg/kg/d PO in 3 doses × 10 d
Mild to moderate intestinal disease				
Drug of choice:[5]		Metronidazole	500-750 mg PO tid × 7-10 d	35-50 mg/kg/d PO in 3 doses × 7-10 d
	OR	Tinidazole[6]	2 g once PO daily × 3 d	≥3 yr: 50 mg/kg/d (max. 2 g) PO in 1 dose × 3 d
		either followed by		
		Iodoquinol[2]	650 mg PO tid × 20 d	30-40 mg/kg/d (max. 2 g) PO in 3 doses × 20 d
	OR	Paromomycin[3]	25-35 mg/kg/d PO in 3 doses × 7 d	25-35 mg/kg/d PO in 3 doses × 7 d
Severe intestinal and extraintestinal disease				
Drug of choice:		Metronidazole	750 mg PO tid × 7-10 d	35-50 mg/kg/d PO in 3 doses × 7-10 d
	OR	Tinidazole[6]	2 g once PO daily × 5 d	≥3 yr: 50 mg/kg/d (max. 2 g) PO in 1 dose × 3 d
		either followed by		
		Iodoquinol[2]	650 mg PO tid × 20 d	30-40 mg/kg/d (max. 2 g) PO in 3 doses × 20 d
	OR	Paromomycin[3]	25-35 mg/kg/d PO in 3 doses × 7 d	25-35 mg/kg/d PO in 3 doses × 7 d
AMEBIC MENINGOENCEPHALITIS, primary and granulomatous				
Naegleria				
Drug of choice:		Amphotericin B[7,8]	1.5 mg/kg/d IV in 2 doses × 3 d, then 1 mg/kg/d × 6 d plus 1.5 mg/d intrathecally × 2 d, then 1 mg/d every other day × 8 d	1.5 mg/kg/d IV in 2 doses × 3 d, then 1 mg/kg/d × 6 d plus 1.5 mg/d intrathecally × 2 d, then 1 mg/d every other day × 8 d
Acanthamoeba				
Durg of choice:		See footnote 9		

* *Availability problems. See table on page 3309.*

1. *Topical 0.02% chlorhexidine and polyhexamethylene biguanide (PHMB, 0.02%, either alone or in combination, have been used successfully in a large number of patients. Treatment with either chlorhexidine or PHMB is often combined with propamidine isethionate* (Brolene) *or hexamidine* (Desmodine). *None of these drugs is commercially available or approved for use in the United States, but they can be obtained from compounding pharmacies (see footnote 2). Leiter's Park Avenue Pharmacy, San Jose, CA (800-292-6773); www.leiterrx.com) is a compounding pharmacy that specializes in ophthalmic drugs. Propamidine is available over the counter in the United Kingdom and Australia. Hexamidine is available in France. The combination of chlorhexidine, natamycin (pimaricin), and débridement also has been successful (K Kitagawa et al, Jpn J Ophthalmol 2003; 47:616). Débridement is most useful during the stage of corneal epithellial infection. Most cysts are resistant to neomycin; its use is no longer recommended. Azole antifungal drugs (ketoconazole, itraconazole) have been used as oral or topical adjuncts (FL Shuster and GS Visvesvara, Drug Resist Update 2004; 7:41). Use of corticosteroids is controversial (K Hammersmith, Curr Opinions Ophthal 2006; 17:327; ST Awwad et al, Eye Contact Lens 2007; 33:1).*
2. *Iodoquinol should be taken after meals.*
3. *Paromomycin should be taken with a meal.*
4. *Not available commercially. It may be obtained through compounding pharmacies such as Panorama Compounding Pharmacy, 6744 Balboa Blvd, Van Nuys, CA 91406 (800-247-9767) or Medical Center Pharmacy, New Haven, CT (203-688-6816). Other compounding pharmacies may be found through the National Association of Compounding Pharmacies (800-687-7850) or the Professional Compounding Centers of America (800-331-2498, www.pccarx.com).*
5. *Nitazoxanide may be effective against a variety of protozoan and helminth infections (DA Bobak, Curr Infect Dis Rep 2006; 8:91; E Diaz et al, Am J Trop Med Hyg 2003; 68:384). It was effective against mild to moderate amebiasis, 500 mg bid × 3 d, in a recent study (JF Rossignol et al, Trans R Soc Trop Med Hyg 2007 101:1025). It is FDA-approved only for treatment of diarrhea caused by* Giardia or Cryptosporidium *(Med Lett Drugs Ther 2003; 45:29). Nitazoxanide is available in 500-mg tables and an oral suspension; it should be taken with food.*
6. *A nitroimidazole similar to metronidazole, tinidazole appears to be as effective as metronidazote and better tolerated (Med Lett Durgs Ther 2004; 46:70). It should be taken with food to minimize GI adverse effects. For children and patients unable to take tablets, a pharmacist can crush the tablets and mix them with cherry syrup (*Humco, *and others). The syrup suspension is good for 7 days at room temperature and must be shaken before use (HB Fung and TL Doan et al, Clin Ther 2005; 27:1859). Ornidazole, a similar drug, is also used outside the United States.*
7. *Not FDA-approved for this indication.*
8. *Although a* Naegleria fowleri *infection was treated successfully in a 9-year-old girl with combination of amphotericin B and miconazole both intravenous and intrathecal, plus oral rifampin (JS Seidel et al, N. Engl. J. Med. 1982; 306:346). Amphotericin B and miconazole appear to have a synergistic effect, but* Medical Letter *consultants believe the rigampin probably had no additional effect (GS Visvesvara et al, FEMS Immunol Med Microbiol 2007; 50:1). Parenteral miconazole is no longer available in the United States. Azithromycin has been used successfully in combination therapy to treat* Balmuthia *infection, but was changed to clarithromycin because of toxicity concerns and for better penetration into the cerebrospinal fluid. In vitro, azithromycin is more active than clarithromycin against* Naegleria, *so may be a choice combined with amphotericin B for treatment of* Naegleria *(TR Deetz et al, Clin Infect Dis 2003; 37:1304; FL Schuster and GS Visvesvara, Drug Resistance Updates 2004; 7:41). Combinations of amphotericin B, ornidazote and rifampin (R Jain et al, Neurol Indian 2002; 50:470) and amphotericin B fluconazole and rifampin have also been used (J Vargas-Zepeda et al, Arch Med Research 2005; 36:83). Case reports of other successful therapy have been published (FL Schuster and GS Visvesvara, Int J Parasitol 2004; 34:1001).*

Infection	Drug	Adult Dosage	Pediatric Dosage
AMEBIC MENINGOENCEPHALITIS (continued)			
Balamuthia mandrillaris			
Drug of choice:	See footnote 10		
Sappinia diploidea			
Drug of choice:	See footnote 11		
ANCYLOSTOMA caninum (Eosinophilic enterocolotis)			
Drug of choice:	Albendazole[7,12]	400 mg PO once	400 mg PO once
OR	Mebendazole	100 mg PO bid × 3 d	100 mg PO bid × 3 d
OR	Pyrantel pamoate[7,13]*	11 mg/kg (max. 1 g) PO × 3 d	11 mg/kg (max. 1 g) PO × 3 d
OR	Endoscopic removal		
Ancylostoma duodenale, see HOOKWORM			
ANGIOSTRONGYLIASIS *(Angiostrongylus cantonensis, Angiostrongylus costaricensis)*			
Drug of choice:	See footnote 14		
ANISAKIASIS (*Anisakis spp*)			
Treatment of choice:[15]	Surgical or endoscopic removal		
ASCARIASIS (*Ascaris lumbricoides,* roundworm)			
Drug of choice:[5]	Albendazole[7,12]	400 mg PO once	400 mg PO once
OR	Mebendazole	100 mg bid PO × 3 d or 500 mg once	100 mg PO bid × 3 d or 500 mg once
OR	Ivermectin[7,16]	150-200 µg/kg PO once	150-200 µg/kg PO once
BABESIOSIS *(Babesia microti)*			
Drug of choice:[17]	Clindamycin[7,18]	1.2 g bid IV or 600 mg tid PO × 7-10 d	20-40 mg/kg/d PO in 3 doses × 7-10 d
	plus quinine[7,19]	650 mg PO tid × 7-10 d	30 mg/kg/d PO in 3 doses × 7-10 d
OR	Atovaquone[7,20]	750 mg PO bid × 7-10 d	40 mg/kg/d PO in 2 doses × 7-10 d
	plus azithromycin[7]	600 mg PO daily × 7-10 d	12 mg/kg/d PO × 7-10 d
Balamuthia mandrillaris, see AMEBIC MENINGOENCEPHALITIS, PRIMARY			
BALANTIDIASIS *(Balantidium coli)*			
Drug of choice:	Tetracycline[7,21]	500 mg PO qid × 10 d	400 mg/k/d (max. 2 g) PO in 4 doses × 10 d
Alternative:	Metronidazole[7]	700 mg PO tid × 5 d	35-50 mg/kg/d PO in 3 doses × 5 d
OR	Iodoquinol[2,7]	650 mg PO tid × 20 d	30-40 mg/k/d (max. 2 g) PO in 3 doses × 20 d

9. Several patients with granulomatous amebic encephalitis (GAE) have been successfully treated with combinations of pentamidine, sulfadiazine, flucytosine, and either fluconazole or itraconazole (GS Visvesvara et al, FEMS Immunol Med Microbiol 2007; 50:1). GAE in an AIDS patient was treated successfully with sulfadiazine, pyrimethamine, and fluconazole combined with surgical resection of the CNS lesion (M Seijo Martinez et al, J Clin Microbiol 2000; 38:3892). Chronic Acanthamoeba *meningitis was successfully treated in two children with a combination of oral trimethoprim/sulfamethoxazole, rifampin, and ketoconazole (T Singhal et al, Pediatr Infect Dis J 2001; 20:623). Disseminated cutaneous infection in an immunocompromised patient was treated successfully with IV pentamidine, topical chlorhexidine, and 2% ketoconazole cream, followed by oral itraconazole (CA Slater et al, N Engl J Med 1994; 331:85) and with voriconazole and amphotericin B lipid complex (R Walia et al, Transplant Infect Dis 2007;9:51). Other reports of successful therapy have been described (FL Schuster and GS Visvesvara, Drug Resistance Updates 2004; 7:41). Susceptibility testing of* Acanthamoeba *isolates has shown differences in drug sensitivity between species and even among strains of a single species; antimicrobial susceptibility testing is advisable (FL Schuster and GS Visvesvara, Int J Parasitiol 2004;34:1001).*

10. B. mandrillaris *is a free-living ameba that causes subacute to fatal granulomatous amebic encephalitis (GAE) and cutaneous disease. Two cases of* Balamuthia *encephalitis have been successfully treated with flucytosine, pentamidine, fluconazole and sulfadiazine plus either azithromycin or clarithromycin (phenothiazines were also used) combined with surgical resection of the CNS lesion (TR Deetz et al, Clin Infect Dis 2003; 37:1304). Another case was successfully treated following open biopsy with pentamidine, fluconazole, sulfadiazine, and clarithromycin (S Jung et al, Arch Pathol Lab Med 2004; 128:466).*

11. A free-living ameba once thought not to be pathogenic to humans. S. diploidea *has been successfully treated with azithromycin, pentamidine, itraconazole, and flucytosine combined with surgical resection of the CNS lesion (BB Gelman et al, J Neuropathol Exp Neurol 2003; 62:990).*

12. Albendazole must be taken with food; a fatty meal increases oral bioavailability.

13. Pyrantel pamoate suspension can be mixed with milk or fruit juice.

14. A. cantonensis *causes predominantly neurotropic disease.* A. costaricensis *causes gastrointestinal disease. Most patients infected with either species have a self-limited course and recover completely. Analgesics, corticosteroids and careful removal of CSF at frequent intervals can relieve symptoms from increased intracranial pressure (V Lo Re III and SJ Gluckman, Am J Med 2003; 114:217). Treatment for* A. cantonensis *is controversial and varies across endemic areas. No antihelminthic drug is proven to be effective and some patients have worsened with therapy (TJ Slom et al, N Engl J Med 2002; 346:668). Mebendazole and a corticosteroid, however, appear to shorten the course of infection (H-C Tsai et al, Am J Med 2001; 111:109; V Chotmongkol et al, Am J Trop Med Hyg 2006; 74:1122). Albendazole has also relieved symptoms of angiostrongyliasis (XG Chen et al, Emerg Infect Dis 2005; 11:1645).*

15. A Repiso Ortega et al, Gastroenterol Hepatol 2003; 26:341. Successful treatment of Anisakiasis *with albendazole 400 mg PO bid × 3-5 d has been reported, but the diagnosis was presumptive (DA Moore et al, Lancet 2002; 360:54; E Pacios et al, Clin Infect Dis 2005; 41:1825).*

16. Safety of ivermectin in young children (<15 kg) and pregnant women remains to be established. Ivermectin should be taken on an empty stomach with water.

17. Exchange transfusion has been used in severely ill patients and those with high (>10%) parasitemia (VI Powell and K Grima, Transfus Med Rev 2002; 16:239). In patients who were not severely ill, combination therapy with atovaquone and azithromycin was as effective as clindamycin and quinine and may have been better tolerated (PJ Krause et al, N Engl J Med 2000; 343:1454). Longer treatment courses may be needed in immunosuppressed patients and those with asplenia. Patients are commonly co-infected with Lyme disease (Med Lett Drugs Ther 2007; 49:49; AC Steere et al, Clin Infect Dis 2003; 36:1078).

18. Oral clindamycin should be taken with a full glass of water to minimize esophageal ulceration.

19. Quinine should be taken with or after a meal to decrease gastrointestinal adverse effects.

20. Atovaquone is available in an oral suspension that should be taken with a meal to increase absorption.

21. Use of tetracyclines is contraindicated in pregnancy and in children <8 years old. Tetracycline should be taken 1 hour before or 2 hours after meals and/or dairy products.

Infection	Drug	Adult Dosage	Pediatric Dosage
BAYLISASCARIASIS *(Baylisascaris procyonis)*			
Drug of choice:	See footnote 22		
BLASTOCYSTIS *hominis* infection			
Drug of choice:	See footnote 23		
CAPILLARIASIS *(Capillaria philippinensis)*			
Drug of choice:	Metronidazole[7]	200 mg PO bid × 20 d	200 mg PO bid × 20 d
Alternative:	Albendazole[7,12]	400 mg PO daily × 10 d	400 mg PO daily × 10 d
Chagas disease, see TRYPANOSOMIASIS			
Clonorchis sinensis, see FLUKE infection			
CRYPTOSPORIDIOSIS *(Cryptosporidium)*			
Non-HIV infected			
Drug of choice:	Nitazoxanide[5]	500 mg PO bid × 3 d	1-3 yr: 100 mg PO bid × 3 d 4-11 yr: 200 mg PO bid × 3 d >12 yr: 500 mg PO q12h × 3 d
HIV infected			
Drug of choice:	See footnote 24		
CUTANEOUS LARVA MIGRANS (creeping eruption, dog and cat hookworm)			
Drug of choice:[25]	Albendazole[7,12]	400 mg PO daily × 3 d	400 mg PO daily × 3 d
OR	Ivermectin[7,16]	200 μg/kg PO daily × 1-2 d	200 μg/kg PO daily × 1-2 d
CYCLOSPORIASIS *(Cyclospora cayetanensis)*			
Drug of choice:[26]	Trimethoprim/sulfamethoxazole[7]	TMP 160 mg/SMX 800 mg (1 DS tab) PO bid × 7-10 d	TMP 5 mg/kg/SMX 25 mg/kg/d PO in 2 doses × 7-10 d
CYSTICERCOSIS, see TAPEWORM infection			
DIENTAMOEBA fragilis infection[27]			
Drug of choice:	Iodoquinol[2,7]	650 mg PO tid × 20 d	30-40 mg/kg/d (max. 2 g) PO in 3 doses × 20 d
OR	Paromomycin[3,7]	25-35 mg/kg/d PO in 3 doses × 7 d	25-35 mg/kg/d PO in 3 doses × 7 d
OR	Tetracycline[7,21]	500 mg PO qid × 10 d	40 mg/kg/d (max. 2 g) PO in 4 doses × 10 d
OR	Metronidazole[7]	500-750 mg PO tid × 10 d	35-50 mg/kg/d PO in 3 doses × 10 d
Diphyllobothrium latum, see TAPEWORM infection			
DRACUNCULUS medinensis (guinea worm) infection			
Drug of choice:	See footnote 28		
Echinococcus, see TAPEWORM infection			
Entamoeba histolytica, see AMEBIASIS			
ENTEROBIUS *vermicularis* (pinworm) infection			
Drug of choice:[29]	Mebendazole	100 mg PO once; repeat in 2 wk	100 mg PO once; repeat in 2 wk
OR	Pyrantel pamoate[13]*	11 mg/kg base PO once (max. 1 g); repeat in 2 wk	11 mg/kg base PO once (max. 1 g); repeat in 2 wk
OR	Albendazole[7,12]	400 mg PO once; repeat in 2 wk	400 mg PO once; repeat in 2 wk
Fasciola hepatica, see FLUKE infection			
FILARIASIS[30]			
Wuchereria bancrofti, Brugia malayi, Brugia timori			
Drug of choice:[31]	Diethylcarbamazine*	6 mg/kg/d PO in 3 doses × 12d[32,33]	6 mg/kg/d PO in 3 doses × 12d[32,33]

22. No drug has been demonstrated to be effective. Albendazole 25 mg/kg/d PO × 20 d started as soon as possible (up to 3 d after possible infection) might prevent clinical disease and is recommended for children with known exposure (ingestion of raccoon stool or contaminated soil) (WJ Murray and KR Kazacos, Clin Infect Dis 2004; 39:1484). Mebendazole, levamisole, or ivermectin could be tried if albendazole is not available. Steroid therapy may be helpful, especially in eye and CNS infections (PJ Gavin et al, Clin Microbiol Rev 2005; 18:703). Ocular baylisascariasis has been treated successfully using laser photocoagulation therapy to destroy the intraretinal larvae (CA Garcia et al, Eye 2004; 18:624).

23. Clinical significance of these organisms is controversial; metronidazole 750 mg PO tid × 10 d, iodoquinol 650 mg PO tid × 20 d, or trimethoprim/sulfamethoxazole 1 DS tab PO bid × 7 d have been reported to be effective (DJ Stenzel and PFL Borenam, Clin Microbiol Rev 1996; 9:563; UZ Ok et al, Am J Gastroenterol 1999; 94:3245). Metronidazole resistance may be common in some areas (K Haresh et al, Trop Med Int Health 1999; 4:274). Nitazoxanide has been effective in clearing organism and improving symptoms (E Diaz et al, Am J Trop Med Hyg 2003; 68:384; JF Rossignol, Clin Gastroenterol Hepatol 2005; 18:703).

24. No drug has proven efficacy against cryptosporidiosis in advanced AIDS (I Abubakar et al, Cochrane Database Syst Rev 2007; 1:CD004932). Treatment with HAART is the mainstay of therapy. Nitazoxanide (JF Rossignol, Aliment Pharmacol Ther 2006; 24:807), paromomycin (P Maggi et al, Clin Infect Dis 2000; 33:1609), or a combination of paromomycin and azithromycin (NH Smith et al, J Infect Dis 1998; 178:900) may be tried to decrease diarrhea and recalcitrant malabsorption of antimicrobial drugs, which can occur with chronic cryptosporidiosis.

25. G Albanese et al, Int J Dermatol 2001; 40:67; D Malvy et al, J Travel Med 2006; 13:244.

26. HIV-infected patients may need higher dosage and long-term maintenance. Successful use of nitazoxanide (see also footnote 5) has been reported in one patient with sulfa allergy (SM Zimmer et al, Clin Infect Dis 2007; 44:466).

27. A Norberg et al, Clin Microbiol Infect 2003; 9:65; O Vandenberg et al, Int J Infect Dis 2006; 10:255.

28. No drug is curative against Dracunculus. *A program for monitoring local sources of drinking water to eliminate transmission has dramatically decreased the number of cases worldwide (M Barry, N Engl J Med 2007; 356:2561). The treatment of choice is slow extraction of worm combined with would care and pain management (C Greenaway, Can Med Assoc J 2004; 170:495).*

29. Since family members are usually infected, treatment of the entire household is recommended.

30. Antihistamines or corticosteroids may be required to decrease allergic reactions to components of disintegrating microfilariae that result from treatment, especially in infection caused by Loa loa. *Endosymbiotic* Wolbachia *bacteria may have a role in filarial development and host response, and may represent a potential target for therapy. Addition of doxycycline 100 or 200 mg/d PO × 6-8 wk in lymphatic filariasis and onchocerciasis has resulted in substantial loss of* Wolbachia *and decrease in both micro- and macrofilariae (MJ Taylor et al, Lancet 2005; 365:2116; AY Debrah et al, PLOS Pathog 2006; e92:0829); but use of tetracyclines is contraindicated in pregnancy and in children <8 yr old.*

Infection	Drug	Adult Dosage	Pediatric Dosage
Loa loa			
Drug of choice:[34]	Diethylcarbamazine*	6 mg/kg/d PO in 3 doses × 12d[32,33]	6 mg/kg/d PO in 3 doses × 12d[32,33]
FILARIASIS[30]			
Mansonella ozzardi			
Drug of choice:	See footnote 35		
Mansonella perstans			
Drug of choice:	Albendazole[7,12]	400 mg PO bid × 10 d	400 mg PO bid × 10 d
OR	Mebendazole[7]	100 mg PO bid × 30 d	100 mg PO bid × 30 d
Mansonella streptocerca			
Drug of choice:[36]	Diethylcarbamazine*	6 mg/kg/d PO × 12 d[33]	6 mg/kg/d PO × 12 d[33]
OR	Ivermectin[7,16]	150 mcg/kg PO once	150 mcg/kg PO once
Tropical Pulmonary Eosinophilia (TPE)[37]			
Drug of choice:	Diethylcarbamazine*	6 mg/kg/d in 3 doses × 12-21 d[33]	6 mg/kg/d in 3 doses × 12-21 d[33]
Onchocerca volvulus (River blindness)			
Drug of choice:	Ivermectin[16,38]	150 mcg/kg PO once, repeated every 6-12 mo until asymptomatic	150 mcg/kg PO once, repeated every 6-12 mo until asymptomatic
FLUKE, hermaphroditic, infection			
Clonorchis sinensis (Chinese liver fluke)			
Drug of choice:	Praziquantel[39]	75 mg/kg/d in 3 doses × 2 d	75 mg/kg/d in 3 doses × 2 d
OR	Albendazole[7,12]	10 mg/kg/d PO × 7 d	10 mg/kg/d PO × 7 d
Fasciola hepatica (sheep liver fluke)			
Drug of choice:[40]	Triclabendazole*	10 mg/kg/d PO once or twice[41]	10 mg/kg/d PO once or twice[41]
Alternative:	Bithionol*	30-50 mg/kg on alternate days × 10-15 doses	30-50 mg/kg on alternate days × 10-15 doses
OR	Nitazoxanide[5,7]	500 mg PO bid × 7 d	1-3 yr: 100 mg PO q12h × 7 d 4-11 yr: 200 mg PO q12h × 7 d >12 yr: 500 mg PO q12h × 7 d
Fasciolopsis buski, Heterophyes heterophyes, Metagonimus yokogawai (intestinal flukes)			
Drug of choice:	Praziquantel[7,39]	75 mg/kg/d PO in 3 doses × 1 d	75 mg/kg/d PO in 3 doses × 1 d
Metorchis conjunctus (North American liver fluke)			
Drug of choice:	Praziquantel[7,39]	75 mg/kg/d PO in 3 doses × 1 d	75 mg/kg/d PO in 3 doses × 1 d
Nanophyetus salmincola			
Drug of choice:	Praziquantel[7,39]	60 mg/kg/d PO in 3 doses × 1 d	60 mg/kg/d PO in 3 doses × 1 d
Opisthorchis viverrini (Southeast Asian liver fluke)			
Drug of choice:	Praziquantel[39]	75 mg/kg/d PO in 3 doses × 2 d	75 mg/kg/d PO in 3 doses × 2 d
Paragonimus westermani (lung fluke)			
Drug of choice:	Praziquantel[7,39]	75 mg/kg/d PO in 3 doses × 2 d	75 mg/kg/d PO in 3 doses × 2 d
Alternative:[42]	Bithionol*	30-50 mg/kg on alternate days × 10-15 doses	30-50 mg/kg on alternate days × 10-15 doses

31. Most symptoms are caused by adult worm. A single-dose combination of albendazole (400 mg PO) with either ivermectin (200 mcg/kg PO) or diethylcarbamazine (6 mg/kg PO) is effective for reduction or suppression of W. bancrofti *microfilaria, but the albendazole/ivermectin combination does not kill all the adult worms (D Addiss et al, Cochrane Database Syst Rev 2004; CD003753).*

32. For patients with microfilaria in the blood, Medical Letter consultants start with a lower dosage and scale up: d1: 50 mg; d2: 50 mg tid; d3: 100 mg tid; d4-14: 6 mg/kg in 3 doses (for Loa Loa *d4-14: 9 mg/kg in 3 doses). Multidose regimens have been shown to provide more rapid reduction in microfilaria than single-dose diethylcarbamazine, but microfilaria levels are similar 6-12 months after treatment (LD Andrade et al, Trans R Soc Trop Med Hyg 1995; 89:319; PE Simonsen et al, Am J Trop Med Hyg 1995; 53:267). A single dose of 6 mg/kg is used in endemic areas for mass treatment (J Figueredo-Silva et al, Trans R Soc Trop Med Hyg 1996; 90:192; J Noroes et al, Trans R Soc Trop Med Hyg 1997; 91:78).*

33. Diethylcarbamazine should not be used for treatment of Onchocerca volvulus *due to the risk of increased ocular side effects, including blindness associated with rapid killing of the worms. It should be used cautiously in geographic regions where* O. volvulus *coexists with other filariae. Diethylcarbamazine is contraindicated during pregnancy. See also footnote 38.*

34. In heavy infections with Loa loa, *rapid killing of microfilariae can provoke encephalopathy. Apheresis has been reported to be effective in lowering microfilarial counts in patients heavily infected with* Loa loa *(EA Ottesen, Infect Dis Clin North Am 1993; 7:619). Albendazole may be useful for treatment of loiasis when diethylcarbamazine is ineffective or cannot be used, but repeated courses may be necessary (AD Klion et al, Clin Infect Dis 1999; 29:680; TE Tabi et al, Am J Trop Med Hyg 2004; 71:211). Ivermectin has also been used to reduce microfilaremia, but albendazole is preferred because of its slower onset of action and lower risk of precipitating encephalopathy (AD Klion et al, J Infect Dis 1993; 168:202; M Kombila et al, Am J Trop Med Hyg 1998; 58:458). Diethylcarbamazine, 300 mg PO once/wk, has been recommended for prevention of loiasis (TB Nutman et al, N Engl J Med 1988; 319:752).*

35. Diethylcarbamazine has no effect. A single dose of ivermectin 200 mcg/kg PO reduces microfilaria densities and provides both short- and long-term reductions in M. ozzardi *microfilaremia (AA Gonzalez et al, W Indian Med J 1999; 48:231).*

36. Diethylcarbamazine is potentially curative due to activity against both adult worms and microfilariae. Ivermectin is active only against microfilariae.

37. AK Boggild et al, Clin Infect Dis 2004; 39:1123. Relapses occur and can be treated with a repeated course of diethylcarbamazine.

38. Diethylcarbamazine should not be used for treatment of this disease because rapid killing of the worms can lead to blindness. Periodic treatment with ivermectin (every 3-12 months), 150 mcg/kg PO, can prevent blindness due to ocular onchocerciasis (DN Udall, Clin Infect Dis 2007; 44:53). Skin reactions after ivermectin treatment are often reported in persons with high microfilarial skin densities. Ivermectin has been inadvertently given to pregnant women during mass treatment programs; the rates of congenital abnormalities were similar in treated and untreated women. Because of the high risk of blindness from onchocerciasis, the use of ivermectin after the first trimester is considered acceptable according to the WHO. Doxycycline (100 mg/day PO for 6 weeks), followed by a single 150 μg/kg PO dose of ivermectin, resulted in up to 19 months of amicrofilaridermia and 100% elimination of Wolbachia *species (A Hoerauf et al, Lancet 2001; 357:1415).*

39. Praziquantel should be taken with liquids during a meal.

40. Unlike infections with other flukes, Fasciola hepatica *infections may not respond to praziquantel. Triclabendazole (*Egaten*; Novartis) appears to be safe and effective, but data are limited (DY Aksoy et al, Clin Microbiol Infect 2005; 11:859). It is available from Victoria Pharmacy, Zurich, Switzerland (www.pharmaworld.com; 41-1-211-24-32) and should be given with food for better absorption. Nitazoxanide also appears to have efficacy in treating fasciolosis in adults and in children (L Favennec et al, Aliment Pharmacol Ther 2003; 17:265; JF Rossignol et al, Trans R Soc Trop Med Hyg 1998; 92:103; SM Kabil et al, Curr Ther Res 2000; 61:339).*

41. J Keiser et al, Expert Opin Investig Drugs 2005; 14:1513.

42. Triclabendazole may be effective in a dosage of 5 mg/kg PO once/d × 3 d or 10 mg/kg PO bid × 1 d (M Calvopiña et al, Trans R Soc Trop Med Hyg 1998; 92:566). See footnote 40 for availability.

Infection		Drug	Adult Dosage	Pediatric Dosage
GIARDIASIS *(Giardia duodenalis)*				
Drug of choice:		Metronidazole[7]	250 mg PO tid × 5-7 d	15 mg/kg/d PO in 3 doses × 5-7 d
	OR	Tinidazole[6]	2 g PO once	50 mg/kg PO once (max 2 g)
	OR	Nitazoxanide[5]	500 mg PO tid × 3 d	1-3 yr: 100 mg PO q12h × 3 d 4-11 yr: 200 mg PO q12h × 3 d >12 yr: 500 mg PO q12h × 3 d
Alternative:[43]		Paromomycin[3,7,44]	25-35 mg/kg/d PO in 3 doses × 5-10 d	25-35 mg/kg/d PO in 3 doses × 5-10 d
	OR	Furazolidone*	100 mg PO qid × 7-10 d	6 mg/kg/d PO in 4 doses × 7-10 d
	OR	Quinacrine[4,45]*	100 mg PO tid × 5 d	2 mg/kg/d PO in 3 doses × 5 d (max 300 mg/d)
GNATHOSTOMIASIS *(Gnathostoma spinigerum)*[46]				
Treatment of choice:		Albendazole[7,12]	400 mg PO bid × 21 d	400 mg PO bid × 21 d
	OR	Ivermectin[7,16] either	200 mcg/kg/d PO × 2 d	200 mcg/kg/d PO × 2 d
	±	Surgical removal		
GONGYLONEMIASIS *(Gongylonema* sp*)*[47]				
Treatment of choice:		Surgical removal		
	OR	Albendazole[7,12]	400 mg/d PO × 3 d	400 mg/d PO × 3 d
HOOKWORM infection *(Ancylostoma duodenale, Necator americanus)*				
Drug of choice:		Albendazole[7,12]	400 mg PO once	400 mg PO once
	OR	Mebendazole	100 mg PO bid × 3 d or 500 mg once	100 mg PO bid × 3 d or 500 mg once
	OR	Pyrantel pamoate[7,13]*	11 mg/kg (max 1 g) PO × 3 d	11 mg/kg (max 1 g) PO × 3 d
Hydatid cyst, see TAPEWORM infection				
Hymenolepis nana, see TAPEWORM infection				
ISOSPORIASIS *(Isospora belli)*				
Drug of choice:[48]		Trimethoprim-sulfamethoxazole[7]	TMP 160 mg/SMX 800 mg (1 DS tab) PO bid × 10 d	TMP 5 mg/kg/d/SMX 25 mg/kg/d PO in 2 doses × 10 d
LEISHMANIA				
Visceral[49,50]				
Drug of choice:		Liposomal amphotericin B[51]	3 mg/kg/d IV d 1-5, 14 and 21[52]	3 mg/kg/d IV d 1-5, 14, and 21[52]
	OR	Sodium stibogluconate*	20 mg Sb/kg/d IV or IM × 28 d	20 mg Sb/kg/d IV or IM × 28 d
	OR	Miltefosine[53]*	2.5 mg/kg/d PO (max 150 mg/d) × 28 d	2.5 mg/kg/d PO (max 150 mg/d) × 28 d

43. Another alternative is albendazole 400 mg/d PO × 5 d in adults and 10 mg/kg/d PO × 5 d in children (K Yereli et al, Clin Microbiol Infect 2004;10:527; O Karabay et al, World J Gastroenterol 2004; 10:1215). Combination treatment with standard doses of metronidazole and quinacrine × 3 wk has been effective for a small number of refractory infections (TE Nash et al, Clin Infect Dis 2001; 33:22). In one study, nitazoxanide was used successfully in high doses to treat a case of Giardia *resistant to metronidazole and albendazole (P Abboud et al, Clin Infect Dis 2001; 32:1792).*

44. Poorly absorbed; may be useful for treatment of giardiasis in pregnancy.

45. Quinacrine should be taken with liquids after a meal.

46. P Nontasut et al, Southeast Asian J Trop Med Pub Health 2005; 36:650; M de Gorgolas et al, J Travel Med 2003; 10:358. All patients should be treated with medication whether surgery is attempted or not.

47. ME Wilson et al, Clin Infect Dis 2001; 32:1378; G Molavi et al, J Helminth 2006; 80:425.

48. Usually a self-limited illness in immunocompetent patients. Immunosuppressed patients may need higher doses, longer duration (TMP/SMX qid × 10 d, followed by bid × 3 wk) and long-term maintenance. In sulfonamide-sensitive patients, pyrimethamine 50-75 mg daily in divided doses (plus leucovorin 10-25 mg/d) has been effective.

49. To maximize effectiveness and minimize toxicity, the choice of drug, dosage, and duration of therapy should be individualized based on the region of disease acquisition, a likely infecting species, and host factors such as immune status (BL Herwaldt, Lancet 1999; 354:1191). Some of the listed drugs and regimens are effective only against certain Leishmania *species/strains and only in certain areas of the world (J Arevalo et al, Clin Infect Dis 2007; 195:1846). Medical Letter consultants recommend consultation with physicians experienced in management of this disease.*

50. Visceral infection is most commonly due to the Old World species L. donovani *(kala-azar) and* L. infantum *and the New World species* L. chagasi.

*51. Liposomal amphotericin B (*AmBisome*) is the only lipid formulation of amphotericin B FDA-approved for treatmetn of visceral leishmania, largely based on clinical trials in patients infected with* L. infantum *(A Meyerhoff, Clin Infect Dis 1999; 28:42). Two other amphotericin B lipid formulations, amphotericin B lipid complex (*Abelcet*) and amphotericin B cholesteryl sulfate (*Amphotec*) have been used, but are considered investigational for this condition and may not be as effective (C Bern et al, Clin Infect Dis 2006; 43:917).*

52. The FDA-approved dosage regimen for immunocompromised patients (e.g., HIV infected) is 4 mg/kg/d IV on days 1-5, 10, 17, 24, 31 and 38. The relapse rate is high; maintenance therapy (secondary prevention) may be indicated, but there is no consensus as to dosage or duration.

53. Effective for both antimony-sensitive and -resistant L. donovani *(Indian); miltefosine (*Impavido*) is manufactured in 10- or 50-mg capsules by Zentaris (Frankfurt, Germany at info@zentaris.com) and is available through consultation with the CDC. The drug is contraindicated in pregnancy; a negative pregnancy test before drug initiation and effective contraception during and for 2 months after treatment is recommended (H Murray et al, Lancet 2005; 366:1561). In a placebo-controlled trial in patients ≥12 years old, oral miltefosine 2.5 mg/kg/d × 28 d was also effective for treatment of cutaneous leishmaniasis due to* L. (V.) panamensis *in Colombia, but not* L. (V.) braziliensis *or* L. mexicana *in Guatemala (J Soto et al, Clin Infect Dis 2004; 38:1266). "Motion sickness," nausea, headache, and increased creatinine are the most frequent adverse effects (J Soto and P Soto, Expert Rev Anti Infect Ther 2006; 4:177).*

Infection		Drug	Adult Dosage	Pediatric Dosage
Alternative:		Meglumine antimonate*	20 mg Sb/kg/d IV or IM × 28 d	20 mg Sb/kg/d IV or IM × 28 d
	OR	Amphotericin B[7]	1 mg/kg IV daily × 15-20 d or every second day for up to 8 wk	1 mg/kg IV daily × 15-20 d or every second day for up to 8 wk

Drug of choice:		Sodium stibogluconate*	20 mg Sb/kg/d IV or IM × 20 d	20 mg Sb/kg/d IV or IM × 20 d
	OR	Meglumine antimonate*	20 mg Sb/kg/d IV or IM × 20 d	20 mg Sb/kg/d IV or IM × 20 d
	OR	Miltefosine[53]*	2.5 mg/kg/d PO (max 150 mg/d) × 28 d	2.5 mg/kg/d PO (max 150 mg/d) × 28 d
Alternative:[56]		Paromomycin[7,13,54]*	Topically 2×/d × 10-20 d	Topically 2×/d × 10-20 d
	OR	Pentamidine[7]	2-3 mg/kg/IV or IM daily or every second day × 4-7 doses[57]	2-3 mg/kg/IV or IM daily or every second day × 4-7 doses[57]
Mucosal[49,58]				
Drug of choice:		Sodium stibogluconate*	20 mg Sb/kg/d IV or IM × 28 d	20 mg Sb/kg/d IV or IM × 28 d
	OR	Meglumine antimonate*	20 mg Sb/kg/d IV or IM × 28 d	20 mg Sb/kg/d IV or IM × 28 d
	OR	Amphotericin B[7]	0.5-1 mg/kg IV daily or every second day for up to 8 wk	0.5-1 mg/kg IV daily or every second day for up to 8 wk
	OR	Miltefosine[53]*	2.5 mg/kg/d PO (max 150 mg/d) × 28 d	2.5 mg/kg/d PO (max 150 mg/d) × 28 d
LICE infestation *(Pediculus humanus, P. capitis, Phthirus pubis)*[59]				
Drug of choice:		0.5% Malathion[60]	Topically	Topically
	OR	1% Permethrin[61]	Topically	Topically
Alternative:		Pyrethrins with piperonyl butoxide[61]	Topically	Topically
	OR	Ivermectin[7,16,62]	200 µg/kg PO	≥15 kg: 200 µg/kg PO

54. *Paromomycin IM has been effective against leishmania in India; it has not yet been tested in South America or the Mediterranean and there are insufficient data to support its use in pregnancy (S Sundar et al, N Engl J Med 2007; 356:2371). Topical paromomycin should be used only in geographic regions where cutaneous leishmaniasis species have low potential for mucosal spread. A formulation of 15% paromomycin/12% methylbenzethonium chloride* (Leshcutan*) in soft white paraffin for topical use has been reported to be partially effective against cutaneous leishmaniasis due to* L. major *in Israel and* L. mexicana *and* L. *(V.)* braziliensis *in Guatemala, where mucosal spread is very rare (BA Arana et al, Am J Trop Med Hyg 2001; 65:466). The methylbenzethonium is irritating to the skin; lesions may worsen before they improve.*

55. *Cutaneous infection is most commonly due to the Old World species* L. major *and* L. tropica *and the New World species* L. mexicana, L. (Viannia) braziliensis, *and others.*

56. *Although azole drugs (fluconazole, ketoconazole, itraconazole) have been used to treat cutaneous disease, they are not reliably effective and have no efficacy against mucosal disease (AJ Magill, Infect Dis Clin North Am 2005; 19:241). For treatment of* L. major *cutaneous lesions, a study in Saudi Arabia found that cral fluconazole, 200 mg once/d × 6 wk appeared to speed healing (AA Alrajhi et al, N Engl J Med 2002; 346:891). Thermotherapy may be an option for cutaneous* L. tropica *infection (R Reithinger et al, Clin Infect Dis 2005; 40: 1148). A device that generates focused and controlled heating of the skin has been approved by the FDA for this indication (*ThermoMed-*ThermoSurgery Technologies Inc., Phoenix, AZ, 602-264-7300; www.thermosurgery.com).*

57. *At this dosage pentamidine has been effective in Colombia predominantly against* L. (V.) panamensis *(J Soto-Mancipe et al, Clin Infect Dis 1993; 16: 417; J. Soto et al, Am J Trop Med Hyg 1994; 50:107). Activity against other species is not well established.*

58. *Mucosal infection is most commonly due to the New World species* L. (V.) braziliensis, L. (V.) panamensis, or L. (V.) guyanensis.

59. *Pediculocides should not be used for infestations of the eyelashes. Such infestations are treated with petrolatum ointment applied 2-4 daily/d × 8-10 d. Oral TMP/SMX has also been used (TL Meinking and D Taplin, Curr Probl Dermatol 1996; 24:157). For pubic lice, treat with 5% permethrin or ivermectin as for scabies. TMP/SMX has also been effective when used together with permethrin for head lice (RB Hipolito et al, Pediatrics 2001; 107:E30).*

60. *Malathion is both ovicidal and pediculocidal; 2 applications at least 7 days apart are generally necessary to kill all lice and nits.*

61. *Permethrin and pyrethrin are pediculocidal; retreatment in 7-10 d is needed to eradicate the infestation. Some lice are resistant to pyrethrins and permethrin (TL Meinking et al, Arch Dermatol 2002; 138:220).*

62. *Ivermectin is pediculocidal, but more than one dose is generally necessary to eradicate the infestation (KN Jones and JC English 3rd, Clin Infect Dis 2003; 36:1355). The number of doses and interval between doses has not been established, but in one study of body lice, 3 doses administered at 7-day intervals were effective (C Fouault et al, J Infect Dis 2006; 193:474).*

63. *Chloroquine-resistant* P. falciparum *occurs in all malarious areas except Central America (including Panama north and west of the Canal Zone), Mexico, Haiti, the Dominican Republic, Paraguay, northern Argentina, North and South Korea, Georgia, Armenia, most of rural China, and some countries in the Middle East (chloroquine resistance has been reported in Yemen, Oman, Saudi Arabia, and Iran). For treatment of multiple-drug-resistant* P. falciparum *in Southeast Asia, especially Thailand, where mefloquine resistance is frequent, atovaquone/proguanil, quinine plus either doxycycline or clindamycin, or artemether/lumefantrine may be used.*

64. P. vivax *with decreased susceptibility to chloroquine is a significant problem in Papua New Guinea and Indonesia. There are also a few reports of resistance from Myanmar, India, the Solomon Islands, Vanuatu, Guyana, Brazil, Colombia, and Peru (JK Baird et al, Curr Infect Dis Rep 2007; 9:39).*

65. *Chloroquine-resistant* P. malariae *has been reported from Sumatra (JD Maguire et al, Lancet 2002; 360:58).*

Infection		Drug	Adult Dosage	Pediatric Dosage
Loa loa, see FILARIASIS				
MALARIA, Treatment of *(Plasmodium falciparum,*[63] *P. vivax,*[64] *P. ovale, and P. malariae*[65]*)*				
ORAL[66]				
P. falciparum or unidentified species acquired in areas of chloroquine-resistant *P. falciparum*[63]				
Drug of choice:[67]		Atovaquone/ proguanil[68]	2 adult tabs bid[69] or 4 adult tabs once/d × 3 d	<5 kg: not indicated 5-8 kg: 2 peds tabs once/d × 3 d 9-10 kg: 3 peds tabs once/d × 3 d 11-20 kg: 1 adult tab once/d × 3 d 21-30 kg: 2 adult tabs once/d × 3 d 31-40 kg: 3 adult tabs once/d × 3 d >40 kg: 4 adult tabs once/d × 3 d
	OR	Quinine sulfate **plus**	650 mg q8h × **or** 7 d[70]	30 mg/kg/d in 3 doses × 3 **or** 7 d[70]
		doxycycline[7,21,71] **or plus**	100 mg bid × 7 d	4 mg/kg/d in 2 doses × 7 d
		tetracycline[7,21] **or plus**	250 mg qid × 7 d	6.25 mg/kg/d in 4 doses × 7 d
		clindamycin[7,18,72]	20 mg/kg/d in 3 doses × 7 d[73]	20 mg/kg/d in 3 doses × 7 d
Alternative:[67]		Mefloquine[74,75]	750 mg followed 12 hr later by 500 mg	15 mg followed 12 hr later by 100 mg
	OR	Artemether/ lumefantrine[76,77]*	6 doses over 3 d (4 tabs/dose at 0, 8, 24, 36, 48, and 60 hours)	6 doses over 3 d at same intervals as adults; <15 kg: 1 tab/dose 15-25 kg: 2 tabs/dose 25-35 kg: 3 tabs/dose >35 kg: 4 tabs/dose
	OR	Artesunate[76]* **plus** see footnote 78	4 mg/kg/d × 3 d	4 mg/kg/d × 3 d
P. vivax acquired in areas of chloroquine-resistant *P. vivax*[64]				
Drug of choice:[67]		Mefloquine[74]	750 mg PO followed 12 hr later by 500 mg	15 mg/kg PO followed 12 hr later by 10 mg/kg
	OR	Atovaquone/ proguanil[68]	2 adult tabs bid[69] or 4 adult tabs once/d × 3 d	<5 kg: not indicated 5-8 kg: 2 peds tabs once/d × 3 d 9-10 kg: 3 peds tabs once/d × 3 d 11-20 kg: 1 adult tab once/d × 3 d 21-30 kg: 2 adult tabs once/d × 3 d 31-40 kg: 3 adult tabs once/d × 3 d >40 kg: 4 adult tabs once/d × 3 d

66. *Uncomplicated or mild malaria may be treated with oral drugs. Severe malaria (e.g., impaired consciousness, parasitemia >5%, shock) should be treated with parenteral drugs (KS Griffin et al, JAMA 2007; 297:2264).*

67. *Primaquine is given for prevention of relapse after infection with* P. vivax *or* P. ovale. *Some experts also prescribe primaquine phosphate 30 mg base/d (0.6 mg base/kg/d for children) for 14 d after departure from areas where these species are endemic (Presumptive Anti-Relapse Therapy [PART]), "terminal prophylaxis"). Because this is not always effective as prophylaxis (E Schwartz et al, N Engl J Med 2003; 349:1510), others prefer to rely on surveillance to detect cases when they occur, particularly when exposure was limited or doubtful. See also footnote 79.*

68. *Atovaquone/proguanil is available as a fixed-dose combination tablet: adult tablets (*Malarone*; 250 mg atovaquone/100 mg proguanil) and pediatric tablets (*Malarone Pediatric*; 62.5 mg atovaquone/25 mg proguanil). To enhance absorption and reduce nausea and vomiting, it should be taken with food or a milky drink. Safety in pregnancy is unknown; outcomes were normal in 24 women treated with the combination in the 2nd and 3rd trimester (R McGready et al, Eur J Clin Pharmacol 2003; 59:545). The drug should not be given to patients with severe renal impairment (creatinine clearancxe <30 mL/min). There have been isolated case reports of resistance in* P. falciparum *in Africa, but Medical Letter consultants do not believe there is a high risk for acquisition of* Malarone*-resistant disease (E Schwartz et al, Clin Infect Dis 2003; 37:450; A Farnert et al, BMJ 2003; 326:628; S Kuhn et al, Am J Trop Med Hyg 2005; 72:407; CT Happi et al, Malaria Journal 2006; 5:82).*

69. *Although approved for once-daily dosing, Medical Letter consultants usually divide the dose in two to decrease nausea and vomiting.*

70. *Available in the United States in a 324-mg capsule; 2 capsules suffice for adult dosage. In Southeast Asia, relative resistance to quinine has increased and treatment should be continued for 7 d. Quinine should be taken with or after meals to decrease gastrointestinal adverse effects.*

71. *Doxycycline should be taken with adequate water to avoid esophageal irritation. It can be taken with food to minimize gastrointestinal adverse effects.*

72. *For use in pregnancy and in children <8 yr.*

73. *B Lell and PG Kremsner, Antimicrob Agents Chemother 2002; 46:2315; M Ramharter et al, Clin Infect Dis 2005; 40:1777.*

74. *At this dosage, adverse effects include nausea, vomiting, diarrhea and dizziness. Disturbed sense of balance, toxic psychosis, and seizures can also occur. Mefloquine should not be used for treatment of malaria in pregnancy unless there is no other treatment option because of increased risk for stillbirth (F Nosten et al, Clin Infect Dis 1999; 28:808). It should be avoided for treatment of malaria in persons with active depression or with a history of psychosis or seizures and should be used with caution in persons with any psychiatric illness. Mefloquine can be given to patients taking β-blockers if they do not have an underlying arrhythmia; it should not be used in patients with conduction abnormalities. Mefloquines should not be given together with quinine or quinidine, and caution is required in using quinine or quinidine to treat patients with malaria who have taken mefloquine for prophylaxis. Mefloquine should not be taken on an empty stomach; it should be taken with at least 8 oz of water.*

75. P. falciparum *with resistance to mefloquine is a significant problem in the malarious areas of Thailand and in areas of Myanmar and Cambodia that border on Thailand. It has also been reported on the borders between Myanmar and China, Laos and Myanmar, and in Southern Vietnam. In the United States, a 250-mg tablet of mefloquine contains 228 mg mefloquine base. Outside the United States, each 275-mg tablet contains 250 mg base.*

76. *The artemisinin derivatives, artemether and artesunate, are both frequently used globally in combination regimens to treat malaria. Both are available in oral, parenteral and rectal formulations, but manufacturing standards are not consistent (HA Karunajeewa et al, JAMA 2007; 297:2381; EA Ashley and NJ White, Curr Opin Infect Dis 2005; 18:531). In the United States, only the IV formulation of artesunate is available; it can be obtained through the CDC under an IND for patients with severe disease who do not have timely access, cannot tolerate, or fail to respond to IV quinidine (www.cdc.gov/malaria/features/artesunate_now_available.htm). To avoid development of resistance, monotherapy should be avoided (PE Duffy and CH Sibley, Lancet 2005; 366:1908). In animal studies artemisinins have been embryotoxic and caused a low incidence of teratogenicity; no adverse pregnancy outcome has been observed in limited studies in humans (S Dellicour et al, Malaria J 2007; 6:15).*

77. *Artemether/lumefantrine is available as a fixed-dose combination tablet (*Coartem *in countries with endemic malaria,* Riamet *in Europe and countries without endemic malaria); each tablet contains 20 mg artemether and 120 mg lumefantrine (M van Vugt et al, Am J Trop Med Hyg 1999; 60:936). It is contraindicated during the first trimester of pregnancy; safety during the second and third trimester is not known. The tablets should be taken with food. Artemether/lumefantrine should not be used in patients with cardiac arrhythmias, bradycardia, severe cardiac disease or QT prolongation. Concomitant use of drugs that prolong the QT interval or are metabolized by CYP2D6 is contraindicated.*

78. *Adults treated with artesunate should also receive oral treatment doses of either atovaquone/proguanil, doxycycline, clindamycin or mefloquine; children should take either atovaquone/proguanil, clindamycin, or mefloquine (F Nosten et al, Lancet 2000; 356:297; M van Vugt, Clin Infect Dis 2002; 35:1498; F Smithuis et al, Trans R Soc Trop Med Hyg 2004; 98:182). If artesunate is given IV, oral medication should be started when the patient is able to tolerate it (SEAQUAMAT group, Lancet 2005; 366:717).*

MALARIA, Prevention of[84]				
All *Plasmodium* species in chloroquine-sensitive areas[63,64,65]				
Drug of choice:[67,85]		Chloroquine phosphate[80,86]	500 mg (300 mg base) PO once/wk[87]	5 mg/kg base PO once/wk, up to adult dose of 300 mg base[87]
All *Plasmodium* species in chloroquine-resistant areas[63,64,65]				
Drug of choice:[67]		Atovaquone/ proguanil[68]	1 adult tab/d[88]	5-8 kg: $^1/_2$ peds tabs/d[68,88] 9-10 kg: $^3/_4$ peds tab/d[68,88] 11-20 kg: 1 peds tab/d[68,88] 21-30 kg: 2 peds tab/d[68,88] 31-40 kg: 3 peds tab/d[68,88] >40 kg: 1 adult tabs/d[68,88]
	OR	Doxycycline[7,21,71]	100 mg PO daily[89]	2 mg/kg/d PO, up to 100 mg/d[89]

79. Primaquine phosphate can cause hemolytic anemia, especially in patients whose red cells are deficient in G-6-PD. This deficiency is most common in African, Asian, and Mediterranean peoples. Patients should be screened for G-6-PD deficiency before treatment. Primaquine should not be used during pregnancy. It should be taken with food to minimize nausea and abdominal pain. Primaquine-tolerant P. vivax *can be found globally. Relapses of primaquine-resistant strains may be retreated with 30 mg (base) × 28 d.*

80. Chloroquine should be taken with food to decrease gastrointestinal adverse effects. If chloroquine phosphate is not available, hydroxychloroquine sulfate is as effective; 400 mg of hydroxychloroquine sulfate is equivalent to 500 mg of chloroquine phosphate.

81. Chloroquine combined with primaquine was effective in 85% of patients with P. vivax *resistant to chloroquine and could be a reasonable choice in areas where other alternatives are not available (JK Baird et al, J Infect Dis 1995; 171:1678).*

82. Exchange transfusion is controversial, but has been helpful for some patients with high-density (>10%) parasitemia, altered mental status, pulmonary edema, or renal complications (VI Powell and K Grima, Transfus Med Rev 2002; 16:239; MS Riddle et al, Clin Infect Dis 2002; 34:1192).

83. Continuous EKG, blood pressure, and glucose monitoring are recommended, especially in pregnant women and young children. For problems with quinidine availability, call the manufacturer (Eli Lilly, 800-821-0538) or the CDC Malaria Hotline (770-488-7788). Quinidine may have greater antimalarial activity than quinine. The loading dose should be decreased or omitted in patients who have received quinine or mefloquine. If more than 48 hours of parenteral treatment is required, the quinine or quinidine dose should be reduced by 30-50%.

84. No drug guarantees protection against malaria. Travelers should be advised to seek medical attention if fever develops after they return. Insect repellents, insecticide-impregnated bed nets and proper clothing are important adjuncts for malaria prophylaxis (Med Lett Drugs Ther 2005; 47: 100). Malaria in pregnancy is particularly serious for both mother and fetus; prophylaxis is indicated if exposure cannot be avoided.

85. Alternatives for patients who are unable to take choloroquine include atovaquone/proguanil, mefloquine, doxycycline, or primaquine dosed as for chloroquine-resistant areas.

86. Has been used extensively and safely for prophylaxis in pregnancy.

87. Beginning 1-2 wk before travel and continuing weekly for the duration of stay and for 4 wks after leaving.

88. Beginning 1-2 d before travel and continuing for the duration of stay and for 1 wk after leaving. In one study of malaria prophylaxis, atovaquone/proguanil was better tolerated than mefloquine in nonimmune travelers (D Overbosch et al, Clin Infect Dis 2001; 33:1015). The protective efficacy of Malarone *against* P. vivax *is variable ranging from 84% in Indonesian New Guinea (J Ling et al, Clin Infect Dis 2002; 35:825) to 100% in Colombia (J Soto et al, AM J Trop Med Hyg 2006; 75:430). Some Medical Letter consultants prefer alternate drugs if traveling to areas where* P. vivax *predominates.*

89. Beginning 1-2 d before travel and continuing for the duration of stay and for 4 wk after leaving. Use of tetracyclines is contraindicated in pregnancy and in children <8 years old. Doxycycline can cause gastrointestinal disturbances, vaginal moniliasis, and photosensitivity reactions.

Infection		Drug	Adult Dosage	Pediatric Dosage

90. Mefloquine has not been approved for use during pregnancy. However, it has been reported to be safe for prophylactic use during the second and third trimester of pregnancy and possibly during early pregnancy as well (CDC Health Information for International Travel, 2008, page 228; BL Smoak et al, J Infect Dis 1997; 176:831). For pediatric doses <1/2 tablet, it is advisable to have a pharmacist crush the tablet, estimate doses by weighing, and package them in gelatin capsules. There is no data for use in children <5 kg, but based on dosages in other weight groups, a dose of 5 mg/kg can be used. Not recommended for use in travelers with active depression or with a history of psychosis or seizures and should be used with caution in persons with psychiatric illness. Mefloquine can be given to patients taking β-blockers if they do not have an underlying arrhythmia; it should not be used in patients with conduction abnormalities.

91. Beginning 1-2 wk before travel and continuing weekly for the duration of stay and for 4 wk after leaving. Most adverse events occur within 3 doses. Some Medical Letter consultants favor starting mefloquine 3 weeks prior to travel and monitoring the patient for adverse events, this allows time to change to an alternative regimen if mefloquine is not tolerated.

92. The combination of weekly chloroquine (300 mg base) and daily proguanil (200 mg) is recommended by the World Health Organization (www.WHO.int) for use in selected areas; this combination is no longer recommended by the CDC. Proguanil (Paludrine; AstraZeneca, United Kingdom) is not available alone in the United States but is widely available in Canada and Europe. Prophylaxis is recommended during exposure and for 4 weeks afterwards. Proguanil has been used in pregnancy without evidence of toxicity (PA Phillips-Howard and D Wood, Drug Saf 1996; 14:131).

93. Studies have shown that daily primaquine beginning 1 d before departure and continued until 3-7 d after leaving the malarious area provides effective prophylaxis against chloroquine-resistant P. falciparum *(JK Baird et al, Clin Infect Dis 2003; 37:1659). Some studies have shown less efficacy against* P. vivax. *Nausea and abdominal pain can be diminished by taking with food.*

94. A traveler can be given a course of medication for presumptive self-treatment of febrile illness. The drug given for self-treatment should be different from that used for prophylaxis. This approach should be used only in very rare circumstances when a traveler would not be able to get medical care promptly.

95. CM Chan et al, Ophthalmology 2003; 110:1420. Ocular lesions due to E. hellem *in HIV-infected patients have responded to fumagillin eyedrops prepared from* Fumidil-B *(bicyclohexyl ammonium fumagillin) used to control a microsporidial desease of honey bees (MJ Garvey et al, Ann Pharmacother 1995; 29:872), available from Leiter's Park Avenue Pharmacy (see footnote 1). For lesions due to* V. corneae, *topical therapy is generally not effective and keratoplasty may be required (RM Davis et al, Ophthalmology 1990; 97:953).*

*96. Oral fumagillin (*Flisint-*Sanofi-Aventis, France) has been effective in treating* E. bieneusi *(J-M Molina et al, N Engl J Med 2002; 346:1963), but has been associated with thrombocytopenia and neutropenia. Highly active antiretroviral therapy (HAART) may lead to microbiologic and clinical response in HIV-infected patients with microsporidial diarrhea. Octreotide (*Sandostatin*) has provided symptomatic relief in some patients with large-volume diarrhea.*

97. J-M Molina et al, J Infect Dis 1995; 171:245. There is no established treatment for Pleistophora. *For disseminated disease due to* Trachipleistophora *or* Brachiola, *itraconazole 400 mg PO once/d plus albendazole may also be tried (CM Coyle et al, N Engl J Med 2004; 351:42).*

98. Albendazole or pyrantel pamoate may be effective (JB Ziem et al, Ann Trop Med Parasitol 2004; 98:385).

Infection		Drug	Adult Dosage	Pediatric Dosage
***Naegleria* species,** see AMEBIC MENINGOENCEPHALITIS, PRIMARY				
***Nacator americanus*,** see HOOKWORM infection				
OESOPHAGOSTOMUM bifurcum

PNEUMOCYSTIS jiroveci (formerly *carinii*) pneumonia (PCP)[99]				
Drug of choice:		Trimethoprim/ sulfamethoxazole	TMP 15 mg/SMX 75 mg/kg/d, PO or IV in 3 or 4 doses × 21 d	TMP 15 mg/SMX 75 mg/kg/d, PO or IV in 3 or 4 doses × 21 d
Alternative:		Primaquine[7,79]	30 mg base PO daily × 21 d	0.3 mg/kg base PO daily × 21 d
		plus clindamycin[7,18]	600 mg IV q6h × 21 d, or 300-450 mg PO q6h × 21 d	15-25 mg IV q6h × 21 d, or 10 mg/kg PO q6h × 21 d
	OR	Trimethoprim[7]	5 mg/kg PO tid × 21 d	5 mg/kg PO tid × 21 d
		plus dapsone[7]	100 mg daily × 21 d	2 mg/kg/d PO × 21 d
	OR	Pentamidine	3-4 mg/kg IV daily × 21 d	3-4 mg/kg IV daily × 21 d
	OR	Atovaquone	750 mg PO bid × 21 d	1-3 mo: 30 mg/kg/d PO × 21 d 4-24 mo: 45 mg/kg/d PO × 21 d >24 mo: 30 mg/d PO × 21 d
Primary and secondary prophylaxis[100]				
Drug of choice:		Trimethoprim/ sulfamethoxazole	1 tab (single or double strength) daily or 1 DS tab PO 3d/wk	TMP 150 mg/SMX 750 mg/m^2/d PO in 2 doses 3d/wk
Alternative:		Dapsone[7]	50 mg PO bid or 100 mg PO daily	2 mg/kg/d (max 100 mg) PO or 4 mg/kg (max 200 mg) PO each wk
	OR	Dapsone[7]	50 mg PO daily or 200 mg PO each wk	
		plus pyrimethamine[101]	50 mg PO or 75 mg PO each wk	
	OR	Pentamidine	300 mg aerosol inhaled monthly via Respirgard II nebulizer	≥5 yr: 300 mg inhaled monthly via Respirgard II nebulizer
	OR	Atovaquone[7,20]	1500 mg PO daily	1-3 mo: 30 mg/kg/d PO 4-24 mo: 45 mg/kg/d PO >24 mo: 30 mg/kg/d PO
River Blindness, see FILARIASIS				
Roundworm, see ASCARIASIS				
***Sappinia diploidea*,** See AMEBIC MENINGOENCEPHALITIS, PRIMARY				
SCABIES *(Sarcopted scabiei)*				
Drug of choice:		5% Permethrin	Topically once[102]	Topically once[102]
Alternative:[103]		Ivermectin[7,16,104]	200 mcg/kg PO once[102]	200 mcg/kg PO once[102]
		10% Crotamiton	Topically once/d × 2	Topically once/d PO × 2
SCHISTOSOMIASIS *(Bilharziasis)*				
S. haematobium				
Drug of choice:		Praziquantel[39]	40 mg/kg/d PO in 2 doses × 1 d	40 mg/kg/d PO in 2 doses × 1 d
S. japonicum				
Drug of choice:		Praziquantel[39]	60 mg/kg/d PO in 3 doses × 1 d	60 mg/kg/d PO in 3 doses × 1 d
S. mansoni				
Drug of choice:		Praziquantel[39]	40 mg/kg/d PO in 2 doses × 1 d	40 mg/kg/d PO in 2 doses × 1 d
Alternaticve:		Oxamniquine[105]*	15 mg/kg PO once[106]	20 mg/kg/d PO in 2 doses × 1 d[106]
S. mekongi				
Drug of choice:		Praziquantel[39]	60 mg/kg/d PO in 3 doses × 1 d	60 mg/kg/d PO in 3 doses × 1 d

99. *Pneumocystis has been reclassified as a fungus. In severe disease with room air P_{O_2} ≤ 70 mm Hg or Aa gradient ≥35 mm Hg, prednisone should also be used (S Gagnon et al, N Engl J Med 1990; 323:1444; E Caumes et al, Clin Infect Dis 1994; 18:319).*
100. *Primary/secondary prophylaxis in patients with HIV can be discontinued after CD4 count increases to >200 × 10^6/L for >3 mo.*
101. *Plus leucovorin 25 mg with each dose of pyrimethamine. Pyrimethamine should be taken with food to minimize gastrointestinal adverse effects.*
102. *Treatment may need to be repeated in 10-14 days. A second ivermectin dose taken 2 weeks later increases the cure rate to 95%, which is equivalent to that of 5% permethrin (V Usha et al, J Am Acad Dermatol 2000; 42:236; O Chosidow, N Engl J Med 2006; 354:1718; J Heukelbach and H Feldmeier, Lancet 2006; 367:1767).*
103. *Lindane (γ-benzene hexachloride) should be reserved for treatment of patients who fail to respond to other drugs. The FDA has recommended it not be used for immunocompromised patients, young children, the elderly, pregnant and breast-feeding women, and patients weighing <50 kg.*
104. *Ivermectin, either alone or in combination with a topical scabicide, is the drug of choice for crusted scabies in immunocompromised patients (P del Giudice, Curr Opin Infect Dis 2004; 15:123).*
105. *Oxamniquine, which is not available in the United States, is generally not as effective as praziquantel. It has been useful, however, in some areas in which praziquantel is less effective (ML Ferrari et al, Bull World Health Organ 2003; 81:190; A Harder, Parasitol Res 2002; 88:395). Oxamniquine is contraindicated in pregnancy. It should be taken after food.*
106. *In East Africa, the dose should be increased to 30 mg/kg, and in Egypt and South Africa to 30 mg/kg/d × 2 d. Some experts recommend 40-60 mg/kg over 2-3 d in all of Africa (KC Shekhar, Drugs 1991; 42:379).*

Infection	Drug	Adult Dosage	Pediatric Dosage
Sleeping sickness, see TRYPANOSOMIASIS			
STRONGYLOIDIASIS *(Strongyloides stercoralis)*			
Drug of choice:[107]	Ivermectin[16]	200 mcg/kg/d PO × 2 d	200 mcg/kg/d PO × 2 d
Alternative:	Albendazole[7,12]	400 mg PO bid × 7 d	400 mg PO bid × 7 d
TAPEWORM infection			
—**Adult** (intestinal stage)			
Diphyllobothrium latum **(fish),** ***Taenia saginata*** **(beef),** ***Taenia solium*** **(pork),** ***Dipylidium caninum*** **(dog)**			
Drug of choice:[107]	Praziquantel[7,39]	5-10 mg/kg PO once	5-10 mg/kg PO once
Alternative:	Niclosamide[108]*	2 g PO once	50 mg/kg PO once
Hymenolepis nana **(dwarf tapeworm)**			
Drug of choice:	Praziquantel[7,39]	25 mg/kg PO once	25 mg/kg PO once
Alternative:	Nitazoxanide[5,7]	500 mg PO once/d or bid × 3 d[109]	1-3 yr: 100 mg PO bid × 3 d[109] 4-11 yr: 200 mg PO bid × 3 d[109]
—**Larval** (tissue stage)			
Echinococcus granulosus (hydatid cyst)			
Drug of choice:[110]	Albendazole[12]	400 mg PO bid × 1-6 mo	15 mg/kg/d (max 800 mg) × 1-6 mo
Echinococcus multilocularis			
Treatment of choice:	See footnote 111		
Taenia solium *(Cysticercosis)*			
Treatment of choice:	See footnote 112		
Alternative:	Albendazole[12]	400 mg PO bid × 8-30 d; can be repeated as necessary	15 mg/kg/d (max 800 mg) PO in 2 doses × 8-30 d; can be repeated as necessary
OR	Praziquantel[7,39]	100 mg/kg/d PO in 3 doses × 1 day then 50 mg/kg/d in 3 doses × 29 days	100 mg/kg/d PO in 3 doses × 1 day then 50 mg/kg/d in 3 doses × 29 days
Toxocariasis, see VISCERAL LARVA MIGRANS			
TOXOPLASMOSIS *(Toxoplasma gondii)*			
Drug of choice:[113]	Pyrimethamine[114]	25-100 mg/d PO × 3-4 wk	2 mg/kg/d PO × 2 d, then 1 mg/kg/d (max 25 mg/d) × 4 wk[115]
	plus		
	sulfadiazine[116]	1-1.5 g PO qid × 3-4 wk	100-200 mg/kg/d PO × 3-4 wk
TRICHINELLOSIS *(Trichinella spiralis)*			
Drug of choice:	Steroids for severe symptoms		
	plus		
	Albendazole[7,12]	400 mg PO bid × 8-14 d	400 mg PO bid × 8-14 d
Alternative:	Mebendazole[7]	200-400 mg PO tid × 3 d , then 400-500 mg tid × 10 d	200-400 mg PO tid × 3 d , then 400-500 mg tid × 10 d
TRICHOMONIASIS *(Trichomonas vaginalis)*			
Drug of choice:[117]	Metronidazole	2 g PO once or 500 mg bid × 7 d	15 mg/kg/d PO in 3 doses × 7 d
OR	Tinidazole[6]	2 g PO once	50 mg/kg once (max 2 g)

107. In immunocompromised patients or disseminated disease, it may be necessary to prolong or repeat therapy, or to use other agents. Veterinary parenteral and enema formulations of ivermectin have been used in severely ill patients with hyperinfection who were unable to take or reliably absorb oral medications (J Orem et al, Clin Infect Dis 2003; 37:152; PE Tarr Am J Trop Med Hyg 2003; 68:453; FM Marty et al, Clin Infect Dis 2005; 41:e5). In disseminated strongyloidiasis, combination therapy with albendazole and ivermectin has been suggested (S Lim et al, Can Med Assoc J 2004; 171:479).

108. Niclosamide must be chewed thoroughly before swallowing and washed down with water.

109. JO Juan et al, Trans R Soc Trop Med Hyg 2002; 96:193; JC Chero et al, Trans R Soc Trop Med Hyg 2007; 101:203; E Diaz et al, Am J Trop Med Hyg 2003; 68:384.

110. Patients may benefit from surgical resection or percutaneous drainage of cysts. Praziquantel is useful preoperatively or in case of spillage of cyst contents during surgery. Percutaneous aspiration-injection-reaspiration (PAIR) with ultrasound guidance plus albendazole therapy has been effective for management of hepatic hydatid cyst disease (RA Smego, Jr., et al, Clin Infect Dis 2003; 37:1073; S Nepalia et al, J Assoc Physicians India 2006; 54:458; E Zerem and R Jusufovic Surg Endosc 2006; 20:1543).

111. Surgical excision is the only reliable means of cure. Reports have suggested that in nonresectable cases use of albendazole (400 mg bid) can stabilize and sometimes cure infection (P Craig, Curr Opin Infect Dis 2003; 16:437; O Lidove et al, Am J Med 2005; 118:195).

112. Initial therapy for patients with inflamed parenchymal cysticercosis should focus on symptomatic treatment with anti-seizure medication (LS Yancey et al, Curr Infect Dis Rep 2005; 7:39; AH del Brutto et al, Ann Intern Med 2006; 145:43). Patients with live parenchymal cysts who have seizures should be treated with albendazole together with steroids (dexamethasone 6 mg/d or prednisone 40-60 mg/d) and an anti-seizure medication (HH Garcia et al, N Engl J Med 2004; 350:249). Patients with subarachnoid cysts or giant cysts in the fissures should be treated for at least 30 d (JV Proaño et al, N Engl J Med 2001; 345:879). Surgical intervention (especially neuroendoscopic removal) or CSF diversion followed by albendazole and steroids is indicated for obstructive hydocephalus. Arachnoiditis, vasculitis, or cerebral edema is treated with prednisone 60 mg/d or dexamethasone 4-6 mg/d together with albendazole or praziquantel (AC White, Jr., Annu Rev Med 2000; 51:187). Any cysticercocidal drug may cause irreparable damage when used to treat ocular or spinal cysts, even when corticosteroids are used. An ophthalmic exam should always precede treatment to rule out intraocular cysts.

Infection	Drug	Adult Dosage	Pediatric Dosage
TRICHOSTRONGYLUS infection			
Drug of choice:	Pyrantel pamoate[7,13]*	11 mg/kg base PO once (max. 1 g)	11 mg/kg PO once (max 1 g)
Alternative:	Mebendazole[7]	100 mg PO bid × 3 d	100 mg PO bid × 3 d
OR	Albendazole[7,12]	400 mg PO once	400 mg PO once
TRICHURIASIS (*Trichuris trichiura*, whipworm)			
Drug of choice:	Mebendazole	100 mg PO bid × 3 d or 500 mg once	100 mg PO bid × 3 d or 500 mg once
Alternative:	Albendazole[7,12]	400 mg PO × 3 d	400 mg PO × 3 d
OR	Ivermectin[7,16]	200 mcg/kg PO daily × 3 d	200 mcg/kg/d PO × 3 d
TRYPANOSOMIASIS[118]			
T. cruzi (American trypanosomiasis, Chagas disease)			
Drug of choice:	Nifurtimox*	8-10 mg/kg/d PO in 3-4 doses × 90-120 d	1-10 yr: 15-20 mg/kg/d PO in 4 doses × 90-120 d 11-16 yr: 12.5-15 mg/kg/d in 4 doses × 90-120 d
OR	Benznidazole[119]*	5-7 mg/kg/d PO in 2 doses × 30-90 d	≤12 yr: 10 mg/kg/d PO in 2 doses × 30-90 d >12 yr: 5-7 mg/kg/d in 2 doses × 30-90 d
T. brucei gambiense (West African trypanosomiasis, sleeping sickness)			
Hemolymphatic stage			
Drug of choice:[120]	Pentamidine[7]	4 mg/kg/d IM × 7 d	4 mg/kg/d IM × 7 d
Alternative:	Suramin*	100-200 mg (test dose) IV, then 1 g IV on days 1, 3, 7, 14, and 21	20 mg/kg on d 1, 3, 7, 14, and 21
Late disease with CNS involvement			
Drug of Choice:	Eflornithine[121]*	400 mg/kg/d IV in 4 doses × 14 d	400 mg/kg/d IV in 4 doses × 14 d
OR	Melarsoprol[122]	2.2 mg/kg/d IV × 10 d	2.2 mg/kg/d IV × 10 d
T. b. rhodesiense (East African trypanosomiasis, sleeping sickness)			
Hemolymphatic stage			
Drug of choice:	Suramin*	100-200 mg (test dose) IV, then 1 g IV on days 1, 3, 7, 14, and 21	20 mg/kg on d 1, 3, 7, 14, and 21
Late disease with CNS involvement			
Drug of choice:	Melarsoprol[122]	2-3.6 mg/kg/d IV × 3 d; after 7 d 3.6 mg/kg/d × 3 d; repeat again after 7 d	2-3.6 mg/kg/d × 3 d; after 7 d 3.6 mg/kg/d × 3 d; repeat again after 7 d
VISCERAL LARVA MIGRANS[123] *(Toxocariasis)*			
Drug of choice:	Albendazole[7,12]	400 mg PO bid × 5 d	400 mg PO bid × 5 d
OR	Mebendazole[7]	100-200 mg PO bid × 5 d	100-200 mg PO bid × 5 d
Whipworm, see TRICHURIASIS			
Wuchereria bancrofti, see FILARIASIS			

113. To treat CNS toxoplasmosis in HIV-infected patients, some clinicians have used pyrimethamine 50-100 mg/d (after a loading dose of 200 mg) with sulfadiazine and, when sulfonamide sensitivity developed, have given clindamycin 1.8-2.4 g/d in divided doses instead of the sulfonamide. Treatment is usually given for at least 4-6 weeks. Atovaquone (1500 mg PO bid) plus pyrimethamine (200 mg loading dose, followed by 75 mg/d PO) for 6 weeks appears to be an effective alternative in sulfa-intolerant patients (K Chirgwin et al, Clin Infect Dis 2002; 34:1243). Atovaquone must be taken with a meal to enhance absorption. Treatment is followed by chronic suppression with lower dosage regimens of the same drugs. For primary prophylaxis in HIV patients with <100 × 16^6/L CD4 cells, either trimethoprim-sulfamethoxazole, pyrimethamine with dapsone, or atovaquone with or without pyrimethamine can be used. Primary or secondary prophylaxis may be discontinued when the CD4 count increases to >200 × 10^6/L for >3 mo (MMWR Morb Mortal Wkly Rep 2004; 53 [RR15]:1). In ocular toxoplasmosis with macular involvement, corticosteroids are recommended in addition to antiparasitic therapy for an anti-inflammatory effect. In one randomized single-blind study, trimethoprim/sulfamethoxazole was reported to be as effective as pyrimethamine/sulfadiazine for treatment of ocular toxoplasmosis (M Soheilian et al, Ophthalmology 2005; 112:1876). Women who develop toxoplasmosis during the first trimester of pregnancy should be treated with spiramycin (3-4 g/d). After the first trimester, if there is no documented transmission to the fetus, spiramycin can be continued until term. If transmission has occurred in utero, therapy with pyrimethamine and sulfadiazine should be started (JG Montoya and O Liesenfeld, Lancet 2004; 363:1965). Pyrimethamine is a potential teratogen and should be used only after the first trimester.

114. Plus leucovorin 10-25 mg with each dose of pyrimethamine. Pyrimethamine should be taken with food to minimize gastrointestinal adverse effects.

115. Congenitally infected newborns should be treated with pyrimethamine every 2 or 3 days and a sulfonamide daily for about one year (JS Remington and G Desmonts in JS Remington and JO Klein, eds, Infectious Disease of the Fetus and Newborn Infant, *6th ed, Philadelphia: Saunders, 2006, page 1038).*

116. Sulfadiazine should be taken on an empty stomach with adequate water.

117. Sexual partners should be treated simultaneously with same dosage. Metronidazole-resistant strains have been reported and can be treated with higher doses of metronidazole (2-4 g/d × 7-14 d) or with tinidazole (MMWR Morb Mortal Wkly Rep 2006; 55 [RR11]:1).

118. MP Barrett et al, Lancet 2003; 362:1469. Treatment of chronic or indeterminate Chagas disease with benznidazole has been associated with reduced progression and increased negative seroconversion (R Viotti et al, Ann Intern Med 2006; 144:724).

119. Benznidazole should be taken with meals to minimize gastrointestinal adverse effects. It is contraindicated during pregnancy.

120. Pentamidine and suramin have equal efficacy, but pentamidine is better tolerated.

121. Eflornithine is highly effective in T.b. gambiense, *but not in* T.b. rhodesiense *infections. In one study of treatment of CNS disease due to* T.b. gambiense, *there were fewer serious complications with eflornithine than with melarsoprol (F Chappuis et al, Clin Infect Dis 2005;41:748). Eflornithine is available in limited supply only from the WHO. It is contraindicated during pregnancy.*

122. E Schmid et al, J Infect Dis 2005; 191:1922. Corticosteroids have been used to prevent arsenical encephalopathy (J Pepin et al, Trans R Soc Trop Med Hyg 1995; 89:92). Up to 20% of patients with T.b.gambiense *fail to respond to melarsoprol (MP Barrett, Lancet 1999; 353:1113). In one study, a combination of low-dose melarsoprol (1.2 mg/kg/d IV) and nifurtimox (7.5 mg/kg PO bid) × 10 d was more effective than standard-dose melarsoprol alone (S Bisser et al, J Infect Dis 2007; 195:322).*

123. Optimum duration of therapy is not known; some Medical Letter consultants would treat ×20 d. For severe symptoms or eye involvement, corticosteroids can be used in addition (D Despommier, Clin Microbiol Rev 2003; 16:265).

Drug	Toxicity in Pregnancy	Recommendations
Albendazole (*Albenza*)	Teratogenic and embryotoxic in animals	Caution*
Amphotericin B (*Fungizone*, and others)	None known	Caution*
Amphotericin B liposomal (*AmBisome*)	None known	Caution*
Artemether/lumefantrine *(Coartem, Riamet)*[1]	Embryocidal and teratogenic in animals	Caution*
Artesunate[1]	Embryocidal and teratogenic in animals	Caution*
Atovaquone (*Mepron*)	Maternal and fetal toxicity in animals	Caution*
Atovaquone/proguanil (*Malarone*)[2]	Maternal and fetal toxicity in animals	Caution*
Azithromycin (*Zithromax*, and others)	None known	Probably safe
Benznidazole (*Rochagan*)	Unknown	Contraindicated
Chloroquine (*Aralen*, and others)	None known with doses recommended for malaria prophylaxis	Probably safe in low doses
Clarithromycin (*Biaxin*, and others)	Teratogenic in animals	Contraindicated
Clindamycin (*Cleocin*, and others)	None known	Caution*
Crotamiton (*Eurax*)	Unknown	Caution*
Dapsone	None known; carcinogenic in rats and mice; hemolytic reactions in neonates	Caution*, especially at term
Diethylcarbamazine (DEC; *Hetrazan*)	Not known; abortifacient in one study in rabbits	Contraindicated
Diloxanide *(Furamide)*	Safety not established	Caution*
Doxycycline (*Vibramycin*, and others)	Tooth discoloration and dysplasia, inhibition of bone growth is fetus; hepatic toxicity and azotemia with IV use in pregnant patients with decreased renal function or with overdosage	Contraindicated
Eflornithine (*Ornidyl*)	Embryocidal in animals	Contraindicated
Fluconazole (*Diflucan*, and others)	Teratogenic	Contraindicated for high dose; caution* for single dose
Flucytosine (*Ancoban*)	Teratogenic in rats	Contraindicated
Furazolidone (*Furoxone*)	None known; carcinogenic in rodents; hemolysis with G-6-PD deficiency in newborn	Caution*; contraindicated at term
Hydroxychloroquine (*Plaquenil*)	None known with doses recommended for malaria prophylaxis	Probably safe in low doses
Itraconazole (*Sporanox*, and others)	Teratogenic and embryotoxic in rats	Caution*
Iodoquinol (*Yodoxin*, and others)	Unknown	Caution*
Ivermectin (*Stromectol*)	Teratogenic in animals	Contraindicated
Ketoconazole (*Nizoral*, and others)	Teratogenic and embryotoxic in rats	Contraindicated; topical probably safe
Lindane	Absorbed from the skin; potential CNS toxicity in fetus	Contraindicated
Malathion, topical (*Ovide*)	None known	Probably safe
Mebendazole (*Vermox*)	Teratogenic and embryotoxic in rats	Caution*
Mefloquine (*Lariam*)[3]	Teratogenic in animals	Caution*
Meglumine *(Glucantine)*	Not Known	Caution*
Metronidazole (*Flagyl*, and others)	None known—carcinogenic in rats and mice	Caution*
Miconazole (*Monistat i.v.*)	None known	Caution*
Miltefosine (*Impavido*)	Teratogenic in rats and induces abortions in animals	Contraindicated; effective contraception must be used for 2 months after the last dose
Niclosamide (*Niclocide*)	Not absorbed; no known toxicity in fetus	Probably safe
Nitazoxanide (*Alinia*)	None known	Caution*
Oxamniquine (*Vansil*)	Embryocidal in animals	Contraindicated
Paromomycin (*Humatin*)	Poorly absorbed; toxicity in fetus unknown	Oral capsules probably safe
Pentamidine (*Pentam 300*, *NebuPent*, and others)	Safety not established	Caution*
Permethrin (*Nix*, and others)	Poorly absorbed; no known toxicity in fetus	Probably safe
Praziquantel (*Biltricide*)	Not known	Probably safe
Primaquine	Hemolysis in G-6-PD deficiency	Contraindicated
Pyrantel pamoate (*Antiminth*, and others)	Absorbed in small amounts; no known toxicity in fetus	Probably safe
Pyrethrins and piperonyl butoxide (*RID*, and others)	Poorly absorbed; no known toxicity in fetus	Probably safe
Pyrimethamine (*Daraprim*)[4]	Teratogenic in animals	Caution*; contraindicated during 1st trimester
Quinacrine (*Atabrine*)	Safety not established	Caution*
Quinidine	Large doses can cause abortion	Probably safe
Quinine (*Qualaquin*)	Large doses can cause absortion; auditory nerve hypoplasia, deafness in fetus; visual changes, limb anomalies, visceral defects also reported	Caution*
Sodium stibogluconate (*Pentostam*)	Not known	Caution*
Sulfonamides	Teratogenic in some animal studies; hemolysis in newborn with G-6-PD deficiency; increased risk of kernicterus in newborn	Caution*; contraindicated at term
Suramin sodium (*Germanin*)	Teratogenic in mice	Caution*
Tetracycline (*Sumycin*, and others)	Tooth discoloration and dysplasia, inhibition of bone growth in fetus; hepatic toxicity and azotemia with IV use in pregnant patients with decreased renal function or with overdosage	Contraindicated
Tinidazole (*Tindamax*)	Increased fetal mortality in rats	Caution*
Trimethoprim (*Proloprim*, and others)	Folate antagonism; teratogenic in rats	Caution*
Trimethoprim-sulfamethoxazole (*Bactrim*, and others)	Same as sulfonamides and trimethoprim	Caution*; contraindicated at term

**Use only for strong clinical indication in absence of suitable alternative.*

Manufacturers of Drugs Used to Treat Parasitic Infections

albendazole—*Albenza* (GlaxoSmithKline)
Albenza (GlaxoSmithKline)—albendazole
Alinia (Romark)—nitazoxanide
AmBisome (Gilead)—amphotericin B, liposomal
amphotericin B—*Fungizone* (Apothecon), others
amphotericin B, liposomal—*AmBisome* (Gilead)
Ancobon (Valeant)—flucytosine
§ *Antiminth* (Pfizer)—pyrantel pamoate
• *Aralen* (Sanofi)—chloroquine HCl and chloroquine phosphate
§ artemether—*Artenam* (Arenco, Belgium)
§ artemether/lumefantrine—*Coartem*, *Riamet* (Novartis)
§ *Artenam* (Arenco, Belgium)—artemether
§ artesunate—(Guilin No. 1 Factory, People's Republic of China)
atovaquone—*Mepron* (GlaxoSmithKline)
atovaquone/proguanil—*Malarone* (GlaxoSmithKline)
azithromycin—*Zithromax* (Pfizer), others
• *Bactrim* (Roche)—TMP/Sulfa
§ benznidazole—*Rochagan* (Brazil)
• *Biaxin* (Abbott)—clarithromycin
§ *Biltricide* (Bayer)—praziquantel
† bithionol—*Bitin* (Tanabe, Japan)
† *Bitin* (Tanabe, Japan)—bithionol
§ *Brolene* (Aventis, Canada)—propamidine isethionate chloroquine HCl and chloroquine phosphate—*Aralen* (Sanofi), others
clarithromycin—*Biaxin* (Abbott), others
• *Cleocin* (Pfizer)—clindamycin
clindamycin—*Cleocin* (Pfizer), others
Coartem (Novartis)—artemether/lumefantrine
crotamiton—*Eurax* (Westwood-Squibb)
dapsone—(Jacobus)
§ *Daraprim* (GlaxoSmithKline)—pyrimethamine USP
† diethylcarbamazine citrate (DEC)—*Hetrazan*
• *Diflucan* (Pfizer)—fluconazole
§ diloxanide furoate—*Furamide* (Boots, United Kingdom)
doxycycline—*Vibramycin* (Pfizer), others
eflornithine (difluoromethylornithine, DFMO)—*Ornidyl* (Aventis)
§ *Egaten* (Novartis)—triclabendazole
Elimite (Allergan)—permethrin
Ergamisol (Janssen)—levamisole
Eurax (Westwood-Squibb)—crotamiton
• *Flagyl* (Pfizer)—metronidazole
§ *Flisint* (Sanofi-Aventis, France)—fumagillin
fluconazole—*Diflucan* (Pfizer), others
flucytosine—*Ancobon* (Valeant)
§ fumagillin—*Flisint* (Sanofi-Aventis, France)
• *Fungizone* (Apothecon)—amphotericin
§ *Furamide* (Boots, United Kingdom)—diloxanide furoate
§ furazolidone—*Furozone* (Roberts)
§ *Furozone* (Roberts)—furazlidone
† *Germanin* (Bayer, Germany)—suramin sodium
§ *Glucantime* (Aventis, France)—meglumine antimonate
† *Hetrazan*—diethylcarbamazine citrate (DEC)
Humatin (Monarch)—paromomycin
§ *Impavido* (Zentaris, Germany)—miltefosine
iodoquinol—*Yodoxin* (Glenwood), others
itraconazole—*Sporanox* (Janssen-Ortho), others
ivermectin—*Stromectol* (Merck)
ketoconazole—*Nizoral* (Janssen), others
† *Lampit* (Bayer, Germany)—nifurtimox
Lariam (Roche)—mefloquine
§ *Leshcutan* (Teva, Israel)—topical paromomycin
levamisole—*Ergamisol* (Janssen)
lumefantrine/artemether—*Coartem*, *Riamet* (Novartis)
Malarone (GlaxoSmithKline)—atovaquone/proguanil
malathion—*Ovide* (Medicis)
mebendazole—*Vermox* (McNeil), others
mefloquine—*Lariam* (Roche)
§ meglumine antimonate—*Glucantime* (Aventis, France)
† melarsoprol—*Mel-B*
† *Mel-B*—melarsoprol
Mepron (GlaxoSmithKline)—atovaquone
metronidazole—*Flagyl* (Pfizer), others
§ miconazole—*Monistat i.v.*
§ miltefosine—*Impavido* (Zentaris, Germany)
§ *Monistat i.v.*—miconazole
NebuPent (Fujisawa)—pentamidine isethionate
Neutrexin (US Bioscience)—trimetrexate
§ niclosamide—*Yomesan* (Bayer, Germany)
† nifurtimox—*Lampit* (Bayer, Germany)
nitazoxanide—*Alinia* (Romark)
• *Nizoral* (Janssen)—ketoconazole
Nix (GlaxoSmithKline)—permethrin
§ ornidazole—*Tiberal* (Roche, France)
Ornidyl (Aventis)—eflornithine (difluoromethylornithine, DFMO)
Ovide (Medicis)—malathion
§ oxamniquine—*Vansil* (Pfizer)
§ *Paludrine* (AstraZeneca, United Kingdom)—proguanil
paromomycin—*Humatin* (Monarch); *Leshcutan* (Teva, Israel; (topical formulation not available in US)
Pentam 300 (Fujisawa)—pentamidine isethionate
pentamidine isethionate—*Pentam 300* (Fujisawa), *NebuPent* (Fujisawa)
† *Pentostam* (GlaxoSmithKline, United Kingdom)—sodium stibogluconate
permethrin—*Nix* (GlaxoSmithKline), *Elimite* (Allergan)
§ praziquantel—*Biltricide* (Bayer)
primaquine phosphate USP
§ proguanil—*Paludrine* (AstraZeneca, United Kingdom)
proguanil/atovaquone—*Malarone* (GlaxoSmithKline)
§ propamidine isethionate—*Brolene* (Aventis, Canada)
§ pyrantel pamoate—*Antiminth* (Pfizer)
pyrethrins and piperonyl butoxide—*RID* (Pfizer), others
§ pyrimethamine USP—*Daraprim* (GlaxoSmithKline)
Qualaquin—quinine sulfate (Mutual Pharmaceutical Co/AR Scientific)
* quinidine gluconate (Eli Lilly)
§ quinine dihydrochloride
quinine sulfate—*Qualaquin* (Mutual Pharmaceutical Co/AR Scientific)
Riamet (Novartis)—artemether/lumefantrine
• *RID* (Pfizer)—pyrethrins and piperonyl butoxide
• *Rifadin* (Aventis)—rifampin
rifampin—*Rifadin* (Aventis), others
§ *Rochagan* (Brazil)—benznidazole
* *Rovamycine* (Aventis)—spiramycin
† sodium stibogluconate—*Pentostam* (GlaxoSmithKline, United Kingdom)
* spiramycin—*Rovamycine* (Aventis)
• *Sporanox* (Janssen-Ortho)—itraconazole
Stromectol (Merck)—ivermectin
sulfadiazine—(Eon)
† suramin sodium—*Germanin* (Bayer, Germany)
§ *Tiberal* (Roche, France)—ornidazole
Tindamax (Mission)—tinidazole
tinidazole—*Tindamax* (Mission)
TMP/Sulfa—*Bactrim* (Roche), others
§ triclabendazole—*Egaten* (Novartis)
trimetrexate—*Neutrexin* (US Bioscience)
§ *Vansil* (Pfizer)—oxamniquine

CHAPTER 254

Immunomodulating Agents

Timothy R. La Pine ✪ Harry R. Hill

Considerable clinical interest and basic science research into the functional mechanisms of the immune response and identification of the specific biologic factors that modulate this response have been generated lately. This research has established that a critical and delicate balance in the regulation of both cellular and humoral function is essential for complete immunologic response to invasive pathogens and that alteration of this regulation may have potential clinical significance. Attempts to augment immune function in the challenged host or during specific immunodeficiency states have focused on numerous modifiers of immune biologic response. These efforts, in combination with advances made in hybridoma and recombinant DNA technology, have resulted in numerous clinical trials conducted to explore the therapeutic utility of immunomodulating agents in the treatment of specific human disease states. I review the biologic agents used to manipulate immune regulation for the prevention and management of infectious diseases in infants and children.

MONOCLONAL ANTIBODIES

The use of serum antibody therapy, in the late 1800s, was among the first clinical attempts to modulate the immune response in the treatment of human sepsis. By the middle 1930s, serum-based therapy was the standard of care for many infectious illnesses, particularly pneumonia. Controlled trials during that time demonstrated that the administration of type-specific pneumococcal serum reduced the mortality rate by 50 percent in patients with pneumococcal pneumonia.[43,44,73] With the introduction of antimicrobial pharmacologic agents in the 1940s, the use of serum antibody therapy for sepsis became less popular. The development of hybridoma technology by Kohler and Milstein[137] in 1975, however, provided the means to generate virtually unlimited amounts of monoclonal antibodies for potential clinical use. This technology in combination with the advances in recombinant DNA technology has allowed researchers to generate highly specific human monoclonal antibodies and to humanize murine monoclonal antibodies.[31,264] Monoclonal antibodies now are considered attractive molecules to be used potentially as antimicrobial agents and immunomodulators, to deliver pharmacologic substances to sites of inflammation, or even to target certain cancerous tissues. This advance has led to the development of monoclonal antibody–based therapies to treat sepsis, septic shock, and a number of inflammatory diseases in infants, children, and adults.

A monoclonal antibody could, in theory, be generated that would alter the clinical course of any infectious or inflammatory disease state. This hypothesis has fostered numerous studies evaluating the use of monoclonal antibodies in a variety of clinical diseases, particularly those related to alloimmune and autoimmune phenomena.[53,64,99,165,207] The use of monoclonal antibodies to alter the pathogenesis of sepsis and septic shock also has received considerable experimental and clinical attention. These efforts have focused on two phases in the development of the septic shock syndrome: (1) to block bacteria and their components that induce shock and (2) to modify the release and action of the proinflammatory mediators that lead to septic shock.

Monoclonal antibody preparations to block bacteria or their components in the development of septic shock were initially employed in early studies using type-specific antisera against *Streptococcus pneumoniae*, *Neisseria meningitidis*, and *Haemophilus influenzae*.[43] Attempts using monoclonal antibody therapy to alter the pathogenesis of bacterial sepsis leading to septic shock have focused on group B streptococcus (GBS) and *Escherichia coli*. These two bacteria are significant causes of neonatal morbidity and mortality. Infants usually acquire these bacterial infections from exposure in the birth canal; however, only a small number of the exposed infants actually develop bacterial sepsis. Factors predisposing infants to acquisition of infection with these organisms include prematurity, prolonged rupture of membranes, and maternal sepsis. Neonatal infections occur more commonly with bacteria that possess specific capsular polysaccharides (i.e., the type III polysaccharide of GBS or the K-1 capsule of *E. coli*). Bacteria bearing these capsules are able to avoid opsonization and subsequent phagocytic killing by polymorphonuclear leukocytes (PMNs). Newborns with deficiencies of type-specific antibodies to these bacterial capsular antigens due to prematurity, which contributes to decreased maternal transplacental antibody transport, or inadequate maternal stores are predisposed to acquisition of GBS and *E. coli* infections.[111] These observations led investigators to hypothesize that passive antibody administration may be beneficial in preventing or reducing neonatal morbidity and mortality observed with these bacterial infections.

Rebecca Lancefield in 1933 originally demonstrated a protective efficacy for GBS antibody therapy using rabbit antisera. She established that this protective efficacy is type specific and classified three types of GBS strains. Antisera raised against type II or type III GBS did not protect against infection with type I bacteria. These experiments also suggested that antibodies to group B non–type-specific determinants (i.e., expressed on all GBS bacteria) are not protective.[82,150,151] Further experiments by Lancefield and coworkers with type I GBS demonstrated that antibodies to both carbohydrate and protein capsular components can be protective.[149,151] The first human studies to suggest that the administration of antibody to the infecting strain of bacteria could improve survival rates from early-onset GBS in infants occurred in the middle 1970s.[229-232] In these studies, fresh whole blood either containing or lacking opsonic antibody was administered to infants with early-onset GBS disease. All nine infants who demonstrated a rise in opsonic antibody after transfusion survived. In contrast, three of the six infants (50%) who received blood lacking antibody to their infection strain died.[228] Subsequent studies have suggested that intravenous immune globulins (IVIG) could offer some protection against GBS infections in experimental animal models.[76,116] Because of their lack of specificity and decreased opsonic activity, however, polyclonal-type IVIG antibody preparations have had only variable and limited ability to alter the course and outcome of GBS or other bacterial infections in clinical trials.[106]

The development of monoclonal antibodies to GBS type III occurred in the early 1980s.[229-232] The GBS type III–specific antibodies, which were of the IgM class, protected rats against intraperitoneal infection with homologous type group B streptococci. Survival rates were 95 to 100 percent for rats protected by monoclonal antibody compared with 17 percent for unprotected rats. Protection was afforded even when therapy was delayed up to 24 hours after inoculation. Antibody administration resulted in the rapid accumulation of PMNs at the site of infection and prevented the depletion of bone marrow granulocyte stores commonly seen in animal models and human neonates with GBS

infection.[231] Monoclonal IgG and IgA antibody preparations also have been generated to type III GBS.[21,190,229] A protective effect in animal models of GBS infection for all three immunoglobulin isotypes has been established.[230] In GBS infections, the ability of an antibody isotype preparation to activate the complement system is related directly to its protective and opsonic activity.[232] IgM is much more active in triggering complement than are monoclonal IgG and IgA preparations,[133,232] which may explain why monoclonal IgM is quantitatively more effective against GBS infections.[110,113,232] Although human monoclonal IgM antibodies to GBS are available and have demonstrated effectiveness in reducing mortality in animal models of GBS sepsis, they have yet to be tried clinically to prevent or to attenuate GBS sepsis and septic shock in human neonates.[210,232]

Concomitant with the studies of monoclonal antibody preparations for use in experimental models of GBS infections were similar studies using monoclonal preparations in *E. coli* sepsis. *E. coli* is an antigenically complex, gram-negative bacterium having more than 150 somatic (O) and 100 capsular (K) antigens. Several factors associated with *E. coli* have been implicated as contributing to the virulence of these organisms. Among these, the K-1 capsular polysaccharide and lipopolysaccharide (LPS) have received the most attention.[26] The K-1 capsular polysaccharide on *E. coli* as a contributing factor to the virulence of this organism was suggested first by Robbins and colleagues in 1974.[214] Subsequent studies established that *E. coli* strains that possess the K-1 capsular polysaccharide are resistant to opsonization through the alternative complement pathway.[28,237] Several investigators have shown that antibody preparations to the K-1 capsular polysaccharide are opsonic and protective against lethal *E. coli* bacteremia in animals.[27] Although protection has been demonstrated primarily with IgM antibody, polyclonal hyperimmune IgG has shown some protection in animal models of lethal *E. coli* sepsis.[209] Because the serum from newborn infants is deficient in opsonic activity for *E. coli*, some investigators suggested that the administration of antibody against *E. coli* K-1 would enhance neonatal resistance to infections with this organism.[29,52] Investigators since have developed murine and human monoclonal IgM antibodies to *E. coli* K-1 and demonstrated that these antibodies are opsonic and protective against lethal *E. coli* infections in animal models.[209] Human clinical trials using monoclonal antibodies to *E. coli* K-1 have not been initiated to my knowledge.

Staphylococci are a major cause of acquired infections in prematurely born infants. Antibiotic resistance among staphylococcal species in these immunocompromised patients is of significant concern. A human chimeric monoclonal antibody has been generated that is opsonic for *Staphylococcus epidermidis* and *Staphylococcus aureus.* In animal models of *S. epidermidis* and *S. aureus* sepsis, this monoclonal antibody enhanced bacterial clearance and significantly improved survival against both staphylococcal species. Clinical trials with this monoclonal antibody are currently under way to determine the clinical usefulness of monoclonal antibody preparations in preventing nosocomial staphylococcal infections in high-risk preterm neonates.[77,254]

During the past several decades, the importance of pneumococcal vaccination for individuals at risk for acquiring infection has been underscored by the emergence of antibiotic resistance among pneumococcal strains and the increased prevalence of invasive pneumococcal disease in immunocompromised patients. Unfortunately, pure pneumococcal capsular polysaccharide vaccines are poorly immunogenic in many immunodeficient patients who are at risk for acquiring infection. This concern has led to the development of monoclonal antibodies against type-specific pneumococcal infections. A human monoclonal IgM antibody has been generated and shown to provide type-specific protection against lethal pneumococcal infections in mice, even in the presence of complement deficiency.[267] Thus, type-specific monoclonal antibody preparations likely could provide protection against pneumococcal infection in high-risk immunocompromised humans.

The use of monoclonal antibodies as a single-agent therapy to treat or to prevent bacterial sepsis has been limited to experimental animal models, primarily because of the narrow spectrum of monoclonal antibody therapy and the exceedingly large number of patients required to demonstrate the efficacy of human monoclonal antibody therapy in clinical trials. The future clinical use of monoclonal antibodies directed at bacteria or their components in the treatment of sepsis requires several clinical considerations. First, because antibodies are more effective in preventing an infection than in treating an established infection, monoclonal antibody therapy is most useful when it is administered early in the course of a disease. Second, the successful implementation of monoclonal antibody therapy directed at a specific pathogen requires refinements in diagnostic laboratory methodology to hasten identification of pathogens, leading to early treatment. Third, monoclonal antibody therapy is pathogen specific, which is problematic in dealing with unknown infections early in their course and with mixed infections with multiple organisms or serotypes. For pathogens that are antigenically variable, use of monoclonal antibody cocktail preparations that combine monoclonal antibodies to common antigenic serotypes may be beneficial. Antibody cocktails also may be designed to include monoclonal antibodies of different isotypes (IgM, IgG, IgA) to further enhance their effectiveness. Fourth, combination therapy with monoclonal antibodies and antimicrobial chemotherapy agents may be an alternative means to treat bacteria and their components in the development of septic shock. Such therapies could potentially reduce the amount or duration of antibiotic treatment needed and reduce the number of antibiotic-resistant pathogens. Combination therapy also may be clinically beneficial in cases in which the antimicrobial agents are toxic themselves. Fifth, monoclonal antibodies may elicit self-neutralizing antibodies. Thus, the administration of a monoclonal antibody could promote the production of antibody against the monoclonal antibody itself, which would diminish the clinical response and potentially cause severe anaphylaxis in cases of antibody retreatment. Likewise, widespread use of monoclonal antibody therapy could select for antibody-resistant pathogens or other serotypes or even entirely different infecting organisms.[148]

Researchers have examined the possible blockade of the proinflammatory cascade that accompanies severe infections.[1,13,86,146] The experimental attempts using monoclonal antibodies to modify the release and action of the proinflammatory mediators that lead to septic shock have focused on the proinflammatory effects of the cytokine family, endotoxin, and the functions of neutrophils and complement.

THE CYTOKINES

LYMPHOKINES AND MONOKINES

The cytokines are a family of small soluble protein molecules responsible for cell-to-cell communication. They are produced by several cell types and play crucial roles in many biologic processes, including growth, inflammation, immunity, and hematopoiesis. During infection, genes for nearly all the cytokines are expressed. The biologic activity of the prototype cytokines, the lymphokines and monokines, include interleukins (ILs) and tumor necrosis factor–α (TNF-α); these molecules, along with the granulocyte colony-stimulating factors, have received considerable attention as potential immunomodulatory agents. In response to pathogen invasion, these cytokines perform a complex series of interactions to initiate a cascade of biologic events resulting in the propagation and subsequent regulation of the inflammatory response, leading to pathogen alienation while maintaining

host preservation. Thus, the cytokine family, through a complex web of interactions, functions to initiate and then both to up-regulate and down-regulate the inflammatory response. On the basis of their roles of either up-regulating or down-regulating immune responsiveness, the cytokines generally and historically have been classified as either proinflammatory or anti-inflammatory molecules. Although many cytokines have the potential to perform dual functions, either directly or indirectly, their proinflammatory or anti-inflammatory properties are of considerable basic science and clinical therapeutic interest.[25,45,62,80,146,154,164,202]

Some prominent proinflammatory cytokines and their cellular sources are listed in Table 254–1. TNF-α and IL-1 generally are considered to be prominent early proinflammatory mediators. They induce gene expression of other proinflammatory cytokines, including IL-6 and IL-8, leading to neutrophil activation, recruitment, and degranulation. TNF-α and IL-1 also activate a secondary cascade of inflammatory mediators, including arachidonic acid–derived prostaglandin I_2, thromboxane A_2, prostaglandin E_2, platelet-activating factor, and the complement system. The colony-stimulating factors and IL-3 also are proinflammatory cytokines that induce bone marrow stem cell production of granulocytes and monocytes in addition to activating neutrophils and inducing production of IL-1 and TNF-α.[25,45,62,80,146,154,164]

Prominent among the anti-inflammatory cytokines (Table 254–2) are IL-4, IL-10, IL-13, and transforming growth factor–β. These cytokines may block endotoxin induction of IL-1 and TNF-α and suppress lymphocyte and monocyte function. In addition, IL-1 receptor antagonist blocks the proinflammatory action of IL-1 by binding its receptor.[25,45,62,80,146,154,164]

Considerable experimental and clinical interest has focused on the proinflammatory cytokines TNF-α and IL-1 as important early mediators in the pathogenesis of sepsis and septic shock syndrome. The basis for the potential therapeutic utility of these two cytokines in human disease states involves two clinically distinct hypotheses: (1) excessive cytokine production results in host immune injury, leading to severe shock; and (2) deficient cytokine production renders a host susceptible to infection by invasive pathogens.[146]

The hypothesis that cytokine overproduction can lead to severe lethal shock is demonstrated in several animal models and is suggested in patients with overwhelming sepsis. The outer membranes of gram-negative bacteria contain lipopolysaccha-

TABLE 254–1 Proinflammatory Cytokines

Cytokine	Function	Predominant Cell Source
Tumor necrosis factor–α	Stimulates interleukin-6 and colony-stimulating factors Depresses erythropoiesis, stimulates interleukin-8 and interleukin-9 Promotes tumor necrosis and endotoxic shock	Monocytes and macrophages
Interleukin-1	Stimulates proliferation and differentiation of T and B lymphocytes Stimulates T lymphocytes to produce interleukin-2 Promotes colony-stimulating factor, interleukin-8 and interleukin-9 production, and endotoxic shock	Macrophages, astrocytes, monocytes, fibroblasts, keratinocytes, B cells, corneal epithelium, and other cell types
Interleukin-2	Stimulates growth of T lymphocytes Stimulates B-lymphocyte and monocyte differentiation Increases cytotoxicity of T lymphocytes and natural killer cells	Activated T lymphocytes
Interleukin-3	Multipotential hematopoietic cell growth factor Stimulates early B and T lymphocytes Mast cell growth factor	Activated T lymphocytes, natural killer cells
Interleukin-5	Stimulates eosinophil formation and differentiation Augments T lymphocyte cytotoxicity and proliferation of B lymphocytes	T lymphocytes, mast cells
Interleukin-7	Supports growth of pre-B lymphocytes Stimulates T lymphocytes	B lymphocytes, bone marrow fibroblasts, monocytes
Interleukin-8	Stimulates neutrophil, monocyte, and lymphocyte activation chemotaxis	Monocytes
Interleukin-9	Stimulates neutrophil, monocyte, and lymphocyte activation chemotaxis Stimulates erythroid progenitors, helper T-lymphocyte growth factor	T lymphocytes
Interleukin-11	T lymphocyte–dependent stimulator of B lymphocytes	Bone marrow fibroblasts
Interleukin-12	Stimulates helper T-lymphocyte differentiation and interleukin-2 production Stimulates interferon-γ production Increases cytotoxicity of natural killer cells	T and B lymphocytes, lymphoblastoid cells
Interleukin-14	Stimulates proliferation of activated B lymphocytes Inhibits immunoglobulin secretion from B lymphocytes	T lymphocytes
Interleukin-15	Stimulates T-lymphocyte function and proliferation Enhances natural killer cell function	Monocytes and macrophages
Interleukin-16	Promotes migration of T lymphocytes	T lymphocytes
Interleukin-17	Stimulates interleukin-6 and interleukin-8 production	T lymphocytes
Interleukin-18	Stimulates interferon-γ and tumor necrosis factor–α production	Macrophages, mononuclear cells, and dendritic cells
Granulocyte colony-stimulating factor	Stimulates neutrophil colony formation	Monocytes and fibroblasts
Granulocyte-macrophage colony-stimulating factor	Stimulates granulocyte and monocyte formation Induces tumor necrosis factor	T lymphocytes, natural killer cells, endothelial cells, fibroblasts, and keratinocytes
Macrophage colony-stimulating factor	Activates monocytes and granulocytes Stimulates macrophage colony formation Induces interleukin-1 and tumor necrosis factor	Fibroblasts, monocytes, and endothelial cells

TABLE 254–2 Anti-inflammatory Cytokines

Cytokine	Function	Predominant Cell Source
Interleukin-4	Stimulates proliferation of T and B lymphocytes and megakaryocytes A growth factor for mast cells and erythroid precursors	T lymphocytes
Interleukin-6	Blocks endotoxin induction of interleukin-1 and tumor necrosis factor B and T lymphocyte–stimulating activity	Monocytes, T and B lymphocytes, fibroblasts, epithelial and endothelial cells
Interleukin-10	Blocks production of interleukin-1 and tumor necrosis factor Inhibits primary allogeneic T-lymphocyte responses Inhibits interleukin-2, interleukin-8, and granulocyte-macrophage colony-stimulating factor	T and B lymphocytes, macrophages and monocytes
Interleukin-13	Blocks production of interleukin-1, tumor necrosis factor, and interleukin-8 Suppresses nitric oxide formation	T lymphocytes
Interleukin-1 receptor antagonist	Binds interleukin-1 receptors, blocking interleukin-1 effects	Monocytes and macrophages
Transforming growth factor–β	Reduces endotoxin-induced interleukin-1 and tumor necrosis factor production	Monocytes and macrophages

rides or endotoxin, which induce the early proinflammatory cytokines TNF-α and IL-1. Although these cytokines may protect the host from infection, if they are expressed in excessive amounts, their effects can result in multiple organ failure and death. During severe sepsis, the levels of both TNF-α and IL-1 increase proportionately with the degree of hypotension and organ failure. The combination of these two cytokines can result in synergism over their individual effects by severalfold, leading to lethal septic shock syndrome.[35,36] In animal models of shock and gram-negative sepsis, TNF-α levels rise rapidly after injection of bacteria or endotoxin, reaching peak concentrations at 60 to 90 minutes, whereas IL-1 levels rise more slowly, peaking at 180 minutes. A similar time course response has been observed in human subjects injected with endotoxin.[36,184] Children with septicemia and purpura fulminans and children with meningococcal disease demonstrated an association between morbidity and mortality and high serum levels of TNF-α and IL-1.[87,192] These studies and others implicate TNF-α and IL-1 as prominent modulators in the development of the septic shock syndrome and suggest that a potential therapeutic benefit may be obtained by inhibiting the production of these cytokines and reducing their proinflammatory effects.

Experimental attempts to attenuate the excessive proinflammatory cytokine activity of TNF-α and IL-1 have focused on (1) inhibiting release of endotoxin, (2) blocking endotoxin–target cell binding and preventing the transmembrane signaling mechanisms leading to production of TNF-α and IL-1, (3) controlling the synthesis of TNF-α and IL-1 by inhibiting or suppressing specific cytokine gene transcription and translation, (4) inhibiting release of TNF-α and IL-1, (5) administering TNF-α and IL-1 neutralizing antibodies and soluble receptors, (6) producing and administering TNF-α and IL-1 receptor antagonists that block specific cytokine binding to target cell receptors, and (7) blocking TNF-α or IL-1 intracellular transmembrane signaling mechanisms and preventing their action on target cells.[154]

The use of monoclonal anti-endotoxin antibodies to inhibit the binding of endotoxin to its target cells has received considerable attention. Numerous in vitro and in vivo animal experiments have suggested that blocking of endotoxin leads to improved survival by inhibiting proinflammatory cytokine production and expression.[193] The initial clinical studies in patients with gram-negative bacteremia treated with immunoglobulin preparations directed against endotoxin demonstrated a significant reduction in mortality rates.[14,222] Further studies suggested a reduction of septic shock in similarly treated high-risk surgical patients.[14] These observations led to the development of several clinical trials using human monoclonal anti-endotoxin antibodies. HA-1A is a human monoclonal antibody against the lipid A moiety of bacterial endotoxin. The mechanism of HA-1A action is to block endotoxin triggering of the intracellular events leading to proinflammatory cytokine synthesis. In placebo-controlled clinical trials of HA-1A, either HA-1A or placebo was infused during the course of 20 minutes to patients with severe sepsis. These patients also received cardiopulmonary support and antibacterial therapy. The etiologic agents of sepsis included *E. coli*, *Pseudomonas*, and *Klebsiella* and *Enterobacter* spp. The authors reported that HA-1A significantly reduced the incidence of mortality in adults with septic shock and gram-negative bacteremia. The mortality rate for those patients who were in severe shock before receiving HA-1A was reduced by 42 percent.[268] Although these early clinical studies using HA-1A were encouraging, a protective role for anti-endotoxin antibodies has not been established in subsequent clinical trials.[168] Anti-endotoxin therapy may be more effective if it is given earlier during the sepsis syndrome before the development of shock. Because bacterial lysis caused by antibiotics is an ongoing process and results in further release of endotoxin, multiple dosing of anti-endotoxin antibodies also may prove beneficial in treating sepsis. The future clinical use of anti-endotoxin antibodies may be in combination with other immunomodulation therapies, directed at simultaneously blocking several steps in both the propagation and action of proinflammatory cytokines.

Studies of cytokine inhibition have focused on controlling TNF-α and IL-1 with anti–TNF-α antibodies directed at these specific cytokines and their receptors. Control of proinflammatory cytokine synthesis is specific for each individual cytokine and requires an understanding of the unique temporal relationships these molecules have during the propagation of inflammatory responses. A critical aspect of TNF-α and IL-1 gene expression in a variety of cell types has been the reported exquisite sensitivity these cytokines have to bacterial endotoxin.[45,62,146,154] Human blood monocytes synthesize TNF-α and IL-1 in the presence of endotoxin. In the absence of endotoxin, however, gene expression occurs, but protein translation does not take place.[223] Thus, these cells may be viewed as being primed for bacterial endotoxin exposure. TNF-α and IL-1 transcription is suppressed by the anti-inflammatory cytokines IL-10, IL-13, and transforming growth factor–β, but the clinical therapeutic benefits these cytokines have in treating septic shock remain to be defined.[47,103,186,224] Agents blocking the lipoxygenase pathway of arachidonate metabolism also have been implicated in the reduction of TNF-α and IL-1 synthesis, and corticosteroids have been shown to sup-

press both TNF-α and IL-1 transcription and synthesis, but only when they have been administered before transcription has been initiated.[78,221] The use of corticosteroids in infants and children with bacterial meningitis has demonstrated that treatment with a combination of dexamethasone and antibiotics results in lower cerebrospinal fluid levels of TNF-α than occurs with treatment with placebo and antibiotics.[192] In addition, patients treated with corticosteroids had fewer neurologic symptoms.[132] Subsequent multicenter trials, however, have failed to establish a protective effect of corticosteroid use in the treatment of children with meningitis.[249] One possible explanation for this discrepancy may be that corticosteroids almost exclusively suppress endotoxin-induced, proinflammatory cytokine gene transcription but have little or no effect on proinflammatory cytokine translation.[62,233] Thus, some investigators have suggested that the early administration of corticosteroids, before transcription has been initiated, would block cytokine synthesis. Timing of corticosteroid administration, therefore, may account for some of the clinical variability seen with its use in children with meningitis. Clinical trials are focusing on TNF-α and IL-1 synthesis with the administration of corticosteroids either before or while antibiotics are administered. Similarly, the temporal use of antibiotics, corticosteroids, and anti-endotoxin therapy may result in an additive therapeutic benefit.

Neutralizing monoclonal antibodies against murine or human TNF-α have been shown to decrease mortality rates in several experimental animal models of sepsis.[18,176,243] Studies with soluble TNF-α receptors or their immunoadhesin constructs also have demonstrated an immunoprotective effect of TNF-α blockade in animal models of endotoxemia or bacteremia.[17] Although anti–TNF-α antibodies are being used with caution in humans, anti–TNF-α treatment in a limited number of patients with established septic shock resulted in increased vascular hemodynamics and left ventricular stroke volume.[97] The in vitro use of free soluble TNF-α receptors to bind TNF-α results in a 10- to 50-fold increase in binding affinity over that observed with anti–TNF-α monoclonal antibodies.[98] Results from phase II clinical trials using soluble TNF-α receptors, however, have not shown improvement in survival rates; moreover, administration of high doses actually increased the incidence of mortality.[98,219]

Certain naturally occurring substances inhibit IL-1 synthesis and action, but they also have effects on many of the other cytokines. Specific inhibitors of IL-1, however, have been identified. Most prominent of these is the IL-1 receptor inhibitor that competes with the binding of IL-1 to its cell surface receptor. Recombinant IL-1 receptor antagonist (IL-1ra) that blocks IL-1 effects has been studied in various animal models.[4,200] For instance, IL-1ra prevents death from endotoxic shock in rabbits.[200] The therapeutic use of IL-1ra in treating septic shock in early phase II human clinical trials showed improved survival rates at 28 days.[79] The subsequent randomized phase III trials, however, failed to show improvement in patients with severe shock.[78] Further clinical studies are ongoing. IL-1ra also has been used in treatment trials of patients with acute myelogenous leukemia. The uncontrolled production of IL-1 by leukemic blasts has been proposed to result in the continued proliferation of these cells and the development of acute myelogenous leukemia. Studies have shown that IL-1ra blocks the spontaneous proliferation and production of granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-1, and IL-6 in the peripheral blood and bone marrow cells of these patients.[211] The potential clinical use of IL-1ra is being investigated in patients with psoriasis, rheumatoid arthritis, and myelogenous leukemia.[100] Similarly, combination therapy with the simultaneous blockade of both TNF-α and IL-1 is being investigated in endotoxin models of shock and a number of clinical disease states.[217]

Another approach to attenuate excessive proinflammatory cytokine responses is the use of pharmacologic agents. Salyer and colleagues[220] demonstrated that pentoxifylline, a methylxanthine derivative that blocks TNF-α transcription and production, could override some of the effects of TNF-α on PMNs. In their study, the profound decrease in human PMN chemotactic ability caused by excessive TNF-α was restored to normal by treatment with pentoxifylline. The specific mechanisms of pentoxifylline's effect are not known, but it has been shown to restore PMN membrane fluidity inhibited by TNF-α that is critical for cell movement.[197] Furthermore, pentoxifylline can block PMN adhesion to endothelium and result in decreased PMN respiratory burst activity, which is thought to be responsible for the improved survival rates seen in pentoxifylline-treated animal models of endotoxin-induced septic shock.[201] Some of the clinical trials using pentoxifylline in surgical patients with early evidence of systemic inflammation have suggested a cardioprotective effect, although other studies have been less convincing.[71,236] Pentoxifylline also has been evaluated in preterm infants with sepsis.[156] A total of 78 infants with documented sepsis were randomly assigned to receive pentoxifylline (5 mg/kg/hr for 6 hours on 6 successive days) or placebo. Pentoxifylline-treated infants had significantly lower levels of TNF-α but not of IL-1. Only 1 of 40 infants in the pentoxifylline-treated group died, compared with 6 of 38 in the control group ($p < .05$). Amrinone, a phosphodiesterase inhibitor, also has been shown to reduce TNF-α levels in LPS-challenged mice.[88] Thus, these and other pharmacologic agents may be useful in preventing or reducing some of the adverse and even fatal effects that are mediated by proinflammatory cytokines.

IVIG may have a potential inhibitory effect on proinflammatory cytokine activity. Patients in the active phase of Kawasaki disease have increased levels of TNF-α and IL-1. These cytokines have been postulated to stimulate local inflammatory responses by regulating leukocyte adherence and activation, leading to the vascular damage that is a critical clinical aspect of this disease. Another suggestion is that the effects of IVIG therapy in Kawasaki disease, and perhaps in other diseases, may be results of the attenuating production of the proinflammatory cytokines TNF-α and IL-1.[6,10,110] Animal models of LPS-induced TNF-α and IL-1 synthesis demonstrate a suppression of mononuclear cell synthesis of these proinflammatory cytokines when they are treated with IVIG.[12] The peripheral blood mononuclear cell production of TNF-α and IL-1, however, in patients with Kawasaki disease receiving IVIG therapy showed decreased synthesis of IL-1 but not of TNF-α.[157,158] The role of IVIG as an immunomodulator has been suggested in an ever growing number of clinical disease states because of its broad immunoregulatory potential.[10,107] Its specific role in arresting proinflammatory cytokine activity, either directly or indirectly, warrants further clinical investigation.

The hypothesis that diminished levels of cytokines may render a host susceptible to development of infection was introduced by Weatherstone and Rich.[252] They suggested that the increased susceptibility to infection observed in premature neonates may be secondary to deficient proinflammatory cytokine production. In their study, they measured cord blood monocyte secretion of TNF-α and IL-1 with and without stimulation of LPS. IL-1 activity by LPS-stimulated preterm monocytes did not differ from that observed by LPS-stimulated adult monocytes. TNF-α activity, however, in the LPS-stimulated monocytes from preterm neonates was significantly lower than that in both stimulated and unstimulated adult monocytes. Thus, they concluded that diminished production of TNF-α may predispose the preterm infant to acquisition of infection. This finding has not been supported by the studies of infected animals, which show markedly elevated TNF-α levels, and subsequent studies in preterm infants have not established a deficiency in TNF-α.[259] Williams and colleagues[259] and Peat and coworkers[203] have, in contrast, shown that mononuclear cells from term newborns produced enhanced levels of TNF-α in response to group B streptococci or endo-

toxin. Ongoing studies are defining the role of cytokine production in neonatal and other infections.

The proinflammatory cytokine IL-2 acts on activated T cells and to some extent on B cells and natural killer cells and causes them to proliferate or differentiate. IL-2 is synthesized by both T cells and natural killer cells.[185,250] Decreased IL-2 production or IL-2 receptor expression has been noted in a number of clinical disease states, most notably in cases of severe combined immunodeficiency disease. Lesser degrees of abnormalities may occur in acquired immunodeficiency syndrome (AIDS), type 1 diabetes mellitus, systemic lupus erythematosus, and hypogammaglobulinemia.[146,154,164] The most intriguing potential for IL-2 in the treatment of disease involves its use in tumor therapy.[216] IL-2 currently is approved for the treatment of metastatic renal carcinoma. Use of IL-2–activated natural killer cells results in a decrease in tumor burden in approximately 20 percent of patients, although serious side effects occur. In addition to its potential role as an antitumor agent, IL-2 shares many of the same effects as interferon-γ (IFN-γ) and may, someday, function as a therapeutic agent in infection, autoimmunity, and immunodeficiency.[154,216]

Both IL-8 and IL-9 have been investigated in various human disease states, primarily because of their powerful role in stimulating neutrophil function, including activation, adhesion, and chemotaxis. Patients with cystic fibrosis, bronchiectasis, and chronic bronchitis have demonstrated elevated levels of IL-8 in their sputum.[212] The sputum from these patients is highly chemotactic to neutrophils, but with treatment with monoclonal antibodies to IL-8, this chemotactic effect was inhibited. Aerosolized IL-8 inhibitors have been used in patients with cystic fibrosis and have resulted in decreased inflammation in these patients.[178,212] IL-8 inhibitors are being evaluated in infants with bronchopulmonary dysplasia. Researchers have speculated that the persistently elevated levels of IL-8 in the tracheal fluid of ventilated preterm infants lead to neutrophil accumulation and the development of pulmonary fibrosis, which may be reduced by IL-8 inhibitors.[129,138] Similar studies are being conducted with IL-9 inhibitors. Thus, these cytokines may play an important role in the acute inflammatory response leading to chronic disease states, and blocking of this response may be of therapeutic benefit. The proinflammatory IL-5 has not been implicated in a specific human disease state, but its strong B-cell proliferative effects suggest that it has a possible role in the pathogenesis of immunodeficiency, and its potent effects on eosinophil production, activation, and migration implicate its action in allergic responses.[33]

The proinflammatory activities of IL-12 and IL-18 are of current immunologic interest as well. IL-12 is an integral immune regulator that is produced primarily by macrophages and dendritic cells.[198] IL-12 has been shown to induce the production of IFN-γ by T cells and NK cells.[171,172,198] IL-18 is another recently described cytokine with many proinflammatory functions.[180] IL-18 was defined initially as IFN-γ–inducing factor.[37,61,155] IL-12 and IL-18, both alone and in synergy, regulate IFN-γ production in response to infection with intracellular parasites and bacteria and in certain autoimmune diseases.* The regulation of these cytokines may be therapeutically beneficial in certain disease states.[66,93] The other proinflammatory cytokines also are in various developmental stages of experimental investigation. As we learn more about their specific actions, we will better be able to determine their use as potential immunomodulating agents.

The anti-inflammatory cytokines have limited clinical use. IL-4 can block both IL-1 and TNF-α transcription.[103,224] IL-4 has been shown to inhibit human neutrophil adhesion to human endothelial cells while enhancing the adhesion of eosinophils.[189] These effects have not been implicated in specific human diseases, but an IL-4 action is suggested in allergic responses. Although IL-6 has both anti-inflammatory and proinflammatory effects, the levels of this cytokine were found to correlate with mortality rates in children with gram-negative and gram-positive sepsis, suggesting that monitoring of IL-6 levels may be of prognostic value.[246] Similarly, IL-10 has been shown to block production of IL-1, IL-6, IL-8, IL-12, and TNF-α as well as GM-CSF in animal models.[54,173] It also has effects on mast cells, T cells, and natural killer cells, and it inhibits primary allogeneic T-cell responses. Thus, IL-10 may have a potential role in treating acute and chronic inflammation and may be effective in suppressing transplant rejection.[15,54] Studies examining the safety and immunomodulatory effects of the intravenous injection of IL-10 in humans demonstrate that it is well tolerated and results in decreased production of both TNF-α and IL-1.[25] Additional clinical studies are being conducted on the potential immunoregulatory effects of the anti-inflammatory cytokines, which may indicate their therapeutic use in human disease states.

COLONY-STIMULATING FACTORS

Colony-stimulating factors are involved principally in the production of neutrophils and monocytes. They were discovered because of their ability to stimulate the formation of colonies of granulocytes and monocyte-macrophages in cultured bone marrow cells and were named according to the primary cell colony type that they elicited. Granulocyte-macrophage colony-stimulating factor (GM-CSF) induces peripheral blood macrophages and granulocytes. It also has other pleiotropic effects, including stimulation of precursors of megakaryocytes, mast cells, and eosinophils. In addition, GM-CSF has effects on neutrophil migration and phagocytosis. Granulocyte colony-stimulating factor (G-CSF) induces peripheral blood granulocytes. Its actions are on both the production and function of neutrophils, including migration, phagocytosis, and superoxide generation. Macrophage colony-stimulating factor (M-CSF) induces peripheral mononuclear phagocytes. IL-3 increases mast cell populations as well as the induction of granulocytes, macrophages, eosinophils, and megakaryocytes.[63,96,154,155,163,183]

Clinical studies with GM-CSF and G-CSF as adjuvant therapy have been performed in individuals with distinct lymphopoietic disorders (i.e., congenital agranulocytosis, cyclic neutropenia, Shwachman-Diamond syndrome) or those due to the consequences of cytotoxic chemotherapy, AIDS, and aplastic anemia. The colony-stimulating factors can stimulate granulocyte and monocyte populations in these individuals, but the response is restricted to the number of available stem cells. Colony-stimulating factor treatment can partially or completely reverse congenital neutropenia and has shown great promise in regeneration of lymphopoietic cells after administration of cytotoxic chemotherapy and high-dose chemotherapy followed by autologous bone marrow transplantation. Recombinant human GM-CSF (rhGM-CSF) also has been shown to be beneficial in patients with aplastic anemia.[9,244] Hammond and colleagues[101] demonstrated a dramatic increase in neutrophil counts in children with cyclic neutropenia treated with recombinant human G-CSF (rhG-CSF). Cyclic neutropenia is a rare disorder characterized by regular 21-day cyclic fluctuations in the number of blood neutrophils, monocytes, eosinophils, lymphocytes, platelets, and reticulocytes. Although the exact mechanism of this disorder is not known, it is attributed to a regulatory abnormality affecting proliferation of stem cells. These infants have recurrent aphthous stomatitis, pharyngitis, lymphadenopathy, fever, and numerous infections during the periods of neutropenia. The length of cycling in treated infants decreased from 21 days to 1 day, and the neutrophil turnover rate increased nearly fourfold, signifi-

cantly reducing the frequency of infection. Recombinant G-CSF also has shown promise for infants and children with neutrophil production disorders. Infants with congenital agranulocytosis, Kostmann syndrome, and Shwachman-Diamond syndrome, disorders characterized by severe, persistent absolute neutropenia, show a dramatic increase in neutrophil count after treatment with rhG-CSF.[24] In addition, rhG-CSF and rhGM-CSF have been used in neutropenic patients with AIDS. Despite the concern that the effects of GM-CSF to activate macrophages may in turn promote replication of human immunodeficiency virus (HIV), current studies are defining the role of rhGM-CSF and rhG-CSF in patients with AIDS.[95,163]

Thus, colony-stimulating factors have emerged as significant modulators of human immune function and lymphopoiesis. Because the colony-stimulating factors can functionally activate mature granulocytes and monocytes, considerable attention has focused on their future role in treating individuals at risk for acquiring infection. English and colleagues[65] reported decreased GM-CSF production by neonatal T cells. Because a major factor contributing to the increased susceptibility of human neonates to severe infections is their inability to produce adequate numbers of neutrophils in response to bacterial infections, these neonates may benefit from colony-stimulating factor treatment during severe infection.[20] Similar treatment in immunologically stressed burn and trauma patients also may prove beneficial.[56,196]

INTERFERONS

INTERFERONS α AND β

The interferons are glycoproteins that were discovered because of their antiviral properties. They are known to possess antitumor and immunomodulatory activities in addition to their antiviral effects.[11] The interferons have been classified into three major groups: α, β, and γ. IFN-α and IFN-β were previously known as type I interferon and have similar protein structures and bind the same receptor. IFN-γ, formerly type II interferon, has a much different structure and its own receptor.[8] IFN-α is produced by leukocytes. The earliest demonstration of its clinical usefulness was in the treatment of AIDS-related Kaposi sarcoma. In these initial studies, a Kaposi sarcoma tumor response occurred in 30 to 50 percent of the patients treated with recombinant IFN-α.[94,142,187,191] Researchers have speculated that IFN-α exerts its antitumor effect by activating cytotoxic T cells. Since then, placebo-controlled clinical trials have shown that IFN-α also may have significant antiretroviral effect in HIV-infected patients.[141,152] Clinical trials have been conducted to determine the effect of early treatment with IFN-α in reducing progression of HIV disease and to determine the therapeutic effect of IFN-α in combination with other drugs in the treatment of HIV infection and HIV-related diseases.[140,140a]

IFN-α also has been used in various parts of the world for the treatment of chronic myeloid leukemia, hairy-cell leukemia, basal cell carcinoma, multiple myeloma, hepatitis B and C, and condylomata acuminata. In chronic myeloid leukemia, early treatment with IFN-α has been reported to elicit complete hematologic remission in more than 70 percent of the patients treated. Many of these patients had total elimination of the Philadelphia chromosome, which is a hallmark of the disease.[239,240,241] Complete to 80 percent remissions also have been reported in the treatment of hairy-cell leukemia.[208] Intralesional injection of IFN-α into basal cell carcinoma of the skin resulted in 81 percent tumor remission as determined by biopsy.[50,125] Despite the variability of the outcomes among reports on the use of IFN-α in the treatment of multiple myeloma, it has been approved as a therapy for these patients in a number of European countries.[174]

IFN-α also is used for the treatment of hepatitis B and C.[155] Clinical responses have been reported to be of long duration, often with complete loss of both hepatitis B surface antigen and evidence of viral replication. In chronic hepatitis C, complete responses to therapy determined by the decline of serum aspartate aminotransferase to normal levels have been observed in 50 to 70 percent of the patients treated. Although serum aspartate aminotransferase levels in half of the patients who had improved returned to pretreatment levels within 6 to 12 months after discontinuation of therapy, nearly 20 percent achieved sustained remission.[57,60,119,139,204] Studies also have shown that IFN-α is useful in treating genital warts, condylomata acuminata caused by papillomaviruses.[32] Intralesional injections of IFN-α completely eliminated warts in more than 50 percent of the patients treated. IFN-α therapy also is suggested to reduce the number of lesions in juvenile laryngeal papillomatosis after systemic use.[169] Thus, IFN-α has therapeutic potential as both an antitumor and an antiviral agent.

IFN-β also has received attention as an antiviral and antitumor agent. Its clinical usefulness as a single-agent therapy is suggested in relapsing multiple sclerosis. The mechanism of IFN-β therapeutic action in multiple sclerosis is unknown.[126] Ongoing studies are investigating IFN-β therapy in combination with IFN-α in the treatment of various malignant neoplasms.

INTERFERON γ

IFN-γ is produced by $CD4^+$ and $CD8^+$ cells as well as by natural killer cells.[108] Investigators have reported that circulating mononuclear cells and T lymphocytes from neonates are markedly deficient in their ability to produce IFN-γ in response to a variety of stimuli, compared with adult cells.[162,226,227,260] Studies using recombinant IFN-γ have shown that preincubation of neonatal neutrophils, which are deficient in their chemotactic ability, with recombinant IFN-γ enhances their chemotactic response to a level equal to that of adult neutrophils.[108] Other studies have shown that neonatal mixed mononuclear cells are deficient in the production of the IFN-γ–stimulating cytokines IL-12 and IL-18 in response to GBS.[112,114,130] In vitro treatment with recombinant IL-12 and IL-18 can correct this defect in IFN-γ production in response to GBS. These findings suggest that a potential role exists for the regulation of IFN-γ in neonatal host defense.

Job syndrome was first described by Davis, Schaller, and Wedgwood[58] in 1965 in two patients with recurrent staphylococcal abscesses. Patients with this syndrome often develop chronic sinopulmonary infections and mucocutaneous *Candida* infections. Hill and coworkers[115] observed that the patients with Job syndrome also have a profound defect in neutrophil chemotactic responsiveness along with extreme hyperimmunoglobulin E. This defect in neutrophil chemotaxis is intermittent and occurs predominantly when the patient is symptomatic.[55,109,115] Because production of IFN-γ by mononuclear leukocytes in patients with hyperimmunoglobulin E is markedly deficient or absent, in vitro studies were conducted to determine the effect of recombinant IFN-γ on the chemotactic responsiveness of neutrophils from patients with this syndrome. After pretreatment with IFN-γ, the chemotactic response of the neutrophils from patients with Job syndrome increased significantly, with an average enhancement of 300 percent above baseline to levels not significantly different from those of matched healthy controls.[128] In four patients with Job syndrome, preliminary trials of IFN-γ therapy with hyperimmunoglobulin E suggested clinical benefit in three, with a significant decrease in eczema as well as in pulmonary symptoms and secretions.

Patients with chronic granulomatous disease (CGD) have an inherited deficiency in the proteins required for nicotinamide

adenine dinucleotide phosphate oxidase activity. Phagocytes with this enzymatic defect are able to engulf bacteria but cannot generate the respiratory burst necessary to kill the organisms. Consequently, patients with CGD suffer severe chronic, recurrent life-threatening infections. The usefulness of treating CGD patients with IFN-γ was suggested by studies showing that this lymphokine can stimulate the respiratory burst of normal phagocytes. Results of studies by Ezekowitz and colleagues[69] and Sechler and coworkers[225] showed that when macrophages from patients with CGD were treated with IFN-γ in vitro, a respiratory burst occurred and superoxide anion was generated. Sechler and colleagues[225] further demonstrated a partial correction in neutrophils and monocytes from patients with CGD after subcutaneous treatment with recombinant IFN-γ. These initial results suggested that when it is administered in vivo to patients with CGD, recombinant IFN-γ could partially correct the defective ability of phagocytes to kill bacteria. Ezekowitz and coworkers[70] extended these findings in a double-blind placebo-controlled trial. They showed that recombinant IFN-γ significantly decreased the relative risk for development of serious infection in patients with CGD, but these studies failed to demonstrate an effect of IFN-γ on respiratory burst activity. This cytokine most likely affects the arginine–nitric oxide pathway in neutrophils and macrophages. Patients who received IFN-γ had a 70 percent reduction in the risk for development of serious infection compared with controls. Overall, IFN-γ decreases the risk for development of infection and the duration of hospitalization in patients with CGD. When it is administered with prophylactic antibiotics, an additive effect occurs, resulting in a nearly 20 percent increase in the infection-free rate of patients with CGD compared with IFN-γ alone.[70] IFN-γ was licensed by the Food and Drug Administration in December 1990 for the treatment of patients with CGD. The authors of the collaborative studies recommended its use with the addition of prophylactic antibiotics for treatment of patients diagnosed with CGD.[84]

TOLL-LIKE RECEPTORS

Toll-like receptors (TLRs) are pathogen pattern-recognition receptors central to innate immune responses.[127] TLRs are a family of type 1 integral membrane glycoproteins that detect pathogens and initiate cytokine production by activation of NF-κB. The ligands recognized by TLRs consist of a wide range of evolutionarily conserved motifs, such as LPS, single- and double-stranded RNA, and zymosan. Collectively, these motifs are called pathogen-associated molecular patterns (PAMPs). TLR recognition of PAMPs contributes to the immediate response and broad specificity of innate immune recognition toward bacterial, viral, fungal, and parasitic pathogens. Twelve TLRs have been described in mammals, with at least 10 known in humans.[2,3,6]

The role of TLRs as immunomodulating agents is of contemporary interest. Amlie-Lefond and colleagues[5] described the potential use of TLR agonists as protective agents against biothreat pathogens. TLRs 1 to 10 in humans act to augment the immune response. TLR agonists can bolster this response and potentially offer protection against specific infections or diseases. Stimulation of TLR-7 and TLR-8 has shown antiviral and antineoplastic properties in humans. A drug known to do this, imiquimod (Aldara), has been shown to be beneficial against human papillomavirus, molluscum contagiosum, genital warts, and basal cell carcinoma.[5,51,242]

Immunomodulatory oligonucleotides stimulate Toll-like receptors and induce cytokine production. Immunomodulatory oligonucleotides offer potential clinical use for treatment of a number of inflammatory diseases, including severe acute respiratory syndrome (SARS), for which clinical trials are under way.[5] Similar use of immunomodulatory oligonucleotides in patients with renal carcinomas and HIV infection also is under investigation. Recent evidence suggests that TLR-3 activation can enhance innate immune response and enhances production of IFN-α.[143] These features render TLR-3 agonists attractive agents in the treatment of HIV-related infections and infections in certain immunocompromised patients.

TLR expression in human neonates is currently being defined.[218] TLR-2, TLR-4, and TLR-8 functions have been described in neonates. Researchers have speculated that deficiency of TLR activation may contribute to the neonate's increased susceptibility to infection.[248] The results of TLR expression in neonates have varied. In general, similar expression of TLRs 1 to 4 occurs in newborn infants and adults. Low-birthweight or premature infants, however, demonstrate significantly decreased expression of TLR-4.[81,242] Most studies describe decreased cytokine production to TLR agonists in neonates compared with adults. Caron and colleagues[147] reported significantly lower LPS stimulation of TLR-4 in neonates compared with adults and speculated that this decreased stimulation may contribute to the neonate's increased susceptibility to *E. coli* and other gram-negative infections.[147] Similarly, Levy and colleagues[161] demonstrated that TLR-8 agonists are beneficial in activating co-stimulatory responses in neonatal antigen-presenting cells and suggested that this type of agent may be used adjuvantly to enhance the neonatal immune response.

NEUTROPHILS AND COMPLEMENT

Recruitment of neutrophils from the bloodstream to extravascular sites of inflammation is a critical event in host defense against bacterial infection and in the repair of tissue damage. Under certain circumstances, accumulation of neutrophils may contribute to vascular and tissue injury. Thus, the regulatory mechanisms involved in neutrophil activation, recruitment, and subsequent degranulation are of potential clinical significance. Neutrophil adherence to and migration through capillary endothelium is a critical early event in the acute inflammatory response. The adhesive interactions between leukocytes and endothelial cell surfaces are regulated by two novel families of glycoproteins: the integrins and the selectins. The β_2 integrins are membrane-bound glycoprotein receptors found on the surface of PMNs. The β_2 integrins CD11 and CD18 are required for adherence of PMNs to endothelial cell surfaces. The selectins also are membrane-bound glycoproteins that mediate neutrophil adhesion to endothelial cells. They include L-selectin, which is found on the surface of PMNs, and P-selectin and E-selectin, which are expressed on the surface of activated endothelial cells.[19,42,235,255,270]

The interaction between the β_2 integrins and the selectins serves to regulate PMN responses during inflammation. In general, the selectins P and E on the activated endothelial cell surface and L-selectin on the PMN cell surface function to facilitate PMN rolling and tethering to activated capillary endothelium. Once this tethering has occurred and the PMN itself is activated, the β_2 integrin CD11/CD18 receptors on the PMN form a tight adhesion with the endothelial cell surface, which facilitates PMN attachment and polarization, leading to migration.[19,42,235,270] Congenital β_2 integrin CD11/CD18 deficiency states have been described (leukocyte adhesion deficiency type I). These patients have profound PMN adhesion and motility defects and recurrent life-threatening infections along with delayed separation of the umbilical cord and juvenile periodontitis.[68,83] A second type, leukocyte adhesion deficiency type II, has been described as being due to a deficiency of sialyl $Lewis^X$, the PMN ligand for E-selectin on endothelial cells.[205] Researchers also have shown that the tethering of PMNs to P-selectin on activated endothelial cells is critical for PMN priming by platelet-

activating factor and that monoclonal antibodies to P-selectin can block this response.[166] Monoclonal antibodies to P-selectin have been used in animal models of ischemia and reperfusion injury and have been shown to reduce significantly the severe edema and endothelial cell injury observed after reperfusion.[261] Similarly, monoclonal antibodies to P-selectin have resulted in significant endothelial cell preservation in animal models of lung injury and cardiac ischemia.[190,256] Monoclonal antibodies to E-selectin and L-selectin also are being tested in animal models.[179] With the rapid advancements occurring in identification of new molecules that influence endothelial cell–leukocyte interactions, we will gain greater understanding of the complexity of cellular communication during inflammation.

BACTERICIDAL/PERMEABILITY-INCREASING FACTOR AND DEFENSINS

In addition to their respiratory burst activity in antimicrobial defense, human neutrophils have been shown to contain a variety of granule-associated antibacterial proteins and peptides.[213] These include bactericidal/permeability-increasing protein (BPI) and the defensin family of peptides. BPI is a 55-kd receptor present in neutrophil granules, which contain two domains. One of the domains binds with LPS to increase membrane permeability and the lysis of gram-negative bacteria, whereas the other promotes the opsonization of gram-negative bacteria.[117] Neutrophil BPI functions best in inflamed tissues, where it acts in concert with defensins and the membrane attack complex of complement to cause cell lysis.

Meningococcemia is a severe gram-negative infection that occurs predominantly in infants and young adults. Mortality rates of meningococcemia range from 10 to 20 percent.[8,30,105,257,263] Endotoxin levels may be profoundly elevated and correlate with the severity of the illness.[30] Recombinant BPI (rBPI) has been used as an adjunct to antimicrobial therapy in children with severe meningococcal sepsis[159]; 14 of 193 patients with severe meningococcal disease who received rBPI (2 mg/kg during 30 minutes) died, compared with 20 of 203 control infants, an insignificant difference. Among the surviving treated patients, however, a modest improvement was noted in long-term functional outcome, suggesting a possible beneficial effect in decreasing complications associated with septic shock.[89,159] Neonates have been shown to have reduced release and activity of BPI, which may contribute to their enhanced susceptibility to gram-negative bacterial infections.[160]

The defensins are strongly cationic, single-chain peptides contained in neutrophil primary, or azurophilic, granules with molecular weights between 3 and 4.5 kd. Defensins compose 50 percent of the protein content of the neutrophil primary granules.[85,266] These peptides possess broad antimicrobial activity against gram-positive and gram-negative bacteria, fungi, mycobacteria, and some viruses. The defensins create voltage-sensitive pores in microbial membranes, resulting in cell lysis. They are divided into α and β defensins. Humans have six human α defensins (HAD 1-6) and two human β defensins (HBD-1 and HBD-2).

The α defensins, HAD 1-6, are made by neutrophils and compose 30 to 50 percent of the primary granule content.[104] Defensins appear at the site of inflammation. They are present after neutrophil degranulation induced by LPS, IL-8, C5a, and other stimuli. They also are found on the epithelial surfaces of the bronchi and in bronchial lavage fluid of patients with various types of inflammatory lung disease. The antimicrobial activity of the defensins is inhibited by high salt content, which may be clinically important in the immune response of patients with cystic fibrosis.[91]

The β defensins are produced by epithelial cells of the respiratory and gastrointestinal tracts.[22,227] HBD-1 is expressed constitutively by epithelial cells in the bronchi and the intestine, whereas HBD-2 synthesis is up-regulated by inflammatory stimuli, including LPS, TNF-α, bacterial infection, and injury. Thus, HBD-1 acts to kill organisms in the absence of inflammation, whereas HBD-2 acts primarily as part of the inflammatory process.

In inflammatory lung disease, such as chronic bronchitis and chronic obstructive lung disease, both α defensins HAD 1-6 and β defensin HBD-2 may be increased significantly, perhaps contributing to airway inflammation.[266] There are no reported clinical disorders of defensin production. Potential roles for the defensins as immunoregulatory-antimicrobial agents are being investigated.

Endotoxin and other proinflammatory mediators activate the complement system and the chemotactic properties of C5a, which recruits neutrophils to sites of infection. Interruption of this process at various levels may be possible with use of monoclonal antibody strategies that counteract the effects of the complement leading to septic shock. Although monoclonal antibodies directed at the specific components of the complement cascade have not been tested in human clinical trials, the use of monoclonal antibodies to inhibit C5a in primates challenged with *E. coli* improved the survival rate and reduced the incidence of adult respiratory distress syndrome.[7,23]

PLATELET-ACTIVATING FACTOR

Platelet-activating factor (PAF) is a potent phospholipid inflammatory mediator with many biologic effects. Its synthesis is regulated by phospholipase A_2, an enzyme associated with the arachidonic acid pathway. PAF has a very short half-life in vivo because of its rapid degradation by PAF acetylhydrolase. PAF is synthesized by many cell types, including macrophages, neutrophils, platelets, eosinophils, endothelial cells, and hepatocytes.[258] Intravenous infusion of PAF into animals results in pulmonary hypertension, bronchoconstriction, neutropenia, thrombocytopenia, and ischemic bowel necrosis.[16,46,102] Production of PAF is stimulated in numerous clinical disease states, including hypoxia and ischemia, and after administration of biologic agents such as LPS, GM-CSF, TNF-α, IL-1, bradykinin, and thrombin.[72,144,182,206,216,262] Corticosteroids decrease levels of PAF by the induction of its natural inhibitor, PAF acetylhydrolase.[92] PAF has been shown to stimulate the production of many other mediators of inflammation, including TNF-α, complement breakdown products, oxygen radicals, catecholamines, prostaglandins, thromboxane, and the leukotrienes.[74,123,144,215,245,269] It also activates endothelial cells and neutrophils and monocytes, leading to their adherence and migration.[181] Thus, PAF is a ubiquitous phospholipid mediator with many biologic effects and interactions within the inflammatory cascade.

The regulation of PAF has been studied in numerous potential clinical disease states, including sepsis and septic shock.[121] In the clinical phase III trials in septic patients and patients in septic shock who received a PAF antagonist, a significant reduction in the mortality rate was noted.[59] The role of PAF, however, in the pathogenesis of necrotizing enterocolitis (NEC) has received considerable recent attention.[39,40] NEC often is a fatal gastrointestinal disease that predominantly affects premature infants. Exogenous administration of PAF into rat mesenteric circulation causes ischemic bowel necrosis and disease similar to that seen in neonatal NEC.[122] Endotoxin-induced intestinal injury is associated with increased PAF levels, and the infusion of high doses of endotoxin into animals produces a similar pathologic model of NEC, which can be prevented by administration of dexamethasone, PAF acetylhydrolase, or PAF receptor antagonists.[38,124] These animal studies suggest a link between PAF and its regulation and the development of NEC and implicate PAF as a poten-

tial endogenous inflammatory mediator in the pathogenesis of neonatal NEC.

Evidence in humans supports an association between PAF and human neonatal NEC. PAF levels are higher in infants with NEC compared with controls, and PAF acetylhydrolase activity is lower in infants with NEC.[41] PAF acetylhydrolase is suppressed with prematurity.[37] Because enteral feedings are necessary for the development of NEC, PAF levels were measured in feeding premature infants. In these studies, feedings alone increased circulating PAF levels but not PAF acetylhydrolase, and infants fed human breast milk had lower PAF levels and a lower incidence of NEC, suggesting a protective effect of human milk through PAF regulation.[170] Human milk is known to have a number of factors protective against infectious disease, including PAF acetylhydrolase.[34,90] Because PAF acetylhydrolase activity is present in human milk and absent in formulas, the suggestion has been made that the protective activity observed in human milk against the development of NEC may result from blocking of PAF-related inflammatory responses.[34] The modulation of the many interactions of PAF within the inflammatory cascade may have future clinical potential in regulating neonatal NEC and other inflammatory disease states.

NITRIC OXIDE

Nitric oxide is a membrane-permeable gas that functions in the regulation of vascular tone and in the inhibition of platelet aggregation and leukocyte adhesion. In addition, nitric oxide has been shown to have antitumor as well as antimicrobial activity. Under normal conditions, nitric oxide synthase induces endothelial cell production of nitric oxide. The signal transduction pathway for nitric oxide is linked to pathways involving vasodilation. Some evidence indicates that the L-arginine–nitric oxide pathway is activated in sepsis, in which the effects of nitric oxide on the vasculature are associated with the severe vascular failure observed during septic shock.[48,136,188,194,195] Thus, inhibition of production of nitric oxide has been proposed as a novel approach for the treatment of the severe hypotension associated with septic shock.[251]

The increased production of nitric oxide observed during septic shock may have several harmful effects. Nitric oxide may be largely responsible for sepsis-induced hypotension. In vitro studies implicate nitric oxide in sepsis-induced myocardial depression, although nitric oxide synthase inhibitors have not been shown to prevent endotoxin-induced myocardial depression in vivo. Nitric oxide also has direct cytotoxic effects, and its overproduction in septic shock can lead to tissue injury and organ failure.[49,75,134] In addition, in vitro experiments suggest that nitric oxide may enhance the release of proinflammatory cytokines during septic shock.[67,194] Production of nitric oxide may, however, have some beneficial effects during septic shock. It is implicated in maintaining visceral and other microvasculature blood flow, both as a counterregulatory mechanism to the vasoconstrictive mediators released during sepsis and by its ability to block platelet adhesion, reducing potential microvasculature stasis and thrombosis.[135,177] In addition, high levels of nitric oxide have antimicrobial activity and enhance LPS-induced production of cytokine,[145] although whether these levels of nitric oxide reflect actual physiologic states has yet to be determined.

Because hypotension during sepsis is an important predictor of organ injury and death, use of nitric oxide synthase inhibitors may improve survival in severe septic shock by increasing mean arterial pressure. Nitric oxide synthase inhibitors have been shown to restore vascular responsiveness to catecholamines in animal models of endotoxin-induced septic shock.[118] In addition, nitric oxide synthase inhibition has been shown to normalize mean arterial pressure in anesthetized animals challenged with endotoxin or TNF-α without causing hypertension.[134] These considerations have led to the use of nitric oxide synthase inhibitors to treat hypotension in patients with sepsis and in those receiving cytokine therapy for cancer.[133,167] Although these agents can alter mean arterial pressure, beneficial effects on clinical outcomes, including survival, are only suggested in human clinical trials.[194] Studies of endotoxin-challenged rats showed that partial nitric oxide synthase inhibition improved survival, whereas complete inhibition of nitric oxide production clearly is harmful, suggesting a beneficial effect with selective partial nitric oxide inhibition. Studies of nitric oxide inhibition that is more selective are being explored, and in the future such therapy may have clinical utility in the treatment of infectious disease states.

CONCLUSION

The initial attempts to augment immune function in the treatment of sepsis consisted of serum antibody therapy. The development of and refinements in hybridoma and recombinant technologies have provided the means to generate highly specific monoclonal antibodies. Although monoclonal antibodies directed toward bacteria and their components currently are not used during a course of sepsis, their future may be in combination with antimicrobial pharmacologic agents to treat infections with certain pathogens. The recent advances in basic science and clinical research also have demonstrated that the cytokine family plays many crucial roles in the pathogenesis of septic shock. The interaction among the proinflammatory cytokines initiates the development of a cascade of biologic events leading to the propagation and regulation of inflammation. Although the proinflammatory cytokines are effective in augmenting immune responses, their overexpression can lead to severe septic shock. The use of neutralizing monoclonal antibodies to endotoxin, anti–TNF-α antibodies, and soluble TNF-α and IL-1 receptors as well as IL-1 receptor antagonists in human clinical trials of septic shock, however, has shown limited therapeutic potential. The future clinical use of cytokine inhibition may include a combination of a number of both recombinant and pharmacologic agents temporally administered to regulate multiple proinflammatory cytokine–mediated steps in the development of septic shock. The hematopoietic growth factors have demonstrated considerable clinical effect, especially in individuals with distinct lymphopoietic disorders and in patients receiving immunosuppressive chemotherapy. The interferons α, β, and γ have received considerable attention during the past decade as potential immunomodulators. IFN-α has shown broad clinical application as an antitumor as well as an antiviral agent; IFN-β is being used with some success in patients with relapsing multiple sclerosis. The stimulatory effect of IFN-γ on human neutrophils is demonstrated in infants and children with specific neutrophil disorders and in neonatal sepsis. Toll-like receptor agonists are emerging as attractive therapeutic agents in a number of infectious diseases. Investigations defining the actions of the integrins and the selectins, bactericidal/permeability-increasing factor and defensins, and platelet-activating factor and nitric oxide may provide novel future clinical therapeutic approaches to attenuate acute inflammatory responses. As we learn more about the complexity of intracellular and extracellular interactions and the delicate balance these molecules have in regulating immune responses, we will be better able to implement their clinical use in regulating infectious disease states in infants and children.

CHAPTER 255

Active Immunizing Agents

Penelope H. Dennehy ✪ Jenifer L. Jaeger ✪ Phyllis T. Losikoff ✪ David L. Pugatch

Prevention of infectious diseases in children by immunization is one of the outstanding accomplishments of medical science. Children enjoy better health today because of effective immunization programs, which in many countries have markedly diminished the morbidity and mortality of once common contagious diseases. The striking decline in the United States in vaccine-preventable childhood diseases is demonstrated in Table 255–1. Immunization programs have led to the global eradication of smallpox, elimination of measles and poliomyelitis in regions of the world, and substantial reductions in the morbidity and mortality attributed to diphtheria, tetanus, and pertussis.[156] The World Health Organization (WHO) estimated that 2 million child deaths were prevented by vaccinations in 2003.

To achieve this progress in child health, scientific technology and medical practice have combined efforts to (1) understand the biology of causal infectious agents, (2) purify these agents and in some cases their components, (3) develop and test safe and effective vaccines, (4) manufacture and administer these vaccines to appropriate segments of the population, (5) develop appropriate indications and implement schedules for immunizations, and (6) identify necessary contraindications.

Infectious diseases can be prevented through immunization by the following means: (1) stimulating an active immunologic defense (e.g., from humoral antibody) through the administration of antigens, usually before natural exposure to an infectious agent (i.e., active immunization), or (2) temporarily supplying preformed human or animal antibody to persons before or soon after exposure to certain infectious agents (i.e., passive immunization). Active immunizations, including the currently available vaccines, are discussed in this chapter. Major vaccines (i.e., those discussed in this chapter) and their composition and routes of administration are listed in Table 255–2.

ACTIVE IMMUNOPROPHYLAXIS: CONSIDERATIONS AND RECOMMENDATIONS

VACCINES

An ideal immunizing agent should include the following characteristics: (1) the agent should be easy to produce in well-standardized preparations that are readily quantifiable and stable in immunobiologic potency, (2) it should be easy to administer, (3) it should not produce disease in the recipient or susceptible contacts, (4) it should induce long-lasting (ideally permanent) immunity that is measurable by available and inexpensive techniques, (5) it should be free of contaminating and potentially toxic substances, and (6) adverse reactions should be minimal and minor in consequence. All these objectives rarely, if ever, are met with the currently available vaccines because they are neither completely safe nor completely effective. Partial immunity or undesirable side effects or reactions, or both, including rare severe reactions, can occur. Nonetheless, vaccines in current use are highly effective and very safe.

All active immunizing agents (vaccines) contain one or more antigens that stimulate a protective immunologic response. Some are live attenuated viruses or bacteria; other vaccines consist of killed microorganisms or contain inactivated components such as exotoxins (i.e., toxoids). In some vaccines, the antigen is a highly defined, single constituent, such as *Haemophilus influenzae* type b (Hib) polysaccharide, whereas in others, the antigen component is less well defined (e.g., live viruses or whole-cell pertussis vaccines composed of killed *Bordetella pertussis* organisms). Immunizing agents are administered in suspending fluids such as sterile water, saline solution, or complex tissue culture fluid that can contain proteins or other constituents derived from the medium from which the vaccine was produced (e.g., serum proteins, egg antigens, or other tissue culture–derived antigens). With some vaccines, certain preservatives, stabilizers, or antibiotics are added; in some cases, these additives can result in hypersensitivity reactions. To enhance immunogenicity, particularly for vaccines containing inactivated microorganisms or their extracted components, adjuvants such as aluminum compounds may be added.

Immunization Schedules

The age and timing of immunization are critical for the success of vaccination. The schedule by which a vaccine is provided is based on multiple factors, including the epidemiology of naturally occurring disease, the age-specific risk of complications caused by the natural disease, the anticipated immunologic response of the host to the antigens, the duration of immunity

TABLE 255–1 Reduction in Morbidity of Some Vaccine-Preventable Diseases in the United States

	Maximum Cases (Yr)	2004	Percent Decrease (%)
Diphtheria	206,939 (1921)	0	100
Pertussis	265,269 (1934)	25,827	90
Tetanus	1,314 (1922-6)	34	97
Poliomyelitis, paralytic	21,269 (1952)	0	100
Measles	894,134 (1941)	37	>99
Mumps	152,209 (1968)	258	>99
Rubella	57,686 (1969)	10	>99
Congenital rubella syndrome	20,000 (1964-5)	0	100
Haemophilus influenzae type b	20,000 (before 1987)	19	>99
Invasive pneumococcal disease (<5 yr)	15,933 (2000)	1,162	93
Hepatitis B	21,102 (1990)	6,212	71
Varicella*	158,364 (1992)	32,931	79

TABLE 255–2 Available Vaccines in the United States for Use in Children and Their Routes of Administration*

Vaccine	Type	Recommended Route
BCG	Live bacteria	ID (preferred) or SC
DTaP	Toxoids and inactivated bacterial components	IM
DTaP, hepatitis B, and IPV (combination)	See DTaP, hepatitis B, and IPV	IM
DTaP, Hib conjugate, and IPV (combination)	See DTaP, Hib, and IPV	IM
DTaP and IPV (combination)	See DTaP and IV	IM
Hepatitis A	Inactivated virus	IM
Hepatitis B	Inactivated viral antigen yeast-derived recombinant	IM
Hepatitis A and hepatitis B (combination)	See hepatitis A and hepatitis B	IM
Hib conjugates	Polysaccharide-protein conjugate	IM
Hib conjugate and DTaP (combination)	See Hib and DTaP	IM
Hib conjugate and hepatitis B (combination)	See Hib and hepatitis B	IM
Influenza	Inactivated viral components	IM
Influenza	Live attenuated virus	Intranasal
Japanese encephalitis	Inactivated virus	SC
Measles	Live attenuated virus	SC
Measles-rubella	Live attenuated viruses	SC
Meningococcal	Polysaccharide	SC
Meningococcal conjugate	Polysaccharide-protein conjugate	IM
MMR	Live attenuated viruses	SC
MMRV	Live attenuated viruses	SC
Mumps	Live attenuated virus	SC
Pneumococcal	Polysaccharide	IM or SC
Pneumococcal conjugate	Polysaccharide-protein conjugate	IM
Poliovirus (IPV)	Inactivated viruses	SC
Rabies	Inactivated virus	IM
Rotavirus	Live attenuated viruses	oral
Rubella	Live attenuated virus	SC
Td and DT (adsorbed)	Toxoids	IM
Tdap	Toxoids and inactivated bacterial components	IM
Typhoid		
Parenteral	Capsular polysaccharide	IM
Oral	Live attenuated bacteria	Oral
Varicella	Live attenuated virus	SC
Yellow fever	Live attenuated virus	SC

**Only major childhood vaccines and selective others are included.*

BCG, bacille Calmette-Guérin (tuberculosis); DT, diphtheria-tetanus toxoids (for children <7 yr); DTaP, diphtheria-tetanus toxoids–acellular pertussis vaccine (for children <7 yr); Hib, Haemophilus influenzae type b conjugate vaccine; ID, intradermal; IM, intramuscular; IPV, inactivated poliovirus vaccine; MMR, live measles-mumps-rubella viruses vaccine; MMRV, live measles-mumps-rubella-varicella viruses vaccine; SC, subcutaneous; Td, tetanus-diphtheria toxoid (for children ≥7 yr and adults); Tdap, diphtheria–reduced tetanus toxoids–acellular pertussis vaccine (for children ≥10 yr and adults).

that can be induced, and, often, the recommended ages for routine health care visits. In general, vaccines are recommended at the youngest age at which significant risk for the natural disease and its complications exist and at which a protective immunologic response to the vaccine will occur. An example is measles vaccine, which in the United States is recommended routinely at 12 to 15 months of age because many children have residual, transplacentally acquired maternal measles serum antibody in the first year of life that will interfere with the antibody response. However, during measles outbreaks in preschool children, measles vaccination is recommended for infants as young as 6 months because the risk of complications with measles is high in children younger than 1 year.[14,25,111] These infants should be vaccinated again at 12 to 15 months of age. Similarly, in countries where measles causes significant morbidity and mortality in infants younger than 9 months, the Global Advisory Group of the WHO's Expanded Programme on Immunization (EPI) has recommended giving measles vaccine to infants as young as 6 months.[250]

The recommended doses of vaccine are determined by the number necessary to achieve a uniform and predictable immunologic response and to sustain protection. Some immunizing agents require the administration of more than one dose for development of an adequate antibody response and require a booster dose to maintain protection; examples are pertussis, diphtheria, and tetanus vaccines. Intervals between doses are based on the kinetics of primary and secondary antibody responses.

Route of Administration

An example of the effect of the route of administration on immunologic response is provided by poliomyelitis vaccines. Inactivated poliovirus vaccines given intramuscularly induce systemic immunity through serum antibody production; however, they do not consistently evoke local secretory immunoglobulin A (IgA) antibodies in the intestinal tract and thereby effectively prevent subsequent transmission of wild-type virus. Because live attenuated oral polio vaccine (OPV) induces optimal intestinal as well as systemic antibody, it was the preferred vaccine for routine immunization of children in the United States against poliomyelitis for 3 decades and remains the recommended vaccine by the WHO for global eradication.[503] Vaccines containing adjuvants must be injected deep into the muscle mass because if they are administered subcutaneously or intradermally, they can cause local irritation, inflammation, granuloma formation, or necrosis.[6,308]

Injectable vaccines should be administered in areas unlikely to cause local neural, vascular, or tissue injury (Table 255–3).[6,308] Although the upper, outer quadrant of the buttocks has been used as a frequent site of immunization, this area ordinarily should not be used because the gluteal region consists mostly of fat in young children and because of potential injury to the sciatic nerve. Ideally, intramuscular injections should be given in the anterolateral aspect of the upper part of the thigh or the deltoid muscle of the upper part of the arm. The anterolateral aspect of the thigh

TABLE 255–3 Site and Needle Length by Age for Intramuscular Immunization

Age Group	Needle Length, inches (mm)	Suggested Injection Site
Infants		
Preterm newborn	5/8(16)	Anterolateral thigh muscle
Term newborn	5/8(16)	Anterolateral thigh muscle
Infant, age 2-12 mo	1 (25)	Anterolateral thigh muscle
Toddlers and Children	5/8-1 (16-25) 1-1 1/4 (25-32)	Deltoid muscle of the arm Anterolateral thigh muscle
Adolescents and Young Adults		
Female and male, weight <60 kg	5/8-1 (16-25)	Deltoid muscle of the arm
Female, weight 60-90 kg or Male, weight 60-118 kg	1 (25)	Deltoid muscle of the arm
Female, weight >90 kg or Male, weight >118 kg	1 1/2 (38)	Deltoid muscle of the arm

Adapted from Pickering, L. K., Baker, C. J., Long, S. S., et al. (eds.): Red Book: 2006 Report of the Committee on Infectious Diseases. 27th ed. Elk Grove Village, IL, American Academy of Pediatrics, 2006.

is preferred for infants because of its muscle mass relative to other sites. For older children, the deltoid muscle usually is sufficiently large for intramuscular injection. The incidence of significant pain in 18-month-old children injected intramuscularly in the thigh is greater than that after deltoid injections and can result in transient limping.[284] The deltoid generally is the preferred site for intramuscular administration of vaccines in children 18 months and older, although some physicians prefer the anterolateral aspect of the thigh for toddlers.[6,308] Subcutaneous inoculations also usually should be given in the thigh of infants and the deltoid area of older children. Intradermal vaccines generally should be administered on the volar aspect of the forearm.

Recommended routes for administration of vaccines are provided in their package inserts and are summarized in recommendations for immunizations by the Committee on Infectious Diseases of the American Academy of Pediatrics (AAP)[6] and the Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention (CDC).[308]

Vaccine Dose

The recommended dose of each immunizing agent is derived from theoretical considerations and vaccine trials. Because inactivated immunizing agents cannot replicate in the host, these vaccines must contain an adequate antigenic mass to stimulate the desired immunologic response. Long-lasting immunity with such vaccines requires repeated doses. Exceeding the recommended dose can be hazardous because of excessive local or systemic concentrations of immunizing agents, whereas administration of doses smaller than those recommended may result in inadequate response and protection.[6,308]

Lapsed Immunizations

In general, intervals between multiple doses of an antigen longer than those recommended do not affect the antibody responses achieved, provided the immunization series is completed. Thus, restarting the series after interruption of the vaccine schedule or giving additional doses is not necessary.

TABLE 255–4 Guidelines for Spacing the Administration of Live and Inactivated Antigens

Antigen Combination	Recommended Minimum Interval between Doses
≥2 inactivated*	None; may be administered simultaneously or at any interval between doses
Inactivated and live	None; may be administered simultaneously or at any interval between doses
≥2 live parenteral†	28-day minimum interval if not administered simultaneously

**If simultaneous administration of diphtheria–reduced tetanus toxoids–acellular pertussis vaccine (Tdap) and meningococcal polysaccharide–protein conjugate vaccine (MCV4) is not feasible (a vaccine is not available), the vaccines should be separated by at least 28 days.*

†Some live oral vaccines (e.g., Ty21a typhoid vaccine, oral poliovirus vaccine, rotavirus vaccine) can be administered simultaneously or at any interval before or after inactivated or live parenteral vaccines.

Simultaneous Administration of Multiple Vaccines

Because most vaccines can be given simultaneously without impairment of effectiveness or safety, multiple vaccines are given to children concurrently.[301] Simultaneous administration of vaccines is particularly important for inadequately immunized children whose return for further immunization is doubtful or for patients with imminent travel plans. An inactivated vaccine and a live virus vaccine can be administered simultaneously at different sites without interference with the immune response. Exceptions are yellow fever and cholera vaccines because if they are administered simultaneously, antibody responses are diminished. If possible, administration of these vaccines should be separated by at least an interval of 3 weeks.[308]

In the case of live virus vaccines, the immune response to one live virus vaccine can be impaired if it is given within 4 weeks of another.[131,308,392] Thus, parenteral live virus vaccines not administered on the same day should be given at least 4 weeks apart. This consideration is the basis of the recommended minimal interval of 1 month (defined as 4 weeks) between doses of measles vaccine, such as would be the case for a previously unimmunized person who is entering college. Guidelines for spacing live and killed antigen vaccines are given in Table 255–4.

Record Keeping, Patient Information, Informed Consent, and Reporting

Accurate record keeping by physicians is required, and parents (or patients) should keep up-to-date immunization records for their children. The 1986 National Childhood Vaccine Injury Act (NCVIA) requires that for routinely recommended childhood vaccines, health care providers record in the child's permanent medical record the date of administration of the vaccine, manufacturer, lot number, and the name of the health care provider administering the vaccines.[6]

As a general principle, all children and their parents or caregivers should be informed about the benefits and risks of any vaccines to be administered. For vaccines currently specified in the NCVIA, Vaccine Information Statements (VISs) have been prepared by the CDC and must be used by vaccine administrators.

Informed consent should be obtained before the administration of vaccines. Some physicians and other health care providers may choose to obtain the parent's signature, but current law does not require written consent. An appropriate alternative to written consent is to note in the patient's record that the VISs have been provided and discussed with the parent, patient, or legal guardian.[6]

TABLE 255–5 Reportable Events Following Immunization, as Required by the National Childhood Vaccine Injury Act*

Vaccine/Toxoid	Adverse Event	For Reporting
Tetanus toxoid–containing vaccines (e.g., DTaP, Tdap, DTP-Hib, DT, Td, or TT)	Anaphylaxis or anaphylactic shock	0-4 hr
	Branchial neuritis	2-28 days
	Any acute complication or sequela (including death) of above events	Not applicable
Pertussis antigen–containing vaccines (e.g., DTaP, Tdap, DTP, P, DTP-Hib)	Anaphylaxis or anaphylactic shock	0-4 hr
	Encephalopathy (or encephalitis)	0-72 hr
	Any acute complication sequela (including death) of above events	Not applicable
Measles, mumps, and rubella virus–containing vaccines in any combination (e.g., MMR, MR, M, R)	Anaphylaxis or anaphylactic shock	0-4 hr
	Encephalopathy (or encephalitis)	5-15 days
	Any acute complication or sequela (including death) of above events	Not applicable
Measles virus–containing vaccines (e.g., MMR, MR, M)	Thrombocytopenic purpura	7-30 days
	Vaccine-strain measles viral infection in an immunodeficient recipient	0-6 mo
	Any acute complication or sequela (including death) of above events	Not applicable
Rubella virus–containing vaccines (e.g., MMR, MR, R)	Chronic arthritis	7-42 days
	Any acute complication or sequela (including death) of above events	Not applicable
Live poliovirus–containing vaccines (OPV)	Paralytic polio	
	In a non-immunodeficient recipient	0-30 days
	In an immunodeficient recipient	0-6 mo
	In a vaccine-associated community case	Not applicable
	Vaccine-strain polio infection	
	In a non-immunodeficient recipient	0-30 days
	In an immunodeficient recipient	0-6 mo
	In a vaccine-associated community case	Not applicable
	Any acute complication or sequela (including death) of above events	Not applicable
Inactivated poliovirus–containing vaccines (e.g., IPV)	Anaphylaxis or anaphylactic shock	0-4 hr
	Any acute complication or sequela (including death) of above events	Not applicable
Hepatitis B antigen–containing vaccines	Anaphylaxis or anaphylactic shock	0-4 hr
	Any acute complication or sequela (including death) of above events	Not applicable
Varicella	No condition specified	Not applicable
Rotavirus vaccine	No condition specified	Not applicable
Hib conjugate vaccines	No condition specified	Not applicable
Pneumococcal conjugate vaccines	No condition specified	Not applicable
Any new vaccine recommended by the CDC for routine administration to children, after publication by the Secretary of a notice of coverage†	No condition specified	Not applicable

**Effective date: November 10, 2008. For updates to the table, see www.hrsa.gov/vaccinecompensation/table.htm.*

†As of December 1, 2004, hepatitis A virus (HAV) vaccines have been added to the VIT under this category. As of July 1, 2005, trivalent influenza vaccines (TIV, LAIV) have been added to the VIT under this category. (Influenza vaccines routinely administered in the United States are trivalent.) As of February 1, 2007, meningococcal (conjugate and polysaccharide) and human papillomavirus (HPV) vaccines have been added to the table under this category. See "News" on the VICP Web site for more information.

The Reportable Events Table (RET) reflects what is reportable by law (42 USC 300aa-25) to the Vaccine Adverse Event Reporting System (VAERS). In addition, individuals are encouraged to report any clinically significant or unexpected events (even if you are not certain the vaccine caused the event) for any vaccine, whether or not it is listed on the RET. Manufacturers are also required by regulation (21 CFR 600.80) to report to the VAERS program all adverse events made known to them for any vaccine.

CDC, Centers for Disease Control and Prevention; DT, diphtheria-tetanus; DTaP, diphtheria-tetanus-acellular pertussis; DTP, diphtheria-tetanus-pertussis; Hib, Haemophilus influenzae *type b; M, measles, MMR, measles-mumps-rubella; MR, measles-rubella; OPV, oral poliovirus; P, pertussis; R, rubella; Td, tetanus-diphtheria toxoid; Tdap, diphtheria–reduced tetanus toxoids–acellular pertussis; TT, tetanus toxoid.*

To increase knowledge about adverse reactions, all temporally associated events severe enough to require the patient to seek medical attention should be reported to the Vaccine Adverse Events Reporting System (VAERS). Health care providers who administer vaccines are required in the United States to report to the VAERS specific adverse events in recipients of the vaccines covered by the act (Table 255–5). This system for reporting adverse events associated with vaccination was established by the U.S. Department of Health and Human Services to foster recognition of vaccine-related reactions and further study, as indicated, to establish possible causation. VAERS forms can be obtained by calling 800-822-7967 or by logging onto their Web site: http://www.vaers.org.

The decrease in the occurrence of vaccine-preventable infectious diseases has resulted in a greater number of adverse events temporally related to immunization than cases of disease. Although in some cases, such as vaccine-associated paralytic poliomyelitis (VAPP), vaccine has been established to be the cause, in other circumstances, such as brain damage alleged to be attributed to whole-cell pertussis vaccine, causation by vaccine has not been proved.[27]

Increased public visibility of vaccine reactions contributed to a marked increase in vaccine litigation in the 1980s as compensation was sought through the judicial system by those alleged to have suffered serious vaccine-related sequelae. A marked increase in manufacturers' actual and anticipated liability costs and subsequent escalating increases in the price of vaccines occurred concomitantly. These and other developments, such as threats to the vaccine supply, concerns by parents about vaccine safety, and recognition of the benefits derived from improved coordination and planning of vaccine programs, led to passage of the 1986 NCVIA and the National Vaccine Injury Compensation Program, a no-fault system to compensate victims of certain presumed vaccine-related events.

The Department of Health and Human Services administers the compensation program. Decisions on compensation are made by the U.S. Court of Federal Claims and are based on the Vaccine Injury Table, which was revised since passage of the original

legislation in response to new findings and analysis by the several Institute of Medicine (IOM) committees. Compensation for injuries occurring after the program's effective date of October 1, 1988, is provided by excise taxes on each vaccine. The program has been successful in reducing vaccine-related litigation, stabilizing vaccine prices, and creating a favorable environment for the introduction of new vaccines.[216]

Vaccine Recommendations and Schedules

In developing recommendations for immunization, multiple factors are considered and include the vaccine's characteristics, scientific knowledge about the principles of immunization, assessment of the benefits of the vaccine, the risk of development of the disease and its complications, vaccine costs, and the risk of having adverse reactions. Changes in relative benefits and risks necessitate continued review of recommendations. In the United States, recommendations for immunization of infants and children are made by two different committees, the ACIP of the CDC and the AAP Committee on Infectious Diseases. These committees work closely together, and, in most circumstances, their recommendations are similar. These two committees and the American Academy of Family Practice (AAFP) issue a single vaccine schedule each year. The 2009 schedule for routine administration of childhood vaccines is given in Figures 255–1 and 255–2.

A major change in 1996 was the establishment of a routine pre-adolescent immunization visit at 11 to 12 years of age.[101] The dose of adult tetanus-diphtheria-acellular pertussis (Tdap) vaccine should be given at that time, as should a dose of the meningococcal conjugate vaccine and the first dose of human papillomavirus (HPV) vaccine.[38] In addition, at this pre-adolescent visit, children not previously vaccinated with hepatitis B, varicella, or the second dose of measles-containing vaccine (or any combination of these vaccines) should be given the necessary immunizations and scheduled for future visits to receive any vaccines not administered during this visit.

Other countries have similar national mechanisms for formulating immunization schedules and recommendations that are based on the local epidemiology of diseases and available vaccines. In developing countries, practices are guided by the WHO EPI.[502] Current recommendations are listed in Table 255–6.

As new vaccines and scientific knowledge become available, vaccine recommendations and schedules are modified and changed. Examples of changes in the last decade include the use of pneumococcal conjugate vaccine beginning at 2 months of age, universal toddler hepatitis A immunization, recommendations for administration of a second dose of varicella vaccine, and the introduction of acellular pertussis vaccines for adolescents and adults.

Implementation of Vaccine Programs

In addition to the availability of safe and effective vaccines and appropriate schedules for their use, effective means of implementation and delivery are necessary for the success of vaccine programs. In the United States, high rates of immunization in school-age children have been achieved, in part because of public health programs for vaccine administration, government support for vaccine purchase, and state laws requiring immunization for school entry. In contrast to rates of approximately 95 percent or higher in school-age children, however, immunization rates in infants and young children in the 1980s were significantly lower.[511] In a survey of 21 primarily urban areas throughout the United States, 11 to 58 percent (median, 44%) of children who entered school in 1991 and 1992 were fully vaccinated by their second birthday. Failure to immunize young children was a major factor in the outbreaks of measles in major urban areas in the United States in 1989 to 1991.[452]

This epidemic and the recognition of low immunization rates prompted a national campaign to achieve the U.S. Public Health Service's goal of a 90 percent vaccine coverage rate in children by the time they were 2 years of age. Initiatives have included improved access to vaccines, education of health care providers in the community, and the development of standards for pediatric immunization practice.[369] These standards have been endorsed by the AAP, AAFP, and other major professional organizations and serve as guidelines to be followed for improving the delivery of vaccines. They include evaluation of the immunization status of patients at all medical visits, the use of valid contraindications, simultaneous administration of all indicated vaccines, and routine audit of the immunization status of patients by providers (Table 255–7). These and other initiatives have resulted in increasing immunization rates of young children. According to the National Immunization Survey, coverage rates in children 19 to 35 months of age in 2005 were 83 percent for completion of the four doses of tetanus-diphtheria-pertussis/diphtheria-tetanus toxoid-acellular pertussis/diphtheria-tetanus (DTP/DTaP/DT), three of poliovirus vaccine, and one dose of measles-mumps-rubella (MMR) vaccine.[152] Vaccination coverage rates in the United States for preschool-age children consistently have been greater than 75 percent since 1995.

Vaccine Contraindications, Precautions, and Use in Special Circumstances

Recommendations for the use of specific vaccines include contraindications and use in special circumstances, such as immunocompromised patients (from underlying disease or therapy, such as high-dose steroids) and pregnancy.[14,111] Established, generic contraindications are moderate or severe illness, a previous anaphylactic reaction to the specific vaccine, and a severe hypersensitivity reaction, such as anaphylaxis, to a vaccine constituent.

The decision to defer immunization in a febrile child should be based on the physician's assessment of the severity of the illness rather than the degree of fever. Children with minor illness and low-grade fever generally should be vaccinated, especially if a child is unlikely to return promptly for the deferred immunization.

Administration of live virus vaccines such as varicella and MMR vaccines generally is contraindicated in patients with altered immunity. However, the morbidity and mortality rates of measles and the lack of complications from vaccination of children infected with human immunodeficiency virus (HIV) have led to recommendations that these children, unless significantly immunocompromised, receive the MMR vaccine.[39,102,484]

Because of a theoretical risk to the developing fetus, administration of live virus vaccines in most cases is not recommended for pregnant women.[12,308] However, inadvertent administration of vaccine is not necessarily a reason for termination of the pregnancy, and some live virus vaccines, such as those for yellow fever and poliomyelitis, can be given safely to pregnant women. Inactivated bacterial and viral vaccines such as tetanus toxoids, hepatitis B, and influenza vaccine, which are composed of antigenic components or killed organisms, can and should be given during pregnancy if indicated.

In some recipients, vaccines can cause severe reactions, which may be a contraindication or precaution to subsequent administration of the specific vaccine. An example is a child in whom a fever of 40.5° C or higher develops after receiving DTaP vaccine, for whom administration of further doses of pertussis-containing vaccine is not indicated in most cases. This recommendation is based on the unproven but reasonable presumption that children who experience adverse reactions after receiving

Recommended immunization schedule for persons aged 0 through 6 Years — United States, 2009 (for those who fall behind or start late, see the catch-up schedule [Table])

Vaccine ▼ Age ▶	Birth	1 month	2 months	4 months	6 months	12 months	15 months	18 months	19–23 months	2–3 years	4–6 years
Hepatitis B[1]	HepB	HepB		see footnote 1	HepB

Meningococcal[10]										MCV	

Range of recommended ages

Certain high-risk groups

This schedule indicates the recommended ages for routine administration of currently licensed vaccines, as of December 17, 2008, for children aged 0 through 6 years. Any dose not administered at the recommended age should be administered at a subsequent visit, when indicated and feasible. Licensed combination vaccines may be used whenever any component of the combination is indicated and other components are not contraindicated and if approved by the Food and Drug Administration for that dose of the series. Providers should consult the relevant Advisory Committee on Immunization Practices statement for detailed recommendations, including high-risk conditions: http://www.cdc.gov/vaccines/pubs/acip-list.htm. Clinically significant adverse events that follow immunization should be reported to the Vaccine Adverse Event Reporting System (VAERS). Guidance about how to obtain and complete a VAERS form is available at http://www.vaers.hhs.gov or by telephone, 800-822-7967.

1.Hepatitis B vaccine (HepB). ***(Minimum age: birth)***

At birth:

- Administer monovalent HepB to all newborns before hospital discharge.
- If mother is hepatitis B surface antigen (HBsAg)-positive, administer HepB and 0.5 mL of hepatitis B immune globulin (HBIG) within 12 hours of birth.
- If mother's HBsAg status is unknown, administer HepB within 12 hours of birth. Determine the HBsAg status as soon as possible and, if HBsAg-positive, administer HBIG (no later than age 1 week).

After the birth dose:

- The HepB series should be completed with either monovalent HepB or a combination vaccine containing HepB. The second dose should be administered at age 1 or 2 months. The final dose should be administered no earlier than age 24 weeks.
- Infants born to HBsAg-positive mothers should be tested for HBsAg and antibody to HBsAg (anti-HBs) after completion of at least 3 doses of the HepB series, at age 9 through 18 months (generally at the next well-child visit).

4-month dose:

- Administration of 4 doses of HepB to infants is permissible when combination vaccines containing HepB are administered after the birth dose.

2. Rotavirus vaccine (RV). ***(Minimum age: 6 weeks)***

- Administer the first dose at age 6 through 14 weeks (maximum age: 14 weeks 6 days). Vaccination should not be initiated for infants aged 15 weeks or older (i.e., 15 weeks 0 days or older).
- Administer the final dose in the series by age 8 months 0 days.
- If Rotarix® is administered at ages 2 and 4 months, a dose at 6 months is not indicated.

3. Diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP). ***(Minimum age: 6 weeks)***

- The fourth dose may be administered as early as age 12 months, provided at least 6 months have elapsed since the third dose.
- Administer the final dose in the series at age 4 through 6 years.

4. *Haemophilus influenzae* type b conjugate vaccine (Hib). ***(Minimum age: 6 weeks)***

- If PRP-OMP (PedvaxHIB® or Comvax® [HepB-Hib]) is administered at ages 2 and 4 months, a dose at age 6 months is not indicated.
- TriHiBit®(DTaP/Hib) should not be used for doses at ages 2, 4, or 6 months but can be used as the final dose in children aged 12 months or older.

5. Pneumococcal vaccine. ***(Minimum age: 6 weeks for pneumococcal conjugate vaccine [PCV]; 2 years for pneumococcal polysaccharide vaccine [PPSV])***

- PCV is recommended for all children aged younger than 5 years. Administer 1 dose of PCV to all healthy children aged 24 through 59 months who are not completely vaccinated for their age.
- Administer PPSV to children aged 2 years or older with certain underlying medical conditions (see *MMWR* 2000;49[No. RR-9]), including a cochlear implant.

6. Influenza vaccine. ***(Minimum age: 6 months for trivalent inactivated influenza vaccine [TIV]; 2 years for live, attenuated influenza vaccine [LAIV])***

- Administer annually to children aged 6 months through 18 years.
- For healthy nonpregnant persons (i.e., those who do not have underlying medical conditions that predispose them to influenza complications) aged 2 through 49 years, either LAIV or TIV may be used.
- Children receiving TIV should receive 0.25 mL if aged 6 through 35 months or 0.5 mL if aged 3 years or older.
- Administer 2 doses (separated by at least 4 weeks) to children aged younger than 9 years who are receiving influenza vaccine for the first time or who were vaccinated for the first time during the previous influenza season but only received 1 dose.

7. Measles, mumps, and rubella vaccine (MMR). ***(Minimum age: 12 months)***

- Administer the second dose at age 4 through 6 years. However, the second dose may be administered before age 4, provided at least 28 days have elapsed since the first dose.

8. Varicella vaccine. ***(Minimum age: 12 months)***

- Administer the second dose at age 4 through 6 years. However, the second dose may be administered before age 4, provided at least 3 months have elapsed since the first dose.
- For children aged 12 months through 12 years the minimum interval between doses is 3 months. However, if the second dose was administered at least 28 days after the first dose, it can be accepted as valid.

9. Hepatitis A vaccine (HepA). ***(Minimum age: 12 months)***

- Administer to all children aged 1 year (i.e., aged 12 through 23 months). Administer 2 doses at least 6 months apart.
- Children not fully vaccinated by age 2 years can be vaccinated at subsequent visits.
- HepA also is recommended for children older than 1 year who live in areas where vaccination programs target older children or who are at increased risk of infection. See *MMWR* 2006;55(No. RR-7).

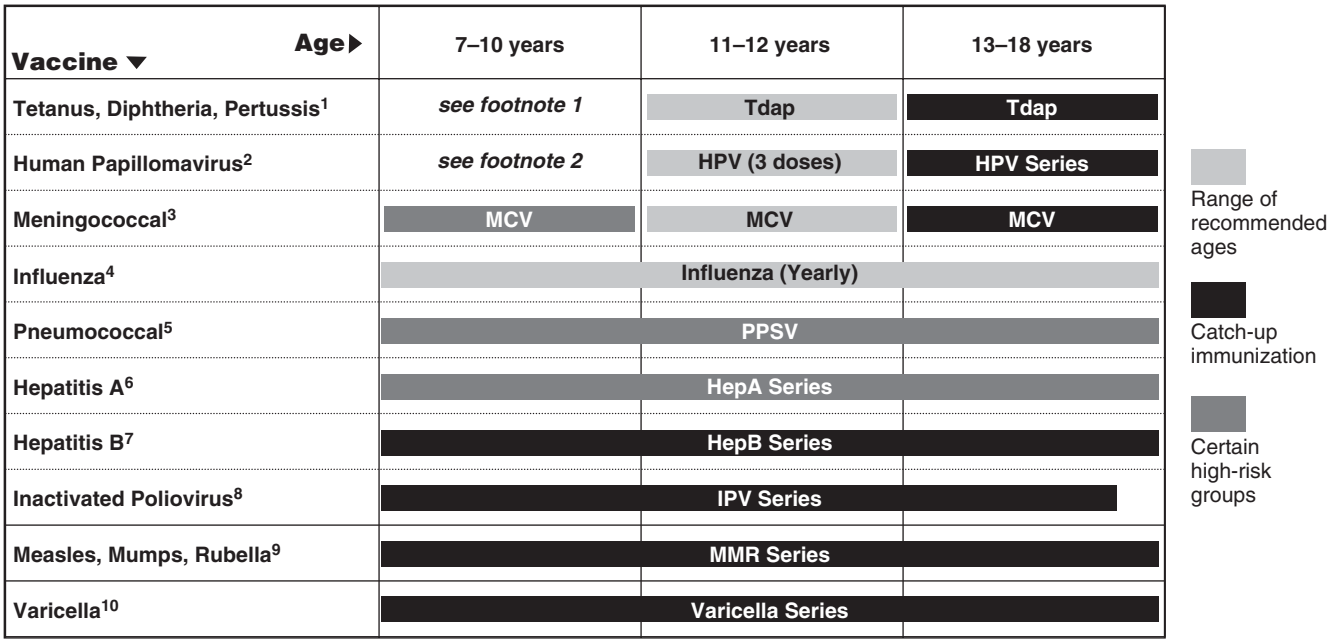
10. Meningococcal vaccine ***(Minimum age: 2 years for meningococcal conjugate vaccine [MCV] and for meningococcal polysaccharide vaccine [MPSV])***

- Administer MCV to children aged 2 through 10 years with terminal complement component deficiency, anatomic or functional asplenia, and certain other high-risk groups. See *MMWR* 2005;54(No. RR-7).
- Persons who received MPSV 3 or more years previously and who remain at increased risk for meningococcal disease should be revaccinated with MCV.

The Recommended Immunization Schedules for Persons Aged 0 though 18 Years are approved by the Advisory Committee on Immunization Practices (http://www.cdc.gov/vaccines/recs/acip), the American Academy of Pediatrics (http://www.aap.org), and the American Academy of Family Physicians (http://www.aafp.org).

Figure 255–1 Recommended immunization schedule for persons aged 0 to 18 years: United States. (*From Centers for Disease Control and Prevention: Immunization Schedules. Available at cdc.gov/vaccines/recs./schedules/default.htm*)

Recommended immunization schedule for persons aged 7 through 18 years — United States, 2009 (for those who fall behind or start late, see the schedule below and the catch-up schedule [Table])



This schedule indicates the recommended ages for routine administration of currently licensed vaccines, as of December 17, 2008, for children aged 7 through 18 years. Any dose not administered at the recommended age should be administered at a subsequent visit, when indicated and feasible. Licensed combination vaccines may be used whenever any component of the combination is indicated and other components are not contraindicated and if approved by the Food and Drug Administration for that dose of the series. Providers should consult the relevant Advisory Committee on Immunization Practices statement for detailed recommendations, including high risk conditions: http://www.cdc.gov/vaccines/pubs/acip-list.htm. Clinically significant adverse events that follow immunization should be reported to the Vaccine Adverse Event Reporting System (VAERS). Guidance about how to obtain and complete a VAERS form is available at http://www.vaers.hhs.gov or by telephone, 800-822-7967.

1.Tetanus and diphtheria toxoids and acellular pertussis vaccine (Tdap). ***(Minimum age: 10 years for BOOSTRIX® and 11 years for ADACEL®)***
- Administer at age 11 or 12 years for those who have completed the recommended childhood DTP/DTaP vaccination series and have not received a tetanus and diphtheria toxoid (Td) booster dose.
- Persons aged 13 through 18 years who have not received Tdap should receive a dose.
- A 5-year interval from the last Td dose is encouraged when Tdap is used as a booster dose; however, a shorter interval may be used if pertussis immunity is needed.

2. Human papillomavirus vaccine (HPV). ***(Minimum age: 9 years)***
- Administer the first dose to females at age 11 or 12 years.
- Administer the second dose 2 months after the first dose and the third dose 6 months after the first dose (at least 24 weeks after the first dose).
- Administer the series to females at age 13 through 18 years if not previously vaccinated.

3. Meningococcal conjugate vaccine (MCV).
- Administer at age 11 or 12 years, at age 13 through 18 years if not previously vaccinated.
- Administer to previously unvaccinated college freshmen living in a dormitory.
- MCV is recommended for children aged 2 through 10 years with terminal complement component deficiency, anatomic or functional asplenia, and certain other groups at high risk. See *MMWR* 2005;54(No. RR-7).
- Persons who received MPSV 5 or more years previously and remain at increased risk for meningococcal disease should be vaccinated with MCV.

4. Influenza vaccine.
- Administer annually to children aged 6 months through 18 years.
- For healthy nonpregnant persons (i.e., those who do not have underlying medical conditions that predispose them to influenza complications) aged 2 through 49 years, either LAIV or TIV may be used.
- Administer 2 doses (separated by at least 4 weeks) to children aged younger than 9 years who are receiving influenza vaccine for the first time or who were vaccinated for the first time during the previous influenza season but only received 1 dose.

5. Pneumococcal polysaccharide vaccine (PPSV).
- Administer to children with certain underlying medical conditions (see *MMWR* 1997;46[No. RR-8]), including a cochlear implant. A single revaccination should be administered to children with functional or anatomic asplenia or other immunocompromising condition after 5 years.

6. Hepatitis A vaccine (HepA).
- Administer 2 doses at least 6 months apart.
- HepA is recommended for children older than 1 year who live in areas where vaccination programs target older children or who are at increased risk of infection. See *MMWR* 2006;55(No. RR-7).

7. Hepatitis B vaccine (HepB).
- Administer the 3-dose series to those not previously vaccinated.
- A 2-dose series (separated by at least 4 months) of adult formulation Recombivax HB® is licensed for children aged 11 through 15 years.

8. Inactivated poliovirus vaccine (IPV).
- For children who received an all-IPV or all-oral poliovirus (OPV) series, a fourth dose is not necessary if the third dose was administered at age 4 years or older.
- If both OPV and IPV were administered as part of a series, a total of 4 doses should be administered, regardless of the child's current age.

9.Measles, mumps, and rubella vaccine (MMR).
- If not previously vaccinated, administer 2 doses or the second dose for those who have received only 1 dose, with at least 28 days between doses.

10.Varicella vaccine.
- For persons aged 7 through 18 years without evidence of immunity (see *MMWR* 2007;56[No. RR-4]), administer 2 doses if not previously vaccinated or the second dose if they have received only 1 dose.
- For persons aged 7 through 12 years, the minimum interval between doses is 3 months. However, if the second dose was administered at least 28 days after the first dose, it can be accepted as valid.
- For persons aged 13 years and older, the minimum interval between doses is 28 days.

The Recommended Immunization Schedules for Persons Aged 0 though 18 Years are approved by the Advisory Committee on Immunization Practices (http://www.cdc.gov/vaccines/recs/acip), the American Academy of Pediatrics (http://www.aap.org), and the American Academy of Family Physicians (http://www.aafp.org).

Figure 255–1 *Continued*

Catch-up immunization schedule for persons aged 4 months through 18 years who start late or who are more than 1 month behind — United States, 2009

The table below provides catch-up schedules and minimum intervals between doses for children whose vaccinations have been delayed. A vaccine series does not need to be restarted, regardless of the time that has elapsed between doses. Use the section appropriate for the child's age.

CATCH-UP SCHEDULE FOR PERSONS AGED 4 MONTHS THROUGH 6 YEARS					
Vaccine	**Minimum Age for Dose 1**	**Minimum Interval Between Doses**			
		Dose 1 to Dose 2	**Dose 2 to Dose 3**	**Dose 3 to Dose 4**	**Dose 4 to Dose 5**
Hepatitis B[1]	Birth	4 weeks	8 weeks (and at least 16 weeks after the first dose)		
Rotavirus[2]	6 wks	4 weeks	4 weeks[2]		
Diphtheria,Tetanus,Pertussis[3]	6 wks	4 weeks	4 weeks	6 months	6 months[3]
Haemophilus influenzae type b[4]	6 wks	4 weeks if first dose administered at younger than age 12 months; 8 weeks (as final dose) if first dose administered at age 12–14 months; No further doses needed if first dose administered at age 15 months or older	4 weeks[4] if current age is younger than 12 months; 8 weeks (as final dose)[4] if current age is 12 months or older and second dose administered at younger than age 15 months; No further doses needed if previous dose administered at age 15 months or older	8 weeks (as final dose)[4] This dose only necessary for children aged 12 months through 59 months who received 3 doses before age 12 months	
Pneumococcal[5]	6 wks	4 weeks if first dose administered at younger than age 12 months; 8 weeks (as final dose for healthy children) if first dose administered at age 12 months or older or current age 24 through 59 months; No further dose needed for healthy children if first dose administered at age 24 months or older	4 weeks if current age is younger than 12 months; 8 weeks (as final dose for healthy children) if current age is 12 months or older; No further dose needed for healthy children if previous dose administered at age 24 months or older	8 weeks (as final dose) This dose only necessary for children aged 12 months through 59 months who received 3 doses before age 12 months or for high-risk children who received 3 doses at any age	
Inactivated Poliovirus[6]	6 wks	4 weeks	4 weeks	4 weeks[6]	
Measles, Mumps, Rubella[7]	12 mos	4 weeks			
Varicella[8]	12 mos	3 months			
Hepatitis A[9]	12 mos	6 months			
CATCH-UP SCHEDULE FOR PERSONS AGED 7 THROUGH 18 YEARS					
Tetanus, Diphtheria/ Tetanus,Diphtheria, Pertussis[10]	7 yrs[10]	4 weeks	4 weeks if first dose administered at younger than age 12 months; 6 months if first dose administered at age 12 months or older	6 months if first dose administered at younger than age 12 months	
Human Papillomavirus[11]	9 yrs	Routine dosing intervals are recommended[11]			
Hepatitis A[9]	12 mos	6 months			
Hepatitis B[1]	Birth	4 weeks	8 weeks (and at least 16 weeks after first dose)		
Inactivated Poliovirus[6]	6 wks	4 weeks	4 weeks	4 weeks[6]	
Measles, Mumps, Rubella[7]	12 mos	4 weeks			
Varicella[8]	12 mos	3 months if the person is younger than age 13 years; 4 weeks if the person is aged 13 years or older			

1. Hepatitis B vaccine (HepB).
- Administer the 3-dose series to those not previously vaccinated.
- A 2-dose series (separated by at least 4 months) of adult formulation Recombivax HB® is licensed for children aged 11 through 15 years.

2. Rotavirus vaccine (RV).
- The maximum age for the first dose is 14 weeks 6 days. Vaccination should not be initiated for infants aged 15 weeks or older (i.e., 15 weeks 0 days or older).
- Administer the final dose in the series by age 8 months 0 days.
- If Rotarix® was administered for the first and second doses, a third dose is not indicated.

3. Diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP).
- The fifth dose is not necessary if the fourth dose was administered at age 4 years or older.

4. *Haemophilus influenzae* type b conjugate vaccine (Hib).
- Hib vaccine is not generally recommended for persons aged 5 years or older. No efficacy data are available on which to base a recommendation concerning use of Hib vaccine for older children and adults. However, studies suggest good immunogenicity in persons who have sickle cell disease, leukemia, or HIV infection, or who have had a splenectomy; administering 1 dose of Hib vaccine to these persons is not contraindicated.
- If the first 2 doses were PRP-OMP (PedvaxHIB® or Comvax®), and administered at age 11 months or younger, the third (and final) dose should be administered at age 12 through 15 months and at least 8 weeks after the second dose.
- If the first dose was administered at age 7 through 11 months, administer 2 doses separated by 4 weeks and a final dose at age 12 through 15 months.

5. Pneumococcal vaccine.
- Administer 1 dose of pneumococcal conjugate vaccine (PCV) to all healthy children aged 24 through 59 months who have not received at least 1 dose of PCV on or after age 12 months.
- For children aged 24 through 59 months with underlying medical conditions, administer 1 dose of PCV if 3 doses were received previously or administer 2 doses of PCV at least 8 weeks apart if fewer than 3 doses were received previously.
- Administer pneumococcal polysaccharide vaccine (PPSV) to children aged 2 years or older with certain underlying medical conditions (see *MMWR* 2000;49 [No. RR-9]), including a cochlear implant, at least 8 weeks after the last dose of PCV.

6. Inactived poliovirus vaccine (IPV).
- For children who received an all-IPV or all-oral poliovirus (OPV) series, a fourth dose is not necessary if the third dose was administered at age 4 years or older.
- If both OPV and IPV were administered as part of a series, a total of 4 doses should be administered, regardless of the child's current age.

7. Measles, mumps, and rubella vaccine (MMR).
- Administer the second dose at age 4 through 6 years. However, the second dose may be administered before age 4, provided at least 28 days have elapsed since the first dose.
- If not previously vaccinated, administer 2 doses with at least 28 days between doses.

8. Varicella vaccine.
- Administer the second dose at age 4 through 6 years. However, the second dose may be administered before age 4, provided at least 3 months have elapsed since the first dose.
- For persons aged 12 months through 12 years, the minimum interval between doses is 3 months. However, if the second dose was administered at least 28 days after the first dose, it can be accepted as valid.
- For persons aged 13 years and older, the minimum interval between doses is 28 days.

9. Hepatitis A vaccine (HepA).
- HepA is recommended for children older than 1 year who live in areas where vaccination programs target older children or who are at increased risk of infection. See *MMWR* 2006;55(No. RR-7).

10. Tetanus and diphtheria toxoids vaccine (Td) and tetanus and diphtheria toxoids and acellular pertussis vaccine (Tdap).
- Doses of Dtap are counted as part of the Td/Tdap series.
- Tdap should be substituted for a single dose of Td in the catch-up series or as a booster for children aged 10 through 18 years; use Td for other doses.

11. Human papillomavirus vaccine (HPV).
- Administer the series to females at age 13 through 18 years if not previously vaccinated.
- Use recommended routine dosing intervals for series catch-up (i.e., the second and third doses should be administered at 2 and 6 months after the first dose). However, the minimum interval between the first and second doses is 4 weeks. The minimum interval between the second and third doses is 12 weeks, and the third dose should be given at least 24 weeks after the first dose.

Information about reporting reactions after immunization is available online at http://www.vaers.hhs.gov or by telephone, 800-822-7967. Suspected cases of vaccine-preventable diseases should be reported to the state or local health department. Additional information, including precautions and contraindications for immunization, is available from the National Center for Immunization and Respiratory Diseases at http://www.cdc.gov/vaccines or telephone, 800-CDC-INFO (800-232-4636).

Figure 255–2 Catch-up immunization schedule for persons aged 4 months to 18 years who start late or who are more than 1 month behind. *(From Centers for Disease Control and Prevention: Immunization Schedules. Available at cdc.gov/vaccines/recs./schedules/default.htm)*

TABLE 255–6 Schedule of the Expanded Programm on Immunization of the World Health Organization*

Age	Vaccines	Hepatitis B†	
		Schedule A or	Schedule B
Birth	BCG, OPV	HB-1	
6 wk	DTP, OPV	HB-2	HB-1
10 wk	DTP, OPV		HB-2
14 wk	DTP, OPV	HB-3	HB-3
9 mo	Measles, yellow fever‡		

**Modifications may be made by the ministries of health in individual countries on the basis of local conditions.*
†Schedule A is recommended in countries where perinatal transmission of HBV is important (e.g., Southeast Asia) and B in countries where perinatal transmission is less important (e.g., Sub-Saharan Africa).
‡In countries where yellow fever poses a risk.
BCG, bacille Calmette-Guérin; DTP, diphtheria, tetanus, and pertussis; HB, hepatitis B; OPV, oral poliovirus.

TABLE 255–7 Standards for Child and Adolescent Immunization Practices*

pertussis immunization are at risk of having similar reactions of equal or greater magnitude on subsequent immunization.[165]

Anaphylactic reactions caused by allergenic components of a vaccine, such as gelatin or egg protein (in vaccine prepared in embryonated chicken eggs), have occurred in rare cases. Vaccines posing a potential risk for egg-sensitive persons include those against measles, mumps, inactivated influenza, and yellow fever. Before administering vaccines to persons with possible hypersensitivity to vaccine constituents, physicians should review current recommendations for these vaccines. In other circumstances, specific immunizations may be contraindicated because of previous reactions and the child's past history, such as with DTaP (e.g., evolving neurologic disorders) and MMR (e.g., immune thrombocytopenia occurring in temporal association with vaccination).[308]

Misconceptions

Appropriate and safe use of vaccines requires knowledge of the patient's relevant medical history, adverse reactions associated with previous receipt of vaccines, and specific indications and contraindications. Without this information, vaccines may be administered inadvertently or not given in circumstances in which immunization is indicated, thereby resulting in missed opportunities for receiving the recommended immunization and susceptibility of the child to a preventable disease. Examples of common misconceptions concerning contraindication to vaccines are given in Table 255–8.

International Travel

Foreign travel often is an indication for giving vaccines not routinely administered to children.[12] The risk of exposure to certain vaccine-preventable diseases may be increased relative to that in the United States, and travelers may be exposed to infections that are uncommon or do not occur in the United States. Examples include vaccines against hepatitis A, typhoid fever, yellow fever, and Japanese encephalitis (JE) (Table 255–9), depending on the location and circumstances of the person's visit. Some countries may require yellow fever vaccination for entry. The second dose of measles vaccine should be given to children and adolescents who have received only one dose (provided 4 weeks or more have elapsed since administration of the first dose), irrespective of age, because the risk of exposure to cases of measles may be substantial in some foreign countries. In addition, children and adolescents should have received all vaccines routinely recommended for their age. Information on vaccine requirements for international travel to different countries is provided in a publication by the CDC entitled *Health Information for International Travel*,[143] which is revised semiannually and can be obtained from the Superintendent of Documents, U.S. Government Printing Office, Washington, D.C., 20402-9235. Information also is available from the CDC International Travelers Hotline by calling 404-332-4559 or on the Internet at the CDC Web site.

Vaccine Safety

Immunizations are among the most cost-effective and widely used public health interventions. Public health recommendations for vaccine programs and practices represent a dynamic balancing of risks and benefits. Vaccine safety or monitoring of risk is necessary to weigh this balance accurately and adjust vaccination policies accordingly.

No vaccine is perfectly safe or effective. As the incidence of vaccine-preventable diseases is reduced, public concern refocuses from the risk of contracting disease to the health risks associated with vaccines. A higher standard of safety generally is expected of vaccines than of other medical interventions because, in con-

TABLE 255–8 Misconceptions Concerning Vaccine Contraindications

- Mild acute illness with low-grade fever or mild diarrheal illness in an otherwise well child
- Current antimicrobial therapy or the convalescent phase of illness
- Reaction to previous vaccine dose that involved only soreness, redness, or swelling in the immediate vicinity of the vaccination site or temperature of less than 105° F (40.5° C)
- Prematurity. The appropriate age for initiating most immunization in the prematurely born infant is the usual recommended chronologic age. Vaccine doses should not be reduced for preterm infants.
- Pregnancy of mother or other household contact. Vaccine viruses in MMR vaccine are not transmitted by vaccine recipients. Although varicella vaccine and influenza vaccine virus has been transmitted by a healthy vaccine recipient to contacts, the frequency is rare, only mild or asymptomatic infection has been reported, and use of vaccine is not contraindicated by pregnancy of either the child's mother or other household contacts.
- Recent exposure to an infectious disease
- Breast-feeding. The only vaccine virus that has been isolated from breast milk is rubella vaccine virus. No evidence indicates that breast milk from women immunized against rubella is harmful to infants.
- A history of nonspecific allergies or relatives with allergies
- Allergies to penicillin or any other antibiotic, except anaphylactic reactions to neomycin or streptomycin. These reactions occur rarely, if ever. None of the vaccines licensed in the United States contain penicillin.
- Allergies to duck meat or duck feathers. No vaccine available in the United States is produced in substrates containing duck antigens.
- Family history of convulsions in persons considered for pertussis or measles vaccination
- Family history of sudden infant death syndrome in children considered for DTaP vaccination
- Family history of an adverse event, unrelated to immunosuppression after vaccination
- Malnutrition

DTaP, diphtheria-tetanus-acellular pertussis; MMR, measles-mumps-rubella.

trast to most pharmaceutical products that are administered to ill persons for curative purposes, vaccines generally are given to healthy persons to prevent the acquisition of disease. Public tolerance of adverse reactions related to products given to healthy persons, especially healthy infants, is substantially lower than that to products administered to persons who are already ill. This lower tolerance of risk for vaccines necessitates investigating possible causes of rare adverse events after administration of vaccinations more aggressively than would be acceptable for other pharmaceutical products. Because vaccination is such a common event, any health problem that occurs after immunization may be attributed to the vaccine. Health effects reported as being associated with vaccines may be true adverse reactions or may be associated with vaccination only by coincidence. Because a temporal relationship alone does not necessarily indicate causation, cause-and-effect relationships often are impossible to establish. Epidemiologic and related studies must be performed to ascertain the incidence and nature of adverse reactions to vaccines, and such studies are important in ensuring a scientific rationale for recommendations for vaccine use and optimal public and professional acceptance of vaccines.

The topic of vaccine safety became prominent during the mid-1970s with increases in the number of lawsuits filed on behalf of patients presumably injured by the DTP vaccine.[223] Legal decisions were made and damages awarded despite the lack of scientific evidence to support claims of vaccine injury.[223] As a result of the liability, prices soared, and several manufacturers halted production. A shortage of vaccines resulted, and public health officials became concerned about the return of epidemic diseases. To reduce liability and respond to public health concerns, Congress passed the NCVIA in 1986.

The NCVIA mandates that all health care providers report certain adverse events that occur after the administration of vaccination with routinely recommended childhood vaccines. As a result, VAERS was established by the U.S. Food and Drug Administration (FDA) and the CDC in 1990. VAERS provides a mechanism for the collection and analysis of adverse events associated with vaccines currently licensed in the United States. Adverse events are defined as health effects occurring after immunization that may or may not be related to the vaccine. VAERS data are monitored continually to detect previously unknown adverse events or increases in known adverse events.[164]

The gaps that exist in the scientific knowledge of rare vaccine adverse events prompted the CDC to develop the Vaccine Safety Datalink (VSD) project.[162] This project involved forming partnerships with four large health maintenance organizations to monitor vaccine safety continually. VSD is an example of a large, linked database and includes information on more than 6 million people. The VSD project allows for planned vaccine safety studies, as well as timely investigations of hypotheses.

In the late 1990s, reports in the lay press questioned the safety of routine immunizations and alarmed parents with unsupported accounts of the dangers of vaccines. One major national television network broadcast a feature piece that linked diabetes to childhood immunizations. In the United Kingdom, a report linked receipt of measles vaccine to the development of autism, and in France, hepatitis vaccine was reported to cause multiple sclerosis (MS).

VACCINATION AND DIABETES

Classen and Classen[169] suggested that certain vaccines, if given at birth, may decrease the occurrence of type 1 diabetes, whereas if initial vaccination is performed after children are 2 months of age, the occurrence of diabetes increases. Other researchers have not found an increased risk for diabetes associated with vaccination.[299] The Classen theory is based on results from experiments in laboratory animals, as well as comparisons of rates of diabetes among countries with different immunization schedules.[169] Applying findings from laboratory animals to humans is fraught with uncertainties. Comparison of diabetes rates among countries with different vaccination policies also provides weak evidence because many factors, including vaccination schedules, may differ by country. In addition, other factors, including genetic predisposition and numerous possible environmental exposures unrelated to the administration of vaccines, may influence the development of diabetes.[298]

The most rigorous epidemiologic study of infant vaccinations and type 1 diabetes to date found that measles vaccine was associated with a decreased risk and no association was found with bacille Calmette-Guérin (BCG), smallpox, tetanus, pertussis, rubella, or mumps vaccine.[66] In a large clinical trial of Hib vaccine conducted in Finland, no statistically significant association was found between the receipt of Hib vaccine and the development of type 1 diabetes during 10 years of follow-up.[293] The IOM Immunization Safety Committee reviewed the clinical and epidemiologic literature in 2002 and concluded that multiple immunizations do not lead to a risk for development of type 1 diabetes.[279]

MEASLES VACCINE AND AUTISM

The causes of autism are unknown. Most experts agree, however, that autism is a condition that begins before birth.[410] Genetic factors seem to play a major role in the development of autism. Autism usually is diagnosed in children when they are 18 to 30 months old, shortly after they have received many of the recommended vaccinations. Because of this coincidence in timing, some parents of children with autism believe that an immunization may have caused their child's condition.

A 1998 report published in *The Lancet* of 12 patients who had inflammatory bowel disease and autism raised the hypothesis that a link could exist between the MMR vaccine and autism.[479] The authors of the report speculated that MMR vaccine was the possible cause of bowel problems, with the resultant malabsorption of essential vitamins and nutrients leading to autism.

Epidemiologic studies in both the United States and Great Britain do not support a causal association between MMR vaccine and inflammatory bowel disease,[198,363] nor do epidemiologic studies support a causal association between MMR vaccine (and other measles-containing vaccines) and autism.[201,202] Expert panels convened by both the IOM and the AAP examined the available data on autism and MMR vaccine. Both panels concluded that the available evidence does not support the hypothesis that MMR vaccine causes autism or associated disorders or inflammatory bowel disease.[252,281]

HEPATITIS B VACCINE AND MULTIPLE SCLEROSIS

Reports of MS developing after receipt of hepatitis B vaccine led to the concern that immunization with hepatitis B vaccine may precipitate the onset of MS or lead to relapses. Since licensure, the safety of the hepatitis B vaccine has continued to be monitored. The several studies conducted did not find a scientific association between hepatitis B vaccination and the development of severe neurologic adverse events such as optic neuritis and Guillain-Barré syndrome (GBS). Two large epidemiologic studies examined the risk of an association between vaccines and MS. The first, a case-control study in a large cohort of nurses, demonstrated no significant association between hepatitis B vaccination and development of MS.[47] A French study of patients with MS found that vaccination did not appear to increase the short-term risk of relapse.[185]

The Immunization Safety Review Committee of the IOM reviewed all available data and issued a report in 2004. The committee concluded that the evidence did not support a causal relationship between hepatitis B vaccine administered to adults and onset or relapse of MS.[279]

THIMEROSAL-CONTAINING VACCINES AND NEURODEVELOPMENTAL DISORDERS

Thimerosal is a mercury-containing preservative that has been used as an additive to biologics and vaccines since the 1930s because it is effective in preventing bacterial and fungal contamination, particularly in multidose containers. The FDA Modernization Act of 1997 required a review and assessment of the risk of all mercury-containing pharmaceuticals. Assessment of vaccines led to the recognition that, during the first 6 months of life, some children could be exposed to a cumulative quantity of mercury that exceeds one of the federal guidelines on methylmercury. However, a significant safety margin is incorporated into all the acceptable mercury exposure limits, and no data determined or evidence was found that any harm was caused by the level of exposure with the existing immunization schedules. In addition, the risk posed by exposure to thimerosal, which contains ethylmercury, not methylmercury, on which the federal guidelines were based, is unknown. However, to avoid any potential risk, the Public Health Service, the AAP, and vaccine manufacturers agreed in July 1999 that thimerosal-containing vaccines should be removed as soon as possible. As of March 2001, thimerosal no longer was used as a preservative in any of the pediatric vaccines given to children 6 years old or younger in the United States.[125]

A possible association between thimerosal-containing vaccines and increasing diagnoses of autism and autistic spectrum disorders has been investigated in studies in the United States and elsewhere. The Immunization Safety Review Committee of the IOM reviewed all available data and, in October of 2001, issued a report stating that the evidence is inadequate to accept or reject a causal relationship between exposure to thimerosal-containing vaccines and the neurodevelopmental disorders of autism, attention-deficit/hyperactivity disorder (ADHD), and speech and language delay. In addition, the report concluded that the hypothesis that exposure to thimerosal could be associated with the development of neurodevelopmental disorders, although not established, is biologically plausible.[282] The IOM committee recommended that thimerosal-free DTaP, hepatitis B, and Hib vaccines be used for infants, children, and pregnant women, provided an adequate supply is available.[282]

Since the IOM report, five large studies have compared the risk of autism in children who received vaccines containing thimerosal with that in children who received vaccines without thimerosal.[42,222,263,275,469] The studies found the incidence of autism to be the same in both groups.

Reference Sources

Several comprehensive sources of information about pediatric vaccines are available. The AAP publishes *The Red Book: Report of the Committee on Infectious Diseases* every 3 years. The next edition will be published in 2009. In the interval between editions, the AAP publishes recommendations in its newsletter *AAP News* and subsequently in *Pediatrics*. The ACIP issues vaccine recommendations and relevant information in *Morbidity and Mortality*

Weekly Report. Manufacturers provide product information for each vaccine in the FDA-approved package inserts.

VACCINES RECOMMENDED FOR ROUTINE ADMINISTRATION

DIPHTHERIA TOXOID

The introduction of diphtheria toxoid–containing vaccine in the 1940s led to a dramatic reduction in the incidence of diphtheria in the United States. From 1980 through 2004, 57 cases of diphtheria were reported in the United States, an average of 2 to 3 per year.[307] Only 5 cases have been reported since 2000. However, diphtheria is still a potentially significant public health problem. Serologic surveys in the United States and England have suggested that many adults are not immune.[186,307,335] Although a study published in 1996 demonstrated that most adults in the United States do have protective concentrations of serum antitoxin,[245] more recent data obtained from a national population based serosurvey published in 2002 revealed that the prevalence of immunity to diphtheria, as determined by the level of diphtheria antitoxin, progressively decreased from 91 percent among children 6 to 11 years of age to approximately 30 percent in those 60 to 69 years of age.[350] Of the reported cases with known patient age since 1980, 58 percent were in persons 20 years of age or older and 44 percent of cases were among persons 40 years of age or older. Most cases have occurred in unimmunized or inadequately immunized persons. The current age distribution of cases corroborates the finding of inadequate levels of circulating antitoxin in many adults. In addition, adequate immunization has not eliminated the potential for transmission of *Corynebacterium diphtheriae* completely because immunization does not prevent carriage of *C. diphtheriae* in the nasopharynx or on the skin.[71,307]

As a result of inadequate immunity in adults as well as in infants and children, an epidemic of diphtheria occurred in the 1990s throughout the former Soviet Union including Russia, Ukraine, and the central Asian republics, with case-fatality rates ranging from 3 to 23 percent.[224,255] In addition, diphtheria continues to be a significant cause of morbidity and mortality in developing countries,[224] and, therefore, it remains a source of possible exposure during travel to endemic countries. Because humans are the only known reservoir for *C. diphtheriae*, universal immunization with a diphtheria toxoid–containing vaccine is the only effective control measure.

Preparations

Diphtheria toxoid is produced by growing toxigenic *C. diphtheriae* in liquid medium. The filtrate is incubated with formaldehyde to convert toxin to toxoid and then is adsorbed onto an aluminum salt adjuvant.

Diphtheria toxoid is available in combination with DTaP for routine immunization of infants and children younger than 7 years of age and for adolescents and adults aged 11 to 64 years as a single booster (Tdap). Two brands of Tdap are available: Boostrix (approved for children 10 to 18 years of age) and Adacel (approved for persons 11 to 64 years of age). DTaP and Tdap vaccines do not contain thimerosal as a preservative. Diphtheria toxoid also is available as a DTaP-inactivated poliovirus (IPV)-hepatitis B combination, a DTaP-inactivated poliovirus (IPV)-*Haemophilus influenzae* type b conjugate combination, and in combination with tetanus toxoid (DT and Td) alone for use when pertussis vaccination is contraindicated. *H. influenzae*, pneumococcal, and meningococcal conjugate vaccines containing diphtheria toxoid or CRM_{197} protein, a nontoxic variant of diphtheria toxin, are not substitutes for diphtheria toxoid immunization.[8]

Pediatric formulations (DT and DTaP) contain a similar amount of tetanus toxoid as adult Td, but they contain three to four times as much diphtheria toxoid. The concentration of diphtheria toxoid (D) for children younger than 7 years of age per 0.5 mL intramuscular dose of DTaP or DT vaccine is 6.7 to 25 limit of flocculation units (Lf), depending on the vaccine manufacturer. Vaccines approved for children 7 years or older and adults (Tdap and Td) contain only a fraction of the diphtheria toxoid (d, 2 to 2.5 Lf) because of adverse reactions related to dose and age.[8,71,307]

Immunogenicity

After a primary series of three properly spaced diphtheria toxoid doses in adults or four doses in infants, a protective level of antitoxin (defined as > 0.1 international unit [IU] of antitoxin/mL) is reached in more than 95 percent of vaccinees. Diphtheria toxoid has been estimated to have a clinical efficacy of 97 percent. Immune response to diphtheria toxoid was measured following administration of each adult Tdap vaccine and compared with that elaborated after Td vaccine. Seroprotective anti-diphtheria levels, defined as a titer of 0.1 or more IU per mL, and booster response rates to diphtheria were determined to be non-inferior following administration of Tdap as compared with Td vaccination.[307]

Adverse Events

Other than local reactions of pain and swelling at the site of vaccine injection, immunization does not cause significant adverse events. These local reactions have been attributed to hypersensitivity reactions in response to the pertussis component and are not a contraindication for administration of further vaccination if otherwise indicated.

Regarding adverse reactions reported following administration of Tdap, vaccination with Boostrix was associated with a statistically higher rate of moderate to severe headache compared with Td, and Adacel was associated with higher rates of mild injection site pain and low-grade fever compared with Td vaccine. No serious adverse events have been reported for Boostrix. There have been two reports of serious adverse events, both characterized as neuropathic reactions, in adults, possibly related to having received Adacel (none reported in adolescents), and in both cases symptoms resolved completely within several days.[71]

Indications

Primary immunization consists of five doses of diphtheria toxoid, provided as DTaP or as DT if pertussis is contraindicated.[8,71,307] The first three doses are administered routinely to children who are 2, 4, and 6 months of age. A fourth dose is administered 6 to 12 months after the third dose, between 12 to 18 months of age, to maintain adequate antibody concentrations for the ensuing preschool years. For those not immunized in infancy, the initial dose is followed by two doses given 2 and 8 to 14 months later. A single booster dose given when the child is 4 to 6 years of age, before school entry, is indicated unless the preceding dose was given after the fourth birthday. Interruption of the recommended schedule or delay in administering subsequent doses during primary immunization does not reduce immunity or necessitate restarting the series.

In 2005, the FDA licensed two vaccines containing tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis antigens (Tdap) for routine use in adolescents and adults. Tdap is approved as a one-time only substitute for the next scheduled or recommended Td booster in those individuals who previously completed their primary vaccination series with DTP or DTaP. The preferred age for Tdap vaccination is 11 to 12 years. Adolescents

aged 11 to 18 years who completed their primary series with DTP or DTaP and received a Td booster at least 5 years previously are encouraged to receive Tdap. Although an interval of 5 years between Td and Tdap is recommended to reduce the likelihood of adverse reactions, periods shorter than 5 years between doses can be used when the patient has an increased risk of exposure to or complications from pertussis. Every 10 years thereafter, tetanus booster should be provided by Td. Adolescents between the ages of 11 and 18 years who have never been vaccinated against tetanus, diphtheria, or pertussis initially should receive Tdap followed by Td for the subsequent two doses at 4 weeks or more and 6 to 12 months following. No pertussis-containing vaccine has been approved for children between the ages of 7 and 10 years. For children in this age group who have not been vaccinated previously, three doses of Td are recommended following the schedule for those aged 11 to 18 years. A booster with Tdap is recommended when these children become adolescents.

After exposure to a case of strongly suspected or proven diphtheria, asymptomatic previously immunized persons should receive a booster of an age-appropriate diphtheria-containing vaccine if at least 5 years have transpired since their last receipt of a diphtheria toxoid–containing vaccine.[8] If not previously immunized, carriers should receive vaccine as soon as identified and should complete the entire series. If a carrier has been immunized and a period of 5 years or more has transpired since they received their most recent booster, a booster containing diphtheria (DTaP, Tdap, DT, or Td) should be administered. Patients recovering from diphtheria infection should be immunized because infection does not confer immunity.

Precautions and Contraindications

The only contraindication to diphtheria toxoid is a history of severe hypersensitivity developing after receipt of a previous vaccine dose. Vaccination with either diphtheria or tetanus toxoid is not known to be associated with an increased risk of having convulsions. Local reactions alone do not preclude continued use.

HAEMOPHILUS INFLUENZAE TYPE B VACCINE

Before the introduction of routine infant and childhood vaccination against Hib, this pathogen was the major cause of invasive bacterial infections in young children in the United States. It was the most common cause of bacterial meningitis and epiglottitis and a significant cause of septic arthritis, occult febrile bacteremia, and pneumonia in children younger than 5 years, in whom it caused an estimated 12,000 cases of meningitis and 8000 additional cases of invasive Hib disease annually.[175] The cumulative risk of Hib disease was approximately 1 in every 200 U.S. children in the first 5 years of life, with the peak incidence of Hib meningitis occurring in infants between 6 and 12 months of age. In high-risk populations, such as Native Americans, rates of disease in the absence of immunizations were higher, and a greater proportion of cases of meningitis occurred in the first year of life than in non–high-risk populations.[175,265,491]

Meningitis and pneumonia caused by Hib remain significant causes of morbidity and mortality, particularly among children younger than the age of 5 years, in many parts of the developing world. As of November of 2006, the WHO estimated that at least 3 million cases of serious disease and approximately 386,000 deaths were attributable to Hib annually. Hib remains the most common cause of non-epidemic bacterial meningitis in unvaccinated children younger than 1 year of age. Mortality rates for Hib meningitis treated with appropriate antibiotics range up to 20 percent, and 30 to 40 percent of survivors suffer severe neurologic sequelae.[506]

Because most cases of Hib disease occur in infancy, vaccines that induce protection before the age of 6 months are necessary for effective control of Hib disease. The Hib polysaccharide capsule is the major virulence factor, and antibodies directed against the polysaccharide antigens are protective. Capsular type b is responsible for more than 90 percent of systemic *H. influenzae* infections. However, purified polysaccharide vaccines induce primarily a T-lymphocyte–independent IgM antibody response that is poorly immunogenic, particularly in children younger than 18 months who lack immunologic memory. Covalent linkage of the purified capsular polysaccharide, polyribosylribitol phosphate (PRP), to a protein carrier creates a conjugate glycoprotein that is T-lymphocyte dependent and elicits protective antibody in infants and young children and significantly greater concentrations of circulating anti-PRP at all ages than does the unconjugated polysaccharide.[320,376] T-cell–dependent antigens involve helper T-lymphocyte activation of a B-cell humoral antibody response. T-cell–dependent antigens also are able to prime for a booster response.

The introduction of Hib conjugate vaccines in the United States, first in children at least 18 months of age in 1987 and for routine infant immunization in 1991, decreased the incidence of meningitis and bacteremia caused by Hib dramatically. As of 2000, the incidence of invasive Hib disease in the United States had decreased by 99 percent since the pre-vaccine era, with an incidence rate of less than 1 case per 100,000 children younger than 5 years old.[137] The remarkably rapid reduction in incidence of disease was partly the result of the ability of the vaccine to reduce asymptomatic nasopharyngeal carriage of the organism, an action that had the indirect effect of reducing exposure and infection in those not immunized (herd immunity).[49,260]

Preparations

Three single-antigen Hib conjugate vaccine products and three combination vaccine products that contain Hib conjugate are available in the United States. All Hib vaccines contain PRP, the organism's polysaccharide capsular antigen. The three currently licensed single-antigen Hib conjugate vaccines, HbOC (HibTITER), PRP-OMP (PedvaxHIB), and PRP-T (ActHIB), are approved for use in early infancy (Table 255–10). Of these prod-

TABLE 255–10 *Haemophilus influenzae* Type b Conjugate Vaccines

Manufacturer	Abbreviation (Trade Name)	Carrier Protein
Wyeth-Lederle Vaccines	HbOC (HibTITER)	CRM_{197} (a nontoxic mutant diphtheria toxin)
Merck & Co.	PRP-OMP*(PedvaxHIB)	OMP (an outer-membrane protein complex of *Neisseria meningitidis*)
Sanofi Pasteur	PRP-T† (ActHIB)	Tetanus toxoid

**PRP-OMP is also available as a combination vaccine with hepatitis B (COMVAX).*
†PRP-T may be reconstituted with diphtheria-tetanus-acellular pertussis (DTaP) (Tripedia, manufactured by Sanofi Pasteur) to form TriHIBit. TriHIBit is approved only for the fourth dose of the DTaP and Haemophilus influenzae *type b (Hib) series. Other licensed formulations of DTaP have not been approved by the Food and Drug Administration for reconstitution and may not be used for this purpose.*
Adapted from Pickering, L. K., Baker, C. J., Long, S. S., et al. (eds.): Red Book: 2006 Report of the Committee on Infectious Diseases. 27th ed. Elk Grove Village, IL, American Academy of Pediatrics, 2006.

ucts, only PRP-T can be mixed with DTaP for the fourth dose. Each conjugate vaccine is chemically and immunologically unique. All three are composed of the type b PRP antigen conjugated to a protein and differ in the protein carrier, size of the saccharide component, and the chemical linkage. The carrier proteins for HbOC, PRP-OMP, and PRP-T are a nontoxic mutant diphtheria toxin, an outer membrane protein from *Neisseria meningitidis*, and tetanus toxoid, respectively. Since July of 2000, the entire Hib vaccine supply for the United States has been thimerosol-free. The dose of each Hib conjugate vaccine is 0.5 mL, given intramuscularly.

Three licensed combination vaccines containing Hib are as follows: (1) DTaP/PRP-T (TriHIBit), which, as noted earlier is the combination of Hib with DTaP approved for the fourth dose only; and (2) PRP-OMP/Hep B (Comvax), the bivalent Hib and recombinant hepatitis B virus (HBV) vaccine approved for use in children aged 6 weeks to 15 months who were born to hepatitis B surface antigen (HBsAg)–negative mothers, and (3) DTaP/IPV/PRP-T(Pentocel), which is approved for immunization at 2, 4, 6, and 15 to 18 months of age.

Immunogenicity and Efficacy

Placebo-controlled field trials of Hib conjugate vaccines in infants in the United States demonstrated nearly 100 percent protection and provided the basis for the initial approval of these vaccines for use in this country. In a study of HbOC in northern California, vaccine efficacy was 100 percent for infants receiving the three-dose schedule at 2, 4, and 6 months of age.[62] In a Navajo population of infants at high risk of acquiring Hib disease who were vaccinated at 2 and 4 months of age with either PRP-OMP or placebo, vaccine efficacy was 100 percent at 1 year of age and 93 percent in total.[422] Licensure of PRP-T was based on immunogenicity in a three-dose schedule that was comparable to that of the other two products. In addition, an efficacy trial in Great Britain and the lack of cases in trials indicate an efficacy of PRP-T comparable to that of HbOC and PRP-OMP.[67,422,462] Although the data are limited, some evidence suggests that administration of the first dose of Hib before the child reaches the age of 6 weeks may result in immunologic tolerance to the Hib antigen and reduce the immune response to subsequent doses.[351]

Adverse Events

Hib vaccines are well tolerated. Local reactions occur in approximately 25 percent of recipients but typically are mild and last less than 24 hours.[200,491] Systemic reactions, such as fever and irritability, are infrequent occurrences. When conjugate vaccines are administered concurrently with DTaP vaccine, the incidence of systemic reactions is similar to that observed when only DTaP is given.[200]

Indications

Routine vaccination against Hib disease is recommended for all children beginning at approximately 2 months of age.[9,89,94] Four vaccines, HbOC, PRP-T, PRP-OMP and DTaP/IPV/PRP-T, are licensed in the United States for use in infants. One of these products, PRP-T, can be given with DTaP, mixed in the same syringe for the fourth dose only.

Two or three doses, depending on the product, given at 2-month intervals (optimal) are indicated by the time that the child is 6 months of age. The recommended age to initiate the primary series is 2 months, with a minimum age of 6 weeks. The minimum interval between doses is 4 weeks, with at least 8 weeks separating the last dose in the primary series and the booster. Excellent immune responses have been achieved when vaccines from different manufacturers have been interchanged in the primary series.[41,60,241] HbOC, PRP-T, and PRP-OMP are considered interchangeable for primary as well as booster vaccinations. If more than a single brand of vaccine is used, the child should receive a three-dose primary series. A final dose of any product, irrespective of the previous vaccines received, is acceptable when the child is 12 to 15 months of age for completion of the Hib immunization schedule. When feasible, the conjugate vaccine product used for the first dose should be used for subsequent doses in children younger than 12 months.

For children in whom Hib immunization has not been initiated by the time that they reach 7 months of age, the recommended schedules differ according to the child's age and the choice of conjugate vaccine.[29,89] Previously unimmunized children between 15 and 59 months should be immunized with at least a single dose of any licensed conjugate Hib vaccine. For previously unimmunized children 5 years or older, immunization is indicated only if they have an underlying condition predisposing to Hib disease, such as asplenia, immunoglobin deficiency, or stem cell transplant, or are immunosuppressed because of chemotherapy or HIV infection. More than one dose may be recommended for this population.[9]

HEPATITIS A VACCINE

The occurrence of hepatitis A is highest in developing countries and reflects the primary route of transmission, fecal-oral, person-to-person spread. In the United States, before a vaccine became available, hepatitis A was a common occurrence and caused substantial morbidity with significant associated costs.[103,304] In 1995, the FDA licensed hepatitis A vaccine, and during the decade that followed the rate of hepatitis A infection in the United States dramatically declined, reaching an all time low of 5683 cases in 2004.[219]

In the pre-vaccine era, the incidence of hepatitis A varied considerably in different populations.[219,445] A shift occurred in the epidemiology of hepatitis A in the United States following the introduction of hepatitis A vaccine. Disease in the United States most commonly occurred in children 5 to 14 years of age.[219] After vaccines were licensed, rates of infection among children declined more rapidly than did rates among adults, thus resulting in similar rates among all age groups. Historically, rates of infection were highest among Alaskan Natives and American Indians, and most cases consistently occurred in a small number of states and counties in the western and southwestern regions of the country. During the decade after vaccine was licensed, age-specific, racial, and geographic disparities narrowed considerably.[219]

Individuals at risk for acquiring hepatitis A infections include close contacts of persons infected with hepatitis A virus (HAV), travelers to developing countries, those who engage in homosexual and bisexual activity, and injecting drug users. However, in approximately 50 percent of reported cases, no risk factor is identified.[10] These infections likely are attributable to fecal-oral spread from asymptomatic contacts. Because children frequently have asymptomatic infections and may shed virus for prolonged periods, they play an important role in transmission of HAV. Children and infants shed virus for longer periods than adults do, as long as several months after the onset of clinical illness. In one study involving adults without an identified source of infection, 52 percent of their households included a child younger than 6 years.[219] Therefore, it has long been recognized that the control and ultimate elimination of hepatitis A by active immunization would be best achieved through universal childhood immunization.[464] However, it was not until 2005 that hepatitis A vaccine was licensed for use in children from 12 to 23 months of age.

Before then, it had been restricted to children older than 2 years old and consequently could not be incorporated readily into routine infant vaccinations. In May of 2006, the ACIP recommended including hepatitis A vaccine in the routine infant immunization schedule.[219]

Before vaccine was available, community-wide outbreaks, recurring every 3 to 10 years in high-risk communities, accounted for much of the occurrence of hepatitis A infection and disease. Outbreaks among children attending daycare and daycare staff are common occurrences and have been associated with community outbreaks.[249] However, the prevalence of hepatitis A infection in daycare center staff and in children and adolescents who previously attended daycare is not increased, a finding suggesting that infections within daycare settings most commonly reflect transmission within the community that extends to these settings.[249] Transmission of HAV also can occur in institutions for the developmentally disabled and in neonatal intensive care units. Transmissions from hospitalized patients to health care professionals have been reported.[10] In addition to these examples of direct person-to-person transmission, infection can be acquired by the ingestion of contaminated food or water.

Preparations

Both inactivated and attenuated HAV vaccines have been developed.[189] However, only inactivated vaccines are licensed in the United States. Inactivated HAV vaccine is prepared by methods similar to those used for inactivated poliomyelitis vaccine. Virus is propagated in human diploid fibroblast cell cultures, formalin inactivated, and adsorbed to aluminum hydroxide adjuvant.[26,219] Two such products are licensed in the United States: Havrix (SmithKline Beecham Biologicals) and Vaqta (Merck & Co.). Both Vaqta and Havrix have two formulations, an adult and a pediatric product with different antigen content (Table 255–11). The pediatric formulation is indicated for persons aged 12 months to 18 years of age. The vaccines can be used interchangeably.[75] Limited data indicate that hepatitis A vaccine may be administered simultaneously with other vaccinations.[10]

Immunogenicity and Efficacy

Inactivated viral vaccine is highly immunogenic. After receiving a single dose, 95 percent of children and nearly all adults seroconvert within 1 month.[26,219] After receipt of a second dose in children, seroconversion approximates 100 percent. Hepatitis A vaccine is immunogenic in children younger than 2 years old who do not have passively acquired maternal antibody.[393,457] In two large clinical trials of inactivated hepatitis A vaccine in children older than 2 years, protective efficacy was greater than 90 percent.[277,493] In a double-blind, placebo-controlled, randomized study in Thailand involving approximately 34,000 vaccinees, the protective efficacy against clinical hepatitis A was 94 percent after administration of two doses given 1 month apart; it was 100 percent after subsequent administration of a 12-month booster dose.[277]

Vaccination also has been demonstrated to be effective in controlling outbreaks in communities with high rates of disease.[219] For example, in a New York State community in which HAV is highly endemic in children, a single dose of vaccine was 100 percent effective beginning 3 weeks after immunization in preventing symptomatic disease.[493] Moreover, observations from countries where routine hepatitis A vaccination of infants or children has been implemented suggest a strong herd immunity effect.[193,203] The duration of protection after vaccination is likely to be prolonged. Protective antibody levels of anti-HAV were observed in 99 percent of children evaluated 5 to 6 years after receiving Vaqta.[492] Kinetic models of antibody decline indicate that protective levels of antibody could be present for more than 25 years in adults and up to 20 years in children.[463,465] No data are available currently to determine whether and when children will need a hepatitis A booster vaccine. In an ongoing study designed to address the need for a booster dose, no cases of hepatitis A among children 9 years after initial vaccination have been reported.[494]

Reduced vaccine immunogenicity has been observed in infants with passively acquired anti–hepatitis A antibody who are administered hepatitis A vaccines.[190,321,325] Studies demonstrated that, despite the presence of lower antibody levels in infants born to anti–hepatitis A–positive mothers, most infants with passively acquired antibody had an anamnestic response to a booster dose 1 to 6 years later.[190,218,291] In most infants, maternally acquired anti–hepatitis A antibody declines to undetectable levels by the time the child reaches 12 months of age.[324] Hepatitis A vaccine is highly immunogenic for all infants when administered when they are older than 1 year of age, irrespective of maternal antibody status.[55,190]

Concurrent administration of immune globulin and vaccine inhibits the peak serum antibody concentration achieved but not the rate of seroconversion.[477] Because antibody levels are much higher the protective concentration, this inhibition is not considered clinically significant and supports passive-active immunoprophylaxis when indicated.

Adverse Events

Except for rare reports of anaphylaxis and anaphylactoid reaction in adults in Europe and Asia, serious reactions to inactivated HAV vaccine have not been reported.[218] Pain, tenderness, and infection at the injection site can occur.[277]

TABLE 255–11 Recommended Doses and Schedules for Inactivated Hepatitis A Vaccines

Age (yr)	Vaccine*	Hepatitis A Antigen Dose	Volume per Dose (mL)	No. of Doses	Schedule
1-18	Havrix	720 ELU	0.5	2	Initial and 6-12 mo later
1-18	Vaqta	25 U†	0.5	2	Initial and 6-18 mo later
≥19	Havrix	1440 ELU	1.0	2	Initial and 6-12 mo later
≥19	Vaqta	50 U†	1.0	2	Initial and 6-18 mo later
≥18	Twinrix‡	720 ELU	1.0	3	Initial and 1 and 6 mo later

**Havrix and Twinrix are manufactured by GlaxoSmithKline Biologicals; Vaqta is manufactured and distributed by Merck & Co.*

†Antigen units (each unit is equivalent to ≈1 μg of viral protein).

‡A combination of hepatitis B (Engerix-B, 20 μg) and hepatitis A (Havrix, 720 ELU) vaccine (Twinrix) is licensed for use in people 18 years of age and older in a three-dose schedule. Havrix 360 ELU in single-dose vials is licensed in the United States but no longer is available.

ELU, enzyme-linked immunosorbent assay units.

Adapted from Pickering, L. K., Baker, C. J., Long, S. S., et al. (eds.): Red Book: 2006 Report of the Committee on Infectious Diseases. 27th ed. Elk Grove Village, IL, American Academy of Pediatrics, 2006.

Indications

In May of 2006, the ACIP recommended that hepatitis A vaccine be integrated as part of the childhood vaccination schedule.[10,26,218] All children should receive hepatitis A vaccine routinely according to the licensed two-dose schedule, with the initial dose administered at age 1 year (12 to 23 months) and the second dose 6 to 12 months later. Catch-up vaccination of unvaccinated children 2 to 18 years of age also can be considered. In addition, hepatitis A vaccination is recommended routinely for the following persons who are at increased risk of acquiring infection:

- All susceptible persons traveling to or working in countries that have a high or intermediate hepatitis A endemicity; these persons should be vaccinated or receive immune globulin before departure
- Persons who receive clotting factor concentrates, especially solvent detergent–treated preparations
- Sexually active homosexual and bisexual males
- Illicit drug users
- Persons working with infected primates or with HAV in a laboratory
- Persons with chronic liver disease; routine vaccination is recommended because these persons may be at increased risk for developing fulminate hepatitis if they become infected with HAV

Although the ACIP guidelines do not recommend routine vaccination of food handlers, consideration may be given to vaccination of these workers in areas where state and local health authorities or private employers determine that vaccination is cost-effective.

Effectiveness of vaccination has not been demonstrated in localized outbreaks occurring in institutions for the developmentally disabled, daycare centers, schools, and prisons; administration of intramuscular immune globulin currently is recommended for close contacts of infected persons in these circumstances. At present, HAV vaccine is not indicated routinely for daycare attendees and staff.

Precautions and Contraindications

Hepatitis A vaccine should not be administered to persons with a hypersensitivity reaction to any of the vaccine components, such as alum or, in the case of Havrix, phenoxyethanol.[10,26,219] Safety data in pregnant women are not available, but the risk is considered to be low or nonexistent because the vaccine contains inactivated, purified viral proteins.

HEPATITIS B VACCINE

HBV infection is a leading cause of acute hepatitis and a major public health problem of global importance. Its incidence is especially high in many Asian and African countries. Individuals with chronic infection are at risk for the development of chronic hepatitis, cirrhosis, and primary hepatocellular carcinoma. Rates of new infection are highest among adults, but chronic infection is more likely to occur in individuals infected as infants or children. These persons not only are at increased risk for chronic and malignant liver disease but also, as chronic carriers, serve as the reservoir for transmission of HBV.

The initial strategies for prevention of hepatitis B through vaccination reflect the varying epidemiology of HBV infection in different areas of the world.[90] In the United States, for example, infection is of comparatively low endemicity and occurs primarily in adolescents and adults. The risk of acquiring infection, however, is much greater in certain populations. Examples include those born and living in areas or among groups in which HBV is highly endemic and those with lifestyles predisposing to the acquisition of HBV, such as male homosexual activity, intravenous drug abuse, and promiscuous heterosexual activity.[3] In contrast, in geographic areas in which HBV infection is highly endemic, infection usually is acquired at birth or during childhood, a pattern resulting in the recommendation for universal vaccination of infants.

In 1991, the CDC initiated a comprehensive hepatitis B vaccination strategy to eliminate transmission of HBV in the United States.[90] Critical elements of this strategy included preventing perinatal transmission of HBV by identifying and providing immunoprophylaxis to infants of HBsAg-positive mothers and universal hepatitis B vaccination of infants to interrupt transmission and prevent future infection. The advantages of this approach included the existence of effective programs of routine childhood immunization, protection without any need to identify specific risk factors, and protection before significant exposure occurred. In addition, the positive effects of universal infant immunization had been observed in Taiwan, where the strategy of universal infant immunization already was being used. In Taiwan, the overall prevalence rate of HBV for children aged 1 to 10 years decreased from 9.8 percent in 1984 to 1.3 percent in 1994.[161]

In 1994, the ACIP expanded the recommendations to include previously unvaccinated children, 11 to 12 years old.[100] In October 1997, these recommendations were expanded still further to include all unvaccinated children 0 to 18 years old and made hepatitis B vaccine available through the Vaccines for Children (VFC) program for persons 0 to 18 years of age who are eligible for this program.[117] The goal of the 1997 recommendations was to increase access to hepatitis B vaccine by encouraging the vaccination of previously unvaccinated children and adolescents 0 to 18 years old whenever they are seen for routine medical visits.[107] This expansion of the recommended age group for receiving vaccination and for VFC eligibility simplifies previous recommendations and the eligibility criteria for receiving VFC vaccine. The other ACIP priorities for giving hepatitis B vaccination to children remained unchanged and included the following groups: all infants; children in populations at high risk for acquiring HBV infection, such as Alaska Natives, Pacific Islanders, and children who reside in households of first-generation immigrants from countries where HBV infection is moderately or highly endemic; previously unvaccinated children 11 to 12 years old; and older adolescents and adults in defined at-risk groups.[90,100]

Between 1990 and 2004, the incidence of HBV infection in the United States declined by 75 percent. The decline was greatest among children and adolescents. Coincident with the decline in HBV incidence, vaccine coverage for children aged 19 to 35 months increased from 16 to 92 percent from 1991 to 2004.[144] Among adolescents 13 to 15 years old, vaccine coverage increased from zero to 74 percent between 1993 and 2004 (CDC, unpublished data). Clearly, since its inception in 1991, many aspects of the national immunization strategy to eliminate HBV transmission have been implemented with great success, especially the routine vaccination of all infants. Nonetheless, many challenges remain.

Despite the overall decline in hepatitis B incidence and the recommendations for routine vaccination of infants and children, increasing proportions of new HBV infections in the United States occur among adolescents and adults who have defined risk factors, including persons with multiple sex partners (more than one partner during the preceding 6 months), men who have sex with men, and injecting drug users.[332] The primary means of preventing these infections is to identify settings such as correctional facilities, sexually transmitted disease clinics, and drug treatment centers where adolescents and adults with high-risk drug and sexual practices can be routinely accessed and vaccinated. In correctional facilities where previously unvaccinated

inmates are offered HBV vaccination, 60 to 80 percent of inmates offered accepted vaccination.[489]

Even though universal screening of all pregnant women has been widely adopted across the United States, fewer than half of all HBsAg-positive pregnant women are identified through prenatal screening.[215] These women with unknown HBsAg status are not screened consistently, even when they are hospitalized during labor and delivery; consequently, their infants do not receive appropriate post-exposure prophylaxis.[453] Furthermore, the birth dose of HBV vaccine, which could serve as a safety net for infants born to mothers for whom testing either was not performed or not performed correctly, was administered to only 45 percent of infants born in the United States in 2004, less than the rate of 54 percent seen before July of 1999, when recommendations were made to suspend the birth dose of hepatitis B vaccine temporarily until a thimerosal-free vaccine became available.[331]

To enhance existing strategies aimed at prevention of perinatal HBV transmission, the ACIP recommended in December of 2005 that all delivery hospitals institute specific policies and procedures to improve identification of infants born to HBsAg-positive mothers and mothers with unknown HBsAg status. These recommendations were made to ensure administration of appropriate post-exposure prophylaxis and a birth dose of HBV vaccine to all medically stable infants. This statement also updated recommendations to improve vaccination coverage of adolescents and children by implementing immunization record reviews for all children 11 to12 years old and children younger than 19 years of age who were born in countries with high or intermediate HBV endemicity and vaccinating all unvaccinated adolescents in settings that provide health care services to this age group.[343]

Preparations

Hepatitis B vaccines consisting of inactivated purified HBsAg derived from chronic hepatitis B plasma were introduced first in the early 1980s. In the late 1980s, two recombinant vaccines (Recombivax HB, Merck & Co.; and Engerix-B, SmithKline Beecham Biologicals) were licensed in the United States and currently are available in both single-antigen and combined formulations. Only the recombinant vaccines are available in the United States, but plasma-derived vaccines are widely used in other areas of the world. The recombinant vaccines contain 10 to 40 μg/mL of HBsAg protein. Pediatric formulations contain no thimerosal or only trace amounts. Vaccine is administered intramuscularly in the anterolateral thigh or deltoid area, depending on the age and size of the recipient. Administration in the buttocks or intradermally has been associated with decreased immunogenicity and is not recommended at any age.

Immunogenicity and Efficacy

The recommended series of three doses of vaccine induces a protective antibody response in more than 95 percent of infants, children, adolescents, and adults younger than 40 years.[11,343] In field trials, efficacy has been 80 to 95 percent and generally correlates with immunogenicity. Protection against disease is virtually 100 percent for persons who develop adequate serum antibody concentrations (anti-HBs ≥10 mIU/mL) after receiving vaccination. Adults older than 40 years of age and immunosuppressed persons are less likely to develop protective anti-HBs concentrations.

Hepatitis B vaccine is highly immunogenic. Therefore, post-vaccination serologic testing is not indicated, with the exception of infants born to HBsAg-positive women, persons with ongoing occupational exposure to blood, and persons with immunosuppressive conditions. Active immunization in combination with passive immunoprophylaxis with hepatitis B immune globulin (HBIG) administered within 12 to 24 hours after birth to infants born to chronically infected mothers is more than 90 percent effective in preventing transmission of HBV to the infant. Active post-exposure vaccination without HBIG administered soon after birth has been shown to be effective in preventing perinatal transmission and is used in areas where the use of HBIG is impractical.[240]

Vaccine-induced protection against symptomatic infection in a normal host is prolonged and correlates with immunologic memory, which has been demonstrated in immunized children and adults for at least 12 years after vaccination. Children immunized at birth are protected for at least 10 years. Thus, a need for routine booster doses has not been demonstrated.

Vaccine failures related to HBV variants with mutations in the S gene leading to conformational changes in the HBsAg protein, the major target for neutralizing anti-HBs antibody, have occurred in fully vaccinated children and perinatally exposed infants who received appropriate active and passive post-exposure prophylaxis and in many cases had protective anti-HBs antibody levels.[273] Although no evidence to date establishes that these escape mutations pose a threat to the effectiveness of current hepatitis B vaccine programs, future surveillance to detect emergence of HBV variants in immunized populations is warranted.[343,514]

Adverse Events

Other than soreness at the injection site, reactions to hepatitis B vaccine rarely occur. Post-vaccination surveillance performed after licensure of the plasma-derived vaccine indicated a possible association between GBS and receipt of the first vaccine dose, but no evidence indicates an association of GBS with recombinant vaccine.[343,344] Anaphylaxis has been estimated to occur in 1 in 600,000 doses distributed.[343,344] Several nonfatal cases have been reported in children.

Indications

Routine immunization with hepatitis B vaccine is recommended for all infants in the United States and should be completed by 6 to 18 months of age for all infants born to HBsAg-negative mothers.[11,336] Delivery hospitals should develop policies that ensure administration of a birth dose for all infants weighing 2000 g or more at birth unless a physician's order to defer immunization is in place and the serologic status of the mother is in the infant's medical record. Administering the first dose of hepatitis B vaccine soon after birth should minimize the risk for development of infection because of errors in maternal HBsAg testing or reporting or from exposure to persons with chronic HBV infection in the household and can increase the likelihood of completing the vaccine series. For infants weighing less than 2 kg who are born to HBsAg-negative mothers, initiation of vaccine should begin starting at 1 month of chronologic age. Administration of the second dose of vaccine is recommended 1 to 2 months after administration of the first dose, followed by a third dose when the infant is 6 to 18 months of age.

Only single-antigen hepatitis B vaccine can be used for doses given to infants between birth and 6 weeks of age. Single-antigen or combination vaccine may be used to complete the series; four doses of vaccine may be administered if a birth dose is given and a combination vaccine containing a hepatitis B component is used to complete the series.

Routine screening of all pregnant women for HBsAg is recommended because of the necessity for administering a birth dose of vaccine and HBIG.[11,343] Infants born to HBsAg-positive mothers, including pre-term and low-birth-weight infants, should be given HBIG (0.5 mL) within 12 hours of birth at a separate injection site, as well as the birth dose of HBV vaccine.[11,343] If a

pre-term infant weighing less than 2000 g is born to an HBsAg-positive mother, the birth dose of hepatitis B vaccine should not be counted toward completion of the vaccine series, and three additional doses of hepatitis B vaccine should be administered beginning when the child is 1 month of age. In addition to receiving HBIG and the hepatitis B vaccine series, infants of HBsAg-positive mothers should be tested for HBsAg and antibody to HBsAg (anti-HBs) at 9 to 15 months of age to identify those with chronic HBV infection or those who may require re-vaccination.[343]

A woman whose HBsAg status is unknown at delivery should undergo blood testing as soon as possible to determine her HBsAg status. The infant should receive the first dose of hepatitis B vaccine within 12 hours. If the woman is found to be HBsAg-positive, her infant should receive HBIG as soon as possible within 7 days. In populations where HBsAg testing of pregnant women is not feasible, all infants should receive hepatitis B vaccine at birth and 2 months and complete the series by the time they reach 6 months of age.

Hepatitis B vaccination is recommended for all children and adolescents younger than 19 years old in the United States. Children who have not been immunized previously may begin the vaccine series during any visit. All children aged 11 to 12 years old should have a review of their immunization records and receive the complete hepatitis B vaccine series if they have not been vaccinated previously. All children and adolescents younger than 19 years old who were born in Asia, the Pacific Islands, Africa, or other intermediate- or high-endemic countries or have at least one parent who was born in one of these areas should have a review of their immunization records and complete the hepatitis B vaccine series if they were not vaccinated previously.[343]

Vaccination also is recommended for those with one or more of the following risk factors for acquiring HBV infection:

- Sexually active heterosexual adolescents and adults who have a recently acquired sexually transmitted disease, are identified as prostitutes, or have had one or more sex partners in the previous 6 months
- Sexually active men who have sex with men
- Household contacts or sexual partners of HBsAg-positive persons
- Injecting drug users
- Persons at occupational risk of acquiring infection through exposure to blood or blood-contaminated body fluids, such as health care workers and public safety workers
- Residents and staff of institutions for the developmentally disabled
- Patients undergoing hemodialysis; vaccination of those with early renal failure is encouraged before they require hemodialysis
- Patients who receive clotting factor concentrates
- Members of households with international adoptees who are HBsAg-positive
- Travelers, especially children, to areas with high and intermediate rates of infection with HBV who have close contact with the local population or are likely to have contact with blood, such as in a medical setting, or sexual contact with residents
- Inmates in long-term correctional facilities

In addition to active and passive immunoprophylaxis of infants born to HBsAg-positive mothers, post-exposure prophylaxis is recommended in the following circumstances:

- Sexual partner of an HBsAg-positive person. A single dose of HBIG within 14 days of the last sexual contact and initiation of the three-dose hepatitis B vaccination is recommended for susceptible persons.
- Household exposure of an unvaccinated infant younger than 12 months old to a primary caregiver who has acute hepatitis B. Infants in this circumstance should receive HBIG, in addition to being vaccinated.
- Accidental percutaneous or per mucosal exposure of a susceptible person to HBsAg-positive blood. This indication is exemplified most by a needle-stick or other accident involving blood in a hospital. Another example is an injury to a susceptible person caused by the bite of an HBsAg-positive child. For this indication, HBIG as well as vaccine is given. Recommendations in these circumstances are complex and based on the availability of the blood source for HBsAg testing and the hepatitis B vaccination status of the exposed person.

Booster doses are not recommended except in the case of patients undergoing hemodialysis and possibly other immunocompromised patients, in whom annual antibody testing should assess the need. An additional dose is indicated for those whose serum anti-HBsAg concentration is less than 10 mIU/mL.

The current recommended doses and schedule for the use of hepatitis B vaccines licensed in the United States in infants and other age groups are shown in Table 255–12 (see elsewhere for more information[11,343]). For completing the hepatitis B vaccine series and achieving complete vaccination for hepatitis B, the two licensed hepatitis B vaccines are interchangeable when administered in doses recommended by the manufacturers.[11,343] In September of 1999, the FDA approved an optional two-dose schedule of Recombivax HB for vaccination of adolescents 11 to 15 years of age. The ACIP recommended that this schedule be included in the VFC program in February 2000.[120] With the two-dose schedule, the adult dose of Recombivax HB is administered to adolescents 11 to 15 years old, with the second dose given 4 to 6 months after the first dose. In immunogenicity studies in adolescents 11 to 15 years of age, antibody concentrations and seroprotection rates were similar with the two-dose schedule and the currently licensed three-dose schedule. Follow-up data collected during the course of 2 years indicate that the rate of decline in concentration of antibody for the two-dose schedule was similar to that for the three-dose schedule. No data are available to assess long-term protection or immune memory after vaccination with the two-dose schedule, and whether booster doses of vaccine will be required is not known. Children and adolescents who have begun vaccination with a dose of the pediatric formulation should

TABLE 255–12 Recommended Doses and Schedules of Hepatitis B Virus Vaccines in the United States

Group	Recombivax HB Dose µg (mL)	Engerix-B Dose µg (mL)
Infants of HBsAg-negative mothers, children, and adolescents <20 yr	5 (0.5)	10 (0.5)
Infants of HBsAg-positive mothers (HBIG also recommended)	5 (0.5)	10 (0.5)
Adolescents 11-15 yr	10 (0.5)*	N/A
Adults (≥20 yr)	10 (1.0)	20 (1.0)
Patients undergoing dialysis and other immunocompromised persons	5 (0.5)	10 (0.5)
<20 yr†	40 (1.0)‡	40 (2.0)§
≥20 yr		

**Adult formulation administered on a two-dose schedule.*
†Higher doses may be more immunogenic, but no specific recommendations have been made.
‡Special formulation for patients administered for patients undergoing dialysis.
§Two 1.0-mL doses administered at one site in a four-dose schedule at 0, 1, 2, and 6 months.
HBIG, hepatitis B immune globulin; HBsAg, hepatitis B surface antigen.

complete the three-dose series with this dose. Similarly, if the formulation administered to an adolescent at the start of a series is not known, the series should be completed with the three-dose schedule.

In December of 2006, the ACIP approved recommendations for hepatitis vaccine use in adults.[344] In settings in which high proportions of adults have risks for acquiring HBV infection, the ACIP recommends universal hepatitis B vaccination for all unvaccinated adults. In other primary care and specialty medical settings in which adults at risk for developing HBV infection receive care, the ACIP recommends that health care providers should inform all patients about the health benefits of vaccination, including risks for acquiring HBV infection, and persons for whom vaccination is recommended, and should vaccinate adults who report having risks for developing HBV infection and any adults requesting protection from HBV infection. To promote vaccination in all settings, health care providers should implement standing orders to identify adults recommended for hepatitis B vaccination and administer vaccination as part of routine clinical services, not require acknowledgment of an HBV infection risk factor for adults to receive vaccine, and use available reimbursement mechanisms to remove financial barriers to receiving hepatitis B vaccination.

Contraindications

The only contraindication to receiving HBV vaccination is a history of anaphylaxis to a previous dose of vaccine. Although data on the safety of HBV vaccines are not available for pregnant women, these vaccines contain only HBsAg and not live virus and should not be deleterious to the developing fetus. Because HBV infection during pregnancy can result in transmission to the newborn, susceptible women at increased risk of acquiring infection should be vaccinated during pregnancy. Inadvertent vaccination of HBsAg-positive persons has no deleterious effects.

HUMAN PAPILLOMAVIRUS VACCINE

Genital HPV infection is thought to be the most common sexually transmitted viral infection, accounting for 6.2 million new cases annually in the United States.[490] The estimated prevalence of HPV infection ranges from 20 to 40 percent among sexually active 20-year-old women.[330] HPV typically infects girls and women soon after sexual exposure.[180,497] Median time from first intercourse to first detection of HPV is only 3 months.[180] The lifetime risk for women to acquire one or more genital HPV infections exceeds 75 percent.[79,330]

More than 40 HPV types can infect the genital tract and are classified on the basis of their association with cervical cancer.[366] The "low risk," non-oncogenic HPV types (e.g., types 6 and 11) are associated with anogenital warts, mild cervical dysplasia, and recurrent respiratory papillomatosis. The "high-risk" oncogenic HPV types are causally linked to several human cancers in both women and men, including cancers of the cervix, vulva, vagina, anus, and penis and a subset of head and neck cancers.[366] Infection with HPV causes virtually all cases of cervical cancer, the second most common cause of death from cancer among women globally, surpassed only by breast cancer.[480] The development of cervical cancer often occurs decades after initial infection. HPV types 16 and 18 account for 70 percent of cervical cancers.[68] Other types account for the remaining 30 percent of cervical cancers, and these types vary in their distribution globally.

Although the incidence of HPV is high, most infections clear without intervention. Seventy percent of new infections clear within 1 year, and 91 percent clear within 2 years.[174] Persistent infection with high-risk HPV types, defined as detection of the same viral type at two or more visits 6 months apart, is the most important risk factor for development of cervical cancer precursor lesions. Studies have demonstrated that persistent infection with a high-risk HPV type is associated with a greater than 10-fold risk of high-grade cervical cancer precursors.[269,358]

A first generation of prophylactic HPV subunit vaccines has been developed.[306] These vaccines are expected to have a significant impact on the incidence of HPV-related cervical and other anogenital cancers in women. Incidence of recurrent respiratory papillomatosis also is likely to decrease as a result of widespread vaccination.

Preparations

In 2006, the FDA licensed the first HPV vaccine for use in girls and women in the United States. This quadrivalent vaccine (GARDASIL, Merck & Co.) contains HPV types 6, 11, 16, and 18 virus-like particles (VLPs) and protects against four HPV types, which together cause 70 percent of cervical cancers (HPV types 18 and 16) and 90 percent of genital warts (HPV types 6 and 11).

The quadrivalent HPV vaccine is prepared from the highly purified VLPs of the major capsid (L1) protein of HPV types 6, 11, 16, and 18. The L1 proteins are produced by *Saccharomyces cerevisiae* and self-assemble into VLPs. The VLPs mimic the HPV virus, but they contain no viral DNA. Each 0.5-mL dose contains 20 μg HPV 6 L1 protein, 40 μg HPV 11 L1 protein, 40 μg HPV 16 L1 protein, and 20 μg HPV 18 L1 protein. The quadrivalent vaccine uses alum as an adjuvant and does not contain thimerosal or antibiotics. The vaccine should be stored at 2° C to 8° C (36° F to 46° F) and not frozen.

Primary vaccination with quadrivalent HPV vaccine consists of three 0.5-mL doses administered intramuscularly. The second and third doses should be administered 2 and 6 months after administration of the first dose.

Immunogenicity and Efficacy

Early data from randomized controlled trials have shown consistently that prophylactic HPV VLP vaccines are immunogenic and efficacious in preventing infection and lesions caused by the targeted HPV types.[306,330,352,444] Vaccine efficacy seems to be mediated by a type-specific humoral immune response. Evaluations of the quadrivalent vaccine have demonstrated that vaccinated individuals develop high antibody titers to the respective HPV types that exceed the antibody titers seen with natural HPV infection.[444] However, the level of antibody that confers a protective response is unknown.[444] For the quadrivalent HPV VLP vaccine, an antibody response significantly greater than placebo was sustained for at least 3 years without booster doses.[352,474] Whereas vaccine efficacy studies have been done only in adolescents ages 13 years and older, immunogenicity bridging studies have been performed in children as young as 9 years of age. Antibody titers to HPV types 6, 11, 16, and 18 were found to be higher in younger adolescents than in young adults.[352] From these data, investigators inferred that protection exists against cervical cancer, cancer precursor lesions, and genital warts, even for young adolescent girls who receive the quadrivalent vaccine.

The results from four randomized controlled trials repeatedly demonstrate that a regimen of three intramuscular injections of HPV VLP vaccine provides high-level protection from infection and lesions caused by targeted HPV types.[306,330] Efficacy from a combined analysis of quadrivalent HPV vaccine efficacy from both phase II and phase III clinical trials is 100 percent against precancerous lesions (carcinoma in situ II/III or adenoma in situ) caused by HPV type 16 or 18, and 99 percent against development of genital warts.[352] Whether HPV vaccines provide long-

term protection and whether booster doses will be necessary is not known. The quadrivalent HPV vaccine has not been found to have efficacy against existing disease or infection caused by HPV.

Adverse Events

HPV vaccines appear to be generally safe and well tolerated. The quadrivalent HPV vaccine has been associated with minimal adverse reactions.[206,352] The most common are mild fever (<38° C) and local injection site reactions such as pain, redness, pruritus, or swelling. Additional data on vaccine safety, including data on pregnancy and fetal and infant outcomes, are being collected in ongoing trials and will continue to be collected in post-licensure studies.

Indications

In March of 2007, the ACIP issued recommendations for the use of the quadrivalent HPV vaccine.[158] Routine vaccination with three doses of vaccine is recommended for girls 11 to 12 years of age. The vaccination series can be started in girls as young as 9 years of age, with physician and parental discretion. Catch-up vaccination is recommended for girls and women 13 to 26 years old who have not been vaccinated previously or who have not completed the full vaccination series. Ideally, vaccination should be administered before potential exposure to HPV through sexual contact occurs.

Vaccine is administered in a three-dose schedule, and the second and third doses should be administered 2 and 6 months after the first dose. Immunogenicity data allow for some degree of flexibility in the dosing schedule, often an important consideration in providing multidose vaccines to adolescents for whom contact with health providers can be sporadic. For the quadrivalent vaccine, the minimum interval from dose 1 to dose 2 is 4 weeks. The minimum interval from dose 2 to dose 3 should not be less than 12 weeks.

Quadrivalent HPV vaccine can be administered at the same visit when other age-appropriate vaccines, such as Tdap, Td, and MCV4 (meningococcal) are provided. At present, recommendations for cervical cancer screening have not changed for girls and women who receive quadrivalent HPV vaccine.

Quadrivalent HPV vaccine can be given to girls and women who have an equivocal or abnormal Papanicolaou (Pap) test, a positive hybrid capture-II high risk test, or genital warts. Vaccine recipients should be advised that data from clinical trials do not indicate the vaccine will have any therapeutic affect on existing Pap abnormalities, HPV infection, or genital warts. However, vaccination of these girls and women would provide protection against infection with vaccine HPV types not already acquired.

Lactating women can receive quadrivalent HPV vaccine. Girls and women who are immunocompromised from either disease or medication can receive quadrivalent HPV vaccine. However, the immune response to vaccination and vaccine effectiveness may be less than in girls and women who are immunocompetent. Quadrivalent vaccine falls into pregnancy category B and is not recommended for use in pregnancy.[352] If an adolescent becomes pregnant during vaccination, subsequent doses should be deferred until after parturition. The vaccine has not been associated causally with adverse outcomes of pregnancy or adverse events to the developing fetus. However, data on vaccination during pregnancy are limited at this time.

Contraindications

Quadrivalent HPV vaccine is contraindicated for people with a history of immediate hypersensitivity to yeast or to any vaccine component.

INFLUENZA VACCINE

Influenza virus infection continues to cause significant morbidity and mortality despite the availability of effective vaccines and antiviral therapy for prevention and treatment of influenza. In the United States, epidemics of influenza typically occur during the winter months and have been associated with an average of approximately 36,000 deaths per year in the United States.[454] Influenza viruses cause disease among all age groups.[234,235,362] Rates of infection are highest among children, but rates of serious illness and death are highest among persons aged 65 years and older, children aged 2 years and younger, and persons of any age who have medical conditions that place them at increased risk for developing complications from influenza.[50,51,233,362] The impact of influenza on both normal children and those with underlying high-risk conditions is appreciable. Attack rates in normal children have been estimated at 10 to 40 percent each year, and approximately 1 percent of these influenza infections result in hospitalization.[236,397]

A major difficulty in the development and provision of satisfactory immunizing agents for the prevention of influenzal disease is the antigenic variation in these viruses. Periodic minor antigenic changes in influenza A or B virus are the major factors in the continuing occurrence of yearly influenzal disease. Although outbreaks generally are limited in magnitude, the resulting morbidity and mortality remain discouragingly high. Major antigenic changes in influenza A virus, as occurred in 1957 to 1958 (Asian strain) and again in 1968 to 1969 (Hong Kong strain), account for the pandemic spread of disease associated with greater overall morbidity and mortality, especially in high-risk populations.

Preparations

Two types of influenza vaccines are licensed in the United States for use in children, inactivated trivalent influenza vaccine (TIV) and live attenuated influenza vaccine (LAIV) (Table 255–13).[13,440] These multivalent vaccines contain three virus strains (usually two type A and one type B), with the composition changed periodically in anticipation of the prevalent influenza strains expected to circulate in the United States in the following winter. Both vaccines are prepared from virus grown in the allantoic sac of the chick embryo.

Inactivated TIV distributed in the United States consists of either subvirion vaccine, prepared by disrupting the lipid-containing membrane of the virus, or purified surface-antigen vaccine. TIV is administered intramuscularly into the anterolateral thigh of infants and young children and into the deltoid muscle of older children and adults. Children younger than 9 years of age who are being immunized against influenza for the first time should receive two doses of TIV given 4 weeks apart, before the start of the influenza season.

Concerns about thimerosal have prompted some parents to reconsider influenza immunization. However, the benefits of protecting children against the known risks of influenza far outweigh the theoretical risks associated with the small amounts of thimerosal in some currently available forms of influenza vaccine. In addition, certain types of TIV can be obtained thimerosal-free and include single-dose Fluzone (Sanofi Pasteur) and Fluvirin (Novartis Vaccines).

Of the four inactivated influenza vaccines currently licensed in the United States (see Table 255–13), only two are approved for persons younger than 18 years of age. One influenza vaccine, Fluzone, is approved for use in children, beginning at 6 months of age. The other influenza vaccine, Fluvirin, is approved in the United States only for persons 4 years of age or older because its efficacy in younger persons has not been demonstrated.

LAIV is cold-adapted, developed by passaging the viruses at successively lower temperatures in tissue culture, so that replica-

TABLE 255–13 Licensed Influenza Vaccines for Different Age Groups: United States, 2006 to 2007 Season

Vaccine	Trade Name	Manufacturer	Dose/Presentation	Thimerosal Mercury Content (μg Hg/0.5-mL Dose)	Age Group
Inactivated					
TIV	Fluzone	Sanofi Pasteur	0.25-mL prefilled syringe	0	6-35 mo
			0.5-mL prefilled syringe	0	≥36 mo
			0.5-mL vial	0	≥36 mo
			5.0-mL multidose vial	25	≥6 mo
TIV	Fluvirin	Novartis (formerly Chiron)	0.5-mL prefilled syringe	<1.0	≥4 yr
			5.0-mL multidose vial	24.5	≥4 yr
TIV	Fluarix	GlaxoSmithKline	0.5-mL prefilled syringe	<1.25	≥18 yr
TIV	Flulaval	GlaxoSmithKline	10-mL multidose vial	25	≥18 yr
Live Attenuated					
LAIV	FluMist	MedImmune	0.2-mL sprayer	0	2-49 yr

LAIV, live attenuated influenza vaccine; TIV, trivalent influenza vaccine.

tion occurs only in the upper respiratory tract.[57,58,173,400] LAIV is administered intranasally. The cold-adapted formulation that is licensed in the United States must be stored at 2° to 8° C (35-46° F). When the vaccine is warmed to room temperature for intended use, it must be used within 30 minutes.

LAIV is licensed by the FDA for healthy individuals aged 5 through 49 years. Children younger than 9 years of age being immunized against influenza for the first time should receive two doses of LAIV given 6 weeks apart, before the start of the influenza season. Studies are ongoing to assess safety and efficacy in children between 6 months and 5 years of age.

Immunogenicity and Efficacy

High post-vaccination hemagglutination inhibition antibody titers develop in the majority of vaccinated children and young adults.[315,370,379] These antibodies are protective against illness caused by strains that are antigenically similar to those strains of the same type or subtype included in the vaccine.[268,370,379,401]

Children younger than 9 years of age who have not been immunized previously against influenza require two doses of TIV or LAIV vaccine administered at least 1 month apart to produce a satisfactory antibody response. Children previously primed with a related strain of influenza by infection or immunization mount a brisk antibody response to one dose of the vaccine. In previously unimmunized populations, such as children younger than 9 years old, a single dose of split-product vaccine may be significantly less immunogenic than is a single dose of whole-virus preparation, and two doses may be required to achieve a satisfactory serum antibody response.[440] Children younger than 9 years of age who received two doses of either TIV or LAIV vaccine in a previous year need only one dose in subsequent years. Children 9 years of age or older require only one dose, regardless of their influenza immunization history.

Variable immunogenicity of influenza vaccine has been reported in immunocompromised individuals, including those with malignant disease. Successful immunologic responses in these populations are most likely to occur when immunized individuals have been primed previously by exposure to antigenically similar influenza strains.[243,316] The optimal time to immunize children with malignant diseases who still must undergo chemotherapy is 3 to 4 weeks after chemotherapy has been discontinued and the peripheral granulocyte and lymphocyte counts are greater than 1000/mm.[6,13]

Corticosteroids administered for brief periods or every other day have only a minimal effect on the antibody response to influenza vaccine. Prolonged administration of high doses of corticosteroids (i.e., a dose equivalent to either 2 mg/kg or greater or a total of 20 mg/day of prednisone) may impair the antibody response. Influenza immunization can be deferred temporarily during the time of receipt of high-dose corticosteroids, provided deferral does not compromise the likelihood of administering immunization before the start of the influenza season.[13]

The effectiveness of inactivated influenza vaccine depends primarily on the age and immunocompetence of the vaccine recipient, the degree of similarity between the viruses in the vaccine and those in circulation, and the outcome being measured. Vaccine efficacy and effectiveness studies may have various end-points, including the prevention of medically attended acute respiratory illness (MAARI), prevention of culture-positive influenza virus illness, prevention of influenza or pneumonia-associated hospitalizations or deaths, seroconversion to vaccine serotypes, or prevention of seroconversion to circulating influenza virus subtypes.

Protection against virologically confirmed influenza illness after immunization with TIV in healthy children older than 2 years of age usually is 70 to 80 percent, with a range of 50 to 95 percent depending on the closeness of vaccine strain match to the circulating wild strain.[440] Efficacy of TIV in children 6 to 23 months of age is lower than in older children, although data are limited. Efficacy of LAIV was 86 to 96 percent against virologically confirmed influenza A (H3N2) virus infection in a large pre-licensure pediatric trial during 1 year. The effectiveness of influenza immunization on acute respiratory tract illness is less evident in pediatric than in adult populations because of the frequency of upper respiratory tract infections and influenza-like illness caused by other viral agents in young children. The protection afforded by influenza vaccine is transient, and yearly immunization is necessary irrespective of whether significant antigenic changes have occurred in a prevailing influenza strain.

Vaccine effectiveness is lower among previously unvaccinated children younger than 9 years of age if they have received only

one dose of influenza vaccine, compared with children who have received two doses. A retrospective study among approximately 5000 children aged 6 to 23 months conducted during a year with a suboptimal vaccine match indicated vaccine effectiveness of 49 percent against medically attended, clinically diagnosed pneumonia or influenza among children who had received two doses of influenza vaccine. No effectiveness was demonstrated among children who had received only one dose of influenza vaccine, a finding illustrating the importance of administering two doses of vaccine to previously unvaccinated children younger than 9 years old.[406] Similar results were observed in a case-control study of children aged 6 to 59 months with laboratory confirmed influenza.[434] A study assessing protective antibody responses after administration of one and two doses of vaccine among vaccine-naïve children aged 5 to 8 years also demonstrated the importance of compliance with the two-dose recommendation.[371]

Two studies documented that TIV vaccine decreases the incidence of influenza-associated otitis media among young children by approximately 30 percent,[171,261] but a third study determined that vaccination did not reduce the burden of acute otitis media (AOM).[270]

Adverse Events

TIV is an inactivated vaccine that contains killed viruses and therefore cannot produce signs or symptoms of influenza caused by active virus infection. The most common symptoms associated with TIV administration are soreness at the injection site and fever. Fever, usually occurring 6 to 24 hours after immunization, affects approximately 10 to 35 percent of children younger than 2 years old. Mild systemic symptoms, such as nausea, lethargy, headache, muscle aches, and chills, also can occur after receipt of TIV.

LAIV generally is well tolerated and may produce mild signs or symptoms related to influenza virus infection that include headache and runny nose or nasal congestion in vaccinees. Transmission of LAIV strains to unimmunized contacts has been documented only once in pre-licensure studies. The proposed explanation for the uncommon occurrence of transmission is that the vaccine virus is shed for a shorter duration and in a much smaller quantity than are wild-type strains.

Indications

Annual immunization with TIV is recommended for the following groups[13,181,440]:

- Healthy children 6 through 18 years of age
- High-risk children 6 months and older AND adolescents with underlying medical conditions, including the following:
  - Asthma or other chronic pulmonary diseases, such as cystic fibrosis
  - Hemodynamically significant cardiac disease
  - Immunosuppressive disorders or therapy
  - HIV infection
  - Sickle cell anemia and other hemoglobinopathies
  - Diseases requiring long-term salicylate therapy, such as rheumatoid arthritis or Kawasaki disease
  - Chronic renal dysfunction
  - Chronic metabolic disease, such as diabetes mellitus
  - Any condition that can compromise respiratory function or handling of secretions or can increase the risk of aspiration, such as cognitive dysfunction, spinal cord injuries, seizure disorders, or other neuromuscular disorders
  - Any girl or woman who will be pregnant during influenza season

To prevent additional cases of influenza and transmission from these cases to at-risk individuals, influenza immunization with TIV or LAIV is recommended for the following persons, unless contraindicated:

- Healthy household contacts and out-of-home caregivers of either high-risk children and adolescents or children younger than 5 years old; immunization of close contacts of children younger than 6 months old is especially important because influenza vaccine is not licensed for use in these infants
- Healthy contacts and caregivers of other children or adults at high risk of developing complications of influenza infection
- Close contacts of immunosuppressed people
- Health care professionals or volunteers in hospitals or medical offices

Previously unimmunized children aged 6 months to younger than 9 years of age should receive two doses of influenza vaccine before the onset of influenza season. Available data suggest that children younger than 9 years who did not receive the second dose of influenza vaccine in the initial year that influenza vaccine was given may not be adequately protected the next influenza season with only one dose. In this group, levels of protection can be suboptimal, especially if the antigenic specificity of the predominant strains has changed from the previous year. Thus, the AAP recommends that two doses be given to these children the following influenza season.[181] This recommendation applies only to the influenza season that follows the first year that a child younger than 9 years old receives influenza vaccine.

Precautions and Contraindications

Current influenza vaccines contain egg proteins and on rare occasion may induce immediate allergic reactions, including anaphylaxis. Skin testing has been used for children with severe anaphylactic reactions to eggs who are to receive influenza vaccine, but these children generally should not receive influenza vaccine because of the risk of reaction, the probable need for yearly immunization, and the availability of chemoprophylaxis against influenza infection. Less severe or local manifestations of allergy to egg or to feathers are not contraindications to administering influenza vaccine and do not warrant performing vaccine skin testing.[13]

Pregnancy is not a contraindication to influenza vaccine administration, and vaccination is advised for pregnant girls and women who have an underlying high-risk condition.[440]

Persons with acute febrile illness usually should not be vaccinated until their symptoms have abated. However, minor illnesses with or without fever do not contraindicate the use of influenza vaccine, particularly in children with mild upper respiratory tract infection or allergic rhinitis.[440]

People should not receive LAIV if they are taking salicylates, have a known or suspected immune deficiency, have a history of GBS, have a history of anaphylactic reaction to egg protein, or have reactive airway disease or other conditions traditionally considered high risk for severe influenza (chronic pulmonary disorders or cardiac disorders, pregnancy, chronic metabolic disease, renal dysfunction, hemoglobinopathies, or immunosuppressive therapy).

Precaution also should be taken when considering LAIV administration to persons with minor acute illness, such as a mild upper respiratory tract infection with or without fever. Although the vaccine most likely can be given in this case, LAIV should be deferred temporarily until the congestion-inducing illness is resolved if nasal congestion will impede the delivery of the vaccine to the nasopharyngeal mucosa.

LAIV or TIV can be used to prevent influenza in those who are in close contact with most immunosuppressed individuals. People who are in contact with severely immunosuppressed individuals, such as those receiving care in a protective environment after undergoing hematopoietic stem cell transplantation, should NOT receive LAIV. For such individuals, TIV is recommended.

MEASLES VACCINE

Since the introduction of both an inactivated and a live virus, attenuated measles vaccine (Edmonston B strain) in the United States in 1963, the reported incidence of measles has decreased by more than 99 percent. Although the incidence of measles has declined in all age groups, the decline has been greatest in children aged 5 to 14 years.

Measles was targeted for elimination in the United States by 1982. Efforts to eliminate measles were not successful as a result of two factors. The first was vaccine failure. In the late 1980s, outbreaks occurred in older children in schools in which immunization rates usually were greater than 95 percent.[247,340,372] Attack rates were 1 to 5 percent because of the accumulation of measles-susceptible individuals from vaccine failure. The recurrent measles outbreaks among vaccinated school-age children in the mid-1980s prompted both the ACIP and the AAP in 1989 to recommend that all children be given two doses of measles-containing vaccine, preferably as MMR.[25,84] Although administration of the second dose originally was recommended either at entry to primary school (ACIP) or middle/secondary school (AAP), the ACIP, the AAP, and the AAFP now recommend that a child be given the second dose at age 4 to 6 years of age rather than delaying it until the child is 11 to 12 years old.[111,337,339,342,345,381,481] The major benefit of administering the second dose is a reduction in the proportion of persons who remain susceptible because of primary vaccine failure. Waning immunity is not a major cause of vaccine failure and has little influence on transmission of measles, and re-vaccination of children who have low concentrations of measles antibody produces only a transient rise in antibody concentration.[337,339,342,345,381,481]

The second factor leading to outbreaks of measles was the failure to implement current immunization strategies, especially in the inner cities, where a high proportion of preschool-age children had not been vaccinated. From 1989 through 1991, the proportion of unvaccinated persons with measles increased, as reflected by outbreaks among unvaccinated inner-city preschool-age children. Multiple barriers to providing timely immunization to these children were identified during investigation of the measles resurgence that occurred between 1989 and 1991. Reported cases of measles declined rapidly after the 1989 to 1991 resurgence because of intensive efforts to vaccinate preschool-age children. Measles vaccination levels among 2-year-old children increased from 70 percent in 1990 to 91 percent in 1997. Since 1993, fewer than 500 cases of measles have been reported annually, and fewer than 200 cases per year have been reported since 1997. A record low annual total of 37 cases was reported in 2004.[287]

Available epidemiologic and virologic data indicate that transmission of measles in the United States has been interrupted. Most cases now are imported from other countries or linked to imported cases. Most imported cases originate in Asia and Europe and occur both among U.S. citizens traveling abroad and persons visiting the United States from other countries. Since 1993, the largest outbreaks of measles in the United States have occurred in populations that refuse vaccination for religious or personal belief reasons. Most outbreaks have involved limited spread from measles imported from outside the United States. During 2005, the CDC reported 66 confirmed cases of measles, 34 of which were from a single outbreak in Indiana associated with infection in a traveler returning to the United States.[151]

Since the mid-1990s, no age group has predominated among reported cases of measles. Relative to earlier decades, increased proportions of cases now occur among adults. Persons aged 20 years and older accounted for only about 3 percent of cases in 1983, whereas in 2001 this age group accounted for 48 percent of all reported cases.

The recommended age for receiving routine vaccination with measles vaccine has been lowered in the past decade from 15 months to 12 to 15 months of age.[135] The decision to lower the age for receiving routine primary vaccination was based on the observation that most children are susceptible to measles by the time that they reach 12 months of age because of waning transplacental immunity.[334,338] Most mothers now have vaccine-induced immunity rather than immunity conferred by infection with wild virus. Antibody concentrations induced by measles vaccination generally are lower than those induced by natural measles. Therefore, measles-specific antibodies acquired transplacentally are lower in infants of vaccinated mothers, and these infants therefore are susceptible at an earlier age.

Preparations

The live measles virus vaccine (Moraten strain) available in the United States is prepared in chick fibroblast cell culture. Each dose of vaccine contains neomycin, sorbitol, and hydrolyzed gelatin as a stabilizer. Preparations include a monovalent (measles only) vaccine and two combinations, measles-rubella, MMR, and measles-mumps-rubella-varicella (MMRV). MMRV is approved for children 12 months through 12 years of age. MMRV should not be administered to persons 13 years of age or older. The ACIP and AAP do not express a preference for use of combination MMRV over separate administration of MMR and varicella vaccines. In all situations in which measles vaccine is to be used, MMR or MMRV should be given if the recipient is likely to be susceptible to contracting rubella, mumps, or varicella.[14,111]

Inadequate protection against measles can result from the administration of improperly stored vaccine. Before reconstitution, measles vaccine must be stored at a temperature between 2° C and 8° C (35.6° F to 46.4° F) or colder and must be protected from light, which may inactivate the virus. Reconstituted vaccine should be stored in a refrigerator and discarded if not used within 8 hours.

Immunogenicity and Efficacy

Immunization produces a mild or inapparent, noncommunicable infection. Measles antibodies develop in approximately 95 percent of children vaccinated at 12 months of age and in 98 percent of children vaccinated at 15 months of age.[338] Studies indicate that serologic evidence of measles immunity develops in more than 99 percent of persons who receive two doses of measles vaccine, separated by at least 1 month, on or after their first birthday.[166,178] Although vaccine-induced antibody titers are lower than those after natural disease, persistence of protective titers for as long as 16 years after administration of vaccine has been demonstrated.[311,339] Most vaccinated persons who appear to lose antibody have an anamnestic response after re-vaccination, thus indicating that they most likely are still immune.[377] A small percentage of vaccinated individuals may lose protection after several years as a result of secondary vaccine failure.[345,513]

Adverse Events

Vaccine-associated symptoms, consisting of fever higher than 39.4° C (102.9° F) occurring 5 to 10 days after immunization or transient rash, develop in 5 to 18 percent of recipients.[319,388] Serious complications related to vaccine use occur far less frequently than after natural measles.[385]

Thrombocytopenia occurs at a rate of 1 case for every 30,000 to 40,000 doses distributed. Based on data from Sweden and Finland, the IOM concluded that a causal association exists between MMR and thrombocytopenia.[280] The decrease in platelet count presumably is caused by the measles component and usually is not clinically apparent. However, thrombocytopenic purpura occurring after vaccination has been reported.

Central nervous system disease, specifically encephalitis or encephalopathy, is reported at a rate of less than 1 case per 1 million doses of vaccine administered. Because the incidence of encephalitis or encephalopathy after the administration of measles vaccination to healthy children is lower than the observed incidence of encephalitis of unknown origin, some or most of the reported severe neurologic disorders may be only temporally, rather than causally, related to measles immunization. The risk of subacute sclerosing panencephalitis (SSPE) in vaccinated children is extremely low and is estimated to be approximately one twelfth the risk of SSPE after a case of natural measles (0.7 SSPE cases per million vaccine doses versus 8.5 cases per million natural measles infections).[64,81,280] Whether measles vaccine causes SSPE is unclear. Some cases of SSPE occur in children with no history of having measles or measles vaccination.[14]

Reactions to measles vaccine are not age-related and occur only in susceptible vaccinees. After re-vaccination, reactions should be expected only in those who failed to respond to the first immunization.

To date, no convincing evidence establishes that any vaccine causes autism or autistic spectrum disorder. Concern has been raised about a possible relation between MMR vaccine and autism by some parents of children with autism. Symptoms of autism often are noticed by parents during the second year of life and may manifest after administration of MMR by weeks or months. Two independent nongovernmental groups, the IOM and the AAP, reviewed the evidence regarding a potential link between autism and MMR vaccine.[252,281,283] Both groups independently concluded that available evidence does not support an association and that the United States should continue its current MMR vaccination policy.

Indications

Unless otherwise contraindicated, measles vaccine is indicated for persons susceptible to measles.[14,111] The recommended age for receiving the first dose of measles vaccine is 12 to 15 months. In high-risk areas, such as those with recurrent measles transmission, the initial dose should be administered when the child reaches 12 months of age. The second dose is given routinely at 4 to 6 years and no later than 11 to 12 years of age. Both doses of measles vaccine preferably should be given as MMR or MMRV. The minimal interval between the two doses is 4 weeks.

Adults born before 1957 generally may be considered immune to measles because of previous natural infection. Those born after 1956 and in whom immunoprophylaxis is indicated should receive two doses of vaccine.

During outbreaks, when the likelihood of exposure to measles is high, measles vaccine should be given to infants as young as 6 months. Seroconversion rates to vaccine are significantly less in children vaccinated before reaching 1 year of age than those in older children. Children immunized before their first birthday then should be re-vaccinated with MMR at 12 to 15 months of age, with a third dose given according to local policy.

Measles remains endemic in many areas of the world. Although vaccination against measles is not a requirement for entry into any country, susceptible children, adolescents, and adults born after 1956 should be offered measles vaccination (usually as MMR) before embarking on international travel. Infants 6 months or older who are traveling to areas where measles is endemic or epidemic should be vaccinated before departure and re-vaccinated at 12 to 15 months. Vaccination of infants younger than 6 months is not necessary because most young infants are protected by maternally derived antibodies.

Exposure of susceptible individuals to measles is not a contraindication to administering vaccination; vaccine given within 72 hours of exposure may provide protection. If exposure does not result in infection, immunization will protect against future infection.

Precautions and Contraindications

Immunocompromised patients with conditions such as lymphoreticular or other generalized malignant disease and primary or secondary immunodeficiency states should not be given live virus, attenuated measles vaccine.[14,111] After cessation of their chemotherapy, these individuals generally should not receive measles vaccine for at least 3 months. However, because the intensity and type of immunosuppressive therapy, radiation therapy, underlying disease, and other factors determine when immunologic responsiveness will be restored, arriving at a definitive recommendation for an interval after cessation of immunosuppressive therapy when measles vaccine can be safely and effectively administered often is not possible.

An exception to the contraindication of administering measles vaccine to immunocompromised patients is asymptomatic HIV-infected patients, for whom measles vaccination, given as MMR at 12 to 15 months of age, is recommended. The need to protect HIV-infected persons who are at increased risk for having severe complications if infected with measles has been balanced against the risk of having adverse reactions. Measles vaccine is not recommended for HIV-infected persons with evidence of severe immunosuppression. A case of progressive measles pneumonitis occurred in a person with acquired immunodeficiency syndrome (AIDS) and severe immunosuppression to whom MMR vaccine was administered,[132] and morbidity related to measles vaccination has been reported in persons with severe immunosuppression unrelated to HIV infection.[21,276,283,285] In addition, the antibody response to measles vaccine in severely immunocompromised HIV-infected persons is diminished.[45,56,346,357,359] In the United States, the incidence of measles currently is very low. Among HIV-infected persons who do not have evidence of severe immunosuppression, no serious or unusual adverse events have been reported after receiving measles vaccination.[349,375,382,442] Therefore, MMR vaccination is recommended for all asymptomatic HIV-infected persons who do not have evidence of severe immunosuppression and for whom measles vaccination would otherwise be indicated. MMR vaccination also should be considered for all symptomatic HIV-infected persons who do not have evidence of severe immunosuppression. Testing asymptomatic persons for HIV is not necessary before administering MMR.[39]

Systemically absorbed corticosteroids can suppress the immune system of an otherwise healthy person. However, neither the minimal dose nor the duration of therapy sufficient to cause immune suppression is well defined. Although the immunosuppressive effects of steroid treatment vary, many clinicians consider that a steroid dose equivalent to or greater than a prednisone dose of 2 mg/kg of body weight per day or a total of 20 mg/day is sufficiently immunosuppressive to raise concern about the

safety of administering live virus vaccines. Persons who have received systemic corticosteroids in doses of 2 mg/kg of body weight or 20 mg daily or on alternate days for an interval of 14 days or longer should avoid receiving vaccination with MMR and its component vaccines for at least 1 month after cessation of steroid therapy.[111] Persons who have received prolonged or extensive topical, aerosolized, or other local corticosteroid therapy that causes clinical or laboratory evidence of systemic immunosuppression also should avoid receiving vaccination with MMR for at least 1 month after cessation of therapy.[111]

The live attenuated measles virus vaccine used for immunization is not communicable. Therefore, contacts of immunocompromised patients should be vaccinated to prevent the spread of natural measles to such patients.

Although no direct evidence has demonstrated that measles vaccine is harmful to a pregnant woman or her fetus, the vaccine should not be administered to women known to be pregnant or who are considering becoming pregnant, because of the theoretical risk of fetal infection associated with a live virus vaccine. Women vaccinated with MMR should avoid conception for 28 days after being vaccinated.[130]

Because measles vaccination may diminish cutaneous manifestations of cell-mediated immunity temporarily, a tuberculin test performed several days to 6 weeks after receiving immunization can yield a false-negative result. Although natural measles infection can exacerbate tuberculosis, no evidence indicates that measles vaccination is associated with such an effect. Therefore, tuberculin skin testing is not a prerequisite for administering measles immunization. If a tuberculin test is indicated, it should be performed on the day of immunization or postponed for 4 to 6 weeks because measles vaccination may suppress tuberculin reactivity temporarily.

In persons allergic to eggs, the risk of having serious allergic reactions such as anaphylaxis after receiving MMR vaccine is extremely low, and skin testing with vaccine is not predictive of allergic reaction to vaccination.[14,288,296] Therefore, obtaining a skin test is not required before administering MMR to persons who are allergic to eggs. Similarly, the administration of gradually increasing doses of vaccine is not required.[111] Data indicate that most anaphylactic reactions to measles- and mumps-containing vaccines are not associated with hypersensitivity to egg antigens but to other components of the vaccines such as the gelatin stabilizer.[242,262,295,318]

Children with a previous history of thrombocytopenic purpura or thrombocytopenia may be at risk for developing clinically significant thrombocytopenia after receiving immunization with MMR.[54,280] The decision to vaccinate should be based on the benefits of immunity to measles, mumps, and rubella and the risk of re-occurrence or exacerbation of the thrombocytopenia after receiving vaccination or from natural infection with measles or rubella. For children in whom thrombocytopenia develops in the month after receiving a dose of measles-containing vaccine, withholding the second dose of measles vaccine is prudent if the incidence of measles remains low.

Receipt of antibody-containing blood products (whole blood, plasma, or parenteral immunoglobulin) may interfere with seroconversion to measles vaccine. High doses of immunoglobulin preparations can inhibit the immune response to measles vaccine for 3 or more months, depending on the dosage.[435] The length of time that such passively acquired antibody persists depends on the concentration and quantity of the blood product received (Table 255–14).[14,308]

As with any condition that induces fever during the second year of life, children predisposed to having febrile seizures may

TABLE 255–14 Suggested Intervals between Immune Globulin Administration and Measles or Varicella Vaccination

Product/Indication	Route	Dose		Interval (mo)*
		U or mL	mg/kg

ITP or Kawasaki disease	IV		1600-2000	11

**These intervals should provide sufficient time for decreases in passive antibodies in all children to allow for an adequate response to measles or varicella vaccine. Physicians should not assume that children are fully protected against measles during these intervals. Additional doses of immune globulin or measles vaccine may be indicated after exposure to measles.*

CMV, cytomegalovirus; HBIG, hepatitis B immune globulin; IG, immune globulin; IM, intramuscular; ITP, immune thrombocytopenic purpura; IV, intravenous; IVIG, intravenous immune globulin; RIG, rabies immune globulin; RBCs, red blood cells; RSV, respiratory syncytial virus; TIG, tetanus immune globulin; VariZIG, varicella-zoster immune globulin.

experience seizures after receiving measles vaccination. Most convulsions that develop after receiving measles immunization are simple febrile seizures and occur in children without known risk factors. Febrile seizures that occur after the administration of vaccinations do not increase the risk for the subsequent development of epilepsy or other neurologic disorders.[52] An increased risk of having seizures after receiving measles vaccination may occur in children with a previous history of convulsions or those with a history of convulsions in first-degree family members.[473] Although the exact risk cannot be determined, it appears to be low. The recommendation to immunize children with a personal history of seizures or those with a history of seizures in first-degree family members is based on factors indicating that the benefits greatly outweigh the risks. Prophylactic use of anticonvulsants usually is not feasible because therapeutic concentrations of many currently prescribed anticonvulsants are not achieved for some time after the initiation of therapy.

MENINGOCOCCAL VACCINE

N. meningitidis became a leading cause of bacterial meningitis in the United States after dramatic reductions in the incidence of *Streptococcus pneumoniae* and Hib infections occurred with the introduction of conjugate vaccines.[425,496] The disease is transmitted by person-to-person spread through close contact. Meningococcal disease is fatal in 10 to 14 percent of cases. Of patients who recover, 11 to 19 percent have permanent hearing loss, mental retardation, loss of limbs, or other serious sequelae.

Each year, an estimated 1400 to 2800 cases of meningococcal disease occur in the United States. Although rates of disease are highest among children aged younger than 2 years old, 62 percent of meningococcal disease in the United States occurs among persons aged 11 years and older.[61] Serogroups B, C, and more recently Y are the major causes of meningococcal disease in the United States, and each serogroup is responsible for approximately one third of cases. The proportion of cases caused by each serogroup varies by age group. Among infants aged younger than 1 year, more than 50 percent of cases are caused by serogroup B, for which no vaccine is licensed or available in the United States.[413] Of all cases of meningococcal disease among persons aged 11 years and older, 75 percent are caused by serogroups (C, Y, or W-135), which are included in vaccines available in the United States.

An increased incidence of meningococcal disease in adolescents and young adults was noted in the United States in the mid-1990s.[258,414] A prospective surveillance study of meningococcal disease among college students by the CDC and the American College Health Association suggested that the incidence is similar to that of the general population of 18- to 22-year-olds but that dormitory residents, especially freshmen, are at increased risk.[73] In a Maryland study, the incidence of disease was significantly higher in on-campus residents than off-campus residents.[257] In 2000, ACIP and the AAP concluded that college students, especially those living in dormitories, are at moderately increased risk for acquiring meningococcal disease compared with other persons their age[119] and recommended that (1) college students and their parents be informed by health care providers of the risks of acquiring meningococcal disease and of the potential benefits of vaccination, (2) college and university health services facilitate implementation of educational programs about meningococcal disease and the availability of vaccination services, and (3) meningococcal vaccine be made available to those persons requesting vaccination. As of November of 2004, a total of 31 states had adopted legislation requiring colleges to provide information on risks of acquiring meningococcal disease either to matriculating students or to students residing on campus, and 10 states had mandated vaccination for certain students, unless a vaccination waiver is provided.

Since the early 1990s, outbreaks of meningococcal disease have occurred with increasing frequency in the United States. From July 1994 to June 2002, a total of 76 outbreaks were identified.[72] Serogroup C accounted for 63 percent of the outbreaks, 25 percent were serogroup B, and 12 percent were serogroup Y. These outbreaks accounted for fewer than 2 percent of the total number of cases of meningococcal disease in the United States during this period. One third of the outbreaks were community-based and the remainder organization-based, occurring in colleges, primary and secondary schools, and nursing homes.

In other parts of the world, the number of cases is much higher.[146] In the sub-Saharan African "meningitis belt," which extends from Mali to Ethiopia, peaks of serogroup A meningococcal disease occur regularly during the dry season. In addition, major epidemics occur every 8 to 12 years. The last epidemic during 1996 to 1997 resulted in 213,658 cases, with 21,830 deaths. Meningococcal disease continues to cause epidemics outside the meningitis belt, including epidemics in the Great Lakes of Africa. Serogroup W-135 also emerged as an epidemic strain causing disease in Saudi Arabia in association with the Hajj pilgrimage in 2000, in Burkina Faso in 2002, and in several African countries in 2003 and 2004.

Preparations

Two meningococcal vaccines are licensed in the United States for use in children and adults against serotypes A, C, Y, and W-135. The tetravalent meningococcal polysaccharide vaccine (MPSV4) was licensed in 1981 for use in children 2 years of age and older and has been recommended for use only for people at increased risk of acquiring meningococcal disease. Each vaccine dose contains 50 mg of each of the four purified bacterial capsular polysaccharides.[123] MPSV4 is available both as a single dose that is thimerosal preservative-free and in 10-dose vials that contain 25 μg of thimerosal/0.5 mL; 50-dose vials no longer are available. The MPSV4 is administered subcutaneously as a single 0.5-mL dose.

The second vaccine, a tetravalent meningococcal polysaccharide–protein conjugate vaccine (MCV4), is licensed for use among persons aged 2 to 55 years.[61] Each dose of vaccine contains 4 μg each of the four capsular polysaccharides conjugated to 48 μg of diphtheria toxoid. MCV4 is available as a single dose that is thimerosal preservative-free. The vaccine is administered intramuscularly as a single 0.5-mL dose.

No vaccine is available in the United States for prevention of serogroup B meningococcal disease because unconjugated group B polysaccharide is poorly immunogenic in humans.

Immunogenicity and Efficacy

POLYSACCHARIDE VACCINE

Protective antibody concentrations are achieved within 10 to 14 days of administration of MPSV4. Both vaccines elicit protective levels of bactericidal antibody to all four serogroups in more than 97 percent of recipients as measured at 28 days after vaccination. The antibody responses to each of the four polysaccharides in the polysaccharide vaccine are serogroup-specific and independent. Group A polysaccharide induces antibody in some children as young as 3 months, although a response comparable to that in adults is not achieved until the child is 4 to 5 years of age.[390] The serum antibody response to serogroup C is age-dependent, with a poor response in children younger than 2 years.[238] Serum concentrations of antibodies against group A and C polysaccharides decrease markedly during the first 3 years after receipt of a single dose of vaccine. The decrease in antibody occurs more rapidly in infants and young children than in adults.[294,510]

Field trials of A and C meningococcal vaccines in Europe and Africa demonstrated efficacy rates against serogroup A of 85 to 95 percent 1 year after vaccination.[390,478] After 3 years, efficacy rates were 67 percent in older children but only 10 percent in children younger than 4 years old at the time of immunization with serogroup A vaccine.[403] In an epidemic, serogroup C vaccine demonstrated clinical efficacy rates similar to those of the serogroup A vaccine.[451]

Serogroup Y and W135 antigens are immunogenic and safe in children more than 2 years of age. However, clinical efficacy has not been demonstrated as yet for these preparations.[4,44,475] Persons with deficiencies of the terminal components of serum complement and those with anatomic or functional asplenia have antibody responses to quadrivalent meningococcal vaccines consistent with protection.[416,419] However, the clinical efficacy of vaccination has not been evaluated in these persons.

CONJUGATE VACCINE

Protective antibody concentrations are achieved within 8 days after administration of MCV4.[61] In studies conducted among persons aged 11 to 55 years that compared the immunogenicity of conjugate vaccine with that of the polysaccharide vaccine at 28 days after vaccination, the percentage of subjects achieving at least a fourfold increase in bactericidal titer for each serogroup was higher in the MPSV4 group than in the MCV4 group for persons older than 18 years of age; nonetheless, the criteria for demonstrating immunologic non-inferiority to MPSV4 were still achieved. The percentage of subjects with at least a fourfold rise was highest for serogroup W-135 and lowest for serogroup Y. The percentage of subjects achieving a protective level of bactericidal antibody was greater than 97 percent for all serogroups in both MCV4 and MPSV4 groups.

Response to re-vaccination with MCV4 was assessed by administering MCV4 to subjects previously vaccinated with MPSV4 or MCV4 and to vaccine-naïve control subjects. All subjects in all three groups achieved protective bactericidal antibody titers at both 8 and 28 days after receiving MCV4. Subjects initially primed with MCV4 achieved higher bactericidal antibody concentrations than those of naïve control subjects for all serogroups except A. In contrast, bactericidal antibody titers of those primed with MPSV4 were lower than those of vaccine-naïve control subjects on both days 8 and 28 for all serogroups.

Little information is available to determine the need for or timing of re-immunization when the risk of acquiring disease continues or recurs. In children aged 11 years and older and in adults, concentrations of antibodies against serogroups A, C, Y, and W-135 3 years after a single dose of MCV4 are equal to or greater than those of people given MPSV4, and the duration of protection after the conjugate vaccine is expected to exceed 5 years. Studies to determine duration of protection and need for re-immunization with MCV4 are under way.

MPSV4 is to be administered subcutaneously, whereas MCV4 is to be administered intramuscularly. More than 100 persons have inadvertently received the MCV4 vaccine by the subcutaneous route. For a subset of these individuals, CDC determined that, although the serologic responses were lower after MCV4 was administered subcutaneously compared with intramuscularly, the proportions of individuals who achieved antibody levels thought to be protective were similar. Therefore, the CDC did not recommend that those who had received MCV4 needed to be re-immunized.[150]

Adverse Events

MPSV4 has been used extensively in mass immunization programs as well as in the military and among international travelers. Adverse reactions to MPSV4 generally are mild; the most frequent reactions are pain and redness at the injection site that last for 1 or 2 days.[48]

Estimates of the incidence of such local reactions have varied, ranging from 4 to 56 percent. Transient fever occurs in as many as 5 percent of vaccine recipients in some studies but is less common in older children and adults.

Among adolescents 11 to 18 years of age, safety of administering MCV4 and MPSV4 was assessed in two randomized, controlled trials. Common adverse reactions after MPSV4 and MCV4 immunization include localized pain, headache, and fatigue, all of which are mild and last for 1 to 2 days. Pain, induration, swelling, and redness at the injection site are slightly greater after administration of MCV4 compared with MPSV4. The frequency of local adverse reactions reported after MCV4 administration was similar to that reported after Td administration, which, like MCV4, is given intramuscularly. Fever is reported by 2 to 5 percent of adolescents who receive either MPSV4 or MCV4.[61]

GBS was reported in 17 persons, including 15 adolescents aged 11 to 19 years, who received MCV4 between July and September of 2006.[150] This CDC study could not determine with certainty whether MCV4 increases the risk for development of GBS. Because invasive meningococcal disease causes significant morbidity and mortality, the ACIP and AAP continue to recommend administration of MCV4. However, given the temporal association, the recommendation is that MCV4 should not be given to adolescents or adults with a history of GBS. Cases of GBS or other clinically significant adverse events after administration of MCV4 should be reported to the CDC (www.vaers.hhs.gov).

Indications

Routine childhood immunization with MPSV4 is not recommended because the infection rate in the general population is low, response is poor in young children, immunity is relatively short- lived, and the response to subsequent vaccine doses is impaired for some serogroups.[15,35,61] Immunization with MCV4 is recommended for children aged 2 to 10 years in high-risk groups, including those with functional or anatomic asplenia, terminal complement component, or properdin deficiencies, and children aged 2 to 10 years who travel to or reside in areas where *N. meningitidis* is hyperendemic or epidemic.

If MCV4 is unavailable, MPSV4 is an acceptable alternative for persons at elevated risk. MPSV4 is not recommended and should not be administered routinely for adolescents aged 11 to12 years or for adolescents entering high school. Adolescents in these age groups are recommended to receive only MCV4.

Routine vaccination of young adolescents (persons aged 11 to 12 years) with MCV4 is recommended at the preadolescent health care visit (at age 11 to 12 years). Students entering college who plan to live in dormitories should be immunized with MCV4 routinely. People at increased risk of acquiring meningococcal disease should be immunized with MCV4 if they are at least 2 years of age. These people include those who have terminal complement or properdin deficiencies, have anatomic or functional asplenia, or travel to or reside in countries where *N. meningitidis* is hyperendemic or epidemic. Because people with HIV infection are likely to be at higher risk of acquiring meningococcal disease, although not to the extent that they are at risk of acquiring invasive *S. pneumoniae* infection, they may elect to be immunized with MCV4 if they are at least 2 years of age. People who wish to decrease their risk of contracting meningococcal disease may elect to receive MCV4 if they are 2 years of age or older. Immunization with MCV4 may be indicated for adolescents previously immunized with MPSV4. These people should

be considered for re-immunization 3 to 5 years after receiving MPSV4 if they remain at increased risk of contracting meningococcal disease. The same recommendation applies to entering college students previously immunized with MPSV4 and for people at high risk of developing an infection.

For control of meningococcal outbreaks caused by vaccine-preventable serogroups, the preferred vaccine in adults and children older than 2 years is MCV4, but MPSV4 is acceptable.

Precautions and Contraindications

Because of theoretical considerations, meningococcal polysaccharide vaccines should not be administered to pregnant women unless the risk of acquiring disease is substantial. However, evaluation of pregnant women immunized during an epidemic in Brazil demonstrated no adverse effects.[348]

Immunization with MCV4 is contraindicated among people known to have hypersensitivity to any component of the vaccine, including diphtheria toxoid, and to dry, natural rubber latex, which is used in the vial stopper. Because of the temporal association between MCV4 and GBS, MCV4 should not be given to adolescents or adults with a history of GBS who are not in a high-risk group for developing invasive meningococcal disease.

MUMPS VACCINE

Live virus mumps vaccine became available in the United States in 1967 and was recommended for routine use in 1977. After vaccine licensure, the incidence of reported mumps cases decreased rapidly. A relative resurgence of mumps occurred in 1986 and 1987. In 1989, the ACIP and AAP implemented a two-dose combined MMR schedule given at 4 to 6 or at 11 to 12 years of age. After implementation of the two-dose MMR vaccination requirement, the incidence of mumps disease decreased and reached a record low of 258 cases in 2004.[132]

Before vaccine licensure in 1967 and during the early years of vaccine use, most reported cases occurred in the 5- to 9-year age group; 90 percent of cases occurred among children 15 years of age and younger. In the late 1980s, a shift toward older children occurred. Since 1990, persons age 15 years and older have accounted for 30 to 40 percent of cases per year.

Between January and October of 2006, more than 5700 confirmed or probable mumps cases were reported, predominantly among patients aged 18 to 24 years, many of whom were college students. Twelve midwestern states were most affected, but sporadic cases were documented in many other states, mostly related to travel from primary outbreak areas. Nearly half of all cases occurred in Iowa, where the resurgence began.[149] The outbreak underscored limitations in the 1998 recommendations relating to prevention of mumps transmission in health care and other settings with high risk for mumps transmission. After reviewing data from this outbreak and previous evidence on mumps vaccine effectiveness and transmission, the ACIP issued updated recommendations for mumps vaccination.[153]

Preparations

The live attenuated mumps virus vaccine (Jeryl Lynn strain) in current use in the United States is prepared in chick embryo cell culture and is available individually (monovalent, mumps only) and in combination as mumps-rubella vaccine, MMR, and MMRV. The AAP and ACIP recommend that combined MMR vaccine be used when any of the individual components is indicated and MMRV is recommended if the vaccinee is 12 months through 12 years of age. Use of single-antigen mumps vaccine is not recommended.

Each dose of vaccine contains neomycin, sorbitol, and hydrolyzed gelatin as stabilizers. Before reconstitution, mumps vaccine must be stored at 2 to 8° C (35.6° F to 46.4° F) or colder and protected from light to avoid inactivation. After reconstitution, the vaccine should be used within 8 hours or discarded.

Immunogenicity and Efficacy

The vaccine induces an asymptomatic, noncommunicable infection. More than 97 percent of susceptible recipients develop protective antibody titers, albeit lower than those after natural infection.[488] Post-licensure studies in the United States demonstrated that one dose of mumps vaccine was 78 to 91 percent effective in preventing clinical mumps with parotitis.[395] Studies of vaccine effectiveness during outbreaks suggested substantially higher levels of protection with a second dose of MMR.[70,256,389]

The effectiveness of the mumps component of MMR vaccine was estimated during the large outbreak in the United Kingdom in 2004 to 2005. Vaccine effectiveness was 88 percent for one dose and 95 percent for two doses. The effectiveness of one dose declined from 96 percent in 2-year-olds to 66 percent in 11- to 12-year-olds, and the effectiveness of two doses declined from 99 percent in 5- to 6-year-olds to 86 percent in 11- to 12-year-olds.[177]

The duration of vaccine immunity is unknown, but serologic data showed persistence of antibody for more than 30 years.[486] However, data from more recent studies suggested that waning immunity may contribute to mumps outbreaks in older vaccinated populations.[177]

Adverse Events

The use of mumps vaccine is associated with very few side effects. Parotitis and fever have been reported rarely. Hypersensitivity reactions, including rash, pruritus, and purpura, have been associated temporally with vaccination, but they are transient and generally mild. Administration of MMR is not harmful if it is given to an individual already immune to one or more of the viruses.[16,111]

The frequency of reported central nervous system dysfunction after vaccination is not greater than the observed background rate in unimmunized persons.[111] The IOM concluded that evidence is inadequate to establish a causal relationship between the Jeryl Lynn strain of mumps vaccine used in the United States and aseptic meningitis, encephalitis, or sensorineural deafness.[280]

Indications

Routine active immunization as MMR in children 12 to 15 months of age is recommended.[16,111,149] Most children will receive a second dose of mumps vaccine in childhood as a result of the recommendation for routine measles re-vaccination with MMR. Susceptible older children, adolescents, and adults also should be vaccinated against mumps.

Evidence of immunity through documentation of vaccination is now defined as one dose of live mumps vaccine for preschool-age children and adults not at high risk for exposure and infection and two doses of live mumps vaccine for school-age children (i.e., grades kindergarten to12) and adults at high risk for exposure and development of infection (i.e., health care workers, international travelers, and students at post–high school education institutions). Additional recommendations for outbreak control include administering a second dose of MMR for preschool children and adults not at high risk for exposure and acquisition of infection if these persons are part of a group that is experiencing an outbreak.[149] To ensure high levels of immunity, especially among groups at high risk for exposure and development of infection,

every opportunity should be used to provide the first or second dose of MMR vaccine to those without adequate evidence of immunity (e.g., documentation of vaccination).

Mumps remains endemic throughout most of the world. Although vaccination against mumps is not a requirement for entry into any country, susceptible children, adolescents, and adults born after 1956 should be offered mumps vaccination, usually as MMR, before engaging in international travel.

Mumps vaccine is of no proven value in the prevention of disease in susceptible individuals after exposure to mumps, probably because the time required to develop protective antibody titers after immunization exceeds the incubation period of clinical mumps. However, if the exposure does not result in infection, the vaccine confers subsequent immunity.

Precautions and Contraindications

Among persons who are allergic to eggs, the risk of having serious allergic reactions such as anaphylaxis after receiving MMR is extremely low, and skin testing with vaccine is not predictive of allergic reaction to vaccination [16,288,296] Therefore, performing skin testing is not required before administering MMR to persons who are allergic to eggs. Similarly, the administration of gradually increasing doses of vaccine is not required.[111] Data indicate that most anaphylactic reactions to measles- and mumps-containing vaccines are not associated with hypersensitivity to egg antigens but rather with hypersensitivity to other components of the vaccines, such as the gelatin stabilizer.[242,262,295,318]

Because of the theoretical risk of fetal damage, mumps vaccine should not be administered to women known to be pregnant or who are considering becoming pregnant. Women vaccinated with MMR should avoid conception for 28 days after vaccination.[130]

Lymphoreticular or other generalized malignancy and primary or secondary immunodeficiency states represent contraindications to the use of mumps vaccine. Exceptions are children with HIV infection who are immunized against measles with MMR (see "Measles Vaccine"). Because infection after vaccination is noncommunicable, susceptible close contacts of immunosuppressed patients should be vaccinated to avoid exposure to mumps in such patients.

After cessation of immunosuppressive therapy, live virus mumps vaccine generally is withheld for at least 3 months. Because the intensity and type of immunosuppressive therapy, radiation therapy, underlying disease, and other factors determine when immunologic responsiveness will be restored, making a definitive recommendation for an interval after cessation of immunosuppressive therapy when mumps vaccine can be safely and effectively administered often is not possible.

The effect of immune globulin preparations on the response to mumps vaccine is unknown. High doses of immune globulin preparations can inhibit the immune response to measles vaccine for 3 or more months, depending on the dosage.[341] If mumps vaccine is given as the MMR vaccine, the recommendations for measles vaccine should be followed (see Table 255–14).

Administration of mumps vaccine should be avoided if the individual is receiving immunosuppressive dosages of systemic corticosteroids. The effects of corticosteroids vary, but many clinicians consider that a dose equivalent to either 2 mg/kg of body weight or 20 mg/day of prednisone is sufficiently immunosuppressive to raise concern about the safety of vaccination with live virus vaccines.

PERTUSSIS VACCINE

Pertussis (whooping cough), caused by the fastidious, gram-negative, pleomorphic bacillus *B. pertussis*, continues to produce significant morbidity and mortality worldwide among young children.[365] In the absence of vaccination, the WHO estimated that approximately 1 million deaths would have occurred from the disease and its complications. In the United States, the number of cases has been reduced by approximately 95 percent during the vaccine era. Despite an effective vaccine, however, pertussis continues to occur in the United States in all age groups. Since the historic low point achieved in the 1980s, the incidence of pertussis has increased steadily. Surveillance data collected by the CDC's National Immunization Program for the periods from 1994 to 1996 and 1997 to 2000 demonstrated that the incidence of pertussis increased 60 percent in adolescents and adults and 11 percent in infants younger than 6 months.[136] Data from the National Notifiable Disease Surveillance System reveal an escalation in the increase in all age groups between 2001 and 2004.[71] Incidence rates among the pediatric population peak in infants younger than 6 months of age and again during adolescence between 11 and 18 years of age.[36] The increase in the number of cases among young infants suggests that a true increase in pertussis circulation has occurred. The number of cases in children old enough to receive vaccine has remained stable. The likely reason that pertussis remains endemic in the United States despite high vaccination rates is that neither infection nor immunization provides life-long immunity. Humans are the only known reservoir for pertussis; immunity wanes after 5 to 10 years, thus maintaining a population of susceptible hosts for the continued circulation of bacteria.

The experiences of countries where rates of pertussis vaccination have markedly declined provide strong support for continuing routine immunization of infants and young children.[165] In the United Kingdom, as a result of adverse publicity about pertussis vaccination, a decrease in immunization rates in 2-year-old children from 77 percent in 1974 to 30 percent in 1978 was followed by an epidemic of 102,500 cases of pertussis. A similar experience occurred in Japan, which reported 13,105 cases and 41 deaths in 1979 after routine immunization had been suspended temporarily in 1975.

In the United States during the 1980s, publicity about alleged serious reactions to pertussis vaccine generated public controversy about the risk of receiving pertussis vaccine that resulted in costly litigation and escalating vaccine costs and also jeopardized vaccine supply and development.[364,391] The experience in countries such as England and Japan, the severity of pertussis in young infants, and the usually benign or self-limited sequelae of pertussis vaccination clearly justify continuing routine childhood immunization. Several risk-to-benefit analyses provided additional evidence in support of vaccination.[165,267]

Effective primary preventive programs necessitate immunizing young infants, usually beginning at 2 months of age, because the morbidity and mortality of pertussis are greatest in infants, especially those younger than 6 months.[99,165] Approximately 26 percent of reported cases in the United States occur in infants younger than 6 months. During the period from 1997 to 2000, the case-fatality rate for infants younger than 6 months was 0.8 percent; 63 percent of these infants were hospitalized with frequent complications including pneumonia (11.8%), seizures (1.4%), and encephalopathy (0.2%).[136] From 2000 to 2004, 100 pertussis-related deaths were reported; 90 percent were among infants younger than 4 months of age and 76 percent occurred in infants younger than 2 months of age.[71] Maintaining high rates of immunization in children beyond infancy, with booster immunization for adolescents and adults, may reduce the risk of infection in infants by decreasing the incidence of infection in older family members and the resultant transmission of *B. pertussis* within the household. Vaccination, including boosters, is essential because the disease is highly infectious and transmission often occurs before adults seek medical care.

Preparations

Whole-cell pertussis vaccine was introduced first in the United States in the 1920s. Not until the 1940s to 1950s, however, did pediatric whole-cell pertussis vaccine became routinely recommended for children. This vaccine, unavailable in the United States since 2002, consisted of a suspension of inactivated *B. pertussis* combined with diphtheria and tetanus toxoids (DTP).[71] To reduce the incidence of local and systemic reactions caused by whole-cell vaccines, less reactogenic pediatric acellular vaccines composed of one or more purified components of *B. pertussis* combined with diphtheria and tetanus toxoids (DTaP) were developed. Initially licensed in 1991 for use as the fourth or fifth dose in the series, DTaP was licensed in 1997 for all five doses in the series. Numerous acellular vaccines formulated from the different components have been tested in children. All currently U.S. licensed vaccines contain detoxified/inactivated pertussis toxin (i.e., pertussis toxoid) and filamentous hemagglutinin (FHA).[199] In addition, most vaccines include one or both of the following *B. pertussis* antigens: pertactin (PRN, a 69-kd outer-membrane protein), and fimbriae proteins (FIM, agglutinogens). The various vaccines differ in the amount of each component. No pertussis-only vaccine is available.

From 2001 until 2008, numerous changes were made to the list of licensed acellular pertussis–containing vaccines available in the United States. Three acellular vaccines currently are available for use in the primary vaccination series for children younger than 7 years of age (Table 255–15). Tripedia (Sanofi Pasteur) and Infanrix (GlaxoSmithKline Biologicals) are licensed for the five-dose DTaP vaccination series, and Daptacel (Sanofi Pasteur) is licensed for the first four doses of DTaP vaccine only. Pediarix (GSK), which combines DTaP with IPV and HBV vaccines, was licensed in 2002 for the first three doses in the DTaP series for use in children 6 weeks to 6 years old and born to mothers known to be HBsAg-negative. This vaccine is not approved for the first HBV vaccine, for the fourth or fifth DTaP dose, or for infants born to women known to be HBsAg-positive or whose hepatitis B status is unknown. TriHIBit (Sanofi Pasteur), the combination of Tripedia and ActHIB (Hib conjugate vaccine), was licensed by the FDA in 2001 for use as the fourth booster dose given when the infant is 15 to 18 months of age and not for use as part of the initial three-dose series. Pentacel (Sanofi Pasteur), which combines DTaP with IPV and Hib (PRP-T) vaccines, was licensed in 2008 for the first four doses in the DTaP series in children 6 weeks to 6 years of age. Kinrix (GSK), a combination of DTaP with IPV, was also licensed in 2008 for use for the fifth dose of DTaP in children 4 to 6 years of age.

For enhanced control of pertussis, routine re-vaccination of adolescents and adults with an acellular pertussis vaccine is recommended now to minimize the morbidity associated with infection in these age groups and to reduce the reservoir of infection. In 2005, the FDA licensed two Tdap vaccines (see Table 255–15); Boostrix (GSK) is approved for adolescents aged 10 to 18 years, and Adacel (Sanofi Pasteur) is approved for adolescents and adults aged 11 to 64 years. Both Tdap vaccines contain the same pertussis antigen components as are in the pediatric vaccines (some in reduced quantities). The tetanus and diphtheria components are the same as for the current adult formations of Td, with reduced diphtheria content as recommended for use in persons 7 years of age and older.

The ACIP recommends that, whenever feasible, the same DTaP vaccine product be used for all doses of the vaccination series. If the vaccine provider does not know or does not have available the type of DTaP previously administered, any of the available licensed DTaP vaccines may be used to complete the vaccination series.[126]

Immunogenicity

The Multicenter Acellular Pertussis Trial evaluated the immunogenicity and safety of 13 different acellular pertussis–containing vaccines as compared with whole-cell DTP administered to infants at 2, 4, and 6 months of age in the United States.[199] Serologic correlates of immunity to diphtheria and tetanus toxoids, defined as antibody levels 0.1 IU/mL or greater, were achieved after vaccination with Tripedia and Infanrix and were comparable with those achieved with DTP vaccination. Pertussis immunity, determined by at least a fourfold rise in antibody titer to pertussis toxin and FHA, was equal to or greater than with DTP, following immunization with either of the two DTaP vaccines noted earlier.[211]

Efficacy

For both whole-cell and acellular vaccines, serologic correlates of immunogenicity have not been established for assessing efficacy. As a result, field and other epidemiologic studies must be performed to demonstrate efficacy. Studies in the United States of household contacts exposed to pertussis indicate that the efficacy of whole-cell vaccine was 80 percent or greater.[99,165,376] Studies reporting lower rates of vaccine efficacy often reflect the use of different criteria for the diagnosis of pertussis and lesser effectiveness of the vaccine in protecting against mild infection than against severe disease.[217] Vaccine-induced immunity persists for at least 3 years and subsequently diminishes with time. Pertussis in individuals previously vaccinated is less severe and is associated with fewer complications than in unvaccinated persons.

In studies of the efficacy of eight acellular pertussis vaccines in infants, rates of prevention of pertussis ranged from 58 to 93 percent.[396] Comparing efficacy among the different products, however, often is not possible because of differences in study design, vaccine schedule (specifically, the number of doses and age of administration), case definitions of pertussis, and other confounding variables. In general, these acellular vaccines appear to be similar in efficacy to most whole-cell vaccines. Whereas in two large trials in Sweden and Italy several acellular vaccines

TABLE 255–15 Acellular Pertussis Vaccines Licensed for Use in the United States

Trade Name	Vaccine Manufacturer	No. of Pertussis Antigens	Antigenic Content	Dose Series Approved
DTaP Vaccines for Children <7 yr of Age				
Tripedia	Sanofi Pasteur	2	PT, FHA	5
Infanrix	GlaxoSmithKline Biologicals	3	PT, FHA, PE	5
DAPTACEL	Sanofi Pasteur	5	PT, FHA, PE, 2 types of FIM	4
Tdap Vaccines for Adolescents				
BOOSTRIX	GlaxoSmithKline Biologicals	3	PT, FHA, PE	1
ADACEL	Sanofi Pasteur	5	PT, FHA, PE, 2 types of FIM	1

DTaP, diphtheria-tetanus-acellular pertussis; FHA, filamentous hemagglutinin; FIM, fimbriae; PE, pertactin; PT, pertussis toxin; Tdap, tetanus-diphtheria-acellular pertussis.

demonstrated substantially greater efficacy than noted in the one U.S. whole-cell vaccine previously approved, other whole-cell vaccines studied appeared to be slightly more effective than were acellular vaccines in other trials.[210] In addition, the vaccines in these Swedish and Italian trials were given in a three-dose schedule, in contrast to the four-dose primary schedule for vaccination of young children in the United States.

Adverse Events

Local and febrile reactions to whole-cell vaccines occur in more than half of DTP recipients.[176] These manifestations usually develop within the first 24 hours and are brief in duration. More serious reactions to whole-cell vaccines are uncommon. Such reactions include prolonged crying for 3 hours or longer occurring within the first 48 hours of receiving vaccination (1% to 3% of DTP recipients) and a temperature of 40.5° C or greater (≥104.8° F) within 48 hours (0.3%); a hypotonic-hyporesponsive episode (HHE) described as collapse or shocklike state within 48 hours and seizure within 3 days of vaccination each was estimated to occur once per 1750 doses.[176] Episodes of inconsolable crying, high fever, and HHE reactions following receipt of DTP vaccine resolved without sequelae. Most post-DTP seizures occurring within 48 hours of receipt of vaccine are brief, self-limited, and generalized and occur in association with fever. These seizures have not been demonstrated to result in the subsequent development of epilepsy or other neurologic sequelae. Predisposing factors include an underlying convulsive disorder, a personal history of previous convulsion, and a family history of convulsions.[106]

The incidence of local and febrile reactions after the administration of acellular vaccines is significantly lower.[199,396] Comparison of rates of adverse events with different acellular vaccines compared with whole-cell vaccines demonstrated similar safety profiles for each of these vaccines.[168,424] The most common adverse events include injection site reactions (erythema, induration, tenderness) and the following mild system symptoms: slight to moderate fever, drowsiness, irritability, and loss of appetite. Rates of local reactions increase with each subsequent dose of DTaP vaccine.[394,455] Booster doses of acellular pertussis vaccine may be associated with extensive local swelling (i.e., limb swelling), especially with vaccines having a high diphtheria content.[404] The pathogenesis of this reaction is not understood but spontaneously resolves without sequelae and is not associated with an increased risk of similar adverse events occurring after receipt of the fifth dose.[17] Severe reactions to acellular vaccines such as prolonged crying for 3 hours or longer, temperatures of 40.5° C or greater (≥104.8° F), HHEs, and seizures are rare occurrences.[168,199,239,247,396,424,456,458] As with local and febrile reactions, these occurrences with acellular pertussis vaccination are significantly less frequent than those that occur after administration of whole-cell vaccination.

SERIOUS NEUROLOGIC ILLNESS

The National Childhood Encephalopathy Study (NCES), a large case-control study from Great Britain that was published in 1985, estimated that the occurrence of acute neurologic illness resulting in hospitalization was 1 in 140,000 DTP vaccinations.[355] In a 10-year follow-up study published in 1993, neurologic sequelae were found to be common occurrences, but no more so than in children with unrelated, acute neurologic illness in infancy,[354] and reviews of the data have disputed the conclusion that pertussis vaccine can cause neurologic sequelae.[27,106,447] More recent data from Canada evaluating more than 12,000 pediatric hospitalizations for serious neurologic illness between 1993 and 2002 found no association after administration of more than 6.5 million doses between development of encephalopathy and receipt of DTaP vaccination.[17] Taken together, the data do not support a role for whole-cell pertussis vaccine in causing brain damage.[88]

Indications

Vaccination against pertussis with DTaP is recommended routinely for children at 2, 4, and 6 months of age, followed by a fourth dose at 12 to 18 months of age and a fifth dose at 4 to 6 years of age.[17,36,71] Immunization can be started when the child is as young as 6 weeks of age if pertussis is prevalent in the community. The interval between administrations of the three doses of the initial series can be as short as 4 weeks. The AAP and ACIP recommend exclusive use of acellular pertussis vaccines for all doses of the pertussis vaccine series.[17,36,71] DTP is not an acceptable alternative because of its higher rates of local reactions, fever, and other common systemic reactions. However, in many countries, including several in Europe as well as in developing countries, whole-cell vaccine remains the recommended product.

A single dose of Tdap is now recommended for adolescents aged 11 to 18 years; the preferred age is 11 to 12 years, for those who have completed their primary DTP/DTaP series and have not yet received the adult tetanus and diphtheria toxoids (Td) booster.[17,36,71] Adults aged 19 to 64 years who have not received Tdap previously should receive a single dose of Tdap in place of the Td booster if 10 years or more have transpired since they last received a tetanus-containing vaccine. Intervals as short as 2 years have been shown to be safe,[17,36,71] and intervals of 2 years or less may be indicated in certain high-risk situations (e.g., adults who are likely to have close contact with an infant younger than 12 months, exposed health care personnel). Women should receive Tdap before becoming pregnant. Women who have not been immunized previously with Tdap should receive Tdap in the immediate postpartum period. Every 10 years thereafter, booster vaccination should be provided by Td (or TT).

Adolescents between the ages of 11 and 18 years who have never been vaccinated against tetanus, diphtheria, or pertussis should initially receive a single dose of Tdap followed by Td for the subsequent two doses at 4 weeks or more and 6 to 12 months later. No pertussis-containing vaccine is approved for children between the ages of 7 and 10 years. For these children who have not previously been vaccinated, three doses of Td are recommended at 0 (initial dose), 4 weeks or more, and 6 to 12 months. The third dose may be delayed until the child is old enough to receive Tdap; otherwise, a booster with Tdap is recommended in adolescence.

As further protection against transmission of pertussis to infants who are at greatest risk of pertussis-related morbidity or mortality compared with other age groups, the ACIP has recommended the use of Tdap vaccine in pregnant girls and women between the ages of 11 and 64 years, including those breast-feeding who have previously not received Tdap vaccine.[17,36,71,307]

Contraindications and Precautions

The contraindications and precautions for administering pertussis vaccine are based on adverse reactions associated with whole-cell vaccine. Although reactions occurring after the administration of DTaP are much less common than are those associated with DTP, at present, the contraindications and precautions for DTaP are the same.[17,36,71] Adverse events temporally related to pertussis immunization that contraindicate further administration of DTaP are as follows:

- An immediate anaphylactic reaction. Subsequent immunization with any of the three components of the vaccine should be avoided.

- Encephalopathy occurring within 7 days. Encephalopathy in this context is defined as a severe, acute, central nervous system disorder unexplained by another cause and may be manifested by major alterations in consciousness or by generalized or focal seizures that persist for more than a few hours without recovery within 24 hours. Additional doses of DT (or Td) vaccine should be substituted for any pertussis-containing vaccine.

Post-vaccination reactions constituting precautions are as follows:

- A convulsion, with or without fever, occurring within 3 days of receiving DTP or DTaP vaccination
- Persistent, severe, inconsolable screaming or crying for 3 or more hours within 48 hours of vaccination
- HHE occurring within 48 hours of vaccination
- Temperature of 40.5° C or of 104.8° F or greater that is unexplained by another cause and occurs within 48 hours of vaccination

With these adverse events occurring in temporal association with DTaP vaccination, the decision to administer additional doses of pertussis vaccine should be considered carefully. In circumstances such as a pertussis outbreak in which the potential benefits of pertussis immunization outweigh the possible risks, vaccination is indicated, particularly because these events have not been proved to cause permanent sequelae. In addition, the risk of these reactions occurring after receipt of DTaP is substantially lower than after receipt of DTP.

In children with an evolving neurologic disorder, pertussis immunization should be deferred until the nature and cause of the disorder have been established. A personal history of having a previous convulsion unrelated to DTaP vaccination or a family history of convulsions (in the absence of a possible evolving neurologic disorder) is not a contraindication.

PNEUMOCOCCAL VACCINE

S. pneumoniae is a leading bacterial pathogen, especially among young children, elderly persons, and persons with predisposing conditions. In children, it is the most common cause of otitis media, occult bacteremia, and bacterial pneumonia requiring hospitalization. After the widespread introduction of conjugate Hib vaccination and subsequent marked decline in occurrence of Hib meningitis, *S. pneumoniae* became a leading cause of bacterial meningitis in children in the United States. In some populations, such as Native Alaskans, the incidence of bacteremia is markedly higher than that reported in other geographic areas of the United States.[197] Groups considered at high risk for invasive pneumococcal disease include children with sickle-cell disease, asplenia, Hodgkin disease, congenital humoral immunodeficiency, HIV infection, and nephrotic syndrome, as well as recipients of organ transplants. Children who have received cochlear implants are at particular risk for developing meningitis.[139] Other chronic diseases associated with an increased risk for development of severe pneumococcal disease include chronic cardiovascular and pulmonary diseases, diabetes mellitus, and renal failure. The role of these chronic diseases in predisposing individuals to the development of pneumococcal infection, however, has been demonstrated primarily in adults. Mortality rates are highest in those who have bacteremia or meningitis, elderly persons, and patients with impaired humoral immunity or certain chronic diseases.

The purified polysaccharide vaccine has been effective in reducing severe disease in the adult population,[76] but it has had little impact in young children because the vaccine is not immunogenic in children younger than 2 years old.[18] In addition, the polysaccharide vaccine has not been effective in preventing otitis media caused by *S. pneumoniae*.[18]

Several factors have made the development of new preventive strategies for pneumococcal disease a high priority.[184] Morbidity and mortality rates of pneumococcal infection appear to be particularly high in developing countries. The increasing incidence of antimicrobial-resistant pneumococci further underscores the need for developing effective pneumococcal vaccines for young children.[69] Resistance of *S. pneumoniae* to multiple antibiotics has increased rapidly in the United States and even more rapidly in other parts of the world.[292] Children younger than 2 years of age have the highest rate of invasive pneumococcal infection but do not develop an effective antibody response to polysaccharide vaccine. In addition, children 2 to 5 years of age may have relatively poor responses to serotypes 6B, 14, 19F, and 23F, common causes of pediatric infections and the most prevalent penicillin-resistant serotypes.

These factors prompted the development of conjugated polysaccharide–protein vaccines, one of which has been licensed in the United States. These vaccines are similar in design to the licensed Hib conjugate vaccines. Because of the large number of serotypes of *S. pneumoniae* that cause disease, development of these conjugate pneumococcal vaccines has been more difficult than has the development of similar vaccines for Hib. Each pneumococcal antigen must be coupled to a protein carrier, and the vaccine must be prepared to ensure that antigen is sufficient to induce an immune response but insufficient to elicit an adverse reaction.

One potential problem with conjugate pneumococcal vaccines is the need to immunize against many different serotypes of pneumococci. Because of local reactions to the protein component, conjugate vaccines that contain more than 12 serotypes may be difficult to produce. As a result, different formulations of conjugate pneumococcal vaccine may be developed that would contain different serotypes targeted for a specific group of patients. Vaccine containing types 4, 6B, 9V, 14, 18C, 19F, and 23F (PCV7) would be necessary for prevention of otitis media in the United States, whereas types 1, 2, and 5 would need to be added to prevent pneumonia in developing countries. In addition, the use of conjugate vaccines against limited serotypes may lead to the emergence of pneumococcal serotypes that are currently less common and require adjustment of a vaccine's composition.[441]

Routine infant immunization using these conjugate vaccines has led to significant reductions in the instances of *S. pneumoniae* disease. Since the widespread introduction of the seven-valent pneumococcal conjugate vaccine in infants in 2000, rates of invasive pneumococcal disease have decreased markedly in the United States. The incidence of all invasive pneumococcal infections has decreased by 80 percent for children younger than 2 years of age and by up to 90 percent for infections caused by vaccine and vaccine-related serotypes.[18,496] An increase in non-vaccine serotype disease has occurred, but it is small compared with the overall reductions in vaccine-type disease.[77,142]

A decline in the incidence of vaccine-type disease in unvaccinated children and adults has occurred since the introduction of routine vaccination for infants in the United States.[142] In addition, rates of invasive pneumococcal disease in infants younger than 2 months of age have decreased significantly, thus providing evidence that vaccinating children aged 2 to 23 months has led to changes in pneumococcal carriage in infants too young to receive PCV7.[398] Herd immunity is estimated to prevent twice as many cases as do the direct effects of vaccination alone.[142] Although the exact mechanism of herd immunity is uncertain, one hypothesis is that vaccinated children are less likely to have nasal carriage of pneumococcus and hence less pneumococcal transmission to their contacts.[192] Use of conjugate vaccines has been demonstrated to reduce nasopharyngeal carriage of vaccine

serotypes.[194,195] Pneumococcal conjugate vaccination also has led to increased nasopharyngeal colonization of children with non-vaccine serotypes.[229,353] Ongoing surveillance of invasive pneumococcal disease is needed to determine whether non-vaccine serotypes will predominate.

Preparations

Two pneumococcal vaccines are available for use in children in the United States. The first is a heptavalent vaccine (PCV7) containing the capsular polysaccharides from serotypes 4, 6B, 9V, 14, 18C, 19F, and 23F conjugated to mutant diphtheria toxin (CRM_{197}). This vaccine (Prevnar, Wyeth Vaccines) was licensed in the United States in 2000. Serotypes included in PCV7 and potentially cross-reactive serotypes (i.e., 6A, 9A, 9L, 18B, and 18F) accounted for 86 percent of cases of bacteremia, 83 percent of cases of meningitis, and 65 percent of AOM cases occurring in children younger than 6 years in the United States during the period 1978 to 1994.[122] The second vaccine (PPV23 [Pneumovax]) is composed of purified, capsular polysaccharide antigens of 23 pneumococcal serotypes. Although 90 different serotypes have been identified, vaccine serotypes in the 23-valent vaccine are responsible for 85 to 90 percent of adult infections and nearly 100 percent of invasive disease and 85 percent of otitis media cases in children.[85,230] Each vaccine is recommended in a dose of 0.5 mL to be given intramuscularly.

Immunogenicity and Efficacy

The immunogenicity of the conjugate polysaccharide vaccine appears to be determined by the pneumococcal polysaccharide serotype, rather than by the carrier protein. Some serotypes (14, 18C, and 19F) are excellent immunogens in that they elicit antibody protection after a single dose, whereas others (6B and 23F) require three doses of vaccine.[213] Conjugate vaccine elicits immunologic memory.[213] The antibody concentrations achieved after the initial series of three doses usually are sustained for only a few months and then decline to nearly pre-immunization levels. A dose of pneumococcal vaccine, either polysaccharide or conjugate, given in the second year of life elicits an amnestic-type response.

The licensed heptavalent polysaccharide conjugate vaccine was studied in a large, prospective, placebo-controlled efficacy trial in northern California involving 38,000 children. The vaccine was 89 percent effective in preventing invasive disease caused by any pneumococcal serotype and 97 percent effective against disease caused by the seven vaccine serotypes.[63] For non-invasive disease, a decrease of 7 percent in the number of cases of otitis media and 23 percent in doctor visits for recurrent otitis (six or more visits per year) occurred in vaccinated children. The study also demonstrated an 11 percent decrease in the number of clinical cases of pneumonia and efficacy of 26 percent against a first episode of radiograph-confirmed pneumonia in vaccines.[254,432]

The ability of the heptavalent vaccine to protect children against AOM also was evaluated in an efficacy trial conducted in Finland.[214] For prevention of AOM caused by pneumococci of any serotype, efficacy was estimated to be 34 percent, whereas efficacy against AOM irrespective of etiology was 6 percent. Efficacy against AOM caused by vaccine-related serotypes was 57 percent, but an increase of 33 percent in the rate of AOM episodes caused by non-vaccine serotypes occurred in the group receiving the heptavalent vaccine in comparison with controls. However, in spite of the increase in disease caused by non-vaccine serotypes, the net effect on pneumococcal AOM was a reduction of 34 percent.

Randomized controlled trials conducted in African children using a nine-valent pneumococcal conjugate vaccine demonstrated efficacy in the prevention of radiologically confirmed pneumonia and vaccine-type invasive pneumococcal disease.[188,303] The vaccine was efficacious in preventing vaccine-type invasive disease in HIV-infected children.[303] One of the trials demonstrated a reduction in all-cause mortality among vaccine recipients.[188] These data have presented a compelling case for extending the benefits of pneumococcal conjugate vaccination to developing countries.

Vaccination with purified polysaccharide vaccine results in serologic type-specific antibody in most healthy adults and older children. Immunocompromised patients may respond less well. In children younger than 2 years old, antibody response is poor to most serotypes, including those most likely to cause infection, such as types 6A and 14.[85,108,230] Patients with AIDS have impaired antibody responses to vaccination, but asymptomatic HIV-infected adults do respond.[85,108]

Vaccine efficacy in preventing serious pneumococcal infection has been demonstrated for the purified polysaccharide vaccine primarily in immunocompetent adults, including elderly persons and those with chronic diseases such as chronic pulmonary and cardiac disorders and diabetes mellitus, which predispose these patients to development of pneumococcal infections. Efficacy against vaccine serotypes ranges from 61 to 75 percent in adults.[76,429] Investigations in adults in whom vaccine protection against pneumococcal infection has been substantially less have been criticized for methodologic problems.[85,108] Efficacy in the limited studies of children has been consistent with that in adults. In children with sickle-cell disease or anatomic asplenia, an octavalent vaccine was highly effective in preventing bacteremic infection.[40]

Adverse Events

Pneumococcal conjugate vaccines appear to be safe. The reactions most commonly reported have been local reactions at the injection site, but they occur at a lower frequency than do local reactions with other childhood vaccines such as DTP.[63]

Local reactions at the injection site, such as erythema and pain, are reported in approximately 50 percent of recipients of the purified polysaccharide vaccine.[18] However, more severe local and systemic reactions, such as fever and myalgia, are rare events that occur in less than 1 percent of vaccine recipients. Severe systemic reactions such as anaphylaxis rarely have been reported.[498] In adults who were re-vaccinated within 1 to 2 years in early studies, local reactions occurred more commonly than did those after initial immunization.[85,108] However, subsequent investigations, including studies in children, indicated no increase in the incidence or severity of local or systemic reactions on re-vaccination after longer intervals.[305,405]

Indications

Recommendations by the AAP and the ACIP for the use of PCV7 have been issued.[33,122] The AAP and ACIP recommend universal use of PCV7 in children 23 months and younger. For children in whom pneumococcal immunization is initiated before they reach 7 months of age, four doses of PCV7 are recommended at 2, 4, 6, and 12 to 15 months of age. For children beginning PCV7 immunization between 7 months and 23 months of age, the recommended schedule differs according to the child's age (see elsewhere for further information[18,33,122]). In addition, two doses of PCV7 are recommended for children 24 to 59 months of age who are at high risk of acquiring invasive pneumococcal infection and have not been immunized previously with PCV7. These children also should receive the 23-valent polysaccharide vaccine (PPV23) to expand serotype coverage.

Routine immunization of children 24 months or older who are at low and moderate risk is not recommended by the AAP at this time.[33] The ACIP recommends that PCV7 be considered for all children 24 to 59 months of age, with priority given to the

following: those aged 24 to 35 months; persons of Alaskan Native, American Indian, or African American descent; and those who attend group daycare centers.[122] Children 24 to 59 months old at high risk who have not previously received PCV7 but who have already received PPV23 should be vaccinated with two doses of PCV7 given 2 or more months apart.[122] Current data do not support a recommendation to replace the PPV23 with PCV7 vaccine for older children and adults.[122]

The purified polysaccharide vaccine is recommended by the AAP[33] for children 5 years or older who have one or more of the following risk factors:

- Sickle-cell disease
- Functional or anatomic asplenia
- Nephrotic syndrome or chronic renal failure
- Immunosuppression, such as from chemotherapy, organ transplantation, or malignant disease
- Cerebrospinal fluid leak
- HIV infection, symptomatic or asymptomatic
- Cochlear implants[139]

For previously vaccinated children 10 years old or younger who are at high risk of acquiring severe pneumococcal infection, re-vaccination with purified polysaccharide vaccine after 3 to 5 years is recommended.[33,122] Such children include those who have functional (e.g., sickle-cell disease) or anatomic asplenia, children and adolescents with HIV infection, and those who have a rapid antibody decline (e.g., nephrotic syndrome, renal failure, or organ transplantation).[231] Re-vaccination should be considered for high-risk older children and adults who were vaccinated 6 years or more previously.

Contraindications

No contraindications to initial vaccination exist.[33,122] The safety of pneumococcal vaccine in pregnant women has not been evaluated, but adverse consequences to the fetus have not been observed in newborns whose mothers were vaccinated inadvertently during pregnancy. Ideally, women at high risk of acquiring pneumococcal disease should be vaccinated before pregnancy. In persons who have had a severe reaction, such as anaphylaxis or a localized, severe hypersensitivity response, re-vaccination should be avoided.

POLIOMYELITIS VACCINE

The widespread implementation of poliovirus vaccine programs resulted in a dramatic reduction in the incidence of paralytic poliomyelitis throughout the world. In contrast to the pre-vaccine era, when more than 18,000 cases of paralytic disease occurred in the United States annually, the last known case in this country caused by indigenous wild-type virus occurred in 1979.[448] Other than rare imported cases, the only cases of paralytic poliomyelitis in the United States since then have been vaccine-related. The effectiveness of polio vaccination has led to major and successful initiatives by the WHO for global eradication of poliovirus infection. Currently, all nations in the Western Hemisphere, the Pacific region (including China), and Europe are free of poliomyelitis.[95,147,407] The number of polio-endemic countries decreased from 125 in 1988 to 6 (Afghanistan, Egypt, India, Niger, Nigeria, and Pakistan) in 2003.[147,504] However, from 2002 to 2005, a total of 21 previously polio-free countries were affected by importations of wild poliovirus type 1 from the 6 nations where wild poliovirus was endemic. Most of these importations were from northern Nigeria, where endemic disease increased dramatically after an 11-month suspension in immunization activities.[148] During that period, 4 countries, Indonesia, Somalia, Sudan, and Yemen, had outbreaks of more than 100 polio cases. Approximately 60 percent of all cases reported globally in 2005 occurred in previously polio-free countries. By the end of 2005, wild poliovirus transmission in all 21 countries except Somalia had been interrupted or substantially curtailed. The hope is, that with a sustained effort, complete global eradication of wild-type polio can be achieved.

The elimination of poliovirus infection has been achieved primarily through the use of OPV. This product had been the vaccine of choice for children in the United States since the early 1960s because it induced optimal intestinal immunity, was painless to administer, and secondarily immunized some contacts by fecal-oral spread of the vaccine virus and thus contributed to the immunity of the population.[80] Because 8 to 10 cases of vaccine-associated paralytic polio (VAPP) occurred annually and the risk of exposure to wild-type poliovirus had been markedly reduced or eliminated in the United States, expanded use of IPV was recommended by the CDC and the AAP beginning in 1997.[28] In 1999, as a result of progress in the global eradication of poliomyelitis, the need for further reduction in the risk for acquiring VAPP, and the acceptance of IPV by parents and physicians,[110] IPV was recommended for the first two doses of poliovirus vaccine for routine childhood vaccination.[31,116] To eliminate the risk of VAPP completely, in January of 2000 an all-IPV schedule was recommended for routine childhood vaccination in the United States.[32,116,124]

Since 2000, outbreaks of paralytic poliomyelitis caused by virulent polioviruses that are derived from OPV vaccine strains have occurred among underimmunized children living in certain economically deprived regions. The low immunization rates in these areas have permitted these viruses, called vaccine-derived polioviruses (VDPVs), to circulate for long periods of time and, by continuous mutation, to acquire biologic properties that are indistinguishable from naturally occurring wild polioviruses. Outbreaks associated with circulating VDPVs have occurred in Hispaniola (2000 to 2001), the Philippines (2001), and Madagascar (2001 to 2002).[121,127,138,297] Retrospective studies also detected the circulation of endemic VDPV in Egypt (1988 to 1993) and the likely localized spread of OPV-derived virus in Belarus (1965 to 1966).[128] Gaps in OPV coverage and the previous eradication of the corresponding serotype of indigenous wild poliovirus were the critical risk factors for all VDPV outbreaks.[298] The VDPV outbreaks were stopped by mass immunization campaigns using OPV. The potential risk of emergence of VDPV has increased dramatically in recent years as wild poliovirus circulation has ceased in most of the world. The risk appears to be highest for the type 2 OPV strain because of its greater tendency to spread to contacts. The emergence of VDPVs underscores the critical importance of eliminating the last pockets of wild poliovirus circulation, maintaining universally high levels of polio vaccine coverage, stopping OPV use as soon as it is safely possible to do so, and continuing sensitive poliovirus surveillance into the foreseeable future. Particular attention must be given to areas where the risks for wild poliovirus circulation have been highest and where the highest rates of polio vaccine coverage must be maintained to suppress VDPV emergence.

Preparations

Trivalent IPV is the only vaccine available for routine infant and childhood immunization in the United States. IPV is prepared by inactivation of naturally occurring polioviruses by treatment with dilute formalin.[85,116] Four trivalent IPV vaccines are now available in the United States: IPOL (Aventis Pasteur), Pediarix (in combination with DTaP vaccine and HBV vaccine, GlaxoSmithKline), Pentacel (in combination with DTaP vaccine and Hib vaccine, Sanofi Pasteur), and Kinrix (in combination with DTaP vaccine, GSK). These vaccines are produced in monkey kidney (Vero) cells, and each contains 40, 8, and 32 D antigen units of poliovirus types 1, 2, and 3, respectively. OPV is no longer available in the United States.

The trivalent OPV formulations available globally contain approximately $10^{6.5}$ 50 percent tissue culture infectious doses ($TCID_{50}$), $10^{5.5}$ $TCID_{50}$, and $10^{6.2}$ $TCID_{50}$ of poliovirus types 1, 2, and 3, respectively. The unequal contribution of each type to the trivalent preparation represents a "balanced" formulation designed to account for the more efficient replication of type 2 OPV virus in the gastrointestinal tract; if type 2 were given in equal concentrations with types 1 and 3, it would interfere with the replication of the two latter types. The live oral OPV strains originally were attenuated by passage in monkeys and in monkey kidney cell culture.

Trivalent IPV is now the preferred vaccine for other developed countries. However, because OPV maintains certain advantages for children in developing countries, including cost, ease of administration, and transmission of vaccine virus to unimmunized contacts, it is the vaccine currently recommended by the WHO EPI.[503] The trivalent form of OPV has been the mainstay of EPI and the WHO Polio Eradication Program for many years. Monovalent OPV vaccines have been introduced for outbreak control in certain settings.

Immunogenicity and Efficacy

Neutralizing antibodies are detectable to all three poliovirus types in 99 percent of recipients of IPV after two doses and in 100 percent after the third dose.[347,438] IPV-immunized children experience a large boost in antibody titer after receiving the third dose.[407] Detectable antibody persists at protective levels for at least 5 years, although geometric mean titers decline considerably.[449] However, few data are available regarding vaccine efficacy of the currently licensed "enhanced-potency" IPV formulations. A case-control study in Senegal indicated lower than expected protection rates of 36 and 89 percent for recipients of one and two doses, respectively.[408] However, because most IPV recipients experience a substantial boost in antibody titer after receiving a third dose, efficacy after three IPV doses likely would be quite high.

An optimal immune response to trivalent OPV requires multiple doses. In developed countries, three doses given at least 2 months apart are sufficient, with antibody prevalence to all three types being approximately 96 percent after the third dose.[347] Detectable serum antibody to all three types persists in 84 to 98 percent of vaccinees 5 years after receiving primary immunization.[310]

OPV efficacy was directly evaluated during a type 1 poliovirus outbreak in Taiwan in the early 1980s. During this outbreak, vaccine efficacy was estimated to be 82, 96, and 98 percent for one, two, and three or more doses, respectively.[299] In tropical countries, the series of OPV at 6, 10, and 14 weeks of age recommended by the WHO EPI fails to produce active immunity in a significant proportion of infants. Low seroconversion rates have been documented in many locations, averaging 73, 90, and 70 percent for types 1, 2, and 3, respectively.[386] Diarrheal disease at the time of immunization is a major factor.[368] The impact of diarrhea on seroconversion persists despite the administration of three or four OPV doses.

The monovalent OPV vaccines have higher type-specific seroconversion rates than does the trivalent vaccine and thus may be more effective when used in response to an outbreak caused by one poliovirus type.[78]

Adverse Events

No serious adverse events have been associated with use of the currently available IPV vaccine.[19,32,116] Because IPV vaccine contains trace amounts of streptomycin, neomycin, and polymyxin B, allergic reactions are possible in recipients with hypersensitivity to one or more of these antibiotics.

The OPV vaccine can cause VAPP, the overall risk of which is approximately 1 case per 2.4 million doses distributed. The rate after the first dose is approximately 1 case per 750,000 doses, including vaccine recipient and contact cases.

Indications

The polio vaccination series in the United States consists of four doses of IPV administered subcutaneously or intramuscularly.[19,32,116] The first and second doses are administered at 2 and 4 months of age, respectively. The third dose is usually given at 6 to 18 months of age, and a fourth dose is given routinely at 4 to 6 years of age, before school entry. Administration of a fourth dose is not necessary if the third dose was given on or after the child's fourth birthday. IPV is a component of Pediarix. Pentacel, and Kinrix. Pentacel may be used in children from 6 months to 18 months of age, and Kinrix may be used for children 4 to 6 years of age.

The ACIP and AAP continue to support the global eradication initiative and use of OPV as the vaccine of choice to eradicate wild-type polio in endemic areas and during epidemics. In the immunization schedule of the EPI of the WHO, doses of OPV are recommended at birth and when the child is 6 weeks, 10 weeks, and 14 weeks of age.[6] In geographic areas with endemic polio, a dose may be given when the newborn is discharged from the hospital. Supplementary doses often are given during mass community programs in these areas. Breast-feeding does not interfere with successful immunization with OPV.

Routine poliovirus vaccination is not necessary in adults residing in the United States. Such individuals are at minimal risk for exposure, and most are adequately protected because of vaccination during childhood. However, vaccination is recommended for individuals who have increased risk for exposure, including persons traveling to countries where poliomyelitis is epidemic or endemic, members of communities of specific population groups experiencing wild-type poliovirus disease, health care workers in close contact with patients who may be excreting wild-type poliovirus, and laboratory workers in contact with specimens that may contain wild-type poliovirus. Previously immunized adults who are at increased risk of exposure to poliomyelitis, such as those traveling to countries where poliomyelitis is still endemic, should receive a single dose of IPV. Available data do not indicate the need for more than a single lifetime booster dose of IPV. Adults who are unvaccinated or whose vaccination status is not documented should receive a primary vaccination series with IPV. This consists of two doses of IPV at 4- to 8-week intervals and a third dose 6 to 12 months after the second dose.

Precautions and Contraindications

IPV is contraindicated in persons who have experienced an anaphylactic reaction after receiving a previous dose of IPV or an anaphylactic reaction to one of the antibiotics in the vaccine preparation (i.e., streptomycin, polymyxin B, or neomycin).[19,32,116]

Poliomyelitis vaccination generally is contraindicated in pregnant women because of the theoretical risk of harm to the fetus. However, no deleterious effects from IPV administered during pregnancy have been demonstrated, and if immediate protection against poliomyelitis is needed, IPV may be given.

ROTAVIRUS VACCINE

Rotavirus, a major cause of childhood morbidity and mortality, causes an annual 440,000 deaths or approximately 5 percent of all childhood deaths worldwide. Rotavirus is also a major cause of acute gastroenteritis in the United States. In their first 5 years

of life, 4 out of 5 children in the United States will develop rotavirus gastroenteritis,[246,412,467] 1 in 7 will require a clinic or emergency department visit, 1 in 70 will be hospitalized, and 1 in 200,000 will die of this disease.[232,459]

Rotavirus gastroenteritis is preventable with live oral rotavirus vaccines. In 1998, the only approved rotavirus vaccine, a tetravalent rhesus-based rotavirus vaccine (RRV-TV, Rotashield, Wyeth Laboratories), was withdrawn from the market in the United States because of an association with an increased incidence of intussusception among vaccinated infants.[367] In 2006, a bovine-based pentavalent rotavirus vaccine (RotaTeq, Merck & Co.) was licensed by the FDA for use in infants in the United States. Both the ACIP of the CDC and the AAP have recommended universal vaccination of U.S. infants against rotavirus.[37,383] In 2008 a live attenuated human rotavirus vaccine (Rotarix, GlaxoSmithKline) was licensed in the United States.

Preparations

The licensed pentavalent rotavirus vaccine is an oral vaccine that contains five live reassortant rotaviruses. The rotavirus parent strains of the reassortants were isolated from human and bovine hosts. Four reassortant rotaviruses express one of the outer capsid proteins (G1, G2, G3, or G4) from the human rotavirus parent strain and the attachment protein (P7[5]) from the bovine rotavirus parent strain. The fifth reassortant virus expresses the attachment protein (P1A[8]) from the human rotavirus parent strain and the outer capsid protein G6 from the bovine rotavirus parent strain. The reassortants are propagated in Vero cells using standard tissue culture techniques.

Pentavalent rotavirus vaccine is provided in a squeezable plastic dosing tube with a twist-off cap designed to allow for the vaccine to be administered directly to infants by mouth. Each tube contains a single 2-mL dose of the vaccine as a liquid buffered-stabilized solution is stored at refrigerator temperatures (2° C to 8° C) for 24 months. Pentavalent rotavirus vaccine should be administered as soon as possible after being removed from refrigeration. The human rotavirus vaccine is a G1 P1A[8] virus attenuated by passage in cell culture. The lyphilized vaccine is stored at 2° to 8° C and must be reconstituted with a supplied diluent prior to administration.

Immunogenicity and Efficacy

The immune correlates of protection from rotavirus infection and disease are not fully understood. In a large phase III clinical trial of pentavalent rotavirus vaccine, an increase in titer of rotavirus group-specific serum IgA antibodies was used as one of the measures of the immunogenicity. Serum samples were obtained from a subset of study participants before they were immunized and approximately 2 weeks after they received the third dose; seroconversion was defined as a threefold or greater increase in antibody titer from baseline. Seroconversion rates for IgA antibody to rotavirus were 95 percent among vaccine recipients versus 14 percent in recipients of the placebo.[471]

The efficacy of pentavalent rotavirus vaccine was evaluated in two phase III trials.[65,471] In these trials, the efficacy of pentavalent rotavirus vaccine after completion of a three-dose regimen against rotavirus gastroenteritis of any severity was 74 percent and against severe rotavirus gastroenteritis was 98 percent. Efficacy was observed against all G1 to G4 and G9 serotypes, but relatively few non-G1 rotavirus cases were reported. Pentavalent rotavirus vaccine reduced the incidence of office visits by 86 percent, emergency department visits by 94 percent, and hospitalizations for rotavirus gastroenteritis by 96 percent. The efficacy of pentavalent rotavirus vaccine in the second rotavirus season after immunization was 63 percent against rotavirus gastroenteritis of any severity and 88 percent against severe rotavirus gastroenteritis. Neither breast-feeding nor concurrent administration of other childhood vaccines appears to diminish the efficacy of a three-dose series of pentavalent rotavirus vaccine.

Adverse Events

Safety with respect to intussusception was evaluated in 71,725 subjects enrolled in phase III efficacy trials.[65,471] For the prespecified 42-day post-immunization end-point, six cases of intussusception were observed in the pentavalent rotavirus vaccine group versus five cases of intussusception in the placebo group (multiplicity-adjusted relative risk, 1.6). The data did not suggest an increased risk of development of intussusception relative to placebo. Among vaccine recipients, no confirmed cases of intussusception occurred within the 42-day period after administration of the first dose, which was the period of highest risk for the previously licensed RRV-TV vaccine. In addition, no evidence of clustering of cases of intussusception was observed within a 7- or 14-day window after immunization for any dose. For the 1-year follow-up period after administration of the first dose, 13 cases of intussusception were observed in the pentavalent rotavirus vaccine group versus 15 cases of intussusception in the placebo group (multiplicity-adjusted relative risk, 0.9).

Among pentavalent rotavirus vaccine and placebo recipients, the incidence of serious adverse events, including deaths, was similar. In the 7-day period after immunization, vaccinees had a small but significantly greater rate of diarrhea, with an excess of 1 percent after dose 1 (10% versus 9%, respectively), 3 percent after dose 2 (9% versus 6%, respectively), and 3 percent after any dose (18% versus 15%, respectively). Similarly, vaccinees had a small but significantly greater rate of vomiting, with an excess of 2 percent after dose 1 (7% versus 5%, respectively) and 2 percent after any dose (12% versus 10%, respectively). The incidence of fever and irritability during the 7-day period after receipt of any vaccine dose was similar among pentavalent rotavirus vaccine and placebo recipients. Among preterm infants given pentavalent rotavirus vaccine and placebo, the incidence of serious adverse events (5.5% versus 5.8%, respectively) was similar.

Vaccine virus was shed in 8.9 percent subjects after receiving dose 1, in no subjects after dose 2, and in 0.3 percent of subjects after dose 3. Shedding was observed as early as 1 day and as late as 15 days after a dose. The potential for transmission of vaccine virus was not assessed through epidemiologic studies.

Indications

Infants should receive three doses of pentavalent rotavirus vaccine administered orally at 2, 4, and 6 months of age (http://www.cdc.gov/vaccines/recs/provisional/downloads/roto-7-1-08-508.pdf) or 2 doses of the human rotavirus vaccine at 2 and 4 months of age.[37,383] The first dose should be administered when the child is between 6 and 14 weeks of age (i.e., on or before 14 weeks, 0 days of age). Subsequent doses should be administered at a minimum of 4-week intervals, and all doses of vaccine should be administered by the time the child is 32 weeks of age (i.e., on or before 32 weeks, 0 days).

Immunization should not be initiated for infants older than 14 weeks because of insufficient data on safety of the first dose of rotavirus vaccine in older infants. Vaccine should not be administered after 8 months of age because of insufficient data on the safety and efficacy of rotavirus vaccine in infants after this age. For infants in whom the first dose of rotavirus vaccine is inadvertently administered off-label at 15 weeks or older, the rest of the rotavirus immunization series should be completed as per the schedule defined earlier, because timing of the first dose should not affect the safety and efficacy of the second and third doses.

Infants documented to have had rotavirus gastroenteritis before receiving the full course of rotavirus immunizations should

still start or complete the three-dose schedule because the initial infection frequently provides only partial immunity.

Infants who are being breast-fed can receive rotavirus vaccine. Like other childhood vaccines, rotavirus vaccine can be administered to infants with transient, mild illnesses, with or without low-grade fever.[308] Rotavirus vaccine can be administered together with DTaP, Hib, IPV, hepatitis B, and pneumococcal conjugate vaccines.

The AAP and ACIP support immunization of preterm infants under the following conditions: the infant is at least 6 weeks of age, the infant is clinically stable, and the first dose of vaccine is given at the time of discharge or after the infant has been discharged from the hospital nursery.

Infants living in households with persons who have or are suspected of having an immunodeficiency disorder or impaired immune status or with a pregnant woman can be immunized. To minimize potential virus transmission, all members of the household should employ measures such as good handwashing after contact with the feces of the immunized infant (e.g., after changing a diaper) for at least 1 week after the first dose of rotavirus vaccine has been given.

An infant who regurgitates, spits out, or vomits during or after receiving a dose of rotavirus vaccine should not have that dose readministered. The infant can receive the remaining recommended doses of rotavirus vaccine at appropriate intervals. If a recently immunized child is hospitalized for any reason, no precautions other than standard precautions need be taken to prevent the spread of vaccine virus in the hospital setting.

Contraindications and Precautions

Rotavirus vaccine should not be administered to infants who have severe hypersensitivity to any component of the vaccine or those individuals who have experienced a serious allergic reaction to a previous dose of rotavirus vaccine.[37,383] The human rotavirus vaccine oral applicator contains latex rubber. Pentavalent rotavirus vaccine may be preferred for children at high risk for acquiring latex sensitization.

Practitioners should consider the potential risks and benefits of administering rotavirus vaccine to infants with known or suspected altered immunocompetence. Children and adults who are immunocompromised because of congenital immunodeficiency, bone marrow transplantation, or solid organ transplantation sometimes experience severe, prolonged, and even fatal rotavirus gastroenteritis. However, no safety or efficacy data are available for the administration of rotavirus vaccine to infants who are potentially immunocompromised.

Rotavirus vaccine should not be administered to infants with acute, moderate to severe gastroenteritis until the condition improves. Rotavirus vaccine has not been studied among infants with concurrent acute gastroenteritis, among whom its immunogenicity and efficacy theoretically can be compromised. Infants with moderate to severe illness should be immunized as soon as they have recovered from the acute phase of the illness.

Infants with preexisting chronic gastrointestinal conditions and who are not undergoing immunosuppressive therapy should benefit from rotavirus vaccine immunization, and the benefits outweigh the theoretical risks. However, the safety and efficacy of rotavirus vaccine have not been established for infants with these preexisting conditions (e.g., congenital malabsorption syndromes, Hirschsprung disease, short-gut syndrome, or persistent vomiting of unknown cause).

After administration of a previously licensed rotavirus vaccine (RRV-TV), an increased risk of intussusception was observed. Available pre-licensure data from a large trial of 70,000 infants show no evidence of an association between intussusception and pentavalent rotavirus vaccine. However, additional post-licensure surveillance data are required to confirm that the vaccine is not associated with intussusception at a lower rate than what would have been detected in pre-licensure trials. In addition, some data suggest that infants with a history of intussusception may be at higher risk of having a repeat episode than are other infants. Therefore, until post-licensure data on safety of rotavirus vaccine are available, the risks and benefits of immunization should be considered when immunizing infants with a previous episode of intussusception.

RUBELLA VACCINE

Rubella is a viral disease that usually is manifested as a mild febrile rash illness in adults and children; however, 20 to 50 percent of infected persons are asymptomatic. Rubella can have severe adverse effects on the fetuses of pregnant women who contract the disease during the first trimester of pregnancy; it causes a wide range of congenital defects known as congenital rubella syndrome (CRS). The primary objective of the rubella vaccination program is to prevent intrauterine rubella infection. The primary strategies for rubella control in the United States are universal childhood vaccination, prenatal screening of pregnant women for rubella immunity, and vaccination of rubella-susceptible women post partum.

In the pre-vaccine era, epidemics of rubella occurred every 6 to 9 years, with the last major epidemic in the United States taking place in 1964 to 1965. The incidence of reported cases of rubella fell sharply after routine rubella immunization of young children was initiated in the United States in 1969. From the estimated 2 million cases per year in the pre-vaccine era, fewer than 1000 cases were reported in 1983. The incidence of rubella continued to fall during the 1980s and 1990s, although clusters of disease occurred among groups of susceptible individuals, including people with religious or philosophic exemptions to immunization. Although rubella had been a disease of childhood, the proportion of remaining cases among people 20 years of age and older increased to 79 percent in 1998.[476] Sustained implementation of the rubella vaccination program resulted in a marked decrease in incidence among all age groups. Since the mid-1990s, most reported cases of rubella have occurred among foreign-born young adults (particularly from Latin America) who were born in countries without routine rubella immunization programs.[196,402]

In October of 2004, 35 years after initiation of the rubella immunization program, an independent panel of international experts was convened by the CDC to assess progress toward elimination of rubella and CRS. Based on data showing fewer than 25 cases of rubella reported each year since 2001, at least 95 percent vaccination coverage among school-age children, an estimated 91 percent population immunity, adequate surveillance to detect rubella outbreaks, and a pattern of virus genotypes consistent with virus originating in other parts of the world, panel members concluded unanimously that rubella no longer is endemic in the United States.[140]

Rubella continues to be endemic in many parts of the world. Internationally imported rubella cases may give rise to indigenous transmission. The United States will need to continue its vigilance against rubella and CRS by the following means: (1) maintaining high vaccination rates among children; (2) ensuring vaccination among women of child-bearing age, especially women born outside the United States; (3) continuing surveillance of both rubella and CRS; and (4) responding rapidly to any outbreak.[140]

Preparations

Since 1979, RA 27/3 (rubella abortus, 27th specimen/third extract) vaccine, prepared in human diploid tissue culture, has

been the only vaccine available in the United States; it replaced the earlier HPV-77 and Cendehill vaccines. RA 27/3 induces higher antibody titers and more closely parallels the immune response after natural infection than did previous vaccines.[320,378] In addition to MMR vaccine, monovalent rubella and measles-rubella and MMRV vaccines are available. MMR and MMRV vaccines generally are used for routine infant immunization programs. Rubella vaccine should be kept at 2° C to 8° C (35.6° F to 46.4° F) or colder during storage and should be protected from light to avoid inactivation of the virus. Once reconstituted, the vaccine should be used within 8 hours.

Immunogenicity and Efficacy

At least 98 percent of susceptible vaccinees aged 12 months or older develop antibody titers that are protective.[356] Vaccine-induced rubella antibodies have persisted in more than 90 percent of vaccinees aged 16 years old after receiving the RA 27/3 vaccine.[167] Lifelong protection against clinical re-infection, asymptomatic viremia, or both, usually results from a single dose of vaccine given early in childhood.

In some cases, vaccinees exposed to natural rubella developed a rise in antibody titer unassociated with clinical symptoms. Re-infection is associated only rarely with viremia. Significant pharyngeal shedding also is observed infrequently. Person-to-person transmission, however, has not been reported. Re-infection caused by wild-type rubella virus also may be observed in individuals with previous natural rubella. The risk of CRS developing from rubella re-infection during pregnancy is extremely low.[409]

Adverse Events

Rubella vaccines generally are well tolerated. The most frequent complaints after vaccination are fever, lymphadenopathy, or rash, which occur in 5 to 15 percent of children 5 to 12 days after receiving vaccination.[20] Transient peripheral neuritis (paresthesia and pain in the arms and legs) has been observed uncommonly, primarily in older age groups.[423]

Approximately 3 percent of children have transient joint manifestations, including arthralgia and, less commonly, arthritis 1 to 3 weeks after being immunized. Although 25 percent of women report having joint pain after being vaccinated, arthritis with objective clinical findings lasting less than 10 days occurs in 13 to 15 percent. Cases of persistent or recurrent joint symptoms have been reported but are rare events. In 1992, the IOM reviewed the existing data on rubella and adverse joint events and concluded that the evidence available was consistent with a causal relationship between rubella vaccination and chronic arthritis in women, although data on current vaccine strains are limited.[272] The incidence of joint manifestations after immunization is lower than that after natural infection at the corresponding age.

Rubella re-vaccination is well tolerated, even among college-age and older vaccinees, and is associated with a much lower incidence of adverse reactions than is primary rubella immunization of young adult populations. Reported rates of joint-related complaints of 4 to 18 percent after re-vaccination are lower than those reported after primary vaccination.[163,426]

Indications

Live virus rubella vaccine generally is recommended for all children aged 12 months or older; it is given as MMR or MMRV when children are 12 to 15 months of age.[20,111,129] A second dose of rubella vaccine administered as MMR or MMRV is given at the time they enter school, usually 4 to 6 years of age, according to recommendations for routine measles immunization. The vaccine should be provided to previously unimmunized preschool-age children or older schoolchildren despite a history of having clinical rubella, unless serologic tests confirm immunity.

Emphasis should be placed on the immunization of the postpubertal male and female population, especially college students and those in the military. Rubella vaccine also should be administered to adolescent girls and women of child-bearing age who lack a history of previous vaccination. Other opportunities for immunization include premarital screening, routine gynecologic examinations, visits for newborn infants and well-child care, or other medical visits. The immediate postpartum period also is an excellent time for giving immunizations. Rubella vaccine may be given after administration of anti-Rho(D) immune globulin, but serologic testing to determine whether seroconversion has occurred should be performed at least 8 weeks after vaccination. When practical, potential vaccinees may be screened for susceptibility. However, vaccination of girls and women of child-bearing age is justifiable, and may be preferable, without previous serologic testing in women not known to be pregnant.

Adults in the United States who were born in countries where rubella vaccination was not offered are at higher risk for contracting rubella and having infants with CRS. Health care practitioners who treat foreign-born adults should document the rubella immunity of these patients with a written record of rubella-containing vaccine or by serologic testing. Susceptible adults, especially women of child-bearing age, should be vaccinated. During rubella outbreaks, all susceptible persons who have no contraindications to rubella vaccine should be identified and vaccinated.

Precautions and Contraindications

Specific contraindications to administration of live rubella vaccine include the following: (1) pregnancy; (2) severe febrile illness; (3) known history of anaphylactic reaction to rubella vaccine, gelatin, or neomycin, which are contained in the vaccine; and (4) immunodeficiency conditions (i.e., malignancy, primary immunodeficiency disease, immunosuppressive or corticosteroid therapy, and radiation therapy).[20,111,129]

Persons with mild immunosuppression, such as those with asymptomatic HIV infection or those taking short-term or low-dose corticosteroids, may be vaccinated.

Postpubertal women of child-bearing age who are known to be pregnant or who are attempting to become pregnant should not be vaccinated. Vaccinated women should be counseled about the need to avoid pregnancy for 28 days after receiving vaccination.[130] Although pregnancy is a contraindication to administering rubella vaccination, the maximal theoretical risk to the fetus is estimated to be 1.6 percent. From 1979 until 1989, the CDC registered 321 susceptible women who inadvertently had received RA 27/3 rubella vaccine within 3 months before or after conception and carried their pregnancies to term. None of their infants had defects compatible with CRS, although 2 percent had serologic evidence of intrauterine infection.[86] Because rubella virus has been isolated from the products of conception of women vaccinated during pregnancy, continued caution with respect to vaccination during pregnancy is advised. However, the evidence available indicates that rubella vaccination inadvertently given during pregnancy ordinarily does not represent a reason to consider interruption of pregnancy.

Although vaccine virus may be isolated from the pharynx, vaccinees do not transmit rubella to others, except in the case of a vaccinated breast-feeding mother. In this situation, the infant may be infected through breast milk and a mild rash illness may develop, but serious adverse effects have not been noted. Infants infected through breast-feeding respond normally to rubella vaccination at 15 months of age. Breast-feeding is not a contraindication to receiving rubella vaccination.

Concern about potential transmission of disease from immunized children to susceptible contacts, including pregnant women,

has not been supported by studies of susceptible household contacts. Therefore, susceptible children whose household contacts are pregnant may be vaccinated.

Persons with a history of thrombocytopenia may experience thrombocytopenia after receipt of MMR vaccine. The decision to vaccinate should depend on the benefits of immunity versus the risk for recurrence or exacerbation of thrombocytopenia, either after vaccination or during natural infection with measles or rubella.

Rubella vaccine should not be given during an interval beginning 2 weeks before and extending 3 months after the administration of immune globulin or blood transfusion. Because rubella vaccine usually is given as MMR or MMRV, and evidence suggests that high doses of immune globulin preparations can inhibit the immune response to measles vaccine for 3 or more months, depending on the dosage, rubella vaccination with MMR or MMRV necessitates deferral for longer periods (see "Measles Vaccine").[20,111,435]

TETANUS TOXOID

The efficacy of active immunization against tetanus was demonstrated most dramatically in military personnel during World War II, when tetanus toxoid virtually eliminated tetanus in injured soldiers.[327] Since the 1940s, routine immunization of civilians in this country with tetanus toxoid has been successful in nearly eliminating tetanus. In almost all cases, disease has been reported in unimmunized or inadequately immunized individuals.[87] The primary three-dose series of a tetanus toxoid-containing vaccine confers protective immunity for 10 years or longer.[71,307]

Without a tetanus booster, immunity wanes over time. The potential for occurrence of tetanus is indicated by the significant number of adults in the United States who lack protective concentrations of serum antibody.[226] Although the incidence of disease is exceptionally low (a total of 624 cases of tetanus were reported in the United States between 1990 and 2004), the case-fatality rate was 18 percent.[384,443]

Neonatal tetanus also has been nearly eliminated in the United States. However it is a leading cause of morbidity in newborns in developing countries. As a result, global elimination of neonatal tetanus remains a goal of the WHO.[96]

Preparations

Tetanus toxoid is prepared by formaldehyde treatment of *Clostridium tetani* toxin.[71,307] It has been prepared in both fluid and aluminum salt-adsorbed preparations, but in the United States, only the latter is available. Fluid toxoid preparations result in a significantly shorter duration of immunity than that induced by aluminum-adsorbed antigens; therefore, adsorbed antigens are recommended.

Tetanus toxoid is available in combination with diphtheria toxoid and acellular pertussis vaccine (DTaP) for routine administration to infants and children younger than 7 years of age and for adolescents and adults aged 11 to 64 years old as a single booster (Tdap). For all persons in whom pertussis vaccine is contraindicated, tetanus toxoid is combined with diphtheria toxoid as either DT or Td (see "Diphtheria Toxoid"). The first two Tdap vaccines approved for use in adolescents and adults in the United States, Boostrix (GlaxoSmithKline Biologicals) and Adacel (Sanofi Pasteur), were licensed in 2005. Preparations of DT, Td, and Tdap are identical in the amounts of tetanus toxoid they contain, but they differ in the quantity of diphtheria toxoid. The dose of Tdap is the same as that of DT or Td, 0.5 mL administered intramuscularly.

Immunogenicity and Efficacy

Adequate primary immunization provides sufficient protective titers of antitoxin for at least 10 years and ensures prompt, anamnestic responses to subsequent booster injections. Immune response to tetanus toxoid was measured following administration of each adult Tdap vaccine and compared with that elaborated after Td vaccine. Seroprotective anti-tetanus antibody concentrations, defined as a titer 0.1 IU/mL or greater, and booster response rates to tetanus were determined to be noninferior after vaccination with Tdap as compared with Td vaccination.[71,307]

Adverse Events

Local reactions of pain, swelling, and induration can occur, but these reactions in children usually are attributable to the pertussis component contained in the vaccine rather than to response to tetanus toxoid. Hypersensitivity reactions can occur in adolescents and adults but very rarely are severe. Neurologic reactions occurring after the administration of tetanus toxoid are rare events. Such reactions include brachial neuritis and GBS.

Regarding adverse reactions reported following Tdap, vaccination with Boostrix was associated with a statistically higher rate of moderate to severe headache compared with Td, and Adacel was associated with higher rates of mild injection site pain and low-grade fever compared with Td vaccine. No serious adverse events have been reported for Boostrix. Two cases of serious adverse advents, both characterized as neuropathic reactions, in adults possibly related to having received Adacel (none reported in adolescents), have been reported, and in both cases symptoms resolved completely within several days.[71,307]

Indications

PRE-EXPOSURE

For primary immunization, doses of tetanus toxoid, provided as DTaP, should be administered when the child is 2, 4, and 6 months of age. [22,36,71] A fourth dose is given 6 to 12 months after the third dose (i.e., at 12 to 18 months of age) to maintain adequate serum antibody concentrations for the ensuing preschool years. For children younger than 7 years of age not immunized in infancy, DTaP is given at 0 (initial dose), 2, 4, and 10 to 16 months later, followed by a single booster dose at age 4 to 6 years, just before school entry.

In 2005, the FDA licensed two Tdap vaccines for routine use in adolescents and adults, Adacel (Sanofi Pasteur, approved for persons 11 to 64 years of age) and Boostrix (GlaxoSmithKline Biologicals, approved for adolescents 10 to 18 years of age). These vaccines are approved for one-time use only in those individuals who have previously completed their primary vaccination series with DTP or DTaP as a substitute for their next Td booster. The preferred age for Tdap vaccination is 11 to 12 years. Catch-up vaccination with Tdap is encouraged for adolescents 13 to 18 years old who completed their primary series with DTP or DTaP and received a Td booster at least 5 years previously. Although an interval of 5 years between Td and Tdap is recommended to reduce the likelihood of adverse reactions, periods shorter than 5 years can be used when increased risks of exposure to or complications from pertussis exist. Every 10 years thereafter, tetanus booster should be provided by Td. Adolescents between the ages of 11 and 18 years who have never been vaccinated against tetanus, diphtheria, or pertussis should receive Tdap initially, followed by Td for the subsequent two doses 4 or more weeks, and 6 to 12 months later. For children between the ages of 7 and 10 years who have not been vaccinated previously, three doses of Td are recommended at 0 (initial dose), 4 or more

weeks, and 6 to 12 months. The third dose may be delayed until the child is old enough to receive Tdap; otherwise, a booster with Tdap is recommended when these children become adolescents. Interruption of the recommended schedule or delay in administering subsequent doses during primary immunization does not reduce immunity.

ANTEPARTUM

In areas of the world where the risk of acquiring neonatal tetanus is significant, previously unimmunized, pregnant women should receive two antepartum doses of a tetanus toxoid-containing vaccine, properly spaced, and should complete the three-dose series subsequently.[13,307] Women immunized more than 10 years previously should receive a booster dose.

The ACIP and the AAP recommend for administration a single dose of Tdap vaccine in pregnancy to women between the ages of 11 and 64 years, including those breast-feeding who have not received Tdap vaccine previously.[22,36,307] If vaccination is not provided before delivery, women should receive a single dose of Tdap in the immediate postpartum period, preferably before being discharged from their hospital or birthing center.

POST-EXPOSURE: WOUND MANAGEMENT

The potential need for immunoprophylaxis is an integral aspect of wound management at the time of trauma or injury. The recommended use of tetanus toxoid in addition to tetanus immune globulin at the time of injury is given in Table 255–16. To ensure adequate immunity, children and adults receiving tetanus toxoid for wound management should be given age-appropriate preparations of vaccines containing diphtheria and pertussis, unless contraindicated, as well as tetanus toxoid.[22,36,307] Specific recommendations depend on the individual's immunization status, the nature of the wound, and the duration of time between when the injury occurred and evaluation and treatment were undertaken. After prophylaxis is provided, primary immunization should be completed subsequently in those lacking the recommended number of doses. This conservative approach to the frequent administration of booster doses of tetanus toxoid in wound management for previously immunized persons is supported by the prolonged immunity from tetanus vaccination and the increased incidence of hypersensitivity reactions associated with receipt of frequent booster injections.[387] Patients convalescing from tetanus infection should complete active immunization because infection often does not confer immunity.

TABLE 255–16 Recommended Tetanus Prophylaxis in Wound Management

History of Tetanus Toxoid (Number of Doses)	Clean, Minor Wounds		All Other Wounds*	
	Td or Tdap†	TIG	Td or Tdap†	TIG
<3 or unknown	Yes	No	Yes	Yes
≥3	No‡	No	No§	No

**Such as, but not limited to, the following: wounds contaminated with dirt, feces, soil, and saliva; puncture wounds; avulsions; and wounds resulting from missiles, crushing, burns, and frostbite.*

†For children younger than 7 years of age; diphtheria-tetanus, acellular pertussis (DTaP) or diphtheria-tetanus (DT) (depending on vaccine status of patient) is preferred to tetanus toxoid (TT) alone. Tdap is preferred to Td for adolescents who have never received Tdap. Td is preferred to TT for adolescents who received Tdap previously or when Tdap is not available.

‡Yes, if more than 10 years since last tetanus-containing vaccine dose.

§Yes, if more than 5 years since last tetanus-containing vaccine dose. More frequent boosters are not needed and can accentuate side effects.

Td, tetanus-diphtheria; Tdap, tetanus-diphtheria-acellular pertussis; TIG, tetanus immune globulin.

Precautions and Contraindications

A history of having an immediate, severe hypersensitivity reaction to tetanus toxoid-containing preparations that is severe or anaphylactic in type is a contraindication to receiving further vaccination.[22,36,71,307] Persons who experience Arthus-type hypersensitivity reactions after receiving tetanus toxoid usually have high serum tetanus antitoxin concentrations and should not be given doses of Td more frequently than every 10 years, even if they have a tetanus-prone wound. If an anaphylactic reaction to a previous dose of tetanus toxoid is suspected, intradermal skin testing may be helpful in determining whether to discontinue tetanus toxoid vaccination.[286] Because tetanus toxoid administration has been associated with recurrence of GBS in rare cases,[278] the decision to give additional doses in persons with a previous history of this syndrome within 6 weeks after receipt of tetanus toxoid should be based on consideration of the benefit of revaccination and the comparative risk of having a recurrence of GBS.[106] No physician-diagnosed cases of anaphylaxis or Arthus reactions or GBS in any adolescent or adult following either Tdap vaccine have been reported.

VARICELLA VACCINE

In the pre-vaccine era, varicella was endemic in the United States, and virtually all persons acquired varicella by the time they reached adulthood. Varicella infection was responsible for an estimated 4 million cases, 11,000 hospitalizations, and 100 deaths each year in the United States.[115] Approximately 90 percent of cases occurred in children, with the highest incidence in children 1 to 6 years old.

Since the introduction of varicella vaccine in 1995, the incidence of varicella has decreased as vaccination coverage has increased, and the number of hospitalizations and deaths from varicella has declined more than 90 percent.[144,427] Active surveillance for varicella has been conducted at sites in Pennsylvania, Texas, and California since 1995 in a CDC-sponsored study.[427] From 1995 to 2000, vaccine coverage in 1- to 2-year-old children rose to approximately 80 percent, whereas overall cases of varicella declined 70 to 80 percent. The greatest decline was in children 1 to 4 years of age, but the number of cases also declined in all other age groups, including infants younger than 1 year old and adults, thus suggesting herd immunity. Decreasing rates of varicella also have been associated with increasing use of varicella vaccine in a daycare center population.[170] Varicella vaccine coverage among 19- to 35-month-old children was estimated by the National Immunization Survey to be 88 percent in 2005.[152]

Despite the high one-dose vaccination coverage and the success of the vaccination program in reducing varicella morbidity and the mortality rate, varicella surveillance indicates that the number of reported varicella cases appears to have plateaued. Increasing proportions of cases represent breakthrough infection (chickenpox occurring in a previously vaccinated person). In 2001 to 2005, outbreaks were reported in schools with 96 to 100 percent varicella vaccination coverage.[208,328,460] These outbreaks had many similarities: all occurred in elementary schools; vaccine effectiveness was within the expected range of 72 to 85 percent; the highest attack rates occurred among the younger students; each outbreak lasted approximately 2 months; and persons with breakthrough infection transmitted the virus, although the breakthrough disease was mild. Overall attack rates among vaccinated children were 11 to 17 percent, with attack rates in some classrooms as high as 40 percent. These data indicate that even in settings where almost everyone was vaccinated and vaccine performed as expected, varicella outbreaks could not be prevented with the current one-dose vaccination policy. Although varicella typically was mild, the outbreaks lasted for several months and

were challenging and costly for health departments to control.[155] These observations led to the recommendation in 2006 for a second routine dose of varicella vaccine.

In June of 2005, the ACIP provisionally recommended a second dose of varicella vaccine in outbreak settings for persons who have had only one dose of varicella vaccine and no disease history (provided an appropriate interval has elapsed since the first dose).[154] On the basis of a 10-year follow-up pre-licensure study of the vaccine, a two-dose vaccination regimen has been determined to be more effective than a one-dose regimen.[313] In a 2006 position statement, the Council of State and Territorial Epidemiologists supported a routine two-dose varicella vaccination policy to improve varicella control and outbreak prevention. In June of 2006, ACIP approved a routine two-dose varicella vaccination policy for children (first dose at 12 to 15 months, second dose at 4 to 6 years) and catch-up vaccinations for children, adolescents, and adults who previously had received only one dose.[154] Establishing a routine two-dose vaccination regimen may make the two-dose outbreak response for susceptible populations more feasible to implement.

Preparations

Three varicella-containing vaccines are now approved for use in the United States: varicella vaccine (Varivax), combination MMRV vaccine (ProQuad), and herpes zoster vaccine (Zostavax). Varicella vaccine was licensed in the United States in 1995. It is a preparation of the Oka strain of varicella-zoster virus (VZV) obtained from the vesicle fluid of a healthy child with varicella that has been attenuated by serial propagation in human embryo lung fibroblasts, guinea pig embryonic cells, and human diploid cell cultures. The vaccine contains trace amounts of neomycin, fetal bovine serum, sucrose, residual components of human diploid (MRC-5) cells, and gelatin. The vaccine does not contain preservatives.

Varicella vaccine is lyophilized and stored frozen at –15° C or colder until reconstituted. Any freezer that reliably maintains an average temperature of –15° C and has a separate sealed freezer door is acceptable for storing vaccine. The vaccine also may be stored at refrigerator temperature (2° C to 8° C) for as long as 72 hours before reconstitution. Vaccine stored at 2° C to 8° C that is not used within 72 hours should be discarded. Reconstituted vaccine should be stored at room temperature and discarded if it is not used within 30 minutes.

In September of 2005, a combined live attenuated MMRV vaccine was licensed for use in persons aged 12 months through 12 years.[145] The attenuated measles, mumps, and rubella vaccine viruses in MMRV are identical and of equal titer to those in the MMR vaccine. The titer of Oka/Merck VZV is higher in MMRV vaccine than in single-antigen varicella vaccine. Each 0.5-mL dose contains a small quantity of hydrolyzed gelatin, human albumin, residual components of MRC-5 cells, neomycin, bovine calf serum, and other buffer and media ingredients. Unlike single-antigen varicella vaccine, MMRV vaccine cannot be stored at refrigerator temperature. MMRV vaccine must be stored frozen at an average temperature of –15° C or lower for up to 18 months. Once reconstituted, the vaccine should be used immediately to minimize loss of potency and should be discarded if it is not used within 30 minutes. The diluent should be stored separately at room temperature or in the refrigerator. MMRV vaccine contains no preservative. In May of 2006, the FDA approved herpes zoster vaccine for use in persons 60 years of age and older. No indications for use of this vaccine in children exist.

Immunogenicity and Efficacy

Varicella vaccine is highly immunogenic in susceptible children. Seroconversion has occurred in more than 96 percent of children aged 12 months to 12 years after one dose of vaccine.[495] Preexisting antibody, if present at 12 months of age, does not appear to interfere with antibody response. As with other viral vaccines, the antibody response after immunization is lower than that from natural disease. Adolescents and adults have age-related decreases in the ability to develop a primary response to varicella virus.[228] Seroconversion rates of 78 to 82 percent after one dose and 99 percent after two doses have been reported in those older than 12 years.[228,495]

In ongoing studies in the United States and Japan, serum antibodies to varicella have been detected for as long as 10 to 20 years after immunization in more than 95 percent of immunized children.[46,290] Antibody concentrations have persisted for at least 1 year in 97 percent of adults and adolescents who were administered two doses of vaccine 4 to 8 weeks apart.[228] Cell-mediated immunity to VZV has been detected in 87 percent of children and 94 percent of adults 5 years after vaccination.[512]

MMRV vaccine was licensed on the basis of equivalence of immunogenicity of the antigenic components, rather than clinical efficacy. Clinical studies involving healthy children aged 12 to 23 months indicated that those who received a single dose of MMRV vaccine developed levels of antibody to measles, mumps, rubella, and varicella similar to those of children who received MMR and varicella vaccines concomitantly at separate injection sites.[312]

Varicella vaccine has been demonstrated to be highly effective in preventing varicella in children and in reducing the severity of infection if they do become infected. In pre-licensure clinical trials, vaccine was 70 to 90 percent effective in preventing varicella and more than 95 percent effective in preventing severe disease.[256,314,373,487] Several post-licensure studies have shown similar results, with vaccine effectiveness ranging from 83 to 100 percent in preventing varicella and 87 to 100 percent in preventing severe disease.[172,285,466] In follow-up studies, chickenpox has developed in approximately 0.2 to 2.3 percent of vaccinated children per year after exposure to wild-type varicella virus, a rate that does not seem to increase with length of time after immunization.[472] These vaccine failure cases are mild, with fewer skin lesions, lower rates of fever, and faster recovery, and they are less contagious than are moderate to severe cases of varicella.[59,428,472,483] These infections have been termed *breakthrough varicella*.

Although findings of some studies have suggested otherwise, most investigations have not identified time since vaccination as a risk factor for breakthrough varicella. Some, but not all, investigations have identified the presence of asthma, use of steroids, and vaccination at younger than 15 months of age as risk factors for breakthrough varicella.[208,225,285,460,470] Breakthrough varicella infection could be a result of several factors, including interference of vaccine virus replication by circulating antibody, impotent vaccine resulting from storage or handling errors, or inaccurate record keeping. Interference from live viral vaccine administered before varicella vaccine could also reduce vaccine effectiveness. A study of 115,000 children in two health maintenance organizations during 1995 to 1999 found that children who received varicella vaccine less than 30 days after MMR vaccination had a 2.5-fold increased risk of breakthrough varicella compared with those who received varicella vaccine before, simultaneously with, or more than 30 days after receiving MMR.[470] Inactivated vaccines (DTaP, Hib, IPV, and hepatitis B) and OPV did not increase the risk of breakthrough varicella if they were administered less than 30 days before administration of varicella vaccine.

In adults and adolescents who have seroconverted, varicella vaccine provides protective efficacy rates of approximately 70 percent after household exposure. In the remaining 30 percent, attenuated disease with fewer skin lesions and little or no systemic toxicity develops, as in children.[228]

Adverse Events

Varicella vaccine produces relatively few adverse reactions.[430,499] The most common adverse reactions that occur after receipt of varicella vaccine are local reactions, such as pain, soreness, erythema, and swelling. Based on information from the manufacturer's clinical trials of varicella vaccine, local reactions after receiving the first dose are reported by 19 percent of children and by 24 percent of adolescents and adults.[430,499] These local adverse reactions generally are mild and self-limited.

A varicella-like rash at the site of injection is reported by 3 percent of children and by 1 percent of adolescents and adults following receipt of the second dose. In both circumstances, a median of two lesions has been present. These lesions generally occur within 2 weeks and usually are maculopapular rather than vesicular.[430,499]

In post-licensure studies, the adverse event most frequently reported is a mild vesicular rash that occurs in approximately 5 percent of vaccinees.[115,227] Most of these generalized rashes occur within 3 weeks, and most are maculopapular. In one study, vesicular rashes that occurred within 2 weeks of vaccination were more likely to be caused by wild-type varicella, whereas rashes that occurred more than 2 weeks after vaccination were more likely to be caused by the Oka vaccine strain.[430]

Systemic reactions are not common. Fever within 42 days of vaccination is reported by 15 percent of children and 10 percent of adolescents and adults. Most of these episodes of fever have been attributed to concurrent illness rather than to the vaccine.

Clinical trials of MMRV that compared events that occurred within 42 days of receiving either MMRV or MMR and varicella vaccine separately in different anatomic sites found the frequencies of local reactions and generalized varicella-like rash similar to those described for varicella vaccine.[312] A temperature of 102° F or higher within 42 days of vaccination was more common in the MMRV group (22%) than in the group that received MMR and varicella vaccine at different sites (15%). A measles-like rash also occurred more frequently in MMRV recipients (3%) than in the group receiving separate injections (2%). Both fever and measles-like rash usually occurred 5 to 12 days after receipt of vaccination. In a postlicensure study, an increased risk of seizure was seen in children 12 to 23 months of age receiving MMRV vaccine when compared with those who received MMR and varicella vaccines given separately in the 7- to 10-day post-vaccination period.[159a]

Varicella vaccine is a live virus vaccine and may result in a latent infection, similar to that caused by wild-type varicella virus. Consequently, zoster caused by the vaccine virus has been reported, mostly among vaccinated children. Based on reports to VAERS, the rate of herpes zoster after varicella vaccination is 2.6 per 100,000 vaccine doses distributed.[115] The incidence of herpes zoster after natural varicella infection in healthy persons younger than 20 years is 68 per 100,000 person-years[244] and, for all ages, 215 per 100,000 person-years.[204] However, these rates should be compared cautiously because the latter rates are based on populations monitored for longer periods than the vaccinees were. Cases of herpes zoster have been confirmed by polymerase chain reaction (PCR) to be caused by both vaccine virus and wild-type virus, a finding thus suggesting that some herpes zoster cases in vaccinees may result from antecedent natural varicella infection.[115,253] Most cases of herpes zoster that occur after administration of vaccine have been mild and have not been associated with complications such as postherpetic neuralgia.

Transmission of the vaccine virus occurs rarely and most often from immunocompromised vaccinees. Of the 15 million doses of varicella vaccine distributed, on only 3 occasions has transmission from immunocompetent persons been documented by PCR analysis.[317,421] All these cases resulted in mild disease without complications. In one case, a child 12 months old transmitted the vaccine virus to his pregnant mother.[326,421] The mother elected to terminate the pregnancy, but fetal tissue tested by PCR was negative for varicella vaccine virus. The other two documented cases involved transmission from healthy children aged 1 year to a healthy sibling aged 4 1/2 months and to a healthy father.[115] Transmission also has occurred from a person with herpes zoster caused by vaccine strain virus.[74] Transmission has not been documented in the absence of a vesicular rash after vaccination. No evidence indicates reversion to virulence of the vaccine strain during transmission; siblings of leukemic vaccine recipients who acquired vaccine virus had mild rash in 75 percent of cases and symptomless seroconversion in 25 percent.[43]

Indications

Varicella vaccine is licensed for use in individuals aged 12 months or older who have not had varicella.[24,34,115,159] The initial dose of varicella vaccine is recommended at 12 to 15 months of age. In June of 2006, the ACIP voted to recommend a routine second dose of varicella vaccine.[159] The second dose should be administered at 4 through 6 years of age, at the same visit during which the second dose of MMR vaccine is given. The second dose may be administered earlier than 4 through 6 years of age if at least 3 months have elapsed following the first dose (i.e., the minimum interval between doses of varicella vaccine for children <13 years is 3 months). However, if the second dose is administered at least 28 days following the first dose, the second dose does not need to be repeated.

A second dose of varicella vaccine also is recommended for persons older than 4 through 6 years of age who have received only one dose. Varicella vaccine doses administered to persons younger than 13 years should be separated by at least 3 months.

Varicella vaccine also is recommended for all children without evidence of varicella immunity by their 13th birthday. Children who have not been vaccinated previously and who do not have a reliable history of chickenpox are considered susceptible. Efforts should be made to ensure varicella immunity by age 13 years, because after this age varicella disease is more severe and complications are more frequent.

All varicella-containing vaccines should be administered by the subcutaneous route. Varicella vaccine has been shown to be safe and effective in healthy children when administered at the same time as MMR vaccine at separate sites and with separate syringes. If varicella and MMR vaccines are not administered at the same visit, they should be separated by at least 28 days. Varicella vaccine also may be administered simultaneously (but at separate sites with separate syringes) with all other childhood vaccines. The ACIP strongly recommends that varicella vaccine be administered simultaneously with all other vaccines recommended at 12 through 15 months of age.

Children with a clinician-diagnosed or verified history of typical chickenpox can be assumed to be immune to varicella. Serologic testing of such children before vaccination is not warranted because most children between 12 months and 12 years of age without a clinical history of chickenpox are not immune. Prior history of chickenpox is not a contraindication to receiving varicella vaccination.

Varicella vaccine should be administered to all adolescents and adults 13 years of age and older who do not have evidence of varicella immunity. Persons aged 13 years and older should receive two doses of varicella vaccine with administration of the doses separated by at least 4 weeks. If a lapse of more than 4 weeks occurs after the first dose, the second dose may be administered at any time without repeating the first dose. Assessment of varicella immunity in all adolescents and adults and vaccination of those who lack evidence of varicella immunity is desirable to

protect these individuals from the higher risk of developing complications from acquired varicella. Vaccination may be offered at the time of routine health care visits. However, specific assessment efforts should be focused on adolescents and adults who are at highest risk of exposure and those most likely to transmit varicella to others.

The ACIP recommends that all health care personnel be immune to varicella. In health care settings, serologic screening of personnel who are uncertain of their varicella history, or who claim not to have had the disease, is likely to be cost-effective. Testing for varicella immunity after administration of two doses of vaccine is not necessary because 99 percent of persons are seropositive after the second dose. Moreover, available commercial assays are not sufficiently sensitive to detect antibody after receipt of vaccination in all instances.

Seroconversion does not always result in full protection against disease, although no data regarding correlates of protection are available for adults. If a vaccinated health care provider is exposed to VZV, the employee should be monitored daily (screen for fever, skin lesions, and systemic symptoms) from day 10 to day 21 after exposure through the employee health or infection control program to determine clinical status. Persons with varicella may be infectious starting 2 days before onset of rash. In addition, the health care worker should be instructed to report fever, headache, or other constitutional symptoms and any skin lesions (which may be atypical) immediately. The person should be placed on sick leave immediately if symptoms occur. The risk of transmission of vaccine virus from a vaccinated person to a susceptible contact appears to be very low, and the benefits of vaccinating susceptible health care providers clearly outweigh this potential risk. Transmission of vaccine virus appears to occur primarily if and when the vaccine develops a vaccine-associated rash. As a safeguard, institutions may wish to consider protocols for personnel who develop a rash following receipt of vaccination (e.g., avoidance of contact with persons at high risk of developing serious complications, such as immunosuppressed persons who do not have evidence of varicella immunity).

MMRV vaccine is indicated for vaccination against measles, mumps, rubella, and varicella in children 12 months through 12 years of age.[145] Persons 13 years of age and older should not receive MMRV. When used, MMRV vaccine should be administered on or after the first birthday, preferably as soon as the child becomes eligible for vaccination. MMRV may be used for both the first and second doses of MMR and varicella in children younger than 13 years. The minimum interval between doses of MMRV is 3 months. However, if the second dose is administered at least 28 days after the first dose, the second dose does not need to be repeated.

POST-EXPOSURE PROPHYLAXIS

Data from the United States and Japan in a variety of settings indicate that varicella vaccine is 70 to 100 percent effective in preventing illness or modifying the severity of illness if it is used within 3 days, and possibly up to 5 days, after exposure.[420,482] The ACIP recommends the vaccine for use in persons who do not have evidence of varicella immunity following exposure to varicella. If exposure to varicella does not cause infection, post-exposure vaccination should induce protection against subsequent exposure. If the exposure results in infection, no evidence indicates that administration of varicella vaccine during the incubation period or prodromal stage of illness increases the risk of vaccine-associated adverse reactions. Although post-exposure use of varicella vaccine has potential applications in hospital settings, pre-exposure vaccination of all health care workers without evidence of varicella immunity is the recommended and preferred method for preventing varicella in health care settings.

Varicella outbreaks in some settings (e.g., childcare facilities and schools) can persist up to 6 months. Varicella vaccine has been used successfully to control these outbreaks. The ACIP recommends a second dose of varicella vaccine for outbreak control. During a varicella outbreak, persons who have received one dose of varicella vaccine should receive a second dose, provided the appropriate vaccination interval has elapsed since the first dose (3 months for persons 12 months to 12 years old and at ≥4 weeks for persons ≥13 years of age).

In 2006, the ACIP approved a revised definition for evidence of immunity to varicella.[159] Revised criteria for evidence of immunity to varicella includes any of the following:

- Documentation of age-appropriate vaccination
  - Preschool-age children 12 months of age and older: one dose
  - School-age children, adolescents, and adults: two doses
  - Laboratory evidence of immunity or laboratory confirmation of disease
  - Born in the United States before 1980
- Diagnosis of varicella or verification of history of varicella disease by a health care provider
- History of herpes zoster based on health care provider diagnosis.

Varicella vaccine is not licensed for use in persons who have blood dyscrasias, leukemia, lymphoma of any type, or other malignant neoplasms affecting the bone marrow or lymphatic systems. According to current ACIP and AAP recommendations, varicella vaccine should not be administered to persons who have cellular immunodeficiencies, but persons with impaired humoral immunity may be vaccinated.[115]

HIV-infected children 12 months of age and older who are in CDC clinical class N, A, or B with $CD4^+$ T-lymphocyte counts of 15 percent or greater and without evidence of varicella immunity should receive two doses of single-antigen varicella vaccine at a minimum interval of 3 months. Varicella vaccine was recommended previously for asymptomatic or mildly symptomatic HIV-infected children (CDC clinical class N and A) with age-specific $CD4^+$ T-lymphocyte counts 25 percent or greater (http://www.cdc.gov/mmwr/PDF/rr/rr4806.pdf).[115] Because data are not available on safety, immunogenicity, or efficacy of MMRV vaccine in HIV-infected children, MMRV vaccine should not be administered as a substitute for the component vaccines when vaccinating HIV-infected children.

Women should be assessed prenatally for evidence of varicella immunity. On completion or termination of their pregnancies, women who do not have evidence of varicella immunity should receive the first dose of varicella vaccine before discharge from the health care facility. The second dose should be administered 4 to 8 weeks later (at the postpartum or other health care visit). To ensure administration of varicella vaccine, standing orders are recommended for health care settings where completion or termination of pregnancy occurs.

Precautions and Contraindications

Varicella-containing vaccines are contraindicated in the following situations: (1) pregnancy, (2) severe febrile illness, (3) known history of anaphylactic reaction to vaccine components, and (4) immunodeficiency states (malignancy, primary immunodeficiency disease, immunosuppressive or corticosteroid therapy, and radiation therapy).[24,34,104,115]

Immunocompromised patients with conditions such as lymphoreticular or other generalized malignancy and primary or secondary immunodeficiency conditions should not be given live attenuated varicella vaccine. Exceptions as previously noted include (1) persons with impaired humoral immunity, (2) asymp-

tomatic or mildly symptomatic HIV-infected children, and (3) susceptible children with acute lymphocytic leukemia in continuous remission for at least 1 year and with a lymphocyte count greater than 700/μL (0.7×10^9/L) and a platelet count greater than 100×10^3/μL (100×10^9/L). With appropriate monitoring, these children have been immunized safely as part of a research protocol.[92,104]

Administration of varicella vaccine should be avoided if the individual is receiving immunosuppressive doses of systemic corticosteroids. The effects of corticosteroids vary, but many clinicians consider a dose equivalent to either 2 mg/kg body weight or 20 mg/day of prednisone to be sufficiently immunosuppressive to raise concern about the safety of vaccination with live virus vaccines.

After cessation of immunosuppressive therapy, varicella vaccine generally is withheld for at least 1 month. Because the intensity and type of immunosuppressive therapy, radiation therapy, underlying disease, and other factors determine when immunologic responsiveness will be restored, making a definitive recommendation for an interval after cessation of immunosuppressive therapy when varicella vaccine can be safely and effectively administered often is not possible.

Transmission of the live attenuated varicella vaccine virus used for immunization has been documented rarely. Therefore, contacts of immunocompromised patients should be vaccinated to prevent the spread of natural varicella to such patients. Vaccinees in whom a rash develops in the month after immunization should avoid direct contact with immunocompromised, susceptible individuals for the duration of the rash.

Receipt of antibody-containing blood products (whole blood, plasma, or parenteral immunoglobulin) may interfere with seroconversion to varicella vaccine. The length of time that such passively acquired antibody persists depends on the concentration and quantity of the blood product received (see Table 255–11).[308]

Although no direct evidence demonstrates that varicella vaccine is harmful to a pregnant female or her fetus, the vaccine should not be administered to women known to be pregnant or considering becoming pregnant within the month because of the theoretical risk of fetal infection associated with a live virus vaccine. Vaccinated women should avoid conception for 1 month after receiving vaccination. The manufacturer, in collaboration with the CDC, has established a Varicella Vaccination in Pregnancy Registry to monitor the maternal-fetal outcomes of pregnant women inadvertently given varicella vaccine. The telephone number for the registry is 800-986-8999.

Varicella vaccine may be considered for a nursing mother. Although most live virus vaccines are not secreted in breast milk, whether varicella vaccine virus is excreted in human milk and, if so, whether the infant can be infected are unknown.

Reye syndrome has occurred in children infected with varicella who receive salicylates. Whether varicella vaccine may induce Reye syndrome is not known, but the vaccine manufacturer recommends that salicylates not be given within at least 6 weeks after administration of varicella vaccine.

DISEASES FOR WHICH COMBINATION VACCINES ARE AVAILABLE

Increasing numbers of new and improved vaccines are being introduced. Incorporation of these vaccines into already complex childhood immunization schedules poses a challenge. In the 2009 Recommended Immunization Schedule in the United States, a minimum of 22 separate injections are needed to immunize a child from birth to 2 years of age.[38,157] At some visits, the administration of three to five separate injections can be indicated.

Combination vaccines represent one solution to the problem of increased numbers of injections. These vaccines incorporate, into a single product, antigens that prevent several diseases. Combinations licensed in recent years in the United States are shown in Table 255–17.

The ACIP, AAP, and AAFP have indicated a preference for the use of licensed combination vaccines over separate injections of the equivalent component vaccines, except in the case of MMRV.[30,113] Separate vaccines should not be combined into the same syringe for administration together unless such mixing is indicated on the package insert approved by the FDA. The safety, immunogenicity, and efficacy of unlicensed combinations are unknown.

Mixing antigens in the same syringe can result in an increase or, more commonly, a decrease in the immunogenicity of one or more components of the combination vaccine. An antigen may have chemical incompatibility with other antigens or may cause interference with the immune response to those antigens when incorporated into a single vaccine. The unpredictability of the effect of combining different products in the same syringe can be the result of interference, antigenic competition, or carrier protein interference. Interference can result from chemical incompatibility among the vaccine antigens and the stabilizers, adjuvants, or preservatives. For example, thimerosal, a preservative used in DTP, a vaccine no longer used in the United States, decreases the potency of poliovirus antigens in IPV. Formulations of DTP/IPV used in Europe and Canada avoid interference by using a different preservative.

Antigenic competition occurs when one or more vaccine strains in a combination vaccine replicate more efficiently than the other strains do. For example, the concentration of the varicella component in MMRV is higher than in single-component varicella vaccine because measles replication interfered with that of varicella.[145] Carrier protein interference was identified when multiple polysaccharide–protein conjugate vaccines using the same carrier protein were administered simultaneously with large doses of the carrier protein antigen. An example would be the simultaneous administration of a tetravalent pneumococcal vaccine conjugated with tetanus toxoid and a DTP-IPV-PRP-T vaccine.[191] This problem should be preventable by using different carrier proteins in new combination conjugate vaccines.

Clinical studies in infants have demonstrated that using some combination vaccine products containing Hib vaccine may induce a suboptimal immune response to the Hib vaccine component. Because of the potential for a suboptimal immune response to

TABLE 255–17 Combination Vaccines Licensed in the United States since 1995

Vaccine	Trade Name	Manufacturer	Date of First Licensure
DTaP-IPV-Hib conjugate (PRP-T)	Pentacel	Sanofi Pasteur	2008
DTaP-IPV	Kinrix	GlaxoSmithKline	2008
Measles-mumps-rubella-varicella	ProQuad	Merck	2005
DTaP-IPV-hepatitis B	Pediarix	GlaxoSmithKline	2002
Hepatitis A-hepatitis B	Twinrix	GlaxoSmithKline	2001
Hib conjugate (PRP-T)–DTaP	TriHIBit	Aventis Pasteur	1996
Hib conjugate (PRP-OMP)–hepatitis B	COMVAX	Merck	1996

DTaP, diphtheria-tetanus-acellular pertussis; Hib, Haemophilus influenzae *type b*, *IPV, inactivated poliovirus vaccine.*

the Hib component,[209] the currently licensed DTaP/Hib combination product should not be used for primary vaccination in infants aged 2, 4, or 6 months.[112]

In general, vaccines from different manufacturers that protect against the same disease are interchangeable. Data are not available on the interchangeability of DTaP vaccines. Vaccines from the same manufacturer should be used throughout a series whenever feasible. Licensure of combination vaccines usually is based on studies indicating that the product's immunogenicity (or efficacy) and safety are similar to those of monovalent products licensed previously. A combination vaccine may be used interchangeably with monovalent formulations and other combination products with similar component antigens produced by the same manufacturer.

VACCINES WITH SELECTIVE INDICATIONS FOR CHILDREN AND ADOLESCENTS

BACILLE CALMETTE-GUÉRIN VACCINE

Effective control of tuberculosis in the United States has been achieved by the early identification and treatment of cases, followed by surveillance of household and other close contacts and institution of appropriate preventive measures for those at high risk for development of disease. In the United States, the mainstay of preventive therapy is isoniazid chemoprophylaxis, which is used in asymptomatically infected persons to prevent the progression of infection to disease. In selected instances, however, the potential for acquiring disease, poor compliance in contacts instructed to take chemoprophylaxis, or failure of chemoprophylaxis may justify the use of immunoprophylaxis.[105] Elsewhere in the world, BCG vaccine is used in more than 100 countries and is recommended routinely at birth by the WHO (see Table 255–6).[501] Of primary concern to pediatricians is the risk to an infant born to a tuberculous mother or living within a household with other identified tuberculous individuals.[23]

Preparations

BCG is a live attenuated strain derived from *Mycobacterium bovis*. All currently available BCG vaccines are derived from the original strain at the Pasteur Institute in Paris, but they have been propagated by different methods in many laboratories and therefore vary in their immunogenic and reactogenic properties. BCG vaccines manufactured by Organon Teknika Corporation (Durham, NC) and Connaught Laboratories (Willowdale, Ontario, Canada) are licensed in the United States. Comparative evaluations of these and other BCG vaccines have not been performed. BCG is administered either percutaneously or intradermally. BCG preparations instilled in treatment of bladder cancer are not intended to be used as vaccines.[105]

Immunogenicity and Efficacy

BCG is used primarily in young infants in an attempt to prevent disseminated and other life-threatening manifestations of *Mycobacterium tuberculosis* disease. However, BCG does not prevent infection with *M. tuberculosis*. The efficacy of different BCG vaccines seems to be highly variable. Two meta-analyses of published clinical trials and case-control studies concerning the efficacy of BCG vaccines concluded that BCG has relatively high protective efficacy (≈80%) against meningeal and miliary tuberculosis in children.[179,411] The protective efficacy against pulmonary tuberculosis, however, differed significantly among the studies, thus precluding a specific conclusion. Protection afforded by BCG in one meta-analysis was estimated to be 50 percent.

Adverse Events

BCG vaccination usually results in scarring at the site of injection. BCG preparations have been associated uncommonly (1% to 2% of vaccinations) with local adverse reactions such as subcutaneous abscess and lymphadenopathy, which are not generally serious. Osteitis affecting the epiphyses of long bones is a rare complication that develops in one per million vaccinees and may occur as long as several years after receiving BCG immunization. The rate may be higher in newborns. Disseminated fatal disease occurs rarely (0.1 to 1 case per million vaccinees), primarily in persons with severely impaired immune systems.[105,309,329,446] Antituberculosis therapy, except for pyrazinamide, is recommended to treat osteitis and disseminated disease caused by BCG. Some experts also recommend treatment of chronic suppurative lymphadenitis caused by BCG. Persons with complications caused by BCG should be referred, if possible, to a tuberculosis expert for management.

Indications

In the United States, administration of BCG should be considered only in limited and select circumstances, such as unavoidable risk of exposure to *M. tuberculosis* and failure or unfeasibility of other methods of control of tuberculosis. The ACIP and the AAP have published recommendations for the use of BCG to control tuberculosis in children.[23,105]

Healthy infants from birth to 2 months of age may be given BCG without tuberculin skin testing; thereafter, BCG is given only to children with a negative tuberculin skin test. In infants and children, BCG immunization should be considered for those who are not infected with HIV in the following circumstances:

- The child is exposed continually to a person or persons with contagious pulmonary tuberculosis resistant to isoniazid and rifampin and the child cannot be removed from this exposure.
- The child is exposed continually to a person or persons with untreated or ineffectively treated contagious pulmonary tuberculosis, and the child cannot be removed from such exposure or given antituberculosis therapy.

Careful assessment of the potential risks and benefits of BCG vaccine and consultation with personnel in local area control programs for tuberculosis are strongly recommended before the use of BCG. When BCG vaccine is given, care should be taken to observe the precautions and directions for administration on the product label.

Skin Test Reactivity

Recipients of BCG should have repeat tuberculin skin tests 2 to 3 months after immunization to establish that tuberculin cellular reactivity has developed. Failure to react dictates the need for repeat BCG vaccination followed by repeat tuberculin testing.[105] The tuberculin reaction to the BCG vaccine available in the United States generally results in 7 to 15 mm of induration after vaccination and diminishes gradually during subsequent years; without re-vaccination or repeated exposure to *M. tuberculosis*, reactivity usually disappears within 10 years.[105] The size of the area of induration may be correlated with the number of doses of BCG.[276] However, tuberculin skin test sensitivity does not correlate with BCG efficacy.[259] In BCG recipients, differentiating between a tuberculin reaction representing acquired tuberculous infection and persisting post-vaccination reactivity is difficult. Because the degree and duration of protection against tuberculous disease afforded by BCG are uncertain, a positive

tuberculin reaction always must be suspected to be indicative of disease.

Precautions and Contraindications

BCG vaccine should not be administered to individuals with burns, skin infections, and primary or secondary immunodeficiencies, including HIV infection. The use of BCG also is contraindicated in persons receiving immunosuppressive medications, including high-dose corticosteroids.

In the United States, where the risk of acquiring tuberculosis is low, BCG vaccine should not be administered to children with known or suspected asymptomatic HIV infection.[105,374] However, in populations where the risk of contracting tuberculosis is high, the WHO has recommended that asymptomatic HIV-infected children receive BCG vaccine at birth or shortly thereafter.[501,505] Although no harmful effects of BCG vaccine on the fetus have been documented, women should avoid receiving vaccination during pregnancy.

CHOLERA VACCINE

Fewer than 300 cases of cholera have been recognized in the United States since the late 1980s.[98] Most cases have occurred in travelers to cholera-affected areas or persons who have eaten contaminated food brought or imported from these areas.[98] Although cholera remains a significant public health concern in African, South American, and Asian countries, even in these countries the risk to U.S. travelers is low. Persons following the usual tourist itinerary who use standard accommodations in countries reporting cholera are at virtually no risk of acquiring infection.[146]

Preparations

As of August 2000, the only cholera vaccine approved for use in the United States was no longer being manufactured or sold.[146] Two oral vaccines have been licensed for commercial use in other countries. One vaccine consists of killed whole-cell *Vibrio cholerae* O1 with purified recombinant B-subunit of cholera toxoid (WC/rBS; Dukoral; SBL Vaccin AB, Stockholm). The other vaccine, an attenuated live oral genetically modified *V. cholerae* O1 strain (CVD 103-HgR; Orochol; Berna Biotech, Bern; known as Mutachol in Canada), is not currently being produced.[266]

Immunogenicity and Efficacy

WC/rBS vaccine confers protection specific to *V. cholerae* serogroup O1.[266] Immunization does not protect against *V. cholerae* serogroup O139 or other species of *Vibrio*. Field trials in Bangladesh, Peru, and Sweden have shown that the WC/rBS vaccine confers 85 to 90 percent protection for 6 months in all age groups after administration of two doses, 1 week apart. In Bangladesh, protection declined rapidly after 6 months in young children, but it was still approximately 60 percent in older children and adults after 2 years.

Adverse Events

More than 5 million doses of WC/rBS vaccine have been supplied worldwide.[266] According to manufacturer information from clinical trials and post-marketing surveillance, mild gastrointestinal symptoms (abdominal pain, cramping, diarrhea, nausea) are most commonly reported, occurring at a frequency of 0.1 to 1 percent. Serious adverse events, including a flulike syndrome, rash, arthralgia, and paraesthesias, are rare, occurring in less than 1 in 10,000 doses distributed.

Indications

Routine immunization is not recommended for travelers.[146,333] Oral cholera vaccines may be considered for those at higher than average risk, such as health professionals in endemic areas, aid workers in refugee camps, and those traveling to remote areas where cholera epidemics are occurring and access to medical care is limited. At present, no country requires proof of cholera immunization as a condition for entry, and the WHO recommends against such a requirement. Some local authorities, however, may require immunization (to determine local requirements, travelers may consult the embassies of the countries to which they will be traveling).

Only limited data are available on the safety and immunogenicity of the vaccine in children aged 1 to 2 years, and protective efficacy has not been studied. Therefore, WC/rBS vaccine is not recommended to be used in children younger than 2 years of age.

Precautions and Contraindications

Oral cholera vaccine should not be administered to persons with a hypersensitivity reaction to any of the vaccine components, Administration of oral cholera vaccine should be postponed for subjects suffering from acute gastrointestinal illness or acute febrile illness.

JAPANESE ENCEPHALITIS VIRUS VACCINE

JE virus, the most important cause of epidemic arboviral encephalitis in Asia, has a wide clinical spectrum, ranging from asymptomatic infection to permanent neurologic sequelae, and a high case-fatality rate of 30 to 70 percent.[361,461] An inactivated mouse brain–derived vaccine has controlled JE virus infection successfully among human populations in Japan, Korea, and Taiwan since 1968.[380] Two other JE virus vaccines have been used widely, primarily in China: an inactivated primary hamster kidney cell–derived vaccine and a live attenuated vaccine.[336] Only the inactivated mouse brain–derived vaccine is available internationally for travelers from non-endemic countries. This vaccine is licensed in the United States for use in persons living in or traveling to Asia.

Preparations

The JE vaccine licensed in the United States is a formalin-inactivated vaccine prepared by purifying JE virus from the brains of mice inoculated intracerebrally with JE virus.[93] Although the vaccine undergoes two major purification steps, including ultracentrifugation, complete removal of mouse proteins is not possible. Each 1-mL dose of vaccine contains less than 50 ng of mouse serum proteins and no detectable murine myelin basic protein.[93] The vaccine contains gelatin from bovine and porcine sources, formaldehyde, and thimerosal as a preservative. This vaccine has limited availability in the United States. A new inactivated cell culture–derived vaccine has been developed but is not expected to be licensed and available in the United States until 2009.

Immunogenicity and Efficacy

Immunogenicity studies in the United States indicate that three doses are needed to provide protective concentrations of serum neutralizing antibody in greater than 80 percent of vaccinees.[399] Protective concentrations have been defined by animal challenge experiments.[380] The longevity of neutralizing antibody after the primary vaccination series is not known. In one Japanese study, protective antibody titers persisted for 3 years after the administration of a booster dose.[300]

A field trial of the currently licensed JE vaccine conducted in Thai children demonstrated an efficacy of 91 percent when compared with placebo.[271] The efficacy for a single year of a prototype of the currently licensed vaccine, field-tested in Taiwanese children, was 80 percent.[274]

Adverse Reactions

JE vaccination is associated with a moderate frequency of local and mild systemic side effects. Local reactions occur in approximately 20 percent of vaccines, and approximately 10 percent have reported systemic side effects such as fever, headache, malaise, or rash.[93]

Neurologic adverse reactions, including acute disseminated encephalomyelitis, also have been reported. In Denmark, acute disseminated encephalomyelitis has been estimated to occur in 1 in 50,000 to 75,000 vaccinees. However, a review of post-marketing data in the United States from 1993 to 1999 found no serious neurologic events occurring after receipt of JE immunization.[450]

Hypersensitivity reactions have been reported. Urticaria or angioedema of the extremities, face, and oropharynx, especially the lips, characterizes these reactions. They occur a median of 12 hours after administration of the first dose of vaccine. The interval between administration of a second dose and onset of symptoms generally is longer, with a median of 3 days and possibly as long as 2 weeks. Reactions have occurred after the administration of a second or third dose when the preceding doses did not cause symptoms. Hypersensitivity reaction rates are similar after the administration of both first and second doses—a rate of approximately 15 to 62 per 10,000 immunizations in U.S. citizens. The vaccine component responsible for these adverse events has not been identified.[93]

Indications

JE vaccine is recommended for persons older than 3 years of age who will be residing in areas where JE is endemic or epidemic.[93] No data are available on vaccine safety and efficacy in infants. The risk for acquiring JE varies highly within endemic regions. Therefore, the incidence of JE in the area of residence, conditions of housing, the nature of activities, and the possibility of unexpected travel to high-risk areas are factors that should be considered in the decision to vaccinate.

JE vaccine is *not* recommended for all travelers to Asia. The vaccine should be offered to persons spending a month or longer in endemic areas during the transmission season, especially if travel will include rural areas. *Health Information for International Travel*, updated regularly by the CDC, provides a useful table that lists affected areas by country and notes the transmission season.[146]

The decision to use JE vaccine should balance the risks for exposure to the virus and the development of illness, the availability and acceptability of mosquito repellents and other alternative protective measures, and the side effects of vaccination.

The recommended primary immunization series is three doses administered on days 0, 7, and 30. An abbreviated schedule of days 0, 7, and 14 can be used when a longer schedule is impractical because of time constraints. Two doses administered 1 week apart will confer short-term immunity in 80 percent of vaccinees. However, this schedule should be used only under unusual circumstances. The last dose should be administered at least 10 days before travel commences to ensure an adequate immune response and access to care if a delayed, adverse reaction occurs.[93] No data are available regarding vaccine safety and efficacy in infants.[7]

The duration of protection is unknown, and definitive recommendations cannot be given on the timing of booster doses. Booster doses may be administered after 2 years.

Precautions and Contraindications

Because generalized urticaria and angioedema can occur within minutes to as long as 2 weeks after administration of vaccination, epinephrine, other medications, and equipment to treat anaphylaxis should be available. Vaccinees should be observed for 30 minutes after receiving vaccination and should be warned about the possibility of delayed development of urticaria and angioedema, which can occur as long as 2 weeks after being vaccinated. Vaccinees should be advised to remain in areas with ready access to medical care for 10 days after receiving a dose of JE vaccine.

Hypersensitivity to proteins of rodent or neural origin, to thimerosal, or to a previous dose of JE vaccine is a contraindication to receiving vaccination.

A study in U.S. military personnel found an association between reactions to JE vaccine and a past history of having urticaria. A history of urticaria should be considered when weighing the risks and benefits of vaccination.

No specific information is available on the safety of JE vaccine in pregnancy. Limited data suggest that the vaccine can be given to patients with altered immune status. Little information is available on the effect of concurrent administration of other vaccines on the safety and immunogenicity of JE vaccine.

RABIES VACCINE

Rabies is a viral zoonosis transmitted in saliva and other tissue of infected mammals. The virus enters the central nervous system of the host and causes an acute, progressive encephalomyelitis that almost always is fatal. Post-exposure prophylaxis is possible because of the long incubation period, usually weeks to months, of this infection.

Wild animals are the most important source of infection for both humans and domestic animals. Rabid, insectivorous bats carrying variants of the rabies virus have been responsible for nearly all human cases of rabies in the continental United States in recent years. Transmission has been shown to occur from even minor and unrecognized bites from infected bats. Of the 36 human cases of rabies diagnosed in the United States between 1980 and 1997, 21 (58%) were associated with bat variants.[114] Wild carnivores, especially skunks, foxes, coyotes, and raccoons, are the terrestrial animals most often infected with rabies. Wildlife rabies occurs throughout the continental United States; only Hawaii remains consistently rabies-free. Domestic animals including dogs, cats, and ferrets also may be infected, with three times as many reports of rabies annually in cats compared with dogs.[141] The likelihood of human exposure to rabies from a domestic animal in the United States is a rare occurrence, a result of effective national rabies control programs. In most other countries (e.g., Asia, Africa, and Latin America), dogs remain the most important potential source of infection. Therefore, international travelers to areas where canine rabies is still endemic have an increased risk of exposure to rabies. Twelve of the 36 human rabies deaths reported to the CDC from 1980 through 1997 appear to have been related to rabid animals outside the United States.[109,373]

Preparations

Three rabies vaccines are licensed commercially for pre-exposure and post-exposure prophylaxis in the United States: human diploid cell vaccine (HDCV), rabies vaccine adsorbed (RVA), and purified chicken embryo cell (PCEC), but only HDCV and PCEC are being produced. The HDCV and PCEC vaccines are licensed for intramuscular administration. The HDCV product for intradermal use is no longer available. HDCV (Imovax Rabies, Sanofi Pasteur) is derived from the Pitman-Moore strain grown

in human diploid cell culture. PCEC (RabAvert, Chiron Corporation-Novartis) is prepared from the fixed rabies virus strain Flury LEP grown in primary culture of chicken fibroblasts.[205] The HDCV and PCEC vaccines each contain the WHO recommended standard of at least 2.5 IU of rabies virus antigen per 1.0-mL intramuscular dose. Although not licensed for use in the United States, two intradermal rabies vaccines are recommended by the WHO and used in countries where the two tissue culture vaccines (HDCV and PCEC) are prohibitively expensive.[5]

Immunogenicity and Efficacy

Viral neutralizing antibodies (VNAs) are produced within 7 to 10 days, and protective immunity usually persists for 2 years or longer. Although a definitive protective titer has not been identified, the WHO[507] and the CDC adhere to working guidelines for an acceptable response to immunization.[82] The CDC currently specifies complete viral neutralization at a 1:5 or greater titer by the rapid fluorescent-focus inhibition test as acceptable; the WHO specifies 0.5 IU/mL or more as acceptable.

No randomized, placebo-controlled, human trials have documented the efficacy of vaccine for pre-exposure or post-exposure prophylaxis. However, substantial field experience, as well as direct evidence from controlled animal studies, demonstrates a protective effect. The paucity of human cases attests to the efficacy of post-exposure prophylaxis with the currently recommended vaccine and immunoglobulin preparations. To date, rabies has not been reported in the United States in any patient who received the currently recommended post-exposure measures. Cases of human rabies occurring after post-exposure administration of prophylaxis have resulted from failure to adhere to established guidelines, such as those of the CDC or the WHO.[91,207,220,431,485]

Adverse Events

Reactions occurring after administration of HDCV or PCEC vaccine are less serious and less common than those associated with the previously available vaccines.[114] Local reactions at the injection site occur in 30 to 74 percent of injections, and mild systemic reactions such as fever, headache, nausea, abdominal pain, muscle aches, and dizziness occur in 5 to 40 percent of vaccine recipients. In one report, approximately 6 percent of persons had an immune complex–like reaction 2 to 21 days after receipt of the booster dose of HDCV.[83] This systemic hypersensitivity reaction occurred less frequently in persons receiving primary vaccination. The reactions have been associated with the presence of beta-propiolactone–altered human albumin in HDCV and the development of IgE antibodies to this allergen.[221]

Indications and Precautions

When used as indicated, both types of rabies vaccine are considered equally safe and effective for both pre-exposure and post-exposure prophylaxis (see the ACIP recommendations[114]). Usually, an immunization series is initiated and completed with one vaccine product. No clinical studies have been conducted that documented a change in efficacy or the frequency of adverse reactions when the series is completed with a second vaccine product. Ideally, an immunization series should be completed with the same product unless serious allergic reactions occur. Corticosteroids, immunosuppressive conditions, and concurrent administration of antimalarials can interfere with the adequate development of an active immune response. Post-vaccination titers should be checked in these circumstances.

For adults, rabies vaccination always should be administered in the deltoid area. For children, the anterolateral aspect of the thigh also is acceptable. The gluteal area never should be used for HDCV or PCEC injections because administration of HDCV in this area results in lower neutralizing antibody titers and decreased immunogenicity.[220]

POST-EXPOSURE PROPHYLAXIS

The essential components of rabies post-exposure prophylaxis are wound treatment and, for previously unvaccinated persons, concurrent administration of human rabies immune globulin (HRIG) and vaccine (Table 255–18).[114] The combination of active and passive immunization is indicated for the treatment of

TABLE 255–18 Rabies Post-exposure Prophylaxis for Individuals not Previously Immunized

Animal Type	Evaluation and Disposition of the Animal	Post-exposure Prophylaxis Recommendations
Wild		
Skunk Fox Raccoon Most other carnivores Bat	Regard as rabid unless animal proven negative by laboratory tests*	Consider immediate vaccination
Domestic		
Dog	Healthy and available for 10 days observation	Persons should not begin prophylaxis unless animal develops clinical signs of rabies†
Cat	Rabid or suspected rabid	Immediately vaccinate
Ferret	Escaped (unknown)	Consult public health officials
Other		
Livestock	Consider individually	Consult public health officials.
Small rodents Large rodents (woodchucks and beavers) Lagomorphs (rabbits and hares) Other mammals		Bites of squirrels, hamsters, guinea pigs, gerbils, chipmunks, rats, mice, other small rodents, rabbits, and hares almost never require antirabies prophylaxis

**The animal should be euthanized and tested as soon as possible. Holding for observation is not recommended. Discontinue vaccine if immunofluorescence test results of the animal are negative.*

†During the 10-day observation period, begin post-exposure prophylaxis at the first sign of rabies in a dog, cat, or ferret that has bitten someone. If the animal exhibits clinical signs of rabies, it should be euthanized immediately and tested.

Adapted from Centers for Disease Control and Prevention: Human rabies prevention: United States, 1999. Recommendations of the Advisory Committee on Immunization Practices (ACIP). M. M. W. R. Morb. Mortal. Wkly. Rep. 48:*1*, *1999.*

all bite and all non-bite exposures inflicted by animals suspected or proven to be rabid. Recommendations for the management of persons with possible exposure to rabies include giving meticulous attention to thorough cleansing of the wound with soap and water. The decision to give rabies immunoprophylaxis depends on the circumstances precipitating the exposure, the species and condition of the animal inflicting the wound, and the prevalence of rabies in local animal populations. Bite and non-bite exposures, including scratches, abrasions, open wounds, or mucous membranes contaminated with saliva, are considered significant. Because the need for preventive measures is based on these specific circumstances, the local department of health should be consulted promptly concerning the necessity for initiating post-exposure prophylaxis.

When possible, the brains of wild animals (skunks, foxes, coyotes, raccoons, and bats), stray dogs or cats, or symptomatic animals implicated in an exposure should be examined in certified laboratories for evidence of rabies. Immunization always should be initiated promptly and discontinued only if laboratory results are negative. Individuals exposed to healthy dogs or cats that are available for observation do not require immediate prophylactic treatment. Implicated healthy domestic dogs or cats should be quarantined and observed for at least 10 days. If symptoms develop that suggest rabies, the exposed individual should begin post-exposure prophylaxis, and the brain of the animal should be examined. An unknown or unavailable animal must be regarded as potentially rabid.

Studies conducted in the United States by the CDC have documented that a regimen of one dose of HRIG and five doses of rabies vaccine (1.0 mL for each dose) given on days 0, 3, 7, 14 and 28 was safe and induced an excellent antibody response in all recipients.[114] If anatomically feasible, the full dose of HRIG (20 IU/kg body weight) should be infiltrated thoroughly in the area around and into the wounds. Any remaining volume should be injected intramuscularly at a site distant from that of vaccine administration. The dose of HRIG should not exceed that recommended and should not be given beyond the seventh day because HRIG can partially suppress active antibody production.

Persons previously fully vaccinated do not require HRIG and should receive only vaccine (two doses 3 days apart) because an amnestic response will occur after the administration of a booster regardless of the antibody titer.[114] Serum for antibody testing should be obtained from persons whose prophylaxis history or immune status is uncertain, and the course of post-exposure active and passive immunoprophylaxis as described for nonimmune individuals should be initiated immediately. If serologic testing demonstrates adequate anti-rabies antibody, post-exposure prophylaxis may be discontinued.

Once initiated, rabies prophylaxis should not be interrupted or discontinued because of local or mild systemic adverse reactions to rabies vaccine. Usually, such reactions can be successfully managed with anti-inflammatory and antipyretic agents such as ibuprofen or acetaminophen. When a person with a history of having had serious hypersensitivity to rabies vaccine must be re-vaccinated, antihistamines can be administered. Epinephrine should be readily available to counteract any anaphylactic reactions, and the person should be observed carefully immediately after receiving vaccination.

PRE-EXPOSURE PROPHYLAXIS

Active immunization should be considered for high-risk groups (i.e., veterinarians, animal handlers and control officers, selected laboratory workers, persons visiting countries where rabies is hyperendemic, and persons whose pursuits may involve frequent contact with rabid animals, such as spelunkers). Persons whose risk of exposure is less but whose access to immediate competent medical care is restricted also should be considered for pre-exposure prophylaxis. The primary series consists of three doses (1.0 mL per dose) administered on days 0, 7, and 21 or 28, given intramuscularly in the deltoid area. This three-dose series provides long-term protective immunity, and routine serologic testing for rabies antibody following primary immunization is not necessary. For those individuals who may be immunosuppressed, measurement of anti-rabies antibodies should be performed. In the case of continued or frequent exposure, serum samples should be tested every 2 years and a booster dose of rabies vaccine provided when the antibody titer falls below the minimum accepted level.[114]

Precautions and Contraindications

Because of the potential consequences of inadequately treated rabies exposure and because no indication exists that fetal abnormalities have been associated with rabies vaccination, pregnancy is not considered a contraindication to post-exposure prophylaxis.[114] If the risk of exposure to rabies is substantial, pre-exposure prophylaxis may also be indicated during pregnancy.

Persons who have a history of serious hypersensitivity to rabies vaccine should be re-vaccinated with caution. Although serious systemic, anaphylactic, or neuroparalytic reactions are rare events during and after the administration of rabies vaccines, such reactions pose a serious dilemma for the patient and the attending physician. A patient's risk of acquiring rabies must be carefully considered before deciding to discontinue vaccination. Advice and assistance on the management of serious adverse reactions for persons receiving rabies vaccines may be sought from the state health department or the CDC.

TYPHOID VACCINE

Typhoid fever, an acute, life-threatening febrile illness caused by the bacterium *Salmonella enterica* serovar *typhi* (*S. typhi*), remains a serious public health problem throughout the developing world. Although disease prevalence varies greatly depending on the specific population studied, current global estimates suggest that 21.6 million cases of typhoid and 200,000 deaths occur annually.[187] In the United States and much of the developed world, typhoid fever has virtually disappeared.[187] Approximately 400 cases of typhoid fever, mostly among travelers, are reported to the CDC each year. Most reported cases in the United States are acquired during travel to developing countries.[97] Therefore, the primary indication for typhoid vaccination in the United States is international travel to an endemic area. In developing countries without safe water and sanitation, mass immunization is a potentially effective strategy to limit both the severity and impact of typhoid fever.[2]

The changing epidemiology of typhoid fever underscores the importance of vaccination in both international travelers and high-risk populations in endemic regions. Current studies report that the highest incidence rate is now found in children younger than 5 years of age and results in more severe disease than previously.[436,439] *S. typhi* is increasingly resistant to ampicillin, chloramphenicol, and co-trimoxazole, and quinolone resistance is now being reported.[418,433] Case-fatality rates, which had decreased from 10 to 1 percent with appropriate antibiotic therapy,[508] could rise again without safe, effective, and affordable vaccination strategies.

Preparations

The three types of typhoid vaccines are as follows: inactivated, whole-cell vaccines; live attenuated bacterial vaccines; and subunit vaccines.[146] The parenteral, heat-phenol-inactivated, whole-cell

TABLE 255–19 Dosage and Schedule for Typhoid Fever Vaccination

Vaccination	Age (yr)	Dose/Route of Administration	No. of Doses	Dosing Interval	Boosting Interval
Oral Live Attenuated TY21a Vaccine					
Primary series	≥6	1 capsule*/oral	4	48 hr	Not applicable
Booster	≥6	1 capsule*/oral	4	48 hr	Every 5 yr
Vi Capsular Polysaccharide Vaccine					
Primary series	≥2	0.50 mL/IM	1	Not applicable	Not applicable
Booster	≥2	0.50 mL/IM	1	Not applicable	Every 2 yr

**Administer with cool liquid no warmer than 37° C (98.6° F).*

Adapted from Centers for Disease Control and Prevention: Health Information for International Travel 2005-2006. Atlanta, U.S. Department of Health and Human Services, Public Health Service, Centers for Disease Control and Prevention, 2005.

vaccine widely used for many years was highly immunogenic but also was highly reactogenic and no longer is available in the United States. It is the only vaccine currently approved for use in children as young as 6 months and is still available in several developing countries because of its affordability, although manufacturing of this vaccine may not be up to international standards.

Two vaccines currently are licensed for use in the United States[57,212]: an oral live, attenuated vaccine (TY21a, Vivotif Berna) and a purified Vi (virulence) capsular polysaccharide of *S. typhi* vaccine (ViCPS) (Typhim Vi, Aventis Pasteur) for intramuscular use. Table 255–19 provides information on vaccine dosage and administration. The time required for primary vaccination differs for the two vaccines, as do the lower age limits for use in children.

Ty21a (Vivotif, BernaBiotech) is an oral, live attenuated vaccine consisting of a stable mutant, Ty21a, developed by chemical mutagenesis of a pathogenic *S. typhi* strain. This vaccine was licensed in the United States in 1989 for use in adults and children 6 years of age and older and is available as an enteric-coated capsule. The four-dose primary vaccine series (in the United States and Canada, three-dose series in other parts of the world) is administered as one capsule every other day, taken 1 hour before a meal, for a total of four capsules. The capsules should be kept refrigerated (not frozen), and all four doses must be taken to achieve maximum efficacy. Each capsule should be taken with cool liquid no warmer than 37° C (98.6° F), approximately 1 hour before a meal. This regimen should be completed 1 week before potential exposure. The vaccine manufacturer recommends that Ty21a not be administered to infants or children younger than 6 years of age.

A parenteral subunit vaccine, ViCPS (Typhim Vi, Sanofi Pasteur), was licensed in 1994 for use in adults and children as young as 2 years of age. Primary vaccination with ViCPS consists of one 0.5-mL (25 μg) dose administered intramuscularly and should be given at least 2 weeks before potential exposure. The manufacturer does not recommend the vaccine for children younger than 2 years of age.

In circumstances of continued or repeated exposure to *S.* serotype *typhi*, booster doses are recommended to maintain immunity after primary immunization. The optimal booster schedule for either vaccine has not been determined. Current recommendations for re-vaccination with either vaccine are provided in Table 255–19. No data have been reported concerning the use of one vaccine as a booster after primary immunization with the other.

Efficacy

Although field trials have demonstrated the efficacy of each vaccine, no comparative studies have been performed.[97] For the heat-phenol-inactivated, whole-cell vaccine, efficacy ranged from 51 to 88 percent and lasted for as long as 7 seven years. The oral, live attenuated Ty21a vaccine stimulates humoral (both serum IgG and mucosal IgA antibodies) as well as cell-mediated immune responses. In trials of the Ty21a vaccine, efficacy ranged from 42 to 96 percent after administration of the initial series of three doses, with the lower efficacies seen in trials from areas with highly endemic disease.[322,437] The optimum schedule for booster immunizations has not been determined for this vaccine. Protective immunity has been shown to persist for at least 7 years in field trials in endemic countries where herd immunity may have an effect.[248] Re-vaccination is recommended with the same four-capsule regimen every 5 years for as long as continued exposure is likely to occur.

Immunization with ViCPS results in seroconversion, defined as a fourfold rise in serum anti-Vi antibody, in 80 percent of vaccinees within 2 weeks in endemic as well as non-endemic areas.[248,264,302] Because the vaccine is administered parenterally, mucosal immunity does not develop. The efficacy of ViCPS vaccine in clinical trials was 72 percent at 17 months[1] and 64 percent at 21 months[302] after administration of a single dose. Polysaccharide vaccines do not stimulate T cells and cannot establish immunologic memory. Additional doses of ViCPS therefore do not elicit a booster effect. Re-vaccination with a single dose is recommended every 2 years for people who remain at risk.

None of the typhoid vaccines approach 100 percent efficacy, and a large inoculum of *S. typhi* can overcome vaccine-induced immunity. Vaccines do not substitute for proper hygiene and appropriate food handling practices.

Adverse Events

Reactions to the oral Ty21a vaccine generally are mild and consist of transient gastrointestinal upset, fever, headache, and occasionally rash; these reactions occur in less than 5 percent of recipients.[97] Adverse systemic effects are reported in less than 1 percent of vaccines, and neither the development of bacteremia nor person-to-person transmission has been reported.[248]

Reactions to the ViCPS vaccine also occur infrequently, reported in approximately 7 percent of recipients.[97] These reactions include tenderness at the injection site, erythema, and induration, fever, and, very rarely, rashes; systemic complaints occur in less than 2 percent.[248] In contrast, reactions to the inactivated, whole-cell vaccine occur more commonly and are more severe; they include fever in as many as 24 percent of recipients, headache, and severe local pain or swelling in as many as 35 percent of vaccinees. Thirteen to 24 percent of vaccinees subsequently have missed school or work.[323]

Indications

Typhoid vaccination in the United States is recommended only for the following groups[21,97,146,251]:

- Travelers to areas where typhoid fever is endemic and in whom a risk of exposure is recognized; risk of exposure is greatest with travel to the Indian subcontinent, Latin America, Asia, the Middle East, and Africa (see www.cdc.gov/travel)
- Persons with intimate exposure to a documented *S. typhi* carrier, such as occurs with continuing household contact
- Laboratory workers who have frequent contact with *S. typhi* and people living in areas outside the United States with endemic typhoid infection

Vaccination is not recommended for persons attending summer camp or for those in areas of natural disaster or for control of common-source outbreaks. Doses and schedules for the different typhoid vaccines are given in recommendations of the CDC.[97,146]

Contraindications

Ty21a is a live attenuated vaccine and should not be given to immunocompromised patients, including those receiving high doses of corticosteroids and persons with HIV infection.[97,146] Ty21a vaccine also should not be administered during a gastrointestinal illness or concurrent with certain antibiotics. The 2006 *Red Book* recommends avoiding antimicrobial therapy for at least 24 hours before the first dose of oral typhoid vaccine through 7 days after the last dose.[21] Reports are conflicting regarding the use of the anti-malarial agents atovaquone and proguanil; however, chloroquine and mefloquine do not appear to interfere with the immune response to oral Ty21a. Neither of the available typhoid vaccines should be given to anyone with a history of having severe local or systemic reactions after receiving a previous dose of vaccine.

Ty21a is not approved for children younger than 6 years of age, and ViCPS is not approved for children younger than the age of 2 years. The whole-cell, inactivated vaccine available outside of the United States is approved for use in for children younger than the age of 2 years and older than 6 months of age.

Information is not available on the safety of these vaccines when they are used during pregnancy. It is prudent on theoretical grounds to avoid vaccinating pregnant women.

YELLOW FEVER VACCINE

Yellow fever occurs only in sub-Saharan Africa and tropical South America, where it causes an estimated 200,000 cases annually.[360] As a result, yellow fever is an important vaccine-preventable disease among travelers to areas where yellow fever occurs. From 1996 to 2002, five cases of yellow fever among unvaccinated travelers from the United States and Europe to areas where yellow fever is endemic were fatal.[118,134,341] The risk to unvaccinated travelers of acquiring yellow fever probably is increasing because potential zones of transmission of yellow fever are expanding to include urban areas with large populations of susceptible humans and abundant competent mosquito vectors. Vaccination is the most effective preventive measure against yellow fever, a disease that has no specific treatment and may cause death in 20 percent of patients.[360]

Preparations

Yellow fever vaccines are derived from the original 17D yellow fever vaccine strain. The live attenuated 17D-204 and 17DD yellow fever strains are the yellow fever vaccines most commonly used.[360] The 17D-204 yellow fever vaccine, which is prepared in chick embryos, is licensed in the United States.[160] Primary immunization consists of a single, subcutaneous injection of reconstituted, freeze-dried vaccine for both adults and children.

Immunogenicity and Efficacy

Seroconversion rates of 93 percent have been documented in young children receiving yellow fever vaccine.[509] Immunity acquired from immunization with the 17D strain virus has been demonstrated to persist for more than 10 years.[160,415,500] Revaccination is required no more frequently than every 10 years.[415]

Adverse Events

The 17D-204 and 17DD yellow fever vaccines are among the safest and most effective viral vaccines.[360] Since 1965, approximately 8 million doses of 17D-derived yellow fever vaccine have been administered to U.S. travelers, and approximately 300 million doses have been administered to persons in areas where yellow fever is endemic. Although 2 to 5 percent of persons who receive vaccine report headaches, myalgia, and low-grade fever 5 to 10 days after receiving vaccination, less than 1 percent will report curtailing their usual activities.

Serious adverse events associated with yellow fever vaccine rarely occur. Immediate hypersensitivity reactions, characterized by rash, urticaria, or asthma, or a combination of these, are uncommon (incidence <1 case per 131,000 vaccinees). Unrecognized allergy to eggs or chicken or to the hydrolyzed gelatin used to stabilize the vaccine may be responsible for hypersensitivity reactions.

Historically, yellow fever vaccine–associated adverse events were seen primarily among infants and presented as encephalitis. Since 1992, five cases of encephalitis among adult recipients of yellow fever vaccine have been reported to the U.S. VAERS.[146] In addition, 10 cases of autoimmune neurologic disease, including patients with GBS and acute disseminated encephalomyelitis, have been reported to VAERS. All patients with yellow fever vaccine–associated neurologic disease had an onset of illness 4 to 23 days after receiving vaccination. All cases were in first-time vaccine recipients. The risk for vaccine-associated neurologic disease does not appear to be limited to infants, and crude estimates in the United States of the reported frequency range from 4 to 6 cases per 1,000,000 doses distributed.

A serious adverse reaction syndrome has been described among recipients of yellow fever vaccines produced by several different manufacturers. This syndrome previously was reported as febrile multiple organ system failure and now is called *yellow fever vaccine–associated viscerotropic disease*. Since 1996, 9 cases of yellow fever vaccine–associated viscerotropic disease, a disease clinically and pathologically resembling naturally acquired yellow fever, have been reported in the United States; an additional 17 cases had been identified worldwide as of October of 2004.[133,468] All U.S. patients required intensive care after experiencing fever, hypotension, respiratory failure, elevated hepatocellular enzymes, hyperbilirubinemia, lymphocytopenia, and thrombocytopenia; 8 of the 9 also had renal failure that required hemodialysis. Six of the U.S. cases were fatal. In several cases for which tissue samples were available, immunohistochemistry demonstrated viral dissemination throughout the body, including liver, lung, spleen, lymph node, brain, and smooth muscle; however, in many cases, tissue samples were not available for histopathologic review or detection of virus. All cases reported thus far have occurred in primary vaccinees.

Yellow fever vaccines must be considered as a possible, but rare, cause of yellow fever vaccine–associated viscerotropic disease that is similar to fulminant yellow fever caused by wild-type yellow fever virus. Accurately measuring the incidence of vaccine-associated viscerotropic disease is currently precluded by lack of adequate prospective data; however, crude estimates in the United

States of the reported frequency range from 3 to 5 cases per 1,000,000 doses distributed. This frequency appears to be higher for persons older than 60 years of age, as high as 19 cases per million doses distributed.

Indications

Yellow fever vaccine is recommended for persons 9 months of age or older traveling to or residing in areas where yellow fever is endemic.[160] Because of the increased risk for development of neurologic complications, infants aged 4 to 8 months should be considered for vaccination only when travel to high-risk areas is required and high-level protection against mosquito exposure is not feasible. Vaccination for international travel is required. To obtain an international certificate of vaccination, a yellow fever vaccine approved by the WHO and administered at a designated yellow fever vaccine center is required. Yellow fever vaccine centers in the United States can be identified by contacting state or local health departments. The International Health Regulations require re-vaccination at intervals of 10 years. Re-vaccination may boost antibody titers; however, evidence from several studies suggests that yellow fever immunity persists for at least 30 to 35 years and probably for life.[160]

Precautions and Contraindications

The risk for having adverse reactions appears to be age-related.[160] Infants younger than 6 months should not receive yellow fever vaccine because of the increased risk of vaccine-associated neurotropic disease developing in this age group.[7] Immunization should be delayed until an infant is at least 9 months of age. In unusual circumstances, physicians considering vaccinating infants younger than 9 months of age should contact the Division of Vector-Borne Infectious Diseases (970-221-6400) or the Division of Global Migration and Quarantine (404-498-1600) at the CDC for advice.

No adverse effects of yellow fever vaccine on the developing fetus have been demonstrated. Vaccine administration to pregnant women, however, generally is not indicated because the vaccine is a live virus. Pregnant women should be considered for vaccination only when travel to high-risk areas is required and protection against mosquito exposure is not feasible.

Whether this vaccine is excreted in breast milk is not known. No reports exist of adverse events or transmission of the vaccine viruses from nursing mother to infant. As a precautionary measure, vaccination of nursing mothers should be avoided because of the theoretical risk of the transmission of virus to the breast-fed infant. When travel of nursing mothers to high-risk yellow fever endemic areas cannot be avoided or postponed, these women may be vaccinated.

Yellow fever vaccine poses a theoretical risk to patients with altered immunity as a result of underlying disease or immunosuppressive therapy. These patients should not be vaccinated. If travel to an epidemic or endemic area is necessary, the patient should be instructed in ways to avoid mosquitoes and given a vaccine waiver letter.

A history of thymus disease has been identified as a contraindication to receiving yellow fever vaccine. Four of the 26 vaccine recipients with yellow fever vaccine–associated viscerotropic disease worldwide have had a history of diseases involving the thymus, all of which are extremely rare, a finding suggesting that compromised thymic function may be another independent risk factor for viscerotropic disease.[53] Health care providers should ask about a history of thymus disorder when they are screening a patient before administering yellow fever vaccine. For persons with such a history, alternative means of prevention should be recommended, if travel plans cannot be altered to avoid yellow fever-endemic areas.

Persons with a history of systemic anaphylaxis to eggs should not be vaccinated because the vaccines contain egg proteins and on rare occasion may induce immediate allergic reactions. Less severe or local manifestations of allergy to eggs or to feathers are not contraindications to yellow fever vaccine administration and do not warrant performing vaccine skin testing.[6] If international quarantine regulations are the only reason to immunize a patient known to be hypersensitive to eggs, attempts should be made to obtain a waiver. If immunization of an individual with a questionable history of egg hypersensitivity is considered essential because of a high risk of exposure, an intradermal skin test may be given as directed in the vaccine package insert.[160]

VACCINES RELATED TO BIOTERRORISM

Two vaccines, anthrax and smallpox, are potentially available to protect children against bioterrorist attacks with *Bacillus anthracis* and variola. Neither vaccine is available commercially at this time and does not have indications for children and adolescents in the absence of a bioterrorist attack.[417] The vaccines are reviewed in the relevant disease-specific chapters.

INVESTIGATIONAL VACCINES

Routine immunizations for children have virtually eliminated many infectious diseases from the United States. These successes have encouraged research to develop vaccines to prevent other serious viral and bacterial diseases affecting children. A 1985 report by the IOM of the National Academy of Sciences reviewed the benefits that would be associated with the development and use of new and improved vaccines in the United States.[182] The report listed 14 diseases for which vaccines were desirable. A 1999 study by the IOM noted that considerable progress had been made since the 1985 study.[183] Seven of 14 vaccines listed in the 1985 study as domestic priorities for development are now licensed. They include acellular pertussis vaccine, LAIV, and vaccines against hepatitis A and B, Hib, varicella, and rotavirus.

The 1999 IOM report used a new quantitative model to compare the cost and health benefits of developing candidate vaccines.[183] This model can be used to evaluate the potential impact of a new vaccine on public health. In the 1999 report, the model was used to evaluate diseases for which candidate vaccines were being developed. The report divided 26 candidate vaccines into 4 groups, from most to least favorable for development. The 4 vaccines in the top tier include a cytomegalovirus vaccine given to adolescents, a universal influenza vaccine, a group B streptococcus vaccine for high-risk adults and pregnant women, and an *S. pneumoniae* vaccine for infants and seniors. Other diseases for which vaccines would be desirable included *Chlamydia trachomatis*, enterotoxigenic *Escherichia coli*, Epstein-Barr virus, *Helicobacter pylori*, hepatitis C virus, herpes simplex virus, HPV, *M. tuberculosis*, *Neisseria gonorrhoeae*, respiratory syncytial virus, parainfluenza virus, *Shigella*, and groups A and B streptococcus.

Two vaccines listed in the 1999 study are now licensed, pneumococcal conjugate vaccine for infants and HPV vaccine. Candidate vaccines are in human trials for many of the other pathogens listed in the 1999 IOM report.

Advances in biotechnology, increased understanding of the virulence factors of infectious agents, and knowledge of the host immune response have led to new approaches for vaccine development.[212] The three general categories of approaches include the following: live vaccines; killed, inactivated, or subunit vaccines; and, most recently, DNA-based vaccines. In addition, newer technologies such as adjuvants or delivery systems and vectors can be applied to improve immunogenicity. Vaccines are

being developed by the application of these newer technologies to numerous infectious agents for which vaccines are not currently available, especially those pathogens listed in the 1999 IOM report.

CHAPTER 256

Passive Immunization

E. Richard Stiehm ✪ Margaret A. Keller

GENERAL PRINCIPLES OF PASSIVE IMMUNITY

DEFINITION

Passive immunization is the administration of antibodies from an immune subject to provide immediate protection against a microbial agent, toxic substance, or cell. In general, passive immunization is used to provide temporary immunity in an unimmunized subject exposed to an infectious disease when active immunization is unavailable (e.g., respiratory syncytial virus infection), is contraindicated (e.g., varicella in an immunocompromised child), or has not been given before exposure (e.g., tetanus, rabies).

Passive immunization also is used in the management of certain disorders associated with toxins (e.g., diphtheria), in certain bites (e.g., snake and spider), in drug overdose (e.g., digoxin), as a specific (e.g., Rh_0[D] immune globulin) or nonspecific (e.g., antithymocyte globulin) immunosuppressant, and in the treatment of certain infectious diseases.

Several types of preparations are used in passive immunization (Table 256–1):

1. standard human immune serum globulin (HISG) for general use, which is available in three forms: immune globulin (IG) for intramuscular use (IGIM), intravenous use (IGIV), and subcutaneous use (IGSC);
2. special high-titer IGs with a known antibody content for specific illnesses;
3. animal serums and antitoxins;
4. monoclonal antibodies (Tables 256–1, 256-2).

These preparations are listed in Table 256–1. Most of the licensed special IGs are for intramuscular use only. Plasma, serum, and even breast milk also can be used in passive immunization.

Passive immunization is not always effective; the duration is short and variable (1-6 weeks), and undesirable reactions may occur, especially if the antibody is of nonhuman origin. High-titer special IGs and IGIVs are identical to regular IGs and IGIVs, except that they are derived from patients hyperimmunized or convalescing from a specific infection or selected from donors with high titers to a specific antigen; they are useful in several disorders in which regular IG and IGIV are of little or no value.

ANIMAL SERUMS AND ANTITOXINS

Animal serums and antitoxins are derived from the serum of immunized animals, usually horses (equine). Because these sera are foreign proteins, they carry a significant risk of sensitization. Thus, they should be administered only when specifically indicated, after sensitivity tests, and by a physician prepared to deal with a hypersensitivity reaction.

A careful history must be taken before an animal serum is injected. Inquiry must be made about asthma, hay fever, urticaria, and previous injections of animal serum. Patients with a history of asthma, allergic rhinitis, or other allergic symptoms on exposure to horses may be dangerously sensitive to the corresponding serum and should be given only with the utmost caution.

SENSITIVITY TESTS FOR ANIMAL SERUM

A scratch, prick, or puncture skin test, followed by an intradermal skin test, always should be performed before any injection of animal serum, regardless of whether the patient has had the serum previously. A scratch, prick, or puncture test is performed by applying a drop of a 1:100 dilution of the serum in saline to the site of a superficial scratch, prick, or puncture on the volar aspect of the forearm and observing it for 20 minutes. A positive control (histamine phosphate, 0.1%) and negative control (saline) also should be applied. A positive reaction consists of erythema or wheal formation 3 mm greater than the control. (Note: previous use of antihistamines may render results of these tests negative.)

If the scratch, prick, or puncture test result is negative, an intradermal test is performed by injecting 0.02 mL of a 1:1000 saline dilution; again, positive (histamine phosphate, 0.1%) and negative control tests should be performed. The reaction is read after 10 to 30 minutes and is positive if a wheal appears that is 3 mm greater than the negative control. If the test result is negative, it should be repeated with 0.02 mL of a 1:100 dilution. For persons with negative histories of animal allergy and no previous exposure to animal sera, the 1:100 dilution may be used initially if the scratch, prick, or puncture test result is negative.

Although intradermal skin tests have resulted in fatalities, scratch, prick, or puncture tests have not but can still be associated with immediate reactions. Therefore, a skin test never should be performed (nor a serum injected) unless a syringe containing 1 mL of 1:1000 epinephrine is within immediate reach.

Skin tests can indicate the probability of sensitivity. However, a negative skin test result is not an absolute guarantee of the absence of sensitivity. Therefore, either a specific history of allergy or a positive skin test reaction with horse serum is sufficient reason for special caution. A positive history of sensitivity to horse dander is an indication of the need for extreme caution.

ADMINISTRATION OF ANIMAL SERUM

If the history and sensitivity test reactions are negative, the indicated dose of serum may be given intramuscularly, with epinephrine at hand. The patient should be watched closely for an hour for adverse reactions.

Intravenous injection may be indicated if a high concentration of circulating antibody is required rapidly, as in severe tetanus or diphtheria. The manufacturer's instructions should be consulted. If they are unavailable, a preliminary dose of 0.5 mL of serum should be diluted in 10 mL of either physiologic saline or 5 percent glucose solution. This preparation should be given intravenously during the course of 5 minutes, and the patient should be watched for 30 minutes for reactions. If no reaction occurs, the remainder of the serum, diluted 1:20, may be given at a rate not to exceed 1 mL/min.

TABLE 256–1 Antibody Preparations Available for Passive Immunity in the United States

Product	Abbreviations and Brand Names	Principal Use
Standard human immune serum globulins for intramuscular or subcutaneous use		
Immune globulin, intravenous	IGIV, IVIG	Treatment of antibody deficiency, immune thrombocytopenic purpura, Kawasaki disease, other immunoregulatory and inflammatory diseases
Immune globulin, intramuscular	IGIM, IG, ISG	Treatment of antibody deficiency; prevention of measles, hepatitis A
Immune globulin, subcutaneous	IGSC	Treatment of antibody deficiency
Special human immune globulins for intramuscular or subcutaneous use		
Hepatitis B immune globulin	HBIG	Prevention of hepatitis B
Varicella-zoster immune globulin	VZIG	Prevention or modification of chickenpox
Rabies immune globulin	RIG	Prevention of rabies
Tetanus immune globulin	TIG	Prevention or treatment of tetanus
Vaccinia immune globulin	VIG, VIGIM	Prevention or treatment of vaccinia, prevention of smallpox
Rh_0(D) immune globulin	RhoGAM	Prevention of Rh hemolytic disease
Special human immune globulins for intravenous use		
Cytomegalovirus immune globulin	CMV-IGIV, CMVIG, CytoGam	Prevention or treatment of cytomegalovirus infection
Hepatitis B immune globulin, intravenous	HBIGIV, HepaGam B	Prevention of hepatitis B (including liver transplantation)
Vaccinia immune globulin	VIGIV	Prevention or treatment of vaccinia, prevention of smallpox
Rh_0(D) immune globulin, intravenous	WinRho SDF	Treatment of immune thrombocytopenic purpura
Botulinum immune globulin	BIG, BabyBIG	Treatment of newborn botulism
Animal serums and globulins		
Tetanus antitoxin (equine)	TAT	Prevention or treatment of tetanus (when TIG is unavailable)
Diphtheria antitoxin (equine)	DAT	Treatment of diphtheria
Botulinum antitoxins (equine)		Treatment of botulism
Latrodectus mactans antivenin (equine)		Treatment of black widow spider bites
Crotalidae polyvalent antivenin (equine)		Treatment of most snake bites
Crotalidae polyvalent immune Fab (ovine)		Treatment of most snake bites
Micrurus fulvius antivenin (equine)		Treatment of coral snake bites
Digoxin immune Fab fragments (ovine)†	Digibind, DigiFab	Treatment of digoxin or digitoxin overdose
Lymphocyte/thymocyte immune globulin (equine)	Equine ATG, Atgam	Immunosuppression
Lymphocyte/thymocyte immune globulin (rabbit)	Rabbit ATG, Thymoglobulin	Immunosuppression
Monoclonal antibodies		
Muromonab (anti-CD3)	OKT3	Immunosuppression
Daclizumab (anti-CD25)	Zenapax	Immunosuppression
Basiliximab (anti-CD25)	Simulect	Immunosuppression
Infliximab (anti–TNF-α)	Remicade	Treatment of inflammatory bowel disease, rheumatoid arthritis
Trastuzumab (anti–HER-2)	Herceptin	Treatment of breast cancer
Rituximab (anti-CD20)	Rituxan	Treatment of B-cell lymphoma, autoimmune diseases
Tositumomab (anti-CD20*)	Bexxar	Treatment of refractory B-cell lymphoma
Omalizumab (anti-IgE)	Xolair	Prevention and treatment of asthma, allergic disorders
Efalizumab (anti-CD11α)	Raptiva	Treatment of psoriasis
Adalimumab (anti–TNF-α)	Humira	Treatment of rheumatoid arthritis, inflammatory bowel disease
Bevacizumab (anti-VEGFR)	Avastin	Treatment of metastatic colon cancer
Cetuximab (anti-EGFR)	Erbitux	Treatment of metastatic colon cancer
Natalizumab (anti–α_4 integrin)	Tysabri	Treatment of multiple sclerosis
Ranibizumab (anti-VEGFR†)	Lucentis	Treatment of macular degeneration
Gemtuzumab (anti-CD33‡)	Mylotarg	Treatment of acute myelocytic leukemia
Alemtuzumab (anti-CD52)	Campath	Treatment of chronic lymphocytic leukemia
Abciximab (anti-GPIIb/IIIa†)	ReoPro	Prevention of thrombosis
Palivizumab (anti-RSV)	Synagis	Prevention of respiratory syncytial virus infection
Ibritumomab (anti-CD20§)	Zevalin	Treatment of refractory B-cell lymphoma

Monoclonal antibody characteristics:
**Radiolabeled with iodine 131.*
†Fab fragment.
‡Conjugated with calicheamicin.
§Radiolabeled with yttrium 90.
EGFR, epithelial growth factor receptor; GP, glycoprotein; HER-2, human epithelial growth factor receptor 2; RSV, respiratory syncytial virus; TNF, tumor necrosis factor; VEGFR, vascular endothelial growth factor receptor.

If the skin test reaction is positive or a history of allergy to animal serum is present and the need for the serum is unquestioned (and epinephrine is at hand), a procedure commonly called desensitization can be undertaken, but any significant desensitization is unlikely to occur. This procedure merely results in establishing temporary tolerance to the serum. Desensitization should be performed by trained personnel with the necessary emergency equipment and drugs immediately available.

Desensitization consists of periodic (at 15-minute intervals) injections or infusions of progressively larger doses of the serum,

TABLE 256–2 USAD Nomenclature for Monoclonal Antibodies*

The suffix -mab is used for all monoclonal antibodies and fragments.	
The following letters preceding -mab identify the product source:	
u	human
e	hamster
o	mouse
i	primate
a	rat
xi	chimeric
zu	humanized
The general disease state subclass for which the monoclonal antibody is used is encoded by the syllables preceding the above:	
Disease or target class	
-vir	viral
-bac	bacterial
-lim	immune
-les	infectious lesions
-circ	cardiovascular
Tumors	
-col	colon
-mel	melanoma
-mar	mammary
-got	testis
-gov	ovary
-pr(o)	prostate
-tum	miscellaneous

**United States Adopted Name.*

starting at a very low dose, until tolerance is achieved. Schedules for intravenous and intradermal, subcutaneous, or intramuscular desensitization are given in the *2006 Red Book*.[21] Administration of sera after desensitization has been achieved must be continuous; protection from desensitization is lost rapidly.

HYPERSENSITIVITY REACTIONS TO ANIMAL SERUM

Hypersensitivity reactions to animal serum may be of four general types:

1. anaphylactic reactions consisting of urticaria or other rashes; respiratory distress with wheezing, dyspnea, cough, hoarseness, or stridor; cardiovascular reactions including tachycardia, hypotension, arrhythmia, cyanosis, shock, and unconsciousness; and gastrointestinal reactions, such as cramps, diarrhea, and vomiting, all occurring seconds to minutes after an injection has been administered;
2. acute febrile reactions consisting of moderate or severe hyperpyrexia within 2 hours after an injection has been given;
3. serum sickness reactions consisting of urticaria, arthritis, adenopathy, and fever occurring hours to days after an injection has been administered, depending on the dose and the presence or degree of previous sensitization (serum sickness occurs within hours or a few days after the second injection and within 7 to 12 days after the first injection); and
4. delayed reactions of varying nature, including peripheral neuritis, nephritis, Guillain-Barré syndrome, and myocarditis.

TREATMENT OF HYPERSENSITIVITY REACTIONS TO ANIMAL SERUM

For anaphylactic reactions, 1:1000 epinephrine at a dose of 0.01 mL/kg (0.5 mL maximum dose) is given subcutaneously or intramuscularly immediately. If improvement is not achieved immediately, 1:10,000 epinephrine at a dose of 0.01 mL/kg is given intravenously. This dose can be repeated every 10 minutes for up to three doses. The 1-mL 1:1000 epinephrine vials must be diluted 1:10 in physiologic saline (now 1:10,000) and injected slowly at a dose of 0.01 mL/kg. (A 1:10,000 dilution in a 10-mL vial also is available.)

Administration of epinephrine may be repeated in 5 to 15 minutes if the response is not satisfactory. Vasopressors and positive-pressure oxygen are helpful. For severe urticaria or edema, particularly edema of the larynx, intramuscular injection of antihistamines and corticosteroids is indicated. Administration of serum therapy (if necessary) should be resumed 6 to 8 hours later or after all visible signs of reaction have subsided.

Mild febrile reactions (temperatures of less than 39° C [102.8° F]) are treated with aspirin, ibuprofen, or acetaminophen. Severe febrile reactions can cause convulsions and death and should be treated rigorously with sponge baths or other cooling means to reduce the temperature promptly. Serum sickness and serum neuritis generally are treated with corticosteroids.

HUMAN IMMUNE SERUM GLOBULIN

Human immune serum globulin (HISG, or gamma globulin) is available in three forms for general use: intramuscular (IGIM), intravenous (IGIV, IVIG), and subcutaneous (IGSC). IGIM is used primarily for the prevention of certain infectious disorders, as outlined in Table 256–1, and less commonly for the treatment of antibody immunodeficiencies; IGIV is used in the treatment of primary and secondary antibody deficiencies, many immunoregulatory disorders (e.g., immune thrombocytopenic purpura, Kawasaki disease), and neurologic disorders (e.g., Guillain-Barré syndrome, peripheral neuritis). IGSC is used exclusively for treatment of antibody deficiency.

Several high-titer IGIMs and IGIVs are available for use in certain illnesses as listed in Table 256–1.

INTRAMUSCULAR IMMUNE GLOBULIN

Pharmacology

Intramuscular immune globulin (IGIM, IMIG) is prepared from pooled human serum by the Cohn alcohol fractionation procedure (thus deriving its alternative name of Cohn fraction II). This procedure and viral inactivation steps remove most other serum proteins, hepatitis viruses, and human immunodeficiency viruses (HIV-1 and HIV-2), thereby providing a safe product for intramuscular injection. It is reconstituted as a sterile approximate 16 percent solution (160 mg/mL) with or without preservative. It contains a wide spectrum of antibodies to viral and bacterial antigens.

IGIM is greater than 95 percent immunoglobulin G (IgG), but trace quantities of IgM and IgA and other serum proteins are present. The IgM and IgA are therapeutically insignificant because of their rapid half-lives (approximately 7 days) and their low concentrations in IG. IG contains all IgG allotypes (Gm and Km types).

IGIM is approved only for intramuscular or subcutaneous use, and intravenous injection of IG generally is contraindicated. IG aggregates in vitro to high-molecular-weight complexes (9.5S to 40S) that are strongly anticomplementary. These aggregates probably are responsible for the occasional systemic reactions to IGIM. The incidence of these reactions is increased if the patient has received IGIM previously or if it is inadvertently given intravenously. Agammaglobulinemic boys with affected male relatives (suggesting X-linked inheritance) may have a lower incidence of

reactions.[395] Small intradermal injections of IGIM are not of value (except as a placebo), and they are contraindicated.

Intramuscular Immune Globulin in Antibody Immunodeficiency

IGIM is used infrequently now for IgG replacement therapy in immunodeficiency. The usual dosage is 100 mg/kg per month, about equivalent to 0.7 mL/kg per month of the 16 percent (160 mg/mL) product. Two or three such injections are given at the onset of therapy as a loading dose, often during the course of a 3- to 5-day period. The maximal maintenance dosage should not exceed 20 or 30 mL per week.

Few studies on optimal dosage are available; however, the Medical Research Council Working Party[395] found that 25 mg/kg per week (100 mg/kg per month) was therapeutically equivalent to 50 mg/kg per week but that 10 mg/kg per week was inadequate. Use of IGIM by this route has been supplanted largely by IGIV administration.

IGIM should be given at multiple sites to avoid giving more than 5 mL at any one site (10 mL in a large adult). The buttocks are the preferred site, but the anterior of the thighs also can be used. Tenderness, sterile abscesses, fibrosis, and sciatic nerve injury may result from these injections. The danger of sciatic nerve injury is especially great in a small malnourished infant with inadequate muscle and fat in the gluteal regions. Large doses of IGIM should not be given to patients with severe thrombocytopenia because of the risk for development of hematoma and infection.

The injections are given initially at monthly intervals. If the patient continues to have infection or if a characteristic symptom (e.g., cough, conjunctivitis, diarrhea, arthralgia, or purulent nasal discharge) recurs at the end of the injection period, the interval between doses is decreased to 3 or 2 weeks. Older patients often report that they can tell when their IgG level is low and they need another injection. During acute infections, IgG catabolism increases, so extra injections of IGIM often are given.

Because high serum levels of IgG cannot be maintained, serial immunoglobulin assays are unnecessary in assessing the effectiveness of treatment. The maximal increase in serum IgG level after a standard IGIM injection will vary from patient to patient and from dose to dose because of different rates of absorption, local proteolysis at the injection site, and distribution within tissues.

An intramuscular injection of 100 mg/kg of IGIM usually raises the IgG serum level by 100 mg/dL after 2 to 4 days.[565] Thus, a recent IGIM injection usually does not obscure the diagnosis of hypogammaglobulinemia.

Intramuscular Immune Globulin and Special Intramuscular Immune Globulins for Prevention of Infectious Diseases

IGIM is recommended for prophylaxis of hepatitis A and measles. The recommended doses are found in the sections on these disorders. Special high-titer IGIMs are available for several disorders (see Table 256–1), such as hepatitis B and varicella. These products are identical to IGIM except for the high titers of specific antibodies. These products also are discussed in the sections on these disorders.

Adverse Effects of Intramuscular Immune Globulin

Although IGIM is one of the safest biologic products available, rare anaphylactic reactions to intramuscular injections have been reported, particularly in patients requiring repeated injections.[166] The Medical Research Council Working Party[395] noted such reactions in 33 of 175 patients (19%) treated during a 10-year period. In all, 85 reactions occurred after approximately 40,000 injections; in eight patients, the injections were stopped as a result of these adverse effects, and one death was recorded. Such reactions occurred at any stage of treatment and were unrelated to any particular lot number of IGIM or its anticomplementary activity. Symptoms include anxiety, nausea, vomiting, malaise, flushing, facial swelling, cyanosis, and loss of consciousness. Immediate treatment with epinephrine and antihistamines is indicated.

Persons who experience such reactions should be evaluated before receiving a repeated injection. Skin testing should be performed with several lots of IGIM.[166] A skin test result that is positive for an old but not a new lot of IG may indicate a particular idiosyncratic reaction to a particular lot. Under these circumstances, incremental doses of IG from a new lot are recommended. In other patients, IgE antibodies to IgG develop and result in positive immediate skin test reactions to all IGIM lots. In many other patients, no cause of the reactions can be found. Some of these patients will tolerate gradually increasing doses of IG, particularly if they are premedicated with a nonsteroidal anti-inflammatory agent, diphenhydramine, or corticosteroids. Finally, in a few patients, antibodies have developed to the IgA present in minute quantities in IG; these IgA antibodies can be detected by serologic means in several laboratories.[623] This topic is discussed further under adverse effects of IGIV.

Administration of exogenous gamma globulin may inhibit the endogenous synthesis of gamma globulin. In a few patients given IGIM or IGIV from early infancy, we have noted depressed IgG levels that return to normal when the injections are stopped. Amer and colleagues[11] reported decreased IgG levels in premature infants given monthly IGIM injections since birth.

IGIM injections or infusions may inhibit antibody responses to live virus vaccines such as measles or varicella. Siber and associates[536] recommend an interval of 3 months between IVIG or IGIM therapy and administration of live virus vaccines after IG doses of less than 40 mg/kg, an interval of 6 months after doses of 40 to 80 mg/kg, an interval of 8 months after doses of 80 to 400 mg/kg, and an interval of 12 months after large doses (1 to 2 g/kg).

Late side effects after IGIM injections are uncommon occurrences; however, fibrosis of the buttocks or localized subcutaneous atrophy may develop at the site of repeated injections in some patients. Repeated injections of IGIM may result in high levels of mercury from the thimerosal preservative. Although symptoms of acrodynia (mercury toxicity) developed in one patient as a result of such therapy,[382] most remain asymptomatic.

INTRAVENOUS IMMUNE GLOBULIN

Intravenous immune globulin (IGIV, IVIG) is further-treated Cohn fractionated human IG that has been rendered free of complexes and is thus safe for intravenous infusion. These products can be given in large quantities for antibody deficiencies[99]; for several autoimmune, inflammatory and neurologic disorders[49,162]; and for prevention of transplant rejection.[289,290]

Pharmacology

The first IGIV produced in the United States in 1981 was Gamimune (Cutter Laboratories), a reduced and alkylated 5 percent solution containing 10 percent maltose.[30] The second IVIG produced was prepared by acidification and treatment with pepsin; the lyophilized powder could be reconstituted as a 3, 6, or 12 percent solution (Sandoglobulin, Sandoz Pharmaceuticals). Since then, several other IGIVs have been introduced by different manufacturers.[443]

Several methods of treating Cohn fraction II, including treatment with proteolytic enzymes, ultracentrifugation, chromatog-

raphy, reduction of sulfhydryl bonds by alkylation, and incubation at low pH, have been used to eliminate high-molecular-weight complexes. Solvent and detergent treatment, pasteurization, and addition of the fatty acid caprylate are used to ensure that viral inactivation occurs.[251] Various stabilizers, such as maltose, albumin, or sucrose, then are added. These variations in manufacturing techniques result in unique characteristics among the different IG products.[443]

Although these products vary somewhat from brand to brand and batch to batch,[545,565] they are for the most part therapeutically equivalent and usually are selected on the basis of cost and convenience. Minor IgA and IgG subclass differences exist.[32,545] Antibody titers to specific pathogens also may vary from lot to lot as well as among different IGIVs.[187] Products differ as to their IgA content, which can be a consideration for patients with anti-IgA antibodies.[32] Premixed liquids have the advantage of convenience because the reconstitution step is not required; however, most solutions must be kept refrigerated.

All IGIV products currently available have all IgG subclasses, adequate serum half-lives (15 to 25 days), wide spectrum of antibody activity, and minimal anticomplementary activity, and they are free of bacterial and viral contamination.[269] Indeed, individual donors are checked for viral pathogens, and the final product is checked for sterility. The ability of the fractionation process to remove viral and prion particles is validated by spiking test pools with model pathogens and subjecting them to the same fractionation process used by the plasma pools for human use. Some of them are 5 to 10 percent solutions; others are lyophilized powders that are reconstituted as 3 to 12 percent solutions.[443,565]

IGIV has several advantages over intramuscular IG, including the following: larger quantities of IgG can be given, high levels of serum IgG can be achieved rapidly, painful intramuscular injections are avoided, tissue pooling and local proteolysis are avoided, and home administration and self-administration are easier to perform.

Administration of Intravenous Immune Globulin

Administration of IGIV requires venous access, sometimes a problem in small children or obese subjects. It also requires close monitoring during the infusion, which usually takes 2 to 5 hours.[565] The initial rate is 0.01 mL/kg per minute, and if no side effects occur, it can be doubled at 15- to 30-minute intervals to a maximal rate of 0.08 mL/kg per minute. Rates above 5 mL/kg per hour (0.08 mL/kg per minute) are not recommended. Vital signs should be monitored frequently, and trained personnel should be available to treat adverse reactions. Adverse effects tend to be associated with rapid rates of infusion in patients with concurrent acute infections, previously untreated patients, or significant time elapse between infusions (>6-week intervals).

IGIV is contraindicated in patients who have had an anaphylactic reaction to IGIV or other blood products. It should be administered with great caution to patients who have IgG subclass deficiencies along with IgA deficiency or anti-IgA antibodies (or both).[146]

In responsible, older patients receiving infusions without adverse effects, infusion by home self-administration can be accomplished with considerable cost savings.[38,324,553] However, in most cases, IGIV infusions are performed in the clinic setting or by a home infusion service.

A few investigators have given high concentrations (9% to 12% solutions) infused rapidly during a period of 20 to 40 minutes; this rapid rate can be tolerated by some patients.[516] However, it should not be done except by experienced personnel equipped to manage adverse reactions.

The brand and lot number should be recorded, as should the dose, premedication, and any side reactions. Cold solutions should be warmed to room temperature before administration.

Premedication, such as acetaminophen or diphenhydramine, often is given 30 minutes before infusions are started, particularly for the first infusion or for patients who have had prior reactions. Intravenous hydrocortisone (6 mg/kg in children, 100-200 mg in adults) can be used for prevention of anticipated severe reactions. Oral prednisone can also be used.

Side Effects of Intravenous Immune Globulins

Certain brands of IVIG may be more reactogenic; in one study involving Kawasaki disease, the two IGIVs used were equivalent therapeutically, but one had a 12-fold (2% versus 25%) increase in side effects.[495]

Immediate reactions, such as headaches, shaking chills, nausea and vomiting, or myalgia and arthralgia that occur during or shortly after the infusions, are common occurrences.[158,565,566] They may occur in as many as 10 percent of recipients, especially with a first infusion or in individuals with prior reactions.[567] They can be treated by slowing or stopping the infusions and giving nonsteroidal anti-inflammatory drugs, diphenhydramine (1 mg/kg), or hydrocortisone or other steroids. On occasion, switching to a different product (generally one available as a solution) may alleviate the reactions.

SEVERE IMMEDIATE REACTIONS. Anaphylaxis, shortness of breath, hypotension and hypertension, and other such immediate reactions are uncommon events. Because they rarely involve IgE antibodies, they are termed anaphylactoid reactions, and they may be associated with cytokine release, complement activation, or presence of vasoactive substance in the preparations.

IMMEDIATE REACTIONS IN IgA-DEFICIENT PATIENTS. An occasional IgA-deficient patient on exposure to blood, plasma, or any form of IG may develop IgE anti-IgA antibodies, which may cause a reaction to the small amount of IgA present in IG.[101] IgG anti-IgA in high titers may cause a complement-mediated anaphylactic reaction.[623] These reactions are extremely rare, however, and testing patients for IgA deficiency before administration of IGIV is unnecessary. Further, patients with profound antibody deficiency do not develop anti-IgA antibodies. For the sensitized patient, use of a low-content IgA product or of premedication is indicated. Although IgA deficiency is rare, patients with this condition should not be given IGIV unless it is absolutely indicated. However, we do not recommend testing for IgA deficiency before administration of IGIV.

ASEPTIC MENINGITIS. Headache is a common occurrence during or after IGIV infusions. Yet some patients develop severe headaches 6 to 24 hours after the infusion, sometimes associated with photophobia, stiff neck, and nausea.[304,615] Several of these patients have had spinal taps that show cerebrospinal fluid pleocytosis but negative viral and bacterial cultures. The symptoms usually resolve after 96 hours. This complication may recur despite changing brands. Most occur when IGIV is used in large doses (e.g., 2 g/kg) for neurologic diseases. Individuals with a past history of migraine may be more susceptible to aseptic meningitis.[523] Such patients may tolerate slow infusions of subcutaneous IG.[482,562] Headaches and aseptic meningitis often can be avoided by premedication with steroids or with antimigraine medications.

RENAL COMPLICATIONS. Renal failure, usually temporary, has been reported with IGIV, particularly among subjects with a history of renal disease.[482,567] When such a problem is anticipated, IGIV should be given slowly at no more than 0.5 g/kg per day.[567]

THROMBOTIC COMPLICATIONS. Several thrombotic events, including stroke, myocardial infarction, transient ischemic events, and central vein thrombosis, have occurred after IGIV infusions.[567] These events may be associated with high doses and rapid infusion, particularly among patients with preexisting cardiovascular illness, obesity, or immobility.[567,651]

RARE SIDE EFFECTS. Transient neutropenia, hemolytic anemia, acidosis, and symptoms of hyperviscosity occur rarely.[92,567]

Transmission of Pathogens, Including Hepatitis C, by Intravenous Immune Globulin

Because IGIV is derived from human donors, a remote chance of transmission of viral or other pathogens exists. Tests of donors and the final products are performed, and newer testing for prions is in place but is not of proven reliability. No instance of HIV infection or Jakob-Creutzfeldt or new-variant (mad cow) Jakob-Creutzfeldt disease has been linked to the use of IGIV. Nonetheless, some patients with immunodeficiency receiving long-term IGIV therapy have developed progressive central nervous system problems.[666]

In the early 1990s, hepatitis C was transmitted by experimental IGIV lots,[354,430] some European preparations,[68,69,352,642] and some commercially available U.S. lots.[119,517] Until the report of an outbreak of hepatitis C in 1994,[119] no U.S. cases of hepatitis associated with a commercially available IVIG had been reported. This transmission occurred shortly after hepatitis C–seropositive donors were excluded from the donor pools used in the manufacture of IGIV.

A plausible explanation for the lack of transmission before this Food and Drug Administration policy was instituted is that the hepatitis C antibodies neutralized trace amounts of hepatitis C virus not eliminated during the fractionation. As of October 1994, 137 suspected cases were reported, 88 of which were confirmed.[119,517] Of the 88 patients, 51 (58%) had primary immunodeficiencies, and 63 percent eventually became symptomatic.

Bjoro and associates[69] reported that immunocompromised patients had a severe and rapidly progressive course of hepatitis C infection and that responses to interferon were poor. Razvi and colleagues[483] have not confirmed this finding in U.S. patients.

Newer manufacturing processes and more rigorous testing seemingly have eliminated the risk for occurrence of hepatitis C transmission.

Intravenous Immune Globulin and Intramuscular Immune Globulin Inhibition of Vaccine Antibody Responses

All IGs contain antibody to measles and other viral and bacterial pathogens and thus may inhibit antibody responses to these vaccines. In general, for IGIM or IGIV in doses less than 100 mg/kg, a period of 3 months should elapse before vaccines are given. For doses between 100 and 400 mg/kg, a period of 6 months should elapse; and for doses of 1000 to 2000 mg/kg, a period of 11 months should elapse. The pediatric *Red Book* gives detailed recommendations.[21]

Intravenous Immune Globulin in Primary Immunodeficiencies

Administration of IGIV is indicated for patients with profound primary antibody deficiency (quantitative and qualitative), for patients with combined immunodeficiencies, and for those with secondary immunodeficiency along with significant antibody deficiency (Table 256–3). Regular infusions of IGIV can keep patients with primary antibody immunodeficiencies free of infections for long periods or lessen the severity and frequency of chronic infections.

TABLE 256–3 Some Immunodeficiencies in Which Human Immune Globulin May Be Beneficial

Antibody deficiencies
Congenital agammaglobulinemias
Common variable immunodeficiency
Immunodeficiencies with hyper-IgM
Transient hypogammaglobulinemia of infancy (sometimes)
IgG subclass deficiency ± IgA deficiency (sometimes)
Antibody deficiency with normal immunoglobulins
Combined deficiencies
Severe combined immunodeficiencies (all types)
Wiskott-Aldrich syndrome
Ataxia-telangiectasia
Short-limbed dwarfism
X-linked lymphoproliferative syndrome
Secondary immunodeficiencies
Malignant neoplasms with antibody deficiencies; multiple myeloma, chronic lymphocytic leukemia, other cancers
Protein-losing enteropathy with hypogammaglobulinemia
Nephrotic syndrome with hypogammaglobulinemia
Pediatric acquired immunodeficiency syndrome
Intensive care patients: trauma, surgery, or shock
Post-transplantation
Burns
Prematurity

Patients with hereditary agammaglobulinemias, common variable immunodeficiency, and immunodeficiencies with hyper-IgM clearly benefit from replacement therapy. In combined antibody and cellular defects and in secondary antibody immunodeficiencies, administration of IVIG serves as an important ancillary treatment, but it does not correct the associated T-cell defect or underlying cause of the secondary immunodeficiency.

The recommended dose of IGIV is 400 to 600 mg/kg, usually given every 3 to 4 weeks.[443,565] It should be given every 3 weeks if symptoms develop late in the period between monthly infusions. In general, the trough IgG level should be maintained at approximately 400 mg/dL higher than the pretreatment level, which will normalize the IgG level in most patients (e.g., a level >600-1000 mg/dL).

Certain patients who experience continued infections may receive even higher doses (i.e., 600-800 mg/kg every 3-4 weeks).[165,297] Patients receiving these larger doses may have less frequent sinopulmonary infections, improved pulmonary function, and decreased number of days of illness and hospitalization compared with when they received lower doses.[565] Some investigators recommend giving even higher doses (i.e., keeping trough levels above 800 mg/dL) in an effort to prevent pulmonary complications.[165,297]

Some patients with severe disease do not respond to higher doses or more frequent infusions because of permanent tissue damage or deep-seated chronic infection.

IGIV also is used in patients with antibody deficiency but with normal or nearly normal immunoglobulin levels; often, these patients need higher or more frequent doses of IGIV because their IgG catabolism is increased as a result of their high serum IgG levels. On occasion, IGIV is indicated in infants with transient hypogammaglobulinemia and persistent infection.

IGIV also has been used in patients with IgG subclass deficiencies, but controlled studies demonstrating efficacy are lacking.[67,323,539]

Special Uses of Intravenous Immune Globulin in Antibody Deficiencies

A syndrome of polymyositis or chronic encephalitis, or both, caused by persistent enteroviral infection in patients with agammaglobulinemia has been treated successfully with very high doses of IGIV containing specific antibody to the virus.[394,476] However, some patients do not respond.[144]

Very high dose IGIV (up to 2 g/kg per day) is used occasionally in patients with primary immunodeficiency who develop parvovirus B19 infection, autoimmune disease such as immune thrombocytopenic purpura, or persistent respiratory viral infection.[565]

SUBCUTANEOUS HUMAN IMMUNE GLOBULIN

An alternative to intramuscular injection of IG or infusion of IGIV is slow subcutaneous infusion of IGIM or IGIV.[3,64,65,195] This route is used extensively in Europe, with a 16 percent preservative-free IG. A recently licensed preservative-free 16 percent product (Vivaglobin, CSL) was licensed in 2006 in the United States for subcutaneous use.[432] However, 10 to 12 percent solutions for IGIV also can be used safely.[562]

These products usually are infused into the abdominal wall or thigh with a battery-operated portable infusion pump.[65,195] The usual dose is 100 to 150 mg/kg per week, the same monthly dose as recommended for IGIV, given at a rate of 0.05 to 0.20 mL/kg per hour. Larger doses and more rapid infusions can be accomplished by using multiple injection sites. If a patient is beginning IGSC therapy and an immediate therapeutic level is sought, loading doses of IGIV at double the monthly maintenance dose can be given 1 week before the start of IGSC. Peak serum IgG levels after IGSC occur 48 to 96 hours after the infusion.

Subcutaneous IG infusions, which can be self-administered, are well tolerated, safe, and preferred by some patients because the side reactions are considerably less.[65,195,236] Indeed, premedication rarely is needed. Thus, they are more suitable than is IGIV for home self-administration.[194,195]

Stiehm and coworkers[562] used this route successfully in patients with poor intravenous access, aseptic meningitis, anaphylactic reactions after receiving IGIV infusions, or rapid gastrointestinal protein loss; they used a 10 percent IGIV solution. Subcutaneous IG has been used safely in IgA-deficient adults with frequent respiratory infections,[236] during pregnancy,[63] and in children.[3]

Rapid administration of subcutaneous infusions of IG has been achieved by using two pumps at four infusion sites and increasing the rate to 20 mL/hr per pump, thereby allowing the entire infusion to be completed in little more than an hour.[195]

IMMUNE GLOBULIN ADMINISTRATION BY OTHER ROUTES (ORAL, INTRATHECAL, AEROSOL, LOCAL)

Multiple types of antibody have been given by unusual routes with varying degrees of success. None except intravitreous injection of monoclonal antibody is standard care.

Oral Immunoglobulin

Breast milk is the ultimate oral passive immune agent with preventive benefit for newborns. Oral IG administered to provide antimicrobial activity to the gastrointestinal tract mimics the action of antibody-rich colostrum and breast milk. In humans, little or no ingested IG is absorbed intact into the systemic circulation.[29] Some oral IG traverses the entire gastrointestinal tract undigested, particularly in premature infants.[74] Oral IG may neutralize microorganisms, inhibit colonization, and prevent microbial attachment to the gastrointestinal mucosa.

ROTAVIRUS INFECTION. Barnes and colleagues[53] fed human IG or placebo for 7 days to premature infants in a nursery in which rotavirus was endemic. Rotavirus-associated diarrhea developed in 6 of 11 babies given placebo and in 1 of 14 given oral IG.

Losonsky and coworkers[363] administered oral human IG to two children with severe combined immunodeficiency and chronic rotavirus infection and demonstrated a decrease in the amount of free rotavirus excretion and survival of the IG through the gastrointestinal tract. Kanfer and associates[301] used oral human IG to treat rotavirus infection that occurred after bone marrow transplantation.

Bovine hyperimmune colostral immunoglobulin enriched in rotavirus antibodies (from immunized cows) also has been used in the prevention of rotavirus infection. Davidson and colleagues[148] prevented rotavirus infection in 55 children admitted to an Australian hospital by administering a 10-day course of bovine colostrum; 9 of 65 control children became infected.

Turner and Kelsey[603] added at least 360 mL of cow colostrum to the formula of 31 term infants aged 3 to 7 months for an average of 101 days (range, 16 to 202 days). Rotavirus infections occurred in 11 (35%) of the colostrum-fed group and 14 (42%) of the control group, an insignificant difference, but symptomatic infection occurred in 1 (3%) of the infants receiving colostrum and 6 (18%) of the controls.

This product also has been used in two studies of the treatment of rotavirus diarrhea in Bangladesh.[403,514] In both studies, less diarrhea, fewer days of illness, less stool output, and more rapid clearance of rotavirus from the stool were noted. Guarino and coworkers[229] used oral human IG (300 mg/kg) as a single dose and observed more rapid recovery from rotavirus diarrhea.

In sum, oral IG is a promising but unproven agent for the prevention and treatment of rotavirus infection.

NECROTIZING ENTEROCOLITIS. Eibl and colleagues[164] were able to prevent necrotizing enterocolitis in all 90 infants given oral IG rich in serum IgA. Six cases occurred in 91 control infants. Rubaltelli and colleagues[497] in Italy achieved similar results with oral monomeric IgG.

CRYPTOSPORIDIAL INFECTION. Bovine colostrum was used successfully to treat cryptosporidial diarrhea in HIV infection.[530]

Borowitz and Saulsbury[82] used oral IG successfully to treat cryptosporidial infection in a child with acute leukemia.

OTHER DIARRHEAS. Oral human IG has been used in the post–bone marrow transplantation period to prevent the development of viral gastroenteritis[301] and to treat nonspecific diarrhea in immunodeficient subjects.[397] Commercial products from bovine colostrum are available in Sweden and India.[188,461]

Considerable experimental study in veterinarian medicine is available on other oral immunoglobulins.

Aerosolized and Intratracheal Immunoglobulin

Aerosolized and intratracheal immunoglobulin has been used with encouraging results in experimental models of pneumonia caused by respiratory syncytial virus (RSV), pneumococci, staphylococci, *Yersinia pestis*, and parainfluenza and influenza viruses.[217,257,446,479-481,489] Aerosolized monoclonal antibodies also are being studied for specific infections, bioterrorist toxins (e.g., anthrax, ricin), and lung immunomodulation.[174,347,471,619]

Rimensberger and colleagues[489] conducted a placebo-controlled trial of aerosolized human IG (not RSV-IVIG) in the

treatment of RSV infection. No significant benefit was found, but the treatment was well tolerated.

Heikkinen and coworkers[248] used an IgA-enriched human IG as a nasal spray twice daily for 8 weeks to reduce respiratory infections in children between 1 and 4 years of age attending daycare. A 42 percent reduction was achieved in the 19 children receiving the IG versus the 20 children in the placebo group. The authors suggested that this treatment also may decrease the incidence of otitis media.

Intrathecal Immunoglobulin

Human IG has been used intrathecally for the treatment of viral encephalomyelitis in patients with antibody deficiency.[172] Monoclonal antibodies occasionally are given intrathecally in cancer therapy.[559] The use of antitoxin intrathecally in tetanus is discussed in the section on tetanus.

Other Routes

Local application of antibody has been used in the prevention or treatment of surgical or traumatic wounds.[311,470] Injections of the monoclonal antibody bevacizumab (Lucentis) into the vitrea to treat macular degeneration are under way.[141] Inner ear injection of infliximab, a tumor necrosis factor monoclonal antibody, has been used in autoimmune neurosensory hearing loss.[613]

Intra-articular IG was of no clinical benefit to patients with rheumatoid arthritis.[43] We have used IG in the conjunctiva of a child with ligneous conjunctivitis, without benefit.

IMMUNE GLOBULIN IN SECONDARY IMMUNODEFICIENCIES

Many chronically ill patients have a primary illness that results in immunodepression and increased susceptibility to infection. These secondary immunodeficiencies are considerably more common than is primary immunodeficiency and are particularly common developments in hospitalized patients. Although most such patients have cellular (T-cell) deficiencies, a number have antibody deficiencies either isolated or combined with other immune defects. These patients may have low immunoglobulin levels, poor antibody responses to antigenic challenge, and low levels of natural antibodies that may result from loss of immunoglobulin, loss of immune cells, or the toxic effect of therapy or infection on the immune system. Table 256–3 lists diseases and conditions in which secondary antibody immunodeficiency can occur.

Laboratory criteria that support the use of IGIV include significant hypogammaglobulinemia (serum IgG < 200 mg/dL or total immunoglobulin [IgG + IgM + IgA] < 400 mg/dL), absent or unexpectedly low titers of natural antibodies, absent or poor response to antigenic challenge (e.g., tetanus, pneumococcal vaccines), and lack of an antibody response to the infecting organism.[566] Some of the more common secondary immunodeficiencies with antibody defects are discussed.

HEMATOLOGIC AND ONCOLOGIC DISEASES

Antibody deficiencies can occur with multiple myeloma, chronic lymphocytic leukemia, lymphoma, and advanced cancer, aggravated by the immunosuppressive agents used in their therapy. A double-blind multicenter study concluded that the prophylactic infusion of 400 mg/kg of IGIV every 3 weeks reduced the incidence of bacterial infections in patients with chronic lymphocytic leukemia.[138] The treatment group had fewer infections with *Streptococcus pneumoniae* and *Haemophilus influenzae*, but no difference was noted in infections caused by other gram-negative bacteria, fungi, or viruses.

This beneficial effect was confirmed in a subsequent study,[192] and although concern has been raised about its cost-effectiveness,[630] IGIV also has been shown to reduce the incidence of infections in patients with multiple myeloma[124] and in those receiving chemotherapy for lung cancer.[519]

PROTEIN-LOSING STATES: ENTEROPATHY, NEPHROTIC SYNDROME, PLASTIC BRONCHITIS

In some pediatric patients, antibody deficiency results from massive proteinuria (nephrosis), diarrhea (protein-losing enteropathy), or loss into the lung (plastic bronchitis) associated with accelerated IgG loss. Most of these patients have minimal trouble with recurrent infection, probably because antibody synthesis is intact and most likely accelerated; however, if the loss of IgG greatly exceeds synthetic capacity, symptomatic severe hypogammaglobulinemia may result. IGIV infusions can be used diagnostically in such cases; a large intravenous infusion, followed by serial measurements of serum IgG levels, can document an accelerated IgG half-life (i.e., <10 days).

These patients are candidates for IGIV therapy if they have recurrent infections or very low IgG levels (e.g., <200 mg/dL). Administration of large and repeated doses is necessary. On occasion, antibody infusions will help control the severe diarrhea of protein-losing enteropathy.[109] Subcutaneous IG has been used in this situation because its delayed release into the circulation may result in higher long-term IgG levels than can be achieved with an equivalent IGIV monthly dose.[562]

INTENSIVE CARE PATIENTS: TRAUMA, SURGERY, SEPTIC SHOCK

Patients undergoing severe stress associated with trauma or extensive surgery have profound exposure and susceptibility to infection and a spectrum of immune deficiencies, including cutaneous anergy, leukocyte dysfunction, hypogammaglobulinemia, and transiently impaired antibody synthesis.[213,414,644] Bowel stasis and hypotension may promote gram-negative sepsis or endotoxemia, or both, along with the development of severe and often irreversible shock.

Early studies by Ziegler and associates[665] and Baumgartner and colleagues[57] suggested that when antisera to a mutant J5 *Escherichia coli* endotoxin with anti–lipid A activity is used in bacteremic or surgical intensive care unit (ICU) patients, the incidence and severity of severe shock could be reduced. However, Calandra and colleagues,[106] using a human IGIV to J5 *E. coli* in 71 patients with gram-negative infections and shock, could not confirm their results. They gave a single infusion of 200 mg/kg; a control group received a similar dose of regular IGIV. No differences were found in mortality rates, onset of time to shock, and complications.

Just and coworkers[294] administered regular IGIV and antibiotics to 50 patients in the ICU thought to have infection and compared their outcomes with those of 54 control patients who received antibiotics alone. Although no difference in survival occurred, they noted a trend indicating that the IGIV-antibiotic group had a shortened stay in the ICU, a shorter period in which respirator therapy was required, and improved renal function as well as a favorable effect on infection (i.e., infections were a less likely cause of death in these patients).

Rodriquez and colleagues[491] gave an IgM-enriched IGIV or albumin to 56 patients with sepsis undergoing abdominal surgery and found a reduction of sepsis from 55 to 25 percent, a significant difference. Another multicenter study of 352 postsurgical

patients confirmed the observation that standard IGIV (400 mg/kg at weekly intervals) reduced the incidence of infections and shortened the stay in the ICU compared with patients treated with placebo or hyperimmune core-lipopolysaccharide IG.[272]

Werdan[634] has reviewed the use of IGIV in sepsis and suggests that certain specific subgroups may benefit (e.g., postoperative sepsis, septic shock with endotoxinemia, and sepsis with neutropenia). A single-institution study from Egypt suggested that IGIV was of benefit in children younger than 2 years in the ICU who had sepsis.[167]

Studies of IGIV in trauma patients requiring surgery[152,157,209] and in patients with head trauma[644] have shown questionable efficacy.

Monoclonal antibodies to endotoxin have been tested in clinical trials of patients in septic shock, but none was of proven efficacy.[418,635,664] Monoclonal antibody to tumor necrosis factor–α also has shown no efficacy in the treatment of adults with septic shock.[2,136] Monoclonal antibodies to interleukin-6 or interleukin-1 receptor likewise have not been shown to be effective in the treatment of shock.[196]

In summary, no compelling data suggest that antibody, either polyclonal or monoclonal, is of benefit in an acutely ill patient with shock.

PREMATURITY

All premature infants have low levels of maternally derived IgG at birth, and levels approaching 100 mg/dL will develop in the first months of life in most.[48] These IgG levels may be further depressed by pulmonary disease (with transudation into the lungs), fever and stress (with increased IgG catabolism), and multiple blood sampling.[500] In addition, their sluggish antibody responses, their concurrent IgM and IgA deficiency, and their immature complement, phagocytic, and T-cell systems render low-birth-weight infants extraordinarily susceptible to development of infection.[356]

Attempts to decrease the incidence of infections in premature infants by using periodic IG injections date to the 1960s. Four controlled studies enrolling a total of 363 infants used IG doses of 80 to 240 mg/kg per month during their stay in the nursery (two studies), for 4 months, and for 1 year.[11,137,154,557] In two studies, a slight decrease in the number and severity of infections was noted, but no difference in survival. These mixed results suggest that IG at the doses used was not of prophylactic value in these patients.

In the last 2 decades, the increasing rate of survival of very tiny premature infants and the availability of IGIV have reawakened interest in the use of antibody to prevent infections in premature infants. In general, IGIV is well tolerated, with minimal adverse effects, in doses of up to 1 g/kg per day.

An initial double-blind clinical trial by Baker and colleagues[44] suggested that IGIV at a dose of 0.5 g/kg at frequent intervals in the first weeks of life significantly reduced the frequency of sepsis, particularly that caused by *Staphylococus epidermidis.* Subsequent studies, however, have not shown a clear benefit.

Meta-analyses of prospective, randomized, placebo-controlled prevention studies (representing 5000 infants) were performed by Jenson and Pollock[282,283] and Ohlsson and Lacy.[438] These studies differed in entry criteria, dose, and brand of IGIV, but most infants were less than 2000 g, were given IGIV therapy within the first week of life, and received doses of at least 400 mg/kg per month; culture-proven sepsis was used as an end-point. Overall, there was a slight reduction (3%) in the incidence of sepsis but no difference in mortality rates, length of stay, or other complications of prematurity, such as necrotizing enterocolitis, bronchopulmonary dysplasia, and intraventricular hemorrhage.

By contrast, IGIV has been of significant benefit in the meta-analysis of six controlled studies for the treatment of neonatal sepsis. For infants with proven sepsis, IGIV reduced the mortality in the control group from 20 percent (27 deaths among 133 infants) to 11 percent (14 deaths among 129 infants; $p = .04$).[439] Among infants with suspected sepsis, there was suggestive evidence of benefit ($p = .05$).

Shamin and coworkers[526] gave sufficient IGIV for 6 months to 15 of 30 matched premature infants with severe bronchopulmonary dysplasia to maintain their IgG levels above 400 mg/dL, whereas the untreated infants had levels below 200 mg/dL. The number of infections, notably pneumonia, was significantly reduced in the IGIV group (5 episodes of pneumonia and 4 other infections) in comparison with the control group (15 episodes of pneumonia and 12 other infections).

Thus, the evidence to date still supports the 1990 National Institutes of Health consensus statement that IGIV should not be given routinely to infants of low birth weight[425] but that it may be of value in selected premature infants at high risk for acquiring infection.

IGIV is sometimes of benefit in premature infants with a history of serious infections and underlying lung disease; most such infants will have hypogammaglobulinemia and should be regarded as having transient hypogammaglobulinemia of infancy. Such infants also need RSV prophylaxis with palivizumab.

Hyperimmune IGIV or monoclonal antibodies enriched in antibodies against specific microbial antigens (e.g., *Staphylococcus aureus*) may be of benefit to certain high-risk newborn and premature infants. Two large multicenter double-blind clinical trials of *S. aureus* hyperimmune human immunoglobulins were completed in infants of very low birth weight. One used IG from donors immunized with a staphylococcal vaccine against serotypes 5 and 8 (termed Altastaph).[61,377] The other used IG from donors with a high titer to C1fA, a staphylococcal fibrinogen-binding protein (termed Veronate).[72,110,150,305] Neither trial showed a significantly decreased severity or incidence of staphylococcal infections.

TRANSPLANTATION

Conditioning regimens to eliminate or to reduce the host's hematopoietic and immune systems before transplantation (bone marrow and solid organ) render these patients extremely susceptible to infection, particularly cytomegalovirus (CMV) infections.[604] Thus, IGIV and CMV-IGIV have been used to prevent infection as well as to modify graft-versus-host disease and to prevent solid organ rejection.

Early studies of IGIV therapy after allogeneic bone marrow transplantation were modestly successful in preventing infections, decreasing graft-versus-host reaction, and increasing survival rates.[56,139,218,577-579] This effect was less dramatic when CMV infection was controlled by ganciclovir and screening of blood products.[231] Two more multicenter studies showed only a modest or no effect on modifying acute graft-versus-host reactions or mortality rates.[140,646] In single-center studies, CMV-IGIV was of no benefit in CMV-positive lung transplant recipients[332] or liver transplant recipients.[222]

IGIV is of benefit in adult kidney transplant recipients with high titers of HLA antibodies. They have a shorter time to transplantation, reduced HLA antibody titers, and improved allograft survival rates.[289,290]

BURNS

Bacterial sepsis, particularly *Pseudomonas* spp. and *E. coli* sepsis, is the leading cause of death in the 300,000 patients hospitalized

annually in the United States for burns.[413,414] The protein loss in these patients induces hypogammaglobulinemia in proportion to the severity of the burn. High-dose IGIV prolongs survival in experimentally burned mice infected with *Pseudomonas* spp., and preliminary studies of hyperimmune IG and plasma in human burn patients were encouraging, but proof of efficacy is lacking[310,472,574] (see later section on burn infections).

HUMAN IMMUNODEFICIENCY VIRUS INFECTION

The rationale for use of IGIV in patients with advanced HIV disease is their increased susceptibility to common bacterial and viral infections, poor primary antibody responses to vaccine antigens despite hypergammaglobulinemia, and, in young children, a limited antibody spectrum to common bacterial pathogens. Although the central immune defect in acquired immunodeficiency syndrome (AIDS) is a loss of helper T-cell ($CD4^+$) number and function, the polyclonal B-cell activation and defective helper T-cell function result in a significant B-cell deficiency.[66,431]

Thus, in children with AIDS, bacterial infections occur more commonly than do opportunistic infections. Immune-mediated thrombocytopenic purpura and viral diseases (e.g., RSV and parvovirus and other disorders amenable to IGIV prophylaxis or therapy) also may develop in patients with AIDS.

After preliminary uncontrolled studies suggested a benefit of IGIV in children with advanced HIV infection,[107,537] two large multicenter controlled studies undertaken by the National Institutes of Health–supported Pediatric AIDS Clinical Trial Group determined the efficacy of IGIV in decreasing infections and improving survival in AIDS patients.[419,555]

In the first study, 372 children received 400 mg/kg of IGIV every 4 weeks or an albumin control for 2 years.[419] Thirty percent of all children in the IGIV-treated group had serious infections compared with 42 percent in the placebo group. Children who were less ill (those with $CD4^+$ lymphocyte counts >200/mL) benefited in particular from IGIV. Children in this category had fewer serious infections and were hospitalized less frequently than were those in the placebo group, and their $CD4^+$ counts dropped less rapidly than did those of the placebo group.[405] The mortality in both groups, however, was identical. Children with $CD4^+$ counts less than 200 cells/mL (i.e., those with severely impaired immunity) who were given IGIV had no significant decrease in infections, days of hospitalization, or mortality compared with their counterparts in the placebo group.

The authors concluded that IGIV significantly reduced the risk for development of serious infection in some children with symptomatic HIV infection, primarily those with $CD4^+$ counts between 200 and 500 cells/mL. In a follow-up study, the placebo group was allowed to cross over to receive IGIV, with a drop in the rate of serious infections and hospitalizations.[408]

In a second trial of IGIV in which all the children received zidovudine, a significant decrease in serious bacterial infections was found again, but this benefit was limited to children who did not receive trimethoprim-sulfamethoxazole prophylaxis for *Pneumocystis jiroveci* pneumonia.[555] A consensus of an HIV Working Group was that HIV-infected children with significant hypogammaglobulinemia or documented poor antibody formation may be candidates for receiving IGIV therapy.[652] IGIV also may be of benefit to HIV-infected children who have recurrent infections not controlled by antibiotics or chronic nonspecific diarrhea with failure to thrive.

IGIV also prevents serious infections in adults with advanced HIV infection.[317]

In addition to preventing serious bacterial infections, IGIV given to children with HIV infection reduced the number of nonserious bacterial infections (by 60% for ear infections, 13% for skin infections, and 10% for other upper respiratory infections) and viral infections by approximately a third in both trials.[404,406-408,555]

Regular IGIV infusion also improved left ventricular function in HIV-infected children with dilated cardiomyopathy.[361] It is also effective in treating certain other complications of HIV infection, including thrombocytopenia,[105,343] red cell aplasia after erythrovirus (parvovirus B19) infection,[325] Guillain-Barré syndrome,[206] and certain drug reactions.[184] IGIV, even in high doses, provides no antiviral activity to HIV.[443]

INTRAVENOUS IMMUNE GLOBULIN IN IMMUNOREGULATORY AND NEUROLOGIC DISORDERS

High-dose IGIV has immunosuppressive and anti-inflammatory effects that render it a valuable agent in the treatment of several autoimmune, inflammatory, and neurologic disorders (Table 256–4).[162,443] A consensus committee has evaluated these uses in terms of likely efficacy.[443]

High-dose IGIV (1 to 2 g/kg) may work by one or more of the following mechanisms:[49,162,540,589]

1. IGIV may decrease the high levels of a pathogenic antibody (such as may be present in myasthenia gravis or idiopathic thrombocytopenic purpura) by accelerating IgG catabolism. IGIV increases IgG levels acutely and increases its catabolism, thus decreasing pathogenic antibodies present in high concentrations. It also saturates the FcRn receptor, thus inhibiting the recirculation of IgG molecules.[658] IGIV also inhibits antibody synthesis by having a direct effect on proliferating B cells, possibly through activation of the FcRII receptor.[510]
2. IGIV contains anti-idiotypic antibodies that can combine with autoimmune antibodies and remove them rapidly from the circulation, which may be a mechanism by which IGIV reduces anti–human leukocyte antigen (HLA) antibodies in transplant recipients.
3. IGIV binds to Fc receptors on reticuloendothelial cells and causes an Fc receptor blockade, thus reducing the destruction of antibody-coated cells in the spleen or liver. It is a mechanism for the rapid response to IGIV noted in patients with immune thrombocytopenic purpura. Dimeric IGIV may be particularly effective in causing FcR blockage.
4. IGIV combines with other surface receptors to inhibit cellular activation; for example, in toxic epidermal necrolysis, IGIV prevents Fas-mediated cell death of keratinocytes by blocking the Fas receptor.[617]
5. IGIV may promote solubilization and clearance of pathologic immune complexes, such as may be present in lupus nephritis.
6. IGIV down-regulates T-cell immune activation by decreasing inflammatory cytokine release or action. In Kawasaki disease, an immediate damping of the cytokine "storm" occurs with this illness.
7. IGIV antibodies neutralize bacterial superantigens and prevent them from activating T cells. It is the probable mechanism for its beneficial effect in toxic shock syndrome.[556,589]
8. IGIV combines with complement components to prevent complement-mediated tissue injury. An example is inhibition of complement-mediated myocyte damage in dermatomyositis.
9. IGIV neutralizes virus or bacterial antigens or toxins that may trigger or cause the disease. An example may be the neutralization of bacterial products in hemolytic-uremic syndrome.
10. IGIV contains substances such as soluble HLA antigens and soluble cytokine receptors that may inhibit immune responses.

TABLE 256–4 Likelihood of Benefit of Intravenous Immune Globulin (IGIV) in Autoimmune, Inflammatory, and Neurologic Diseases

Proven benefit*
Kawasaki disease
Graves ophthalmopathy
Immune thrombocytopenic purpura (e.g., idiopathic)
Dermatomyositis
Post–bone marrow transplantation
Neurologic diseases
  Guillain-Barré syndrome
  Chronic inflammatory demyelinating polyneuropathy
  Multifocal motor neuropathy
  Demyelinating neuropathy with IgM gammopathy

Probable benefit†
Toxic shock syndrome
Post-infectious thrombocytopenic purpura
Neonatal isoimmune or autoimmune thrombocytopenic purpura
Neonatal isoimmune or autoimmune hemolytic anemia
Autoimmune or isoimmune neutropenia
Autoimmune hemolytic anemia
Toxic epidermal necrolysis
Prevention of antibody-mediated kidney transplant rejection
Autoimmune uveitis
Neurologic diseases
  Polymyositis
  Lambert-Eaton myasthenia syndrome
  Myasthenia gravis
  Stiff-man syndrome
  Relapsing-remitting multiple sclerosis

Possible benefit‡
Anticardiolipin antibody syndrome
Coagulopathy with factor VIII inhibitor
Bullous pemphigoid and other blistering skin diseases
Churg-Strauss vasculitis
Vasculitis with antineutrophil cytoplasmic antibodies
Other vasculitides
Stevens-Johnson syndrome
Severe rheumatoid arthritis
Systemic lupus erythematosus
Autoimmune diabetes mellitus
Post-transfusion purpura
Prevention of allograft rejection in high-risk patients with solid organ transplants
Recurrent spontaneous abortion
Cardiomyopathy
Severe persistent high-dose steroid-dependent asthma
Chronic urticaria
Autoimmune liver disease
Delayed pressure urticaria
Neurologic diseases
  Multiple sclerosis

HTLV, human T-lymphotropic virus; POEMS, polyneuropathy, organomegaly, endocrinopathy, M protein, skin changes.

The illnesses for which IGIV may be of benefit often are of unknown cause, refractory to standard treatment, somewhat responsive to steroids, and associated with local or generalized immune activation with fever, inflammatory cells, and cytokine release.[435] Large doses of IGIV (e.g., usually 1 to 2 g/kg/day) are necessary and may need to be repeated at weekly intervals. IGIV preparations may not always be equivalent in action; Tsai and associates[602] found that certain brands of IGIV were less effective in Kawasaki disease than were others.

If a favorable response does not occur immediately or within a few weeks, it probably will not occur later. Proof of efficacy requires a double-blind study (e.g., as conducted for Kawasaki disease) or dramatic reversal of progressive severe disease (e.g., as noted in some cases of toxic shock syndrome). The use of IGIV in Kawasaki disease is covered in another chapter.

MONOCLONAL ANTIBODIES

Monoclonal antibodies specific for a single antigenic epitope have been available for laboratory use for several decades and are used increasingly as therapeutic agents. The first monoclonal antibody, licensed in 1984, was a murine antilymphocyte antibody (anti-CD3 [OKT3]) used for immunosuppression in transplant recipients. Since then, 18 other monoclonal antibodies have been licensed for treatment, and many others are being studied in the United States and abroad (see Table 256–1).[104]

NOMENCLATURE AND STRUCTURE

The generic names of therapeutic monoclonal antibodies have been codified, as summarized in Table 256–2.[104] All end in *mab* or *nab*. Preceding this ending is a one- or two-letter prefix that denotes the animal from which it has been produced (e.g., *o* for mouse, as in murom*o*nab; *u* for human, as in adalim*u*mab).

Two types of monoclonal antibodies contain both human and murine components. Chimeric monoclonal antibodies, designated *xi*, contain the Fab portion of a murine IG and the Fc portion of human IG, usually an IgG1 molecule (e.g., ritu*xi*mab). Humanized monoclonal antibodies, designated *zu*, have only the antibody-combining site of a murine IG (termed the complemen-

tary determinant region), and the rest of the molecule is a human IgG1 molecule (e.g., omali*zu*mab). Chimeric and humanized antibodies are less antigenic and have a longer half-life than do mouse monoclonal antibodies and thus usually are preferred.

One completely human monoclonal antibody is derived from isolated and recombined human L and H chains (adalimumab).

The final prefix before the source prefix designates the disease for which the antibody is used (e.g., *vir* for viral disease, *lim* for immune modulation, *tu* for cancer). Examples include pali*vi*zumab, oma*li*zumab, trans*tu*zumab. Sometimes the last consonant is dropped for the sake of pronunciation. The beginning of the generic name is left to the manufacturer, as is, of course, the trade name.

FRAGMENTED AND CONJUGATED MONOCLONAL ANTIBODIES

Two of the licensed monoclonal antibodies are Fab fragments of the whole molecule. Fragmented molecules retain their antibody activity, but their survival and therapeutic duration are markedly shortened. They include abciximab (ReoPro) directed against platelet glycoprotein IIb/IIIa for prevention of thrombosis and ranibizumab (Lucentis) directed against vascular endothelial growth factor for intravitreous injection into the eye for macular degeneration. It is derived from bevacizumab (Avastin) used for treatment of metastatic cancers.

Three of the licensed monoclonal antibodies are combined with other molecules to increase their therapeutic effectiveness. Two of these are anti-CD20 (B-cell) antibodies similar to rituximab that are radiotagged and used for rituximab-refractory B-cell lymphomas. Ibritumomab (Zevulin) is conjugated to yttrium 90, and tositumomab (Bexxar) is conjugated to iodine 131. Thus, these monoclonal antibodies deliver radiation only to cells carrying the CD20 antigen.

A third tagged antibody is gemtuzumab ozogamicin (Mylotarg) used in the treatment of relapsed acute myelocytic leukemia. It is conjugated with the potent antitumor antibiotic calicheamicin to increase its concentration on myeloid cells expressing CD33.

Uses of Monoclonal Antibodies

Therapeutic monoclonal antibodies developed to date are licensed for graft rejection, cancer, autoimmunity (e.g., rheumatoid arthritis, inflammatory bowel disease, immune cytopenias), thrombosis, infectious disease, multiple sclerosis, asthma and allergy, and macular degeneration. Like many new drugs, monoclonal antibodies also are used for disorders other than those for which they are licensed.

Only one of these antibodies, palivizumab (Synagis), directed against RSV, is used in infectious diseases for the prevention of RSV infection in high-risk infants (see section on RSV).[23] However, monoclonal antibodies to microbial antigens and inflammatory mediators will play an important role in tomorrow's battle with infectious pathogens. For example, monoclonal antibodies to anthrax toxin, staphylococcal antigens, and HIV antigens and co-receptors are being studied in clinical trials.

PASSIVE IMMUNITY IN BACTERIAL DISEASES

Antibodies have been used for a century for the prevention and treatment of infectious diseases (Table 256–5). In bacterial disease, antibodies neutralize toxins, facilitate opsonization, and, with complement, promote bacteriolysis; in viral disease, antibodies block viral entry into uninfected cells, promote antibody-directed cell-mediated cytotoxicity by natural killer cells, and neutralize virus alone or with the participation of complement.

Before the use of antibiotics, antibodies were the only specific agents for the treatment of certain infections. Although this role has been supplanted largely by antibiotics, antibody still has a crucial role in the treatment of certain infectious diseases (see Table 256–5). The remainder of this chapter discusses the roles of antibody in prevention and treatment of bacterial and viral diseases. Other reviews are available.[112,113,351]

ANTHRAX

Anthrax is a rare but serious infectious disease, predominantly of ruminant animals, caused by an aerobic gram-positive rod, *Bacillus anthracis*.[132,367,368] Humans can be infected through the skin (cutaneous anthrax), by ingestion (gastrointestinal anthrax), or by inhaling the spores (inhalational anthrax).[368] Inhalational anthrax results from prolonged exposure to animal hides or carcasses and infected soil or, rarely, by deliberate spore exposure in the bioterrorism setting, as occurred among U.S. postal workers in 2001.[284,367]

After inhalation, the spores are ingested by alveolar phagocytic cells and transported to regional nodes, where they germinate and release exotoxins (lethal toxin and edema toxins), which damage cell membranes, increase capillary permeability, initiate pulmonic changes, and ultimately lead to shock and cardiovascular collapse.

A vaccine is available for individuals at high risk for exposure and the military. It is effective against cutaneous anthrax but of unproven efficacy against inhalational anthrax.[83] Others are in development.[85]

Before the antibiotic era and as early as 1903, anthrax antitoxin (usually equine) was used in therapy for anthrax.[211,322] An antitoxin would be of value in a bioterrorism attack, both before exposure and after exposure. The Centers for Disease Control and Prevention (CDC) and the National Institutes of Health are collecting plasma units from military recruits and volunteers immunized with the anthrax vaccine[171] to develop a human high-titer IGIV from these donors.[133]

Several monoclonal antibodies against anthrax antigens have been produced.[31,88,126,266,373,384,409,576,626] The best studied is a human monoclonal antibody 5H3 (ABthrax).[126] ABthrax was safe and well tolerated either intravenously or intramuscularly in human volunteers and provided good antibody titers with a half-life of 15 to 19 days.[576] The U.S. government plans to buy 20,000 treatment doses of this monoclonal antibody for the Strategic National Stockpile, contingent on approval by the Food and Drug Administration.[254]

Recommendation

No current commercial antitoxin is available in the United States for prophylaxis or treatment. The only available source is the limited supply of immune plasma stockpiled by the U.S. army. This supply would be used in conjunction with antibiotics and with vaccine, the latter to provide immunity after metabolism of the antibody.

BOTULISM, BOTULINUM ANTITOXIN, AND BOTULISM IMMUNE GLOBULIN

Botulism, a severe paralytic poisoning, results from ingestion or absorption of neurotoxins or spores from *Clostridium botulinum*. Several clinical variants are recognized: food poisoning from ingestion of contaminated canned food, wound botulism from a

contaminated local infection, inhalational botulism among individuals working with the toxin or in bioterrorism,[34] infant botulism from ingestion of *C. botulinum* spores, and adult-type infant botulism in adults with preexisting gastrointestinal disease. In the last two types, ingested spores multiply in the gastrointestinal tract and elaborate toxin, and the absorbed toxin results in a paralytic disorder.[62,123]

There are reports of botulism as a result of the cosmetic use of an unapproved botulinum toxin A.[128,554]

Seven immunologic types of *C. botulinum*, designated A through G, have been identified, each elaborating an immunologically distinct toxin. Almost all human botulism has resulted from the ingestion of toxins A, B, and E, the last usually associated with fish and marine mammal products.[326,327,527]

Japanese studies, reviewed by Dolman and IIda,[155] indicate that antitoxin therapy is effective for type E botulism. The mortality rate associated with type E botulism was 49 percent in 135 untreated cases and 3.5 percent in 85 antitoxin-treated cases.

Tacket and associates[585] noted that 46 patients who had type A food-borne botulism and who received trivalent antitoxin had a lower mortality rate (27%) than did 13 patients who did not receive antitoxin (46% mortality). Early antitoxin administration resulted in a shorter clinical course.

The presence of toxin in the blood long after the appearance of clinical symptoms or the ingestion of toxin gives theoretical support to the use of antitoxin to prevent further binding of toxin to tissue. Some antitoxin remains in the circulation for more than 30 days, thus indicating that a single initial dose is adequate therapy.

Equine antitoxins to types A, B, and E are the primary antitoxins available in the United States. The decision to use antitoxin is complicated by its unknown efficacy and its side effects, but approximately 80 percent of patients with ingestion-type botulism receive antitoxin.[527]

Recommendations

All forms of botulism, except for infant botulism, are treated with bivalent (types A and B) and type E antitoxin as soon as possible, after testing for sensitivity to horse serum.[14,21,123,527] They are

available in the United States from the CDC in Atlanta, Georgia (404-639-3670 or 2888). One vial of bivalent antitoxin contains 7500 IU of type A and 5500 IU of type B antitoxin, and one vial of type E antitoxin contains 5000 IU. They usually are given intravenously. Both vials are given unless the toxin type is known; additional doses usually are unnecessary, but with severe wound infections, higher doses may be needed, as guided by antibody titers.

Antitoxin can be given prophylactically to individuals known to have ingested contaminated food. The risk for development of serum reactions (about 10%) must be weighed against the risk of contracting the disease. An investigational equine botulism heptavalent IG fragment $F(ab')_2$ also is being studied for treatment.[255]

A 5-year, placebo-controlled, double-blind trial of human botulinum intravenous immune globulin (BIG) for infant botulism showed a significant reduction in hospital days, mechanical ventilation, tube feedings, and days of hospitalization in the BIG recipients, with considerable cost savings.[35] BIG should be started immediately after the illness is suspected. The dose is 50 mg/kg. Each vial contains 200 mg and is diluted to a 50 mg/mL 5 percent solution. One treatment costs about $45,000.

OTHER CLOSTRIDIAL INFECTIONS

CLOSTRIDIUM DIFFICILE INFECTIONS

Clostridium difficile is a ubiquitous spore-forming anaerobe often involved in antibiotic-associated diarrhea and pseudomembranous colitis.[14] The severity of the disease can range from an asymptomatic carrier state to fulminant colitis with toxic megacolon. Toxic strains of *C. difficile* release two antigenically distinct toxins, both of which have potent cytotoxic and inflammatory properties.[135] Infection generally leads to an antibody response to the toxins, and most individuals older than 2 years have such antibodies; thus, *C. difficile* antibodies are present in IGIV preparations.[507]

High levels of IgG antibodies acquired after colonization are associated with the asymptomatic carrier state; individuals who have persistent diarrhea have significantly lower serum IgG but not IgA to toxin A.[345] Several patients have been identified with relapsing symptomatic disease who have low IgG antibody levels to toxin A.[244,353] Some of these patients had low levels of IgG[353] or IgG1 subclass deficiency[244] and were treated successfully with IGIV.

Recommendations

Patients with refractory *C. difficile* infections (with or without a global antibody deficiency) can be treated with 300 to 500 mg/kg of IGIV every 1 to 3 weeks.[292,393,637,638] Such therapy has been shown to increase antitoxin levels, to control diarrhea, and to prevent relapses during the treatment period.[353,507] However, controlled trials have not been conducted, and thus IGIV treatment is unproved.[286,292]

Studies with an oral anti–*C. difficile* bovine IG for both treatment and prevention were initiated several years ago.[629]

GAS GANGRENE (*CLOSTRIDIUM PERFRINGENS*)

Treatment of gas gangrene with equine antitoxin to *Clostridium perfringens* was of unproven efficacy and no longer is available. Food poisoning caused by *C. perfringens* is self-limited and is not treated with antitoxin.

TETANUS (*CLOSTRIDIUM TETANI*)

See the later section on tetanus, tetanus antitoxin, and tetanus immune globulin.

DIPHTHERIA AND DIPHTHERIA ANTITOXIN

Diphtheria is caused by toxigenic strains of *Corynebacterium diphtheriae* and occasionally *Corynebacterium ulcerans*. Diphtheria is exceedingly uncommon now because of widespread immunization, but a massive epidemic in the countries of the former Soviet Union occurred in the 1990s, with many fatalities.[296,620]

Many of the adverse consequences of diphtheria result from the toxin elaborated and absorbed from the diphtheritic membrane. This toxin not only has a local effect of perpetuating membrane formation but also is distributed through the blood to the heart, nervous system, kidney, and other organs. The larger the membrane, the more toxin elaborated; in addition, more toxin is elaborated from a membrane involving the pharynx and tonsils than from one involving the larynx and trachea.

Diphtheria toxin is present in three forms: (1) circulating and unbound, (2) loosely bound to tissues, and (3) firmly bound to tissues. Antitoxin neutralizes circulating toxin and competes with and partially neutralizes loosely bound toxin but has no effect on tissue-bound toxin. Thus, optimal passive immunity must be initiated at an early stage of the disease by the intravenous route so that toxin can be intercepted before it becomes tissue bound.

In the 1890s, diphtheria antitoxin was used successfully to prevent spread to newly admitted pediatric patients and nurses.[173a]

Antitoxin of animal origin remains the mainstay of treatment, as it was in the pre-antibiotic era. Diphtheria was the first illness in which antiserum was used as standard therapy. Emil von Behring was awarded the first Nobel Prize in Medicine (in 1901) for this achievement. Fibiger[183] proved the efficacy of diphtheria antitoxin in 1898 when he showed that 5 of 204 patients given horse antitoxin died, whereas 14 of 201 not given antiserum died. Paschlau[458] demonstrated the importance of early administration of antitoxin in 1949; the fatality rate of 197 cases treated within 48 hours was 1.96 percent versus 8.9 percent when treatment was delayed until the fourth or fifth day. Other authors have noted similar findings.[592,593]

Tasman and associates[592,593] emphasized the importance of intravenous administration of antitoxin because rapid achievement of high blood levels results in rapid neutralization of antitoxin and the appearance, within 30 minutes, of antitoxin in saliva. They showed that the mortality rate and the severity of the myocarditis and neuritis in experimental diphtheria in guinea pigs could be reduced by giving antitoxin intravenously rather than intramuscularly.

McCloskey and Smilack[386] determined the antitoxin content of standard human IG. None of the lots tested contained diphtheria antitoxin in sufficient titer to allow its use for antitoxin therapy. They suggested that an IVIG with higher titer antitoxin be developed to eliminate the risk of giving horse serum intravenously. Indeed, such a product is produced and used in the Ukraine.[178]

Recommendations

Diphtheria antitoxin of equine origin is indicated for all suspected or proven cases of diphtheria.[15] It is available in vials containing 20,000 U from the CDC. Before administration, skin tests must be performed to determine sensitivity. If the patient has a previous history of serum reactions or these test results are

positive, a schedule of desensitization as outlined earlier must be followed.

The amount of antitoxin given depends on the location and the extensiveness of the membrane, the degree of systemic toxicity, and the duration of illness. The preferred route is intravenous, although intramuscular administration has been used historically in milder cases.

In all cases, diphtheria antitoxin should be given promptly rather than be delayed while awaiting bacterial confirmation of the diagnosis.[15]

In cutaneous diphtheria, antitoxin is of uncertain value. When used, the dose is 20,000 to 40,000 U to prevent toxic sequelae. In pharyngeal or laryngeal disease, 20,000 to 40,000 U is given; in nasopharyngeal disease, 40,000 to 60,000 U is given; and in extensive disease with neck edema or disease of more than 3 days' duration, 80,000 to 120,000 U is given.[15] Although antimicrobial therapy is a valuable aid in the treatment of diphtheria, it is not a substitute for antitoxin therapy.

Routine use of antitoxin in an asymptomatic, exposed susceptible patient is not recommended. With heavy exposure or an extremely susceptible host, antitoxin, 5000 to 10,000 U intramuscularly, can be given in addition to antibiotics and diphtheria immunization. Proof of efficacy is lacking, however.

Human IGIV has variable amounts of diphtheria antitoxin, so it cannot be used as a replacement for animal antitoxin.[15]

PERTUSSIS

Pertussis antiserum was used in the 1930s for the treatment of pertussis.[84] Human pertussis IG was developed in the 1960s but was shown to have no additive benefit to antibiotics in the treatment of pertussis[45,410] and no longer is available commercially.

Granström and coworkers[219] used an experimental human hyperimmune serum from subjects immunized with a two-component acellular vaccine to treat 33 children, and an equal number received an albumin placebo. Both groups received the same antibiotic and supportive treatment. The treated children had decreased coughing and whooping, particularly if treatment was started early.

Ichimaru and colleagues[268] successfully used a high-titer human IGIV preparation to treat a severely ill 1-year-old child.

Bruss and associates[97] studied a 4 percent high-titer human pertussis IG in 26 children with pertussis and found that the product was safe at three dose levels (250, 750, and 1500 mg/kg) and provided good serum pertussis IgG levels with a half-life of 38 days. Little antibody appeared in nasal secretions. Efficacy was not evaluated in this study, but the product was effective in the treatment of aerosol-induced pertussis in mice.[96]

A subsequent randomized placebo-controlled trial was begun that enrolled 25 infants; it was terminated because of unavailability of study product. Preliminary analysis did not suggest a clinical benefit in symptoms such as cough, apnea, and oxygen desaturation compared with the placebo.[239]

Recommendation

No agent is available for passive immunity for pertussis.

RESPIRATORY AND OTHER BACTERIAL INFECTIONS

Respiratory tract infections caused by group A streptococci, *S. pneumoniae*, *H. influenzae* type b, and, to a lesser extent, *Neisseria meningitidis*, *Chlamydia pneumoniae*, and *Mycoplasma pneumoniae* are well recognized as occurring more frequently in patients with primary antibody deficiencies, and these infections can be reduced markedly by the regular administration of IGIV or IGIM.[351,433] Furthermore, specific animal antisera to some of these organisms were used in the early 1930s for the treatment of severe infections (e.g., meningitis), even after the introduction of sulfonamides.[10] Efficacy varied but was clearly better than no treatment at all, and a combination of sulfonamides and antibody seemed to be synergistic.[10]

Small doses of IGIM (100 mg/kg per month) did not prevent or improve the course of respiratory infections in normal children.[54,186] However, Nydahl-Persson and colleagues[429] gave 24 children with repeated bacterial respiratory infection (pneumonia or otitis) either trimethoprim-sulfamethoxazole or IGIV, 400 mg/kg per month; both agents were effective in reducing the number of infections in comparison with a control group.

Santoshan and associates[513] administered a human intramuscular IGIM prepared from the sera of donors immunized with pneumococcal, meningococcal, and *H. influenzae* type b polysaccharide vaccines (termed bacterial polysaccharide immune globulin [BPIG]) to Apache Indian infants living on reservations in Arizona. The 222 infants in the study group received 80 mg/kg of BPIG at 2, 6, and 10 months of age, and the 218 infants in the control group received saline injections at the same ages. During the study period, seven cases of invasive *H. influenzae* type b disease and four cases of invasive pneumococcal disease occurred in the control group compared with one and two cases, respectively, in the BPIG-treated group, a significant difference ($p < .05$).

OTITIS

Immunologically normal otitis-prone children seem to derive little preventive or therapeutic benefit from low-dose IG given intramuscularly (100 mg/kg per month)[291] or intravenously (200 mg/kg per month).[299]

In patients with primary immunodeficiency, the frequency and severity of otitis are diminished dramatically by the use of IG in large doses. In children with secondary antibody deficiency associated with HIV infection, IGIV in large doses (400 mg/kg per month) reduced the frequency of otitis by 60 percent.[407,408] Patients with subtle immunologic abnormalities such as IgG subclass deficiencies, partial IgA deficiency, and polysaccharide antibody deficiencies may have recurrent otitis that can be reduced with a large dose of IGIV (e.g., 400 mg/kg per month).[299,323,429,534,539]

BPIG also was shown to reduce the number of episodes of pneumococcal otitis media in high-risk Native American infants.[534] It did not, however, decrease the total number of episodes of otitis media. Large doses of RSV-IVIG (750 mg/kg per month) reduced the frequency of non-RSV otitis in young infants.[541] This product may have high antibody titers to bacteria and other viruses.[169]

Ishizaka and coworkers[275] successfully treated seven children with recurrent pneumococcal otitis with IGIV.

These studies indicate that low-dose IGIM is ineffective in the prevention or treatment of otitis, but high doses of IGIV (e.g., >400 mg/kg per month) may reduce the frequency and severity of otitis in immunodeficient and otitis-prone normal children, probably by reducing both virally and bacterially mediated disease.[243] Englund and Glezen[169] suggested that passive immunization transplacentally from a recently immunized pregnant mother with *H. influenzae* or pneumococcal vaccine also should be considered.

IGIV should not be used routinely for otitis-prone normal children but in extreme cases can be considered after failure of prophylactic antibiotics and pneumococcal immunization.

SINUSITIS

Sinusitis is a common occurrence in immunodeficient patients and is difficult to prevent or to eradicate, even with optimal treatment. Mofenson and colleagues[407] found that neither IGIV, 400 mg/kg per month, or three times weekly sulfonamide prophylaxis prevented sinusitis from developing in children with HIV infection.

In patients with no or subtle immune defects (e.g., IgG subclass deficiencies, impaired polysaccharide antibody deficiencies), high-dose IGIV sometimes may decrease the frequency and severity of sinusitis.[86,127,478,539]

LOWER RESPIRATORY TRACT INFECTIONS

Although high-dose IGIV is of proven benefit in preventing pneumonia in immunodeficient subjects,[103] no evidence has established that it will prevent pneumonia in normal subjects. Anecdotal cases of IGIV used as adjunctive therapy for refractory viral pneumonia have been reported.[505,569]

CYSTIC FIBROSIS

Winnie and associates[645] suggested that IGIV may improve pulmonary function in pulmonary exacerbations of cystic fibrosis. All subjects received antibiotics, were older than 12 years, and had no long-term benefit from the IGIV. Van Wye and coworkers[614] had similar results with the use of hyperimmune *Pseudomonas* IVIG in patients with cystic fibrosis.

A controlled trial of *Pseudomonas* hyperimmune IGIV in 116 patients with cystic fibrosis was discontinued because a 6-month interim analysis showed no reduction in acute pulmonary exacerbations.[474]

Balfour-Lynn and colleagues[47] suggested that high-dose IGIV was of short-term benefit, both in improving pulmonary function and in decreasing the need for steroids, in selected patients with cystic fibrosis and respiratory obstruction receiving inhaled and oral steroids.

BURN INFECTIONS

Kefalides and associates[310] reduced the mortality rate of severely burned children by administering plasma (1 mL/kg for each 1% of surface area burned) or IGIM (1 mL/kg on days 1, 3, and 5) from 40 to 20 percent. They concluded that solutions containing antibodies (plasma or IG) were more effective in reducing the complications of infections than were other colloids. However, Stone and colleagues[574] could not achieve any clinical benefit from IGIM therapy (0.4 mL/kg every third day until skin coverage) in 60 burned subjects versus 40 controls.

Convalescent plasma, special IG with high antibody titer to *Pseudomonas*, and *Pseudomonas* vaccines also have been used in burn patients in an attempt to reduce infections, but without proof of efficacy.[143,156,288,416,533]

An observational study suggested that the combined use of IGIV and polymyxin B reduced the number of septic episodes and shortened the length of hospital stay in severely burned children.[372]

GRAM-NEGATIVE INFECTIONS

The most extensive use of IG for infections in adults has involved trauma, shock, and postoperative patients thought to have gram-negative infections, as reviewed earlier under secondary immunodeficiency.[57,106,152,209,294,664,665] A meta-analysis involving 492 patients receiving polyclonal IGIV for sepsis and septic shock suggested a benefit, particularly among adults.[9] Monoclonal antibodies to endotoxin or cytokines were not of benefit. We conclude that this is a promising yet unproven use for IGIV.

NEWBORN SEPSIS

As noted earlier, newborns and premature infants in particular are highly susceptible to bacterial sepsis and its sequelae. In addition to antibiotics, leukocytes, granulocyte colony-stimulating factor, and IGIV have been used as adjunctive therapy. As discussed earlier under secondary immunodeficiencies, numerous studies on the prevention and treatment of newborn sepsis are available and suggest only slight benefit in prevention but significant benefit in treatment of established sepsis.

Thus, IGIV is recommended for all septic premature infants not responding well to conventional therapy. It may be particularly valuable for neutropenic septic infants because it may help mobilize leukocytes from the storage pool. We recommend a dose of 500 mg/kg daily for 4 days and repeated as necessary.

STAPHYLOCOCCAL INFECTIONS

Staphylococcal infections are ubiquitous and of varying severity. They include superficial skin infections, acute infections such as abscesses and wound infections, deep-seated indolent cellulitis, and three toxin-mediated diseases: scalded skin syndrome, toxic shock, and acute food poisoning. Antibiotics usually are effective in controlling the infections, but in some instances, the organism is antibiotic resistant or the disease is rapidly progressive. IGIV may be of adjunctive benefit in some of these situations.[311,624]

STAPHYLOCOCCAL TOXIC SHOCK SYNDROME

Patients with staphylococcal toxic shock syndrome, often associated with tampon use by menstruating women, have a rapid onset of fever, shock, macular desquamating rash, and multisystem organ failure.[27,398] The pathogenesis of the disorder results from infection with a strain that releases toxic shock syndrome toxin (TSST-1).[27] Approximately 20 percent of all staphylococcal isolates carry the gene for this toxin.[364] TSST-1 is a potent superantigen that directly activates the 5 percent of T cells that have a Vβ2 T-cell receptor[364]; such activation results in the rapid release of multiple cytokines and a clinical picture of rapidly progressive illness.

IGIV contains neutralizing antitoxins to the staphylococcal (and streptococcal) superantigens[589] and has been used successfully both in animal models of toxic shock syndrome[27] and in several patients.[55,435,455,518] Although no controlled clinical trials have been performed for staphylococcal toxic shock syndrome, most authorities recommend large IVIG doses, at least 400 mg/kg, in addition to antibiotic treatment and circulatory support.[27] IGIV also down-regulates cytokine synthesis and action and inhibits immune activation, thereby providing additional benefits.[27]

Higuchi and coauthors[256] reported a large family that had recurrent episodes of staphylococcal toxic shock syndrome associated with normal immunoglobulin levels but low serum antibody titers to staphylococcal superantigens; two boys in the family achieved successful prophylaxis with regular IGIV infusions.

NEONATAL STAPHYLOCOCCAL INFECTIONS

A second situation in which antibody may be of value is neonatal staphylococcal infection. Coagulase-negative staphylococcal infection, such as with *S. epidermidis*, is the most common cause of sepsis in premature infants and is aggravated in part by the use of catheters and parenteral lipid infusions.[44,187]

One controlled study showed that IGIV was of value in decreasing the incidence of but not eliminating infections,[44] but this benefit has not been found in all trials of IGIV in newborns.

This variability may be explained by differing amounts of staphylococcal antibodies present in different IGIV brands and lots, particularly opsonic antibodies, which have been shown in animal models to be the most important correlate of clinical protection.[187] Because antibody variability exists in lots of IGIV made from pools of thousands of donors, it is not surprising that Krediet and colleagues[331] could not reliably increase the opsonic titers of premature infants by administering single-donor fresh-frozen plasma. However, polyclonal hyperimmune staphylococcal human IGIVs also have not been of benefit (see IGIV in secondary immunodeficiencies). Monoclonal antistaphylococcal antibodies are under study.

REFRACTORY STAPHYLOCOCCAL INFECTIONS

A final use of IG is for the treatment of antibiotic-resistant chronic staphylococcal infection, along with intravenous antibiotics. Waisbren[624] treated 16 such patients with an antibiotic–gamma globulin combination, with recovery noted in 13 of them. Indeed, hyperimmune plasma and immunoglobulin from subjects immunized with staphylococcal toxoids are widely used in Russia with apparent success.[311]

We (E. R. S.) successfully treated a woman with antibiotic-resistant dissecting cellulitis of the scalp with a combination of high-dose IVIG and antibiotics. Animal studies support such a combined approach.[187a]

Recommendations

Large doses of IGIV are indicated for the treatment of staphylococcal toxic shock syndrome.[27] The recommended regimen is a single dose of 1 to 2 g/kg or 400 mg/kg daily for 5 days. A repeated dose may be necessary because of rapid clearance of IGIV in this illness.[27]

The value of IGIV in refractory chronic staphylococcal infections is unproven, although anecdotal reports of efficacy exist.[624]

IGIV is not recommended routinely for the prevention of infection in premature newborn infants. As noted earlier, IGIV may be of adjunctive benefit in the treatment of neonates with sepsis, particularly those with neutropenia.[283] We recommend 500 mg/kg on 4 consecutive days if the patient has not responded to optimal antimicrobial and supportive management. This regimen may be repeated as needed.

STREPTOCOCCAL INFECTIONS

Circulating antibody may play a role in the prevention and treatment of group A streptococcal infection.[302] Newborns rarely develop invasive streptococcal illness, in part because of protective transplacental antibodies.[302] Equine antitoxin was used with some success in the treatment of erysipelas and scarlet fever in the 1920s and 1930s.[366,582] A preventive streptococcal vaccine to the M component has been proposed but as yet is unavailable.

INVASIVE GROUP A INFECTIONS

Invasive group A streptococcal infections, including septicemia, necrotizing fasciitis or myositis, and toxic shock syndrome, are of increasing severity and frequency.[13] Streptococcal pyrogenic exotoxins, including types A, B, and C, and mitogenic factor elaborated by certain strains of streptococci may be responsible for these serious complications of infection. Streptococcal pyrogenic exotoxins are potent superantigens that activate certain T lymphocytes directly and lead to the massive production of multiple cytokines, with resultant shock, fever, and organ failure. IGIV contains neutralizing antibodies to these antigens,[426,427] but at varying titers from batch to batch.[520]

Invasive soft tissue infections with group A streptococcus may benefit from high-dose IGIV.[145,207,426] By contrast to these reports, Mehta and colleagues[396] could not document a benefit for IGIV in patients admitted to the ICU with invasive group A infections from any cause.

STREPTOCOCCAL TOXIC SHOCK SYNDROME

Many case reports have attested to the value of IGIV in streptococcal toxic shock syndrome since the report by Barry and coauthors in 1992.[55,348,465] Kaul and colleagues[306] reported a study of 21 consecutive patients at several Canadian medical centers in 1994 and 1995 treated with IGIV and compared them with 32 similar patients not given IGIV at the same centers for the 3 preceding years. Both groups received appropriate antibiotics and were similar with regard to demographics, severity score, and timing of intervention. The median IGIV dose was 2 g/kg. The survival rate for the IGIV-treated group was significantly greater at 7 and 30 days (90% and 67%, respectively) than that in the untreated controls (50% and 34%, respectively; $p = .02$), and the days of hospitalization were insignificantly shortened (29 versus 39). Serum from the IGIV-treated patients caused a marked inhibition of lymphocyte mitogenic activity to their own bacterial isolates after a single IGIV dose.

PANDAS SYNDROME

Swedo and coauthors[581] reported a syndrome of tics or obsessive-compulsive behavior, or both, occurring in prepubertal children soon after the onset of a streptococcal infection. They termed this disorder pediatric autoimmune neuropsychiatric disorder associated with streptococcal disease (PANDAS syndrome). They reported suggestive benefit of IGIV.[466]

Recommendations

IGIV is recommended for moderate and severe cases of streptococcal toxic shock syndrome, even if the organism has not been identified. The recommended dose is 1 to 2 g/kg given in a single dose or in divided doses of 400 mg/kg. Repeated administration of IGIV may be necessary after a few days because of rapid IGIV catabolism.

IGIV is probably of benefit in severe streptococcal soft tissue infections.

IGIV is of unproven benefit in PANDAS syndrome.[443]

TETANUS, TETANUS ANTITOXIN, AND TETANUS IMMUNE GLOBULIN

Antitoxin for the treatment of tetanus was introduced into medicine by Behring and Kitasato[460] in 1890; large doses (50 to 100 mL) of serum from horses immunized with tetanus toxin

were used. The dose was increased gradually to 300 to 500 mL, equivalent to 300 to 500 U of antitoxin. As the means to increase the production and concentration of antitoxin developed and a high mortality rate persisted, the dosage of antitoxin was increased until doses as high as 200,000 U, repeated at weekly intervals, were recommended.[460] Despite such heroic therapy, no solid proof of efficacy was obtained.

However, in 1960, Brown and colleagues,[89] using sequential analysis, found that the mortality rate was 49 percent in 41 patients with tetanus who received 200,000 U of antitoxin, a statistically significant difference that established therapeutic efficacy. Extensive controlled studies established that mortality rates did not improve when doses of 100,000 to 500,000 U were used.[365,606-608]

Similarly, Patel and associates[460] could find no difference in the mortality rates of patients with tetanus treated with antitoxin doses of 5000 to 60,000 U. Adequate blood levels of antitoxin were noted in all cases, even in fatal cases, with a dose of 10,000 U. In mild cases, no antitoxin was necessary. They and others have reported considerable differences in mortality rates, ranging from 0 to 98 percent; the rate depends primarily on the severity of illness rather than on the dose of antitoxin.

Athavale[40] established that antitoxin was of benefit in tetanus neonatorum and in tetanus in children up to 12 years of age. Antitoxin affected the mortality rate in mild and moderate cases but not in severe ones. A dose of 10,000 U was as effective as one of 30,000 U.

The mechanism of action of antitoxin is to neutralize toxin before it is transported to the nervous system through the circulation. Antitoxin also can neutralize toxin locally and prevent its systemic absorption. Thus, antitoxin can be given locally, at the site of production of toxin (e.g., at the site of a wound), intravenously (in severe cases), or intramuscularly (in less severe cases).

In 1962, an estimated 750,000 annual doses of equine tetanus antitoxin were needed in the United Kingdom, which is equivalent to more than a million doses in the United States.[499] Serum sickness occurs in 6 to 14 percent and fatal anaphylaxis in 1 of every 100,000 injections. Thus, hyperimmune human tetanus immune globulin (TIG), first available in the early 1960s, gradually has replaced equine tetanus antitoxin.

Rubbo and Suri[498] and Rubinstein[499] showed that TIG given intramuscularly (5 to 10 U/kg) provides adequate circulating antitoxin levels and is maintained in the circulation for considerably longer than is equine tetanus antitoxin.

The efficacy of TIG is equivalent to that of equine tetanus antitoxin. McCracken and associates[388] compared the results of 550 U of TIG with 10,000 U of tetanus antitoxin in the treatment of tetanus neonatorum. Among the 65 infants in each treatment group, no difference was noted in severity, length of hospitalization, need for sedation or gavage feeding, or mortality rate. Blake and colleagues[70] analyzed 545 tetanus cases reported to the CDC from 1965 to 1971 and could find no difference in the outcome of patients treated with equine tetanus antitoxin versus TIG.

Gupta and associates[235] gave TIG intrathecally to alternate patients with early tetanus. Among 49 patients given intrathecal TIG (250 U), three got worse and one died; among 48 patients given intramuscular TIG (1000 U), 15 got worse and 10 died. No side effects occurred. Herrero and coworkers[253] could not prove a benefit of administering intrathecal antitoxin for tetanus neonatorum. Although an early meta-analysis of intrathecal therapy cast doubt on its efficacy,[4] studies from India[197] and Brazil[401] and a larger meta-analysis[295] suggested beneficial effect of intrathecal antibody.

TIG can be given along with tetanus toxoid (10 Lf U) for passive-active immunization. A dose of 250 U of TIG given intramuscularly at a site different from that of the toxoid does not interfere with the active antibody response.[387]

Lee and Lederman[350] measured the tetanus antitoxin titers in 29 lots of IGIV and noted considerable variability, although all lots had titers greater than 4 U/mL (mean, 21 U/mL). All lots would provide sufficient anti–tetanus toxin antibody if used at doses of 100 mg/kg as an alternative to TIG or tetanus antitoxin.

Recommendations

PROPHYLAXIS

If a non-immunized person sustains a serious injury or a bite, 250 to 500 U of TIG should be given intramuscularly as soon as possible.[26] The larger dose is used in the event of an extensive wound or delay in treatment. TIG is available for intramuscular administration in individual vials containing 250 U. Alum-precipitated toxoid to initiate active immunity is given at a different site with a separate syringe.

Human IGIV also can be used if TIG is not available, at a dose of 200 to 400 mg/kg.[26]

If TIG or IGIV is unavailable, 3000 to 5000 U of tetanus antitoxin (equine) is administered (after screening and testing for serum sensitivity have been performed).[26] Equine antitoxin for human use is available in several countries where TIG is unavailable. Equine tetanus antitoxin is available for veterinary use in vials containing 1500 or 20,000 U.

TREATMENT

In addition to administration of antibiotics and management of the wound, TIG should be given, but the optimal dose has not been established. At least 500 U is recommended, but doses as high as 3000 to 6000 U have been used. Part of the TIG is infiltrated near the wound, and the remainder is administered intramuscularly.[26] If the wound is extensive, TIG can be diluted with saline to infiltrate the entire area. TIG also is indicated for the treatment of tetanus neonatorum. Recent meta-analyses suggest that intrathecal use is of benefit in both adults and infants.[295]

If TIG is unavailable, equine tetanus antitoxin should be given in a single dose of 100,000 U, with 50,000 U given intramuscularly and 50,000 intravenously (after appropriate testing for sensitivity). On recovery, the patient should undergo primary immunization.

In tetanus neonatorum, McCracken and associates[388] found that 500 U of TIG given intramuscularly and 10,000 U of equine antitoxin were equally efficacious. Intrathecal TIG has been recommended[235,295,401] but is not always of benefit.[60,253] However, TIG is not licensed for this use.

PASSIVE IMMUNITY IN VIRAL INFECTION

ENTEROVIRUSES

POLIOVIRUS

Before the development of poliomyelitis vaccines in the mid-1950s, IGIM was used extensively for the prevention of poliomyelitis. Bodian[75,76] showed that Red Cross IGIM had neutralizing antibody to all three strains of poliovirus in approximately equal titer and that rhesus monkeys given intramuscular poliovirus could be protected against disease by the subcutaneous administration of IGIM.

Bloxsom,[73] in an uncontrolled study performed during a 1948 Texas epidemic, gave 841 contacts an average dose of 2 mL of IGIM and noted only four cases at 1, 2, 3, and 42 days after administration of the IGIM injection. His interpretation was that IGIM had been given too late to prevent the first three cases and that protection had worn off in the fourth case.

A committee on immunization of the National Foundation for Infantile Paralysis recommended in March 1951 that a controlled study be conducted on the efficacy of IGIM for the prevention of poliomyelitis during epidemics. Hammon and associates[242] subsequently undertook a massive field study in communities in three states during poliomyelitis epidemics.

Fifty-five thousand children aged 1 to 11 years received either IGIM (average dose, 0.14 mL/lb) or gelatin in a double-blind fashion. During the first week after injection was administered, 12 cases occurred in the IGIM recipients and 16 cases in the gelatin recipients. In the two groups, 3 and 23 cases occurred in the second week and 6 and 38 cases occurred in the third to fifth weeks, respectively. When protection was incomplete, decreased severity was noted. Protection waned by 6 weeks and disappeared by 8 weeks. These clinical results were confirmed by isolation of the virus or a rise in antibody titer in affected patients.

IGIM was an inefficient method of poliomyelitis prophylaxis in that it prevented only one case for every 500 to 2000 injections, and then only for a brief time. Its chief value was in close family contacts of affected children and in aborting severe local epidemics.

Recommendations

The use of IGIM rarely is indicated for the prevention of poliomyelitis. An exposed unimmunized subject can be given 0.31 mg/kg of IGIM. An unimmunized patient who is traveling to an endemic or epidemic area and who cannot have vaccine can be given this dose of IGIM for temporary protection.

An immunodeficient patient inadvertently exposed to live attenuated polio vaccine who is excreting poliovirus in stool may be a candidate for receiving IGIV and oral IG in an effort to rid the gastrointestinal tract of the virus.

OTHER ENTEROVIRUSES

Enteroviruses, particularly echoviruses and coxsackieviruses, can cause severe disease in neonates[274] and in immunodeficient patients, particularly those with X-linked agammaglobulinemia. IGIM and IGIV have been used in both groups for the prevention and treatment of these infections.

MENINGOENCEPHALITIS. Chronic enteroviral meningoencephalitis with severe neurologic findings may develop in agammaglobulinemic patients; the incidence has decreased since routine treatment with IGIV has been instituted for these patients. IGIV does not prevent all cases, possibly because of differing titers of antibodies to different enteroviral serotypes. McKinney and coworkers[391] summarized the results of treatment of 42 patients with chronic enterovirus meningoencephalitis: 10 received IGIM or plasma, but only 1 survived, a patient who received high-titer human serum; 10 received IGIV, and 7 survived; and 12 received both intraventricular IGIV and systemic IGIV, and 6 improved and 10 survived.

Misbah and colleagues[402] reviewed the cases of 15 patients with chronic enteroviral meningoencephalitis not included in the McKinney report, some of whom, however, had been described by others.[161,328] Of 5 patients treated with IGIV, 3 survived, and of 10 treated with IGIV and intraventricular or intrathecal IGIV (only 1 patient received intrathecal, not intraventricular, IGIV), 5 survived. Mellouli and colleagues[399] successfully treated an agammaglobulinemic boy who developed echovirus meningoencephalitis while receiving IGIV with intraventricular IG through an Omaya reservoir in addition to aggressive intravenous therapy.

Quartier and associates[476] reported complete clinical and virologic remission, as determined by both culture and polymerase chain reaction (PCR) assay, in one patient treated with IGIV and a brief course of pleconaril; remission was maintained for 37 months by keeping the serum IgG trough level at 800 mg/dL. A second patient was treated with IGIV and pleconaril, but intraventricular IG was added when cerebrospinal fluid pleocytosis persisted after 11 months of therapy. Complete clinical and virologic remission resulted and persisted at the 20-month follow-up. This study indicated that cerebrospinal fluid PCR assay can be used, in addition to viral culture, as a guide to successful therapy.

NEONATAL ENTEROVIRAL INFECTION. Severe and sometimes fatal disseminated enterovirus infection can develop in neonates.[477] Case reports have suggested benefit with the use of IGIV.[274,287,610] Kimura and coworkers[318] treated coxsackievirus B3 infection in four term infants with IGIV; the three who were treated early survived, but the infant treated 6 days after the onset of infection died. Abzug and associates[5] treated nine infants with echovirus and coxsackievirus B infection with IGIV but without apparent benefit; however, three of five infants who received high-titer IGIV had a shortened period of viremia. Rentz and colleagues[488] suggested that the maternal plasma might be used in lieu of IGIV as a source of high-titer antibody in newborns with a severe enteroviral infection. In sum, IGIV is of uncertain value, particularly if its titer against the particular virus is not known.

Nagington and colleagues[415] used IGIM successfully in an echovirus 11 outbreak in a special care nursery, but Kinney and coworkers[319] could not demonstrate a benefit of using IGIM in a similar nursery with the same virus. Pasic and associates[459] administered IGIV at 400 mg/kg prophylactically (neutralization titer, 1:32) during a nursery echovirus 6 outbreak and thought that the severity of illness was decreased, although viral transmission continued.

Recommendations

IGIV may be used for critically ill neonates with disseminated enterovirus infection, although its benefit is unproven. In an outbreak situation with a known serotype and the availability of IGIV with significant titer to this serotype, IGIV should be considered. Multiple doses of 500 mg/kg as well as single doses of 750 to 1000 mg/kg have been used.[5,287,318,610]

For chronic enteroviral meningoencephalitis, McKinney and colleagues[391] recommend that sufficient IGIV be administered to maintain an IgG serum trough level of 900 to 1000 mg/dL. Even higher doses may be needed if the IGIV titer for the infecting virus is low. Quartier and coworkers[476] used 500 mg/kg of IGIV every 24 to 48 hours for 2 weeks, followed by 500 mg/kg two to three times per week for 6 weeks and then gradual reductions, but with maintenance of the trough IgG level at greater than 800 mg/dL.

Administration of IGIV by intraventricular catheter should be considered for patients who do not improve despite receiving aggressive therapy with IGIV. IGIV for intraventricular administration should have a neutral pH, be given slowly, and be at room temperature.[391] Dwyer and Erlendsson[161] used 6 percent IGIV intraventricularly starting at doses of 120 mg/day and increasing to 600 mg/day during the first week of treatment, followed by doses of 300 mg/day for 1 to 4 weeks. Quartier and

colleagues[476] administered 300 mg of IGIV daily for 15 days and then 300 mg three times a week to a patient whose intravenous IGIV therapy had failed. The duration and frequency of both intraventricular and intravenous IGIV must be individualized and determined by clinical and virologic response and normalization of cerebrospinal fluid and ventricular fluid. An IGIV with a high titer to the infecting serotype should be used for both systemic and intraventricular therapy.

HEPATITIS A

The widest use for human IGIM has been for the prevention of hepatitis A, but this indication has been decreased by the widespread use of hepatitis A vaccine.[16] The efficacy of IGIM was demonstrated in 1945 by Stokes and Neefe[570] in aborting an epidemic in a children's summer camp, by Havens and Paul[245] in controlling an institutional epidemic, and by Gellis and associates[198] in preventing hepatitis A in the Mediterranean theater of operations at the close of World War II. The administration of combined IGIM and hepatitis A vaccine and scrupulous cleanliness can be used to interrupt the intestinal-oral circuit of transmission to abort an incipient epidemic.

IGIM is efficacious in preventing hepatitis A if it is given within 2 weeks of the last exposure.[16] Protection persists for 6 to 8 weeks. Stokes and associates[571] noted that a single small dose of IGIM (0.02 mL/kg) provided a degree of protection for up to 9 months in individuals residing at an institution in which hepatitis A was endemic.

The effectiveness of IGIM in hepatitis A varies from 80 to 95 percent, depending on how soon it is administered after exposure and the severity of the exposure.[627] IGIM suppresses clinical manifestations of the disease, but anicteric hepatitis is not prevented, and the ratio of anicteric to icteric hepatitis may be as high as 12:1.[337] Because the period of protection exceeds the expected duration of the IGIM, the concept of passive-active immunity has emerged; as a result of continuous exposure, a mild illness ensues and in turn confers long-lasting immunity.[337,571,627]

In initial studies, Stokes and Neefe[570] used an IGIM dose of 0.15 mL/lb. Other early workers used doses of 0.06 to 0.12 mL/lb.[198,245] Stokes and associates[571] in 1951 showed that doses as low as 0.01 mL/lb were effective in limiting spread but not in totally preventing hepatitis. Hsia and colleagues[263] in 1954 also noted that a dose of 0.01 mL/lb was effective in preventing hepatitis among family contacts. However, Ward and associates[628] in 1958 were able to reduce the incidence of hepatitis in institutionalized patients from 19.5 to 7.4 cases per 1000 with 0.01 mL/kg and to 1.7 cases per 1000 with 0.06 mL/kg. The larger dose may be particularly important in adults because they are subject to more severe disease.

The use of serologic tests for hepatitis A provides a way to determine the immunity of a subject, the presence of inapparent infection, the titer of hepatitis A virus (HAV) in lots of IGIM, and the validity of the passive-active immunity concept.[570,571] In other earlier studies, Krugman[338] showed that an IGIM preparation with a titer of 1:3200 by an immune adherence test was effective in neutralizing the infectivity of MS-1 serum, a substance known to contain HAV. Among seronegative children who received the IGIM–hepatitis A mixture, six remained seronegative and two became seropositive; one became ill. By contrast, hepatitis developed in 8 of 14 children who received MS-1 serum without IG.

Most current lots of IGIM have anti-HAV antibodies when they are assayed by a competitive-inhibition radioimmunoassay. Titers greater than 1:100 are protective.[546]

RECOMMENDATIONS

HOUSEHOLD AND SEXUAL CONTACTS. Individuals, either adults or children, with a known intimate exposure to hepatitis A, such as a household or sexual contact, should be given a single IGIM dose of 0.02 mL/kg as soon as possible after being exposed.[16] Hepatitis A vaccine also can be initiated. Serologic testing for hepatitis A is unnecessary and may delay the administration of IGIM. The use of IGIM longer than 2 weeks after exposure has occurred is not indicated.[16]

SCHOOL EXPOSURE. IGIM usually is not necessary for children and their teachers exposed to a single case of hepatitis A in the classroom of a day school. However, if several children are infected or if transmission in the school is documented, IGIM (0.02 mL/kg) and immunization are indicated for the students and teachers. New students and employees should be given IGIM and vaccine for 6 weeks after the last case is identified.[16] IGIM prophylaxis is recommended for children and staff exposed at a boarding school or in a school for retarded children, where opportunities for transmission by the fecal-oral route are increased.

INSTITUTIONAL OUTBREAKS. Hepatitis A outbreaks in institutions such as boarding schools, daycare centers, facilities for the mentally retarded, and prisons require aggressive action. Other cohorts, employees, and adult members of the households of infants who wear diapers and who attend these daycare facilities should be treated immediately with 0.02 mL/kg of IGIM. If recognition of an outbreak is delayed 3 weeks or more after onset of the index case or if spread to other cohorts, staff, or household contacts appears to be occurring, all personnel (staff and children) should be given IGIM. If an outbreak of hepatitis A is traced to a food handler, IGIM should be given to close contacts and other restaurant employees.[111]

HOSPITAL AND CLINIC EXPOSURE. Administration of IGIM to unimmunized hospital employees caring for patients with hepatitis A or to patients usually is not recommended unless evidence of an outbreak among patients or between patients and staff exists.[16]

COMMON-SOURCE EXPOSURE. These cases generally are identified too long after the exposure occurs for IGIM to be effective. If a person has been exposed within the previous 2 weeks, IGIM can be given (0.02 mL/kg).[16]

COMMUNITY OUTBREAKS. Unless a source of the infection is identified, mass use of IGIM is ineffective and not recommended because it will not interfere with transmission.[39] Immunization is recommended.

FOREIGN TRAVEL. Individuals going to developing countries should receive vaccine 1 month before departure. If the departure date is less than 1 month away, 0.02 mL/kg of IGIM and vaccine can be used.[16] The IGIM will provide immediate protection and not interfere with efficacy of the vaccine. If exposure to hepatitis A will continue beyond 3 months, the IGIM dose should be 0.06 mL/kg and repeated every 5 months if exposure to hepatitis A continues and the patient cannot be immunized.

PRIMATE EXPOSURE. Certain subhuman primates such as chimpanzees may carry HAV. Animal handlers should observe scrupulous hygiene and be given hepatitis A vaccine. If bitten and unimmunized, they should receive 0.02 mL/kg of IGIM and vaccine.

NEEDLE EXPOSURE. IGIM is indicated for susceptible persons accidentally inoculated with blood or serum from a patient with hepatitis A. The recommended dose is 0.02 mL/kg; pregnancy is not a contraindication to the administration of IGIM.

NEWBORN INFANTS OF INFECTED MOTHERS. If the mother becomes symptomatic with acute hepatitis A between 2 weeks before and 1 week after delivery, the infant can be given 0.02 mL/kg of IGIM. Efficacy has not been established, however.

HEPATITIS B AND HEPATITIS B IMMUNE GLOBULIN

Hepatitis B virus causes a wide spectrum of illness ranging from asymptomatic seroconversion to fulminant hepatitis. Although most normal subjects recover completely, the carrier state occurs commonly in exposed immunocompromised subjects, such as newborns, patients taking immunosuppressive medications, and patients with primary or secondary immunodeficiencies.

Transmission occurs after exposure to blood or other body fluids, through inoculation or sex, and by close personal contact such as may occur in daycare centers. The main route of transmission used to be by blood transfusion, but with donor testing, this route no longer is common in developed countries. An important route of transmission is from the mother to her newborn infant, who is likely to remain chronically infected for a lifetime. This route usually can be prevented by active and passive immunization.

IMMUNE GLOBULIN IN HEPATITIS B

The initial study of IGIM in hepatitis B was conducted in 1945 by Grossman and associates,[228] who treated alternate battle casualties given whole blood or plasma with two 10-mL injections of IGIM 1 month apart. The incidence of icteric hepatitis was 1.3 percent in 384 IGIM-treated patients and 9.9 percent in 384 control patients, a highly significant difference that suggested a beneficial effect of IGIM.

In 1947, Duncan and associates[160] reported the results from a similar study, although they gave only one 10-mL injection; hepatitis occurred in 1.2 percent of 2406 patients in the IGIM-treated group and in 0.9 percent of patients in the control group, an insignificant difference. However, the mean incubation period was significantly prolonged in the IGIM-treated group (to 103 days) compared with the control group (87 days).

Holland and associates[260] could not alter the incidence or severity of post-transfusion hepatitis in 84 open heart surgery patients given two 10-mL doses of IGIM 1 month apart in comparison to 83 non–IGIM-treated controls. These findings were confirmed in a large cooperative study of 5189 transfused cardiovascular patients given 10 mL of IGIM during the first, fourth, and seventh postoperative weeks.[216] Redeker and associates[484] could not demonstrate that IGIM protected spouses of individuals with type B hepatitis. Similarly, Kuhns and colleagues[340] could not reduce the incidence of post-transfusion hepatitis B with 20 mL of IGIM. Both these latter studies used IGIM with low titers of antibody to hepatitis B surface antigen (anti-HBs).

Several factors probably are responsible for the variation in effectiveness of IGIM in hepatitis B. One is the variable degree of exposure to hepatitis B virus, which can be massive (as with a blood transfusion) or minimal (e.g., a household contact). A second factor is the variable levels of anti-HBs antibody in different lots of IGIM. Because IGIM does not always contain high titers of anti-HBs, it is not recommended for hepatitis B prophylaxis.

HEPATITIS B IMMUNE GLOBULIN

Soon after hepatitis B surface antigen (HBsAg) and its antibody (anti-HBs) were identified, researchers realized that measurement of the antibody content of IG would permit selection of lots (or donors) with high titers of anti-HBs; such selection results in IG lots with anti-HBs titers of at least 1:100,000 by radioimmunoassay. This product, hepatitis B immune globulin (HBIG), has been licensed since 1978 for prevention of hepatitis B.[17,120,122]

Krugman and associates[333,335,337] in 1971 evaluated high-titer HBIG in institutionalized children injected with the infective serum MS-2. Hepatitis developed in all 11 children exposed to MS-2 serum; two became icteric, and five remained HBsAg carriers after 320 days. Among five children given MS-2 serum and standard IG, hepatitis developed in three, two were icteric, but none became a carrier. Of 10 children exposed to MS-2 serum and HBIG, six were completely protected, one had a transient infection, and three developed classic hepatitis. They concluded that HBIG was 70 percent effective under these circumstances. Their later studies confirmed that HBIG could reduce the incidence, severity, and carrier rate of HBsAg significantly after prenatal exposure to hepatitis B virus.[338]

Szmuness and associates[583] tested the efficacy of HBIG versus IGIM by giving either standard IGIM or HBIG to institutionalized children at admission and at 4-month intervals for 1.5 to 2 years and compared the incidence of hepatitis with that in untreated subjects. Both globulin-treated groups had a lower attack rate (11% versus 25% in the untreated subjects) and a lower incidence of persistent antigenemia (none in the globulin-treated group versus 13.5% in the untreated group). Thus, both IGIM and HBIG were effective in preventing or modifying nonparenterally transmitted hepatitis B in an endemic setting.

Of note is that anti-HBs developed in 55 percent of the patients treated with standard IGIM, whereas antibody developed in only 23 percent of the patients treated with HBIG, thus suggesting that passive-active immunity occurred more frequently in the group that received standard IGIM than in the group that received HBIG.

Seeff and associates[522] gave either HBIG or standard IGIM to 302 individuals definitively exposed orally or parenterally to material that was infectious for hepatitis B. The incidence of both clinical and subclinical hepatitis during the first 6 months was 0.7 percent in the HBIG-treated group and 6.1 percent in the IGIM-treated group. At 6 months, 32 percent of the IGIM recipients and 6 percent of the HBIG recipients had antibody, a finding indicative of minimal passive-active immunity in the HBIG-treated group.

Grady[215] reported similar results with HBIG after accidental exposure. The incidence of hepatitis at 6 months was 7 percent (of 251 patients) with standard IGIM, 5 percent (of 208 patients) with intermediate-titer HBIG, and 2 percent (of 253 patients) with high-titer HBIG. This protection waned after 6 months, and differences in the groups became less apparent after 9 months, possibly because of reexposure, delayed onset of infection, or failure of passive-active immunity

PREVENTION OF VERTICAL TRANSMISSION

Beasley and associates[58,59] studied the efficacy of HBIG in preventing perinatal transmission of the hepatitis B virus carrier state from a mother to her newborn infant. HBIG or placebo was

given at birth to the infants of hepatitis B early antigen (HBeAg)–positive, HBsAg-positive carrier mothers, and the infants were monitored for at least 15 months. Of 61 placebo recipients, 92 percent became carriers; of 67 infants who received 1.0 mL of HBIG at birth, 54 percent became carriers; and of 57 infants who received 0.5 mL of HBIG at birth and at 3 and 6 months, 26 percent became carriers. Passive-active immunization, indicated by the presence of anti-HBs, occurred in 27 percent of the single-dose group and in 61 percent in the three-dose group.

On the basis of these and other studies[285,487] suggesting that multiple HBIG doses were more effective in interrupting vertical transmission of the HBsAg carrier state than was a single HBIG dose, advisory committees in the early 1980s recommended that all infants of HBsAg-positive mothers be given HBIG (0.5 mL) immediately after birth and again at 3 and 6 months.[120,122] However, many of these infants became infected sometime after their last HBIG dose (i.e., in the second or third year of life), thus indicating a need for more durable active immunity.

Wong and associates[650] studied the efficacy of hepatitis B vaccine given in conjunction with HBIG in the prevention of vertical transmission of the carrier state from mother to infant. They gave hepatitis B vaccine (36 infants), hepatitis B vaccine plus one dose of HBIG (35 infants), hepatitis B vaccine plus seven monthly HBIG doses (35 infants), or placebo (35 infants) to infants of HBsAg-positive mothers. In all vaccine groups, development of a persistent carrier state was reduced significantly in comparison to the placebo group (21% with hepatitis B vaccine alone, 2.9% with hepatitis B vaccine plus one dose of HBIG, and 6.8% with hepatitis B vaccine plus seven doses of HBIG versus 73.2% for placebo groups). That anti-HBs developed in all infants of the treatment groups indicated that HBIG did not interfere with active immunization.

This and other studies[131,300,586] indicate that HBIG given at the same time as hepatitis B vaccine provides optimal passive-active immunity for long-lasting prevention of the carrier state, and this dose is the current recommendation. Studies in adults also confirm that HBIG given before or simultaneously with the first dose of hepatitis B vaccine does not interfere with the antibody response to hepatitis B vaccine.[584,659] This approach will not prevent every case of vertical transmission because some infants may acquire the infection in utero.

HBIG is not of value in the treatment of either acute[6] or chronic[486] hepatitis B infection.

HEPATITIS B IMMUNE GLOBULIN IN LIVER TRANSPLANTATION

Liver transplantation in a patient infected with hepatitis B is associated with a high rate of its recurrence in the new liver (about 50% in 3 years) and subsequent mortality. The HBIG doses needed to prevent re-infection are very high, and thus HBIG often is given intravenously.[595] One brand of HBIG (Nabi-HB) is formulated as a preservative-free 5 percent solution rather than the usual 16 percent formulation; it has been tested but not licensed for intravenous use.[596] A second 5 percent formulation (HepaGam B, Cangene) was licensed in 2007 for intravenous administration. Despite their lower protein content, these 5 percent products provide levels of HBs antibody equivalent to or higher than those of the 16 percent formulations.

The 5 percent HBIG given intravenously or by the usual intramuscular route will reduce the rate of recurrence of hepatitis B.[508] In a retrospective analysis of 359 such transplants, hepatitis B recurrence was 74 ± 6 percent in 67 patients given no HBIG, 74 ± 5 percent in 83 patients given HBIG for 2 months, and 36 ± 4 percent in the 209 patients given HBIG for 6 months or longer.

Grazi and coworkers[221] reduced significantly the recurrence rate in HBsAg-positive, hepatitis B virus DNA–negative cirrhotic individuals undergoing liver transplantation with the use of HBIG for 1 year after transplantation; recurrence was noted in 8 of 10 controls (80%) and 4 of 25 HBIG-treated patients (16%). Several other reports are available.[595,596]

In addition to HBIG therapy, pre-transplantation and post-transplantation antiviral drugs such as lamivudine are used. When administered in the immediate pre-transplantation period to patients with a high viral burden, these drugs enhance the effectiveness of HBIG because less virus must be neutralized.[594] Long-term maintenance of antivirals with discontinuation of HBIG after several months may be feasible.[649]

Preliminary studies of monoclonal antibodies to hepatitis B antigens are under way.[663] They would be particularly useful for liver transplantation because of the large antibody doses required.

Recommendations

PROPHYLAXIS

HBIG is recommended after a person's parenteral or mucous membrane (oral, sexual, ophthalmic) has contact with blood or body fluids from individuals with hepatitis B or with HBsAg-positive materials (e.g., blood, plasma) and for neonates born to HBsAg-positive mothers (Table 256–6).[17] It is available in 0.5-mL prefilled syringes and 1- and 5-mL vials. Two products are 5 percent product, whereas others are the usual 16 percent product characteristic of most special IGIMs for specific infectious diseases. Both contain equivalent amounts of anti-HBs antibodies per milliliter. The older 5 percent product (Nabi-HB) has been used intravenously after liver transplantation, but it is an off-label use.

Exposure to Blood That Contains (or May Contain) Hepatitis B Surface Antigen

No prospective studies have tested the efficacy of a combination of HBIG and hepatitis B vaccine in preventing hepatitis B after accidental exposure, including exposure by the percutaneous, ocular, and mucous membrane routes, as well as by human bites that penetrate the skin. Because health care workers at risk for incurring such accidents are candidates for receiving hepatitis B vaccine and because the combination of HBIG and hepatitis B vaccine is more effective than HBIG alone in perinatal exposure, this combination also is recommended after accidental exposure.

If the exposed patient is unimmunized and the blood or secretions come from an individual known to be HBsAg positive or if the infection status of the source is unknown but the source is high risk, immediate prophylaxis is indicated. A single dose of HBIG (0.06 mL/kg or 5 mL for adults) should be given intramuscularly as soon as possible, preferably within 24 hours of exposure.[17] Hepatitis B vaccine should be given simultaneously at a different site and repeated after 1 and 6 months (see Table 256–6). After massive exposure (i.e., by blood transfusion), much larger doses of HBIG probably are indicated.

If the exposed patient has been immunized but the serologic response is not known, anti-HBs titers should be determined and the individual managed according to the results; if nonresponsive (anti-HBs <10 mIU/mL by radioimmunoassay), HBIG and a full series of vaccine should be given. In patients with a contraindication to vaccine, two doses of HBIG (0.06 mL/kg) should be used, the second administered 1 month after the first. Two doses of HBIG also should be given to an exposed health care worker who is known to have no response to two series of hepatitis B vaccine.[17] Current recommendations from the CDC[115b] for nonoccupational exposures are to administer vaccine alone to previously immunized individuals as a booster dose without the need to document serologic response if the exposed person has written

TABLE 256–6 Hepatitis B Post-exposure Recommendations for Hepatitis B Immune Globulin (HBIG) and Hepatitis B Vaccine

	HBIG		Hepatitis B Vaccine	
Type of Exposure	**Dose**	**Recommended Timing**	**Dose**	**Recommended Timing**
Perinatal				
Infant of HBsAg-positive mother	0.5 mL IM	Within 12 hr of birth	0.5 mL	First dose within 12 hr, repeat 2 times
Infant of mother whose HBsAg status is unknown	0.5 mL IM	Within 7 days of birth if mother is found to be HBsAg positive	0.5 mL	First dose within 12 hr, repeat 2 times
Premature infant (<2000 g) whose mother's HBsAg status is unknown	0.5 mL IM	Within 12 hr of birth (unless maternal HBsAg test result is negative by this time)	0.5 mL	First dose within 12 hr, repeat 3 times
Mucous membrane or percutaneous with known non-occupational exposure				
Nonvaccinated	0.06 mL/kg IM	Immediately	0.5 mL*	First dose immediately, repeat 2 times
Previously vaccinated, known responder	None	None	None	
Previously vaccinated, unknown response	0.06 mL/kg IM if HBs	Test patient for antiHBs; omit HBIG† if > 10 mIU/mL	0.5	Give booster†
Previously vaccinated, known nonresponder	0.06 mL/kg IM	Immediately, may repeat in 1 month if < 10 mIU/mL‡	0.5 mL*	Give booster immediately, repeat 2 times if necessary
Sexual—known exposure				
Nonvaccinated	0.06 mL/kg IM	Immediately, but no later than 14 days	0.5 mL*	First dose immediately, repeat 2 times
Vaccinated†	None	None	0.5 mL	Give booster if unknown response

**Dose for individuals younger than 20 years. The adult vaccine dose is 1.0 mL. The dose for immunosuppressed patients and patients undergoing dialysis varies with the vaccine used. Vaccine doses given are for Recombivax HB or Engerix-B.*

†Recent CDC recommendations[115b] for exposure (sexual, sexual assault, percutaneous, or mucosal) from a source with unknown hepatitis B status are to forgo vaccine and HBIG if the exposed patient is already immunized and has written documentation of complete vaccine series and did not receive serologic testing for response. Individual assessments of potential risk must be made. See text.

‡See text for discussion of persons who have not responded to two vaccine series.

HBsAg, hepatitis B surface antigen

documentation of a completed hepatitis B vaccine series. The *Red Book*[17] also agrees with this booster vaccine approach. We recommend a more individualized approach for assessing risks of the addition of HBIG.

Perinatal Exposure

Among mothers who are HBsAg positive and HBeAg positive, 85 percent of their untreated infants will become infected and be chronic carriers, and chronic hepatitis, cirrhosis, or hepatic cancer will develop in some of them. If the mother is HBsAg positive only, the risk of her offspring's becoming a carrier is less but is still significant. Accordingly, these infants should receive HBIG prophylaxis.

INFANTS BORN TO MOTHERS WHO ARE HBsAg POSITIVE. For optimal passive-active immunity, HBIG (0.5 mL) is given to the newborn at birth (preferably in the delivery room but within 12 hours at the latest). Hepatitis B vaccine (at a dose half that of the adult dose) is begun simultaneously and repeated at 1 and 6 months (see Table 256–6). This combination is only approximately 90 percent effective in preventing the carrier state because intrauterine infection will not be prevented.

TERM INFANTS BORN TO MOTHERS NOT TESTED FOR HBsAg. If the HBsAg status of the mother is unknown, hepatitis B vaccine should be given to the term infant within 12 hours, and HBIG should be administered as soon as the mother is shown to be a carrier. Its effectiveness is diminished markedly if administration is delayed beyond 48 hours after birth but is given up to 7 days after birth.[17]

The mother should be tested immediately; if she is HBsAg negative, vaccine is continued as recommended for other infants. If the mother is found to be HBsAg positive later, HBIG and hepatitis B vaccine should be given to her infant, even if a significant delay has occurred. After the final dose, the infant can be tested for HBsAg and anti-HBs at 12 to 15 months to determine the success of the HBIG and vaccine regimen. If HBsAg is present, the infant is a carrier; if anti-HBs is present, the child was successfully immunized. Administration of HBIG at birth should not interfere with polio or diphtheria-pertussis-tetanus (DPT) vaccines starting at 2 months of age.

PREMATURE INFANTS. Premature infants with birth weights less than 2000 g who are born to women not tested for HBsAg should be given 0.5 mL HBIG within 12 hours of birth unless the mother's HBsAg test results can be available within 12 hours and are negative. Immunization should be started immediately and repeated for a total of four doses (rather than the usual three doses) because of the poorer response of preterm infants to the vaccine.[17]

Sexual Exposure to Hepatitis B or a Carrier of Hepatitis B

Sexual exposure (including rape) to an individual who has hepatitis B or is a carrier is an indication for administration of HBIG (0.06 mL/kg intramuscularly, 5 mL maximum) and initiation of hepatitis B vaccination. HBIG should be given as soon as possible but not after 14 days post-exposure. If only HBIG is given, a second dose of HBIG is recommended after 30 days. The CDC[115b] also recommends booster vaccine alone in this situation if written documentation is available for a completed hepatitis B vaccine series.

Possible Exposure

After possible exposure (percutaneous, ingestion, sexual) to an unidentified person or body fluid in which the HBsAg status is

unknown, the decision to treat with HBIG must be made individually on the basis of the likelihood that the source is HBsAg positive and the seriousness of the exposure. Hepatitis B vaccine should be initiated immediately if the exposed person is not immunized. Current *Red Book* recommendations and CDC recommendations[17] suggest that with an unknown source, vaccine alone is acceptable for an unvaccinated exposed patient and no treatment is required if the exposed person has written documentation of having previous immunization. We recommend a more individual approach to assess risks.

Ideally, the source subject should be tested for HBsAg positivity; if the results are available within 7 days for a percutaneous exposure and 14 days for a sexual exposure,[17] HBIG (0.06 mL/kg) can be given immediately and again at 1 month if the source is HBsAg positive and the patient did not or could not receive vaccine. When the source subject cannot be tested or when the source is likely to be HBsAg positive, HBIG is administered immediately.

If the exposed individual is a high-risk patient (e.g., immunodeficient, immunosuppressed, institutionalized, or undergoing hemodialysis) or is in an environment or health care unit for which past environmental control measures have been ineffective, HBIG should be given in addition to hepatitis B vaccine.

HBIG is not indicated on a routine basis after administration of blood transfusions. School or hospital exposure or usual household exposure is not an indication for HBIG, but household exposure is an indication for vaccine for unimmunized exposed persons.[17]

HEPATITIS B IMMUNE GLOBULIN IN LIVER TRANSPLANTATION

For patients who are HBsAg positive at the time they undergo liver transplantation or in the rare situation in which the donor of the liver is HBsAg positive, administration of HBIG is recommended in the preoperative period and after transplantation to prevent recurrence in the transplanted liver.[221,412,508,509,594-596]

The exact dose, frequency, route, and duration of HBIG in this situation have not been established, but the dose is large and adds significantly to the cost of the transplant procedure.

The typical regimen is to use very high HBIG doses (i.e., 10,000 units) before transplantation and immediately after transplantation, along with antiviral medications.[594] The HBIG is continued for several months, the dose determined by monitoring of the hepatitis B viral burden by PCR. After several months, the HBIG may be reduced or discontinued, but the antivirals are continued.[649]

HEPATITIS C

Early studies suggested that lots of polyvalent IGIM or HBIG not screened for hepatitis C antibodies provided some protection against the acquisition of non-A, non-B hepatitis (presumably hepatitis C) after heart surgery or hemodialysis.[321,512,543]

Two studies provide some evidence for a prophylactic effect of IGIM. Piazza and colleagues[468] gave polyvalent IGIM (from pools containing antibodies to hepatitis C virus [HCV]) or placebo monthly for 4 to 20 months to the seronegative sexual partners of 884 subjects who were seropositive for HCV. One of the 450 (representing 560 subject-years) in the IGIM group became infected versus 6 of the 449 (500 subject-years) in the placebo group ($p = .03$; relative risk, 10.7). The authors concluded that sexual transmission of hepatitis C occurs and that IG has a protective effect.

Féray and associates[181] reviewed the records of 218 patients with hepatitis C co-infection undergoing liver transplantation who received an HBIG product that contained antibody to HCV. The incidence of HCV viremia 1 year after transplantation was significantly lower (25 of 46 [54%]) in patients receiving HBIG than in those not receiving it (162 of 172 [94%]; $p < .001$). They also reviewed 210 transplanted HCV-seronegative patients and found that hepatitis C developed within 1 year in 18 of 68 patients (26%) who received the HBIG product containing anti-HCV antibody, compared with 40 of 86 patients (47%) who did not receive HBIG, a significant difference ($p < .001$) suggesting a preventive effect of hepatitis C antibodies.

Also supporting this concept was the observation that HCV was transmitted by pooled human immune globulin in the early 1990s, shortly after HCV antibody–positive donors were excluded from the donor pool.[119,517] These antibodies presumably neutralized the small amounts of HCV present in the unscreened lots. Indeed, Yu and colleagues[657] demonstrated that HCV antibodies in unscreened immune globulin lots containing HCV antibodies prevented low-dose infection in chimpanzees. Screened IGIM lots after 1991 lacking HCV antibodies did not prevent infection.

Because HBIG can prevent recurrence of HBIG among patients with hepatitis B undergoing liver transplantation,[221,509] researchers have postulated that hepatitis C antibodies might prevent recurrence in hepatitis C–positive liver transplant recipients.

EXPERIMENTAL HEPATITIS C IMMUNE GLOBULIN

This product (HCV-IGIV) is derived from human plasma units rejected for HBIG or IVIG manufacture because of the presence of hepatitis C antibodies: it does not contain hepatitis C as tested by PCR.

Krawczynski and colleagues[330] showed that HCV-IGIV delayed but did not prevent experimental hepatitis C infection in chimpanzees compared with regular IVIG without hepatitis C antibodies.

Willems and colleagues[641] gave HCV-IGIV to 26 hepatitis C–positive liver transplant recipients during the ahepatic and postoperative periods, without decreasing the rate of recurrence of hepatitis C. Davis and colleagues[149] reported a multicenter double-blind study of HCV-IGIV (Civacir, Nabi) in hepatitis C–positive liver transplant recipients. No effect occurred on HCV RNA levels, but some decrease in liver enzyme activities compared with the control patients was noted.

Thus, the use of antibody to prevent development of hepatitis C after liver transplantation has not been successful, possibly because of the inadequacy of the doses used or the lack of critical antibodies in the preparations. Studies using monoclonal antibodies, alone or in combination with other monoclonals or polyclonals, are in progress.[81,308,447]

Recommendation

No passive immune product is available for hepatitis C prophylaxis.

HERPESVIRUSES

The common herpesviruses that cause human infection are cytomegalovirus, Epstein-Barr virus, herpes simplex virus types 1 and 2, varicella-zoster virus, and human herpesviruses 6, 7, and 8. Although these DNA viruses produce latent infection that can reactivate, particularly in immunodeficient patients, the major uses of IGs have been in the prevention of primary varicella-zoster virus infection and prevention and treatment of cytomegalovirus infection in transplant recipients.

CYTOMEGALOVIRUS

Use of Cytomegalovirus Intravenous Immune Globulin or Intravenous Immune Globulin in Transplantation

Human antibodies to cytomegalovirus (CMV) in the form of CMV-IGIV (CMVIG) or IGIV have been used for more than a decade to prevent development of CMV infection in bone marrow and solid organ transplant recipients. CMVIG is prepared from the plasma of donors with high anti-CMV titers, but regular IGIV also contains anti-CMV antibodies at lower titer. Early studies used CMVIG or IGIV alone, but later studies have combined IG with antiviral agents.

Early studies in renal and liver transplant recipients showed the efficacy of CMVIG or IGIV.[100,175,189,548] Two meta-analyses demonstrated decreased CMV mortality rates with the use of CMVIG or IGIV in bone marrow and solid organ transplant recipients.[210,648] Others also have shown a similar prophylactic benefit of IGIV or CMVIG.[56,231,400,535] Ruutu and coworkers[504] showed no prophylactic benefit of CMVIG in CMV-seronegative bone marrow transplant recipients.

Several factors that have reduced the need for CMVIG or IGIV in transplant recipients include the realization of a markedly reduced risk for development of CMV if both the donor and recipient are CMV antibody negative (D–/R–), the use of CMV-seronegative or filtered blood products, the early detection of CMV by PCR, and the use of ganciclovir-valganciclovir prophylaxis or early treatment.[240]

Snydman and colleagues,[549] in an open label, multicenter study in liver transplantation, found that the combination of CMVIG and ganciclovir was superior to different immunosuppressive regimens in historical controls. Campbell and colleagues[108] recommended universal prophylaxis for the patients at highest risk, children receiving liver transplants (D+/R–), but the role of immunoglobulin was uncertain.

In heart and lung transplants, the use of CMVIG for CMV infection prophylaxis has been recommended by some groups if either the donor or the recipient is CMV seropositive. Weill and associates[631] showed that combined ganciclovir and CMVIG reduced the incidence of CMV infection in high-risk lung transplant recipients compared with historical controls. Ruttmann and colleagues[503] showed, in a retrospective study, decreased morbidity due to CMV infection in lung transplant recipients given both CMVIG and ganciclovir compared with the use of ganciclovir alone.

Zamora and associates[662] recommended intravenous ganciclovir and CMVIG for all lung transplant recipients if either the donor or recipient is CMV seropositive; and in the situation of D+/R–, they gave seven infusions of CMVIG in the first 90 days after transplantation. Other investigators[80,609] and consensus statements[147,473] permit the use of combined therapy with CMVIG in high-risk heart-lung transplant recipients and other solid organ recipients, despite the absence of definitive controlled studies.

Use of Cytomegalovirus Intravenous Immune Globulin in Perinatal Cytomegalovirus Infection

Another use of CMVIG may be the treatment of in utero CMV infection.[421] Two infusions of CMVIG were given intraperitoneally at 28 and 29 weeks' gestation to a CMV-infected fetus. The therapeutic benefit was unclear because the infant had intracranial calcifications at 2 weeks of age but was free of neurologic symptoms at 1 year of age.

Nigro and associates[423] treated a pregnant woman with primary CMV infection and in utero infection of one twin fetus with intravenous CMVIG at 30 weeks' gestation. CMVIG also was injected into the amniotic sac. The affected twin had better growth, decreased placental thickening, and lessened cord edema. Although born with CMV infection and hepatosplenomegaly, the child was normal at the age of 2 years.

Subsequently, Nigro and colleagues[422] gave 31 pregnant women with primary CMV infection at least one dose of CMVIG (200 mg/kg) during pregnancy. There was ultrasonic evidence of CMV infection in 15 fetuses. Nine women received additional CMVIG into their amniotic sac or umbilical cord. Only one woman gave birth to an infant with CMV infection, compared with 7 of 14 women who did not receive CMVIG during pregnancy. All of these women had in utero infection confirmed by CMV-positive (culture or PCR) amniotic fluid.

In a second group of 37 pregnant women with primary CMV infection (but without confirmatory amniocentesis) who were given 100 mg/kg of CMVIG monthly until delivery, none had an infant with CMV infection compared with three infants delivered to 47 untreated pregnant women.[423] Although these data are encouraging, the women in the study were not randomized, nor were the results statistically significant.

Nigro and colleagues[424] used CMVIG successfully to treat chronic cervical CMV infection associated with either recurrent abortion or infertility in three women.

Recommendations

Patients undergoing allogeneic human stem cell transplantation who are at risk for acquiring CMV disease (e.g., a CMV-seropositive recipient or a CMV-seronegative recipient and a CMV-seropositive donor) should receive either prophylactic antiviral therapy or preemptive antiviral therapy after early detection of infection by CMV PCR. CMVIG no longer is recommended for prevention of CMV disease.[77]

For solid organ recipients, the highest risk is a CMV-seropositive donor and a CMV-seronegative recipient, in which case antiviral prophylaxis is used. Antiviral prophylaxis rather than CMVIG or IGIV is used currently in kidney and liver transplantation.[281,525] In high-risk situations such as heart-lung transplants with either the donor or the recipient CMV seropositive, CMVIG is added at some centers to antiviral therapy, despite lack of proof by multicenter, randomized studies.[80,473,609]

CMVIG or IGIV in combination with antiviral agents is used to treat severe CMV disease, such as pneumonia, in transplant recipients.[193,448,462,485,661] For CMVIG, 400 mg/kg on days 1, 2, and 7 and 200 mg/kg on days 14 and 21 have been used in addition to antiviral therapy,[485] although others have used a lower dose (100 mg/kg every other day for 2 weeks).[199] IGIV, 500 mg/kg every other day for 10 to 59 days, followed by 500 mg/kg once or twice weekly for an extended period, also has been reported.[448] Garcia-Gallo and colleagues[193] have reported the use of CMVIG as an adjunct to antiviral therapy to prevent development of pneumonitis in lung transplant recipients with invasive CMV disease and as preemptive therapy (with ganciclovir) in post-transplant recipients with persistent CMV viral load.

CMVIG for in utero CMV infection is not recommended routinely but may be of some value in selected situations with confirmed ultrasonic evidence of fetal infection.

EPSTEIN-BARR VIRUS

Epstein-Barr virus (EBV), the etiologic agent of infectious mononucleosis, causes severe infection in immunocompromised patients and males with X-linked lymphoproliferative syndrome. IGIV has been given to EBV-seronegative males with X-linked lymphoproliferative syndrome in an attempt to prevent EBV infection, but EBV infection developed in some of them while they were taking IGIV.[185]

Transplant recipients with EBV-induced post-transplantation lymphoproliferative syndrome or hepatitis have been treated successfully with a combination of IGIV or CMVIG, antiviral therapy, and interferon-α.[151,434,587] A similar approach was not successful in X-linked lymphoproliferative syndrome.[441] CMVIG was used in one case because it contains higher titers of anti-EBV antibody than does IGIV.[151] One case of fulminant EBV hepatitis was treated successfully with liver transplantation, antiviral therapy, and CMVIG.[180]

A recent multicenter trial indicated that CMVIG given to liver transplant recipients did not prevent post-transplantation lymphoproliferative disease or other EBV disease.[222] However, the EBV serology was unavailable in 50 of the 82 donors, hampering interpretation of the results.

Ohta and colleagues[440] reported marked improvement of a patient with chronic EBV hepatitis following kidney transplantation by treatment with the anti-CD20 monoclonal antibody rituximab after failure of reduction of immunosuppression. There are other reports of the use of rituximab in the treatment of EBV-induced post-transplantation lymphoproliferative disease in stem cell[177,532] or solid organ transplants.[252,590,655]

Rituximab has also been used in preemptive therapy in stem cell transplantation based on EBV viral load.[134,612] Boesch and colleagues[78] reported the successful use of rituximab to treat an adolescent without immunodeficiency who developed EBV-associated lymphoproliferative disease that involved massive submucosal infiltration of B cells in the lingual tonsils, trachea, and bronchi and resultant near-complete airway obstruction unresponsive to steroids.

Recommendations

Current approaches to EBV-induced post-transplantation lymphoproliferative disease include reduction of immunosuppression and consideration of preemptive therapy or treatment with rituximab,[551] although antiviral medication, anticytokine therapy, chemotherapy, and immunotherapy all have been used. In a recent literature review, Giulino and colleagues[206a] found evidence of a better response to rituximab in children compared with adults and suggested that rituximab may be appropriate as first-line therapy for post-transplantation lymphoproliferative disease in children. The role of IGIV or CMVIG is not clearly defined.

HERPES SIMPLEX INFECTIONS

Antibody has a preventive effect in herpes simplex virus (HSV) infection in the newborn period. Mothers with a reactivated herpes infection during delivery are 10-fold less likely to transmit HSV to their newborn infants during vaginal delivery than are mothers with primary HSV infection at delivery, presumably because of the transplacental transfer of anti-herpes antibody.[18] IGIV containing HSV antibodies has not been used in the prevention of neonatal herpes infection, although Whitley[636] has proposed that HSV monoclonal antibody or hyperimmune IGIV be evaluated for treatment of disseminated neonatal disease.

Masci and colleagues[381] compared monthly IGIV(400 mg/kg) with intermittent acyclovir treatment (800 mg twice daily, 1 week each month) in patients with recurrent genital HSV infection for 6 months and noted fewer recurrences in the IGIV-treated group.

Recommendation

IGIV is not recommended for the prevention or treatment of HSV infections.

VARICELLA-ZOSTER VIRUS AND VARICELLA-ZOSTER IMMUNE GLOBULIN

Immune Globulin in Varicella

After success was achieved with IGIM in the prevention of measles and hepatitis, IGIM was evaluated for the prevention of varicella. Although Funkhouser[191] in 1948 showed some beneficial effects of standard IGIM in the prevention of varicella in an uncontrolled study, Greenberg[225] and Schaeffer and Toomey[515] were unable to prevent chickenpox in exposed children with IGIM doses of 2.5 to 20 mL.

Others have reported anecdotal evidence for the efficacy of IGIM in large doses during the early stages of chickenpox and herpes zoster. These claims included prompt relief of pain in zoster[633] and rapid resolution of skin lesions.[349,490] However, even high-titer IG (zoster immune globulin) does not prevent dissemination of herpes zoster.[560]

Ross[496] in 1962 gave 242 children IGIM in doses of 0.1 to 0.6 mL/lb within 3 days of exposure to chickenpox; 209 similarly exposed, uninjected children were used as controls. The attack rate was the same (97%) in both groups, thus indicating that IGIM does not prevent varicella under these conditions. However, with doses of IGIM above 0.2 mL/lb, the severity of the disease was reduced, as indicated by a decreased number of pox and reduced temperature. Children receiving the largest dose of IGIM (0.6 mL/lb) had maximal temperatures of 38.9° C (102° F) versus 41.1° C (106° F) for controls and 40 pox versus 207 for controls. Other investigators also have reported similar but uncontrolled observations that IG modifies the severity of chickenpox.[273,601]

Varicella-Zoster Immune Globulin in Varicella

The prophylactic value of large IG doses in decreasing the incidence and severity of varicella led to a trial of high-titer plasma or IG preparations to prevent varicella.[46] These preparations include zoster immune globulin (ZIG) and plasma (ZIP) from convalescing zoster patients and varicella-zoster immune globulin (VZIG) prepared from high-titer plasma from normal adults.

Brunell and associates[95] in 1969 selected convalescing patients with zoster whose complement-fixing antibody titers were 1:256 or greater and prepared ZIG from their plasma; this material had titers considerably higher than standard IG did. Exposed children from six families in which chickenpox was occurring were given ZIG or IG at doses of 2 mL. In none of six children receiving ZIG did chickenpox develop, whereas it developed in all six children given IG. No antibody developed in the ZIG-treated group, thus indicating that the disease was prevented.

Because this dose did not prevent varicella in leukemic children or other high-risk patients, a larger dose (5 mL) was used in a later study to successfully modify or to prevent varicella in eight of nine high-risk children.[93,94] Severe varicella developed in one child given a less potent preparation of ZIG. These observations were confirmed in two later studies. Judelsohn and associates[293] gave ZIG to 56 exposed high-risk children; mild varicella occurred in 7 patients and was prevented in the others, most of whom were susceptible as determined by absence of serum antibody. Gershon and colleagues[200] gave ZIG to 15 seronegative high-risk exposed children; varicella was severe in 1, mild in 9, and subclinical in 5. Subclinical infection was determined by the acquisition of membrane antibody, as detected by fluorescent microscopy.

Orenstein and associates[445] studied 553 exposed, high-risk patients who received ZIG of two different titers (1:1280 versus 1:2560 or greater). They found that the clinical attack rate after receipt of ZIG correlated with the type of exposure (varicella

developed in 36% with household exposure, 7.7% with hospital exposure, and 0% with school exposure), the rise in antibody titer (45% of patients without a fourfold titer increase became ill compared with 22% of patients with a fourfold or greater rise in titer), and the titer of the administered ZIG (significantly more complications and deaths occurred in recipients of the lower titer ZIG).

Because of the limited supply of ZIG and ZIP, VZIG from normal adults became the commercially available product in the United States. Zaia and associates[660] compared the efficacy of ZIG and VZIG in immunocompromised children exposed to varicella. Varicella attack rates and the clinical severity in recipients of VZIG and ZIG did not differ significantly. A higher incidence of subclinical infection was indicated by the rise in antibody titer in ZIG recipients (31.3%) versus that in VZIG recipients (16%). A larger dose of VZIG (2.5 mL/10 kg versus 1.25 mL/10 kg) reduced the frequency of subclinical infection (from 20% to 4.3%). Varicella developed in several high-risk patients with demonstrable serum antibody at exposure, thus indicating that history-negative, seropositive patients are at risk for development of clinical varicella-zoster infection and should be given VZIG regardless of antibody titer.

In 2006, VZIG from the Massachusetts Pubic Health Laboratories became unavailable, replaced by a new investigational VZIG product, VariZIG, available through FFF Enterprises (800-843-7477).[116] IGIV and acyclovir prophylaxis are reasonable alternatives if VariZIG is not available.[28]

Intravenous Immune Globulin in Varicella Prophylaxis

Paryani and colleagues[456,457] in 1984 observed that IGIV at doses of 200 to 300 mg/kg resulted in serum varicella-zoster virus antibody titers comparable to those in patients receiving VZIG at standard doses. Subsequently, Chen and Liang[125] demonstrated that varicella was prevented by a single dose of IGIV at 200 mg/kg in five children with leukemia.

Immunocompromised patients who are receiving IGIV at 400 mg/kg are thought to be protected for 3 weeks after infusion and do not require additional VZIG on exposure.[28] However, Ferdman and Church[182] reported that varicella occurred in two HIV-infected children receiving 500 mg/kg of IGIV after exposure to varicella 7 and 11 days after infusion. Both had mild disease and responded well to acyclovir. They suggest that for patients with profound immunodeficiency, VZIG can be given in addition to IGIV. Kavaliotis and associates[307] found that an IGIV dose of 1 g/kg given within 6 to 24 hours of exposure was 90 percent effective in preventing varicella in an oncology unit, with no additional advantage noted with administration of VZIG.

Tokat and colleagues[598] described a 32-year-old man with severe varicella pneumonia that progressed to acute respiratory distress syndrome. IGIV (400 mg/kg for 5 days) was given with a successful outcome.

Recommendations

The decision to administer VZIG or IGIV or acyclovir to prevent chickenpox is based on the patient's susceptibility, the type of exposure, and the patient's immune competence.

DETERMINATION OF SUSCEPTIBILITY

With the exception of bone marrow transplant recipients, most immunocompromised individuals with previous varicella infection are considered immune; however, their immune status should be confirmed with varicella antibody titers. Healthy adults reared in the United States are considered immune even without a history of varicella, zoster, or vaccination, but immunocompromised children and adults without a history of varicella are considered susceptible because of their higher risk for development of severe infection. Bone marrow transplant recipients are considered susceptible regardless of the varicella history of the donor or recipient. If varicella or herpes zoster develops after transplantation, the patient then is considered to be immune.[116,232]

An immunocompromised, unimmunized child without a history of chickenpox is considered susceptible even if antibody titers are present because receipt of blood products containing immunoglobulin may result in transient seropositivity. Alternatively, such patients who received VZIG may have had asymptomatic varicella with the subsequent development of varicella antibodies, yet they may not be protected on re-exposure.[28] The value of antibody titer to determine susceptibility in these patients is controversial. However, oncology patients who have been vaccinated for varicella before illness and have been seropositive for varicella antibodies before receipt of blood products are considered immune and do not routinely need VZIG. The severity of immune compromise is also a factor, and bone marrow transplant recipients are considered susceptible despite prior history of immunization or disease.

VZIG is not recommended for immunodeficient patients who have been vaccinated in the past, provided they previously were shown to have varicella antibody, even if they are seronegative at the time of exposure. These individuals are expected to have mild disease.[116] However, verifying varicella immunity with antibody before forgoing VZIG administration in this situation seems to be a reasonable approach.

TYPE OF EXPOSURE

Individuals residing in the same household as a patient with varicella, persons who have had face-to-face contact with a patient considered infectious, and patients sharing the same hospital room are considered to have significant exposure. Because the duration of exposure that results in transmission is not known, each exposure must be evaluated individually. Contact with a varicella vaccine recipient with a varicella rash must be considered a significant exposure for an immunodeficient patient because the vaccinee may have wild-type virus infection; vaccine strain virus rarely has been transmitted.[232]

CANDIDATES FOR VARICELLA-ZOSTER IMMUNE GLOBULIN OR INTRAVENOUS IMMUNE GLOBULIN (Table 256–7)

Normal Adults, Children, and Adolescents

Normal children, adolescents, and adults exposed to chickenpox or zoster usually are not candidates for receiving VZIG or IGIV. They may be given chickenpox vaccine if they are older than 12 months. VZIG is not necessary for normal term infants exposed

TABLE 256–7 Candidates for Varicella-Zoster Immune Globulin (VZIG) After Significant Exposure

Immunocompromised children without a history of varicella and without documented response to immunization*
Susceptible, pregnant women
Newborn infants whose mother had an onset of varicella within 5 days before delivery or within 48 hours after delivery
All hospitalized premature infants born at less than 28 weeks of gestation or less than 1000 g at birth, regardless of maternal history
Hospitalized premature infants of more than 28 weeks' gestation whose mother has no history of chickenpox or who is seronegative; may consider its use for other premature infants. See text.

**Severity of immune compromise is a factor in the decision to give VZIG despite immunization and disease history. See text.*

to varicella after 48 hours of life, but it is considered optional for infants younger than 1 week.[202]

Immunocompromised Children and Adults

The principal use of VZIG is to prevent chickenpox in susceptible immunocompromised children exposed to zoster or chickenpox (see Table 256–7). These children include those with primary immunodeficiency and those with secondary immunodeficiency, including HIV infection and neoplastic disease, and those receiving immunosuppressive therapy (e.g., systemic steroids, chemotherapy).[37,437,445]

Term and Premature Newborns

Newborns who acquire varicella after birth are not at high risk for development of severe disease and are not candidates for receiving VZIG, with the possible exception of those whose mothers have severe skin disease.[28] Newborn infants born to mothers in whom varicella developed within 5 days before delivery or within 2 days after delivery are at high risk for having severe varicella because they have not received transplacental protective antibodies.[116] Others, questioning the validity of these limits, have treated a small number of infants born to mothers in a window ranging from 7 days before delivery to 5 days after delivery with IGIV (500 mg/kg) and a prophylactic acyclovir regimen.[265]

Exposed hospitalized premature infants born at less than 28 weeks' gestation or less than 1000 g should receive VZIG. These infants are susceptible, regardless of the maternal history of varicella, because of incomplete transplacental transfer of maternal antibody. Hospitalized premature infants with significant exposure who were born at more than 28 weeks' gestation and whose mothers do not have a history of varicella or are seronegative also are considered candidates for receiving VZIG because transplacental antibody would not be present.[28,116]

Gold and colleagues[212] showed that gestational age of more than 28 weeks and birth weight above 1000 g do not always accurately predict the presence of maternal varicella antibody. Ogilvie[437] suggested that infants born before 30 weeks' gestation be given VZIG and that some infants born after 28 weeks will lose their maternal antibody by 60 days of age; she recommends antibody testing on exposure if it can be performed quickly to assess the need for VZIG. Linder and colleagues[360] also noted that only 24% of prematures born at 29 to 35 weeks had positive FAMA (fluorescent antibody to membrane antigen) titers at 2 months of age.

Gold and associates[212] recommended the routine use of VZIG in the neonatal ICU if the FAMA assay is not available to determine susceptibility. Previous administration of blood products in the neonatal ICU may render these results uninterpretable.

Pregnant Women

Susceptible pregnant women are candidates for receiving VZIG because of their increased risk for development of severe varicella pneumonia.[547]

DOSAGE

VariZIG brand of VZIG is supplied in lyophilized vials of 125 U (reconstituted to a 5% solution for intramuscular use). The dose of VZIG is 125 U/10 kg intramuscularly. The minimal dose for infants is 125 U (one vial), and the maximal dose is 625 U for adults (five vials).[28,117]

Although VZIG should be given to susceptible candidates as soon as possible after exposure for maximal protection, it can be given up to 96 hours after exposure.[112] A second dose is not needed for subsequent exposure unless it occurs beyond 3 weeks after administration of the VZIG dose.[28] IGIV (400 mg/kg)[116] is an acceptable alternative if the child has a bleeding diathesis and cannot receive intramuscular injections or if VZIG is not available.

VZIG is not recommended for the treatment of chickenpox, zoster, disseminated varicella, or post-herpetic neuralgia; zoster immune globulin did not prevent dissemination of zoster in immunocompromised patients.[560]

HUMAN IMMUNODEFICIENCY VIRUS INFECTION

As noted earlier in the chapter, regular infusions of IGIV have been used to prevent concomitant infection in patients with HIV infection, notably children, who have compromised immune systems with antibody deficiencies. Attempts to use HIV-specific antibody to prevent HIV infection or to provide an antiviral effect have met with very limited success.

These studies have used human immune plasma or hyperimmune HIV immunoglobulin (HIVIG) from asymptomatic HIV-seropositive patients, porcine antisera, or monoclonal antibodies.[564] In two of three controlled clinical trials of immune plasma in adult patients with AIDS, a modest clinical benefit was achieved as judged by decreased opportunistic infections, a slight increase in $CD4^+$ cell counts, and improved survival; however, no striking decreases in viral burden were noted.[277,355,621]

In a double-blind, placebo-controlled multicenter study, HIV-seropositive pregnant women receiving zidovudine were given HIVIG monthly during the last trimester of pregnancy, and their newborns were given one HIVIG dose at birth; no effect on the rate of maternal-fetal HIV transmission versus that in a similar group given regular IGIV was found.[563] The rate of transmission in both groups was unexpectedly low (less than 5%), so the study was discontinued after 800 patients had been enrolled because the study was not statistically powered to detect a slight reduction in transmission rates.

Another study[561] examined the antiviral effect of large doses of HIVIG in 30 children with moderately advanced HIV infection who were receiving stable antiviral treatment and showed a measurable viral burden. No striking beneficial effect was observed as indicated by plasma HIV RNA levels, cellular viral culture titers, or immunologic assays.

Despite these failures, efforts to develop antibody preparations that will neutralize the virus continue; such preparations would be particularly valuable after needle-stick, perinatal, or sexual exposure.[564] Under study are monoclonal antibodies to neutralizing regions of the virus, antibodies to co-receptors that may interfere with HIV attachment, or combinations of antibodies with different specificities, including combinations of HIVIG with monoclonal antibodies.[33,102,342,358,359,452] An effective neutralizing antibody also would provide valuable information toward an effective vaccine.

Recommendations

IGIV is used in immunosuppressed patients with HIV infection to prevent bacterial and viral infections and to treat certain complications (e.g., thrombocytopenia, anemia of parvovirus infection) but has no direct antiviral activity. HIVIG or plasma derived from infected patients has little or no antiviral activity or clinical benefit for HIV-infected adults or children, nor has HIVIG given during pregnancy decreased maternal-infant transmission.

Monoclonal antibodies directed against the virus or its cellular receptors show considerable promise but are not yet available.

MEASLES

The first successful prophylaxis of measles with convalescent serum was reported by Cenci[114] in 1907. Convalescent serum was

used in the United States first in 1916 by Park, Freeman, and Zingher, who gave either 4 or 8 mL of serum to 41 recently exposed children at New York Metropolitan Hospital.[453,667] Measles did not develop in any of the 20 children who received the 8-mL dose and developed in only three of the 20 children who received the 4-mL dose. Park and Freeman[453] in 1926 found that 6 to 10 mL of convalescent serum was 92 percent efficacious in preventing measles in recently exposed individuals, a finding confirmed and extended by Stillerman and associates.[568] Placental extracts containing serum antibodies also were used in the prevention and modification of measles.[390]

Stokes and colleagues[573] and Ordman and associates[444] both confirmed in 1944 that immunoglobulin given immediately after exposure could prevent or modify measles and given in the early stages of clinical illness could lessen its severity. Greenberg and coworkers[224] in 1955 noted a lower incidence of measles encephalitis in IGIM-modified measles.

A major use of IGIM in the 1960s was to diminish the side effects of the Edmonston strain of measles vaccine. Krugman and associates[336] in 1962 noted that the simultaneous administration of 0.02 mL/lb of IG at the time of Edmonston measles vaccination reduced the incidence of high fever from 40 to 14 percent and the incidence of rash from 10 to 2 percent. The mean titer of measles antibody achieved was somewhat reduced by the IGIM, and a slight decrease in the rate of seroconversion was noted; nonetheless, the vaccine-IGIM combination was 95 percent effective.[572] The current measles vaccine does not require the need for concomitant IGIM injections.

Audet and colleagues[41] report that the measles neutralizing antibody titer in recent IGIV lots is decreasing because of the lower titer of vaccine-induced antibodies compared with natural infection among donors. Although not tested, IGIM probably has lower titers of measles antibodies, so that the recommended prophylactic doses may be inadequate.

Recommendations

IGIM or IGIV can be given to susceptible contacts within 6 days of exposure to prevent or to modify measles. Infants younger than 1 year, immunocompromised patients, and pregnant women are at risk for development of severe disease and should receive immunoprophylaxis.[19] Because immunodeficient patients with HIV infection may contract measles after exposure despite receiving immunization, they should receive passive immunoprophylaxis.[201] IGIM also can be given to close family contacts. Measles vaccine has some efficacy if it is given within 72 hours of exposure and is preferred for the management of outbreaks in healthy children older than 1 year.[19]

The standard dose of IGIM is 0.25 mL/kg for healthy patients and 0.5 mL/kg for immunocompromised subjects. The maximal dose is 15 mL. IGIV at comparable doses also can be used, but one should realize that the titers in both products may be diminished in recent years.[41]

Immunodeficient children receiving regular IGIV treatments at doses of at least 100 mg/kg are protected for 3 weeks after its administration. Additional IGIV can be considered if the exposure occurs more than 2 weeks after the IGIV dose.[19]

Administration of IGIM to a healthy infant precludes the use of measles vaccine for 5 months, and after the administration of large doses of IGIV, longer intervals are needed (e.g., 8 to 11 months).[19]

MUMPS

Mumps immune globulin was ineffective as postexposure prophylaxis, and this product no longer is manufactured in the United States.[20]

PARVOVIRUS

Human parvovirus B19, also termed erythrovirus, the cause of the benign childhood exanthem termed fifth disease (slapped-cheek syndrome), also may cause polyarthropathy, transient aplastic crises in patients with hemolytic anemia, chronic red cell aplasia in immunocompromised patients, and hemophagocytic syndrome.[91,271,656] Patients susceptible to chronic parvovirus infection include those with congenital[591] or acquired immunodeficiencies,[130,325] those receiving immunosuppressive therapy,[656] and organ transplant recipients.[303,378] In utero parvovirus infection can result in hydrops fetalis.[600] The use of parvovirus DNA PCR has facilitated establishment of the diagnosis in immunodeficient patients unable to make antibodies or in patients who have passively acquired parvovirus antibodies.

Parvovirus B19 has tropism for marrow erythroid progenitor cells because these cells express the blood group P antigen, the cellular receptor for the virus. Most adults have encountered and made antibodies to parvovirus, and thus IGIV is an excellent source of antiparvovirus antibodies.[521] IGIV has been used successfully to treat parvovirus-induced red cell aplasia.[344] Patients with AIDS are particularly susceptible to this disease. Successfully treated patients have decreased viremia, reticulocytosis, and resolution of the anemia within 2 weeks. Sometimes relapse or persistent infection occurs, requiring maintenance IGIV therapy, particularly in patients with HIV infection and low $CD4^+$ cell counts.[325]

IGIV has been used successfully to treat parvovirus B19 anemia resulting from chemotherapy,[392] rituximab therapy,[528] or both.[276,552] However, IGIV was not of value in four children with persistent parvovirus infection undergoing chemotherapy for acute lymphocytic leukemia.[176] IGIV also has been used successfully for treatment of parvovirus B19 anemia in renal transplant recipients.[129,379,449,550]

Viguier and coauthors[618] administered 1 g/kg of IGIV for 2 days to treat successfully a 33-year-old woman with parvovirus B19–associated polyarteritis nodosa and fever, palpable purpura, intense myalgia, paresthesias, and polyarthritis of the hand joints. IGIV has been used with success in parvovirus B19–associated chronic fatigue syndrome in three adults[315] and one teenage boy.[389]

IGIV has been used as a supplement to transfusions in severe in utero parvovirus infection with hydrops fetalis. Selbing and coworkers[524] described a 24-week pregnant women with severe preeclampsia whose fetus had ascites and pericardial effusion; she was given 25 g of IGIV with resolution of the ascites, effusion, and anemia. Matsuda and colleagues[383] treated a parvovirus-infected hydropic fetus with two injections of immunoglobulin into the fetal peritoneum with resolution of the anemia and the hydrops.

Rugolotto[501] treated an anemic newborn secondary to intrauterine parvovirus infection with IGIV (1 g/kg every 3 weeks for 8 months). Heegaard and coauthors[247] reported similar success of IGIV, in addition to in utero transfusions. Earlier attempts to treat older infants with persistent parvovirus-induced congenital anemia with IGIV were unsuccessful.[90]

Human neutralizing monoclonal antibodies have been generated from infected individuals[204] for possible future therapeutic use.

Recommendations

Red cell aplasia caused by parvovirus infection in immunodeficient patients, including those with HIV infection, should be treated with IGIV, 400 mg/kg per day for 5 days or 1 g/kg per day for 2 days.[91,325,411] If relapse is likely to occur because of the patient's severe immunocompromised status, IGIV at 400 mg/kg can be given every 4 weeks.

Neonates with persistent congenital anemia caused by parvovirus B19 should receive 400 mg/kg of IGIV for 5 days, with additional doses given if the anemia does not resolve.

Pregnant women carrying fetuses with in utero hydrops fetalis caused by parvovirus B19 infection also may be candidates for IGIV therapy.

RABIES AND RABIES IMMUNE GLOBULIN

Rabies is the ideal disease for passive immunization because the exact moment, the exact source, and the exact location of exposure usually are known. Furthermore, the long incubation period and the fact that the virus remains localized to the wound for several days enhance the effectiveness of passive immunization. Although a rabies serum was prepared initially in 1889 by Babes and Lepp,[42] experiments of Habel[238] in mice, guinea pigs, and monkeys involving the use of rabbit hyperimmune serum demonstrated that antibody worked by two mechanisms: (1) neutralizing the virus while it is still in tissues and (2) retarding the spread of virus within the nervous system, thereby prolonging the incubation period and permitting active immunity by vaccine to become established.

On the basis of these studies, a World Health Organization Expert Committee in 1950 recommended that a field trial of the efficacy of hyperimmune rabies serum in conjunction with vaccine be conducted.[173] It was undertaken in Iran because multiple bites by a single rabid wolf coming into isolated villages were not uncommon occurrences, and this severe exposure had an associated 40 to 50 percent mortality. In 1954, a single rabid wolf bit 27 individuals, 17 of whom were bitten on the head. These 17 were divided into three groups: five received vaccine alone, seven received vaccine and one dose of antirabies serum, and five received vaccine and two doses of antirabies serum.[50] Three of five persons treated with vaccine alone died of rabies, one of seven in the one-dose antiserum group died, and none of five in the two-dose antiserum group died.

Antibody studies conducted on these patients indicated that a single or a double dose of antiserum, followed by 14 to 21 daily doses of vaccine, results in significant levels of circulating antibody for as long as 50 days.[237] The antibody found early is supplied passively; after the tenth day, the antibody present is a result of the vaccine. Thus, optimal treatment requires both passive and active immunization.

Before 1971, the only available antiserum was of equine origin. It is still the only product available in some countries. Since 1971, human rabies immune globulin (RIG) has been available in the United States and many other countries and is preferred because of the lessened risk of serum reactions.[538] In addition, human antibody has a half-life in the circulation twice that of equine antibody, with the result that higher levels of passive antibody are maintained. However, the antibody response to the vaccine given concomitantly is suppressed more effectively.[362]

A case of fatal rabies was reported in a 19-year-old man bitten on the finger by a rabid mongoose despite the recommended postexposure prophylaxis (RIG and five doses of human diploid cell rabies vaccine).[531] Possible reasons for failure included (1) inadequacy of the recommended dose of RIG; (2) vaccine injection into the gluteal region, where more fat is found than in the recommended deltoid region; and (3) decreased antibody response to the vaccine as a result of a possible immunodeficiency state.

Prevention of rabies consists of three essential components: thorough washing of the wound with a 20 percent soap solution followed by irrigation with povidone-iodine,[71,502] passive immunization with rabies antibody, and active immunization. Although most cases of failure are caused by lack of adherence to these three strategies,[469] isolated cases of rabies occurring despite appropriate management have been reported.

Wilde and associates[640] reported failure of prophylaxis in five Thai children who received multiple bites on the face and head; they suggested that failure to infiltrate all wounds with RIG and surgical closure before the wound was infiltrated might have been factors. Hemachudha and coauthors[249] reported failure of prophylaxis in a child with minor scratches on the nose and in a woman with a deep wound on the cheek; they suggested that direct inoculation of virus into nerve endings may have occurred.

Goudsmit and associates[214] found that a human monoclonal antibody combination was equivalent to RIG when it was used with vaccine in a hamster model of rabies.

Recommendations

Human RIG or animal antiserum is recommended in nonimmunized individuals for all bites by animals in which rabies cannot be ruled out and for nonbite exposure to animals proved to be or suspected of being rabid.[22,121] Such treatment should be given as early as possible after exposure and followed by vaccine administration. Two human RIG products are available in the United States, BayRab and Imogam Rabies-HT; both are prepared from the plasma of hyperimmunized donors. The recommended dose of 20 IU/kg of RIG must not be exceeded because higher doses can suppress the vaccine response.

If RIG is not available, the dose of equine RIG is 40 IU/kg, and desensitization may be required. We now recognize[267] that the entire RIG dose should be infiltrated around the wounds. If this is not anatomically feasible, any remaining RIG should be given intramuscularly.[22]

Wilde and colleagues,[640] recognizing the difficulty in infiltrating multiple wounds with a small volume of RIG, suggested dilution of the RIG. The World Health Organization[653] recommends dilution of the RIG twofold to threefold in saline to ensure an adequate volume for infiltration. RIG should not be frozen, and if it is frozen, it should not be used.

Although administration of one of the three vaccines licensed in the United States should be started at the same time as RIG, the vaccine and RIG should not be administered in the same syringe or with the same syringe or needle. Only two of the licensed vaccines are currently produced, human diploid cell rabies vaccine and purified chicken embryo cell vaccine. Vaccine should be given in the deltoid muscle or, for an infant, in the anterolateral aspect of the thigh and at an anatomic site removed from the injury or any injection sites of RIG.

If RIG is not available immediately, immunization should be started and RIG given if it is available within 7 days.[22,121] If vaccine is not available immediately, RIG should be administered and the vaccine given as soon as possible. If both RIG and vaccine are delayed, both should be given whenever available, regardless of the interval between exposure and treatment.[22,121]

RIG is not recommended for patients who previously have received a full postexposure vaccine course of human diploid cell rabies vaccine, rabies virus adsorbed, or purified chicken embryo cell vaccine; who have received a three-dose pre-exposure intramuscular series of these vaccines; who have received a three-dose pre-exposure intradermal human diploid cell rabies vaccine used in the United States; or who have been immunized with any vaccine and have a documented rabies titer.[22,121]

Postexposure prophylaxis of immunodeficient patients is problematic. Jaijaroensup and coauthors[280] reported poor or nondetectable neutralizing antibody in five HIV-infected patients who received intradermal vaccine and proposed that higher doses of vaccine or additional boosters be considered. Serologic failure of both pre-exposure and postexposure rabies immunizations in children with HIV infection[450,597] has been reported.

Thus, immunodeficient patients should undergo serologic testing to document seroconversion after completion of the

vaccine. An adult patient with lymphoma[246] was attacked by a rabid jackal and received RIG and rabies vaccine while chemotherapy was delayed. When antibody titer was low after the series of vaccines, a second course of vaccine and RIG was administered. The patient survived both the lymphoma and rabies exposure.

RIG is not indicated for the treatment of rabies. Hemachudha and colleagues[250] described a patient with rabies who developed total limb and facial paralysis after receiving RIG.

RESPIRATORY SYNCYTIAL VIRUS

Acute RSV infection of the respiratory tract is the most common cause of hospitalization of infants and young children and thus is a significant public health expense. For high-risk patients such as premature infants and infants with chronic lung disease, RSV infection can be severe and life-threatening. The observation that passively transferred maternal antibody provided some protection from RSV infection[436] led to the development of passive immunity products to prevent and to modify the severity of infection. No effective vaccine exists.

RESPIRATORY SYNCYTIAL VIRUS–INTRAVENOUS IMMUNE GLOBULIN

The first product used was RSV-IGIV (RespiGam), a 5 percent polyclonal human intravenous IG prepared from healthy donors with high RSV-neutralizing antibody titers. RSV-IGIV was licensed in 1996 after studies in high-risk infants demonstrated its efficacy. Groothuis and colleagues[226] conducted a prospective, blinded, randomized trial at five centers and showed that 58 premature infants who received RSV-IGIV at 750 mg/kg per month during the winter months had a significantly lower incidence of RSV lower respiratory tract disease than that observed in 58 premature control infants who did not receive RSV-IGIV (6.9% versus 24.1%; $p = .01$). The RSV-IGIV–treated patients also had a lower incidence of moderate to severe RSV lower respiratory tract disease ($p = .006$), fewer days of hospitalization ($p = .020$), and fewer days in the ICU ($p = .05$).

Another large RSV-IGIV multicenter, double-blind, placebo-controlled study[475] of 510 infants with either prematurity or bronchopulmonary dysplasia also demonstrated decreased number of hospitalizations (13.5% versus 8.0%; $p = .047$), decreased total number of RSV hospital days ($p = .045$), and decreased days with oxygen use ($p = .007$). RSV-IGIV also decreased days of hospitalization for any respiratory illness by 38 percent and total respiratory illness hospital days by 46 percent, presumably because of antibodies to other respiratory pathogens.

An added benefit of RSV-IGIV prophylaxis was a decreased incidence of otitis media (number of episodes, 0.15 per patient versus 0.78 per control; $p = .003$).[243,541]

In 1997, the American Academy of Pediatrics recommended RSV-IGIV for high-risk children with prematurity or bronchopulmonary dysplasia[12] but not for infants with cyanotic congenital heart disease[227,542] because of the risk for development of serious side effects. RSV-IGIV no longer is available.

PALIVIZUMAB

In 1996, palivizumab (Synagis), a humanized IgG1 monoclonal antibody against the F (fusion) glycoprotein of RSV,[208,575] entered clinical trials. Palivizumab neutralizes both type A and type B RSV and is 50 to 100 times more potent than RSV-IGIV.[511] A multicenter, randomized, double-blind, placebo-controlled study of 1502 high-risk infants (premature infants and infants younger than 2 years with bronchopulmonary dysplasia) demonstrated the efficacy of 15 mg/kg of palivizumab given intramuscularly every 30 days.[270] It resulted in significantly decreased number of RSV hospitalizations (55%; $p < .001$), RSV hospital days ($p < .001$), and days of oxygen therapy ($p < .001$).

Palivizumab was licensed in 1998, the first monoclonal antibody approved for the prevention of an infectious disease. Postlicensure studies also have supported its effectiveness.[463,494,544] Although debate continues about the cost-effectiveness of palivizumab in some countries,[309,442,580] palivizumab prophylaxis for high-risk infants is now the standard of practice in the United States.[23]

In 2003, Feltes and colleagues[179] reported the results of an international, randomized, double-blind, placebo-controlled trial of palivizumab prophylaxis in 1287 children with congenital heart disease. This study showed a 45 percent reduction in RSV hospitalizations, a 56 percent reduction in total number of hospital days, and a 73 percent reduction in total number of hospital days with oxygen with the use of palivizumab. European cardiologists and the American Academy of Pediatrics recommend use of palivizumab for infants with hemodynamically significant heart disease (uncorrected, partially corrected, or with residual disease), pulmonary hypertension or chronic lung disease, and hemodynamically significant dilated or hypertrophic cardiomyopathy causing cyanosis or requiring cardiac medication.[23,599]

The use of palivizumab for more than one season has been a concern because of the theoretical risk of side effects resulting from the development of an antibody to the murine component.[346,428] Null and colleagues[428] found that only one child of 55 receiving palivizumab for a second season developed an anti-palivizumab titer of greater than 1:40. This child had a titer of 1:160 on day 30 that fell to 1:10 on day 120 (30 days after the fourth injection), suggesting a nonspecific reactivity. No associated adverse events occurred, and the palivizumab trough concentrations were as expected.

Palivizumab or other RSV antibodies are not indicated for the treatment of RSV infection. Saez-Llorens and colleagues[506] found in a small pharmacokinetic study that although palivizumab was safe, it was of no clinical benefit for previously healthy children with acute RSV infection. Banna and colleagues[51] successfully used palivizumab and steroid therapy to treat an adult woman with RSV-related pneumonia after stem cell transplantation. An experimental RSV monoclonal antibody (Medi-493), given intravenously, was not of benefit for intubated patients with RSV infection and respiratory failure.[376] Studies of high-titer monoclonal antibodies may yield different results.[190]

PASSIVE IMMUNITY IN RESPIRATORY SYNCYTIAL VIRUS TREATMENT

Although a single dose of 1500 mg/kg of RSV-IGIV was of no benefit in normal and high-risk children with RSV infection,[492,493] DeVincenzo and associates[153] gave a single dose of RSV-IGIV (1500 mg/kg) to 11 bone marrow transplant recipients after the onset of RSV infection. All but one patient also received ribavirin. Only one patient died in this group, which compares favorably with historical controls given ribavirin therapy alone.

Ghosh and coworkers[203] gave IGIV (500 mg/kg every other day) and aerosolized ribavirin to 14 adult bone marrow transplant recipients with RSV upper respiratory tract infection to prevent pneumonia and death. Ten patients resolved their infection, pneumonia developed in four, and two died. Aerosolized human IGIV was of no clinical benefit in the treatment of patients with RSV infection.[489]

Recommendations

Palivizumab is indicated for prevention of RSV infection during the RSV infection season for high-risk premature infants or infants with chronic lung disease.[23] The period of prophylaxis should be individualized, depending on the duration of the local RSV infection season.

CANDIDATES FOR PROPHYLAXIS[23]

1. Infants younger than 24 months with chronic lung disease of prematurity requiring medical treatment in the past 6 months at the start of the RSV infection season. Two seasons of treatment may be required for some infants who require ongoing medical treatment.
2. Premature infants without chronic lung disease who were born before 32 weeks' gestation. Infants born at 28 weeks or earlier may benefit from 12 months of prophylaxis, whereas infants born at 29 to 32 weeks' gestation may benefit most from prophylaxis for 6 months,[23] although decisions should be individualized.
3. Premature infants of 32 to 35 weeks' gestation who have two or more high-risk factors and are younger than 6 months at the start of the RSV infection season. Such factors may include severe neuromuscular disorders, group daycare, school-age siblings, environmental air pollutants, and congenital abnormalities of the airways.[511]
4. Children younger than 24 months with hemodynamically significant heart disease. These criteria include children requiring medication for congestive heart failure, children with moderate to severe pulmonary hypertension, and children with cyanotic heart disease. Children with hemodynamically insignificant heart disease are not candidates for palivizumab. This category includes atrial septal defect, small ventricular septal defect, pulmonic stenosis, mild coarctation of the aorta, and patent ductus arteriosus.

   Children who have had surgical correction and do not require medications for congestive heart failure also are not candidates for prophylaxis. After cardiopulmonary bypass, a postoperative dose of palivizumab can be given to maintain protection because decreased levels of antibody have resulted from cardiopulmonary bypass.[179]
5. Infants who are severely immunocompromised can be considered for prophylaxis, although there are no studies on which to base a recommendation.

POSSIBLE INDICATIONS

1. Palivizumab in addition to implementation of strict isolation practices may be of value in aborting a nosocomial outbreak of RSV infection in the premature nursery.[1,142] However, current dosing recommendations for outpatients may not be adequate for some hospitalized premature infants.[654]
2. Patients with cystic fibrosis who are younger than 2 years also may be candidates for RSV prophylaxis, but no data exist on which to base a recommendation.
3. Older high-risk infants who received palivizumab the previous season but remain unwell, are immunocompromised, or have recently undergone a procedure such as transplantation or operation may benefit from a second season of palivizumab. They include immunodeficient infants receiving IGIV because IGIV has only low titers of RSV antibodies.

DOSAGE AND ADMINISTRATION

Prophylaxis is given monthly from just before the start of the local RSV infection season until the end of the season. Usually, five injections are given from November to March, but starting earlier or extending into April may be required. Thus, it is important to be aware of the local outbreak data. If an infant develops RSV infection while receiving prophylaxis, palivizumab should be continued because more than one RSV strain could infect the patient in a single season.[23]

The dose of palivizumab is 15 mg/kg per month given intramuscularly. It is supplied in 50- and 100-mg vials.

As discussed before, palivizumab is not indicated for the treatment of RSV infections.

ROTAVIRUS

Several reviews have summarized the role of oral IG in the prevention and treatment of rotavirus infection.[79,148,241,632] Its effectiveness varies, in part because of differences in antibody titer in the various products.[53,163,229,230,258,403,514] Human IG has been used to prevent rotavirus infection; Barnes and colleagues[53] gave human gamma globulin orally to low-birth-weight infants in a nursery in which rotavirus was endemic. Patients given human IG had milder disease than placebo recipients did.

Human IG has been infused into the duodenum[230] to treat two children with prolonged rotavirus infection. One patient responded rapidly, but the other had a prolonged course. Losonsky and coworkers[363] gave human IG to three immunodeficient patients and demonstrated that it survived passage of the gastrointestinal tract in an immunologically active form.

Pooled colostrum concentrate from hyperimmunized pregnant cows with high titers to several rotavirus serotypes[98] has been used in several studies. In a controlled study, bovine immune colostrum[603] did not prevent development of symptomatic rotavirus infection in infants, but treated patients had a decrease in the duration of diarrhea. Immune bovine colostrum also was used prophylactically for 2 weeks in 10 infants in a baby care center, with evidence of a protective effect.[163]

A double-blind, placebo-controlled trial of oral lyophilized rotavirus bovine colostrum in Bangladesh showed that a 4-day course decreased diarrhea, the need for oral rehydration, and viral shedding.[514] Mitra and associates[403] also showed that cow colostrum[603] significantly shortened the duration of diarrhea and decreased stool output. Hilpert and colleagues[258] demonstrated that rotavirus colostrum decreased virus excretion in infants with rotavirus diarrhea.

A lactobacillus engineered to express a neutralizing antibody fragment of a llama immunoglobulin (lactobodies) was given orally to experimental animals with rotavirus diarrhea and markedly shortened disease duration, severity, and viral load.[451,611]

A recently licensed vaccine for rotavirus seems safe and effective.[24]

Recommendation

Because rotavirus infection usually is self-limited, no commercial passive antibody product has been developed, although it would be of use in developing countries. The neutralizing titer of human IG probably is not high enough to be consistently beneficial. Oral vaccines may decrease the need for antibody-based therapies.

RUBELLA

IGIM rarely is used for prevention of rubella because of its uneven efficacy. Early studies suggested some prophylactic benefit. Korns[329] in 1952 showed that one lot of IGIM at a dose of 0.1 mL/lb partially protected mentally handicapped institutionalized subjects against development of epidemic rubella. Rubella developed in 9 of 45 IGIM-injected subjects versus 35 of 60 noninjected controls, a significant difference. However,

another IGIM lot was ineffective, and a third was only slightly effective, suggesting that the titers of rubella antibodies varied significantly.

Studies in epidemic situations have shown that 5 mL of IGIM can prevent development of clinical rubella,[220] but Brody and coworkers[87] showed that an IGIM dose of 0.55 mg/kg resulted in a decreased clinical attack rate but also a high incidence of subclinical infection. Military recruits were protected by a 15-mL dose of IGIM administered before exposure.[262]

Extensive studies on IGIM prophylaxis of rubella conducted by Green, Krugman, and their associates[223,334] did not demonstrate a protective effect of 0.12 to 0.2 mL of IGIM per pound. Lundström and coworkers[369] gave 251 exposed pregnant Swedish women 4 mL of convalescent rubella IGIM and 28 exposed pregnant women 24 mL of standard IGIM. Rubella developed in 6 of the 251 (2.4%); three of these six women aborted, and one had an infant with probable congenital rubella. None of the 28 women given 24 mL of standard IGIM contracted rubella. Their subsequent study demonstrated that convalescent rubella IGIM given to pregnant women with clinically manifested rubella did not protect against congenital rubella or lessen the probability of fetal damage.[370]

Recommendations

IGIM prophylaxis is not indicated for children and nonpregnant adults exposed to an infected contact because of the mildness of the infection.

IGIM is not recommended for most exposed pregnant women because the clinical syndrome may be masked and congenital rubella not prevented. For exposed pregnant women who will not consider abortion if rubella develops, a large dose of IGIM may be of some value. A dose of 0.55 mL/kg of IGIM given intramuscularly is the recommended dose.[25] However, mothers who have received such prophylaxis after exposure have delivered infants with congenital rubella.[25]

VACCINIA, VARIOLA, AND VACCINIA IMMUNE GLOBULIN

Vaccinia virus is closely related antigenically to smallpox (variola) virus, and thus immunity to vaccinia virus through vaccination prevents smallpox.[420] Although smallpox has been eradicated from the world since 1977, the virus nonetheless exists in a few research laboratories and is a potential weapon in biologic warfare.

Vaccination is still given to members of the military, to some health care workers, and to laboratory workers who handle cultures or animals contaminated with vaccinia virus, some recombinant vaccinia viruses, and other orthopoxviruses (e.g., monkeypox or cowpox). Passive immunization occasionally is necessary after laboratory accidents, inadvertent vaccination of high-risk individuals, and exposure of high-risk individuals to a recently vaccinated individual.

Passive immunization against variola was known as early as 1895, when Hlava and Honl[259] showed that schoolchildren could be protected from variola by the injection of 3 to 10 mL of serum from a cowpox-immune calf. At the same time, protective human antibodies developed after vaccination, and passive transmission of these antibodies from mothers to infants was demonstrated.[558] Thereafter, effective prevention of smallpox by well-organized mass vaccination campaigns diminished interest in passive immunization.

Janeway, quoted by Enders,[168] found neutralizing vaccinia antibody in IG in 1944, and Verlinde and Spaander[616] in 1949 found high titers of such antibodies in convalescent IG from recently vaccinated individuals. Gispen and associates[205] in 1956 developed a human vaccinia immune globulin (VIG) that did not interfere with active immunity, and they proposed its use with vaccine as prophylaxis against vaccinia encephalitis. Human VIG is derived from the plasma of vaccinated donors.[118]

The value of human VIG in treating smallpox or disseminated vaccinia is based on the presence of viremia, which leads to secondary dissemination. Administration of neutralizing antibody will prevent or limit the spread of infection and thus modify clinical expression of the disease.

Studies on the efficacy of VIG in treating smallpox and vaccinia complications were initiated by Kempe and colleagues in 1955.[52,312] They used a VIG that was prepared from recently vaccinated donors with a neutralizing titer of 1:256 to 1:512, in contrast to titers of 1:16 or 1:32 in standard IGIM. The households of new admissions to the Madras (India) Smallpox Hospital were visited, and alternate family contacts received VIG (1.0 g in adults, 0.5 g in children).[312] After 25 days, eight cases of smallpox developed in 75 contacts not given VIG, and two cases developed in 56 contacts given VIG, a significant difference. A similar, more extensive study disclosed 21 cases of smallpox (four severe) among 379 contacts serving as controls and five cases of smallpox (none severe) among 326 contacts given VIG.[313]

Kempe[314] also reported the results of 300 cases of smallpox vaccination (vaccinia) complications treated with VIGIM, including 62 cases of generalized vaccinia, 132 cases of eczema vaccinatum, 23 cases of vaccinia necrosum, 12 cases of vaccinia encephalitis, and 28 cases of autoinoculation. In addition, VIGIM was given prophylactically to 44 eczematoid children requiring smallpox vaccine (0.6 to 1.2 mL/kg). VIGIM did not affect the course of vaccinia encephalitis. Twenty-seven of 28 patients with autoinoculation who received VIGIM did well. Nine deaths occurred in the 132 patients with eczema vaccinatum given VIGIM; this 7 percent mortality compares favorably with the usual mortality of 30 to 40 percent with supportive care only. All 62 patients with generalized vaccinia who were given VIGIM did well, although four children required a second course.

Seven of the 23 patients with vaccinia necrosum who received VIGIM died (30%); however, this disease generally is fatal, and immune defects were present in most of these patients.[52] These results strongly supported the efficacy of VIGIM and subsequently were confirmed by studies in Sweden[371] and the United Kingdom.[529]

In 1997, Kesson and coauthors[316] reported a severely immunocompromised patient with progressive vaccinia who had inadvertently received a vaccinia melanoma oncolysate vaccination but was successfully treated with VIGIM and ribavirin. Nanning[416a] studied the effect of VIGIM on postvaccinia encephalitis. He gave a placebo or 2 mL of VIG to Dutch military recruits at the time of primary vaccination; three cases of encephalitis occurred in 43,630 vaccinated recruits given VIG, compared with 13 cases in 53,044 recruits in the control group. This 77 percent reduction is statistically significant.

INTRAMUSCULAR VACCINIA IMMUNE GLOBULIN AND INTRAVENOUS VACCINIA IMMUNE GLOBULIN

Two types of VIG are now available, VIGIM (for intramuscular use) and VIGIV (for intravenous use). VIGIM was approved in the United States in 2005 for specific indications: treatment of infections that involve accidental implantation in the eye (except for isolated keratitis), mouth, or other hazardous areas; eczema vaccinatum; progressive vaccinia; severe generalized vaccinia; and vaccinia in patients with burns, impetigo, varicella-zoster, poison ivy, or severe eczema.

Both licensed VIG preparations are prepared from the plasma of vaccinated donors; one is produced by DynPort Vaccine Company LLC, Frederick, Maryland, and the other is produced by Cangene, Mississauga, Ontario, Canada[647] (http://www.fda.gov).

VIGIV used at a dose of 100 mg/kg results in a more rapid and higher antibody peak than does an injection of VIGIM.[261] The first civilian treated with VIGIV was a woman with vaccinia blepharoconjunctivitis; she also received topical antiviral medication.[264] Another laboratory worker with ocular vaccinia also was treated with a single dose of VIGIV.[357]

Recommendations

Complications of vaccination are the usual indications for VIG. They include accidental or intentional vaccination of a patient with a contraindication to the vaccine, autoinoculation of the eye, eczema vaccinatum, severe generalized vaccinia, and vaccinia necrosum.

The initial dose for VIGIM is 0.6 mL/kg. In adults, the dose must be divided and administered during the course of 24 to 36 hours. Repeated doses can be given at 2- to 3-day intervals for vaccine complications until recovery begins, as evidenced by no new lesions. VIG should be given as soon as possible after diagnosis is established.[7,115]

For unimmunized patients exposed to smallpox, VIGIM in combination with vaccine can be given. A dose of 0.6 mL/kg should be given as soon as possible, preferably within 1 to 3 days.[7,385,605] Current recommendations from the U.S. Army Medical Research Institute of Infectious Diseases suggest that VIGIM may be of value in postexposure prophylaxis of smallpox when it is given within the first week after exposure and concurrently with vaccination. Vaccination alone is recommended for those without contraindications. Both vaccine and VIGIM should be given if more than 1 week has elapsed since exposure occurred.

The current supplies of VIGIM would not permit its routine use in combination with vaccine for bioterrorism exposure,[115] but if additional supplies become available, a VIGIM dose of 0.3 mL/kg in combination with vaccine could be used. No data are available on the use of VIGIV for a bioterrorism exposure or its combination with vaccination.

Recommendations for VIGIM for vaccinia complications are summarized on the CDC bioterrorism Web site (http://www.bt.cdc.gov/agent/smallpox/vaccination/vig.asp). Cidofovir also has been used.[84a,84b] VIGIM is not indicated for established smallpox, postvaccinial encephalitis, or hypersensitivity and toxic rashes that occur after vaccination. However, the lack of efficacy of VIGIM in the past does not exclude a potential beneficial effect for VIGIV. The pathogenesis of vaccinial encephalitis is poorly understood and may involve both infection and immune response,[261a] and thus VIGIV may be beneficial.

Inadvertent vaccination of a pregnant woman occasionally results in fetal complications, with an estimate of one case of fetal vaccinia for 10,000 to 100,000 vaccinated pregnant women. Although VIGIV has not been licensed for this purpose, it can be offered. The VIGIM is now considered an investigational preparation because of a change in color with age; further, VIGIM contains a mercury preservative, so it should not be used in pregnant women. Some investigators suggest use of VIGIV if it is given within 10 days of vaccination of a pregnant woman.[115,115a,417]

In ocular vaccinia, VIGIM is contraindicated for isolated vaccinial keratitis because it may increase corneal scarring,[357] as suggested by animal studies. If additional indications for VIGIM exist, such as conjunctivitis, blepharitis, and eczema vaccinatum, the presence of keratitis is not a contraindication for use of VIGIM. Indeed, scarring can occur from vaccinial keratitis in the absence of VIGIM treatment. Topical medications also are recommended.[464]

REGIONAL VIRUSES

ARGENTINE HEMORRHAGIC FEVER

Junin virus, the etiologic agent of Argentine hemorrhagic fever, causes a febrile illness with high mortality rates from vascular or neurologic complications.[467] Patients may either improve or have severe hemorrhagic or neurologic manifestations (or both) within the first 2 weeks of illness.[374] Maiztegui and colleagues[374] found that immune plasma given before the ninth day of illness to 91 patients reduced the mortality rate to 1.1 percent compared with a mortality rate of 16.5 percent in the 97 patients given normal plasma ($p < .01$). Ten of the patients who received immune plasma relapsed with fever and cerebellar signs after several weeks, as did eight others who were not part of the study. The neurologic relapse was self-limited in all but one patient, who died.

Difficulty in obtaining immune plasma, possible neurologic complications of plasma treatment, and lack of efficacy late in the course of the disease have led to the use of ribavirin, despite its limitation late in the disease.[170] An effective, live attenuated viral vaccine has now been developed.[375]

EBOLA INFECTION

Ebola virus, a filovirus, causes severe and often fatal hemorrhagic fever; it has no effective treatment. Kudoyarova-Zubavichene and coworkers[339] reviewed the use of hyperimmune goat or equine serum in the prevention and treatment of Ebola infection. Goat hyperimmune serum protects guinea pigs from experimental infection if it is given less than 24 hours before exposure and provides some benefit if it is given within 72 hours after exposure. This product was used for emergency prophylaxis in four patients exposed by laboratory accidents. Mild infection developed in one definitely exposed patient, but Ebola disease did not develop in the other three patients with questionable exposure. All four patients also received recombinant human interferon-α–2. Equine serum has protected baboons from low-dose virus challenge but not cynomolgus monkeys from a high-dose virus challenge.[278] Equine serum given to monkeys on the day of infection and 5 days later did not prevent death.[279]

Gupta and coauthors[234] reported that a murine polyclonal immune serum protected 100 percent of normal mice and mice with severe combined immunodeficiency after a lethal challenge. Wilson and colleagues[643] were able to protect mice with monoclonal antibodies to Ebola glycoprotein for up to 2 days after infection. Parren and associates[454] were able to protect guinea pigs by giving a human neutralizing antibody up to 1 hour after infection with Ebola virus. Protection of mice by neutralizing monoclonal antibody before and up to 2 days after virus was also shown.[588] Thus, antibody may be a useful agent in the prevention of Ebola disease. Other human monoclonal antibodies have been developed.[380]

Recommendation

The use of antibody in prevention and treatment of Ebola infection is unproved, but monoclonal antibodies are being developed. Animal studies support a role for antibody in the prevention of Ebola infection.

TICK-BORNE ENCEPHALITIS

Tick-borne encephalitis is caused by a flavivirus that is endemic in Russia and eastern and central Europe. Several neurologic syndromes are associated with this infection: febrile headache, aseptic meningitis, meningoencephalitis, meningomyeloencephalitis, and postencephalitic syndrome.[159] Meningoencephalitis is the most severe form and can result in death or permanent paresis. Effective vaccines are available[159,233] and have been successful in dramatically lowering the incidence of this disease.[341]

Passive immunization with a hyperimmune human globulin has been used for postexposure prophylaxis in endemic countries, but it may result in antibody-dependent enhancement of infection.[320,625] Arras and colleagues[36] question these case reports compared with the large number of doses of passive antibody given. Günther and Hagland[233] contend that hyperimmune globulin is not indicated for children younger than 14 years because of concerns that antibody may worsen the disease. The lack of efficacy trials also has led to questioning of the use of this product.[8]

However, von Hedenström and colleagues[622] have recommended its use for postexposure prophylaxis in addition to immunization. In a review of 656 patients with tick-borne encephalitis in southern Germany, Kaiser[298] concluded that postexposure prophylaxis with hyperimmunoglobulin is less effective than is vaccine and should be used only when necessary. Vaccine is the best method for disease prevention.

SECTION XXV

OTHER PREVENTIVE CONSIDERATIONS

CHAPTER 257

PUBLIC HEALTH ASPECTS OF INFECTIOUS DISEASE CONTROL

Laurene Mascola ❂ David E. Dassey

The dramatic achievements of public health in the 20th century have improved our quality of life: an increase in life expectancy, a worldwide reduction in infant and child mortality rates, and the elimination or reduction in incidence of many communicable diseases. Public health is the science of protecting and improving the health of communities through education, promotion of healthy lifestyles, and research for prevention of disease and injury.[175] Its core functions can be summarized as assessment, assurance, and development of policies. Public health involves the application of many different disciplines, including biology, sociology, mathematics, anthropology, public policy, medicine, education, psychology, computer science, business, engineering, and more.[13] Its scope covers many human health areas, including birth defects, disabilities, communicable diseases, emergency preparedness and response, environmental health, genetics and genomics, health promotion, injury and violence, travelers' health, vaccines and immunizations, and safety and health in the workplace.

For the benefit of this textbook, this chapter focuses on communicable disease control, although the very same principles can be applied to many other health problems. Key tools for control of public health problems fall into two categories: recognition-evaluation and intervention. Foremost among the tools for recognition and evaluation is surveillance, which can be defined as the systematic collection of information about the occurrence of disease and risk behaviors in a community. When an unusual cluster of disease is recognized through surveillance or serendipity, an investigation is indicated. This investigation includes a description of the disease or problem, determination of the pattern of its occurrence in the community, formulation of hypotheses of the cause of the unusual frequency, testing of the hypotheses, and framing of control methods. Of assistance in both surveillance and epidemic investigation is the recognition of common patterns of disease spread either within groups of people or from the environment to people.

Many tools are available for communicable disease intervention. Two important categories are not considered in this chapter because they are addressed at length elsewhere in this book; one is immunization, and the other is treatment of individual patients. Public health tools that are discussed here include isolation, quarantine, chemoprophylaxis, water and food sanitation (including the special situation of international travel), and vector control.

Other public health tools are not discussed here but are as relevant to the control of infectious diseases. They include but are not limited to short- or long-term modifications to human behaviors that affect exposure to infectious diseases such as sexual behavior, food preparation methods, and intravenous drug use practices. In addition, certain control measures, such as vaccination and chemoprophylaxis or chemotherapy, can be applied to animals to decrease the risk of their spreading diseases to humans.[184] And last, control measures that can be applied to the environment, such as proper disposal of waste and appropriate design and proper maintenance of buildings and other equipment, can reduce opportunities for transmission of diseases. An example of such a control measure is proper maintenance of spas or cooling towers to prevent transmission of *Legionella*.

SURVEILLANCE

Public health surveillance is the ongoing, systematic collection, analysis, interpretation, and dissemination of data about a health-related event for use in public health action to reduce morbidity and mortality rates and to improve health. Data disseminated by a public health surveillance system can be used for immediate public health action, program planning and evaluation, and formulation of research hypotheses.[83] Surveillance involves the collection, collation, and analysis of data and feedback of information. When it is used properly, this information helps in directing disease control activities and evaluating their impact. In the primary collection of information, three major factors must be defined. The first is the population to be surveyed, which may be circumscribed geographically (e.g., the inhabitants of the region surrounding the New York City World Trade Center towers) or restricted to a certain age group (e.g., infants, for the surveillance of birth defects, or child-bearing women, for surveillance of postpartum infections) or to a certain institution (e.g., a school, a hospital, the U.S. military). Second, the data to be monitored can be as crude as the number of cases of disease or deaths from a disease. Additional information that could be collected and be useful epidemiologically includes the characteristics of ill persons with regard to age, sex, place of residence, and occupation or detailed characteristics of the organisms involved, such as antibiotic sensitivity, serogroup, nucleic acid molecular profile, or site of the body from which an isolate was recovered. The third and most important element of the reporting system is the primary reporting source. Unless a report of disease is initiated by a physician, infection control professional, or laboratory, no information is generated. Incentives to the primary reporting source to maintain good reporting—such as ongoing feedback—are essential for maintaining a useful surveillance system. Increased use of automated reporting systems using electronic medical records and laboratory results has the potential for improving completeness and timeliness of surveillance data.[67]

In each state, reporting of specified infectious diseases is required by law. However, state laws vary with regard to the persons who are responsible for reporting, the diseases or conditions that are reportable, and the circumstances under which

reporting is to occur.[178,274] Specific information generally is available on request from state or local health agencies.

Collection of surveillance information on the occurrence of disease is pointless unless the data are used to initiate or to modify control actions. The first step is collation and analysis, which may be done at the level of the local health department, the state health department, or the federal government. If this step is performed in a timely fashion, problems can be recognized early and a response initiated.

After this information is collated and analyzed, the results are fed back to the primary reporting source and to others interested in the data. Such feedback serves to maintain interest in the reporting system, thereby maintains the quality of data obtained, and continuously updates persons at each level of the surveillance system about the changing patterns of occurrence of disease and new strategies for disease prevention and control.

One vehicle for the feedback of national surveillance information is the *Morbidity and Mortality Weekly Report* (*http://www.cdc.gov/mmwr/*), which is published by the Centers for Disease Control and Prevention (CDC). Also published by the CDC are periodic summaries of surveillance activities relating to specific diseases. Regular summaries of surveillance activities also are published by the World Health Organization (*http://www.who.int/wer/en/*) and by many state and local health departments.

Identification of a disease problem in the course of surveillance should prompt an attempt to control the problem. Control may involve the initiation of an outbreak investigation if surveillance data suggest an unusual frequency of occurrence of a disease or the adjustment in a public health program if, for example, surveillance data suggest that vaccine is not being given to a particular age group of susceptible people.

OUTBREAK INVESTIGATION

When faced with a possible outbreak, a useful approach is for the investigator to address the inquiry systematically.

1. *Verify the diagnosis.* Review of available clinical and laboratory information and examination of a few patients will permit the creation of a list of possible diagnoses and will suggest additional diagnostic specimens that may be needed to secure the diagnosis. The investigation may proceed without a microbiologic diagnosis if a clearly defined clinical syndrome can be identified. With or without microbiologic confirmation, a standardized case definition is needed.

2. *Confirm the existence of an epidemic.* Through the use of an objective and standardized case definition, the baseline incidence of the illness (number of cases per period of time) before the apparent occurrence of an epidemic should be determined by review of appropriate microbiologic, serologic, or clinical records. Armed with these data, the investigator can decide whether recent events indicate an unusual clustering of illness (i.e., whether an outbreak or epidemic [a large outbreak] exists).

3. *Describe the time, place, and person*. Graphic display of the distribution of cases in time not only confirms the existence of an epidemic but also indicates whether the outbreak is waxing or waning. It may permit judgment about whether the outbreak is spread from person to person or from a common source of exposure and an estimate of the incubation period. Comparison of the characteristics of case patients with regard to age, sex, geographic location, exposure risks, and other relevant factors with those of persons who reasonably might be considered to have been at risk (exposed) but who did not become ill forms the basis for making epidemiologic hypotheses. Determining the attack rate (number ill/[number ill + number well]) is a useful method of describing the risk for development of illness in various groups.

4. *Frame an epidemiologic hypothesis.* By taking the diagnosis (presumed or confirmed) and the pattern of occurrence of disease into account, the investigator may hypothesize one or several possible common sources of infection and one or more modes of spread (food or water borne, airborne, vector borne, or by a particular therapeutic or diagnostic procedure, and from a single point source or an ongoing source of exposure). Alternatively, the hypothesis may be of person-to-person spread. Any thought of an intentional release of a pathogen should be shared immediately with public health authorities

5. *Identify the control group or groups.* Central to the epidemiologic process is identification of a group of persons in whom illness might have developed but did not.[110] The activities and exposures that set well persons apart from sick persons often point to the source of the outbreak. For gastroenteritis occurring after a church supper, one control group might be those who went to the supper but did not get sick, and another control group might be residents of the same community who did not attend the supper. For histoplasmosis in schoolchildren occurring after a school clean-up program, controls might be the well children.

6. *Test the hypothesis statistically.* The attack rates of illness among persons exposed or not exposed to a hypothesized source then are compared by using the number of cases and controls in each group. A true common source should be associated with a higher attack rate in those exposed to it than in those not so exposed. Statistical tests are useful for assessing the significance of differences observed in attack rates of those exposed and not exposed.

7. *Explain the outliers.* Any case that occurs in a person apparently not exposed to an implicated common source needs to be explained. As an example, if vanilla ice cream is implicated as the common source in a food-borne outbreak and ill persons are found who ate only chocolate ice cream, one might hypothesize reasonably that cross-contamination of the ice cream scoop has occurred. Faulty memory of exposure to a common source and the simultaneous occurrence of endemic cases unrelated to the outbreak may complicate this stage of the investigation.

8. *Confirm the hypothesis microbiologically.* Cultures of the implicated common-source material may permit recovery of the infectious agent. When a microorganism is isolated, typing methods may be used to support the epidemiologic hypothesis by demonstrating that the same strain was responsible for disease in all affected patients and can be recovered from the common source. Traditional methods for typing microorganisms—serotyping, biotyping, antimicrobial sensitivity testing, and immunoblotting—remain very useful. In recent years, these techniques have been supplemented and, in some settings, replaced by nucleic acid–based typing methods, such as plasmid profile analysis, pulsed-field gel electrophoresis of chromosomal DNA, and polymerase chain reaction assay to identify genome segments.[220,315] However, culturing of the agent from a particular site without any epidemiologic implication of that site as a source of infection provides little or no information needed to direct control measures.

9. *Implement control measures.* Knowledge of the agent, source, and mode of spread permits drafting of control measures and their implementation. Without careful attention to this step, the investigation is an academic exercise only.

10. *Measure the impact of control measures.* This step doubles as the ultimate test of the epidemiologic hypothesis and as an assessment of the design and implementation of the control measures. Surveillance for the occurrence of disease in groups shown to be at high risk is the most common technique used for this measurement, and a decrease in the attack rate to zero (no new cases of disease) or to the baseline incidence of disease is the measure of success.

Several exercises illustrating these principles, including communicable and noncommunicable disease outbreaks, can be found at the CDC's training site for epidemic intelligence service officers (*http://www.cdc.gov/eis/casestudies/casestudies.htm*).

COMMON PATTERNS OF DISEASE SPREAD

DISEASE SPREAD FROM ANIMALS TO PEOPLE

Many infectious diseases are transmitted from other animals to humans (zoonoses). Of all emerging diseases in the 20th and 21st centuries, more than 75 percent are zoonotic in origin.[138] From the United States perspective alone, emerging zoonotic diseases that have caused human infection or concern include West Nile virus, anthrax (weaponized to cause intentional harm by contaminating some mail), severe acute respiratory syndrome (SARS) pandemic caused by a newly identified coronavirus,[279] monkeypox,[285] bovine spongiform encephalopathy,[41] and H5N1 avian influenza.[229] Physicians who routinely inquire about animal contacts as part of the clinical and epidemiologic history of an ill patient frequently find valuable clues to an obscure diagnosis.[1] Table 257–1 lists infectious disease agents for which some suggestive or definitive evidence exists that the disease can be spread from animal to human, either directly or by a vector.[1,21,161,189,303] A distinctive disease name associated with the organism also is listed, as are the various animal groups that have been suggested or shown to act as sources of transmission to humans. The frequency with which an animal group serves as a source of infection for humans and the frequency with which a vector is involved are indicated in a semiquantitative fashion.

Perhaps the most recent disease recognized to be spread from animals to humans by mosquitoes in the United States is West Nile virus. West Nile virus was introduced first in the northeastern part of the United States in the summer and fall of 1999. By 2005, West Nile virus activity detected in mosquitoes, people, dead birds, captive sentinel animals, and other sources had been reported from 596 counties in 42 states.[84] From a global standpoint, a devastating zoonotic disease emerged in November 2002 in China; called SARS, it was identified as being caused by a new human coronavirus and was thought to be transmitted from animals and the markets that trade in live game animals to humans.[253] In 1997, the highly pathogenic avian influenza strain H5N1 emerged and infected 18 humans in Hong Kong; it continues to infect humans, felids, pigs, and other mammals, leaving the world in anticipation of a possible next influenza pandemic.[204] In recent years, infections with zoonotic diseases such as rabies, trypanosomiasis (Chagas disease), West Nile virus, and human lymphocytic choriomeningitis have caused infections in organ recipients, escalating the damage caused by zoonotic diseases to a new paradigm.[43,80,196]

Omitted in Table 257–1 are many species that may be infected with the organism but do not appear to act as a source of human infection. Also omitted are certain rare or accidental infectious diseases. The complex life cycles of some parasites are difficult to display in tabular form. Details of the clinical manifestations, differential diagnoses, and treatments of the zoonoses are found in the appropriate chapters elsewhere in this book. For a complete description of the circumstances under which each agent is spread from animal to person, consult a textbook of zoonoses.[1,22] Excluded from Table 257–1 are several interesting groups of infectious diseases in which human beings and animals appear to interact but in which infection does not spread from animals to people. The first group includes organisms that infect both animals and humans from a common source in nature. Such organisms include *Burkholderia pseudomallei*, *Blastomyces dermatitidis*, and *Aspergillus* spp., which can infect a wide variety of animal species, including humans, from soil or other inanimate sources.

A few diseases are spread from humans to animals. Perhaps the most prominent example is *Herpesvirus hominis*, which can cause fatal encephalitis in nonhuman primates when it is spread from humans.[172] Tuberculosis also can spread from humans to nonhuman primates, and even elephants, as well as the reverse. *Cryptococcus neoformans* and *Histoplasma capsulatum* live in animal feces but do not infect animals. From the fecal material, these organisms may spread to infect humans. Some organisms can be transmitted by fomites of animal origin. They act as mechanical carriers, and the process does not involve infection of the animals. Examples include *H. capsulatum*, which has been observed to be spread by chicken feathers, and *Coccidioides immitis*, which can be spread in bales of wool contaminated with fungus-laden dust.

Another group of diseases are spread from person to person through an insect vector, either typically or on occasion. Filariasis is a prime example of a disease in which vector-borne person-to-person spread is the rule. Typhoid and yaws have been shown to be spread by vectors on occasion. Evidence that *Mycobacterium leprae* can be recovered from mosquitoes and sandflies[292] that have fed on patients with lepromatous leprosy exists, as does speculation that such mosquitoes or sandflies may serve as vectors of transmission.

DISEASE SPREAD FROM PERSON TO PERSON

As members of groups including the family, school, camp, daycare center, and religious organizations, children are at risk of acquiring or spreading infectious agents that are transmitted from person to person. Knowledge of the typical patterns of spread can be useful in planning surveillance or in designing control measures. For example, recognition that diarrhea commonly results from person-to-person spread in daycare centers and that it can indicate inadequate hygienic practices may justify specific surveillance for diarrhea in that setting. Documentation of secondary cases in various categories of contacts of cases of meningococcal disease permits focusing the delivery of chemoprophylaxis on just the high-risk groups.

In this section, spread in the family and schools is discussed, but several groups of interest are only briefly mentioned. The important areas of transmission of disease within daycare centers and within hospitals are discussed in separate chapters in more depth. Maternal transmission of specific infections to the fetus or neonate also is reviewed elsewhere in this book. Spread of enteric diseases within institutions for the mentally challenged is recognized widely as an important problem, but it does not impinge directly on the practice of most pediatricians and is not discussed in this chapter.

Infection caused by the human immunodeficiency virus (HIV), which leads to the acquired immunodeficiency syndrome (AIDS), is one of the conditions for which public health surveillance is most critical. The CDC has reported that in 2003, more than 1 million persons in the United States were estimated to be living with HIV infection.[116] During 2001 to 2004, HIV infection was diagnosed in an estimated 157,253 persons in 33 states that have been conducting name-based HIV/AIDS surveillance for at least 4 years.[116] Another CDC report, which collects data from those 33 states, Guam, and the Virgin Islands, showed that whereas HIV infection reporting decreased year to year from 2001 to 2003, it increased 1 percent from the end of 2003 (38,188 cases) through the end of 2004 (38,730 cases).[42] From 2001 to 2004, the estimated number of HIV/AIDS cases by year of diagnosis decreased among children younger than 13 years (124 cases to 48 cases), remained stable in those aged 13 to 14 years (at 60 cases), and increased in those aged 15 to 19 years (291 cases to 326). Survival after a diagnosis of AIDS was established was

HF, Hemorrhagic fever; HGE, Human granulocytic ehrlichiosis.

greatest among children with perinatally acquired HIV infection compared with other age groups. Maternal transmission and person-to-person sexual and blood-borne spread of HIV infection are at the top of the list of public health concerns and are covered extensively in Chapter 204.

THE FAMILY

Spread of disease agents in the family can be considered in two stages: introduction of the agent into the family, usually by a single member ("index case" or "index carrier"), and spread to other family members. Spread to other members can be described in terms of rapidity and intensity, the latter commonly measured by the secondary infection rate (or secondary attack rate), which is defined as the proportion of the contacts of the index carrier or index case who become infected (or ill) in a given interval after exposure. The secondary infection rate varies from agent to agent and may be affected by the age and sex of the introducer; the size of the family; crowding; the age of household contacts; previous immunity; and interventions attempted, including vaccination, isolation, treatment, and chemoprophylaxis. The ratio of the secondary attack rate to the incidence of disease in the community is a measure of the importance of the family as a focus of disease.[131]

Of the bacteria spread by the respiratory route, pneumococci, group A streptococci, meningococci, and *Haemophilus influenzae* historically have been studied most completely. In a 1950s study of English families of five persons each (mother, father, and three children, the youngest of whom was younger than 5 years), type-specific introduction of pneumococci was attributed most frequently to the middle child.[31] The oldest and middle children were the most efficient spreaders of pneumococci to other family members. Among household contacts, children were more likely than were their parents to become infected. The overall secondary infection rate was 9 percent.

Whereas older studies supported the idea that parents do not obtain disease from their children, keeping the theory of "an immunologic barrier between adults and children" intact, others have demonstrated an extremely high rate of transmission of penicillin-resistant *Streptococcus pneumoniae* between parents and children.[170,186] The recent routine administration of a seven-valent pneumococcal conjugate vaccine (PCV7) to young infants has altered the epidemiology of pneumococcal colonization, invasive infection, and transmission not only in vaccinated children but in nonimmunized persons as well, similar to what has been observed with the conjugate vaccine for *H. influenzae* type b.[203] Conjugate vaccines interrupt the transmission of vaccine-type strains among vaccinees and their household members.[139] Several reports have documented the reduction of incidence of pneumococcal nasopharyngeal carriage of vaccine serotypes.[308] One study among vaccinated South African children showed a reduction of nasal carriage of pneumococcal vaccine serotypes from 36 percent in control children to 18 percent in vaccine recipients. Another study among vaccinated Israeli toddlers also showed a 50 percent reduction in new colonization by vaccine serotypes compared with controls. The decrease in nasopharyngeal colonization by vaccine serotypes resulting from conjugate vaccine in children has conferred benefits to their nonimmunized contacts through herd immunity. The incidence of invasive pneumococcal disease among adults aged 50 years or older caused by the seven conjugate serotypes in the United States declined 55 percent (95% confidence interval, –58% to –51%) from 1998-1999 to 2002-2003.[205] Pneumococcal carriage also was altered in adults as demonstrated by a study in which adults who lived in a household in which at least one child had been vaccinated appropriately with PCV7 had a lower likelihood of having PCV7-type pneumococci carriage than did adults living in a household in which no child had been vaccinated (adjusted odds ratio, 0.49; 95% confidence interval, 0.28-0.83).[149] In addition, the vaccine interrupted the transmission of resistant pneumococci from children to adults, which was not associated with an increased use of that vaccine. Kyaw and colleagues[194] showed that among all age groups between 1999 and 2004, the estimated number of cases caused by pneumococcal strains with reduced susceptibility to penicillin or multiple antibiotics fell by half after the introduction of the conjugate vaccine.

One interesting association, needing validation, recently showed that *S. pneumoniae* carriage, specifically of vaccine-type strains, was negatively associated with *Staphylococcus aureus* carriage in children, suggesting that *S. pneumoniae* carriage protects again *S. aureus* carriage in children.[269] Therefore, if *S. pneumoniae* carriage decreases in children because of vaccination efforts and causes increasing *S. aureus* carriage, this change could have important implications, especially in light of the recent worldwide emergence of methicillin-resistant *S. aureus* (MRSA) disease among children. Prior incidence of *S. aureus* infections in children is unknown, although nasal carriage of the organism in all age groups is estimated to be 32.4 percent, and carriage with the organism has long been known to be one of the most strongly associated risk factors for subsequent infection.[191] Fortunately, MRSA carriage prevalence estimates were found to be much lower, at 0.8 percent, and unusual in healthy persons, with age older than 60 years and being female found to be risk factors. However, family outbreaks of invasive community-associated MRSA infections have occurred, even though intrafamilial spread of invasive disease remains a relatively rarely reported phenomenon.[182,183] A study that evaluated 249 MRSA skin and soft tissue infections from 11 university-affiliated emergency departments in August 2004 found that 18 percent reported close contact with a person who had a similar infection.[236] The epidemiology of this disease is still being elucidated, and no current recommendations exist for screening or treatment of carriers of this organism.

Children with group A streptococcal infection in members of families in Cleveland, Ohio, were even more important than were children with pneumococcal infection as introducers and recipients of intrafamilial transmission and carriage; the organism may persist for many months, resulting in multiple cases of disease in a family widely separated in time.[179] A more recent reference also corroborates the fact that children are most likely to introduce group A streptococci into the home and spread disease and that children with sore throats are likely reservoirs of group A streptococci for adults who develop invasive disease.[118] Crowding, as measured by the number of rooms in the house, also influences the development of invasive group A streptococcal infection, although familial transmission of invasive group A streptococcal infection is a rare occurrence. Only a few studies have described intrafamilial transmission of invasive group A streptococcal infections.[132] However, a consensus working group concluded that no definite recommendations should be made regarding chemoprophylaxis to household contacts of persons with invasive group A streptococcal infection.[305]

The pattern of spread of meningococcal infection has been reported to be strikingly different. An article in 1971 stated that the most common introducers of meningococci into families are men, followed distantly and in decreasing order of frequency by women, girls, and boys.[143] Once meningococcal bacteria are introduced, all family members may become infected, although studies of carriers in household transmission of meningococcal disease in Brazil suggest that spread may proceed from an adult to older children and only thereafter to infants.[237] A 1993 study by Tappero and colleagues[304] showed in Los Angeles County, California, that 45 percent of persons with sporadic meningococcal disease had household contact with an adult man recently released from or employed by the county's men's jail system, establishing a new risk factor for acquisition of meningococcal

disease. The recently approved quadrivalent meningococcal conjugate vaccine (MCV4), licensed in January 2004 for use in persons aged 11 to 55 years, also may exert substantial herd immunity effects through reductions in acquisition of nasopharyngeal carriage for this disease as well.[150] Before the development of this vaccine, carriage of meningococci could persist for months, although half of the secondary cases of meningococcal disease occurred within 5 days of the index case.[143,237]

Children younger than 5 years have the greatest risk of acquiring serious disease from *H. influenzae* type b infection. Before vaccination was routine, overall carriage rates were less than 5 percent, although high rates of colonization had been reported in settings such as daycare, where young children are in close contact, and in families with a child who had invasive *H. influenzae* type b disease.[230] Among unvaccinated contacts of persons with *H. influenzae* type b disease, children younger than 5 years have the highest carriage rates (30-40%), with rates dropping progressively with increasing age.[17] However, the epidemiology of *H. influenzae* type b disease has been changed markedly by the use of vaccines; the annual incidence of disease in children younger than 5 years fell more than 99 percent (from 100/100,000 to 0.3/100,000) from 1990 to 2000 after the introduction of conjugate vaccines.[2,68] Unlike earlier polysaccharide vaccines, conjugate vaccines appear to prevent colonization as well as disease; one study using a matched case-control analysis showed that conjugate vaccines had an 81 percent efficacy in decreasing colonization.[238] Before this vaccine as well, mostly because of nasopharyngeal carriage of the index cases, secondary cases of *H. influenzae* type b disease occurred within 5 days of the index case.[129,142]

An ever-present respiratory bacterial pathogen, *Bordetella pertussis*, spreads easily within families. In a study of 21 families in Finland, 83 percent of the family members of primary cases showed serologic evidence of secondary infection.[228] Secondary attack rates for symptomatic disease were lower in older children and adults. Children 2 to 15 years of age were more likely to introduce pertussis into the family than were younger children or family members older than 15 years. However, adults may be of increasing importance as reservoirs of *B. pertussis*, leading to infection in infants.[208,223] A German study of 122 households with an index case of pertussis showed that adult index cases were as likely to spread pertussis within the family as were index cases who were children. Fourteen (78%) of 18 adults and 74 (71%) of 104 children spread pertussis to at least one other family member.[321] Outbreaks have been reported in which an adult or adolescent with persistent bronchitis acted as a source of pertussis for children and other adults.[86,193] In the United States during 2002 to 2003, of the pertussis cases reported to the CDC for which the age of the person was known, 23 percent occurred in persons 20 years or older, up from 20 percent during the prior 3 years.[85] The annual incidence of pertussis among persons aged 10 to 19 years also increased from 5.5 per 100,000 to 10.9 in 2003.

Both tuberculosis and leprosy usually are acquired by children from adults who introduce the mycobacteria into the household.[122] These introducers typically shed large numbers of bacteria from the respiratory tract (especially from the nose in lepromatous leprosy) for months or years. Secondary attack rates are similar for the two diseases and are highest for tuberculosis in children younger than 5 years.[267] For leprosy, children of all ages beyond the neonatal period are at significant risk.

Introducers who are ill tend to be more efficient spreaders of bacteria in the respiratory tract. In the Cleveland study,[179] spread of group A streptococci was 2.7 times as frequent when the introducer was symptomatic as when the introducer was asymptomatic. Spread of group A streptococci was observed in Egyptian families particularly frequently if the person who introduced the strain into the household was ill enough to seek medical care or if the strain persisted in the respiratory tract of the introducer for 3 months or more.[111] Nasal shedders of bacterial pathogens have been shown to be more efficient spreaders, and nasal shedding commonly is found early in illness.[221] In 14 (56%) of the 25 episodes of transfer of pneumococci observed in Virginia families, the spreader experienced sneezing, rhinorrhea, nasal congestion, or cough during the 2-week period in which transfer occurred, whereas such symptoms were present in only 159 (37%) of the other 423 2-week periods of observation.[145] Again, this finding may relate to higher rates of recovery of pneumococci from the nose during symptoms of upper respiratory tract infection.

Crowding can be an important risk factor for spread of disease. Crowding has been observed inconsistently to affect spread of pneumococci. English families living in only two rooms had a secondary infection rate of 16.0 percent, whereas those living in four or more rooms had an 11.2 percent secondary infection rate.[31] Floor space was not shown to affect spread in families in Syracuse, New York.[107] Severe overcrowding, inadequate ventilation, and altered host susceptibility were important factors in an outbreak of pneumococcal disease in a large urban jail.[168] Limited ventilation of houses seems to promote the spread of meningococci in the meningitis belt in Africa.[137] In a population-based case-control study, household crowding was shown to be a risk factor for *H. influenzae* disease.[91] Ill children were 2.6 times more likely to live in households containing one or more persons per room than were well children in control families. Crowding also was found to be a risk factor for pediatric invasive group A streptococcal disease.[118] The magnitude of risk associated with MRSA infection or colonization increased as the extent of crowding or closeness to a teammate with an illness increased, as evidenced in outbreaks of MRSA among athletic teams and in jails.[53,241]

The changing epidemiology of measles and mumps demonstrates the impact of vaccines on the transmission of viral diseases spread by the respiratory route. The age at which a person is most at risk for acquiring one of these diseases is determined largely by the communicability of the virus and the completeness of immunity. Long before vaccines were available for measles, varicella, and mumps, Hope-Simpson[169] calculated that disease developed in 75 percent of susceptible family contacts exposed to a case of measles, whereas the corresponding figures for varicella and mumps were 61 percent and 31 percent, respectively. In that study, the mean ages at which infection occurred were 5.6, 6.7, and 11.5 years for measles, varicella, and mumps, respectively, typical of ages obtained in the pre-vaccine era. Spread of measles before the introduction of vaccine occurred primarily in younger school-age children (5 to 9 years of age) within the community, with secondary spread to siblings occurring within the family. From 1960 to 1964, 53 percent of all measles cases occurred in children 5 to 9 years of age and 37 percent in children younger than 5 years.[126] However, new cases are now most likely to occur in older school-age children and college students, whereas preschoolers, especially those too young to receive vaccine, constitute a continuing pool of susceptible persons.[219] In 2004, of 37 cases, 49 percent were in children younger than 5 years, 19 percent were in children 5 to 19 years of age and persons aged 20 to 34 years, and 14 percent were in infants younger than 12 months.[52] A comparable change has been seen in the epidemiology of mumps, with a decreasing proportion of cases in younger school-age children and an increasing proportion in older children, adolescents, and young adults.[92,310] The "new" epidemiology of mumps disease was confirmed in a recent outbreak of mumps in 11 states in the United States from January 1 to May 2, 2006, which resulted in 2597 cases.[87] The median age of case patients was 21 years, and the outbreak started among college students.

Another childhood viral disease, varicella, has undergone significant changes in its epidemiology. Varicella vaccine has been

shown to be more than 85 percent effective in preventing varicella in clinical practice,[311] resulting in a dramatic decrease in varicella disease (between 71% and 84%) as measured in three varicella disease active surveillance sites across all ages groups, along with an observed 66 percent national decrease in varicella-associated deaths.[242,286] However, as the vaccine is not 100 percent effective in preventing every case of varicella, mild cases of varicella continued to occur in vaccinated persons (known as breakthrough disease). These vaccinated cases are half as contagious as are unvaccinated cases to household members unless they have 50 lesions or more.[287]

For respiratory syncytial virus, secondary attack rates of infants have been estimated at 45 percent, higher than the corresponding rate of 27 percent for all family contacts.[147] The infant's older sibling is the most frequent introducer of respiratory syncytial virus into the family. In a recent report among infants in a community study from Guinea-Bissau, researchers found that mothers with recent exposure to respiratory syncytial virus were two times more likely to infect boy children (prevalence ratio = 2.04 [1.18-3.53]) than girls.[299] These findings await corroboration.

In the Cleveland families study of the 1960s, common respiratory diseases (including the common cold, rhinitis, laryngitis, and bronchitis) occurred more often in young school-age children than in preschool children and more frequently in siblings of school-age children than in preschool children without such siblings.[103] Secondary attack rates of common respiratory diseases averaged 25 percent, were highest in children younger than 5 years (37-49%), and were similar in preschool children with or without siblings in school.

The epidemiology of some acute respiratory diseases also may be changing. Transmission varies both with levels of immunity and with opportunities for exposure of susceptible persons. A comparison of the Cleveland family study data with data from a more recent longitudinal study of children in daycare suggested that out-of-home childcare may be lowering the age of first exposure to and infection with acute respiratory pathogens.[102] Young children in daycare are more likely than children in home care to have more than six upper respiratory tract infections per year and more than 60 days of illness per year.[314] In a study of lower respiratory tract infections in children younger than 2 years, children hospitalized with lower respiratory tract infection were three times more likely to have received care in a daycare center attended by six or more children.[11] A Japanese study evaluated the carriage rates of respiratory bacterial pathogens in children attending daycare centers and found high colonization rates by respiratory bacterial pathogens (especially by antibiotic-resistant strains), suggesting horizontal spread among children in daycare centers. More than 50% of children carried more than one pathogen.[222] Not surprisingly, crowding in the child's home also was observed to be an independent factor that increased the risk of acquiring respiratory disease.

In the Seattle Virus Watch study of family spread of influenza virus in 1972, school-age children were the most likely family members to acquire community-acquired infection and then to introduce the infection into the household; they also were most at risk for spread from other family members (57-63% secondary attack rate).[124] However, secondary attack rates among all household members were highest (70-75%) when the introducer was younger than 5 years. For infants in the first year of life, the risk of acquiring influenza infection is related to the number of siblings in the household.[140] Studies using laboratory confirmation of transmission of influenza confirm the importance of disease transmission from children to their parents (attack rate, 13.6%) and their siblings (attack rate, 19.9%) and support the recent 2008 recommendations of the Advisory Committee on Immunization Practices (ACIP) of the CDC to expand the routine age of annual influenza vaccination to children aged 6 months to 18 years.[263] Much attention has been placed recently on the role of children in the spread of influenza viruses to family members and the community, especially with respect to pandemic influenza planning.

Parvovirus B19 infection appears to be transmitted effectively within families, with a secondary attack rate of 50 percent among close contacts; the risk of transmission seems to decrease with advancing age.[73,187] The risk for pregnant women to acquire acute parvovirus B19 infection increases with an increasing number of children in the household. Having children 6 to 7 years old resulted in the highest risk for acquiring acute infection in these mothers.[193] Preschool-age children, especially those in daycare, may introduce cytomegalovirus infection into the family, infect seronegative mothers-to-be, and thereby pose a risk to the fetus if the woman with cytomegalovirus infection is pregnant.[250] The risk of transmission of cytomegalovirus from child to mother is greatest if the child is younger than 20 months.[3]

Several novel respiratory viruses recently have been associated with acute respiratory infection in humans. A new disease caused by a human coronavirus, SARS, was introduced into the world in the fall of 2002. Between November 2002 and July 2003, more than 8000 cases, with almost 800 deaths, occurred in 32 countries. Children had less severe morbidity and lower mortality rates compared with adults. The virus was thought to be transmitted by the respiratory route, mostly through large droplets.[201,319] Household transmission from a known SARS case occurred at a secondary average attack rate of 14.9 percent, although mostly among adults in one Hong Kong study.[197] Another newly studied respiratory virus, human metapneumovirus, is thought to play an important role in infections in young children, having a spectrum of disease similar to that of respiratory syncytial virus.[320] Information on the epidemiology of this RNA virus in families is still being evaluated. Two other paramyxoviruses that cause encephalitis and respiratory tract disease in humans, Hendra and Nipah viruses, have been identified recently in Australia and Malaysia. Neither of these viruses has caused pediatric infections to date.[319]

The potential spread of other strange and newly emerging or potentially emerging diseases within families was illustrated recently during an outbreak of monkeypox (a zoonotic DNA double-stranded orthopoxvirus) in the Midwestern United States in June 2003.[285] Transmission occurs primarily by large droplets or direct contact, although the disease is much less transmissible than is smallpox. In this small outbreak of 37 human infections, one cluster of three cases occurred in the same family, mostly through person-to-person transmission.

The spread of some enteric diseases within the family also has been studied. In two community outbreaks of shigellosis, Weissman and associates[317] found that in 86 percent of families, the bacterium was introduced by a child younger than 10 years. The secondary attack rate averaged 31 percent and was highest in children younger than 5 years. The secondary attack rate was significantly higher in families with an initial case in a preschool-age child than in families with an initial case in an older person. Spread within the family did not correlate with family size or household crowding but appeared to be highly dependent on whether an ill preschool-age child was in the family.

After a food-borne outbreak of Norwalk virus (now referred to as norovirus) gastroenteritis associated with a school cafeteria occurred, secondary transmission was reported in 44 percent of the households with a primary case. In households with a primary case, the risk for occurrence of secondary illness was twice as high among preschool-age children (70% attack rate) as among adults (31%); other investigators have found lower attack rates in households, ranging from 15 to 26 percent.[101,160,167] de Wit and colleagues[101] showed that a risk factor for development of norovirus

gastroenteritis was having a household gastroenteritis contact, with that risk being slightly higher if the household contact was a child rather than an adult. Another outbreak in 2004 among 191 children who acquired norovirus after playing in a recreational water fountain found that in 111 families in which information was complete, the secondary attack rate for illness was 15 percent and occurred mostly among parents (74%) of the affected schoolchildren.[167] As expected, risk for spread of illness into households was higher if the primary case was a child.[141]

Poliovirus seems to spread more readily than does *Shigella* in families. Gelfand and associates[134] studied household contacts of children found to have wild poliovirus infection. Among household contacts, evidence of recent infection, usually no later than 1 month after that in the index child, was found in 73 percent of adults, 96 percent of older siblings, and 84 percent of younger siblings. By studying the spread of live poliomyelitis vaccine virus strains in families, they found a secondary infection rate among susceptible persons of 53 percent in a lower economic group and 9 percent in a higher economic group.[135] Secondary infection rates were higher with type 3 poliovirus (77%) than with type 1 (47%) or type 2 (36%). Virus appeared to spread more readily from those with pharyngeal excretion and less readily from adults than from children.

In the older study of Cleveland families, generically termed "infectious gastroenteritis" was introduced most commonly by children younger than 6 years.[103] The secondary attack rate averaged 11 percent and was highest in children younger than 8 years. The secondary attack rate was related directly to the number of major gastrointestinal symptoms (vomiting, diarrhea, and abdominal pain) suffered by the index case: 10 percent for contacts of those with one symptom, 16 percent for contacts of those with two, and 32 percent for contacts of those with all three.

Helicobacter pylori infections cluster within families, and the family is the most important source for transmission.[108] Families of children with *H. pylori* infection identified in the gastric antrum after endoscopy were studied for the presence of *H. pylori* antibody. Seventy-four percent of the parents of infected children were seropositive, compared with 24 percent of the parents of uninfected children; 82 percent of the siblings of infected children also were positive. In addition, in a study conducted among 241 sibling and nonsibling children aged 2 to 18 years, compared with children with no infected siblings or nonsiblings and adjusting for age, the odds of acquiring *H. pylori* infection were 2.3, 3.2, and 9.4 for children residing with at least one infected nonsibling, one infected sibling, or at least one infected sibling and one nonsibling, respectively. This study thereby implicates intersibling transmission as a route of *H. pylori* infection in childhood as well.[133] Another study also corroborated that having an infected mother or at least one infected sibling was a risk factor, whereas the influence of infected fathers was nonsignificant.[185] A study of 215 adults in England found an association between seropositivity for *H. pylori* antibodies and a history of crowded living conditions in childhood.[226] However, another study did not find crowding to be a risk factor, nor was the size of the family.[185]

In a community-wide study of rotavirus transmission, children younger than 2 years were most likely to introduce the infection into the family.[188] In persons living in households with a child younger than 2 years, the risk of becoming infected was 2.9 (for adults) to 3.5 times (for children 10 to 17 years of age) higher than that for persons of comparable age in other families. A similarly high risk of household transmission (21%) was found if a young child had rotavirus in the home.[101] Young children attending daycare centers also are likely to introduce infections associated with parasitic enteropathogens into their families. A study in Houston, Texas, found a 17 percent secondary attack rate for giardiasis in families with a child who became infected in daycare facilities.[256] At least one secondary case of giardiasis was identified in 47 percent of all households with a *Giardia*-infected child during an outbreak at a Washington, DC, daycare center.[258] During an outbreak of diarrheal disease at a daycare center in Oklahoma, stool samples were positive for *Cryptosporidium* in 23 percent of the household contacts of children with confirmed *Cryptosporidium* infection.[156] *Cryptosporidium parvum* has family transmission and infectivity rates as high as those of *Shigella*, which has added concern in countries where the prevalence of family HIV seropositivity is high and in whom the parasite can cause more severe morbidity.[240]

Young children may acquire asymptomatic hepatitis A infection in daycare centers and transmit this infection to adult household contacts, who may become quite ill.[312] In a population with a low prevalence of hepatitis A, adults who lived in the same household with children of primary school age were at increased risk of acquiring the infection during community outbreaks, with the risk increasing as the number of primary school–age pupils sharing the household increased.[273] Households with a primary school–age child had better than a threefold higher risk of having hepatitis in an unmatched analysis. The epidemiology of this disease will change as well with the recent ACIP recommendation for routine vaccination of all children aged 1 year to 18 years with hepatitis A vaccine.[65]

International adoptees may introduce infectious diseases that are endemic in the child's country of origin into families that might otherwise not be at risk. In one study, parents of hepatitis B surface antigen (HBsAg)–seropositive adopted children were five times more likely to have serologic evidence of hepatitis B virus infection than were parents of HBsAg-seronegative adoptees.[130] Children from various countries also have been shown to have tuberculosis, cytomegalovirus infection, congenital syphilis, and infections with enteric pathogens when they join their adopted families.[171] Careful screening has been recommended for such children to identify and to treat these infections and thereby to prevent transmission.[231]

SCHOOLS

A well-known fact is that infectious disease agents are transmitted easily among children in daycare centers. Lu and colleagues[211] showed that risks of acquiring diarrheal disease and upper respiratory tract infection in children who attended daycare centers are greater than those in home-schooled children; the difference was most significant for children younger than 1.5 years. Interventions that have proved valuable for reducing the incidence of infections within childcare centers include the following: formal written policies for infection control within the childcare center, formal education of staff in childcare centers concerning infection control practices, practice of good hand hygiene by both staff and children, appropriate cleaning of contaminated surfaces, separation of food preparation and diaper changing areas, exclusion of certain ill children, cohorting of ill children when exclusion is not possible, adequate age-appropriate immunization of childcare attendees and staff, and optimal ratios of children to staff.[29]

Evans and Maguire[117] summarized 95 reported outbreaks of infectious intestinal disease in schools and nurseries in England and Wales between 1992 and 1994 (7% of 1280 reported outbreaks). The most common pathogens were *Salmonella*, *Shigella sonnei*, and noroviruses. The mode of transmission was mainly from person to person in 55 outbreaks and mainly food-borne in 30. The mean attack rate was 30 percent, and median duration was 10 days; the attack rate and duration varied with the pathogen involved. Forty-five (1.5%) of the 3118 people reported ill were admitted to the hospital. The authors concluded that outbreaks

in schools and nurseries are common occurrences, attack rates are high, and such outbreaks often are prolonged. Effective infection control policies and appropriate training of staff are needed.

A CDC study of meningococcal disease in schools between January 1989 and June 1994 identified 22 clusters in 15 states.[327] Three quarters of the school clusters occurred in secondary schools. The estimated incidence of secondary meningococcal disease among schoolchildren aged 5 to 18 years was 2.5 per 100,000 population, a relative risk of 2.3. More than 70 percent of secondary cases occurred within 2 weeks of the index case. Surveillance in preschool and school settings in England and Wales during the course of a 6-year period identified 114 clusters of meningococcal disease; 20 clusters were reported in preschool settings, 43 in primary, 46 in secondary, and 5 in independent schools.[100] The relative risk for development of more cases in the 4 weeks after a single case occurred compared with the background rate was raised in all settings, ranging from a relative risk of 27.6 in preschool settings to a relative risk of 3.6 in secondary schools. Most (68%) secondary cases occurred within 7 days of the first case. Although risk for occurrence of more cases of meningococcal disease in schools was higher, especially in preschool settings, whether widespread use of antibiotics after single cases reduces risk of more cases could not be determined. College students, particularly freshmen living in dormitories, have an increased risk of acquiring meningococcal disease, and the recommendation of the American Academy of Pediatrics is that these students and their parents be informed of this increased risk and that vaccination with the quadrivalent conjugate meningococcal vaccine be offered.[16,254]

Attack rates of shigellosis during a group of outbreaks in elementary schools ranged from 0.4 to 1.1 percent; the higher values occurred in schools with larger numbers of children younger than 8 years.[307] Enforced handwashing and disinfection of items potentially contaminated with feces have been associated with control of a shigellosis outbreak in an elementary school.[136]

Typically, spread in schools is less than that in families. In a measles outbreak that involved children in 20 of 26 classrooms in one school, the attack rate in unimmunized pupils with no history of measles was only 16 percent.[97] Landrigan[195] observed in a community outbreak that measles spread most quickly in situations in which unvaccinated children were brought together for the first time; in urban areas, such spread occurred in daycare centers and nursery schools, whereas in rural areas, where children seldom attended daycare centers, it occurred in elementary schools. Measles spread rapidly in a school with children ranging in age from 5 to 14 years due to a high personal belief exemption policy.[63] Although it no longer is endemic in the United States, measles continues to be imported. An outbreak in a boarding school started from a student who returned from the Middle East and caused 11 confirmed cases, including 9 students in the school. High coverage with two doses of measles-containing vaccine among students was effective in limiting the extent of the outbreak.[51] Health care providers should maintain a high index of suspicion for measles, especially in those who have traveled abroad recently, and recommendations for two doses of measles-containing vaccine in all school-age children should be followed.

Schools may serve to spread infection from family to family. In outbreaks of measles, mumps, and pertussis, children infected within classroom settings appear to have spread disease to younger siblings at home. These outbreaks have occurred in school settings in which a high proportion of students have been immunized previously.[32,219,233] In outbreaks of measles and mumps, failure of the vaccine to evoke a protective immunologic response (primary vaccine failure) has been a more significant factor resulting in susceptibility to infection than has waning immunity from previous successful vaccination (secondary vaccine failure).[105,112] Failure of primary coverage due to shortage of measles-mumps-rubella (MMR) vaccine resulted in a large cohort of United Kingdom children in the mid-1990s receiving only MR, thus remaining susceptible to mumps; a large outbreak among young adults 18 to 25 years old occurred in 2004 to 2005 as a result.[57] A large outbreak in the United States in 2006, however, was due to a combination of primary and secondary vaccine failure.[88] Pertussis outbreaks are being recognized increasingly in schools, with a substantial proportion of cases occurring among older children and adolescents, with subsequent spread to the community.[61,74] Waning immunity has been shown to be a particular problem leading to susceptibility to pertussis in adolescents and adults[157]; the American Academy of Pediatrics Committee on Infectious Diseases now recommends that adolescents 11 to 18 years of age receive a booster dose of acellular pertussis vaccine.[6,33]

Miller and associates[232] described a diphtheria outbreak in an elementary school in which 34 percent of all students were found to be infected and clinical diphtheria developed in 30 percent of the unimmunized students. The reason for the intense spread was not found.

The absence of tuberculosis infection and disease among children is a key indicator of a community's success in interrupting the transmission of tuberculosis.[26] The resurgence of tuberculosis in the United States in 1985 to 1992 included a reversal of the long-term decline in the incidence of tuberculosis among children, which indicated a failure of the public health system to prevent transmission of the disease. A study of 165 children with tuberculosis in California in 1994 found that for 59 (37%), an adult source-case was identified.[209] Factors that contributed to transmission to children included delayed reporting, delayed initiation of contact investigations, and poor management of adult source-cases. Improvements in contact investigations might have prevented 17 (10%) of those cases.

Although most pediatric tuberculosis infection is caused by adults with active disease, outbreaks of tuberculosis in children have been reported[180,297]; in most cases, the outbreaks occurred in schools. Widespread tuberculin skin test (Mantoux) screening of school-age children has been shown not to be cost-effective[234]; screening is recommended only for groups of children considered to be at high risk for development of infection.[30,252] Recent review articles highlight the importance of caring for the child's disease in the context of the family and community.[120,215,216]

Settings that result in a greater level of person-to-person contact than is found in typical classroom settings, such as participation in school sports[79,235] or attendance at a boarding school (or summer camp), also can result in more efficient transmission of disease.[34,283] Outbreaks of community-associated MRSA have occurred among football teams at both the high-school and college levels.[241,271]

The number of varicella outbreaks in childcare settings and schools has declined since initiation of varicella immunization in the United States in 1995, but problems remain.[69] One-dose varicella vaccination does not provide sufficient herd immunity levels to prevent outbreaks in school settings, where exposure can be intense. Furthermore, transmission of varicella among vaccinated children is effective, and the difficulty in establishing the diagnosis of mild cases in vaccinated persons hinders early implementation of control measures.[210] Vaccine failure is associated with administration to children younger than 19 months, administration to children with eczema, and a longer time since immunization.[151,199] Furthermore, as one dose of varicella vaccine was deemed insufficient to prevent school outbreaks and to allow a further decrease in related morbidity and mortality,[210] the ACIP recommended in June 2006 a two-dose varicella vaccination for children and a second-dose, catch-up program for children, adults, and adolescents who previously had only one dose.[324]

FOOD- AND WATER-BORNE ILLNESSES

According to a 1999 estimate, food-related disease develops in an estimated 76 million people each year in the United States, thus rendering food safety one of the most important objectives of public health officials.[225] The most common clinical manifestations of food-borne illness are gastrointestinal. The CDC periodically publishes a summary of food-borne illnesses in the United States based on active surveillance by the CDC (FoodNet data)[62] as well as incidence summaries of reported cases and outbreaks of several food-borne diseases.[77] Physicians must work in conjunction with public health officials by confirming diagnoses and promptly reporting findings or suspicions so that food-borne outbreaks can be recognized in a timely fashion to control and to prevent these illnesses most effectively.[45] Proper food preparation, whether it is done commercially or in the home, is critical for community health. Outbreaks have resulted from cross-contamination, improper cooking, and inherently risky raw foodstuffs including unpasteurized dairy products[99,213,313,318]; on occasion, the etiologic agent cannot be identified.[295] Poor personal hygiene may lead to environmental contamination of hands or food, with disastrous consequences.[96] Drinking water, taken for granted in some parts of the world, continues to spread diseases such as norovirus gastroenteritis, giardiasis, cryptosporidiosis, cholera, hepatitis A, and typhoid fever.[227,243,280] Water-borne infections from municipal drinking water are rare events when water companies are well managed and the treatment process includes filtration as well as disinfection.[326] Municipal water systems that draw supplies from open sources such as rivers and lakes are prone to contamination,[28] and ground water sources may become contaminated and cause illness.[90,296]

BIOTERRORISM AND DISASTER RESPONSE

Unfortunately, an important responsibility of public health officials is to help prepare the nation and pediatricians for the possibility of biologic or chemical terrorism and natural disasters. Children have special vulnerabilities to biologic terrorism and chemical agents because of their unique physiology and the limited availability of age-appropriate and weight-appropriate antidotes and treatment.[217,251] In addition, clinicians' lack of familiarity with presenting clinical syndromes from either biologic or chemical exposures can delay establishment of the appropriate diagnosis and initiation of treatment.[94,251] In April 2000, the CDC issued a strategic plan for preparedness and response to biologic and chemical terrorism.[40] Eighteen months later, in October 2001, the first case of intentional exposure to *Bacillus anthracis* was reported in Palm Beach County, Florida. Eventually, 23 cases of anthrax were identified as a result of intentional exposure, predominantly through envelopes containing or contaminated with highly purified anthrax spores. Eleven cases were inhalational and 12 cutaneous (one was pediatric); one cutaneous case was laboratory acquired. Four individuals died.[79,181] Public health officials had to address the public's fear and hysteria after the initial cases were reported. Guidelines for the proper handling of mail and recommendations for rational use of antibiotics, including prophylaxis, were developed quickly and disseminated.[82] Subsequently, autonomous detection systems were developed in postal facilities to detect aerosolized *B. anthracis*.[72] Special recommendations for anthrax prophylaxis were required for children and breast-feeding mothers because ciprofloxacin was the agent of choice for adults and could not be used in these groups.[81,217] Many more cases of anthrax probably were prevented, in part as a result of the rapid response and recommendations of public health officials to this bioterrorist attack. However, certain barriers need to be addressed to fully provide protection for children against biologic and chemical terrorism agents. The Strategic National Stockpile, which is a national repository of antimicrobial agents, chemical antidotes, antitoxins, and other life-support medications and equipment, can stockpile only items licensed by the U.S. Food and Drug Administration (FDA) and only for their FDA-approved indications.[218] Often FDA indications for antimicrobial and other therapeutic agents for children after release of biologic terrorist agents are lacking, causing the stockpile to be deficient in certain therapeutic agents for children.

The CDC also identified smallpox virus as a likely bioterrorism agent and developed guidelines for preparations in case of a threat related to smallpox.[325] On June 21, 2002, the ACIP of the CDC made the following recommendations with respect to smallpox vaccination:

- Under current circumstances, with no confirmed smallpox and the risk of an attack assessed as low, vaccination of the general population is not recommended, as the potential benefits of vaccination do not outweigh the risks of vaccine complications.
- Smallpox vaccination is recommended for persons predesignated by the appropriate bioterrorism and public health authorities to conduct investigation and follow-up of initial smallpox cases that would necessitate direct patient contact.
- Smallpox vaccination is recommended for health care personnel at risk for exposure to the initial smallpox cases in facilities that are pre-designated to receive these patients.

Updated smallpox recommendations are summarized in a recent article.[71] Undoubtedly, as the situation changes and perhaps improved vaccines against smallpox virus and other biologic agents are developed, the CDC and other public health agencies will issue updated recommendations and guidelines for combating and preventing infections related to bioterrorism.

Terrorism preparedness is a unique and, it is to be hoped, rare component of general emergency and disaster preparedness. Since December of 2004 through 2006, several natural disasters of significant proportions have struck the world, causing extreme destruction, loss of lives and property, and potential exposure to infectious diseases.[206] These have included tsunamis in Sri Lanka, Thailand, and Indonesia (2004); earthquakes in Sumatra, Pakistan, and India (2005); powerful hurricanes, Katrina and Rita, in the United States (2005); and volcanic eruptions in El Salvador (2005) and Indonesia (2006). During these disasters, infections can result from compromised personal hygiene; wounds and injuries; contaminated food and water, such as diarrheal disease from viruses (e.g., rotavirus and hepatitis A), parasites, and bacteria (cholera, shigellosis, leptospirosis, typhoid, *Vibrio cholerae* and *Vibrio vulnificus*); and vector-borne diseases. The vector-borne diseases may vary, depending on the location of the disaster, but may consist of West Nile virus, rabies, dengue, and malaria.[206] After hurricanes Rita and Katrina, illnesses caused by *V. vulnificus*, *Vibrio parahaemolyticus*, and nontoxigenic and toxigenic *V. cholerae* were reported.[114,301] These findings underscore the importance of prompt recognition and appropriate management of these often rare diseases by pediatricians during and after disaster situations.

CONTROL METHODS

ISOLATION

Indications for isolation of patients with infectious diseases have changed greatly in this century with increasing knowledge of modes of spread and with antimicrobial therapy, which rapidly renders patients with many diseases noninfectious. Isolation of patients with diphtheria was shown to be of value in Providence,

Rhode Island, in 1904 to 1913 and probably remains so today. The attack rate among family contacts of diphtheria patients treated at home was 6.5 percent, whereas that among contacts of patients treated in the hospital was 4.3 percent; after adjustment for the ages of contacts in the two groups, hospitalization was associated with a 43 percent decrease in cases among household contacts.[106] Heymann's *Control of Communicable Diseases Manual* still suggests strict isolation for pharyngeal diphtheria and contact isolation for cutaneous diphtheria until cultures are negative after cessation of antibiotherapy. Specific therapy has made such institutional isolation unnecessary for some diseases.[161]

Isolation of patients with bacilliferous leprosy, which once was a central part of leprosy control, no longer is necessary because dapsone and rifampin quickly kill most *M. leprae*, thereby rapidly preventing further risk of transmission.

Indications for and techniques of isolating patients in hospitals to prevent nosocomial transmission are discussed elsewhere in this book. An extensive, practical discussion of disease control strategies, including isolation, is readily available in *Control of Communicable Diseases Manual*.[161] The *Red Book Report of the Committee on Infectious Diseases* of the American Academy of Pediatrics also is an important resource for information about isolation recommendations.[255] In most instances, the need for isolation of children at home is occasioned by bacterial respiratory disease, diarrhea, acute viral diseases of childhood, conjunctivitis, contagious skin diseases, and arthropod-borne diseases.

For bacterial respiratory diseases for which therapy rapidly and consistently renders a patient noninfectious, isolation of infected children may be as brief as 1 or 2 days (as for group A streptococcal pharyngitis or meningococcal infections). Isolation of patients known to have pertussis still is recommended for at least 5 days after the initiation of erythromycin or other therapy. For patients with infection or colonization by vancomycin-resistant enterococcus, standard and contact precautions remain in force until culture results from multiple sites (stool, wound, perineal area) are negative on three separate series of cultures obtained at least 1 week apart.[70]

An attempt should be made to limit contamination with the feces of children with diarrhea. Careful handwashing is of great importance, both for the children and for those who take care of them. Clothing and linen contaminated with excreta should be laundered. Adults who are infected with and may be excreting *Salmonella*, *Shigella*, *Yersinia enterocolitica*, hepatitis A virus, or other enterically transmitted pathogens should be excluded from preparing food or providing direct care to young children. (See Chapter 258 for recommendations for excluding children from daycare.)

Indications for isolation of patients with acute viral diseases of childhood depend on the severity of the illness and the degree of contagiousness. No value has been established for isolation for the common acute viral respiratory diseases. For rubella, isolation is recommended only from women in early pregnancy. Currently, children with SARS would be strictly isolated in the hospital even if they are not seriously ill. Isolation of patients with poliomyelitis within the home is of little value because spread occurs most commonly during the prodrome. The same holds true for measles, which spreads efficiently, although the period of communicability can extend until 4 days after the onset of rash, and children with measles should be kept home from school at least that long. Attempts are made to isolate children with varicella and mumps from school for 7 and 9 days, respectively, after the onset of typical illness; these diseases spread less efficiently than measles does.[169] Isolation of children with influenza would also be difficult because most cases are infectious before they are symptomatic.[63] Children with conjunctivitis caused by transmissible agents should be excluded from school during the acute phase of illness. This form of isolation may help limit the spread of *H. influenzae* biogroup *aegyptius*, pneumococci, picornavirus, adenovirus, and *Chlamydia trachomatis*.

Children with contagious skin diseases should avoid having skin contact with other children outside their family. Those with molluscum contagiosum, herpes simplex, impetigo, or MRSA skin infections should avoid engaging in wrestling or other contact sports.[19] Children with MRSA skin infections are becoming increasingly prevalent; in addition to single-case occurrences, these children are also involved in outbreaks on athletic teams, in daycare centers, and in other situations where crowding and skin-to-skin contact occur.[183] Children with scabies should be excluded from school until the day after treatment. Children with tinea corporis should avoid gymnasia, swimming pools, and contact sports.

Children in the early phases of arthropod-borne diseases, when the infecting organism still may be in the blood, should avoid being bitten by the vector. The wide variety of such illnesses includes arboviral diseases, bartonellosis, leishmaniasis, microfilarial infections, malaria, and African trypanosomiasis.

QUARANTINE

In addition to containing the spread of contagious illnesses through isolation, quarantine is another less commonly used control measure. The history and practice of quarantine began in Italy to control plague as early as the 14th century by requiring ships arriving in Venice from infected ports to anchor for 40 days before landing.[39] The Italian word *quaranta*, meaning forty, turned into the commonly used word *quarantine*. Although the term *isolation* refers to separation of people known to have an illness, the strategy of *quarantine* refers to keeping people who have been exposed to an illness but who may or may not be infected away from the general population.[75] Health departments in the past and recent present have used quarantine infrequently for people exposed to illnesses for which they refuse prophylactic treatment (such as vaccine-preventable diseases) or for diseases of historical or medical importance, such as plague, diphtheria, cholera, smallpox, and yellow fever.[206,260] However, not until the arrival in 2002 of SARS, an untreatable infectious viral disease spread mostly by droplets, was this control measure used with regularity. Its effectiveness in decreasing the spread of SARS was aided by the long incubation period of the disease and the fact that the peak of viral shedding was during the second week of illness.[161,177] Contacts of patients suspected of having SARS were placed in quarantine for 10 days.[161] The viral hemorrhagic fever agents (Ebola, Marburg) recently were added as quarantinable diseases along with pandemic influenza. With the possibility of a pandemic influenza strain imminent, the strategy of quarantine as an early containment measure once again has become prominent in some disease control plans.[60]

CHEMOPROPHYLAXIS

The word *chemoprophylaxis* is used in this section to describe the use of antimicrobial agents to prevent acquisition of infection before exposure (as with malaria), to treat asymptomatic infection and thereby to prevent disease (as with isoniazid treatment of tuberculin skin test–positive children), to treat contacts of a proven case before presentation of signs or symptoms in the contacts (as with pertussis), and to treat disease and thereby to prevent its complications (as with primary prevention of acute rheumatic fever). In each situation, the primary purpose is to prevent a disease by administration of an antimicrobial agent that affects the causative microorganism.

The decision to initiate chemoprophylaxis and the choice and dosage of agents require careful consideration of both the child's

clinical status and the epidemiologic factors that may place the child at risk for acquiring the disease. Local public health departments should be notified of exposure to reportable communicable diseases; they may need to conduct an investigation to ensure that all exposed persons have been identified and, when necessary, treated or placed under observation. In addition, they often can provide useful additional information on recommended treatment regimens.

A summary of several diseases for which chemoprophylaxis may be administered to children is given in Table 257–2. Some special situations, such as chemoprophylaxis for immunodeficient children and perioperative prophylaxis to prevent epidemics, are omitted from the discussion. For more detailed discussion of antimicrobial drug use in prevention of disease, one should consult the regularly updated *Red Book* of the American Academy of Pediatrics.[7]

Acute rheumatic fever that occurs after streptococcal pharyngitis can be prevented in 90 percent of patients by administration of repository penicillin.[98,275] Secondary prophylaxis for prevention of bacterial endocarditis after acute rheumatic fever also can be up to 90 percent effective and depends largely on the faithfulness with which an effective drug is taken. For acute glomerulonephritis, one study has suggested that antibiotics will prevent the development of acute glomerulonephritis after group A streptococcal pharyngitis,[265] but the apparent reduction in incidence was not statistically significant. No evidence indicates that administration of antibiotics will prevent the development of acute glomerulonephritis after streptococcal skin infection.[316] Studies to determine the effectiveness of chemoprophylaxis and optimal drug regimens are still needed.[300]

Invasive group A streptococcal infection also is associated with necrotizing fasciitis and streptococcal toxic shock syndrome. For household contacts of index patients, routine screening for and chemoprophylaxis against group A streptococcal infection are not recommended. Providers and public health officials may choose to offer chemoprophylaxis to household contacts who are at an increased risk of contracting sporadic disease or dying of group A streptococcal infection.[153,262]

Cholera typically is not spread from person to person in households. However, in developing countries, if the household secondary attack rate is known to be high, family contacts have been treated prophylactically with tetracycline or doxycycline to prevent illness.[302] Mass treatment of the community never is warranted; improvement of food and water hygiene and attention to rehydration are more important.[277,278] At present, nearly all strains of *V. cholerae* in Bangladesh are resistant to tetracycline, trimethoprim-sulfamethoxazole, and erythromycin. Although the strains are still sensitive to ciprofloxacin, the minimal inhibitory concentration is increasing, and azithromycin and ciprofloxacin are being administered in their place. Patients with cholera recover even without an antibiotic if hydration is maintained, but antibiotics should be used for severely and moderately dehydrated patients to reduce excess losses of fluids and electrolytes and to minimize the supply and logistical requirements for caring for a large patient population. Vaccines are poorly immunogenic, especially in children, and provide modest protection at best.[163]

Prevention of secondary cases of sporadic invasive meningococcal disease depends on rapid identification of close contacts and administration of an effective antibiotic. The risk for spread of meningococcal disease among household contacts of a patient can be reduced by an estimated 89 percent if they take antibiotics known to eradicate meningococcal carriage. In the United States, the primary means for prevention of sporadic meningococcal disease is antimicrobial chemoprophylaxis of close contacts of infected persons.[64] Close contacts include household members, daycare center contacts, and anyone directly exposed to the patient's oral secretions (e.g., through kissing, mouth-to-mouth resuscitation, endotracheal intubation, or sharing of cigarettes or pipes). The attack rate for household contacts exposed to patients who have sporadic meningococcal disease is an estimated four cases per 1000 persons exposed, which is 500 to 800 times greater than for the total population. Because the rate of secondary disease for close contacts is highest during the first few days after onset of disease in the index patient, antimicrobial chemoprophylaxis should be administered as soon as possible (ideally within 24 hours after identification of the index case patient). Conversely, chemoprophylaxis administered later than 14 days after onset of illness in the index patient is probably of limited or no value. Oropharyngeal or nasopharyngeal cultures are not helpful in determining the need for chemoprophylaxis and may unnecessarily delay institution of this preventive measure. Internationally, no uniform recommendations have been established for chemoprophylaxis,[264] and jurisdictions vary with respect to their recommendations for prophylaxis, in the absence of an outbreak, of other types of close contacts and even for the index case. Rapid initiation of a chemoprophylaxis program after two cases of meningococcal disease were identified in a school potentially would have prevented 50 percent of subsequent cases in the clusters described.[327] A European study examined the efficacy of chemoprophylaxis after single cases of meningococcal disease in daycare or nursery settings, comparing countries recommending chemoprophylaxis only to close contacts and those recommending chemoprophylaxis for all children in the same nursery. Results suggested that possible benefit was achieved from mass prophylaxis, although the difference was not statistically significant.[27]

Rifampin, ciprofloxacin, and ceftriaxone are 90 to 95 percent effective in reducing nasopharyngeal carriage of *Neisseria meningitidis*, and all are acceptable alternatives for chemoprophylaxis. However, rifampin is associated with adverse side effects and is not recommended during pregnancy.[281] Systemic antimicrobial therapy for meningococcal disease with agents other than ceftriaxone or other third-generation cephalosporins may not reliably eradicate nasopharyngeal carriage of *N. meningitidis*. If other agents have been used for treatment, the index patient should receive a chemoprophylactic antibiotic for eradication of nasopharyngeal carriage before being discharged from the hospital. Given that the widespread use of rifampin in an outbreak setting might lead to the circulation of isolates resistant to rifampin, use of ciprofloxacin or ceftriaxone should be considered. More trials comparing the effectiveness of ceftriaxone, ciprofloxacin, and rifampin for eradication of *N. meningitidis* could provide important insights.[128]

To prevent gonococcal ophthalmia neonatorum, a prophylactic agent should be instilled into the eyes of all newborn infants; this procedure is required by law in most states. All of the prophylactic regimens listed here prevent gonococcal ophthalmia. However, the efficacy of these preparations in preventing chlamydial ophthalmia is less clear, and they do not eliminate nasopharyngeal colonization by *C. trachomatis*.[76] Ocular prophylaxis is warranted because it can prevent sight-threatening gonococcal ophthalmia and because it is safe, easy to administer, and inexpensive. Recommended regimens include erythromycin (0.5%) ophthalmic ointment in a single application or tetracycline ophthalmic ointment (1%) in a single application. One of these recommended preparations should be instilled into both eyes of every neonate as soon as possible after delivery. If prophylaxis is delayed (i.e., not administered in the delivery room), a monitoring system should be established to ensure that all infants receive prophylaxis. All infants should be administered ocular prophylaxis, regardless of whether they are delivered vaginally or by cesarean section. Single-use tubes or ampules are preferable to multiple-use tubes. Bacitracin is not effective. Use of povidone-iodine has not been studied adequately. The best method for preventing neonatal gonococcal and chlamydial disease is the diagnosis and treatment of gonococcal and chlamydial infections in pregnant women; not all women, however, receive prenatal

TABLE 257–2 Chemoprophylaxis against Communicable Diseases in Children

Disease	Target Group	Value of Chemoprophylaxis	Recommended Drug	Vaccine for Target Group	References
Acute glomerulonephritis	Those with group A streptococcal infection in nephritis outbreaks	Proposed	Benzathine penicillin G IM Penicillin V PO	No	265, 316
Acute rheumatic fever	Those with group A streptococcal infection other than impetigo	Shown	Benzathine penicillin G IM Penicillin V PO Erythromycin PO	No	98, 275, 300
	Those with previous acute rheumatic fever	Shown	Benzathine penicillin G IM Penicillin V PO Sulfadiazine or sulfisoxazole PO Erythromycin PO		
Anthrax	Those exposed in an intentional release	Proposed	Doxycycline PO Ciprofloxacin PO Amoxicillin PO	Yes	49, 176
Chlamydia	Infant born to mother with genitoanal chlamydial infection	Shown	Erythromycin PO Topical antibiotic therapy alone is inadequate and is unnecessary if systemic treatment is administered.	No	76
	Sexual contacts of confirmed cases	Shown	Erythromycin PO Azithromycin PO Doxycycline PO		
Cholera	Close contacts of case	Rarely indicated	Tetracycline PO Doxycycline PO Trimethoprim-sulfamethoxazole PO Furazolidone PO Erythromycin PO	Yes (limited value)	163, 277, 278
Diphtheria	Close contacts	Shown	Erythromycin PO Benzathine penicillin G IM	Yes	119, 224, 244
Gonorrhea	Infant born to mother with gonorrhea	Shown	Ceftriaxone IM Topical antibiotic therapy alone is inadequate and is unnecessary if systemic treatment is administered.	No	76
	Sexual contacts of confirmed cases	Shown	Ceftriaxone IM Cefixime PO Ciprofloxacin PO Ofloxacin PO Levofloxacin PO In a single dose plus treatment for chlamydia if chlamydial infection is not ruled out		
Group A streptococcus	Household contacts	Unknown		No	153
Haemophilus influenzae type b	Index case All household contacts when at least 1 contact younger than 48 months is partially immunized or unimmunized	Shown	Rifampin (contacts) Cefotaxime or ceftriaxone (index case)	Yes	9, 23, 95, 154
Influenza	Close contacts High-risk patients Unvaccinated patients	Shown	Amantadine PO Oseltamivir PO Rimantadine PO Zanamivir inhaled	Yes	4, 152
Leprosy	Household contacts	Shown	Dapsone Rifampicin	No	15, 289
Malaria	Travelers to malarious areas	Shown	Specifics are highly detailed. Consult an authority.	No	14, 50, 125, 144
Meningococcal disease	Close contacts of index case who shared oral secretions	Shown	Rifampin PO Ceftriaxone IM Ciprofloxacin PO	Serogroups A, C, Y, W135	27, 64, 100, 128, 264, 281, 327
	Index case		Same		
Ophthalmia neonatorum (chlamydia and gonorrhea)	Neonate at birth	Shown	Tetracycline ointment Erythromycin ointment	No	76

TABLE 257–2 Chemoprophylaxis against Communicable Diseases in Children—cont'd

Disease	Target Group	Value of Chemoprophylaxis	Recommended Drug	Vaccine for Target Group	References
Pertussis	Close contacts, irrespective of vaccination status	Proposed	Erythromycin PO Azithromycin PO Clarithromycin PO Trimethoprim-sulfamethoxazole PO	Yes	5, 104, 148, 291, 298
Plague	Contacts of pneumonic case Those exposed in an intentional release	Proposed	Ciprofloxacin PO Doxycycline PO Amoxicillin PO	Yes	174
Syphilis	Infant born to mother with syphilis	Shown	Consult an expert. See CDC recommendations.	No	76
	Sexual contact of confirmed case	Shown	Benzathine penicillin G IM		
Tuberculosis	Close contact of a case, Mantoux nonsignificant	Shown	Isoniazid PO Rifampin PO	Bacille Calmette-Guérin (BCG) (limited indications in United States)	44, 78, 290
	Mantoux significant	Shown	Same		
Yaws	Close contact	Shown	Benzathine penicillin G IM Penicillin V PO	No	12, 284

care. For sexually transmitted gonorrhea, partners of case patients should be treated with a drug or drugs that will eradicate the organism at all anatomic sites of exposure, not waiting for test results. Concurrent treatment of chlamydial infection generally also is warranted.[76]

Because the number of tuberculosis cases has dropped in the United States and the disease has became concentrated among persons at high risk in particular subpopulations, consequently, most U.S. children have negligible risk for acquiring latent tuberculosis infection (LTBI).[44] Among children at low risk, most positive tuberculin skin test results are false-positives caused by nonspecific reactivity or exposure to nontuberculous mycobacteria in the environment. False-positive results lead to unnecessary health care expenditures and anxiety for the child, family, school, and health care workers. Thus, whereas the testing of children with an expected high prevalence of LTBI is desirable, mass testing of children with a low prevalence of LTBI is counterproductive and should not be undertaken. The optimal approach is to perform tuberculin skin testing only of those children with specific risk factors for acquiring LTBI, thereby diminishing the number of false-positive results. Factors that have correlated highly with risk for LTBI among children in more than one study include the following: previous positive tuberculin skin test result; birth in a foreign country with high prevalence; nontourist travel to a high-prevalence country for longer than 1 week; contact with a person with tuberculosis; and presence in the household of another person with LTBI. Isoniazid prophylaxis can prevent development of infection in uninfected tuberculin-negative contacts of tuberculosis cases.[290] Isoniazid prophylaxis also has been shown to decrease the incidence of disease in tuberculin-positive children. In certain treatment programs for LTBI among children in the United States, the completion rate associated with 6 to 9 months of self-supervised isoniazid therapy is only 30 to 50 percent. Because LTBI among young children might progress rapidly to tuberculosis disease, daily observed therapy is recommended. The only recommended regimen for treatment of LTBI in HIV-uninfected children is a 9-month course of isoniazid as self-administered daily therapy or by daily observed therapy twice weekly. Routine monitoring of serum liver enzyme concentrations is not necessary but should be considered in children at risk for development of hepatic disease.[78] Children with LTBI, who are most likely to benefit from daily observed therapy because of their high risk for rapid progression of infection to disease, include contacts of persons with recently diagnosed cases of pulmonary tuberculosis, infants and young children, and children with immunologic deficiencies, especially HIV infection.

Chemoprophylaxis of leprosy has been shown in a meta-analysis to be an effective way to reduce the incidence of leprosy, particularly in household contacts.[289] Rifampicin has been the drug tested most often[15]; the role of chemoprophylaxis needs to be re-examined with use of newer drugs, given the continuing case detection rates globally.

Prophylaxis of contacts to pertussis cases has been questioned in recent analyses, although past studies have demonstrated benefits.[104,148] Administration of erythromycin prophylaxis to contacts of pertussis cases during a community outbreak was associated with a decreased likelihood of occurrence of secondary cases, and delays in beginning erythromycin treatment of primary cases and prophylaxis of contacts were associated with increased secondary spread.[291] Similarly, in a study of a pertussis outbreak in an institutionalized population, erythromycin was shown to be effective in reducing the attack rate and severity of disease among exposed persons.[298] Twelve trials with 1720 participants, including 10 trials investigating treatment regimens and two investigating prophylaxis regimens, were summarized in a meta-analysis.[5] Results showed that short-term antibiotics (azithromycin for 3 days, clarithromycin for 7 days, or erythromycin estolate for 7 days) were equally effective with long-term antibiotic treatment (erythromycin estolate or erythromycin for 14 days) in the microbiologic eradication of *B. pertussis* from the nasopharynx. Side effects were fewer with short-term therapy. No differences were noted in clinical improvement or microbiologic relapse between short- and long-term treatment regimens. Contact prophylaxis (of contacts older than 6 months) with antibiotics did not significantly improve clinical symptoms or decrease the number of cases that developed culture-positive *B. pertussis*. The authors con-

cluded that antibiotics are effective in eliminating *B. pertussis* from patients with the disease, rendering them noninfectious, but do not alter the subsequent clinical course of the illness. Effective regimens for both treatment and chemoprophylaxis include 3 days of azithromycin, 7 days of clarithromycin, 7 or 14 days of erythromycin estolate, and 14 days of erythromycin ethylsuccinate. Considering microbiologic clearance and side effects, 3 days of azithromycin and 7 days of clarithromycin are the best regimens. Seven days of trimethoprim-sulfamethoxazole also appeared to be effective for the eradication of *B. pertussis* from the nasopharynx and may serve as an alternative antibiotic treatment for patients who cannot tolerate a macrolide. Evidence was insufficient to determine the benefit of prophylactic treatment of pertussis contacts.

Erythromycin and benzathine penicillin G have been shown to be effective in eliminating pharyngeal carriage of *Corynebacterium diphtheriae* in 92 and 84 percent, respectively, of those treated.[224] The effectiveness of these drugs as chemoprophylaxis against diphtheria has not been studied. However, the high incidence of diphtheria in nonimmune household contacts of cases,[106] the side effects of diphtheria antitoxin, and the delay associated with and the possible false negativity of cultures are points in favor of giving chemoprophylaxis. Because the vaccine is directed against the toxin, immunized persons still may be carriers and become infected; thus, chemoprophylaxis should be administered to all close contacts after nasopharyngeal cultures have been obtained, regardless of immunization status. All close contacts should have samples cultured and be monitored by a public health representative for 7 days.[119] Patients with positive cultures should complete a full course of antimicrobial treatment. Previously immunized contacts should receive a booster dose of vaccine. Active immunization should be initiated for those who have not been immunized fully in the past.[244]

Individuals with primary or secondary pneumonic plague caused by infection with *Yersinia pestis* are potential sources of person-to-person spread, as would be people exposed through the criminal release of plague bacteria by aerosol. Recommendations for the use of antibiotics after exposure to a plague weapon are conditioned by the lack of published trials in treating plague in humans, the limited number of studies in animals, and the possible requirement to treat large numbers of persons. A number of possible therapeutic regimens for treatment of plague have yet to be studied adequately or submitted for approval to the FDA. A working group offered consensus recommendations based on the best available evidence.[174] It recommends that the tetracycline class of antibiotics be used to treat pneumonic plague if aminoglycoside therapy cannot be administered, which might be the case in a mass exposure scenario when parenteral therapy is either unavailable or impractical. Doxycycline would be considered pharmacologically superior to other antibiotics in the tetracycline class for this indication because it is well absorbed without food interactions, is well distributed with good tissue penetration, and has a long half-life. The fluoroquinolone family of antimicrobials has demonstrated efficacy in animal studies against plague. In studies of mice with experimentally induced pneumonic plague, ciprofloxacin has been demonstrated to be at least as efficacious as aminoglycosides and tetracyclines. In vitro studies also suggest equivalent or greater activity of ciprofloxacin, levofloxacin, and ofloxacin against *Y. pestis* compared with aminoglycosides or tetracyclines. However, no trials of the use of fluoroquinolones in human plague have been performed, and they are not FDA approved for this indication. Thus, in a setting requiring mass postexposure prophylaxis, the drugs of choice are doxycycline, ciprofloxacin, and chloramphenicol; the same holds for pregnant women. However, physicians have recommended that ciprofloxacin and other fluoroquinolones not be used in children younger than 16 to 18 years because of a link to permanent arthropathy in adolescent animals and transient arthropathy in a small number of children, and chloramphenicol should not be given to children younger than 2 years. No comparative studies assessing efficacy or safety of alternative treatment strategies for plague in children have or can be performed. Given these considerations, the working group recommends that children in the contained casualty setting receive streptomycin or gentamicin. In a mass casualty setting or for postexposure prophylaxis, doxycycline is recommended.[174]

Mass campaigns of treatment of patients with yaws and their community contacts have been successful in markedly decreasing the prevalence of the disease, although transmission has not been stopped completely.[12,284]

Prevention of malaria generally is discussed in terms of prophylaxis among nonimmune travelers visiting regions of the world where malaria remains endemic. New concepts of mass treatment in high-risk regions also are being explored by some researchers.[144] For short-term prevention, chloroquine is effective prophylaxis against malarial parasitemia caused by *Plasmodium vivax*, *Plasmodium ovale*, *Plasmodium malariae*, and chloroquine-sensitive strains of *Plasmodium falciparum;* however, chloroquine resistance of *P. falciparum* has spread to most areas of the world with malaria.[50] Thus, persons anticipating travel to areas with chloroquine-resistant *P. falciparum* must weigh carefully the risks of acquiring disease and the problems associated with prophylaxis for small children and pregnant women.[14,125] Health care providers needing assistance with diagnosis or management of suspected cases of malaria should call the CDC Malaria Hotline, 770-488-7788 (Monday to Friday, 8 AM to 4:30 PM, Eastern time); for emergency consultation after hours, call 770-488-7100 and request to speak with a CDC Malaria Branch clinician. Detailed recommendations for prevention of malaria also are available on the Internet at *http://www.cdc.gov/travel/diseases.htm#malaria*.

P. vivax and *P. ovale* have an extra-erythrocytic (hepatic) form, and thus relapse may occur after chloroquine therapy has been stopped. Primaquine, taken as terminal prophylaxis after leaving the malarious area, decreases the risk of having relapses; however, it may cause severe hemolysis in persons with glucose-6-phosphate dehydrogenase deficiency. The decision to give terminal prophylaxis with primaquine depends on individual factors, including the degree of the traveler's risk of acquiring *Plasmodium* with an extra-erythrocytic form and the potential for having adverse reactions; primaquine generally is indicated for persons who have had prolonged exposure in endemic areas.

Four antiviral drugs are available for treatment and prophylaxis of influenza; FDA approval differs by strain of influenza (type A or type B) and by the patient's age. Surveillance of circulating strains of influenza A viruses found increasing amantadine- and rimantadine-resistant viruses after 2005. Therefore, those antivirals should not be used as first-line drugs for either treatment or prophylaxis of seasonal influenza. Zanamivir and oseltamivir are chemically-related antiviral drugs known as neuraminidase inhibitors that have activity against influenza A and B viruses alike. Both zanamivir and oseltamivir were first approved in 1999 for treatment of uncomplicated influenza virus infections; shortly thereafter resistant strains of influenza began to be detected. Neuraminidase inhibitor resistance remained low in the United States through the 2006-2007 influenza season. In 2007-2008, increased resistance to oseltamivir was reported among A (H1N1) viruses in many countries.[323a] In the United States, approximately 10 percent of influenza A (H1N1) viruses, no A (H3N2) viruses, and no influenza B viruses were resistant to oseltamivir during the 2007-2008 influenza season. No viruses resistant to zanamivir were identified.[47a] Zanamivir is now approved for chemoprophylaxis of children 5 years of age or older and for treatment of influenza among children 7 years of age or

older; it is administered by inhaler.[63a] Oseltamivir is approved for treatment and chemoprophylaxis among persons 1 year of age or older. Recommended treatment and chemoprophylaxis dosages of oseltamivir for children vary by the weight of the child. Consult with the Centers for Disease Control and Prevention for oseltamivir and zanamivir dosages and current information about antiviral resistance. One study determined the efficacy of postexposure prophylaxis and treatment of ill index cases with oseltamivir in an attempt to prevent influenza transmission in households randomized to receive treatment (5 days) if illness developed or postexposure prophylaxis for 10 days.[152] Postexposure prophylaxis provided a protective efficacy of 59 percent for households against proven influenza and 68 percent for individual contacts, compared with treatment of index cases alone. Postexposure prophylaxis of household contacts of those with influenza reduces the secondary spread of influenza in families when the initial household case is treated. This study included 129 exposed children aged 1 to 12 years, for whom postexposure prophylaxis protection was slightly lower at 55 percent.

The use of antiviral drugs for treatment and chemoprophylaxis of influenza is a key component of influenza outbreak control in institutions. In addition to antiviral medications, other outbreak-control measures include instituting droplet precautions and establishing cohorts of patients with confirmed or suspected influenza, reoffering influenza vaccinations to unvaccinated staff and patients, restricting staff movement between wards or buildings, and restricting contact between ill staff or visitors and patients. The majority of published reports concerning use of antiviral agents to control influenza outbreaks in institutions are based on studies of influenza A outbreaks among nursing home populations that received amantadine or rimantadine. Less information is available concerning use of neuraminidase inhibitors in influenza A or B institutional outbreaks. When confirmed or suspected outbreaks of influenza occur in institutions that house persons at high risk, chemoprophylaxis should be started as early as possible to reduce the spread of the virus. In these situations, having preapproved orders from physicians or plans to obtain orders for antiviral medications on short notice can substantially expedite administration of antiviral medications. When outbreaks occur in institutions, chemoprophylaxis should be administered to all residents, regardless of whether they received influenza vaccinations during the previous fall, and should continue for a minimum of 2 weeks. If surveillance indicates that new cases continue to occur, chemoprophylaxis should be continued until approximately 1 week after the end of the outbreak. The dosage for each resident should be determined individually. Chemoprophylaxis also can be offered to unvaccinated staff members who provide care to persons at high risk. Chemoprophylaxis should be considered for all employees, regardless of their vaccination status, if the outbreak is suspected to be caused by a strain of influenza virus that is not well matched to the present vaccine.

Guidelines for which populations would require postexposure prophylaxis to prevent inhalational anthrax after the release of a *B. anthracis* aerosol as a biologic weapon will need to be developed by public health officials, depending on epidemiologic circumstances. These decisions would require estimates of the timing, location, and conditions of the exposure. Ongoing case monitoring would be needed to define the high-risk groups, to direct follow-up, and to guide the addition or deletion of groups requiring postexposure prophylaxis. Ciprofloxacin, doxycycline, and penicillin G procaine are approved by the FDA for postexposure prophylaxis of inhalational anthrax. Therefore, for postexposure prophylaxis, the same antibiotic regimen as that recommended for treatment should be used for prevention; prophylaxis should be continued for at least 60 days after exposure. As noted previously, ciprofloxacin and other fluoroquinolones should not be used in children younger than 16 to 18 years because of a link to permanent arthropathy in adolescent animals and transient arthropathy in a small number of children. However, as with mass prophylaxis for plague, balancing these risks against the risks of anthrax infections caused by an engineered antibiotic-resistant strain, an expert panel recommends that ciprofloxacin be used as a component of combination therapy for children with inhalational anthrax. For postexposure prophylaxis or after a mass casualty attack, monotherapy with fluoroquinolones is recommended by the working group.[49] The American Academy of Pediatrics has recommended that doxycycline not be used in children younger than 9 years because the drug has resulted in retarded skeletal growth in infants and discolored teeth in infants and children.[5a] However, the serious risk of acquisition of infection after an anthrax attack supports the consensus recommendation that doxycycline, instead of ciprofloxacin, be used in children if antibiotic susceptibility testing, exhaustion of drug supplies, or adverse reactions preclude use of ciprofloxacin. According to the CDC recommendations for the bioterrorist attacks in 2001, in which *B. anthracis* was susceptible to penicillin, amoxicillin was a suitable alternative for postexposure prophylaxis in infants and children.[81,176] In a contained casualty setting, the working group recommends that children with inhalational anthrax receive intravenous antibiotics. In a mass casualty setting and as postexposure prophylaxis, the working group recommends that children receive oral antibiotics. The United States anthrax vaccine is licensed for use only in persons aged 18 to 65 years because studies to date have been conducted exclusively in this group. No data exist for children, but on the basis of experience with other inactivated vaccines, the vaccine probably would be safe and effective.

Since the introduction of a conjugate vaccine against *H. influenzae* type b in the United States and other countries, rates of invasive disease have plummeted to almost undetectable levels.[23] Developing countries with effective vaccine programs have experienced similar success.[95] Prophylaxis is indicated for household and close contacts to a case of *H. influenzae* type b infection when an unimmunized or partially immunized child younger than 4 years has been exposed.[9] Replacement of type b strains with other invasive serotypes has been documented[154]; however, no proven benefit has been shown for antibiotic prophylaxis for strains other than type b.

DRINKING AND RECREATIONAL WATER

Provision of a safe water supply is a major public health function that factors in preventing water-borne communicable diseases as well as exposure to chemicals such as heavy metals and pesticides. Purification of water occurs both naturally and through human intervention. Natural methods include evaporation and condensation, filtration through the earth, and a series of processes acting during the flow of a stream or on standing: aeration, light-accelerated plant growth, gravity, and oxidation and reduction of organic material by bacteria.[245] Municipal water treatment programs use a variety of measures, including protection of the watershed, chemical disinfection, and filtration of surface water supplies such as lakes and rivers, to ensure the safety of community water supplies.[326] Failure in one of these systems can result in widespread outbreak of water-borne disease.[198] Although many such outbreaks involve a few dozen to a few hundred persons, more than 400,000 cases of illness may have resulted from an outbreak of cryptosporidiosis in Milwaukee, Wisconsin, in 1993.[212] The outbreak was associated with a marked increase in turbidity of the water supply and failure of coagulation and filtration at the water treatment plant to remove oocysts of *Cryptosporidium* from the treated water. An outbreak of toxoplasmosis occurred in Greater Victoria, British Columbia, Canada, in 1995,

resulting in at least 100 cases, including children and 38 pregnant or postpartum women (nearly 1% of all pregnant women)[28]; unfiltered surface water contaminated by rain run-off was blamed for the contamination. Since 1971, the CDC and the Environmental Protection Agency have maintained a voluntary surveillance system for the reporting of water-borne disease outbreaks.[24] The factors apparently resulting in these outbreaks include treatment deficiencies, use of untreated ground water, deficiencies in the distribution system, and use of untreated surface water. An increasingly important problem is the occurrence of outbreaks of water-borne disease associated with recreational water use, as for swimming or wading,[38,214,259] hot tubs and spas,[192,268] water parks,[59] and decorative fountains.[164] Diseases transmitted in this manner include shigellosis, cryptosporidiosis, norovirus gastroenteritis, viral conjunctivitis, giardiasis, legionellosis, enterohemorrhagic *E. coli* O157:H7 gastroenteritis, and *Pseudomonas* dermatitis.[326] Although cryptosporidiosis and giardiasis cases can occur sporadically, outbreaks of each disease are well documented. During the years 1991 to 2000, *Cryptosporidium* was identified as a causal agent of 38 percent (40 of 106) of reported cases of recreational water–associated outbreaks of gastroenteritis of known and suspected infectious etiology.[165] During the same period, *Giardia* was identified as a causal agent of 9.4 percent (10 of 106) of reported cases of recreational water–associated and 16 percent (21 of 130) of reported drinking water–associated outbreaks of gastroenteritis of known or suspected infectious etiology.[166] Deaths may occur, especially with cases of primary amebic meningoencephalitis caused by *Naegleria* infection in persons who recently have been swimming.[66]

MILK SANITATION

Milk has been demonstrated as the vehicle of transmission in outbreaks of brucellosis, tuberculosis, and diphtheria as well as in outbreaks of diseases caused by group A streptococci, *Salmonella*, *Shigella*, *Campylobacter*, *Listeria*, *Y. enterocolitica*, and staphylococcal toxin.[261] Although the quality of milk has improved steadily in the United States[246]—largely through mechanization and sanitation of milking operations, pasteurization, and cold storage—the use of raw milk as a "health food" continues to account for outbreaks of disease, particularly outbreaks caused by *Salmonella* and *Campylobacter*.[55,202] Children sometimes drink raw milk while visiting dairy farms on school field trips or other youth activities; a retrospective survey of state health departments identified 20 outbreaks involving a total of 458 cases of *Campylobacter* enteritis occurring as a result of such activities during the period 1981 to 1990.[322]

The quality of milk is monitored by a standard bacterial plate count, the phosphatase test (an assay for prior pasteurization), and measurement of the density of coliform organisms.[127] Nonetheless, pasteurized milk has been associated with outbreaks of enteric disease and listeriosis.[123,207] Both post-pasteurization contamination at the dairy[276] or in transit[158] and intrinsic bovine contamination with survival of organisms despite adequate pasteurization[248] have been suggested as possible mechanisms of transmission. The incidence of outbreaks of milk-borne disease has decreased greatly in the past 40 years in the United States. From 1993 to 1997, fewer than three milk-borne outbreaks per year were reported for the entire country.[247]

FOOD SANITATION

Foods other than milk have been shown to be the vehicle of transmission in numerous outbreaks caused by a wide range of bacteria, viruses (hepatitis A, noroviruses), and parasites, in addition to many naturally occurring toxins and man-made chemicals. Several reports of illness associated with tortillas have been published.[54] The incubation period is short (<24 hours), and the dominant symptoms are headache and nausea. These characteristics suggest an as yet unidentified preformed toxin or chemical agent. Rarely, the contamination is done with criminal intent.[36,309] Major public health programs in the United States involving inspection of meat and poultry, shellfish sanitation, and inspection of public eating and drinking places have had a significant impact, notably in reduction of the incidence of tuberculosis and brucellosis in cattle and limitation of spread of typhoid, hepatitis A, and vibriosis by contaminated shellfish. Significant problem areas remain, however, such as in schools. From 1973 through 1997, states and local health departments reported 604 outbreaks of food-borne disease in schools, with a median number of 25 outbreaks annually (range, 9 to 44). In 60 percent of the outbreaks, a cause was not determined; in 45 percent, a specific food vehicle of transmission was not determined. *Salmonella* was the pathogen most commonly identified, accounting for 36 percent of outbreak reports with a known etiology. The most commonly reported food preparation practices that contributed to these school-related outbreaks were improper food storage and holding temperatures and food contaminated by a food handler.[99]

Inherent contamination of meat, poultry, and eggs with *Salmonella*, *Yersinia*, Shiga toxin–producing *E. coli*, *Listeria*, and other pathogens and deficiencies in food storage and preparation both in eating establishments and in the home still contribute to outbreaks and sporadic cases.[20,200,282,293] Several outbreaks of *E. coli* O157:H7 infection and hemolytic-uremic syndrome have been related to apple juice,[93,162] lettuce,[266] spinach,[58] and other food items. In addition, new problems can result from changes in the food industry and in patterns of food consumption.[155,249] Since the 1970s, several large outbreaks of salmonellosis have been associated with the widespread distribution of fresh produce, a previously rare vehicle of *Salmonella* transmission.[56] These outbreaks have occurred after notable increases during the past 2 decades in the per-capita consumption of fresh fruits and vegetables in the United States.[288] Larger, centralized production and processing facilities with extensive distribution networks may increase the number of persons affected when commercial products do become contaminated. In a global economy, the importation of food from resource-poor countries is another source of contaminated food. For example, multistate outbreaks have been linked to the importation of foods, such as cyclosporiasis associated with raspberries from Guatemala[159] and strawberries from Mexico contaminated with hepatitis A virus.[173] Adequate cooking of foods, proper canning techniques (both commercial and home), and refrigeration are major contributors to control of outbreaks of food-borne disease. In approximately half of the outbreaks of food-borne disease, one or more food preparation practices are reported to be contributing factors; improper storage or holding temperature is reported in approximately two thirds of these outbreaks, and poor personal hygiene of the food handler in approximately two fifths.[247]

Although the number of outbreaks reported to public health authorities represents only a small fraction of those that occur, these reports can provide important insight into the epidemiology of food-borne disease. From 2000 to 2004, the number of outbreaks and the number of cases reported annually remained relatively constant (Table 257–3). The specific cause is confirmed in approximately 30 percent of all outbreaks, and of these, bacterial pathogens, particularly *Salmonella*, account for the majority. Other infectious etiologic agents include *Clostridium botulinum*, *Clostridium perfringens*, *Campylobacter*, *Shigella*, *Vibrio cholerae*, hepatitis A virus, *Giardia*, and *Trichinella spiralis*. From 2000 to 2004, *Salmonella enteritidis* remained the most commonly isolated cause of outbreaks of food-borne disease.

TABLE 257–3 Food-Borne Disease Outbreaks and Cases Reported in the United States, 2000-2004, by Etiology

	2000*	2001†	2002‡	2003§	2004¶

HEALTH INFORMATION FOR INTERNATIONAL TRAVEL

International travel, whether by child or adult, necessitates preparation beforehand to obtain the proper immunizations and contingency plans for the possibility of encountering unsanitary food or water during the travel.[18,121,239] Illnesses acquired abroad may not be manifested until return home, with consequent diagnostic difficulty.

Needs for active and passive immunization are covered elsewhere in this book and are summarized fully in two continuously updated CDC publications to which the reader is referred: *Health Information for International Travel*[47] (which can be purchased online at *http://wwwn.cdc.gov/travel/contentYellowBook.aspx* or from the Superintendent of Documents, U.S. Government Printing Office, Washington, DC 20402) and the *Morbidity and Mortality Weekly Report* (available at *http://www.cdc.gov/mmwr/*). The CDC travel Web site also is very helpful as a source of up-to-date information for travelers (*http://wwwn.cdc.gov/travel/default.aspx*).

Safe water may be found in many hotels in large cities throughout the world, but only water from adequately chlorinated sources can be considered truly safe. Where chlorinated water is not available, canned or bottled carbonated beverages and beverages made from boiled water (as well as beer or wine) may be safe; however, transmission of cholera by uncarbonated bottled mineral water has been described.[25] Ice made from untreated water may contaminate an otherwise safe beverage, either directly or by leaving contaminated water on the outside of the container. Although heat treatment by boiling vigorously for at least 1 minute is the most reliable method to render questionable water potable, chemical treatments also can be used.[46] Cloudy water should be strained through a clean cloth into a container to remove any sediment or floating matter before treatment with heat or iodine. Although chlorine has been used for chemical disinfection, its germicidal activity varies greatly with pH, temperature, and the organic content of the water to be purified, and therefore it is less reliable than iodine. Detailed information and illustrations can be found at the Web site of the U.S. Environmental Protection Agency.[113] Such information is important for coping with domestic natural disasters as well as foreign travel. More specific information on how to keep water safe is as follows:

Heat

1. Bring the water to a vigorous boil for 1 minute. Allow to cool at room temperature—do not add ice. At very high altitudes, for an extra margin of safety, boil for several minutes or use chemical disinfection.

2. Add a pinch of salt to each quart or pour the water from one clean container to another several times to aerate and improve the taste.

Chemicals

1. Tincture of iodine. Follow the manufacturer's directions. Let stand for at least 30 minutes.

2. Tetraglycine hydroperiodide tablets (can be purchased at pharmacies and sporting goods stores). The manufacturer's instructions should be followed. If the water is cloudy, the number of tablets should be doubled; if the water is extremely cold, an attempt should be made to warm the water, and the recommended contact time should be increased to achieve reliable disinfection.

3. Household bleach will kill some but not all types of disease-causing organisms that may be in water. If the water is cloudy, filter it through clean cloths or allow it to settle and draw off the clear water for disinfection. Add $^1/_8$ teaspoon (or 8 drops) of regular, unscented, liquid household bleach for each gallon of water, stir it well, and let it stand for 30 minutes before use. Store disinfected water in clean containers with covers.

Food should be selected carefully. In areas of the world where hygiene and sanitation are poor, the traveler should avoid intake of salads, uncooked vegetables, unpasteurized milk, and milk products such as cheese and should eat only fruits and vegetables that can be peeled by the traveler or have been cooked and are still hot.

Children younger than 2 years have a high risk of acquiring traveler's diarrhea.[257] Immediate medical attention should be sought for an infant or child with blood or mucus in the stool, fever with rigors, or persistent vomiting or diarrhea with dehydration. Because infants and small children are especially at risk for becoming dehydrated, parents need to be aware of the signs of dehydration and be prepared to use oral rehydration solutions (ORS) as a preventive measure while medical attention is being obtained. Replacement of fluid losses may be achieved best by the use of an ORS containing appropriate concentrations of electrolytes and glucose. Recent efforts to improve the efficacy of ORS have focused on solutions of reduced osmolarity (e.g., sodium ranges of 60 to 75 mEq/L and glucose ranges of 75 to 90 mmol/L). These solutions generally preserve the 1:1 molar ratio of sodium to glucose that is critical for efficient co-transport of sodium but present a lower osmolar load to the intestinal tract than does the original WHO ORS.[109] In a meta-analysis that evaluated the effects of reduced-osmolarity ORS in 15 randomized trials of nearly 2400 children, a reduced-osmolarity ORS was associated with less frequent use of unscheduled intravenous fluids and less vomiting. In addition, a statistically significant reduction in stool output was observed. The incidence of hyponatremia was not significantly elevated among children who received reduced-osmolarity ORS in these trials.[146]

Although prophylaxis with several different agents, including trimethoprim-sulfamethoxazole, doxycycline, fluoroquinolone antibiotics, and bismuth subsalicylate, may prevent some cases of traveler's diarrhea in adults, no drug has been shown to be both safe and effective for this purpose in children. When diarrhea is severe or associated with fever or bloody stools, self-treatment with a 3-day course of ciprofloxacin, levofloxacin, norfloxacin, or ofloxacin usually is recommended. One- and 2-day courses also may be effective.[294] Azithromycin is an alternative for travelers to areas with fluoroquinolone-resistant *Campylobacter*, such as Thailand, and for pregnant women, children, and those who do not respond to a fluoroquinolone within 48 hours. Rifaximin, a nonabsorbed oral antibiotic derived from rifampin, has been approved by the FDA for treatment of traveler's diarrhea caused by noninvasive strains of *E. coli* in patients 12 years of age or older. It has been available in Europe since 1987.[115,270] Iodoquinol is especially dangerous because of its association with subacute myelo-optic neuropathy. Administration of bismuth subsalicylate, as found in Pepto-Bismol or other generic products, may lead to salicylate toxicity.

VECTOR CONTROL

Techniques of environmental control of vectors responsible for the transmission of disease have included eradication of habitats for mosquito larvae, construction of rat-proof houses, and elimination of rodent habitats.[323] In some instances, dam construction, large-scale irrigation projects, and deforestation have led to increases in the density of vectors responsible for the trans-mission of schistosomiasis, onchocerciasis, and mosquito-borne diseases.

Chemical control of vectors, which seemed so attractive a few years ago, has been complicated by environmental contamination by undegraded chemicals and by the appearance of vectors resistant to the organochlorine insecticides (DDT, dieldrin), organophosphorus insecticides (malathion, fenitrothion), and carbonates (propoxur, carbaryl). The persistence of DDT and dieldrin in the environment has resulted in their being banned in some countries and their use being severely restricted in others. Ultra-low-volume spraying, as with malathion in the control of malaria, has permitted the use of minimal amounts of insecticide while still effecting a decrease in the incidence of disease over a considerable area.[190]

The rising incidence of tick-borne diseases, including ehrlichiosis and Lyme disease in certain parts of the United States, has led to an increased interest in methods for the control of ticks and their animal hosts. Area-wide spraying of pesticides in residential areas may reduce tick populations but also may pose health or environmental risks if these chemicals are applied improperly. Personal protection includes avoidance of vector-infested areas, wearing of protective clothing, application of insect repellents to skin (e.g., *N, N*-diethyl-*m*-toluamide, DEET) or to clothing (permethrin), and frequent inspection for and prompt removal of attached ticks. These individual preventive measures can be practiced in any circumstance where exposure to infected ticks may occur.[10]

The rising incidence of West Nile virus in the United States since its first detection in New York City in 1999 has led to new advances in repellant choices, even though repellants containing DEET or picaridin, when used as labeled, are still the most effective defenses.[272,306] Repellants containing oil of lemon eucalyptus provide protection similar to that of low concentrations of DEET. Two percent soybean oil also can be used for short (approximately $2^1/_2$ hours) periods of exposure.[8,48]

Experimental work with genetic and biologic control of vectors with insect growth regulators,[37] as with the use of larvivorous fish, chemosterilized male mosquitoes, and parasites that attack the vector, has had limited success.[10,35]

CHAPTER 258

Infections in Daycare Environments

Ellen R. Wald

The ever-increasing number of young women in the work force has contributed to the large number of infants and toddlers receiving out-of-home care. Current estimates are that approximately 75 percent of the mothers of children younger than 5 years work outside the home and that 13 million children receive some form of child daycare. About half of these children receive care in their own homes provided by parents or relatives. Twenty percent receive care in family daycare, and 28 percent are cared for in daycare centers. As children grow older, families increasingly rely on center care and decrease the use of parental care.[24]

The term *daycare* is used to describe a variety of different options for the supervision of children in the absence of their parents. Types of daycare include (1) large daycare centers housed in nonresidential settings that provide care for at least seven children in one location (included here are situations in which the parent's employer is the sponsor of the daycare center, frequently at the site of employment, and also preschool and nursery schools in which childcare is provided in a structured, primarily educational setting); (2) daycare homes in which care is provided in a residential setting for six or fewer children; (3) before- and after-school care designed to bridge the gap between organized schools (e.g., preschool or public or private school) and parental departure for or return from work; and (4) cooperatives in which childcare is rendered by parents who alternate in caring for their own children as well as other enrolled children.

The quality of care provided to children attending various daycare facilities varies widely. Although daycare centers are licensed in most states, only 23 percent of children in out-of-home care are enrolled in these facilities.[205] State regulations vary from state to state; some are quite lenient in setting suggested ratios for staff to child, whereas others have no regulations governing group size. Even if impeccable regulations and well-trained caregivers were available, the regulations would not protect the vast majority of children who are in unlicensed facilities.

Many factors contribute to the transmission of infectious agents in the daycare setting (Table 258–1), the most important of which are host factors relating to the immunologic susceptibility of young children. Once infection is established, it is transmitted easily because of the natural tendency for intimacy in an age group that has not established acceptable toileting practices and is ignorant of basic hygienic practices. Respiratory and gastrointestinal pathogens frequently contaminate toys.

Caregivers may have received insufficient training in infection control practices. A lack of policy regarding immunization and health care screening of employees may contribute to the spread of infection. In addition, overcrowding, understaffing, and poorly designed physical environments foster transmission of infectious agents in daycare facilities. A lack of or inadequate number of handwashing facilities for both children and providers creates an almost insurmountable barrier to infection control.

TABLE 258–1 Risk Factors for Infectious Disease in Daycare

Children
Immunologic susceptibility to infectious agents
Lack of toilet training
Natural tendency to intimacy
Frequent oral contact with environment
Lack of awareness and practice of good hygiene
Caregivers
Insufficient training in infection control
Lack of policy regarding immunization
Inadequate screening for infectious diseases
Environmental and Economic Problems
Inappropriate staff-child ratios
Overcrowding
Failure to separate age groups
Poorly designed physical layout
Inadequate or poorly placed sinks
Failure to separate toilet areas from areas of food preparation
Parental pressure to admit sick children to daycare

Major risk factors for spread of infection are related to the age of the participants, the number of children, and the ratio of staff to children. The last is determined in part by the age of the children and the experience of the daycare provider. In overcrowded situations with inadequate staff, infection is spread easily because of inadequate washing of hands and attention to other facets of infection control.

Factors identified as particularly important in the spread of gastrointestinal organisms are large numbers of diaper-aged children in centers where staff members who diaper children are also responsible for food preparation.[15,77] Separating diaper-aged children from those who are older is important to limit spread of enteric illness. If meals are prepared in the daycare setting, separating this activity from toilet areas is essential. If food is brought from home, it should be transported properly and stored to avoid spoilage. Lack of attention to this issue may result in additional illness. Daycare centers that operate for profit also are at higher risk for having infectious disease outbreaks, probably as a result of lower staff-to-children ratios.[119] Finally, parents may not withdraw ill children from attendance at daycare voluntarily because of the expense and inconvenience of creating alternate childcare arrangements.

MODES OF TRANSMISSION OF INFECTIOUS DISEASES IN DAYCARE

The most important pathogens and their modes of transmission of infection in daycare are shown in Table 258–2. Respiratory infections are by far the most common causes of illness in infants, toddlers, and preschoolers, regardless of whether these children attend daycare.

RESPIRATORY

For some microbiologic species causing infection, the mode of transmission is the airborne route. The organism is aerosolized and remains in the air, like cigarette smoke. Direct contact with the infected individual is not necessary for spread of the infection. Illnesses known to be transmitted by this means include measles, varicella, and tuberculosis.

Most commonly, respiratory organisms are spread by the production of droplets laden with infective particles. These droplets may be transmitted directly from mucosa-to-mucosa when close physical contact occurs. More often, droplets land on nonporous surfaces (e.g., cribs, tables, chairs) or on clothes and paper (fomites) and remain infective for minutes to hours. Hand contact with contaminated surfaces and fomites can result in infection if the hands touch the nasal or conjunctival mucosa.[80] Agents that can be transmitted by droplet spread (mucosa to mucosa), from finger to mucosa, or by fomites include most respiratory viruses (respiratory syncytial virus [RSV], rhinovirus, human metapneumovirus, coronavirus, human herpes virus 6 [HHV-6], influenza virus, parainfluenza virus, adenovirus, parvovirus B19, measles virus, mumps virus, rubella virus, and varicella-zoster virus), *Haemophilus influenzae* type b (Hib), *Streptococcus pneumoniae*, *Neisseria meningitidis*, and *Streptococcus pyogenes*.[64,65,68,76,79,80] Finger-to-mucosa spread of respiratory pathogens is the most important and common mechanism for transmission of viral and bacterial infections.[87] Consequently, handwashing is an essential element of preventing spread of infection.

GASTROINTESTINAL

Spread of gastrointestinal organisms is by fecal-oral transmission. The number of organisms required to produce infection will determine whether infection occurs by person-to-person spread or whether a food or fluid intermediary is required. For example, rotavirus, *Giardia lamblia*, and *Shigella* spp. are transmitted readily in very small numbers of organisms on the hands (without obvious gross contamination) after person-to-person contact or by touching infected surfaces. In contrast, *Salmonella*, rarely a cause of diarrheal outbreaks in the daycare setting, requires large numbers of organisms to produce infection. Accordingly, an intermediary step of food or beverage contamination is required to allow organisms to replicate up to the necessary inocula.

Numerous studies have demonstrated fecal organisms on daycare center environmental surfaces with which infants and toddlers have had contact, as well as on the hands of care providers.[54,107,206,213] Contamination of the environment is highest when the daycare children are younger than 3 years old. This age predilection correlates with the number of children still wearing diapers.[207] Important pathogens, including fecal bacteria, rotavirus, hepatitis A virus (HAV), and *G. lamblia* cysts, are able to survive on environmental surfaces for periods ranging from hours to weeks.[35,114]

TABLE 258–2 Pathogens and Modes of Transmission of Infection in Daycare

Mode of Transmission	Bacteria	Viruses	Parasites
Respiratory	*Haemophilus influenzae* type b *Streptococcus pneumoniae* *Neisseria meningitidis* *Streptococcus pyogenes* *Bordetella pertussis* *Mycobacterium tuberculosis* *Kingella kingae*	Adenovirus Coronavirus Human metapneumovirus Influenza A and B Measles Mumps Parainfluenza Parvovirus B19 Respiratory syncytial Rhinovirus Rubella Varicella	
Fecal-oral	*Campylobacter* organisms *Clostridium difficile* *Escherichia coli* O157:H7 *Salmonella* organisms *Shigella* organisms	Enteroviruses Hepatitis A Adenovirus Astrovirus Calicivirus Enterovirus Rotavirus Astrovirus	*Cryptosporidium parvum* *Enterobius vermicularis* *Giardia lamblia*
Person-to-person by skin contact	*Streptococcus pyogenes* *Staphylococcus aureus*	Herpes simplex	*Pediculus capitis* *Sarcoptes scabei* *Trichophyton* species *Microsporum* species
Contact with blood, urine, or saliva		Cytomegalovirus Hepatitis B Herpes simplex Human immunodeficiency virus	

Adapted from American Academy of Pediatrics: Children in out-of-home child care. In *Pickering, L. (ed): 2006 Red Book: Report of the Committee on Infectious Diseases. 27th ed. Elk Grove Village, IL, American Academy of Pediatrics, 2006, p. 132.*

SKIN

Bacterial, viral, and parasitic infections of the skin can be transmitted by person-to-person spread by direct contact. Bacterial pathogens such as *S. pyogenes* and *Staphylococcus aureus* usually are not primarily invasive unless a break in the integument occurs, such as after minor trauma (e.g., insect bites). Herpes simplex virus may be transmitted from skin or mucosa to skin by direct contact, again only if the skin is broken. Infestations such as scabies and lice are transmitted by person-to-person spread by mobile parasites. The superficial dermatophytes responsible for tinea infections (*Trichophyton*, *Microsporum*, and *Epidermophyton*) are transmitted by person-to-person spread or by contact with infected fomites such as combs, hairbrushes, and hats.

BLOOD, URINE, AND SALIVA

Hepatitis B virus (HBV), hepatitis C virus (HCV), human immunodeficiency virus (HIV), and cytomegalovirus (CMV) can be transmitted by blood and sexual activity (presumably resulting in microtrauma, thereby leading to blood exposure). Transmission of HCV by sexual activity is an uncommon occurrence, however. Although both HBV and HIV can be demonstrated in urine and saliva, exchange of these body fluids is very unlikely to transmit infection. At daycare centers, transmission of CMV probably occurs between attendees by contamination of toys with saliva. Mothers and care providers can become infected with CMV by the finger-to-mucosa route after contamination of hands by urine or saliva.

PATTERNS OF INFECTION IN DAYCARE

Infections in children in daycare occur in several different patterns (Table 258–3).[73] Most of the increased infectious disease burden found in daycare centers is experienced by the children themselves. They have an excess of respiratory and gastrointestinal infections when compared with children who are in home care.[138,139,211] Certain specific infections, such as those caused by Hib, rotavirus, and RSV, are shouldered almost exclusively by the children. However, adult personnel working as providers occasionally experience some of the same respiratory and gastrointestinal infections as the children. Examples of infections for which daycare attendees and staff share an increased burden include shigellosis, giardiasis, and invasive meningococcal disease.

TABLE 258–3 Patterns of Occurrence of Infections Experienced in Daycare

Patterns of Occurrence	Examples
Clinical manifestation of infection primarily in children	Respiratory syncytial virus, rotavirus infections
Infection affecting children, daycare staff, and close family members	Shigellosis, giardiasis, *Neisseria meningitidis* infection
Inapparent infection in children with clinically important infection in adult contacts	Hepatitis A
Inapparent or mild infection in children and adults but with possibly serious consequences for fetus in pregnant contact	Cytomegalovirus infection, rubella, parvovirus B19 infection, coxsackievirus A16 infection

Adapted from Goodman, R. A., Osterholm, M. T., Granoff, D. M., et al.: Infectious diseases and child day care. Pediatrics 74:134-139, 1984. Copyright 1984, American Academy of Pediatrics.

Several infections barely recognizable in a daycare child (because these infections are mild or asymptomatic) cause significant repercussions when spread to adults, whether parents or daycare providers. The most notable of these diseases is hepatitis A, which in adults tends to be an illness of moderate severity and often leads to extended absences from work.

Finally, with some infections, clinical manifestations in adults are mild, but the infection may have potential effects on the fetus if the childcare provider or mother of a daycare attendee is pregnant. CMV and rubella virus are associated with severe birth defects if infection occurs in the first trimester. Infection with parvovirus B19 during pregnancy poses a risk for the development of nonimmune hydrops in the fetus.

INFECTIOUS AGENTS IN DAYCARE

INFECTIONS SPREAD BY THE RESPIRATORY ROUTE

Viral Upper Respiratory Infections

Respiratory viruses (rhinovirus, coronavirus, RSV, human metapneumovirus, parainfluenza virus, influenza virus, adenoviruses, HHV-6, and Epstein-Barr virus) are the most common causes of infection in preschool-age children.[17,50,65,216] The range of clinical manifestations includes asymptomatic infection, simple upper respiratory infection (rhinitis), acute otitis media, pharyngitis, croup, tracheitis, bronchiolitis, and pneumonitis. Disease may be mild or severe and involve a single level or more than one level of the respiratory tree. Children may experience multiple infections with each agent because of antigenic diversity within virus subtypes (e.g., influenza A virus), existence of multiple subtypes (e.g., rhinoviruses, coronaviruses), and failure of immunity to develop after a single exposure (e.g., RSV). Viruses are shed from the site of infection (conjunctiva, nose, throat), even before clinical symptoms develop, thereby rendering control of the spread of these infections in daycare difficult. Documentation that children in daycare (family or large daycare centers) experience more respiratory infections than those noted in children in home care is ample.[51,60,93,121-123,138,139,188,190,211] The risk of acquiring infection for children in group or family care is intermediate, between that for large daycare centers and home care.[211]

The most common bacterial complication of viral upper respiratory infection is acute otitis media. The peak age incidence of otitis media is between 6 and 18 months, similar to that of viral upper respiratory tract infections. Most children have had at least one episode of acute otitis media by the time they reach their second birthday, and approximately one third will have had at least three episodes by that time.[199] Not surprisingly, because the frequency of episodes of viral respiratory infections is increased in children attending daycare, these children experience a notable increase in the frequency of episodes of otitis media.[165,188,190,192,211] Two reviews strongly supported the notion that attendance at daycare is a major risk factor for acquiring acute otitis media (Table 258–4).[171,204] Wald and colleagues[211] provided data indicating that the risk of hospitalization for performance of myringotomy with tube placement was highest for children in large daycare environments. Similarly, the risk of contracting recurrent acute otitis media and persistent middle ear effusion also is higher for children in daycare than for those who receive care at home.[43,58,189,202] Researchers do not recommend that children with mild respiratory infections be excluded from daycare or be separated from the group of well children because this strategy has not been shown to achieve an overall reduction in infections for children in daycare facilities.

TABLE 258–4 Comparisons of Annualized Rates of Acute Respiratory Tract Infections, Otitis Media, and Antibiotic Treatment among Children in Various Modes of Childcare

CMV, cytomegalovirus.

Systemic Viral Infections

CYTOMEGALOVIRUS

CMV is a common cause of infection in preschool-age children. Most often, the infection is completely asymptomatic.[94] Rarely, the child may experience a febrile illness with lymphadenopathy and hepatosplenomegaly. Sources of CMV in the daycare setting are infants and children who have been infected by their mothers by vertical transmission in utero (1% to 2%), perinatally (2% to 3%), or post partum through breast-feeding (≈6%). Strangert[190] reported the isolation of CMV from 7 of 10 children between 21 and 30 months of age in one daycare center. Strom[193] found that 13 of 18 (72%) children between 24 and 36 months of age in a single nursery excreted CMV. Children younger than 3 years of age who acquire CMV after birth excrete CMV in urine and saliva for 6 to 42 months (mean, 18 months).[5] Other investigators demonstrated that peak rates of infection occur in children between 1 and 3 years of age, when viral excretion may be documented in as many as 70 percent of children in daycare, as shown in Table 258–5.[1,95,104,134,150,152]

Infection in preschool-age children leads to viral shedding documented by positive CMV cultures obtained from swabs of the throat (thereby contaminating saliva) and urine. Transmission probably occurs through fomites (toys and blankets) contaminated with saliva, rather than by respiratory droplets.[186] Shedding of CMV is as chronic among infected toddlers in daycare centers as it is in children with perinatal or congenital infection.[5,151,152]

CMV is a problem if acquisition of infection occurs during early pregnancy in daycare providers or mothers of children attending daycare.[1-4] Such acquisition may lead to clinically evident congenital CMV infection (microcephaly, hepatosplenomegaly, chorioretinitis, psychomotor retardation, and deafness) in approximately 5 percent of infected children. Another 10 to 15 percent of infants experience occult, but potentially damaging, infection that results in milder degrees of hearing loss and learning disabilities.[187]

PARVOVIRUS B19

Parvovirus B19, the etiologic agent of erythema infectiosum, or fifth disease, is spread by the respiratory route. Viral replication, viremia, and nasopharyngeal shedding occur approximately 1 week before the development of clinical symptoms. This benign disease of childhood (in a normal host) may occur in preschool- and school-age children. The clinical illness is characterized by an erythematous rash on the face that gives a "slapped-cheek" appearance.[113] Patients usually do not have fever or other constitutional symptoms. The rash progresses after the first day and spreads as a maculopapular eruption beginning on the proximal ends of the extremities and extending to the distal portions and trunk. After several days, these lesions develop into a lacy reticular pattern on the proximal parts of the extremities and then fade. Unrecognized in immunocompetent hosts is an infection of the erythrocyte precursor that leads to transient red blood cell aplasia.

In adults, parvovirus B19 infection frequently causes arthralgia and arthritis. Its clinical importance in the context of daycare infections is transmission from an infected preschool-age child to a pregnant mother or daycare provider.[69] In a large outbreak of erythema infectiosum in Connecticut, 19 percent of susceptible adult school personnel became infected; the highest rates of seroconversion were observed in personnel in contact with large numbers of young children. Infection of the fetus may lead to nonimmune hydrops secondary to infection of erythrocyte progenitor cells. Estimates of fetal loss when a pregnant woman of unknown antibody status is exposed to parvovirus are 2.5 percent after household exposure and 1.5 percent after occupational exposure in a school or daycare facility.[13]

COXSACKIEVIRUS A16

Epidemics of infection with coxsackievirus A16 cause hand, foot, and mouth disease, a clinical syndrome characterized by a vesicular exanthem on the distal parts of the extremities and mild stomatitis. Two outbreaks have been reported in children attending daycare.[56,57] The disease is mild in children but has a high attack rate. Its importance relates to the possibility of infection developing during pregnancy, which may lead to spontaneous abortion.[57,143]

Local Bacterial Infections

STREPTOCOCCUS PYOGENES OR GROUP A STREPTOCOCCI

Group A streptococci (GAS) are a frequent cause of respiratory and skin infections. The most common expression of infection with GAS is the development of pharyngitis and fever in an elementary school-age child. Usually, the throat infection is accompanied by tender anterior cervical nodes. In classic infection, none of the usual signs of viral upper respiratory disease—coryza, cough, and conjunctivitis—are present. Illness peaks in the late winter and spring. In contrast, streptococcal infection of a preschool-age child or child in daycare takes the form of a protracted upper respiratory infection. Specifically, these patients have low-grade fever, persistent nasal discharge, anorexia, and cervical adenopathy.

Although exposure of daycare children to an index case of streptococcal pharyngitis can be assumed to result in secondary cases, relatively few epidemics of GAS infection have been reported in daycare facilities.[55,91,184] An outbreak occurred in a daycare center in which preschool children shared facilities with kindergarten children in an after-school program.[184] During a 3-month period, 47 percent of the daycare population had positive cultures for GAS or positive results on a rapid antigen-detection test. Outbreaks of scarlet fever and perianal cellulitis each have been reported from daycare centers.[133] A cluster of 12 cases of perianal cellulitis, characterized by a well-demarcated rash around the anus with itching, rectal pain, blood-streaked stools, and occasionally a purulent discharge, was reported from a kindergarten setting in Denmark.[154] Children with GAS infections of the throat or skin should be excluded from daycare for 24 hours after the initiation of appropriate antibiotic treatment.

Invasive Bacterial Diseases

HAEMOPHILUS INFLUENZAE TYPE b

Hib used to be the major bacterial pathogen of childhood and was responsible for meningitis, epiglottitis, pneumonia, facial cellulitis, and septic arthritis. These infections occurred in children between 2 months and 5 years of age, with a peak occurring in those between 6 and 18 months of age. The organism colonizes the nasopharynx before becoming bloodborne; hematogenous dissemination results in a distant focus of infection. Infected children usually have a several-day history of mild upper respiratory symptoms followed by an abrupt onset of high fever and localized symptoms indicating the site of infection (e.g., irritability or seizures in central nervous system infection, cutaneous findings in cellulitis). Colonized individuals who lack anticapsular antibody are susceptible to the development of invasive disease.[75]

In the 1980s, considerable debate ensued regarding whether children in daycare had a higher risk for having primary episodes of infection with Hib than did those in home care. The risk that primary disease will develop in an individual child is defined as the risk of Hib disease in that child in the absence of known contact with another case in the previous 60 days. Many Hib infections have occurred in children attending daycare centers,[34,61,71,98,136,163,196] with estimates of 28 to 40 percent in several studies.[98,163] However, the presence and magnitude of the increased risk have shown significant variation that was dependent on the age of the child, the type and size of the daycare facility, and the geographic location of the facility. In general, studies have found that the risk of contracting primary Hib infection is highest in younger children (≤23 months of age) during their first month of enrollment in daycare and in children attending a larger daycare center, as opposed to a daycare home.[98,163]

An additional concern was whether the risk of development of secondary cases of Hib infection in the daycare setting was significantly elevated. Although several studies substantiated an increased risk for secondary cases of invasive Hib infection in daycare attendees exposed to another attendee infected with Hib,[14,60,124] others did not.[135,147] Based on available data,[14,60,124,135,147] the risk that secondary disease will develop in daycare classroom contacts of a child with invasive Hib probably was higher than

that in children of similar age in the general population; however, the magnitude was not well defined and depended on the characteristics and geographic location of the daycare center. Management of daycare attendees younger than 2 years who were exposed to an individual with invasive Hib infection was controversial.[45]

The availability and universal use (in infancy) of effective vaccines for the prevention of Hib infection have changed the epidemiology of infections caused by this pathogen dramatically.[181] Schulte and coworkers[176] reviewed the pattern of invasive Hib infection in New York State. These investigators demonstrated a dramatic decline in the incidence of Hib disease in children younger than 5 years old, both those in daycare and those in home care. The decrease in cases of infection attributable to Hib occurred in children attending daycare centers before it was observed in non-daycare attendees, perhaps because of the requirement for Hib vaccine before enrollment in daycare. Rarely, cases are reported among fully vaccinated children in a daycare center.[129] The virtual disappearance of this once common and serious problem and the high immunization rates with Hib vaccine obviate a lengthy discussion regarding the need for rifampin prophylaxis after exposure to cases of invasive disease. In the rare instance of a case of invasive Hib disease occurring in a family daycare center housing other susceptible children (<4 years of age), all daycare contacts (adults and children) should receive rifampin, 20 mg/kg/day once daily for 4 days, to a maximum dose of 600 mg.

NEISSERIA MENINGITIDIS

N. meningitidis is a gram-negative, polysaccharide-encapsulated diplococcus found colonizing the nasopharynx. It is the second leading cause of meningitis in the United States. Other manifestations of infection include pericarditis, sepsis, and pneumonia. Similar to that in patients experiencing infection with Hib, the attack rate is highest in children 2 months to 5 years of age, with a peak in children between 6 and 12 months of age. The pathogenesis is hematogenous dissemination from the nasopharynx as a site of colonization. Household contacts exposed to patients with meningococcal disease have a significantly higher risk of acquiring that disease than does the general population.[46,130,132]

Secondary spread of infection with *N. meningitidis* has been recognized as a potential risk, especially in situations of crowding such as in military barracks and college dormitories. In addition, reports suggest that the risk of acquiring secondary disease caused by *N. meningitidis* is increased in the daycare setting.[44,101,117,142,172] In a Belgian report,[49] exposure in a daycare nursery during a prolonged meningococcal epidemic conferred a risk for infection that was 76 times greater than that in children of similar age who received care at home. Prompt institution of rifampin prophylaxis is the recommended strategy for management of all intimate child contacts of a person with invasive *N. meningitidis* disease, to prevent development of secondary or associated illness. A single oral dose of ciprofloxacin (500 mg) or an intramuscular dose of ceftriaxone (250 mg) is an alternative for adult contacts. Physicians do not recommend that throat cultures be performed to identify those who require prophylaxis. The cultures may be insensitive, and waiting for results will delay the administration of appropriate management.

STREPTOCOCCUS PNEUMONIAE

Pneumococci are the most common cause of bacterial infections of the upper and lower respiratory tracts, including otitis media, sinusitis, and pneumonia.[177] As respiratory pathogens, they also cause other upper respiratory tract infections, such as conjunctivitis, and important systemic illnesses, including occult bacteremia, bacteremic periorbital cellulitis, and meningitis. Multiple antibiotic–resistant *S. pneumoniae*, a problem that began in the 1960s, is now widespread in South Africa, in large parts of Europe, and, since 1990, in the United States.

Although *S. pneumoniae* has been the most common cause of otitis media and otitis media is the most common infection caused by *S. pneumoniae*, the rarity of performing tympanocentesis (despite the frequency of otitis media in children in daycare) explains the delayed appreciation that *S. pneumoniae* is spread easily in the daycare setting. The ease of transmission of penicillin-resistant *S. pneumoniae* (tracked by antibiotic resistance patterns, capsular types, and genetic patterns) in the daycare setting now has been demonstrated amply.[52,86,160,161] In addition, although the increased risk of the acquisition by children of secondary cases of pneumococcal disease in daycare versus home care is unknown, several outbreaks of invasive *S. pneumoniae* disease in daycare centers have brought greater attention to this issue.[38,161] A study of children in an Ohio daycare center[164] showed that prophylactic doses of antibiotics and frequent use of antibiotics were risk factors for nasopharyngeal carriage of antibiotic-resistant *S. pneumoniae*. A cluster of cases of invasive pneumococcal disease occurring in young children in childcare[31] involved a 12F serotype of pneumococcus that was penicillin-sensitive; three of six children in the daycare facility experienced bacteremic infections. In a more recent outbreak of disease, three cases of meningitis caused by multidrug-resistant serotype 14 *S. pneumoniae* occurred at a daycare center over a period of 5 days.[38]

Several reports claim that rifampin is ineffective or only partially effective in eradicating carriage of *S. pneumoniae*.[161,164] However, this finding may be explained by inadequacy of the dose of rifampin,[161] lack of compliance with drug administration, or inappropriate timing for test-of-cure cultures.

A pneumococcal conjugate vaccine containing seven common serotypes of *S. pneumoniae* (PCV7) was licensed in March of 2000. The vaccine is administered to children at 2, 4, and 6 months of age and again when they are between 12 and 15 months old. In a large field trial conducted at the Kaiser Permanente Vaccine Study Center, the vaccine performed very well. The trial achieved a 93 percent reduction in invasive disease (meningitis and bacteremia), a 73 percent reduction in consolidative pneumonia, and a 7 percent reduction in episodes of otitis media.[21] Universal use of the vaccine has reduced the most serious manifestations of infection with *S. pneumoniae* substantially.[9] In addition, use of PCV7 and other pneumococcal conjugate vaccines has been shown to reduce nasopharyngeal colonization with the serotypes of *S. pneumoniae* contained in the vaccine, including the carriage of antibiotic-resistant *S. pneumoniae*.[41,42] This secondary effect of the conjugate vaccines has resulted in a decreased number of instances of colonization and disease among the contacts of vaccinees.[72]

KINGELLA KINGAE

Kingella kingae is a fastidious gram-negative coccobacillus that colonizes the oropharynx and is becoming increasingly recognized as an important cause of skeletal infections in young children (<2 years of age). An outbreak of skeletal infections in a childcare center in Minnesota involving two confirmed and one possible case of osteomyelitis and septic arthritis in the same toddler classroom was described.[109] In addition to causing osteomyelitis and septic arthritis, which are the major manifestations of disease, *K. kingae* also causes bacteremia and endocarditis.[219]

MYCOBACTERIUM TUBERCULOSIS

The number of reported cases of tuberculosis has been on the decline in the United States since 1992 and includes a decrease in the number of infected children. In general, children with tuberculosis are not infectious. Rather, an adult in the environ-

ment invariably has active disease. Three clusters of cases of tuberculosis in children have been traced to attendance at daycare.[106,118,140] Screening of all daycare personnel, both staff and volunteers, with tuberculin skin testing is essential to eliminate this problem. One case of tuberculosis in a 9-year-old boy resulted in positive tuberculin skin tests in 79 percent of his classroom contacts and 16 percent of his daycare contacts.[40]

INFECTIONS OF THE GASTROINTESTINAL TRACT

Giardia lamblia

G. lamblia is one of the most common causes of diarrhea in the daycare setting.[20,162,178] Infection can be caused by the ingestion of as few as 10 cysts. Transmission most commonly results from person-to-person spread, although waterborne outbreaks have been documented.[108] Parents of daycare attendees are at risk for acquiring infection.[157] Demonstration of *G. lamblia* cysts on environmental surfaces indicates additional potential for transmission.[35] Infection with this parasite causes infestation of the duodenum and proximal jejunum and results in asymptomatic carriage more often than clinical disease.[97] After an incubation period of approximately 2 weeks, symptomatic patients experience diarrhea, intermittent abdominal pain, anorexia, and flatulence. The most notable feature of the infection is its tendency to become protracted, thereby leading to weight loss, failure to thrive, and anemia. The diagnosis is made by recovery of the organism from stool or occasionally by examination of duodenal aspirates or intestinal biopsy specimens.[102,200] After resolution of the symptoms, either by virtue of treatment or by spontaneous cure, patients may continue to shed cysts for a very long time.[97] Treatment is not recommended for asymptomatic individuals shedding *G. lamblia* cysts. For symptomatic individuals, treatment may be undertaken with metronidazole, furazolidone, nitazoxanide, or quinacrine. Relapses occur in approximately 15 percent of patients.

Cryptosporidium

Cryptosporidium is a cause of severe diarrhea in immunocompromised hosts, but infection usually results in self-limited illness in immunocompetent children and adults.[37] The parasite may be spread by person-to-person spread or through food or water. The usual clinical symptoms are watery diarrhea and low-grade fever with abdominal pain and weight loss. Vomiting occurs in approximately 30 percent of patients.

Cryptosporidium, like *G. lamblia*, has a very low infectious dose for humans. Ninety percent of infant nonhuman primates will become infected with 10 to 50 oocysts.[131] Spread of infection is facilitated in daycare centers because oocysts shed in the feces of infected persons are highly resistant to common disinfectants. Many outbreaks of diarrhea caused by *Cryptosporidium* have been reported from daycare centers.[7,8,36,39,85,137,198] Asymptomatic children and adults shed oocysts for weeks after infection.[34]

The diagnosis is made by examination of stool for oocysts with special stains. Recommended treatment is a 3-day course of nitazoxanide. Exclusion from daycare is recommended until the patient is asymptomatic.

Shigella

Infection with *Shigella* organisms causes illness of variable severity but easy transmissibility. Accordingly, *Shigella* is one of the most common causes of diarrhea outbreaks in the daycare population,[25,27,68,155] and *Shigella* infection was among the first enteric diseases recognized to be spread in daycare centers. Infection can be caused by as few as 10 to 100 organisms. Although a low inoculum is sufficient to cause infection, the organism does not survive well outside the human host. Person-to-person transmission is considered more important than environmental contamination. Although infection with *Shigella* may be caused by one of four species (*Shigella sonnei*, *Shigella flexneri*, *Shigella dysenteriae*, and *Shigella boydii*), *S. sonnei* and *S. flexneri* are the most common.

Shigellosis is primarily a disease of young children. In outbreaks, younger children have the highest attack rate and are the most effective transmitters of infection.[201] Daycare personnel and family contacts also experience high attack rates.[90,197] After an incubation period of several days, fever and watery diarrhea, followed by crampy abdominal pain, tenesmus, and mucoid bloody stools, occur in patients with classic disease. In many cases, the illness is mild and self-limited and is indistinguishable from other causes of gastroenteritis. The presence of fecal leukocytes on examination of stool provides supportive information; stool culture is diagnostic.

Treatment of shigellosis with an appropriate antimicrobial effectively terminates the illness. Antimicrobial treatment decreases the duration of symptoms and fecal shedding. Untreated persons continue to excrete organisms for several weeks. Susceptibility varies both within and outside the United States, and, therefore, testing of stool isolates is indicated.

Campylobacter jejuni

Campylobacter jejuni is the most common cause of bacterial diarrhea in children in the United States, but it is less likely than *Shigella* to cause outbreaks of diarrheal disease in daycare centers.[99,115,149] Most often, a high inoculum of *Campylobacter* is required to produce infection, thereby necessitating a food or water vehicle. Less often, transmission can occur by person-to-person spread of smaller numbers of organisms. The clinical findings are variable, but the usual onset includes fever, abdominal pain, and diarrhea. Many cases resemble classic shigellosis. Watery diarrhea and low-grade fever with only modest constitutional signs of illness also may be observed. The illness usually lasts between 3 and 7 days. The diagnosis can be made by culture of stool; examination of stool by darkfield microscopy or direct smear may be very informative if performed by an experienced observer.

Treatment with erythromycin and azithromycin is effective in terminating excretion of the infective organism, which may be important in controlling epidemics or outbreaks. The impact of macrolides on the clinical course of disease is variable.

Salmonella

Salmonella is the most common cause of bacterial diarrhea in many parts of the United States, but it is an uncommon cause of gastroenteritis outbreaks in daycare centers.[120] Because the organism is widespread in nature and has 2200 different serotypes, it has been very difficult to control. Infection usually occurs after the ingestion of contaminated food or beverages. Person-to-person spread seldom occurs, except in infancy, when the infective dose is low.[217]

The most common expression of infection with *Salmonella* is uncomplicated gastroenteritis. The illness begins approximately 12 to 36 hours after exposure and often is characterized initially by vomiting and subsequently by diarrhea. Abdominal pain and fever are frequent accompaniments; occasionally, stools contain mucus and blood. Although most cases are self-limited, *Salmonella* infection can be distinguished from other causes of gastroenteritis by its occasionally protracted course. The diagnosis is made by culture of stool. In general, antimicrobials are not recommended unless bacteremia is documented or the episode becomes protracted and severe. Management of special

hosts, such as neonates and immunocompromised patients, is controversial. Although some authors recommend antimicrobial therapy for these groups, few data support this recommendation. Exclusion from daycare is recommended until the diarrhea resolves. Once stools are normal, little reason exists to restrict attendance. Obtaining stool cultures from daycare contacts or the index case in convalescence is not necessary.[201] A very high rate of asymptomatic colonization with *Salmonella* of multiple serotypes has been documented in daycare centers in Mexico.[141]

Clostridium difficile

Clostridium difficile is the classic cause of pseudomembranous colitis in patients who have received or are receiving antimicrobial agents, and it rarely causes disease unassociated with antimicrobial use. The organism, a gram-positive, spore-forming rod, is distributed widely in soil and in the gastrointestinal tract of humans. It frequently is found colonizing asymptomatic newborns. Disease is a consequence of the elaboration of toxin or toxins by vegetative organisms. Hospital environments and daycare facilities are reservoirs for the organism.[110,111] During outbreaks of *C. difficile* diarrhea in daycare centers, environmental contamination is increased, as is recovery of *C. difficile* from the hands of children and staff.[111]

Clinical symptoms include fever, diarrhea, and abdominal cramps. Stools may contain blood and mucus. The illness varies in severity from mild to life-threatening. The diagnosis of *C. difficile* gastroenteritis is made by recovery of the toxin from a stool sample. Treatment includes cessation of antibiotics and supportive care. Specific antimicrobial therapy with oral vancomycin or metronidazole may be necessary to achieve clinical cure. Metronidazole is favored in an era of concern regarding the development of vancomycin-resistant enterococci after the use of oral vancomycin. Children and personnel should be excluded from daycare until they are asymptomatic.

Escherichia coli

Several outbreaks of diarrhea caused by various *Escherichia coli* strains have been associated with significant morbidity and mortality in the childcare setting. In 1986, an outbreak of diarrhea caused by *E. coli* O157:H7 was reported from a daycare attended by 107 children.[185] Thirty-four percent of attendees became ill, with a significant increase in risk for younger children. Approximately one third of the children with diarrhea had bloody stools, and hemolytic-uremic syndrome developed in three children. Although infection with *E. coli* O157:H7 usually occurs after the ingestion of contaminated beef, person-to-person spread of infection most likely occurred in this epidemic. The diarrheal illness also was documented in family members of ill children. Subsequent epidemiologic studies in Minnesota confirmed the mode of transmission for *E. coli* O157:H7 to be person-to-person in the daycare setting.[18] Accordingly, symptomatic children should be excluded from daycare until stools are formed and culture-negative for *E. coli* O157:H7. Unfortunately, fecal shedding of *E. coli* O157:H7 may be quite prolonged in young children.[195]

E. coli O157:H7 is recovered from stool samples after being plated on MacConkey-sorbitol agar. Sorbitol-negative colonies of *E. coli* are picked and screened with O157 antisera by tube agglutination. Several sensitive, specific, and rapid immunologic assays for detection of Shiga toxin are available commercially. Antibiotic treatment is not recommended for persons with diarrhea caused by *E. coli* O157:H7.[218] Hemolytic-uremic syndrome develops in approximately 5 to 10 percent of children infected with *E. coli* O157:H7.

Outbreaks of diarrhea caused by enteropathogenic *E. coli* in the childcare setting have been characterized by chronic, often relapsing diarrhea in infants and toddlers.[23,153] The diarrheal illness has had a high attack rate (56% to 90%) and has led to prolonged hospitalization in 8 to 30 percent of affected children.

Rotavirus

Rotavirus is the most common etiologic agent of gastroenteritis in infants and children and the leading cause of hospitalization for gastroenteritis in industrialized countries, including the United States.[22,89,125] It is an important cause of diarrhea in developing countries as well and contributes substantially to the worldwide mortality figures for gastroenteritis. It is the pathogen most commonly present in daycare settings.[47]

Rotavirus frequently is recovered from asymptomatic hosts, especially neonates and infants.[30] It is shed in large numbers in the stool of symptomatic patients, thereby contributing to the high prevalence of the virus on environmental surfaces during outbreaks.[215] Viral shedding occurs both before and after symptoms have appeared.[156] Only a low inoculum is needed to cause infection.

Most illnesses caused by rotavirus occur in the winter in temperate climates, but they occur year-round in tropical areas. The peak attack rate is in the 6- to 24-month-old age group. After a brief incubation period of 2 to 3 days, patients may have prodromal respiratory symptoms (coryza and cough) and then varying combinations of vomiting, diarrhea, and low-grade fever that last 3 to 5 days. The range of severity is broad, and dehydration occasionally may be profound. Spread of rotavirus infection is extremely common in hospitals.[169] Not surprisingly, transmission within a daycare center is very rapid, and many outbreaks have been reported in this setting.[16,145,146,156,168] In prospective studies of diarrheal illness in children attending daycare, rotavirus was implicated in 6 to 24 percent of cases of gastroenteritis,[15,88,194] as well as in 20 to 40 percent of outbreaks.[16] Daycare workers and family contacts are at risk for acquiring rotavirus infection.

Rotavirus cannot be cultivated easily in tissue culture in a viral diagnostic laboratory. The diagnosis is made with an antigen-detection method on a stool specimen. Treatment is supportive, and exclusion from daycare is recommended until the diarrhea resolves.

In early 2006, a bovine rotavirus-based pentavalent rotavirus vaccine (Rota-Teq) was licensed for use in U.S. infants. Three doses of the vaccine are given orally at 2, 4, and 6 months of age.[12] In 2008, a monovalent attenuated human rotavirus (Rota Rix) was licensed for a two-dose schedule given orally at 2 and 4 months. Both have been shown to be effective against rotavirus of any severity.

Norovirus

Noroviruses are nonenveloped RNA viruses that have a worldwide distribution and are a major cause of sporadic and epidemic gastroenteritis. Transmission is by person-to-person spread through the fecal-oral route or through contaminated food or water. Outbreaks frequently are observed in closed populations, including childcare centers and on cruise ships. The attack rate usually is high. Two reports highlighted the transmissibility of this agent in the childcare setting.[74,96]

Astroviruses

In addition to rotavirus and noroviruses, astroviruses are common causes of diarrheal outbreaks in daycare[6,183] and other closed populations. Children younger than age 4 years of age are infected most commonly, and the illness has a winter predominance similar to that caused by rotaviruses. Transmission usually is by person-to-person spread by the fecal-oral route. This illness is indistinguishable from the other viral causes of gastroenteritis.

Hepatitis A Virus

HAV, an enterovirus, is the most common cause of acute hepatitis in children. As with other enteric pathogens, this organism is transmitted by the fecal-oral route. Manifestations of infection vary remarkably according to age. In young children (<6 years), infection with HAV may be entirely asymptomatic or associated with relatively mild and nonspecific symptoms such as low-grade fever, anorexia, nausea, vomiting, and diarrhea in 30 percent of patients.[11] Jaundice, a more specific marker of liver disease, occurs in fewer than 10 percent of children younger than 6 years.[70] In contrast, adults with hepatitis A often are icteric in conjunction with other gastrointestinal symptoms. Infection, when symptomatic, usually lasts several weeks but occasionally can become protracted.

HAV is shed in high density in the stool of infected persons from 2 weeks before until 1 week after the onset of clinical symptoms. Transmission is primarily by person-to-person spread, but fomites may play an important role because the organism can persist and remain infective in the dried state for months.[126] The diagnosis usually is made by detecting serologic evidence of marker antibodies against HAV (immunoglobulin M anti-HAV). Treatment is symptomatic. Prevention of illness in contacts can be accomplished with intramuscular immune serum globulin and, more recently, with hepatitis A vaccine.[214] A study conducted among children residing in a Hasidic Jewish community in New York State demonstrated the efficacy of inactivated hepatitis A vaccine in preventing hepatitis A during 7 months of follow-up after vaccination.[148]

HAV can be spread easily in daycare centers with diaper-aged children because of the facility of person-to-person transmission.[78] Spread of infection is barely noticeable until symptomatic HAV infection develops in an adult contact (usually a parent or daycare worker). Other contacts, including siblings, extended family members, and babysitters, also are affected frequently. Cases of hepatitis A in communities have been associated with direct and indirect contact with child daycare settings.[209] The risk of a hepatitis outbreak occurring in a daycare center has been shown to be related directly to the number and age of children in attendance and the hours that the center is open. Larger centers with longer hours and diaper-aged children have the highest rates of infection and greatest incidence of spread to the community.[77] Hepatitis A vaccine is now recommended for all children at 1 year of age (i.e., 12 to 23 months).[11] Integration of this vaccine into the routine childhood immunization schedule will reduce the risk of transmission of HAV in daycare dramatically.

INFECTIONS SPREAD BY SKIN CONTACT

Group A Streptococci

GAS have become a less common cause of impetigo and pyoderma in children during the last decade, with a concomitant rise in the number of cases caused by *S. aureus.* Nonetheless, these organisms still can cause superficial infection of traumatized skin (insect bites, scratches), cellulitis, and erysipelas. The latter infections can result in an abrupt onset of fever and dramatic cutaneous erythema and tenderness often accompanied by regional adenopathy. An outbreak of perianal *S. pyogenes* infection in a daycare center has been reported. Typical signs and symptoms include perianal inflammation, itching, rectal pain, and blood-streaked stool. Four documented cases in three children and two presumed cases were treated without obtaining specific cultures.[175] The diagnosis of streptococcal skin infection can be made by careful performance of wound or surface cultures (obtained after carefully cleansing the periwound area) or examination of tissue aspirates. Spread of typical impetigo occurs commonly within families and presumably also would occur within daycare centers. Children should be excluded from daycare until they have completed 24 hours of appropriate antimicrobial therapy (of a 10-day course).

Scabies

Scabies is an infection of the skin caused by infestation with the female mite *Sarcoptes scabiei.* Transmitted by person-to-person spread from an infested individual, the mite buries itself beneath the stratum corneum and burrows along for its 30-day life span while laying two to three eggs per day. The larval and nymphal mites scatter after hatching to embed themselves in skin at distant sites. Some 3 to 6 weeks later, a pruritic eruption (worse at night) develops and leads to excoriation, bleeding, and crusting. The distribution of lesions varies with age. In adults and older children, the eruption, which consists of papules, vesicles, and nodules, occurs commonly in the interdigital spaces of the hands, on the extensor surface of the elbows, and around the umbilicus, waist, axillary lines, and genital area. In infants and young children, vesicular and eczematous lesions are found on the hands and feet, as well as on the face and head.

The diagnosis is made by scraping the lesions and demonstrating the mite, ova, or mite feces. Treatment of the index case should be undertaken with a scabicide, preferably 5 percent permethrin, applied to the entire body. Alternative, less desirable drugs are lindane and crotamiton. Asymptomatic contacts should be treated simultaneously because they may be infected unknowingly and may be capable of transmitting the mite during this asymptomatic period. Clothing and bed linen should be washed, dry cleaned, or stored for a week to ensure that they are not infectious.

Although scabies is spread primarily by intimate personal contact, skin-to-skin transmission can result from prolonged casual contact, as occurs in institutional settings, nursing homes, and daycare centers.[174] Mites can survive on inanimate surfaces for 2 to 3 days, a period that permits transmission by fomites such as clothes, bed linen, and furniture. An outbreak of scabies was reported in a hospital-affiliated daycare facility.[174] Elimination of the problem required a coordinated effort with simultaneous treatment of all potentially infected individuals. An infected child should be excluded from daycare for 24 hours after treatment is undertaken. More commonly, transmission occurs within the family setting.

Head Lice

Head lice infestation occurs commonly in daycare and school-age children as a consequence of infection with *Pediculus capitis.* The insect, a hemophagocytic ectoparasite, obtains nourishment by sucking capillary blood from the scalp. Female lice attach egg cases (nits) to the hair shafts at or very near the scalp. The eggs hatch 8 to 11 days later, and the louse nymphs are released.

The diagnosis is made when the symptoms of scalp pruritus, excoriation, pyoderma, and regional lymphadenopathy cause the caregiver to inspect the scalp closely. Nits are observed readily, although live lice may be difficult to see, especially in light infestations. Transmission is by direct contact with or spread by fomites of live lice. Spread by fomites is facilitated with common storage of hats and coats.

Treatment is with permethrin shampoos to eradicate the lice. Nits can be removed mechanically with spiral combs after preparation of the hair with vinegar soaks or a commercially prepared rinse. All clothing and infested bedding can be disinfected by machine washing or drying (at temperatures of ≥128.3°F [53.5°C]), dry cleaning, or storage in plastic bags for approximately 10 days.

INFECTIONS SPREAD BY CONTACT WITH BLOOD, URINE, AND SALIVA

Hepatitis B Virus

HBV is a DNA-containing virus that causes infections with a wide range of clinical manifestations from asymptomatic seroconversion to fatal hepatitis. Infection is more likely to be asymptomatic in children than in adults.[128] Common symptoms include fever, fatigue, anorexia, malaise, and jaundice. Other gastrointestinal symptoms, such as nausea, vomiting, and diarrhea, may be prominent. Joint symptoms (arthritis and arthralgias) and cutaneous lesions (papular acrodermatitis) may be noted early in the course of the illness.

The most common modes of transmission of HBV in adults are contact with blood and sexual activity. Young children usually acquire infection with HBV by vertical transmission from their mother at delivery. The maternal infection may be acute or chronic. Infection acquired vertically by an infant usually is asymptomatic, but it leads to chronic carriage of hepatitis B surface antigen in most cases. With increasing immigration and adoption of infants from HBV-endemic areas, more HBV-carrier children will be identified.[83]

Transmission of HBV within the daycare setting has been documented twice in the United States[48,179] and once in Australia.[127] In one U.S. case, the probable source was a bite by a child who was a carrier of HBV.[179] In the other, a daycare worker with chapped hands was exposed to the blood of a child who was an HBV carrier.[48] The case in Australia involved an aggressive 21-month-old child with weeping dermatitis and a history of biting other children. Three other investigations failed to demonstrate transmission in daycare facilities despite long-term contact, including one situation with a high potential for blood exposure.[48,179,180] The most recent surveillance activity showed only 1 of 496 HBV-infected children in daycare to be without a family member as a potential source.[63] In Japan, where the background prevalence of hepatitis B surface antigen carriage is higher than that in the United States, data suggested that transmission of HBV most probably occurs among children in nursery schools.[84] Implementation of the current recommendation to screen all parturients for HBV and to undertake universal immunization against hepatitis B in infancy is the most effective way to prevent the spread of this infection. The National Immunization Survey provides vaccination coverage estimates for children aged 19 to 35 months of age. The last published results for the estimated vaccination with at least three doses of hepatitis B vaccine in 2004 was 92.4 percent.[28] Because of the low risk of transmission within the daycare setting, the American Academy of Pediatrics (AAP), the American Public Health Association, and the Centers for Disease Control and Prevention (CDC) do not recommend exclusion of HBV-infected children from daycare or HBV screening of children as a criterion for entry.[11]

Cytomegalovirus

CMV can be transmitted by blood, urine, and saliva, as described earlier.

Human Immunodeficiency Virus

To date, HIV infection has not been reported to be transmitted in a daycare center. In light of its rare horizontal transmission to nonsexual contacts within households with an infected member, HIV would not be expected to spread in daycare.[66,103] The risk of transmission of HIV is less than 1 in 500 exposures, even when direct inoculation with HIV-infected blood has occurred by needle-stick injury to a health care worker. The risk of exposure other than by direct inoculation is far less than 1 in 500. The risk in daycare is even lower. Potential high-risk situations may involve HIV-positive children who are persistent biters or who have extensive weeping skin lesions.

One example of possible transmission of HIV between siblings was reported from Germany.[210] In this case, a bite may have been the source, although complete information on other interactions between the brothers was not available. Other reports indicated a lack of transmission to 35 individuals bitten or scratched by a person infected with HIV.[53,182,203] In addition, a study of family members of children infected with HIV reported no seroconversion to HIV in nine contacts bitten by HIV-infected children and seven uninfected children who bit children infected with HIV.[170] These studies support the lack of evidence for transmission of HIV in the daycare setting.

VACCINE-PREVENTABLE DISEASES

DIPHTHERIA

Diphtheria is now a very rare disease in the United States; fewer than five cases a year are observed. The infection can cause nasal symptoms, membranous pharyngitis, obstructive laryngotracheitis, or skin manifestations. The prominent symptoms are usually a severe sore throat and croup accompanied by toxemia.

Corynebacterium diphtheriae is spread by droplets from people with infection or who are carriers after intimate contact. Individuals are susceptible if they have not been immunized or have been immunized only partially. Treatment is with antitoxin and antibiotics (erythromycin or penicillin). Prophylaxis can be accomplished with erythromycin or penicillin if an individual is found to be a carrier. Immunization with a diphtheria toxoid–containing vaccine is effective in preventing disease and spread of infection.

INFLUENZA

Influenza is a common cause of upper respiratory infection in preschool-age children. The severity of infection is variable, from mild nasal congestion to a severe sepsis syndrome. Influenza is transmitted by person-to-person spread through droplets. Secondary transmission to household and daycare contacts is a very common occurrence. Enthusiasm for annual universal immunization of children has escalated in the last few years and now is recommended for all children 6 through 59 months of age. In addition, immunization is recommended for household contacts and out-of-home caregivers of children 0 to 59 months of age.

VARICELLA

Varicella, or chickenpox, is a common, highly contagious infection of childhood that affects more than 80 percent of the population by the time they reach 10 years of age. The infection is spread easily by the airborne route and by respiratory droplets. It is characterized by a pruritic, generalized vesicular rash that occurs in one to six crops, each crop separated by 24 to 36 hours. Fever usually is mild. The most common complication is secondary bacterial pyoderma. Varicella-zoster virus remains latent in the body after primary infection but can be reactivated as herpes zoster or "shingles," in which case it is manifested as a vesicular eruption involving one to three sensory dermatomes. If infection is acquired in early pregnancy, varicella embryopathy (limb bands or amputation) has been noted in a small fraction of children.

Rates of varicella peak during the preschool and kindergarten years (3 to 6 years), and only 20 percent of children remain susceptible to chickenpox after reaching 8 years of age. Data on the

relative risk of varicella development in children in daycare are minimal.[59,105] However, outbreaks of varicella in daycare centers are known to occur commonly, and the prevalence of varicella in children who attend daycare appears to be higher than that documented for the general population.[62] Children with varicella are excluded from daycare but may return 6 days after the onset of rash or when all their lesions are crusted.

In 1995, varicella vaccine became available for universal use in children between 12 and 15 months of age. The availability of this vaccine altered the epidemiology of varicella in the United States dramatically. The vaccine has been demonstrated to be highly effective during most outbreaks of varicella in daycare[33,67,100] and in clinical practice.[208] The general effectiveness of the vaccine is 83 to 86 percent against all forms of the disease and 97 to 100 percent against moderate to severe disease. The varicella vaccine is available in combination with measles, mumps, and rubella vaccines (as MMRV) and also as a monovalent vaccine. The Advisory Committee on Immunization Practices made a provisional recommendation for a universal routine two-dose varicella vaccination, with a first dose given when the child is 14 to 15 months of age and a second dose at 4 to 6 years of age.[29a]

MEASLES

Measles (rubeola) is a highly contagious respiratory infection. After many years of decline, it again reached epidemic proportions in impoverished and medically underserved inner-city areas in the United States between 1989 and 1992. Although susceptibility to measles virus infection occurs when maternal antibody wanes, the peak age group for measles in the pre-immunization era was children between 5 and 9 years old. More recently, outbreaks have involved preschool-age children, thus setting the stage for outbreaks in daycare facilities.

Measles virus is spread by droplets, hand transmission, and the airborne route. The illness usually is moderate to severe; high fever and prominent respiratory symptoms (cough and coryza) and conjunctivitis are present for several days before onset of the rash. Diarrhea occasionally may be a prominent feature. After the rash erupts, the fever and respiratory symptoms persist for several more days. Pneumonia and encephalitis are complications of measles virus infection; each occurs at an incidence of 1 per 1000 cases.

Measles is prevented effectively by immunization. Current recommendations are to immunize twice: once when the child is between 12 and 15 months of age and again at 4 to 6 years of age.[11] In epidemic situations, primary immunization may be given before a child is 12 months of age. In such cases, another vaccination is given when the child is between 12 and 15 months of age, and the first is not counted toward the two required for full protection.

When measles is diagnosed in a child attending daycare after several days of illness, intramuscular immune serum globulin is the most effective way to prevent secondary cases in susceptible contacts. When there has been a single recent exposure to a case of measles, administration of MMR vaccine within 3 days of exposure should be effective in preventing natural infection.

RUBELLA

Rubella, another exanthematous disease of childhood, is much milder than is rubeola but attacks a similar age group. As with measles, until recently rubella had been nearly eradicated by routine universal immunization with MMR vaccine.

Clinically, rubella is characterized by mild fever, lymphadenopathy (postauricular and occipital), and rash. The illness is difficult to distinguish from other viral exanthems. Infection may be completely asymptomatic. Children with documented rubella should be excluded from daycare until 5 days after the onset of illness.

If rubella is contracted during the first or early second trimester of pregnancy, a severe fetal infection resulting in microcephaly, deafness, congenital heart defects, eye disorders, and psychomotor retardation may result. Acquisition of infection during pregnancy may be a potential hazard for daycare personnel or mothers of children who attend daycare if an outbreak of rubella occurs in the daycare setting. In a large outbreak of rubella in Nebraska, 14 children (9 of whom were <12 months old) and 2 parents acquired their infection in a daycare center.[44]

The incidence of congenital rubella syndrome can be minimized by appropriate immunization of preschoolers and personnel. No specific recommendations exist for care after exposure of a susceptible pregnant adult.

PERTUSSIS

Pertussis, or whooping cough, is a highly communicable respiratory disease caused by *Bordetella pertussis*. The attack rate and severity of disease are highest in the first year of life. The illness classically is divided into three phases: catarrhal, paroxysmal, and convalescent. In the first stage, the child has no fever but has symptoms, primarily rhinorrhea and a cough. When the nasal symptoms resolve, however, the cough becomes and remains very prominent for many weeks. The cough is characterized by paroxysms that are followed by an inspiratory effort (whoop) or leave the child exhausted and occasionally apneic. The convalescent stage is the many weeks necessary for complete recovery. Treatment with erythromycin is effective in decreasing the shedding of organisms, but it does not alter the course of the disease.

Complete immunization with a five-dose series of acellular pertussis vaccine is effective in preventing most cases of pertussis, although illness does occur in partially and occasionally in fully immunized children.[32] After one has been exposed to a case, erythromycin, clarithromycin, or azithromycin provides effective prophylaxis, despite the negligible clinical effect of these drugs after the paroxysmal stage begins. Prophylaxis is recommended for exposure in daycare. If appropriate, booster doses of acellular diphtheria-tetanus-pertussis vaccine should be given to exposed children in a daycare or household setting. A child with pertussis should be excluded from daycare until 5 days of an appropriate course of a macrolide (azethromycin or erythromycin) has been received.[32] Daycare workers are an appropriate target group for receipt of a tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine licensed as a single booster vaccine for persons 11 to 64 years of age.[29]

POLIOMYELITIS

Poliovirus is an enterovirus that now rarely causes disease in the United States. Although most infections with poliovirus are subclinical, in the pre-immunization era, polio was the major cause of acquired paralytic disease, especially in older children and young adults. In some developing countries, it remains a major health problem.

Poliomyelitis is prevented effectively by use of either the live oral poliovirus vaccine or the inactivated, enhanced-potency parenteral vaccine (IPV).[159] The Advisory Committee on Immunization Practices of the CDC and the AAP recommend a four-dose all-IPV vaccine schedule for routine immunization of all infants and children in the United States.

MUMPS

Mumps is a relatively benign infection of childhood that often is asymptomatic. The most prominent clinical feature is parotitis. Occasionally, a clinically significant central nervous system infection causes unilateral sensorineural deafness. This infection had been dramatically reduced by widespread use of the MMR vaccine until 2005 to 2006, when a large outbreak was documented in the Midwest of the United States. Children with mumps should be excluded from the daycare setting until the parotid swelling subsides or, if the swelling is prolonged, until 9 days after the onset of swelling.

ROTAVIRUS

Rotavirus is now a vaccine-preventable infection that is transmitted by person-to-person spread through the fecal-oral route. Availability of two different oral vaccines to be administered in infancy has dramatically altered the epidemiology of this infection.

HEPATITIS B

HBV is a vaccine-preventable infection that is spread by contact with blood, urine, and saliva, as described earlier.

MANAGEMENT OF INFECTIONS

EXCLUSION POLICY

The AAP and the American Public Health Association have reached a consensus regarding exclusion policies for children attending daycare.[10] The recommendations reflect the understanding that when children have moderate to severe illnesses, they should not be allowed to participate in usual activities or may require more individualized care than available and that the spread of certain communicable diseases within the daycare center will be reduced by the exclusion of people with infections. Accordingly, children known to have highly infectious illnesses should not be allowed to attend daycare until treatment is initiated (e.g., head lice or GAS infections) or the symptoms have resolved (e.g., diarrhea caused by *Shigella*, rotavirus, or *Giardia*) or until transmissibility has waned, as in pertussis, varicella, measles, and mumps. In addition, children should be excluded if the contagiousness of their illness is uncertain (e.g., if a child has a high fever and a rash). A complete list of recommendations for exclusion is presented in Table 258–6.

Important conditions that do not necessarily require exclusion from daycare include (1) asymptomatic excretion of an enteropathogen, (2) nonpurulent conjunctivitis, (3) a rash without a fever or behavioral change, (4) CMV infection, (5) the carrier state of HBV infection, (6) HIV infection, and (7) parvovirus B19 infection in an immunocompetent host. Any exceptions to this statement are found in the individual discussions of the infectious agents. For many infections, the highest risk of transmission of disease occurs before the appearance of recognizable symptoms. Once illness occurs, other children already have been exposed, and exclusion is a less effective strategy. For this reason, exclusion has not been shown to be successful in reducing the frequency of viral upper respiratory tract infections.

TABLE 258–6 Recommendations for Exclusion from Daycare

Symptoms
Illness that prevents the child from comfortably participating in program activities
Illness that results in a greater need for care than the staff can provide without compromising the health and safety of other children
Any of the following conditions in a child: fever, lethargy, irritability, persistent crying, difficulty breathing, or other manifestations of possible severe illness
Diarrhea or stools that contain blood or mucus
Escherichia coli O157:H7 or *Shigella* infection, until the diarrhea resolves and two stool cultures are negative for these organisms
Vomiting two or more times during the previous 24 hours, unless the vomiting is determined to result from a noncommunicable condition and the child is not in danger of dehydration
Mouth sores associated with drooling, unless the child's physician or local health department states that the child is noninfectious
Rash with fever or behavior change, until a physician has determined that the illness is not a communicable disease
Specific Diseases
Purulent conjunctivitis (defined as pink or red conjunctiva with white yellow eye discharge, often with matted eyelids after sleep and eye pain or redness of the eyelids or skin surrounding the eye) until examined by a physician and approved for re-admission, with treatment
Tuberculosis, until the child's physician or local health department authority states that the child is noninfectious
Impetigo, until 24 hours after treatment has been initiated
Streptococcal pharyngitis, until 24 hours after treatment has been initiated
Head lice (pediculosis), until after the first treatment
Scabies, until after treatment has been given
Varicella, until all lesions have dried and crusted (usually 6 days)
Pertussis, until 5 days of appropriate antibiotic therapy has been completed
Mumps, until 9 days after the onset of parotid gland swelling
Measles, until 4 days after the onset of rash
Hepatitis A, until 1 week after the onset of illness or jaundice (if symptoms are mild)

PROPHYLAXIS OF INFECTION

Prophylaxis is a strategy that may be helpful in the management of some infections that occur in daycare centers. For example, if a child has had invasive disease caused by *N. meningitidis*, rifampin prophylaxis for all daycare contacts may prevent secondary or associated cases. If a child has pertussis, exposed children may be protected by a booster immunization, if appropriate, and administration of erythromycin or azithromycin for prophylaxis. Intramuscular immune serum globulin may be used to protect susceptible contacts after exposure to measles.

VACCINATION

Vaccination can be used as a strategy to prevent infection during epidemics in a community. For example, immunization with MMR vaccine is successful in terminating epidemics of measles in elementary or high schools. Varicella vaccine also can be used throughout a community and up to 3 days after exposure to curtail the spread of chickenpox. Hepatitis A vaccine is an appropriate intervention for controlling an outbreak of hepatitis A in daycare centers and other settings.[92]

HBV rarely has been reported to be transmitted in a daycare setting in the United States. Hepatitis B vaccine, now recommended for universal use in infants, protects against transmission of infection if a carrier of HBV is identified.

PREVENTION OF INFECTIONS

VACCINATION

Currently, the 14 vaccine-preventable diseases for a preschool child are diphtheria, tetanus, pertussis, polio, influenza, measles, mumps, rubella, varicella, rotavirus, Hib infection, *S. pneumoniae* infection, hepatitis A, and hepatitis B. The timely and appropriate use of immunizations will eliminate or dramatically reduce these problems within the daycare setting. Studies have shown that children who attend registered daycare facilities are more likely to be up to date in their immunizations than are children cared for at home.[88] Laws requiring age-appropriate vaccination of children attending licensed child daycare programs exist in almost all states.[26]

TABLE 258–7 Immunizations for Daycare Employees

Vaccine	Personnel	Schedule
Diphtheria, tetanus	All	Every 10 yr
Pertussis	All	Once
Measles-mumps-rubella	All	If born after 1955, evidence of previous infection or 2 doses at least 1 mo apart
Varicella	Nonimmune	Two doses 1 mo apart
Polio	All	Primary immunization with inactivated poliovirus vaccine if needed; consider booster if previously immunized
Influenza A/B	All	Annually
Hepatitis B	Advised	0, 1, and 6 mo
Hepatitis A	All	Two doses 1 mo apart

EDUCATION

An integral part of the control of infection within a daycare center is education of staff and families. The staff must understand the general principles of infection transmission and control. Education before job placement and frequent inservice seminars reinforce the importance of some basic techniques, especially handwashing. Supervision is essential to ensure compliance with policies.[112] Two studies showed a modest benefit of increased attention to handwashing in preventing respiratory infections in children younger than 2 years old and in preventing episodes of diarrhea in children older than 2 years.[166,167] A possible role for alcohol-based hand gels is being explored as a strategy to reduce transmission of respiratory and gastrointestinal illnesses in the home.[116,173] Applicability to the daycare environment also has been evaluated as part of several multipronged interventional programs.[81]

Parents should be educated regarding recognition of illness, especially illnesses for which the child receives the best care at home. The rationale and importance of compliance with daycare center rules should be emphasized. The childcare program should inform parents of the need to share information about communicable illnesses in the child or a family member.

WRITTEN POLICIES

Each daycare facility should have written policies for managing child and employee illness.[10] It should have written procedures for handwashing, personal hygiene policies, environmental sanitation policies and procedures, and policies for filing and updating immunization records. Employees should be screened for tuberculosis by skin testing when hired and annually if the skin test initially is negative. If the skin test result is positive, a chest radiograph should be obtained. Other recommendations regarding immunization of daycare employees are shown in Table 258–7. Screening daycare attendees or employees for HIV, HBV, or CMV is not necessary.

PHYSICAL PLANT CHARACTERISTICS

In the planning of daycare facilities, areas for infants and toddlers should be separated from those for older children. Because fecal contamination is related strongly and inversely to age, having physical premises large enough to separate children younger than 3 years of age from older children is important. If such separation cannot be achieved, an age restriction should be placed on admission. The kitchen and food storage areas should be separated from the toilet space. Because contamination of hands is the most critical factor in transmission of infection, handwashing facilities must be available to staff and children. Such facilities are especially important in the diaper-changing and food preparation areas. The handwashing facility preferably should be pedal-operated and in easy reach of soap and towel dispensers.

When construction materials are selected, the choice should be based on durability and ease of cleaning. Diaper-changing areas should be made of materials that can be cleaned easily and are light in color so that soilage can be detected. A pedal-operated, closed receptacle is ideal for disposal of soiled diapers. Only paper diapers should be used. The toddler area should be equipped with training toilets and junior-sized toilets. The use of potty chairs should be discouraged. If they are used, they should be emptied into the toilet, cleaned in a utility sink, and disinfected after each use.[10] These areas must be cleaned frequently.

HYGIENIC STANDARDS/INTERVENTIONS

The key factor in prevention of disease in the daycare setting is maintenance of optimal hygienic standards based on recognized mechanisms of transmission of infection. Handwashing is considered the single most important preventive measure,[19,73,112,157] in recognition of the finding that both respiratory and enteric pathogens are spread by contaminated hands.

Haskins published a review article in 2000 summarizing the published reports of interventional studies designed to reduce the frequency of common respiratory and gastrointestinal infections.[81] Although he concluded that studies indicate that multidimensional interventional programs can reduce infection rates, he acknowledged a wide variety of methodologic problems that could confound interpretation of the data. Similarly, the same set of methodologic concerns can be applied to two studies assessing the effect of probiotic infant formula on infections in childcare centers.[82,212] The differences in reported outcomes may be more a function of study design than of actual effectiveness.

CHAPTER 259

Human Bites

Ellie J. C. Goldstein

Human bites have been recorded since the biblical era and currently are a common cause of serious medical and surgical diseases. They are the third most frequent type of bite after dog and cat bites. Reports of secondary infection occurring after a human bite in children have been noted in the United States since at least 1910.[42] Approximately 30 to 50 percent of human bites are accidental and result from injuries that are self-inflicted (such as bitten lips and nail biting) or from injuries suffered while playing sports or games, during falls, during dental therapy, and during treatment of seizures. They also may be intentional, with 50 to 70 percent resulting from aggressive behavior. Fighting is the primary cause of human bites, but aggressive bites also may occur during play (especially in the childcare setting). In addition, bite wounds may be incurred in the course of restraining impaired patients, as a consequence of criminal or police activities, or from child abuse and child battering.[25] Sexual bites or "love nips" account for 5 to 20 percent of adult human bite wounds and may be either intentional or accidental and occur in children of all ages.[1,64,78,79]

INCIDENCE AND EPIDEMIOLOGY

In 1977 the New York City Department of Health altered its reporting system to include human bites. From that year's data of 892 reports, Marr and colleagues[51] noted an incidence of 10.7 human bites per 100,000 population per year, with a range of 0.9 to 60.9 per 100,000 population for different geographic areas. Although a bias was suggested that median income, population density, and younger age might have been factors in this geographic variance, it could not be substantiated. Stockheim and colleagues[70] noted 734 human bite incidents, of which 84 percent were deliberate, in New York City schools for the 1999 and 2000 school years. There was a 2.8:1 male-to-female ratio, with 0.07 percent of both general education and special education students initiating bite incidents. In 2001 to 2002, the Edinburgh Adult Accident and Emergency Department reported an annual incidence of 45.1 human bites per 100,000 catchment population.[75] Merchant and colleagues[54] noted that human bites accounted for approximately 0.4 percent of all pediatric emergency department visits. Human bites have their peak incidence in the spring and early summer for both children[4,48] and adults[51] and on Saturdays, especially for the 15- to 30-year-old age group. Alcohol and drug abuse may play roles in some of these instances. For children[14,48] and adults,[51] bites occur more commonly in males than in females (1.35-1.5:1), except for the 15- to 20-year-old and the 55- to 60-year-old age groups, in which females are bitten more frequently; human bites occur most often in men 20 to 25 years of age. Most bites in teenagers are associated with aggressive behavior. This pattern was documented in 1936 by Welch,[77] who reported that teenagers accounted for 5 of 13 human bite cases, some of which resulted in amputations. Farmer and Mann[20] noted that 12 percent of their patients with bites at a large urban hospital were younger than 20 years. Bites to the lip occurred most often in women (78% in women versus 22% in men) and to the lower lip (65%) more often than the upper lip (35%).[73] Baker and Moore[4] reported that of 322 children who suffered human bites, 21 percent were younger than 5 years, 21 percent were 5 to 10 years of age, and 58 percent were older than 10 years. When corrected for gender, 64 percent of the girls and 39 percent of the boys were 12 years of age or older.

Biting is a common occurrence in the childcare center setting, for which it is the third most frequently reported injury. The incidence peaks in midmorning and during the early school year

in September. Toddlers from 13 to 30 months of age are bitten more often than are infants and other preschoolers,[69] and males are bitten more frequently than are females.[24] Bites account for 3 and 6 percent of reported injuries in boys and girls, respectively,[22] and may be self-inflicted in many cases.[14] Other researchers have noted that approximately 50 percent of all children enrolled in daycare suffer bite wounds, with a rate of 3.9 bites per child per year in general, but 9.4 bites per male child per year for full-time enrollees.[24,67] Garrard and colleagues[24] reported that 104 of 224 children (46%) experienced 347 bites in a single year, and Solomons and Elardo[67] noted that 66 of 133 children (50%) experienced 224 bites in a 42-month period. Fortunately, most of these bites are minor and do not break the skin. A higher proportion of bites in younger children (such as preschoolers) are to the face, whereas most bites in adolescents are on the upper extremities and hands.

Paronychial infections are not actual bites, but when infection occurs, it is related to contamination by oral flora when children bite or suck their fingers. Brook[11] noted children from 2 to 9 years of age (mean age, 5 years 8 months) who were treated at a children's hospital for paronychial infection and reported the bacteriologic and clinical findings of these infections.

Bites as harbingers or signs of child abuse are noted more commonly in the 0- to 4-year-old age group[60]; the age of the abusing parents was younger than 20 years for mothers and younger than 22 years for fathers. An attempt should be made to identify the biter and measure distances between circular bite marks to ascertain the spread. In addition, biting children may have learned this behavior from abusive adults and may themselves be victims of human bites.

BACTERIOLOGY

The bacteriology of these wounds, including occlusional bites, clenched-fist injuries, and paronychia, reflects the human oral flora of the biter and has been the focus of various studies.[8,12,27,32,34,36,71] Human saliva and dental plaque can contain more than 42 different species of bacteria in concentrations of 10^8 colony-forming units per milliliter. Table 259–1 lists common human bite wound isolates and their relative frequency of isolation. Alpha-hemolytic streptococci, especially *Streptococcus anginosus*, are the most frequent isolates. Other common bacterial isolates include *Streptococcus pyogenes*, *Staphylococcus aureus*, *Haemophilus* spp., *Eikenella corrodens*, and oral anaerobes, especially *Fusobacterium*, *Prevotella*, *Veillonella*, and *Peptostreptococcus* spp. Cultures of virtually all infected bite wounds grow bacterial pathogens; wound cultures of patients who initially are seen less than 8 hours after incurring an injury, before the development of clinical infection, yield potential bacterial pathogens in 85 percent of cases.[26,32] The bacteriology of early-treated, colonized wounds is remarkably similar to the bacteria isolated from wounds evaluated later with established infection. The average bite wound yields between 3.4 and 5.4 bacterial isolates per wound, including 1.7 to 2.4 aerobes and 1.7 to 3 anaerobes.[12,32,71] Anaerobes were recognized as important pathogens and markers for serious bite infections, especially bite infections involving the hand, as early as 1936.[5,10,30,57,58,77] Anaerobes are isolated from more than 50 percent of human bite wounds, almost always in mixed culture with aerobes, and they are associated more often with more serious infections, amputation, and the presence of abscesses.[30,32,71] Many of the anaerobes isolated from human bite wounds, especially *Prevotella* and *Porphyromonas* spp., are β-lactamase producers.[12,36,71]

E. corrodens, a capnophilic, gram-negative rod that is part of the normal human oral flora, has been recognized as an important pathogen in approximately 20 percent of clenched-fist injuries.[27,34] It has an unusual antimicrobial susceptibility pattern in that it is susceptible to penicillin but resistant to first-generation cephalosporins, β-lactamase-stable penicillins (such as oxacillin), and erythromycin.[28,33] When unrecognized or treated with the incorrect antibiotic, *E. corrodens* has been associated with therapeutic failure.[27] Usually isolated in mixed culture, it may be missed by

TABLE 259–1 Approximate Prevalence and Bacteriology of Isolates from Human Bite Wound Infections

Isolate	Prevalence (%)	Present in OB	Present in CFI
Aerobes			
Streptococci			
Alpha-hemolytic	28-90	+	+
Streptococcus anginosus	52	+	+
Beta-hemolytic			
Group A	14-26	+	+
Other	12	+	+
Gamma-hemolytic	3-33	+	–
Enterococci	6-11	–	+
Staphylococcus aureus	13-55	+	+
Coagulase-negative staphylococci	6-53	+	+
Haemophilus influenzae	2-6	+	+
Haemophilus species (other)	11-20	+	+
Eikenella corrodens	10-30	+	+
Micrococcus species	3-5	–	+
Moraxella species	3	+	–

microbiologists because of its slow growth characteristics and overgrowth of other bacterial colonies. *E. corrodens* produces a small colony that "pits" or "corrodes" the agar surface and has a light yellow pigment and an odor like that of hypochlorite bleach.

The bacteriology of paronychial infections is similar to that of other human bite infections, except that aerobes and anaerobes each have been isolated in pure culture in 27 percent of cases.[11] Brook[11] found a total of 3.6 isolates per specimen: 1.4 aerobes, 2 anaerobes, and 0.2 *Candida albicans;* β-lactamase–producing organisms, including isolates of *Prevotella melaninogenica* and *Prevotella oralis*, were found in 45 percent of the wounds.

In addition to oral bacterial infection, human bites have been associated with viral infections such as those caused by herpes simplex virus,[23,52] cytomegalovirus,[52] hepatitis B virus,[13,16,41] hepatitis C virus,[19] and possibly human immunodeficiency virus (HIV),[1,3,7,17,43,52,61,63,66,72] as well as syphilis,[21] tuberculosis,[26] actinomycosis,[9] and tetanus.[55,62]

CLINICAL MANIFESTATIONS

Human bites may be categorized into three groups: (1) bites resulting in paronychial infection, (2) occlusional bites, and (3) clenched-fist injuries. Patients in the latter two categories may be seen early (<8 hours after injury) for wound care or tetanus boosters or late (>8 hours after injury), usually because of established infection or infectious complications. All share the predominance of oral aerobic and anaerobic bacteria as primary etiologic pathogens. Noninfectious complications may include injury to tendons and nerves or fractures. Potential complications of human bites are noted in Table 259–2. Table 259–3 lists some of the diseases acquired as a result of human bites. The incidence of infection developing after human bites is estimated to be 10 to 30 percent. Because of the typically superficial nature of human bite wound injuries in children, the infection rate in children is estimated to be approximately 10 percent.

BITES RESULTING IN PARONYCHIAL INFECTION

Paronychia is an infection (inflammation) of the structures of the distal phalanx, either those surrounding the nail or the bone itself. Most are caused by finger sucking in younger children but may be caused by accidental biting. The area is red, tender, and swollen and may have some underlying purulence.

OCCLUSIONAL BITES

Occlusional bites occur when the teeth actually contact any part of the human anatomy. Human bite wounds occur most often on the upper extremity (18-71%), the head and neck (4-33%), the thorax and abdomen (6-25%), the breasts or genitals (3-25%), and the lower extremity (3-11%).[4,24,32,51,74] Vale and Noguchi[74] reported the anatomic distribution of bite marks in 67 forensically evaluated cases, including 13 (19%) cases in children younger than 15 years old. They noted more than one bite mark in 40 percent of victims and that female victims were bitten most frequently on the breasts, arms, and legs, whereas bites to males more often were on the upper extremities and shoulders. Marr and colleagues[51] did not differentiate the location of bites by sex of the victim but noted that 15 percent were to the head and neck, 12 percent were to the thorax and abdomen, 61 percent were to the upper extremities, 4 percent were to the lower extremities, and 9 percent were to unknown locations. Similarly, MacBean and colleagues[48] reported that 20 percent of human bites were to the face and head; 58 percent were to the hand, wrists, and arms; 5 percent were multiple injuries; and 9 percent were to "missing/other body regions." Our experience with teenagers and adults is similar to those cited,[48,51] perhaps because of a selection bias involving patients who seek medical care or come to the attention of infectious disease consultants. When the hand is involved, wounds tend to occur most frequently on the terminal phalanx of the middle (long) finger of the dominant hand.[8,18,32] Bites to the upper extremities occur most frequently in toddlers (66%), infants (71%), and preschoolers (46%)[24] and in children overall (42%).[4]

Most wounds are minor and require routine care with cleansing and bandaging. The infection rate after occlusional bite wounds has been estimated to be 10 to 30 percent, 87 percent of which may require hospitalization.[4,46] Wounds to the hand and with any edema or crush injury and those that involve a bone or a joint have a greater potential to become infected. Infections, when they occur, usually are manifested as cellulitis. If the child is treated early,[18,45] these injuries rarely result in serious complications. Patients in whom treatment is delayed (>12 hours after injury) probably have a preselection bias because they usually seek attention for an already established infection. These infections generally spread proximally and not distally and in less than 5 percent of cases have associated fever, lymphangitis, or lymphadenopathy. A malodorous discharge or abscess may be present if anaerobes are involved.

Complications may be limited to skin defects (when skin avulsion has occurred), but septic arthritis and osteomyelitis may develop if the joint or bone is involved.[37] In immunocompromised hosts, such as those with hematologic malignancy or neutropenia, sepsis may occur. Amputation may be necessary as a result of the initial bite in approximately 2 to 5 percent of cases or as a result of serious chronic infection in 0 to 18 percent of cases.[5,18,45,47,53,56,77] Tendon injury, primary nerve injury and tenosynovitis, compartment syndrome, and resultant secondary nerve damage may occur.[59]

CLENCHED-FIST INJURIES

Clenched-fist injuries, or "fight bites," are the most serious of human bite wounds and occur when the closed fist of one person strikes another in the teeth and a break in the skin occurs.[38] The most common cause is a fight, although cases can occur during contact sports or boxing if gloves are not worn. The metacarpophalangeal joint (knuckle) of the middle (long) finger of the dominant hand is involved most frequently.[27,34,65] The break in the skin may be only 2 to 5 mm in length but often results in penetration into the joint or even the bone. Patients and physicians may underestimate the potentially serious nature of these wounds. During the initial contact, bacteria penetrate the knuckle area and, on relaxation of the hand, are carried by the tendons further back into the potential spaces of the hand. Infection may spread laterally, between the collateral and accessory ligaments, or dorsally into the thin-walled bursa overlying the metacarpal head or into the palmar deep spaces of the hand. The typical patient avoids seeking attention because of the circumstances surrounding the injury and often wakes up 6 to 8 hours later with a painful, throbbing, swollen, infected hand and then seeks medical attention. Often, the patient has a purulent exudate emanating from the injury, which may be foul-smelling if *P. melaninogenica* or other anaerobes are present, and the patient comes to the physician with the hand elevated to diminish the pain. The swelling usually spreads proximally and not distally from the site of injury.

The physician should take samples for both aerobic and anaerobic cultures and secure the assistance of a surgeon experienced in hand cases. Chuinard and D'Ambrosia[15] and others[49,50,60] have outlined the surgical management of these wounds; such management includes a determination, under a bloodless field, of whether penetration of the joint capsule has occurred or whether only localized cellulitis is present. Complications occur frequently, and in our experience, these patients have a 50 percent chance of developing septic arthritis, osteomyelitis, or both. The range of motion of the hand usually is limited by swelling and edema but also may be limited as a result of tendon or nerve injury or severance. Permanent limitation of range of motion and joint stiffness are frequent results of osteomyelitis in the affected joints. Osteomyelitis, which usually involves the small bones of the hand, often is manifested as continued pain, swelling, and erythema with or without drainage at 10 days to 3 weeks after the injury has occurred.[20] Osteomyelitis and septic arthritis caused by *E. corrodens*, often in association with alpha-hemolytic streptococci, frequently are insidious and persistent and may lead to amputation, especially if treated with the wrong antibiotics.[27] Other complications include fracture, collar-button abscess, and muscle atrophy.

POTENTIAL FOR TRANSMISSION OF THE HUMAN IMMUNODEFICIENCY VIRUS

Reports[3,43,66,72] have noted the transmission of HIV from biter to victim. HIV is isolated uncommonly from the saliva of infected persons, and when recovered, it has been in low number. Consequently, the possibility of HIV transmission occurring is considered unlikely, though negligible.[7,17,61,63] Rickman and Richman[63] reviewed instances of reported HIV transmission via human bites and concluded that "no well documented case of HIV transmission through bites exists"; the risk of HIV transmission occurring is possible biologically but appears to be unlikely. A review and commentary of professional sports-related injuries also noted the unlikely possibility of HIV being transmitted via sporting events and outlined similar commonsense control measures.[52] Most schools allow preschool-aged children with HIV to attend child-care centers unless a significant, real risk exists in an individual's behavior or hygienic habits.[17]

TREATMENT

The basic elements of management are outlined in Table 259–4. They include obtaining a complete history of the circumstances of the injury, with an attempt to identify the biter. If the biter is identified, some questions about the presence of herpes and other potentially orally transmitted viral diseases should be asked. Awareness of the potential for child abuse or battering must be considered, and a search should be performed for other associated injuries. The examination must include an evaluation of range of motion if a hand or joint is involved; determination of the integrity of tendons, nerves, and the vascular supply; and a diagram of the location of the bite marks. Because most victims have multiple wounds, a thorough search of the entire body should be made and the wounds should be measured. Special attention must be paid to any wound close to bones or joints, especially when it involves the hands, and the possibility of bone or joint penetration should be considered. Radiographic studies of the hand should be obtained for all clenched-fist injuries or in any situation in which suspicion of fracture or the potential for osteomyelitis exists. Magnification radiography may be helpful in identifying bone penetration. If tetanus immunization is not current, a toxoid booster should be given. If the patient has no record of immunization, tetanus immunoglobulin and tetanus toxoid should be administered.

The wound should be cleansed with normal saline, and any foreign body or debris and necrotic tissue should be removed. Cautious débridement is indicated for some wounds, with care being taken to not create a potential skin defect. The wound then is irrigated, with a syringe and needle/catheter tip used as a

Drain abscess
Administer antimicrobial agents
Prophylactic therapy, 3 to 5 days
Longer duration for established infection
Elevate injured area
Immobilize wound area (3 days for hands)
Have the patient exercise the injured area (if previously immobilized)
Close the wound
Primary for face and head
Delayed for early wounds
Secondary intent for infected wounds
Administer tetanus toxoid
Obtain radiograph (if indicated)
Submit health department report (if required)

high-pressure jet to diminish the bacterial inoculum. Aerobic and anaerobic cultures should be obtained, and Gram stain performed if infection is present. In cases of clenched-fist injury, a hand surgeon should examine the patient to determine whether the joint capsule or bone has been compromised.[15] With many hand infections, especially after exploration of clenched-fist injuries, immobilization in a plaster splint is recommended. Elevation of a swollen or inflamed part is crucial to healing. The elevation should be maintained above the level of the heart. Promises made by patients or family to "keep the hand up" should not be accepted unless a properly fitting sling is issued or made from a scarf; in addition, a tubular stockinette and an intravenous pole may be used. Legs and hands also can be elevated with pillows. The use and value of topical agents have not been studied, although most patients have applied them before seeking medical attention.[32]

Approximately 14 to 32 percent of victims of occlusional bite wounds will require hospitalization,[54,71] compared with approximately 55 percent of those with clenched-fist injuries.[71]

Antimicrobial agents should be selected empirically according to the most likely pathogens and their usual susceptibility patterns to antimicrobial agents.[29,35,39,40] If cultures are performed, therapy should be adjusted according to the organisms isolated and their specific susceptibility to antimicrobial agents. The activity of antibiotics commonly used against the usual human bite wound pathogens is outlined in Table 259–5. Common pathogens that need to be considered in the selection of antimicrobial therapy include streptococci, *S. aureus*, *Haemophilus* spp., *E. corrodens*, and β-lactamase–producing oral anaerobes. The oral agent of choice is amoxicillin-clavulanic acid; for penicillin-allergic children, a combination such as trimethoprim-sulfamethoxazole plus clindamycin can be substituted. Many other combination regimens, including cefuroxime plus clindamycin or metronidazole, may be used. The intravenous agents of choice are ampicillin-sulbactam and ticarcillin-clavulanate.[2] For penicillin-allergic children, combination therapy with an extended-spectrum cephalosporin or trimethoprim-sulfamethoxazole plus clindamycin should be administered.[2] Additional potentially useful intravenous agents include cefoxitin, imipenem, or ertapenem and combinations of such agents as cefuroxime or cefotaxime plus metronidazole. First-generation cephalosporins are of limited utility because of poor activity against *E. corrodens* and some anaerobes[28,33] and should not be used as empirical monotherapy. Erythromycin also has poor activity against *E. corrodens* and *Fusobacterium nucleatum*,[35] and its use as monotherapy can lead to therapeutic failure. Newer macrolides, including azithromycin, show improved activity when compared with erythromycin against the spectrum of bite wound pathogens, but *Haemophilus* spp., and *F. nucleatum* remains relatively resistant.[35]

The quinolones, particularly moxifloxacin, exhibit broad activity against the pathogens implicated in bite wounds.[71] The risk-to-benefit ratio should be considered before they are administered because the quinolones are not approved for use in children younger than 18 years old. Linezolid, an oxazolidinone, appears to be more active than are the macrolides against the gram-positive organisms and fusobacteria isolated from human bite wounds, but some aerobic gram-negative organisms are at the susceptibility breakpoint.[31] Once patient-specific cultures return, antimicrobial therapy should be adjusted in accordance with the patient's individual isolates and susceptibility pattern. The duration of antimicrobial therapy is determined by the type and severity of infection. Prophylactic antimicrobial agents typically are given for 3 to 5 days, whereas the course for established infection usually is longer, such as 10 to 14 days for cellulitis and 4 to 6 weeks for septic arthritis and osteomyelitis. If any question exists about the prompt filling of a prescription because of financial or other concerns, a dose of intramuscular or intravenous antibiotics should be administered and hospitalization considered.

Patients' wounds should be re-examined within 24 to 48 hours. If outpatient therapy is initiated and the cellulitis advances, hospitalization is indicated. Table 259–6 lists the reasons for hospitalization of patients with human bite wounds. Such indications include patient noncompliance and virtually all clenched-fist injuries.

Infected wounds should not be closed. However, the value and risks associated with primary closure in patients who are initially seen less than 8 hours after injury and without any symptoms or signs of established infection have not been studied in a prospective or randomized manner. Exceptions are wounds to the face and neck and losses of the lip, for which early primary closure has been successful.[73,76] However, the information about those wounds probably is not applicable to bite wounds to the hands or other parts of the body for several reasons: (1) head and face wounds are débrided and copiously irrigated with as much as a liter of normal saline, which diminishes the bacterial inoculum; (2) most surgeons give a course of 5 or more days of antibiotics; (3) the blood supply to the head and face area is superior to that of most other anatomic areas; and (4) these areas are rarely dependent, and, therefore, edema and swelling resolve more rapidly or do not develop. The use of primary wound closure in early-treated, uninfected wounds remains at the physician's dis-

Septic arthritis
Progression of infection despite outpatient therapy

cretion. Wounds to the hands should be observed and left open for either delayed primary or secondary closure.

In general, hyperbaric oxygen therapy for human bite wounds remains of unproven benefit. Lehman and colleagues[44] prospectively studied the use of a portable hyperbaric oxygen chamber in 16 of 43 patients admitted to the hospital for human bite infections of the hand, almost all caused by clenched-fist injuries. They found that no benefit was obtained for mild or moderate infections, but the duration of the hospital stay was shortened (4.7 versus 11.2 days) in patients with severe infections. Although the authors thought that return of function was more rapid in the hyperbaric group, limitations in follow-up precluded evaluation and the institution of an early, aggressive exercise program may have been an important factor.

PREVENTION

Mast and colleagues[52] reviewed both risk and prevention strategies for the transmission of blood-borne pathogens during sports. Prevention strategies include appropriate infection control measures in the sports setting and education of young athletes, as well as their coaches and trainers. Bites may occur in the daycare setting, even "when caregivers are vigilant." The use of "disciplinary techniques," including a developmentally appropriate curriculum ("busy, happy children are less likely to get into serious mischief"), avoidance of too much open space in classrooms, and discipline that pays attention to redirected positive behavior, has been advocated.[67,68] More attention should be given to the victim than to the aggressor; teachers should work with the biter on behavior modification with reinforcement, extinction, and punishment strategies, which should be limited to "time-out" procedures.

CHAPTER 260

Animal Bites

Morven S. Edwards

> Many children delight in teasing dogs, and without caution go too near them, by which they get miserably torn and mangled. . . . What these boys had been doing to enrage the dog we cannot tell, but suspect they had been tormenting him in some way, thinking that as he was chained he could not injure them. But they were mistaken in this, and one of them is likely to be bitten very severely.[5]

HISTORICAL ASPECTS

The consequences to children of bites resulting from provoking dogs, as noted in the opening quotation, were of concern in the 19th century just as they are today.[23] In early reports, infected bite wounds were noted to contain fusiform bacilli and spirochetal organisms.[80] We now appreciate that a vast number of aerobic and anaerobic organisms comprising the normal flora of the biting animal's mouth are potential bite-wound pathogens.

The importance of débridement and drainage in treatment of infected bite wounds was understood in the pre-antibiotic era, but these infections carried a high morbidity rate.[78] In a report from 1936, amputation was required in one third of cases in which treatment was delayed for 24 hours or longer.[98] Adjuncts to cleansing, such as electrocauterization and even radiation therapy, were used in efforts to prevent or treat infection, but not until the introduction of penicillin was the outcome of bite-wound infections improved over that achieved by symptomatic therapy alone.[78]

EPIDEMIOLOGY

More than 108 million cats and dogs are kept as pets in the United States.[43] The estimated annual incidence is 1 to 2 million

dog bites, 400,000 cat bites, and 45,000 snake bites.[42,96] The direct medical cost annually for dog bites alone is $165 million.[81] Rabbits, skunks, squirrels, horses, rats, hogs, and monkeys cause at least 1 percent of bite injuries. Unprovoked pet ferret attacks have caused severe facial injuries.[74] Taken together, however, bites from nondomestic animals, generally thought to pose a higher risk for transmission of rabies, constitute less than 1 percent of reported bite wounds. The right arm is bitten most frequently, presumably because of defensive attempts by victims using their dominant arm. At least three quarters of bites are located on extremities. Facial bites comprise only 10 percent of the total, but two thirds of them are sustained by children younger than 10 years of age.

Children are the most common victims of animal bites. From one half to three fourths of dog bites are reported in persons younger than 20 years of age. The peak incidence is in children 5 to 14 years of age. Many bites do not require a visit to the physician and are not reported. The number of children with bites reported exceeds those of all reportable childhood diseases.[14] Up to 1 percent of all pediatric emergency department visits during the summer months are for treatment of animal bites.[27,54] Most bites occur in late afternoon and early evening hours. Boys sustain dog bites twice as often as do girls, but girls are bitten more frequently by cats.[66]

Large dogs account for most animal bites and are implicated most frequently in bites with a fatal outcome. Ten to 20 fatal human attacks occur yearly in the United States. At least 25 breeds of dogs were implicated in 238 fatalities from dog bites during the past 25 years, but pit bull–type dogs and rottweilers were involved in more than half the deaths.[87] These animals can exert a biting force of 1500 psi, several times that of a German shepherd. The severity of wounds inflicted by pit bull breeds also is due to their tendency to inflict multiple bites and to bite and grind their molars into tissue. Ninety-four percent of injuries caused by pit bulls in one study were the consequence of unprovoked attacks.[8] In most instances (75%), the dog's owner is known by the victim, although only a small percentage of bites are caused by a family-owned dog. Stray dogs account for 10 percent of bites inflicted. When the circumstances are known, most mammalian bites are provoked, although the victim may not have agitated the animal intentionally.[19,91]

Infection is a common complication of animal bites. Between 3 and 20 percent of dog bites and 20 to 50 percent of cat bites for which medical care is sought become infected.[43,96] With the exception of monkey bites, which have a high infection rate, infection seldom develops after bites by other mammals. Factors influencing the risk for development of infection include the patient's age, type and location of the wound, and length of time that transpires between the bite and initiation of treatment. Wounds of the hand are more likely to become infected than are those of the arm, leg, or face.[18] Puncture wounds more often become infected than do lacerations, superficial wounds, or wounds with skin and soft tissue defects.[1] Infection is likely to develop when wounds are repaired surgically or when care is delayed more than 24 hours after injury.

MICROBIOLOGY

The mammalian mouth has been viewed as a microbial incubator supporting the growth of some 200 species of facultative organisms and obligate anaerobes.[33] The oral flora of the animal, rather than skin flora of the victim, is the source of most isolates from bite wounds,[66] but both can be sources for infection. Infections usually are polymicrobial and contain mixed aerobic-anaerobic isolates. Table 260–1 enumerates bacterial isolates from the wounds of 50 patients with dog bites and 57 patients with cat bites that were infected at the time of arrival at an emergency department for care.[93] A median of five bacterial isolates were found per culture. Slightly more than half the wounds yielded both aerobes and anaerobes, and anaerobes alone were isolated from slightly more than a third of the wounds. *Pasteurella* spp. were the isolates most frequently found in dog and cat bites (50% and 75%, respectively), with *Pasteurella canis* being isolated most commonly from dog bites and *Pasteurella multocida* subspecies *multocida* and *septica* the most common isolates from cat bites. *Pasteurella* carrier rates are as high as 66 percent for dogs and 90 percent for cats, so one is not surprised that this organism is associated so commonly with bite-wound infections. Infection has occurred as a consequence of bites by large cats, including lions,[17] cougars,[57] and tigers,[21] as well as by house cats. The type of wound commonly inflicted (i.e., puncture by cats versus laceration by dogs) might explain the species-specific disparity in infection rates.

TABLE 260–1 Bacteria Isolated from 50 Infected Dog Bites and 57 Infected Cat Bites

	Number of Patients (%)	
Bacteria	**Dog Bite**	**Cat Bite**
Aerobes		
Pasteurella	25 (50)	43 (75)
Streptococci	23 (46)	26 (46)
Staphylococcus aureus	10 (20)	2 (4)

Anaerobes		
Fusobacterium	16 (32)	19 (33)
Bacteroides	15 (30)	16 (28)
Porphyromonas	14 (28)	17 (30)
Prevotella	14 (28)	11 (19)
Propionibacterium	10 (20)	10 (18)
Peptostreptococcus	8 (16)	3 (5)
Eubacterium	2 (4)	1 (2)
Others	1 (2)	5 (9)

Modified from Talan, D. A., Citron, D. M., Abrahamian, F. M., et al.: Bacteriologic analysis of infected dog and cat bites. N. Engl. J. Med. 340:*85-92, 1999.*

Other aerobic agents commonly isolated from infected dog or cat bites include streptococci, staphylococci, *Moraxella*, *Neisseria*, and corynebacteria. Although streptococci often are beta-hemolytic, *Streptococcus pyogenes* was isolated from only 12 percent of dog bites and none of the infected cat bites in one large series.[93] *Staphylococcus aureus* was isolated frequently from infected dog bites but infrequently from cat bite wounds. Species such as *Capnocytophaga canimorsus* and *Neisseria weaveri*, previously classified under the Centers for Disease Control and Prevention alpha-numeric system, are notable because infections in association with these species have occurred in splenectomized persons or those with immunocompromising conditions.[4,61]

Animal bites are implicated as a vehicle for transmission of a number of systemic infectious diseases caused by viruses, fungi, and mycobacteria, in addition to bacteria (Table 260–2).[33] For

some of these infections, the lists of animals that may transmit the infection are extensive. For example, tularemia can be transmitted by the bite of a wild boar, coyote, hog, lamb, muskrat, opossum, raccoon, rat, skunk, squirrel, snapping turtle, or weasel.[6,20,64]

CLINICAL MANIFESTATIONS

Signs of infection after animal bites develop within hours to several days after injury. Infection is the usual reason that patients seek medical attention more than 12 hours after injury, whereas those seen earlier are more concerned with prophylaxis or surgical repair. Findings suggestive of wound infection include localized swelling, erythema, and pain with or without serosanguineous or purulent drainage (Fig. 260–1). The clinical findings vary with the infecting organism, site of injury, and type of bite.

The characteristic findings of *P. multocida* infection, which include intense pain, swelling, and erythema, develop rapidly, often within hours after injury. Cellulitis is usually evident within 24 to 36 hours after the bite; occasionally the manifestation is delayed for 3 to 5 days. Despite these intense local symptoms, patients generally are afebrile, and less than 20 percent have lymphangitis and regional adenitis. Patients with wound infection caused by staphylococci or streptococci usually experience less intense pain, have a delay between injury and the onset of symptoms of days rather than hours, and may have a more diffuse, less fiery cellulitis. Gas in tissues of the forearm clinically suggestive of clostridial gas gangrene has occurred in infections caused by *Streptococcus anginosus* and *Streptococcus mutans* after horse bite lacerations.[68] Wound infection clinically resembling that caused by *P. multocida* from which the related but more unusual gram-negative rod *Actinobacillus lignieresii* was isolated has been reported in a child who sustained a facial bite by a horse.[26]

"Seal finger" deserves mention because failure to initiate appropriate therapy can result in permanent sequelae. The etiologic agent is unknown; a possible role is suggested for *Mycoplasma*.[9] Infection can result from contact through a laceration from the skin of a seal or from a seal tooth- or claw-associated puncture wound.[67] The incubation period averages 4 to 8 days, and the onset is characterized by severe pain and often massive swelling and erythema. In some cases, regional adenopathy and ascending lymphangitis occur. A predilection for involvement of the joint closest to the inoculation site has been noted. Once the diagnosis is established, treatment should be initiated with a tetracycline, the drug class of choice.

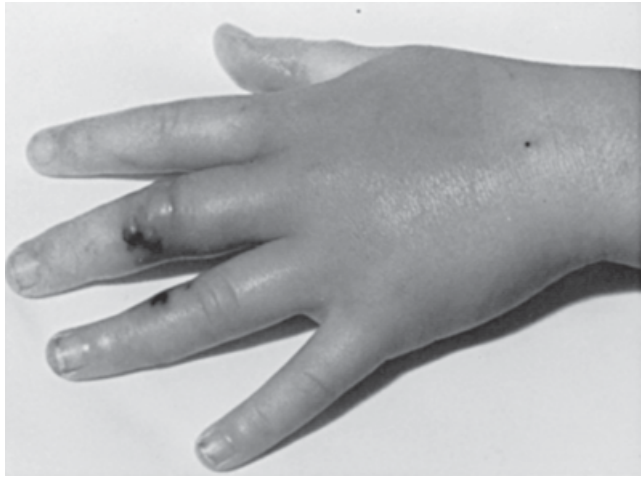

Figure 260–1 Dog bite wound–associated tenosynovitis in a 4-year-old girl. Group D *Streptococcus* was isolated from the wound culture.

In patients with systemic infections transmitted by animal bites, the incubation periods and clinical manifestations vary with the causative agent. For example, streptobacillary rat-bite fever occurs after an incubation period of less than 1 week, whereas spirillary rat-bite fever, or sodoku, has a 2-week asymptomatic interval after the bite. However, rat-bite fevers caused by *Spirillum minor* and *Streptobacillus moniliformis* can occur together. For most of the infections listed in Table 260–2, the bite wound serves as the site of inoculation and has healed completely during the incubation period. For example, fatal encephalitis has resulted from the bite or scratch of a monkey that is actively shedding B virus *(Herpesvirus simiae)*. Institution of acyclovir treatment intravenously at the time of injury may abort progression of the disease.[11,73] The symptoms heralding the onset of systemic infections caused by animal bites do not depend on the mode of transmission and are discussed in their respective chapters. A high index of suspicion can be required to trace the infection to the animal source. For example, most cases of human plague in the United States result from bites by infected fleas, but contact with a domestic cat infected with *Yersinia pestis* can be the source of infection.[38] With tularemia, an ulcerative[81] or pustular[34] lesion develops at the bite site 4 to 7 days after injury and is associated with fever, chills, and painful regional adenopathy. In a case of *Mycobacterium marinum* infection that developed after a dolphin bite, one of several discrete fluctuant masses containing the isolate developed in an area just proximal to the original wound.[37] With cat-scratch disease caused by *Bartonella henselae*, a papule or pustule may be present at the original bite site when systemic signs develop.

The jaws and teeth of dogs are likely to produce multiple puncture wounds, as well as jagged lacerations with devitalized tissue. These lesions can be associated with depressed skull fractures, sometimes in more than one cranial region.[100] Puncture wounds, particularly those inflicted by cat bites, often are deceptively innocuous. Inoculation of organisms deep into poorly vascularized areas, such as tendon sheaths, fascia, joints, and bones, is likely to result in an infected wound.

Some of the complications resulting from direct extension or generalized spread of infection caused by animal bites are summarized in Table 260–3. Tenosynovitis caused by *P. multocida* can be apparent within hours or can present days to weeks after

injury, when persistence of swelling, tenderness or pain, and a mass overlying the involved tendon sheath suggest the diagnosis. *Pasteurella* osteomyelitis that develops after a cat bite is characterized by pain, swelling, and tenderness over the involved bone.[55] With chronic infection, a draining sinus or a persistently draining wound can be the presenting signs. When the periosteum has been entered, osteomyelitis can develop despite early administration of local and antibiotic treatment. Feline incisors are more likely to penetrate the periosteum than are canine incisors, but osteomyelitis can occur as a consequence of dog bites as well.[55]

Bites to the cranium occur with relative frequency in small children because their heads are at the level of the mouth of medium- to large-sized dogs. Complications of perforating cranial bites in children include compound depressed skull fractures, dural lacerations, and extensive intracerebral injuries, which can prove fatal.[17,100] Brain abscess and meningitis can occur as complications of these injuries (see Table 260–3).

Generalized or systemic complications from animal bites occur usually, but not exclusively, in hosts with altered immune status. Bacteremia and fatal endocarditis caused by this organism have occurred in immunocompetent patients. Common underlying findings in infections associated with *Capnocytophaga canimorsus* are splenectomy, alcoholism, and chronic lung disease.[79] Disseminated intravascular coagulation, hypotension, cutaneous gangrene, and renal failure have occurred in patients with leukemia or lymphoma and in association with steroid therapy. Symptoms ensue 1 day to 2 weeks after dog or, occasionally, cat bites occur; the overall mortality rate from *C. canimorsus* septicemia exceeds 20 percent.[25] Although removal of bilaterally affected knee joint prostheses was required to achieve cure of infection caused by *P. multocida* and *Pseudomonas aeruginosa* in one report,[72] cure also has been achieved with antibiotics and drainage with the prosthesis remaining in situ.

DIAGNOSIS AND TREATMENT

The most important aid in establishing the diagnosis of infection after animal bite wounds is the proper use of wound cultures. A culture need not be obtained from children evaluated in the immediate postinjury period (the first 8 hours) unless the bite is located on the face or hand or signs of infection are present. Isolates from an uninfected but contaminated wound reflect the normal flora of the biting animal and do not predict the future development of infection. Routine determination of the microorganisms colonizing bites on the face or hands is useful because of the potentially devastating consequences of infection at these locations. After the wound has been cleansed, culture should be performed routinely when evaluation is at an interval exceeding 8 hours from the time of injury, except for wounds evaluated more than 24 hours after injury and with no signs of infection.

When material is obtained for wound culture, the microbiology laboratory should be informed that the source of the specimen is an animal bite wound. This information should optimize accuracy because *P. multocida* can be mistaken morphologically for *Neisseria* or *Haemophilus influenzae*. Appropriate media must be used for the isolation of anaerobes, and gram-negative rods should be considered pathogens. A blood culture should be obtained for children with a temperature greater than 38.9°C [102°F] rectally) or if systemic toxicity is evident, although associated bacteremia occurs rarely.[34] Radiographic evaluation of the bite-injured area is indicated when the periosteum has been penetrated. A computed tomographic or magnetic resonance imaging study may be an aid to detecting periosteal defects, particularly in children with cranial bite wounds. For patients in whom wound infection has extended locally, sutures, if present, should be removed and material from the involved tissue compartment harvested for study. Material should be aspirated from areas of cellulitis or drained from areas of frank abscess formation. If osteomyelitis is suspected, a bone biopsy specimen should be submitted for Gram stain, culture, and histopathologic evaluation. If the course of the wound infection is indolent, acid-fast stains and mycobacterial cultures should be performed. Serum for serologic testing should be obtained from patients with symptoms suggesting cat-scratch disease, tularemia, syphilis, or blastomycosis. The details of the indicated diagnostic evaluation for systemic infections transmissible by animal bite (see Table 260–3) are specified in the appropriate chapters.

The first step in care of the wound is to cleanse it and the surrounding area. Visible dirt should be sponged away gently to avoid further damage to traumatized tissue. The wound should be irrigated copiously with normal saline. Cleansing by high-pressure syringe irrigation with a 20-mL syringe and 19-gauge needle is effective.[95] This method of irrigation decreased the incidence of infection associated with wounds from dog bites by fivefold, from 69 to 12 percent. Puncture wounds should be cleansed but not irrigated because irrigation may damage tissues further.

Devitalized tissues should be cautiously débrided. The issue of closure for bite wounds is controversial because of concern that sutured wounds have an increased rate of infection. No difference in the infection rate in 57 patients assessed prospectively was noted by one investigator, with the exception of those suffering hand bites, which were more likely to become infected when sutured.[18] In another prospective study, primary closure in patients presenting less than 8 hours after injury was associated with only slightly higher development of wound infection than that occurring after nonbite wound lacerations.[22] After appropriate cleansing and débridement have been achieved, most nonpuncture animal bite wounds except those involving the hand can be treated by primary closure without substantially increasing the risk of development of infection.[39,65]

Definitive data on which to base the use of antibiotic prophylaxis after animal bites are lacking. Smith and colleagues[90] provide a summary of prospective clinical trials that have addressed the issue. One investigator found that oxacillin did not reduce the incidence of infection after dog bite wounds[31] but did after cat bites.[32] Another study found a trend toward a reduced rate of infection, particularly for hand wounds, for patients receiving penicillin prophylaxis after incurring dog bites.[18] Significantly lower infection rates were observed for prophylaxis of wounds in patients presenting at 9 to 24 hours after injury but not for those presenting less than 9 hours later in another study.[15] Prophylactic

dicloxacillin, cephalexin, or erythromycin was not beneficial therapy for low-risk dog bite wounds in another prospective study because infection rates for wounds in both the antibiotic and control groups did not exceed 5 percent.[27]

A meta-analysis of eight randomized trials totaling 783 patients with dog bite wounds found that prophylactic antibiotics did reduce the incidence of infection.[24] The estimated cumulative incidence of infection was 16 percent in controls, and the relative risk was 0.56 (95% confidence interval 0.38-0.82) in patients given antibiotics. Treatment of approximately 14 patients was required to prevent one infection. Thus, one view is that prophylaxis has a role, but it should be used selectively.[19] Alternatively, some researchers consider antibiotic use therapeutic rather than prophylactic in this setting and suggest that antibiotic therapy be given in all cases of dog bites except those initially evaluated more than 24 hours after injury with no clinical signs of infection.[99]

Until additional data are available, a reasonable approach appears to be administration of prophylactic antibiotics in the following circumstances: (1) dog bites more than 8 hours old; (2) moderate to severe dog bites less than 8 hours old, especially if edema or crush injury is present; (3) puncture wounds, particularly if bone or joint penetration may have occurred; (4) facial wounds; (5) all hand bites; (6) wounds in the genital area; and (7) wounds in immunocompromised persons.[43,66,95,97]

Empiric treatment should be directed toward the most common infecting organisms: *P. multocida*, staphylococci, streptococci, and anaerobes.[66] Amoxicillin-clavulanate is active against almost all species of bacteria found in bite wounds and is the drug of choice for empiric oral treatment.[3,16,44] The recommended dosage is 40 mg/kg/day administered at 8-hour intervals. Erythromycin is only moderately active against *P. multocida*.[66,92] A recommended oral regimen for penicillin-allergic children is trimethoprim-sulfamethoxazole (10 mg/kg/day of the trimethoprim component) plus clindamycin (30 mg/kg/day).[3] Numerous other combination regimens such as cefuroxime axetil (30 mg/kg/day) plus clindamycin or metronidazole (30 mg/kg/day) can be used. For hospitalized patients requiring treatment, ampicillin-sulbactam (200 mg/kg/day) and ticarcillin-clavulanate (200 mg/kg/day) are the drugs of choice.[3] Imipenem (80 mg/kg/day) is an alternative choice. Consideration should be given, in the era of methicillin-resistant *S. aureus*, to empiric addition of clindamycin or vancomycin to the regimen in children with serious bite injuries, pending culture results. For penicillin-allergic children, combination therapy with an extended-spectrum cephalosporin or trimethoprim-sulfamethoxazole plus clindamycin should be administered.[3]

Newer macrolides, including azithromycin, show improved activity (versus erythromycin) against the organisms causing animal bite wound infections, but some strains of staphylococci and fusobacteria are resistant.[47] Azithromycin is more active than is clarithromycin against all *Pasteurella* spp.[45] To date, clinical trials documenting its efficacy are not available, and the use of regimens for which clinical experience exists is advisable. Similarly, quinolones and, in particular, gatifloxacin and moxifloxacin exhibit broad activity against the spectrum of pathogens isolated from bite wounds, with the exception of fusobacteria.[48,49]

Penicillin is the drug of choice for *P. multocida* infection. This organism has a median minimal inhibitory concentration to penicillin G of 0.1 to 0.8 μg/mL.[34] Other antibiotics with in vitro activity are ampicillin, tetracycline, chloramphenicol, cephalothin,[92] trimethoprim-sulfamethoxazole, and third-generation cephalosporins.[34] Cefuroxime is potentially useful and more active than is cephalexin.[44] Antibiotics with poor activity against *P. multocida* include the penicillinase-resistant penicillins, clindamycin, and aminoglycosides.[92]

As a general guideline, a suggested duration of therapy, assuming that proper drainage has been established, is 10 days for cellulitis or localized abscess, 2 to 3 weeks for tenosynovitis, and 3 to 4 weeks for osteomyelitis. When improvement is evident, treatment can be completed orally. At least 4 weeks of intravenous therapy should be administered to patients with endocarditis. Although the number of patients is too small to establish the required dosage with certainty, ampicillin (400 mg/kg/day) has been used successfully for the treatment of *P. multocida* meningitis.[10,51a] Antimicrobial therapy for wound infections should be adjusted according to the susceptibility of organisms isolated from the wound cultures.

In every child sustaining a bite wound, immunization status should be determined to assess the need for tetanus prophylaxis and whether rabies prophylaxis should be undertaken (see the appropriate chapters).

REPTILE BITES

Approximately 8000 people in the United States are bitten yearly by poisonous snakes. Approximately half occur in people younger than 20 years old. The curiosity of children can contribute to this exposure because many are bitten while handling poisonous snakes.[75] Between 9 and 15 persons die of snake bites each year.[59]

Venomous snakes are divided into four families, two of which, the Crotalidae (rattlesnakes, copperheads, and water moccasins) and the Elapidae (coral snakes), are found in the United States. Snake venoms are among the most complex of proteins. The local effects of the venom of pit vipers (Crotalidae), which is rich in proteolytic activity, include swelling, pain, edema, ecchymosis, and tissue necrosis with the formation of bullae.[85] Systemic effects result from increased blood vessel permeability and hemolysis and may include hematuria, hematemesis, and disseminated intravascular coagulopathy.[85] The venom of the eastern coral snake causes minimal local tissue destruction. It is a neurotoxin that produces paresthesia of the involved extremity, followed by involvement of the cranial nerves and bulbar paralysis.

Since the preantibiotic era, researchers have recognized that the oral flora of snakes' mouths frequently consists of multiple organisms, particularly gram-negative bacilli, staphylococci, and anaerobes.[76,102] Goldstein and associates[46] isolated 58 aerobic and 28 anaerobic organisms after culturing the venom from 15 rattlesnakes. The aerobes most commonly isolated were *P. aeruginosa*, *Proteus* spp., and *Staphylococcus epidermidis*. Among the anaerobes, *Clostridium* spp. were the isolates found most frequently; *Bacteroides fragilis* also was recovered. Defecation of prey during ingestion contributes to this preponderance of gastrointestinal flora. When the fangs are cleansed carefully before collection, the venom itself is sterile, thus indicating that bacterial isolates potentially contaminating snake bite wounds are a reflection of the oral flora.

In persons sustaining alligator bite wounds, infection is caused most commonly by *Aeromonas hydrophila*. A report of mixed infection with *A. hydrophila*, *Enterobacter agglomerans*, and *Citrobacter diversus* and the frequency with which *Proteus vulgaris* and *Pseudomonas* spp. are isolated from alligator mouths suggest that treatment of alligator bites should be directed at gram-negative species.[36] *Vibrio* infection should be suspected in victims of shark bites, as well as all wounds exposed to salt water.[77] *Aeromonas* spp. and other gram-negative bacilli, as well as *S. aureus* and anaerobes, all can infect shark bites.[84]

The exotic pet industry is growing in the United States, and the common green iguana is a popular pet. Few cases of infections from iguana bites have been reported because these creatures are generally nonaggressive, but *Serratia marcescens* cellulitis has been observed.[53]

The role of empiric antibiotics after reptile wounds is undefined, as is the incidence of infection and subsequent

complications. The inflammatory changes of envenomation can be difficult to differentiate from those of infection. At least one instance of osteomyelitis as a complication of an infected snake bite has been documented.[86] Some experts suggest using a broad-spectrum antibiotic for injuries with severe tissue involvement but not for bites with minor or minimal envenomation.[86] Others suggest that prophylactic antibiotics are not required in snake bite victims.[62,94] Amoxicillin-clavulanate is an appropriate oral antimicrobial and ampicillin-sulbactam plus gentamicin is an appropriate parenteral regimen for empiric treatment of reptile bite wounds.[3] The oral alternatives for penicillin-allergic children are the same as those given for other animal bite wounds; one parenteral regimen for a penicillin-allergic child is clindamycin plus gentamicin. Treatment should be guided by the results of Gram stain and susceptibility testing.

CHAPTER 261

Bioterrorism

Robert J. Leggiadro

The intentional delivery of *Bacillus anthracis* spores through mailed letters or packages established the clinical reality of bioterrorism in the United States in the autumn of 2001.[7,32] An understanding of the epidemiology, clinical manifestations, and management of the more credible biologic agents is critical to limiting morbidity and mortality from a bioterrorism attack.[14,26,29,38]

Implementation of an effective response to deliberate release of biologic agents by terrorists requires detection and reporting of cases as soon as possible.[5,10] Prompt recognition of unusual clinical syndromes and increases above seasonal levels in the incidence of common syndromes or deaths from infectious agents is critical to an effective response.[5,21,29,36]

HISTORY

The concept of biologic warfare or terrorism is not a new one. In 1346 the Tatar force attacking Kaffa (also, Caffa) (now Feodossia, Ukraine) was struck by a plague epidemic.[11] To take advantage of this development, the Tatars catapulted the corpses of their plague victims into Kaffa. An outbreak of plague did occur in the city, representing one of the first biologic attacks recorded.[51]

Smallpox first was used as a biologic weapon during the French and Indian War of 1754 to 1767.[11] Apparently, British troops deliberately infected Native Americans with smallpox by giving them blankets from infected patients.

A secret branch of the Japanese army, Unit 731, reportedly caused outbreaks of plague by dropping plague-infected fleas over populated areas of China in World War II.[28] Bomb experiments of weaponized anthrax spores were conducted by the Allies on uninhabited Gruinard Island near the coast of Scotland and resulted in heavy contamination in 1942.[45] Viable anthrax spores persisted until the island was decontaminated with formaldehyde and seawater in 1986.

In response to a perceived German biologic warfare threat, the United States began research into the offensive use of biologic agents in 1943 at Camp Detrick (renamed Fort Detrick in 1956) in Frederick, Md.[19] President Nixon stopped all offensive biologic and toxin weapon research and production by executive order in 1969. Included among the agents destroyed as a result

of this action were *B. anthracis*, botulinum toxin, *Francisella tularensis*, *Coxiella burnetii*, Venezuelan equine encephalitis virus, *Brucella suis*, and staphylococcal enterotoxin B. Begun in 1953, the U.S. defensive program at Fort Detrick continues today as the U.S. Army Medical Research Institute of Infectious Diseases (USAMRIID).

The Biological and Toxin Weapons Convention was ratified in 1972 and went into effect in 1975.[52] It prohibits the development, production, stockpiling, or transfer of biologic weapons agents (microbial pathogens and toxins) for other than peaceful purposes and any devices used to deliver these agents. One hundred forty-three states are parties to the convention, with an additional 18 signatories. Unfortunately, the treaty was not accompanied by effective provisions for verification.

Although the Soviet Union signed the convention at its inception in 1972, it formed and funded an organization known most recently as Biopreparat (Chief Directorate for Biological Preparations) 2 years later.[16] This organization was designed to carry out offensive biologic weapons research, development, and production concealed behind legal and civil biotechnology research. Its capacity for production of biologic weapons included plague, tularemia, glanders, brucellosis, anthrax, smallpox, and Venezuelan equine encephalomyelitis.[1]

An incident at a military microbiology facility in Sverdlovsk (now Yekaterinburg) in the former Soviet Union in 1979 proved to be a grim warning of the dangers of biologic weapons science.[40] An accidental aerosolized release of anthrax spores resulted in at least 79 cases of anthrax, including 68 deaths. This largest reported outbreak of inhalational anthrax occurred in people living or working within a 4-km zone downwind of the facility.

Iraq's biologic warfare program commenced in earnest in 1985 after initial explorations in the late 1970s.[54] By the end of the Persian Gulf War in 1991, Iraqi scientists had investigated the biologic warfare potential of five bacterial strains, one fungal strain, five viruses, and four toxins. The United Nations Special Commission suspects that from 1991 to 1995, Iraq actively preserved biologic weapons capability, including botulinum toxin, anthrax, and *Clostridium perfringens* spores.[16]

The Japanese cult Aum Shinrikyo made several unsuccessful attempts at disseminating anthrax from rooftops and trucks in central Tokyo in the early 1990s before successfully releasing sarin nerve gas into Tokyo's subways and killing a dozen people in 1995.[53] A large community outbreak of salmonellosis was caused by the intentional contamination of restaurant salad bars for political reasons by members of a religious commune in The Dalles, Oregon, in 1984.[49]

EPIDEMIOLOGY

Potential biologic weapons share several characteristics. Ease of acquisition and production is a primary consideration. Other ideal properties include the potential to be aerosolized (particle size, 1-10 μm) and dispersed over a wide geographic area, as well as resistance to sunlight, desiccation, and heat. The potential to cause lethal or debilitating disease and person-to-person transmission are important features, as is lack of effective therapy or prophylaxis.[22,26,38]

Any small or large outbreak of disease merits evaluation as a potential biologic event.[41] Unusually high rates of disease (e.g., a cluster of life-threatening pneumonia cases in previously healthy adults), as well as unusual clinical syndromes, should signal a warning. Once definition of the cause and rate of attack have been determined, an epidemic curve based on the number of cases during a specific time can be calculated. The epidemic curve in a biologic event triggered by a point-source exposure most likely would be compressed, with a peak occurring in a matter of hours or days. The occurrence of a second curve peak would be possible with contagious agents as a result of person-to-person transmission. The steep epidemic curve expected in a bioterrorism attack is similar to what would be seen with other point-source exposures such as food-borne outbreaks.

Several epidemiologic clues may be helpful in determining whether further investigation into an outbreak as a potential biologic attack is warranted. A large epidemic, especially in a discrete population; more severe disease than expected for a given pathogen; and a disease unusual for a given geographic area (e.g., pulmonic tularemia in an urban setting) are major indicators. Multiple simultaneous epidemics of different diseases, outbreaks with both human and zoonotic consequences, and unusual strains or susceptibility profiles are additional helpful parameters. Variable attack rates as a function of agent release relative to the interior or exterior of a building also would be useful.[41] Although most bioterrorism attacks will be covert,[5,10] intelligence revealing plans for an attack, terrorist claims of deliberate release, or direct physical evidence of an attack obviously would point to a biologic event.

The emergence of mosquito-borne West Nile virus encephalitis in New York City in the summer of 1999 is an example of a naturally occurring outbreak that had elements of a potential bioterrorist attack.[5,21,47] This outbreak represented a disease occurring in an unusual (previously nonendemic) area, as well as one with zoonotic (birds) in addition to human consequences. It marked the first documented appearance of West Nile virus in the Western Hemisphere and the first arboviral outbreak in New York City since the yellow fever epidemics of the 19th century.[21] A large avian die-off, affecting primarily crows, preceded the outbreak in humans by at least several weeks.

CRITICAL BIOLOGIC AGENTS

In addition to anthrax, critical biologic agents include brucellosis, plague, Q fever, and tularemia; smallpox, viral encephalitis, and viral hemorrhagic fever; and illnesses related to botulinum and staphylococcal enterotoxin B toxins (Table 261–1).[5,33,36] The five more credible biologic agents are discussed further.

ANTHRAX

B. anthracis is a large sporulatory, gram-positive rod with three distinct life cycles featuring multiplication of spores in soil, animal (herbivore) infection, and human infection.[34] Anthrax continues to occur in developing countries where the organism is highly endemic and the use of animal anthrax vaccine is not comprehensive (e.g., Iran, Iraq, Turkey, Pakistan, and sub-Saharan Africa). Human cases may be classified as either agricul-

tural or industrial. Herders, butchers, and slaughterhouse workers in direct contact with infected animals are susceptible to acquiring agricultural infection, and workers in mills that process animal hair and those handling bone meal may acquire industrial infection.[43]

The three forms of human anthrax are cutaneous, inhalational, and gastrointestinal. The most common form is cutaneous, which is acquired through contact with an infected animal or animal products. The much less common inhalational form results from the deposition of spores in the lungs, and gastrointestinal anthrax occurs after the ingestion of infected meat. Because human-to-human transmission of anthrax has not been reported, standard precautions are recommended for hospitalized patients with all forms of anthrax infection.[30,48]

In the United States, 224 cases of cutaneous anthrax were reported between 1944 and 1994.[30] Most cases in recent decades were a result of exposure to wool or animal hair.[43]

The clinical features and course of the first 10 confirmed cases of inhalational anthrax associated with bioterrorism in the United States in the fall of 2001 have been reported.[32] Epidemiologic investigation indicated that the outbreak was a result of intentional delivery of *B. anthracis* spores through mailed letters or packages. The median incubation period was 4 days and ranged from 4 to 6 days. Several clinical features of these patients were not emphasized in earlier reports of inhalational anthrax, a previously rare disease. Drenching sweating, nausea, and vomiting were common manifestations of the initial phase of illness in this outbreak. Pleural effusions were a remarkably consistent clinical feature. No predominant underlying diseases or conditions were noted.

None of the 10 patients had an initially normal chest radiograph. In addition to characteristic mediastinal widening (Fig. 261–1), paratracheal or hilar fullness, pleural effusions, and parenchymal infiltrates were noted. Computed tomography of the chest was more sensitive than was chest radiography in revealing mediastinal lymphadenopathy, and an elevation in the proportion of neutrophils or band forms represented an early diagnostic clue.

Inhalational anthrax previously was reported to be a biphasic illness with influenza-like symptoms such as fever, cough, malaise, fatigue, and chest discomfort in the first phase, followed briefly by 1 to 2 days of improvement before development of the acute phase 2 to 5 days later.[13] However, this brief period of improvement between the initial and fulminant phases of illness was not observed in the first intentional outbreak associated with mail.[27]

The 55 percent survival rate in these patients was higher than previously reported (<15%). Limited data on treatment of survivors suggest that early treatment with a fluoroquinolone and at least one other active drug (e.g., rifampin, clindamycin, or vancomycin) may improve survival.[7,48]

Nasal congestion, rhinorrhea, and sore throat, infrequently seen in this series, might help distinguish influenza-like illness from inhalational anthrax.[15] Newer diagnostic methods for *B. anthracis* infection include polymerase chain reaction (PCR), immunohistochemistry, and sensitive serologic tests. Recommendations for antibiotic treatment of inhalation anthrax include use of either ciprofloxacin or doxycycline, plus one or two additional antibiotics known to be active in vitro against *B. anthracis.* Additional antibiotics include clindamycin, vancomycin, imipenem, meropenem, chloramphenicol, penicillin, ampicillin, rifampin, and clarithromycin. Corticosteroids should be considered for meningitis or significant mediastinal edema.[3,27]

Cutaneous anthrax is characterized by a skin lesion evolving from a papule, through a vesicular stage, to a depressed black eschar, often surrounded by significant edema and erythema.[18,46,48] The lesion, which may mimic a spider bite, is usually painless and located on exposed parts of the body (i.e., face, neck, and arms). The incubation period ranges from 1 to 12 days but commonly is less than 7 days. With effective antimicrobial therapy, fatalities are rare occurrences (<1%). Cutaneous anthrax occurred in a 7-month-old infant who was exposed at his mother's workplace as a result of the Fall 2001 attack. This infant displayed severe microangiopathic hemolytic anemia with renal involvement, coagulopathy, and hyponatremia, unusual findings with cutaneous anthrax.[23]

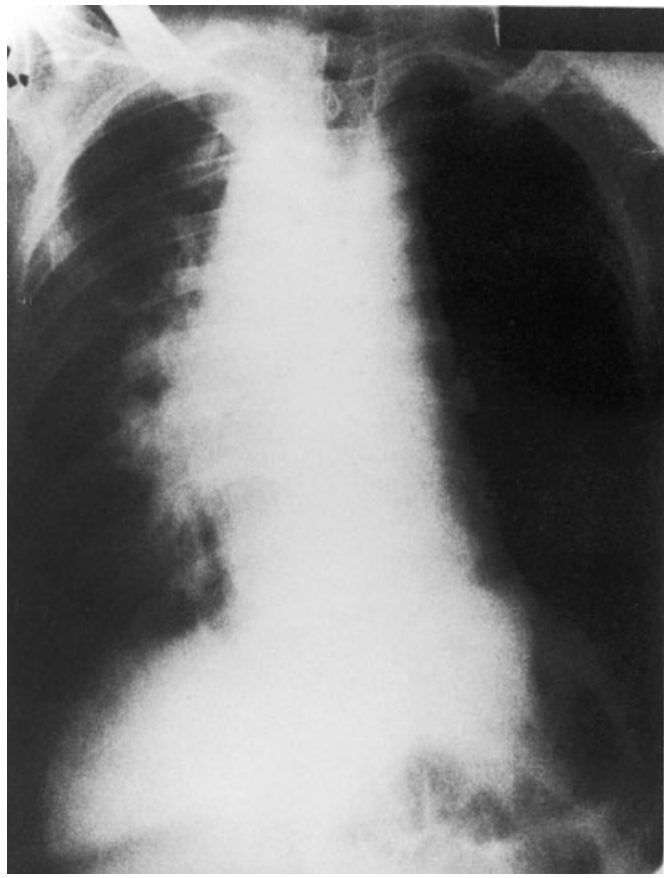

Figure 261–1 Chest radiograph showing a widened mediastinum secondary to hemorrhagic mediastinitis in a patient with a fatal case of inhalation anthrax. *(From LaForce, F. M., Bumford, F. H., Feeley, J. C., et al.: Epidemiologic study of a fatal case of inhalation anthrax. Arch. Environ. Health* 18*:798-805, 1969. Reprinted with permission of Helen Dwight Reid Educational Foundation. Published by Heldref Publications, 1319 Eighteenth St., NW, Washington, DC 20036-1802. Copyright 2000.)*

The organism grows readily on sheep blood agar and forms rough, gray-white colonies 4 to 5 mm in size with characteristic comma-shaped or "comet tail" protrusions.[34] *B. anthracis* is differentiated from other *Bacillus* spp. by an absence of the following: hemolysis, motility, growth on phenylethyl alcohol blood agar, gelatin hydrolysis, and salicin fermentation. Biosafety level 2 conditions for safe specimen processing in the microbiology laboratory and prompt confirmation of suspected isolates at the Centers for Disease Control and Prevention (CDC) or the USAMRIID in Fort Detrick are warranted.[30,43]

Postexposure vaccination with an inactivated, cell-free anthrax vaccine may be indicated along with ciprofloxacin, doxycycline, or amoxicillin chemoprophylaxis after a proven biologic event has occurred.[48,50] Recommendations for postexposure prophylaxis (and prolonged therapy following initial therapy for inhalational or cutaneous anthrax) include three options: (1) a 60-day course

of antibiotics followed by careful clinical observation, (2) extension of antibiotic therapy to 100 days, or (3) extension of antibiotic therapy to 100 days combined with administration of anthrax vaccine in three doses at 2-week intervals.[3,27] Pre-exposure vaccination may be indicated for the military and other select populations or for groups for which a calculable risk can be assessed.

SMALLPOX

After a worldwide eradication program, the last known endemic case of smallpox occurred in Somalia in 1977, and the World Health Organization declared smallpox eradicated in 1980.[24] No animal reservoir exists. Current recognized stocks of variola virus are authorized only at the CDC in Atlanta and a Russian state laboratory in Koltsovo. However, additional variola isolates, either long held unreported or acquired through security breaches, also may exist. Because vaccination against smallpox ceased in the United States in 1972, virtually the entire population now would be considered susceptible because immunity wanes over the course of time. Release of an aerosol would be the most likely route of transmission during an act of bioterrorism.

Smallpox is transmitted by respiratory secretions and requires close person-to-person contact. The incubation period generally is 12 to 14 days, with a range of 7 to 17 days. The prodromal illness of classic variola major features an acute onset of malaise, fever, rigors, vomiting, headache, and backache. Two to 3 days later, a discrete rash appears on the face, hands, forearms, and mucous membranes; it spreads to the legs and then centrally to the trunk during the second week of illness. Lesions progress from macules to papules to pustular vesicles during the course of 1 to 2 days. Umbilicate scabs form 8 to 14 days after onset and leave depressions and depigmented scars.[25]

In contrast to varicella (chickenpox), the rash of smallpox is centrifugal, with a concentration of lesions on the face and extremities, including the palms and soles, versus the trunk in varicella (Fig. 261–2). Smallpox lesions also are synchronous in stage of development, whereas the lesions of chickenpox appear in crops every few days, which results in lesions at very different stages of maturation in different areas of the skin. Any confirmed case of smallpox represents an international emergency and must be reported to national authorities through local and state health departments.[24]

Historically, the mortality rate associated with smallpox was 30 percent for unvaccinated contacts, and currently no antiviral therapy of proven efficacy has been developed. Supplies of vaccinia vaccine and vaccinia immune globulin are available only through the CDC.[24] Postexposure vaccination and strict quarantine are indicated for all household and other face-to-face contacts of suspected smallpox cases.[24]

In a limited outbreak with few cases, hospitalized patients should receive care in negative-pressure rooms with high-efficiency particulate air filtration. In addition, precautions using gloves, gowns, and masks are indicated. Home isolation and care are appropriate for most patients in larger outbreaks.[24]

Between January 24 and October 31, 2003, 37,901 volunteers in 55 jurisdictions received 38,885 smallpox vaccinations through the U.S. Department of Health and Human Services program, with a take rate of 92 percent.[9] The Vaccine Adverse Event Reporting System (VAERS) received 822 adverse event reports related to these vaccines, an overall reporting rate of 217 per 10,000 vaccinees. Seven hundred twenty-two nonserious reports to VAERS included multiple signs and symptoms of mild systemic and self-limited local reactions, including fever, rash, pain, and headache.[9]

No cases of preventable life-threatening adverse reactions, such as eczema vaccinatum, progressive vaccinia, or fetal vaccinia, were reported. No cases of vaccinia contact transmission occurred. No vaccinee or contact of this program received vaccinia immune globulin. Rigorous smallpox vaccine safety screening, educational programs, and older vaccinees may have contributed to low rates of preventable life-threatening adverse reactions.[9]

Figure 261–2 The lesions of smallpox are at the same stage of development on each area of the body, are deeply embedded in the skin, and are more densely concentrated on the face and extremities. *(From Henderson, D. A.: Smallpox: Clinical and epidemiologic features. Emerg. Infect. Dis. 5:537-539, 1999.)*

One-hundred adverse events were designated as serious, resulting in 85 hospitalizations, two permanent disabilities, 10 life-threatening illnesses, and three deaths. Among the serious adverse events, 21 cases were classified as myocarditis and/or pericarditis and 10 as ischemic cardiac events that were not anticipated on historical data. Two cases of generalized vaccinia and one case of postvaccinial encephalitis also were detected.[9]

PLAGUE

Plague, a zoonotic illness caused by the gram-negative bacillus *Yersinia pestis*, is primarily a disease of rodents, with transmission occurring through infected fleas. Human disease is acquired through rodent flea vectors, as well as respiratory droplets from animals to humans and humans to humans. Transmission of plague to humans in the United States primarily is via the bites of fleas from infected rodents. From 1970 to 1995, 341 cases of human plague were reported in the United States, most commonly from Arizona, California, Colorado, and New Mexico.[44] Indications of a deliberate release of plague bacilli would include the occurrence of cases in locations not known to have enzootic infection, in persons without known risk factors, and in the absence of previous rodent deaths.[28]

The three clinical forms of human plague are bubonic, primary septicemic, and pneumonic. Bubonic plague, characterized by the development of an acute regional lymphadenopathy, is the most

frequent clinical form and accounts for 80 to 90 percent of U.S. cases.[44] However, the pneumonic form would be the most likely manifestation as a result of release of an aerosol during a biologic attack.[22,28] This clinical form is the least common, but it has the highest mortality rate; it is almost always fatal if antibiotics are not begun within 24 hours of the onset of symptoms. Septicemic plague without obvious lymphadenopathy may be more difficult to diagnose than is bubonic plague because of nonspecific manifestations (i.e., fever, chills, abdominal pain, nausea, vomiting, diarrhea, tachycardia, tachypnea, and hypotension).[28] Delay in establishing the diagnosis and initiating appropriate therapy may lead to death.[28,37]

The incubation period for primary pneumonic plague is 1 to 3 days. Fever, chills, headache, and rapidly progressive weakness are characteristic of all clinical forms of plague. Cough, dyspnea, and hemoptysis are distinctive of primary pneumonic plague. The sudden appearance of a large number of previously healthy patients with fever, cough, shortness of breath, chest pain, and a fulminant course leading to death should suggest the possibility of pneumonic plague or inhalational anthrax immediately. The presence of hemoptysis would strongly suggest plague.[4,28]

Y. pestis may be identified in clinical specimens by Gram, Wright-Giemsa, Wayson, and immunofluorescence staining methods, in addition to standard bacterial culture. Appropriate clinical specimens include lymph node aspirates and blood, as well as tracheal washes or sputum smears if pneumonic plague is suspected. Tests that would be used to confirm a suspected diagnosis, including antigen detection, immunoglobulin M (IgM) enzyme immunoassay, and PCR assay, are available only through state health departments, the CDC, and military laboratories.[28]

Effective therapy is available in the form of streptomycin, gentamicin, chloramphenicol, doxycycline, and ciprofloxacin.[28] Parenteral aminoglycoside therapy is recommended in a contained casualty setting (modest number of patients requiring treatment); oral therapy is recommended in a mass casualty scenario.[28] The potential benefits of doxycycline and ciprofloxacin in the treatment of pneumonic plague infection in children substantially outweigh the risks.[10,28] An inactivated, whole-cell *Y. pestis* vaccine was discontinued by its manufacturers in 1999 and no longer is available.[28]

In addition to standard precautions, droplet precautions are indicated for all patients with suspected plague until pneumonia is excluded and appropriate therapy has been initiated. Droplet precautions should be continued in patients with confirmed pneumonic plague for 48 hours after the initiation of appropriate therapy.[28] Only standard precautions are recommended for bubonic plague.

TULAREMIA

The etiologic agent of this zoonotic illness is *F. tularensis*, a gram-negative coccobacillus. The disease may be acquired from ticks and deer flies, contact with animals such as rabbits and rodents, ingestion of contaminated water, or inhalation of aerosols. In a bioterrorist event, inhalation of an aerosol would be the most likely route of infection.[4,17] Human-to-human transmission of tularemia has never been reported. The annual incidence of tularemia in the United States is less than 200 cases; all suspected or confirmed cases must be reported to health authorities.

Clinical forms of the disease include ulceroglandular, glandular, oculoglandular, oropharyngeal, pneumonic, and typhoidal, the type reflecting the organism's portal of entry.[20,31] Either pneumonic alone or typhoidal, with or without a pneumonic component, would be the most likely clinical manifestation of tularemia as a result of aerosol release during a biologic attack.[4,17] The incubation period for tularemia is 3 to 6 days, with a range 1 to 21 days. Typhoidal tularemia may manifest as fever of unknown origin. Standard precautions are indicated for hospitalized patients with all forms of tularemia.[17]

The diagnosis is established most often by serologic testing, and isolation of *F. tularensis* from clinical specimens requires cysteine-enriched media or inoculation of laboratory mice. In addition to a need for special media, the laboratory should always be informed when tularemia is suspected because of the potential hazard to laboratory personnel. Suspected isolates should be confirmed by the CDC or USAMRIID through local or state health departments.[17]

Effective therapeutic agents include streptomycin, gentamicin, tetracycline, ciprofloxacin, and chloramphenicol; post-exposure prophylaxis with doxycycline or ciprofloxacin may be considered.[17] The benefits of tetracycline or ciprofloxacin therapy may outweigh the risks for children younger than 8 years in select clinical situations, including tularemia.[17,35] A live attenuated vaccine for pre-exposure use is available through the USAMRIID.[12]

BOTULISM

Seven distinct but related neurotoxins, A through G, are produced by different strains of *Clostridium botulinum*, an anaerobic gram-positive rod. The most common types in U.S. food-borne outbreaks are A, B, and E; outbreaks with unusual botulinum toxin types (i.e., C, D, F, and G, or E not acquired from an aquatic food) would suggest deliberate release.[2] Classic neuroparalytic disease is acquired through the ingestion of preformed neurotoxin. Other forms include localized infection (wound botulism) and *C. botulinum* intestinal colonization in infants with in vivo toxin production (infant botulism). Botulism in the United States is seen most often in small clusters or single cases associated with home-canned foods. Although airborne transmission of botulinum neurotoxin does not occur naturally, aerosolization of preformed toxin would be the most likely route of transmission in a bioterrorism event.[2,22] Sabotage of food supplies is also possible. Botulism is not transmitted from human to human; standard precautions are recommended for hospitalized patients.

The incubation period for food-borne botulism generally is 12 to 36 hours (range, 6 hours to 8 days). The clinical manifestations of disease acquired by inhalation would be the same as those for food-borne botulism. Early manifestations include blurred vision, diplopia, and dry mouth. Patients are afebrile with a clear sensorium.

Later clinical features indicative of more severe disease include dysphonia; dysarthria; dysphagia; ptosis; and symmetric, descending, progressive muscular weakness with respiratory failure.[2] Clinical suspicion is critical because a recognized source of exposure may be absent in a biologic attack. Botulism is a reportable disease.

A toxin neutralization bioassay in mice is used to identify botulinum toxin in serum, stool, or food. *C. botulinum* also may be cultured from stool and food. Electromyography can be helpful diagnostically. Botulinum antitoxin of equine origin, available from the CDC and state or municipal health departments, should be administered as soon as possible to patients symptomatic with botulism after testing for hypersensitivity to equine sera.[2,19] A pentavalent toxoid of *C. botulinum* toxin types A, B, C, D, and E is available as a vaccine under investigational drug status through the CDC or Department of Defense.[2,12]

VIRAL HEMORRHAGIC FEVER

The term viral hemorrhagic fever (VHF) refers to a clinical illness associated with fever and a bleeding diathesis caused by a

virus belonging to one of four distinct families: Filoviridae (e.g., Ebola, Marburg), Arenaviridae (e.g., Lassa fever), Bunyaviridae (e.g., Rift Valley fever), and Flaviviridae (e.g., yellow fever). VHF agents are RNA viruses normally transmitted to humans from animal reservoirs or arthropod vectors, although the natural reservoirs and vectors of the Ebola and Marburg agents are unknown. Most of these agents are considered serious, potential biologic threats because of their potential to be aerosolized and their high morbidity and/or mortality rates. Clinical features vary with the specific virus, but all are capable of causing fever, myalgia, prostration, petechiae, hemorrhage, and shock.[6]

Treatment generally is supportive, although ribavirin has some in vitro and in vivo activity against arenaviruses and bunyaviruses, but not against filoviruses or flaviviruses. VHF-specific barrier precautions, as well as airborne precautions, are recommended for any patient with suspected or documented VHF. Effective prophylaxis following exposure to an VHF agent is not available.[6]

PREPAREDNESS AND RESPONSE

Being prepared for a bioterrorist attack or any other large-scale infectious disease outbreak relies on similar critical elements.[21,29,39,42,47] Clinician awareness and education are paramount. Because practicing physicians most likely will be the first group to encounter diseases caused by biologic weapons, they must be familiar with the signs and symptoms of the more credible biologic agents (e.g., smallpox, anthrax).[29,39,42] Recognition of an unusual case or cluster of illnesses should prompt a report to the local public health authorities.[8,21] Improved communication between human and animal health authorities is warranted because many potential bioterrorist agents, such as anthrax, brucellosis, Q fever, plague, and tularemia, are zoonotic diseases.[21] Knowledge of the processes by which the hospital laboratory, the local or state health department, or the CDC performs diagnostic studies to implicate or exclude biologic agents also is important.[5,21,29] Local, state, and federal public health agencies must coordinate plans for dealing with a large-scale outbreak caused by a biologic event.[5,8,21,47] They should address rapid investigation of the outbreak, public education, mass distribution of antibiotics and vaccines, the capacity to care for mass casualties, and proper, expeditious treatment of the dead.[5,21,29,47]

CHAPTER 262

Bacterial Laboratory Diagnosis

Bobby L. Boyanton, Jr. ❂ James Versalovic

The plethora of bacterial pathogens causing infections in children poses multiple challenges for the pediatrician. Overlapping or similar clinical presentations may result in the simultaneous consideration of established and emerging pathogens. Fortunately for pediatric medicine, the continuous development and refinement of molecular strategies has complemented ongoing improvements in routine approaches for the laboratory diagnosis of bacterial infections.

Bacteria are unicellular prokaryotic organisms that may cause infections as single pathogens or disease-causing strains. At the same time, commensal bacteria comprise 90 percent of the cellular content of human beings, with an estimated 10^{14} bacteria compared with estimates of 10^{13} human cells.[7] The gene content of the intestinal microbiota is estimated to be 100-fold greater in magnitude than the content of the human genome. The challenge for diagnostic microbiology laboratories often becomes a quest to distinguish potential pathogens from commensal bacteria not involved in disease. Such pathogens may belong to a specific clonal or genetic lineage with well-characterized toxins or virulence factors. Additionally, polymicrobial infections may be caused by two or more pathogens, resulting in mixed infections. In the current era of metagenomics, scientists are beginning to understand disorders of microbial ecology and how changes in complex bacterial communities may affect human health.

Bacteria are defined by several unifying features, including the ability to proliferate as single-celled organisms lacking a nuclear membrane or cellular organelles. Their ability to proliferate as free-living cells enables the diagnostic laboratory to employ routine culture-based approaches for pathogen isolation. In addition to culture on plated (solid) or liquid media, pathogens or toxins may be detected directly by protein (antigen) immunoassays or nucleic acid (DNA or RNA) diagnostics. Adaptive immune responses to specific pathogens may be exploited for pathogen detection by antibody immunoassays, and such approaches may offer diagnostic solutions when pathogens cannot be cultured readily in the laboratory.

The sections in this chapter will be grouped by the basic category of infection. The central issues of specimen collection, transport, and reporting will be considered within the context of each type of infection. More detailed diagnostic strategies are described in other chapters of this edition and in the context of specific pediatric infections. Rather than provide a detailed listing of tests and methods, this chapter will highlight basic laboratory strategies and important diagnostic principles important for each category of pediatric infections (Table 262–1).

RESPIRATORY TRACT INFECTIONS

Bacterial pathogens represent important causes of pediatric upper and lower respiratory tract infections. Other pathogens such as respiratory viruses or fungi may cause respiratory tract infections and mimic the clinical presentations of bacterial infections. Furthermore, children may be co-infected with viruses and bacteria so that even if a predominant bacterial pathogen is identified, a viral pathogen also may need to be considered. Respiratory tract infections caused by different pathogens may have overlapping features and may not be clinically distinguishable with respect to the etiologic agent.

BACTERIAL CULTURES OF THE UPPER RESPIRATORY TRACT

The diagnoses of upper and lower respiratory tract infections require sampling of different sites and by different methods. Upper respiratory tract specimens include throat or nasopharyngeal swabs, sputa, or tracheal aspirates and are considered nonsterile. Lower respiratory tract specimens include bronchoscope-assisted collections of fluids or tissues of the lower respiratory tract and are considered relatively sterile samples. The distinctions between sterile and nonsterile specimens are important considerations in the laboratory because potential pathogens must be distinguished from the commensal microbiota of the respiratory tract.

The throat and nasopharynx may serve as important reservoirs and primary sites for upper respiratory tract infections. Oropharyngeal or throat swabs from children may be processed for antigen immunoassays, throat cultures, or nucleic acid amplifica-

TABLE 262–1 Basic Laboratory Strategies for Diagnosis of Bacterial Infections

Site of Infection	Rapid Assessment	Routine/Special Tests
Central nervous system	CSF Gram stain	CSF culture DNA amplification
Gastrointestinal tract		
Gastric	*Helicobacter pylori* serology Urea breath testing	Tissue urease testing Histology with special stains
Intestinal	Stool microscopy (O&P) Stool antigen testing	Stool culture
Genitourinary tract	Urinalysis Urine Gram stain	Urine culture DNA amplification
Peripheral blood	Leukocyte count/differential Serology	Blood culture
Respiratory tract	Direct Gram stain Urine antigen testing	Respiratory culture DNA amplification
Wounds and superficial sites	Direct Gram stain	Tissue/aspirate culture

CSF, cerebrospinal fluid; O&P, ova and parasites.

tion. Bacterial cultures are recommended as a standard approach in the laboratory to evaluate patients with suspected streptococcal pharyngitis.[29,54] Swabs made of synthetic fibers such as Dacron are preferable for collection and are used to obtain samples from the tonsillar areas and posterior oropharynx. Plated media with blood agar, including media selective for streptococci, are used to isolate *Streptococcus pyogenes* or other β-hemolytic streptococci from throat swabs. Non–serogroup A β-hemolytic streptococci, especially groups C and G, may cause pharyngitis and may be isolated from throat cultures. *Arcanobacterium hemolyticum*, a gram-positive pathogen that may cause pharyngitis in adolescents, can be isolated from throat cultures after prolonged incubation (>72 hours) and has colonies that produce small zones of β-hemolysis.[2,41] Nasopharyngeal cultures and sinus aspirates may be useful for the evaluation of children with acute otitis media and sinusitis.[13,88] Although nasopharyngeal or sinus aspirate cultures are not performed routinely, pathogens such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, or *Moraxella catarrhalis* may be isolated on plated media with blood or chocolate agar and may facilitate establishing the diagnoses in children with protracted illnesses.[13,24] Collection of sinus aspirates may require sinus endoscopy by pediatric otorhinolaryngologists. Bacterial cultures of sinus aspirates should include both routine (aerobic) and anaerobic cultures with blood agar and media capable of isolating fastidious pathogens such as *Haemophilus* spp.

BACTERIAL CULTURES OF THE LOWER RESPIRATORY TRACT

The diagnosis of pneumonia can be challenging, even with the proper clinical specimens for laboratory evaluation. In a recent report, evidence of a potential etiologic agent varied tremendously (24 to 85% of cases) among children being evaluated for pneumonia, depending on the numbers and types of tests performed.[82] A pathogen was identified in 79 percent of hospitalized children (age range, 2 months to 17 years) with radiographically confirmed lower respiratory tract infections.[57] Sputum Gram stain and cultures are recommended as standard approaches for the evaluation of bacterial pneumonia or of infections of the lower respiratory tract, especially in older children and adolescents. In young children, sputum samples may be difficult to obtain, and bronchoscope-assisted collection of lower respiratory tract specimens may be required. Sputum and bronchoscopic specimens are evaluated routinely by light microscopy and Gram stain in order to visualize polymorphonuclear infiltration and predominant microbial morphologies. Careful Gram stain evaluation continues to be a useful tool for routine evaluation of patients suspected of having acute bacterial pneumonia. The presence of abundant neutrophils and a single predominant microbial morphotype provides strong support for the diagnosis of acute bacterial pneumonia.[61,98] Neutrophils may be sparse in children with neutropenia, so the immune status of patients should be considered.

Sputum and tracheal aspirate cultures are plated on different solid media including blood agar, chocolate agar, and MacConkey agar for a minimum of 48 hours. Primary bacterial etiologies of acute bacterial pneumonia such as *S. pneumoniae*, *Staphylococcus aureus*, and *S. pyogenes* are isolated routinely by sputum culture on plated blood agar. In a recent study of radiographically confirmed pneumonia in children, 60 percent of cases included a bacterial pathogen and 73 percent of cases with a bacterial pathogen included *S. pneumoniae* as the primary agent.[57] Up to 23 percent of children in this study yielded evidence of viral and bacterial co-infections in the context of pneumonia. Gram-positive pathogens can be diagnosed by morphologic and limited biochemical testing. The successful isolation of *S. pneumoniae* from sputum or bronchoscopic cultures continues to be the top priority for the laboratory evaluation of bacterial pneumonia in children. Colonies of *S. pneumoniae* may be visible as alpha-hemolytic colonies on blood agar, requiring 24 to 48 hours for successful culture. Optochin susceptibility and Gram stain morphology are key tests for identification of pneumococcal isolates.[16,63]

Different media formulations may be important for the isolation of different respiratory pathogens. Chocolate agar may be important for the isolation of fastidious pathogens such as non-typeable *H. influenzae*, whereas other *Haemophilus* spp. may be identified subsequently with additional agar-based nutrient testing and limited biochemical evaluation. Gram-negative pathogens such as *Klebsiella pneumoniae* or *Pseudomonas aeruginosa* may be cultivated on MacConkey agar. Cases of aspiration pneumonia in pediatrics may necessitate the addition of anaerobic cultures with plated blood agar and selective media for organisms such as *Bacteroides* or *Fusobacterium* spp.[12] Tracheal aspirates may facilitate establishing the diagnosis of aspiration pneumonia, ventilator-associated pneumonia, and tracheitis. Like sputum cultures, tracheal aspirate cultures are considered nonsterile, and differential or selective media are helpful. Children, especially younger pediatric patients, may not produce sufficient or adequate sputum for evaluation in the laboratory. If sputum is difficult to obtain, tracheal aspirates or induced sputum specimens may be collected. Bronchoscope-assisted collection, such as bronchial wash or bronchoalveolar lavage (BAL), may be necessary for adequate sampling and assessment. Such specimens should be evaluated by direct Gram stain and usually lack confounding features of the upper respiratory tract such as epithelial cell shedding. Bronchial wash and BAL cultures also should be plated on different media such as blood and MacConkey agar in addition to thioglycollate broth for the isolation of gram-positive and gram-negative bacterial pathogens. Unusual bacterial respiratory pathogens such as *Legionella* spp. must be cultured on specialized media such as buffered charcoal yeast extract (BCYE) agar.[93]

Children with cystic fibrosis and associated respiratory tract infections pose special challenges for the diagnostic microbiology laboratory.[58] *S. aureus* is an important cause of respiratory tract infections in cystic fibrosis. Although *S. aureus* isolates usually are relatively easy to grow and identify in the laboratory, small-colony variants with different colonial features can be identified in up to 50 percent of patients with cystic fibrosis.[39,40] The small-colony variants are nonhemolytic, nonpigmented, and slow-growing, rendering them difficult to identify as *S. aureus*. Media such as mannitol salt agar can effectively support *S. aureus* auxotrophs while minimizing overgrowth for successful isolation. *P. aeruginosa* also represents a primary respiratory pathogen of special significance in this population. *P. aeruginosa* can be observed by sputum Gram stain and cultured on blood agar during routine examination of respiratory cultures. *P. aeruginosa* isolates that are mucoid in appearance in routine cultures may be associated with virulent features.[50,62] Although these organisms usually can be identified by routine biochemical approaches, isolates from patients with cystic fibrosis may be difficult to identify by conventional methods. In these cases, DNA sequencing may be helpful for identification purposes. In addition, organisms of the *Burkholderia cepacia* complex may contribute to the respiratory pathology of cystic fibrosis, and nine different species comprise the *B. cepacia* complex.[48] One species in particular, *Burkholderia cenocepacia*, has been associated with most cases of cepacia syndrome, an overwhelming systemic infection that may cause rapid demise and preempt pulmonary transplantation.[52] The specialized media required to culture these organisms are additional formulations that complement the routinely used media for respiratory cultures. Although *B. cepacia* complex organisms can be cultured and identified by biochemical testing as members of the complex, speciation requires DNA sequencing of informative target genes, which typically is performed by reference laboratories. The identification of particular species by

molecular methods may affect decisions regarding lung transplantation and appropriate patient management.[4,58]

ANTIGEN AND ANTIBODY IMMUNOASSAYS

Direct immunoassays for antigens or antibodies specific to individual pathogens may facilitate establishing the diagnoses of atypical pneumonia, bacterial pneumonia, pertussis, and legionellosis. Such immunoassays may be used to detect pathogens directly in respiratory tract specimens, serum, or urine. The most common application of direct antigen detection in pediatrics is rapid immunoassay-based screening for *S. pyogenes.* Point-of-care tests include optical and membrane immunoassays for detection of antigens specific for *S. pyogenes* (group A Streptococcus).[46,96] Immunoassay-based screening of *S. pyogenes* should be supplemented with throat cultures, and direct nucleic acid amplification represents an alternative for diagnosis of streptococcal pharyngitis.[17,35,73]

Antigen immunoassays that rely on immunofluorescence may be helpful for establishing the diagnosis of legionellosis and pertussis in respiratory tract specimens, although these tests have diminished sensitivities compared with direct DNA detection.[26,49,75] Immunoassays may detect circulating IgM or IgG antibodies specific for *Mycoplasma pneumoniae* or *Chlamydia pneumoniae* and provide a minimally invasive diagnostic modality. However, serologic tests usually are supplanted by direct DNA amplification due to superior sensitivity and specificity.

Alternative methods of diagnosing respiratory infections include urinary antigen testing for *Legionella pneumophila* or *S. pneumoniae*.[3,38] Urinary antigen testing for *L. pneumophila* provides excellent sensitivity and is a useful adjunctive test, especially when delays in specimen transport and culture processing are encountered. If the diagnosis is considered after initiation of broad-spectrum therapy, it may be more convenient to obtain a urine specimen because antigen excretion may occur for several weeks.[45,85] In the case of *S. pneumoniae*, urinary antigen testing has been controversial, but this test may be useful in cases for which transport of the specimen is delayed and cultures may be nonviable.

MOLECULAR DIAGNOSTICS—NUCLEIC ACID AMPLIFICATION AND PROBES

A patient with a chronic, nonproductive cough with or without fever may highlight the need for evaluation of atypical respiratory pathogens. These organisms include *Bordetella pertussis* and other *Bordetella* spp., *C. pneumoniae*, and *M. pneumoniae*. Nasopharyngeal aspirates or Dacron swabs should be sampled for the diagnosis of *Bordetella* pathogens, including *Bordetella parapertussis*, *B. pertussis*, and *Bordetella holmesii*.[95] Infections caused by these organisms cause similar symptoms, although *B. pertussis* is more widely prevalent and causes more serious infections. When considering respiratory infections by *Bordetella* spp., most laboratories process nasopharyngeal aspirates or swab specimens for direct DNA amplification. Immunoassays and culture also may be performed for *Bordetella* spp. using direct immunofluorescence or specialized media, respectively, but sensitivities are reduced compared with DNA amplification.[30,32,55] Pathogens associated with atypical pneumonia such as *C. pneumoniae* and *M. pneumoniae* are difficult to culture in most laboratory settings. Therefore, throat swabs or sputum specimens from patients suspected of having atypical pneumonia should be directed for testing by serology or direct DNA amplification.[28,60] A significant proportion of children up to 15 years of age with *C. pneumoniae* or *M. pneumoniae* infections will either present with pneumonia or subsequently progress to pneumonia if untreated.[33,74,99] The diagnosis of *M. pneumoniae* as a cause of atypical pneumonia requires IgM serologic testing or molecular methods for direct detection. The utility of polymerase chain reaction (PCR) has been demonstrated for the detection of *M. pneumoniae* DNA in throat swabs, sputa, and lower respiratory specimens.[14,21,56,59] DNA probe-based hybridization and real-time PCR have been used successfully for detection and diagnosis of streptococcal pharyngitis using throat swabs.[17,90]

GASTROINTESTINAL TRACT INFECTIONS

Infections of the gastrointestinal (GI) tract may occur in different regions such as the stomach, small intestine, or colon, and direct sampling of intestinal contents may or may not be required. Bacterial cultures of intestinal contents remain important for the diagnostic evaluation of infectious gastroenteritis or colitis, but other approaches such as breath testing and direct antigen detection may be important for assessment of different bacterial pathogens. An obvious challenge with diagnostic approaches for GI tract infections is the need to distinguish pathogens from commensal bacteria.

GASTRIC INFECTIONS

In the stomach, *Helicobacter pylori* and a restricted set of other *Helicobacter* spp. may cause chronic gastritis and predispose patients to an increased lifetime risk of developing peptic ulcer disease and gastric cancer.[10,92] Nonendoscopic approaches are attractive for diagnostic evaluation of children because pediatric patients usually present with dyspepsia and evidence of chronic or erosive gastritis without evidence of peptic ulcer disease. Diagnostic methods include the collection of peripheral blood for assessment of serum IgG antibodies to *H. pylori.*[92] Detection of *H. pylori* may be performed conveniently in children without endoscopy or culture by fecal antigen testing or the urea breath test.[64,92] If biopsy sampling is required, *H. pylori* may be visualized by special stains in addition to the typical pattern of mixed inflammation seen on hematoxylin and eosin (H&E) stained biopsy specimens. Additionally, rapid tissue-based urea testing may be performed directly with biopsy samples by different colorimetric tests.[64] The detection of other *Helicobacter* spp. such as "Candidatus Helicobacter heilmannii" may require visualization with special stains following esophagogastroduodenoscopic evaluation of gastric biopsy specimens.[83]

INTESTINAL INFECTIONS AND STOOL CULTURES

Acute bacterial gastroenteritis usually is caused by various gram-negative enteric pathogens, and direct visualization of stool specimens by Gram stain rarely is beneficial in evaluating patients with infectious gastroenteritis. Routine stool cultures should be performed with at least two selective and differential media formulations (e.g., MacConkey agar, xylose-lysine-deoxycholate agar, Hektoen enteric agar) in order to distinguish candidate enteric pathogens from the commensal microbiota. The inoculated formulations are incubated at 37°C for 24 to 48 hours. Likely enteric pathogens such as *Salmonella* spp. and *Shigella* spp. can be distinguished by their lactose-negative phenotype on differential media, followed by comprehensive biochemical panels for confirmation of genus and species identifications. As a rule, gram-negative enteric bacterial pathogens share close phylogenetic relationships, and as such, species-level identification necessitates comprehensive biochemical panels that may be

performed via automated (e.g., Vitek, bioMérieux; MicroScan, Dade Behring) or manual approaches (e.g., API, bioMérieux) in the laboratory.

Additional pathogens such as enterohemorrhagic *Escherichia coli* (EHEC) and *Campylobacter jejuni* may require different approaches for detection. EHEC may be cultured on MacConkey-sorbitol agar medium, but occasionally, EHEC isolates may be able to ferment sorbitol. In addition to plate-based screening for the lack of sorbitol-fermenting capacity, direct toxin immunoassays or real-time PCR may be used to test EHEC organisms. Importantly, many EHEC isolates belong to serotypes other than O157:H7, limiting the value of serotyping in the laboratory. Microaerobic bacterial species such as *C. jejuni* or *Campylobacter coli* may cause acute bacterial gastroenteritis and require specialized media and atmospheric conditions for culture.[44] Most diagnostic microbiology laboratories currently include microaerobic cultures for *Campylobacter* spp. as part of routine stool culture procedures. *C. jejuni* and *C. coli* are thermophilic campylobacters that can be cultured readily at 42° C in the laboratory and identified by microscopic morphology and biochemical testing. Hippurate hydrolysis is the key laboratory feature for identification of *C. jejuni*, although rare hippuricase-negative mutants have been isolated.[42,76] *Campylobacter fetus* tends to be associated with invasive infections and usually is isolated from surgical and blood cultures, instead of stool cultures, at 37° C.[9,78,100] *Yersinia enterocolitica* and *Yersinia pseudotuberculosis* can cause clinical symptoms mimicking appendicitis[25] and may contaminate blood products due to their ability to thrive at lower temperatures.[11,71] If suspected, laboratory evaluation of *Yersinia* spp. usually must be requested in addition to routine stool cultures because *Yersinia* spp. require different culture conditions, such as incubation at room temperature on MacConkey or cefsulodin-irgasan-novobiocin (CIN) agar.

DIRECT ANTIGEN DETECTION

Clostridium difficile is a primary cause of disorders of intestinal microbial ecology such as antibiotic-associated colitis and antibiotic-associated diarrhea. This bacterial pathogen includes two toxin genes, *tcdA* and *tcdB*, in a mosaic genome[80] that encode proteins with well-defined enteropathogenic and cytopathic effects.[80,94] Direct toxin detection is the most commonly used approach for the diagnosis of toxigenic *C. difficile* infection (see Chapter 51**)** because *C. difficile* isolates lacking toxin production (non-toxigenic *C. difficile*) are not associated with disease. Briefly, commercial stool immunoassays consist of antibodies that detect the presence of toxins, TcdA or TcdB, directly in stool specimens. Stool toxin immunoassays for *C. difficile* detection are relatively insensitive (30-60%) when compared with next-generation molecular methods and may require repeated testing.[1,84] Anaerobic culture with specialized media such as cycloserine-cefoxitin-fructose agar (CCFA) can be followed by direct toxin detection in cultured organisms to improve diagnostic sensitivity.[69] However, because of the labor-intensive nature of bacterial culture-based strategies and mammalian cell culture methods for cytotoxicity studies, direct toxin detection by various commercial antigen immunoassays provides an attractive strategy for most laboratories. DNA amplification for direct toxin gene detection in fecal specimens is a new option for diagnostic laboratories, and toxin gene testing may eventually supplant immunoassays for toxin detection.[6,91] In addition to their usefulness in detecting *C. difficile*-associated disease, direct antigen tests for *Campylobacter* spp. and EHEC provide alternative diagnostic modalities if stool samples are collected in physicians' offices at remote clinic locations and preserving the organism's viability in clinical specimens poses a challenge.[23,67]

BACTEREMIA AND SEPSIS

The annual incidence of sepsis and number of sepsis-related deaths in the United States have steadily increased from 83 cases per 100,000 population in 1979 to 240 cases per 100,000 population in 2000.[53] Shifts in the etiologic patterns of sepsis also have been noted in recent years. Since approximately 1990, gram-positive pathogens have surpassed gram-negative pathogens as primary causes of sepsis. However, in early-onset sepsis in very-low-birth-weight infants, gram-negative pathogens, especially *E. coli*, are predominant causes of sepsis in the era of maternal prophylaxis targeting *Streptococcus agalactiae*.[86] Fortunately, most pathogens associated with sepsis can be cultured routinely using automated blood culture systems.

PERIPHERAL BLOOD CULTURES

The diagnosis of bacteremia requires the growth of pathogenic bacteria from peripheral blood, and continuously monitoring, automated detection systems are used routinely for this purpose. Blood samples from infected individuals typically contain low levels of organisms (1-10 organisms per mL in adults) so that incubation with continuously monitoring systems usually requires a minimum of 8 to 12 hours of inoculation before detection of growth in a blood culture bottle. Infants and young children typically contain higher concentrations of organisms in peripheral blood in cases of bacteremia and sepsis (10-100 organisms/mL), so smaller blood volumes are sufficient for detection. Blood culture bottles have been adapted for pediatric patients, with smaller blood volumes required for continuously monitoring systems. Weight-based, graduated volumes of peripheral blood collection enhanced efforts to successfully isolate pathogens in immunocompromised children[27] and may have more general implications for pediatrics. Pediatric collection systems may not be sufficient for older children and adolescents, and older patients may need sampling of larger peripheral blood volumes combined with adult blood culture bottles.

Automated blood culture systems yield positive signals usually within 24 hours of inoculation, and signal-positive samples must be processed for rapid Gram-stain assessment and subculturing onto blood agar media. In the absence of a signal, blood culture bottles typically are incubated for a minimum of 5 days. With the currently sophisticated liquid medium formulations, incubations rarely need to be extended beyond 7 to 10 days. In one comprehensive study of blood culture samples spanning a 16-month period, HACEK microorganisms were detected in only 16 of 15,826 (0.1%) samples, and all isolates were detected within 3 days of incubation.[70] Aerobic blood culture bottles usually are used in pediatric practice because of the relative paucity of systemic anaerobic infections in children. In specific cases, anaerobic bottles may be added for comprehensive evaluation. Direct Gram-stain evaluation facilitates patient management by providing microscopic morphologies at the time of subculture from a positive, blood culture. Occasionally, organisms are not visualized by Gram stain despite a positive signal; accordingly, supplemental staining by acridine orange or species-specific nucleic acid probes may be performed.

Positive blood cultures are transferred to media containing blood agar and alternative formulations for fastidious organisms, depending on the Gram-stain morphology. Following successful subculture on plated media (usually 24-48 hours after a positive signal is generated in an automated blood culture system), microscopic evaluation by Gram stain and biochemical testing are performed routinely to facilitate species-level identification. Depending on the species identification, organisms can be con-

sidered likely pathogens or likely contaminants. Time to detection of peripheral blood cultures also may be helpful, as coagulase-negative staphylococci associated with true pediatric infections were isolated 11 hours postinoculation versus isolates from chronically ill patients with contamination (mean time to positivity equaled 24 hours).[31] Several reports have documented the primary pathogens to consider in peripheral blood cultures, and organisms, which represent likely contaminants.[97] In neonates, predominant pathogens include *E. coli* and *S. agalactiae* (group B streptococcus). Gram-positive pathogens include *S. aureus*, coagulase-negative staphylococci, *S. pneumoniae*, *Listeria monocytogenes*, and *E. faecium*. Predominant gram-negative pathogens include *E. coli* and other enteric organisms, *P. aeruginosa*, and *Kingella kingae*. These pathogens can be isolated using routine culture methods that include chocolate agar.

CENTRAL NERVOUS SYSTEM INFECTIONS

In children, acute bacterial meningitis and meningoencephalitis represent the most common central nervous system (CNS) infections caused by bacterial pathogens. The most likely causes of acute bacterial meningitis in children depend on the age groups and include pathogens that are culturable using routine methods in the microbiology laboratory. In neonates, *S. agalactiae*, *L. monocytogenes*, *S. pneumoniae*, and *E. coli* are the pathogens found most commonly. In infants and children younger than 2 years of age, *S. pneumoniae*, *Neisseria meningitidis*, and *S. agalactiae* were the most commonly identified pathogens, whereas *N. meningitidis* and *S. pneumoniae* represent the most likely pathogens in older children.[79] Childhood vaccination strategies have diminished the risk of meningitis due to *H. influenzae* serotype b infection in North America.[15]

DIRECT MICROSCOPIC EXAMINATION OF CEREBROSPINAL FLUID

If acute bacterial meningitis is suspected, cerebrospinal fluid (CSF) specimens should be submitted routinely for Gram stain and culture. CSF is usually collected in sterile tubes as sequential volumes for testing in different areas of the clinical laboratory. CSF should be collected in the initial fraction for the microbiology laboratory and transported rapidly to minimize contamination risks while preserving pathogen viability.[20] Immediate Gram-stain evaluation is useful, but its sensitivity is limited by the requirement for 10^5 organisms/mL for visualization. Pathogens such as *L. monocytogenes* are often difficult to visualize directly because the organisms are often present in lower concentrations. Gram-stain evaluation may "facilitate the rapid" assessment of the presence of bacterial pathogens, as well as provide microscopic morphologic information (e.g., gram-negative cocci versus gram-positive cocci) in order to guide patient management. Direct microscopic evaluation of CSF includes Wright-Giemsa stains for leukocytes so that neutrophils or lymphocytes can be distinguished and quantified. CSF specimens may also demonstrate elevated total protein and reduced glucose levels in cases of acute bacterial meningitis.[22] Elevated CSF lactate concentrations also may be consistent with bacterial meningitis and active inflammation.[47,51]

BACTERIAL CULTURES OF CEREBROSPINAL FLUID

Regardless of the Gram stain results, CSF specimens are plated routinely on media containing blood and chocolate agar and are incubated for 48 to 72 hours at 37° C. Most bacterial pathogens of the CNS may be isolated successfully on blood agar, although chocolate agar improves the yield and reduces time to positive culture for pathogens such as *N. meningitidis* and *S. pneumoniae*. *N. meningitidis* may be identified readily by microscopic morphology and limited biochemical testing (e.g., oxidase testing, sugar fermentation).[72] *S. pneumoniae* and *S. agalactiae* usually can be identified by microscopic morphology, limited biochemical testing, and Lancefield group determination. If gram-negative enteric rods are visualized by CSF Gram stain, culture on MacConkey agar may be indicated in order to provide a differential medium to facilitate isolation of pathogens such as *E. coli*. Prior antimicrobial treatment may preclude performing bacterial culture, even if antimicrobial agents were administered only several hours before CSF collection.

Liquid bacteriologic media such as thioglycollate broth also are used routinely to maximize opportunities for successful culture of bacterial pathogens. Children undergoing neurosurgical interventions, including placement of prosthetic devices such as ventricular shunts or drains, may be at risk for acquiring CNS infections caused by *S. aureus* or coagulase-negative staphylococci, as well as the primary bacterial pathogens that cause CNS infections.[43,81,89] CSF samples obtained from CSF shunts may yield clinically significant cultures of coagulase-negative staphylococci in thioglycollate cultures.

DIRECT ANTIGEN AND NUCLEIC ACID DETECTION

Direct bacterial antigen testing of CSF rarely is useful for establishing the diagnosis of bacterial meningitis and is not recommended routinely.[34,65,68] Direct Gram-stain evaluation of CSF enables the laboratory to detect organisms not evaluated by antigen testing and matches or exceeds the sensitivity of bacterial antigen detection. Direct DNA amplification may improve the diagnostic accuracy for bacterial pathogens such as *N. meningitidis*. More than 4000 CSF specimens were screened in one study describing real-time PCR for detection of bacterial pathogens in CSF[19]; the improvement in the meningococcal detection rate was 2.9 percent. That is, 87 additional cases of meningococcal meningitis were identified by real-time PCR and missed entirely by culture. *M. pneumoniae* may cause meningoencephalitis or transverse myelitis in children, and DNA amplification of *M. pneumoniae* in CSF facilitated establishing the diagnoses of *Mycoplasma* infections in these patients.[8]

GENITOURINARY TRACT INFECTIONS

The principal bacterial pathogens that cause urinary tract infections in children include gram-negative enteric bacteria such as *E. coli* and *Proteus* spp., and other pathogens such as *Enterococcus* spp., *P. aeruginosa*, and *S. aureus*.[101] *E. coli* represents the most common cause of nongonococcal urethrocystitis, and yeasts including *Candida* spp. may be isolated as clinically significant pathogens in bacterial urine cultures.

BACTERIAL URINE CULTURES

Pediatric urinary tract infections (UTIs) usually are diagnosed by semiquantitative evaluation of urine cultures obtained by various collection methods.[101] Urine samples usually are obtained as voided urine or via urinary catheters, although suprapubic needle aspiration in infants also may be performed. In young children, urinary catheters may be required in order to obtain adequate urine specimens. Likely bacterial pathogens can be cultured on plated media with standardized volumes using inoculating loops in the laboratory. Plated media including blood agar and MacConkey agar typically are used for urine cultures, and plates

are incubated for 24 to 48 hours at 37° C. Likely pathogens are defined as predominant pathogens that exceed 100,000 organisms per mL in clean-catch voided urine specimens. In "sterile" catheter specimens from young children (especially younger than 2 years of age), lower cutoff values of 10,000 to 50,000 organisms/mL may be clinically significant. Importantly, 65 percent of cultures with colony counts between 10,000 and 49,000 colony-forming units/mL yielded mixed cultures with evidence of contamination.[36] If one or two predominant pathogens are found at concentrations exceeding those of commensal bacteria by 10-fold or more, they may be clinically significant and should be reported by the laboratory. The urinary Gram stain may represent a useful test for rapid screening of young, febrile children with suspected UTIs.[101]

The relative abundance of the likely pathogens in comparison with the commensal microbiota, in addition to the estimated concentrations of organisms by routine culture, is an important consideration for laboratories. Organisms such as corynebacteria, lactobacilli, coagulase-negative staphylococci, and gamma- or non-hemolytic streptococci may be considered as likely commensal bacteria. Laboratories should consider likely commensal organisms of males and females in different age groups. Yeasts may be part of the commensal genitourinary microbiota in adolescent females, and *Gardnerella vaginalis*, although usually part of the commensal microbiota, may cause infections if isolated as predominant pathogens from female patients. Fungi, especially yeasts, are a prominent cause of nosocomial urinary tract infections in children and are isolated in routine urine cultures.

DIRECT ANTIGEN OR NUCLEIC ACID DETECTION

Especially in adolescent females, sexually transmitted pathogens such as *Chlamydia trachomatis* and *Neisseria gonorrhoeae* often require molecular diagnostics for detection because of the relative difficulty and inadequate sensitivity of culture or antigen testing.[66] Endocervical swabs or urine specimens may be submitted for DNA amplification or hybridization for either *C. trachomatis* or *N. gonorrhoeae*. Sexually active adolescents have a high incidence of *C. trachomatis* and *N. gonorrhoeae* infections in addition to pathogen-associated pelvic inflammatory disease.[87] Nucleic acid amplification methods facilitate widespread screening of sexually active adolescents via self-collected urine and vaginal samples. Direct antigen detection for either pathogen also may be helpful, but nucleic acid detection methods have largely supplanted antigen detection by virtue of greatly improved sensitivity.[66]

MISCELLANEOUS AND SUPERFICIAL SITE INFECTIONS

Miscellaneous cultures may be processed for evaluation of tissue abscesses, infected wounds, ocular and ear specimens, and superficial or skin infections. Surgical site infections may include wound infections and abdominal abscesses, as well as complications associated with pediatric liver transplantation, including surgical leaks at sites of anastomosis.[37] Tissue specimens and aspirates of superficial sites generally are recommended, and swabs of superficial sites are discouraged for routine microbiologic evaluation. Direct Gram stain may be helpful for rapidly assessing optimal culture strategies and for focused consideration of potential pathogens. Bacterial cultures from such miscellaneous sites are plated on solid media, including blood agar, chocolate agar, and MacConkey agar. Thioglycollate broth also may be useful as a liquid medium for supplemental cultures of sterile specimens such as tissue or aspirates. Evaluating for bartonellosis is difficult because *Bartonella henselae* is extremely difficult to culture. The diagnosis usually is accomplished through serologic testing and histologic assessment of lymph node tissue using special silver impregnation stains to highlight microorganisms. However, DNA amplification from tissue provides a rapid and sensitive diagnostic modality in suspected cases, especially when organisms are visible.[5,18,77]

SUMMARY

Pediatric infections present a multitude of challenges for the diagnostic microbiology laboratory. Point-of-care methods such as direct antigen testing for *S. pyogenes* in the context of throat infections continue to make a major impact in routine diagnostics. Expanded proliferation of point-of-care tests, including direct antigen and nucleic acid detection, will increase the role of pediatric office-based testing for screening of children. The laboratory continues to evolve, with a multipronged approach to patient diagnosis and disease monitoring. Rapid assessment methods using microscopy and qualitative antigen or antibody detection continue to contribute to evaluation of sterile body fluids and disease screening in the laboratory. The ability to grow organisms by routine culture methods remains important for in-depth studies of pathogens in the laboratory, including antimicrobial susceptibility testing. Molecular testing is eroding the role of biochemical testing and cumbersome phenotypic approaches to pathogen identification. Nucleic acid amplification, sequencing, and array-based diagnostics will expand the contributions of molecular testing to the diagnosis and monitoring of pediatric infections in the future.

CHAPTER 263

Fungal Laboratory Analysis: Specimen Collection, Direct Detection, and Culture

David A. Bruckner

Fungi were regarded as insignificant causes of infection historically. The most important factor responsible for the increase in the number of fungal infections has been an alteration in the immune response of humans. Organ transplant recipients, particularly during the post-transplant period, and patients with malignant neoplasms and debilitating immunologic or metabolic disorders such as systemic lupus erythematosus, diabetes mellitus, alcohol, or intravenous drug abuse are particularly susceptible to fungal infections. Opportunistic fungi of low or limited virulence are detected with increasing frequency in subcutaneous or disseminated infections.

SPECIMEN COLLECTION

When an infectious process is suspected, the most appropriate techniques directed toward the detection of the etiologic agent must be ordered by the physician. Knowledge of the pathophysiology of the disease process is important in determining the optimal time for specimen collection. These collections include specimens for culture, direct detection of the agent using antigen tests, nucleic acid detection, stains, or antibody methods.[1,3,5,7,8] All specimens should be considered hazardous, and universal precaution must be used for all specimen-collection procedures. A sufficient quantity of a specimen must be obtained for the techniques required to detect the fungal agent directly, for culture, for antigen detection, or for serology. Procedures used for specimen collection for culture of bacteria also can be used for culture of fungi (Table 263–1). Microbiologists and pathologists are available to guide physicians in selecting the most appropriate specimen for culture and other tests to achieve rapid detection of maximum recovery of the microorganism causing the infection. Most clinical laboratories have established guidelines for specimen collection with minimal volumes of specimen to be collected. In addition, specimens should be collected in sterile containers before the initiation of therapy to ensure that optimal recovery of organisms is achieved. An important factor is that adequate specimen volumes, which include up to 5 mL of cerebrospinal fluid (CSF) and 200 mL urine for fungal culture, be submitted to the laboratory. Specimens collected for 24 hours,

TABLE 263–1 Specimen Collection Guidelines

Specimen	Recommendations	Transport Device/Comments
Abscess/wounds	Collect as per bacterial culture.	Collect in sterile container with as much material as possible. If swab used, use exclusively for mycology. RT
Blood	Collect as per bacterial culture.	BacT/Alert, BACTEC, ESP, or Septi-Chek (biphasic) bottles. Isolator (lysis-centrifugation). RT, never refrigerate
Bone marrow	Collect as per bacterial culture	Collect in sterile container, Isolator, or heparin (green top) tube. If clotted may have to homogenize or cut into pieces to place on mycology media. RT
CSF	Collect as per bacterial culture. Fluid volumes greater than 1 mL should be centrifuged or filtered.	Collect in sterile container. RT, never refrigerate
Eye	Corneal scrapings should be inoculated directly onto mycology media. Vitreous fluid should be collected by needle aspiration.	Direct inoculation onto mycology media. Vitreous fluid can be placed in a sterile container or the syringe with needle removed can be sent to the laboratory. RT
Fluids other than CSF and urine	Collect as per bacterial culture. Fluid volumes greater than 1 mL should be centrifuged or filtered.	Collect in sterile container. RT
Hair	Can use Wood lamp to help select infected hairs. Also scrape border of infected area if lesions are present.	Place hairs in sterile container. RT
Nails	Swab surface with 70% alcohol. Collect softened material from beneath nail bed.	Use sterile container or directly inoculate mycology media. RT
Prostatic secretions	Empty bladder before giving prostate massage. For detection of *Blastomyces* and less commonly *Coccidioides*, *Cryptococcus*, and *Histoplasma*.	Place in sterile container or directly inoculate mycology plates. RT
Respiratory	Collect as per bacterial culture using same rejection criteria for sputum. Early morning sputum is the preferred specimen.	Use sterile container. RT
Skin	Disinfect surface area with 70% alcohol to remove bacterial contaminants. Scrape skin surface at the edge of the lesion.	Use sterile container or directly inoculate mycology media. RT
Tissue/biopsy	Collect specimen per surgical technique.	Sterile container to which a small amount of sterile saline may be added to keep tissue moist. RT
Urine	Collect as per bacterial culture. Early morning specimen is preferred. Use midstream collection technique.	Use sterile wide-mouthed container. RT
Vaginal	Collect specimen as per bacterial culture. Primarily for *Candida* infections.	Swab transport device. RT

CSF, cerebrospinal fluid; RT, room temperature.

such as urine and sputa, are unsuitable for fungal culture because of bacterial overgrowth. Swab specimens are considered inadequate for the recovery of fungi, particularly when multiple culture tests (bacteriology, mycology, mycobacteriology, and virology) from the same swab specimen are requested. In many instances, surgeons send tissue for a histologic diagnosis and neglect to submit a request for culture. If an infection caused by a dimorphic fungi such as *Coccioides immitis* is suspected, the physician should notify the laboratory because of hazards associated with culturing this organism. A poorly collected specimen may result in the failure to recover the organism, or it may lead to therapy directed at a contaminating or commensal organism.

Specimens should be transported to the laboratory as soon as possible under optimal conditions, which usually are advised in the laboratory specimen collection manual that should be available to all physicians. Specimen transport and storage at room temperature are recommended. Ideally, specimens should be received in the laboratory within 2 hours of being collected. If a delay occurs in setting up cultures, the specimen should be held at room temperature or 4°C to prevent bacterial overgrowth. Unacceptable specimens that should not be processed include specimens in containers that leak, specimens received many days postcollection, and specimens held under inappropriate temperature conditions. Some fungal isolates such as *Cryptococcus neoformans* and *Histoplasma capsulatum* do not survive well at refrigerated or freezing temperatures.

DIRECT DETECTION

In the laboratory, direct wet mounts or smears can be prepared and a portion of the specimen can be used for culture (Table 263–2). Blood, CSF, and urine also can be used for the detection of antigens and nucleic acids by enzyme immunoassay, latex agglutination, polymerase chain reaction (PCR), and radioimmunoassay.[2,5,6] These assays have proven to be useful for the detection of infections caused by *Aspergillus*, *C. neoformans*, and *H. capsulatum*.[2] Although PCR techniques may be used for the direct detection of fungal infections, they are used in research or have been validated in specific laboratories for clinical use but are not readily available in most clinical laboratories.[5] Direct microscopic examination, including frozen sections of tissue to provide an immediate presumptive diagnosis, should be performed on most specimens. A definitive diagnosis may be made when specific fungal elements pathognomonic for fungal infections are detected in direct specimen stains. Examples include *Blastomyces dermatitidis*, *C. neoformans*, *Coccioides immitis*, and *Pneumocystis jiroveci*. Detection of wide and narrow, wavy or ribbon-like, nonseptate hyphae is consistent with a Zygomycetes infection. Direct specimen examinations always must be followed with culture because the direct examination can never be used to rule out infection, and recovery of the organism may be necessary for speciation.

TABLE 263–2 Methods for Detection of Fungi in Human Specimens

Stain/Method	Use	Comments
Aspergillus galactomannan	To detect galactomannan in serum	An EIA test used as an adjunct to culture for the detection of *Aspergillus* in high-risk patients. Test has low sensitivity and specificity.
Acid-fast, modified	To detect *Nocardia*	Most *Nocardia* will stain pink.
Calcofluor white	Stains chitin and cellulose of fungal cell wall	Rapid detection of fungi and *Pneumocystis.* Staining time is 1 minute; requires fluorescent microscope. Organisms fluoresce blue-white. May be used with Evans blue to suppress background fluorescence.
Cryptococcal antigen test (EIA)	Detects antigen in CSF and blood	A reliable and sensitive method for the detection of cryptococcal antigen. Can be used to monitor therapy.
Giemsa	Stains most bacteria and fungi	Used for the detection of *Histoplasma* and *Penicillium marneffei* in blood and bone marrow. *Pneumocystis* trophozoites and intracystic sporozoites can be detected. Organisms stain blue-purple.
Gomori methenamine silver (GMS)	Stains most organisms in tissue	Fungi including *Pneumocystis* cysts stain gray-black. Difficult to control staining reaction and may be difficult to interpret due to background staining.
Gram stain	Used primarily for detection of bacteria	Yeast cells and pseudohyphae stain gram-positive; *Cryptococcus* stains gram-positive surrounded by a capsular halo; hyphae will stain gram-negative.
Hematoxylin and eosin	Used to demonstrate patient's tissue reactions	Fungi stain violet to blue-purple. Can see fungal pigments.
Histoplasma urine antigen (EIA)	To identify infections of *H. capsulatum*	More sensitive and faster than culture. Test could cross-react with *Coccidioides immitis*.
India ink	To detect *Cryptococcus* in CSF specimens	To help detect capsule of *Cryptococcus neoformans*. Not very sensitive, and capsule may be difficult to detect.
Papanicolaou	Used to detect the presence of malignant cells	Fungal elements stain pink.
Periodic acid–Schiff (PAS)	Stains glycogen, mucin, mucoproteins, and glycoprotein	A mucin stain used to stain the capsular mucopolysaccharide of fungal organisms. Capsule will have a pink-magenta or purple color.
Pneumocystis DFA	Detects *Pneumocystis* cysts and trophozoites	Rapid staining method specific for *Pneumocystis* in respiratory specimens.
PCR	Can be used for direct detection of fungal pathogens	Not commercially available but has been developed in specific diagnostic laboratories for the detection of selected fungal pathogens.
Potassium hydroxide	To detect yeast and hyphal elements	Used as a clearing agent to make fungi more visible in tissue, hair, nails, and body fluids. Digests proteinaceous material of host cells, leaving fungi intact.
Wright	Stains most bacteria and fungi	Used for the detection of *Histoplasma* and *Penicillium marneffei* in blood and bone marrow. *Pneumocystis* trophozoites and intracystic sporozoites can be detected. Organisms stain blue-purple.

CSF, cerebrospinal fluid; DFA, direct fluorescent antibody; EIA, enzyme immunoassay; PCR, polymerase chain reaction.

Serology may be used to diagnose fungal infections either because other direct detection methods were negative or the organism failed to grow in culture. In general, serology is not as sensitive as are other direct methods such as antigen detection, particularly in immunocompromised patients. Serology has been useful in the diagnosis of *C. immitis* and *H. capsulatum* infections and can be used to follow successful therapy in coccioidiomycosis.[6] Serologic methods used include complement fixation, enzyme-immunoassay, immunodiffusion, and latex agglutination.

PRIMARY ISOLATION MEDIA

The most reliable and sensitive means of diagnosing a fungal infection is isolation of the organism on culture media.[1,3,7,8] A variety of media are commercially available for primary isolation of fungal organisms (Table 263–3). The medium chosen should support the growth of fungal isolates while inhibiting bacterial organisms from specimens collected from nonsterile sites. Traditional antibiotics used include chloramphenicol, gentamicin, penicillin, and streptomycin. Antibacterial agents can inhibit actinomycetes; therefore, media without antibiotics should be chosen if this agent is suspected, or a combination of media with and without antibiotics could be used.

Media may use cycloheximide, a protein synthesis inhibitor to suppress the growth of saprophytic fungi. It also inhibits *Aspergillus*, *Candida*, *Cryptococcus*, *Trichophyton*, and most Zygomycetes. Cycloheximide can be used in combination with various antibacterial agents listed earlier.

Chromogenic media are useful for the recovery and identification of *Candida* spp.[4] Dermatophyte test medium was designed specifically for the culture and isolation of dermatophytes. Other media used can be those containing caffeic acid for the detection of *Cryptococcus neoformans* by its phenol oxidase activity or media overlaid with olive oil (long-chain fatty acid source) for the recovery of *Malassezia furfur*.

When processing tissue, avoid the use of a mortar and pestle or tissue grinder. Hyphal elements, particularly aseptate hyphae, are easily destroyed in this process, rendering culture recovery impossible. Recommendations are to mince the tissue with a scissors or scalpel blade into 1-mm cubes and place these fragments onto the agar surface.

Nonselective media will permit the recovery of rapidly growing yeast and fungi, as well as fastidious, slow-growing fungi. Selective media will enhance the recovery of slower-growing dimorphic fungi while inhibiting the faster-growing yeast and fungi that may contaminate the medium

TABLE 263–3 Primary Isolation Media

Media	Supplements	Use
CHROMagar	Chromogenic substrates and antibiotics	Selective and differential medium for recovery of clinically important yeasts. Assimilation of chromogenic substrates and colony color development allow presumptive identification of common *Candida* species.
Dermatophyte test medium	Chloramphenicol, cycloheximide, gentamicin	Selective and differential medium for recovery of dermatophytes *(Epidermophyton*, *Microsporum*, *Trichophyton)*. Medium turns from yellow to red with growth of dermatophytes.
Inhibitory mold agar (IMA)	Chloramphenicol; chloramphenicol may be added	Selective and enriched medium used to isolate cycloheximide-sensitive fungi *(Candida*, *Cryptococcus*, *Histoplasma*, *Zygomycetes*, some *Aspergillus)* and inhibit bacterial growth.
Mycosel	Chloramphenicol and cycloheximide	Selective medium for isolation of dimorphic fungi and dermatophytes. Chloramphenicol inhibits bacterial growth and cycloheximide inhibits rapidly growing molds and yeasts.
Potato flake agar	Can be made selective by addition of chloramphenicol and cycloheximide	Useful for recovery of dermatophytes.
Sabouraud brain heart infusion agar (SABHI)	Used with (selective) or without antibiotics. Antibiotics include chloramphenicol, cycloheximide, penicillin and streptomycin. Could add sheep blood for recovery of *Histoplasma*	General purpose medium for growth of dimorphic and other fungi.
Sabouraud dextrose agar (SDA)	None	General purpose medium supporting growth of aerobic actinomycetes and all fungi.
	With olive oil on surface	Selective for cultivation of *Malassezia furfur*.
Yeast extract phosphate medium	Ammonium hydroxide and chloramphenicol	Selective medium promotes recovery of slow-growing dimorphic fungi. Chloramphenicol inhibits bacterial growth and ammonium hydroxide inhibits growth of other fungi.

and render isolation of the slower growing organisms impossible.

In general, a battery of media, including media containing sheep blood (BHI and Sabouraud's brain heart infusion agar [SABHI]), is used for the recovery of fungal isolates. Although sheep blood inhibits conidiation, it does improve the recovery of fungal isolates. Agar plates or screw-capped tubes can be used for isolating fungal isolates. Most mycologists prefer agar plates because of the ease of handling the cultures, and the larger surface area provides for better isolation of colonies. Plates usually are sealed with air-permeable tape or shrink-wrap to prevent inadvertent opening of the plate and also to slow down or retard dehydration of the media because many plates are held for 4 weeks in the laboratory before the specimen is signed out as negative. Examination of culture plates or agar tubes should be performed in a certified biologic safety cabinet. Most fungi will grow on routine bacteriology plates; however, the incubation time usually is short and may not allow sufficient time for the fungi to grow and be visually noticed on the plates.

CHAPTER 264

VIRAL LABORATORY DIAGNOSIS

Marjorie J. Miller

In the past, clinical and virologic services were perceived as too impractical and nonproductive to warrant implementation in the hospital laboratory. Cell culture propagation and maintenance, a requirement for isolation of virus, was considered complex, slow, expensive, and beyond the scope of the typical laboratory. Availability of commercial reagents and products also was a constraining factor. Serology, one of the earliest methods used for viral diagnosis, was limited by the delay in timely reporting of results, rendering it a more useful tool for epidemiologic rather than clinical purposes. In addition, few treatments were available for viral infections, further diminishing interest in and emphasis on the importance of clinical and laboratory diagnosis of viral infections. This circular cause-and-effect resulted in reduced and inappropriate utilization of such services when available and

TABLE 264–1 Why Clinical Virologic Laboratory Services Should Be Available on a Routine Basis

Knowledge of etiology in the clinical setting tunes the physician's interest and leads to better care.
Knowledge of viral infection reduces inappropriate antibiotic administration.
Knowledge of viral etiology reduces the cost and discomfort of unnecessary diagnostic procedures and lengthy hospital stays.
Virologic diagnosis is critical for the use of presently available antiviral drugs. As new drugs are developed, such diagnosis becomes even more important.
Wider use of viral diagnostic services leads to a better understanding of disease processes: viral-bacterial interactions and the relationship of viruses to "noninfectious diseases" such as myocardial infarction and pancreatitis.
Success and failure of viral vaccines are monitored more accurately.
Better patient awareness results from specific viral study. Patients like to know their illness, and such knowledge can be useful historically when future medical illnesses occur.
More accurate prognosis of disease outcome is possible when the specific etiologic agent is known.
The routine availability and use of viral diagnostic services make the physician more aware of priorities in medical research. The morbidity and mortality associated with specific viral agents, such as respiratory syncytial virus, should lead to interest in the development of new vaccines.

offered little reason to expand the availability of such services elsewhere.

Fortunately, technologic developments have allowed virologic diagnostic services to be integrated into many hospital laboratories.[293] Advances include commercial availability of (1) traditional and modified cell lines and media; (2) monoclonal antibodies for the detection of viral antigens directly in patient specimens and identification of culture isolates; (3) rapid (<30 minutes) virus antigen detection kits; (4) traditional molecular assays; and, more recently, (5) real-time molecular assays. Many manufacturers offer laboratory educational and technical support to assist in the validation and implementation of these assays. These technologic advances enable laboratories to provide effective diagnostic services; turnaround time to results and charges are similar to those for other areas of the microbiology laboratory.[125,126,201,240]

Presently, clinical laboratories have a variety of options when offering virologic services. Services may range from referral to a reference laboratory to limited detection of viral antigens (e.g., respiratory syncytial virus, influenza, rotavirus) or expansion to include culture and molecular assays. Whatever the choice, diagnosis is the foundation of all medical care. Specific reasons why clinical virologic laboratory services should be routinely available are listed in Table 264–1.

This chapter presents general aspects of diagnosis of viral infections, including specimen selection, collection, and transport; conventional and modified culture for virus isolation and identification; and rapid detection of viral antigens and nucleic acids directly in specimens. Specific aspects of diagnosis are presented in the respective chapters covering the particular viral agents.

SPECIMEN COLLECTION AND TRANSPORT

Laboratory diagnosis of viral infections depends primarily on the collection of appropriate specimens, in sufficient volume, at the correct time during the course of the illness using optimal transport and storage conditions. Improvements in the sensitivity and accuracy of laboratory assays will be rendered insignificant if the input sample is compromised.

SPECIMEN COLLECTION SITES

The selection of appropriate sites for collection of specimens as early in the acute phase of the illness as possible is critical to the recovery of viruses. A guide to recommended collection sites for specific viral syndromes is presented in Table 264–2. In general, the extent of the diagnostic investigation should be dictated by the characteristics of the illness being studied. For example, in common respiratory illnesses such as pharyngitis or croup, collection of a single specimen from the throat usually is all that is necessary. In other situations in which an illness is severe or unique, collection of specimens from multiple sites is important. In addition, in unusual cases, serum should be obtained for frozen storage in case subsequent serologic studies are required.

In unusual and severe illnesses, invasive procedures (e.g., brain, cardiac, liver, lung biopsies; needle aspiration of body fluids) frequently must be performed to obtain material for laboratory study. Many medical specialists argue against using these invasive procedures because little can be done to treat viral illnesses. However, in our experience, the knowledge gained from a positive viral identification justifies some risk incurred in collecting specimens. At present, antiviral drugs are similar to antibacterial and antifungal agents in that they generally can be used effectively only after definitive identification of the etiologic agent. Demonstration of a viral etiologic agent in diseases such as encephalitis, pneumonia, or cardiac disease can prevent the unnecessary administration of antibiotics and steroids. In many cases, overutilization of services, patient trauma, and overall cost can be reduced when a viral etiologic agent is confirmed. Finally, the prognosis of a particular illness is more accurate when the specific etiologic agent is known.

COLLECTION OF SPECIMENS

Specimens for virus culture or direct examination generally are obtained as they are for other microbiologic studies. The primary purpose of a transport medium is to provide a protective protein, neutral pH, and antibiotics for control of microbial contamination and, most importantly, for prevention of desiccation. Many viral transport and storage media are available commercially or are prepared readily in the laboratory; their utility has been reviewed.[16,50,147] Convenient and practical collection devices, such as the Culturette (Becton Dickinson, Cockeysville, Md) or the Virocult (Medical Wire and Equipment Co., Victory Gardens, NY), consist of a swab, usually Dacron or rayon, on a plastic or aluminum shaft accompanied by a self-contained transport medium (Stuart or Amies). These devices are routinely available in most hospitals for bacteriologic culture. Calcium alginate swabs, which are toxic to herpes simplex virus (HSV), and wooden shafts, which may be toxic to viruses as well as the cell culture system itself, should not be used. Saline or holding media that contain serum also should be avoided. Useful liquid transport media (2-mL aliquots in screw-capped vials) consist of tryptose phosphate broth with 0.5 percent bovine albumin; Hanks balanced salt solution with 5 percent gelatin or 10 percent bovine albumin; or buffered sucrose phosphate (0.2 mol/L, 2-SP),[131,147] which has been used as a combined transport medium for viral, chlamydial, and mycoplasmal culture requests[291] and is appropriate for long-term frozen storage of specimens and isolates.[131]

Some of these transport media also have been evaluated and found acceptable for use in rapid methods (e.g., enzyme-linked immunosorbent assay [ELISA][227,328] and polymerase chain reaction [PCR]).[207]

TABLE 264–2 Specimen Collection Guide for the Diagnosis of Viral Infections Based on the Viral Syndrome and Etiologic Agent Suspected

Main Location or Category of illness	Clinical Diagnosis	Specimen Collection Source		Other Sources	Etiologic Agent Suspected*
		Most Practical	*Most Definitive*		
Upper respiratory tract	Common cold, nasopharyngitis	Nasopharynx/ nose	Nasopharynx/ nose	Nasopharyngeal/ nasal wash, stool blood	Rhinoviruses, coronaviruses, parainfluenza viruses, respiratory syncytial virus enteroviruses, adenoviruses
	Pharyngitis	Throat	Throat	Stool, blood	Adenoviruses, enteroviruses, Epstein-Barr virus, influenza viruses, parainfluenza viruses
	Herpangina, other enanthems	Throat	Lesions	Stool, blood	Enteroviruses, herpes simplex virus
	Laryngitis, laryngotracheitis	Throat	Larynx or trachea	Nasopharyngeal/ nasal wash	Parainfluenza viruses, influenza viruses
	Parotitis, other salivary gland enlargement	Throat	Stensen duct	Urine, blood, cerebrospinal fluid	Mumps virus, enteroviruses
Lower respiratory tract	Bronchitis, bronchiolitis, pneumonia	Throat	Bronchoalveolar lavage, bronchial washing biopsy	Stool, blood, sputum, nasopharyngeal/ nasal wash	Respiratory syncytial virus, human metapneumovirus, parainfluenza viruses, adenoviruses, influenza viruses, cytomegalovirus
	Pleurodynia	Throat	Throat	Stool	Enteroviruses
	Pleural effusion	Pleural fluid	Pleural fluid	Throat, stool, blood	Enteroviruses, adenoviruses
Heart	Myocarditis, pericarditis, conduction defects	Throat	Pericardial fluid, biopsy	Stool, blood, urine	Enteroviruses, influenza viruses, adenoviruses
Central nervous system	Meningitis	Throat	Cerebrospinal fluid	Stool, blood, urine	Enteroviruses, mumps virus, arboviruses, herpes simplex virus type 2, lymphocytic choriomeningitis virus
	Encephalitis	Throat	Brain biopsy	Cerebrospinal fluid, stool, blood, urine	Arboviruses, mumps virus, enteroviruses, herpes simplex virus type 1, influenza viruses
	Guillain-Barré syndrome, cerebellar ataxia, transverse myelitis, poliomyelitis	Throat	Throat	Stool, blood, cerebrospinal fluid	Influenza viruses, arboviruses, enteroviruses, Epstein-Barr virus
Genital tract	Orchitis, epididymitis	Throat	Testicular biopsy	Stool, blood, urine	Mumps, enteroviruses, lymphocytic choriomeningitis virus
	Herpes genitalis	Lesions	Lesions	Vagina, cervix, urethra	Herpes simplex virus

**This listing includes only the more commonly associated agents: It is likely that with more general use of viral diagnostic services, new virus-disease associations will be made.*
HIV, human immunodeficiency virus.

Throat

Specimens from the throat should be obtained with a swab in a manner similar to that used for bacterial culture. The posterior pharyngeal wall and tonsillar surfaces, any inflamed or erythematous areas, and any visible lesions are swabbed firmly without contact with the tongue and anterior oral cavity.

Nose and Nasopharynx

Specimens should be collected with nasopharyngeal swabs that have thin, flexible wire shafts by inserting the swab into the nasopharynx and rotating it to obtain the maximal number of ciliated, columnar epithelial cells and then placing the swab in transport medium. Alternatively, a flexible nasal probe with a cupped tip may be used (Rhinoprobe, Rhinotechnics, San Diego, Calif).[144,332] Nasopharyngeal cultures can be obtained from infants by the wash technique described by Hall and Douglas.[119] In this method, a small amount of sterile phosphate-buffered saline (3-7 mL) is squeezed into the nose with a nasal bulb aspirator (1 oz, tapered) and then immediately withdrawn and placed in a sterile, screw-capped container. Alternatively, nasopharyngeal aspirates may be obtained with a mucus collection device. An appropriately sized catheter is inserted nasally into the posterior of the nasopharynx; intermittent suction is applied as the catheter is withdrawn. Aspirate is washed through the tubing with 5 to 8 mL of transport medium or sterile phosphate-buffered saline. Washes and aspirates (versus swabs) are preferred for direct antigen detection because more epithelial cells are obtained with this method.[4]

Other Respiratory Specimens (Sputum, Tracheal Aspirates, Bronchial Washings, Bronchoalveolar Lavage)

Collection depends on the volume obtained. Volumes of 0.5 mL or larger should be placed in a sterile container and sealed tightly. If the volume is less than 0.5 mL, the specimen is placed in 2 mL of transport medium.

Eye

Exudate or pus should be removed first with a sterile swab. Conjunctival specimens may be obtained by pressing a swab premoistened with sterile saline firmly against the inflamed areas. The swab is returned to the self-contained transport device, or the tip is broken off into 2 mL of transport medium. Corneal scrapings should be obtained by an ophthalmologist or other trained person and placed in transport medium immediately.

Body Fluids Other than Blood

Body fluids such as urine (clean voided, 10-20 mL), cerebrospinal fluid (CSF) (2-5 mL), pleural effusion, and peritoneal, pericardial, or joint fluid should be collected under sterile conditions and placed in securely sealed, sterile containers. For small volumes (<0.5 mL), the specimen may be placed in transport medium.

Lesions

For lesions, fresh vesicles should be selected because recovery of virus from older lesions decreases significantly. Gently swab the area with sterile saline. Rupture the vesicle and collect both fluid and cells from the base of the lesion. Material obtained from several lesions may be pooled. Desiccation must not be allowed to occur; swabs should be submitted moistened with their self-contained transport medium or, if that is unavailable, placed in 2 mL of transport medium. Specimens may be collected with a swab or aspirated with a 26-gauge needle attached to a tuberculin syringe. Aspirated fluid should be rinsed into 1 to 2 mL of transport medium.

For direct antigen detection by immunofluorescence (IF) (direct fluorescent antibody [DFA]), the vesicle is ruptured as previously described and epithelial cells are collected by firmly swabbing the base of the lesion. Cells are transferred to a clean glass slide by firmly rolling the swab back and forth over a 5- to 10-mm area (dime size); for differentiation of HSV types 1 and 2 (HSV-1 and HSV-2) and varicella-zoster virus (VZV), three areas should be prepared.

Stool and Rectal Specimens

Because of initial studies with polioviruses and other enteroviruses, culture of fecal material has been overemphasized in virology. Both enteroviruses and adenoviruses can be recovered readily from stool, but because these agents are carried in the lower gastrointestinal tract for considerable periods of time after acute infection, use of this source for establishing the diagnosis of specific illnesses is limited. A specimen of fecal material is practical only when the specific primary diagnosis is diarrhea or when concomitant serologic study with paired sera can be performed.

For recovery of enteroviruses, fresh stool specimens are better than are rectal swabs; 2 to 5 g (2-3 tsp) of formed or liquid specimen should be transferred to a sterile, leak-proof container. However, from a practical point of view, a rectal swab is the simplest method of specimen collection. A rectal swab can be obtained immediately, whereas collection of a stool specimen usually entails considerable delay. Of importance is that the swab contain visible stool; the swab should be inserted 3 to 5 cm into the rectum, rolled against the mucosa, and then transported in a Culturette or similar device.

Blood

Some viruses can be recovered from serum or red blood cells (RBCs), but in general, leukocytes are a better source of virus. Fresh blood (optimally 5 mL) is collected in a suitable anticoagulant (heparin, ethylenediaminetetraacetic acid [EDTA], acid citrate dextrose) and transported to the laboratory for processing by density gradient centrifugation[132] or other methods to enrich for leukocytes. EDTA is the anticoagulant of choice because it is an acceptable transport for culture, as well as for molecular methods such as hybridization and PCR.

Bone Marrow

Approximately 2 mL should be aspirated into a tube or syringe containing heparin anticoagulant, mixed thoroughly to prevent clotting, and transported without further additives or diluents.

Biopsy Specimens

For biopsy specimens, fresh tissue obtained from the affected site should be placed in 2 mL of transport medium to prevent desiccation.

Autopsy Specimens

Most postmortem specimens are almost useless for viral cultivation because of the manner in which autopsies usually are performed. If labile agents are to be recovered, the autopsy should be performed within 4 hours of death. All tissues (1-2.5-cm cubes) for study should be obtained aseptically, and individual tissue should be collected with sterile instruments and placed in separate sterile containers. Because the usual autopsy routine entails fixation of specimens, of vital importance is that specimens for viral isolation not be placed in containers with fixatives such as formalin or other preservatives.

TRANSPORT TO THE LABORATORY

The method of handling specimens from the time of collection to laboratory processing is critical for preservation of virus infectivity and subsequent recovery in culture. In general, the less time that transpires between collection and inoculation into cell culture, the greater the chance of recovering the virus. Specimens should not be frozen or exposed to temperatures higher than 22° C. For short-term storage (<5 days) of most viruses, the specimen should be held at 4° C until it can be processed in the laboratory. For transport to the laboratory, this temperature can be achieved with the use of cold packs or simply by placing one ice cube next to the specimen container within an aluminum foil wrapping.

Although the degree of sensitivity varies, all viruses are inactivated by ultraviolet light. Therefore, shielding specimens from sunlight is important and can be accomplished by using opaque transport boxes or wrapping individual specimens in aluminum foil or opaque paper.

When considerable delay between collection and culture will elapse (transport to other laboratories, holiday schedules, and so on), special preparation is necessary. Such preparation needs to be individualized and based on the most likely viral cause of a particular illness. For example, when an enteroviral etiologic agent is suspected, freezing the specimen (–70° C) and shipping it with dry ice are satisfactory. In contrast, a urine specimen from a patient with possible cytomegalovirus (CMV) infection should not be frozen. It should be shipped under wet ice at 4° C because CMV in urine is stable for several days at this temperature. In addition, media that protect viruses against the deleterious effects of temperature fluctuations, particularly freeze-thawing, are available for transport as well as for long-term storage.[131,147] For specific characteristics of individual viruses, see Chapters 164-204 and the general references at the end of this chapter.[180,216,278,293]

LABORATORY DIAGNOSIS OF VIRAL INFECTIONS

Previously, the perception that isolation of virus was difficult, nonproductive, and too slow to be of clinical utility, combined with the lack of consistently available reliable reagents, discouraged the use of diagnostic virology services. Since the mid-1980s, a dramatic increase has occurred in the quality and availability of diagnostic reagents, primarily monoclonal antibodies, which has significantly improved the turnaround time of reporting virology results. Direct detection of viral antigens in clinical specimens such as the herpes group viruses (HSV, VZV, CMV); respiratory syncytial virus (RSV); influenza viruses; adenoviruses; and rotaviruses, usually by IF; an immunoperoxidase (IP) test; or ELISA has become routine and has made obtaining same-day results a reality. In addition, detection of viral antigens in cell culture by the application of IF/IP staining or ELISA, before the appear-

ance of cytopathic effect (CPE), has greatly reduced the time needed to report a positive result. More recently, molecular techniques for the direct detection and quantitation of viral nucleic acids in specimens[69,142,237] have begun the transition process from research tool to routine use in the clinical laboratory as commercial reagents become readily available, methods are simplified and standardized, and some assays are manufactured in kit format. Methods for the laboratory diagnosis of specific viral infections are presented in Chapters 164-204, and detailed methods are provided in the general references at the end of this chapter.[142,180,216,257,278,293] Table 264–3 summarizes specific methods for the laboratory identification of viruses, in addition to indications for serologic study of selected viruses.

VIRUS ISOLATION

Despite technologic advances and innovations, culture remains the cornerstone of the diagnostic virology laboratory. Culture still is among the most sensitive of diagnostic methods because theoretically, a single infectious virus can be detected. Unlike rapid methods, which are limited to the detection of a specific viral antigen or nucleic acid, culture is open-ended and permits the detection of unexpected viruses, new viruses, or multiple viruses within the same specimen. In addition, a broad range of specimens can be evaluated, whereas rapid methods usually are approved or licensed for use with specimens collected from specific sites. Viruses that can be isolated and identified readily include adenoviruses, HSV, VZV, CMV, enteroviruses, rhinoviruses, influenza and parainfluenza viruses, RSV, rubella virus, mumps virus, and measles virus. The number and type of isolates encountered depend on the patient population, season, and type of specimens submitted. For optimal laboratory diagnosis, indicating the virus suspected on the requisition is important because some viruses require specific cell lines, procedures for identification, or both. Cultures are maintained for different time frames before finalizing a report of negative results, depending on the virus being sought; for example, HSV cultures usually are observed for 5 to 7 days, CMV for 1 month, and all others for 2 to 4 weeks. Improvements and modifications in culture methods have resulted in more rapid identification of isolates, with greater than 70 percent being reported within 5 days.[67,137]

Traditional Culture

Although animals such as suckling mice and chicken embryos originally were the only means of isolating viruses, most laboratories now use cell culture exclusively. A variety of cell lines capable of supporting the growth of a broad spectrum of viruses can be obtained fresh weekly from commercial sources. After inoculation of the specimen, cultures are observed at regular intervals for evidence of viral infection characterized by the appearance of CPE or the ability to hemadsorb or hemagglutinate RBCs. Adenoviruses, CMV, HSV, VZV, rhinoviruses, and enteroviruses can be identified and reported by their characteristic CPE. The mean time between inoculation of a specimen and the appearance of CPE usually is 1 week or less for most of this group, except CMV and some adenoviruses, which may require longer incubation. Cultures containing HSV and enteroviruses often are positive within 1 to 2 and 3 to 5 days, respectively. In the event of atypical or questionable CPE, IF with monoclonal antibodies can be used to identify CMV, VZV, HSV-1, HSV-2, adenoviruses, enteroviruses, and some select coxsackieviruses and echoviruses in infected cell cultures. Although it rarely is performed, the neutralization test is used to definitively identify adenoviruses and enteroviruses if serotyping is requested for epidemiologic or other reasons.[142,278]

Respiratory viruses, including parainfluenza and influenza viruses, which may or may not produce CPE, generally can be detected within 5 to 7 days of inoculation of the specimen with the traditional hemadsorption method, in which a suspension of guinea pig RBCs is added to the cell culture. The RBCs are observed to adhere to tissue culture cells infected with these viruses, usually 3 to 5 days after the inoculation of specimens for most isolates.[213] An adaptation of this method uses cell culture medium and guinea pig RBCs in a microtiter plate format to detect viral hemagglutinins in suspension. The results are similar to those observed with hemadsorption, but the adapted method is more rapid and simple to perform when screening numerous specimens.[151] RSV is identified presumptively, usually within 3 to 5 days of inoculation of the specimen, by its typical CPE (syncytium formation) and inability to hemadsorb/hemagglutinate guinea pig RBCs. This group of viruses is identified definitively by IF with monoclonal antibodies.[142,278]

Finally, the traditional method for isolation and identification of rubella virus uses primary African green monkey kidney cells in conjunction with the interference assay. After specified intervals following inoculation have transpired, cultures are challenged with a second virus, usually echovirus 11, incubated for an additional 3 to 4 days, and examined for CPE. The presence of rubella virus interferes with growth of the challenge virus, and no CPE is observed; on the other hand, if the challenge virus grows and produces CPE, the specimen is considered negative for rubella virus. Final identification of the isolate requires neutralization of the interference with specific rubella antibody.[216,278]

Serologic diagnosis is recommended for viruses that are difficult or impossible to isolate in commonly available cell cultures or that require special techniques for detection of their presence. For instance, in most cases of arbovirus infection, the study of paired sera for antibody development is the most rewarding for diagnosis. Human immunodeficiency virus (HIV) infection generally is identified best by the demonstration of serum antibody or antigen with the use of ELISA. Measles virus is relatively difficult to grow, and identification can take considerable time; when measles is suspected, the diagnosis is confirmed most easily by serologic study. Paired sera collected 1 week apart usually reveal a fourfold antibody titer rise. Alternatively, demonstration of specific IgM antibody allows the diagnosis to be established with the use of a single serum sample. Similarly, serology is useful for establishing the diagnosis of mumps virus. Although mumps virus can be isolated in the same cell lines used for other paramyxoviruses and detected by hemadsorption/hemagglutination as previously described, such requests are rare. Rubella virus requires 2 or more weeks for isolation and specific identification. Because of this delay, rubella virus infection, other than that acquired congenitally, is confirmed best by serologic study. In all instances of suspected congenital rubella, isolation of the virus should be attempted.

Modified Culture

A variety of physical and chemical methods have been evaluated for their ability to enhance the rapid detection of virus in culture.[137] These methods include the effect of low- and high-speed rolling of cultures, centrifugation, chemicals such as dimethyl sulfoxide, hormones such as dexamethasone, and enzymes such as trypsin on the isolation of viruses. Early detection of viral antigens in culture by IF and IP, before the appearance of CPE, also has been evaluated.[89,208,241,263] A technique that entails the physical method of centrifugation with early antigen detection in cell culture and is called variously the shell vial assay (SVA), the spin-amplified technique, or culture-amplified antigen detection is used routinely in most laboratories to decrease the

TABLE 264–3 Common Laboratory Methods for Virus Isolation, Identification, and Direct Detection and Most Useful Methods for Diagnosis of Specific Viral Illnesses

Virus	Culture/Direct Detection	Identification of Isolates	Serology	Most Useful Method for Diagnosis of Specific Viral Illness
Adenoviruses	Primary HEK, A549, WI-38, HEp-2, HeLa, KB cell, R-Mix, R-Mix Too culture/FA, ELISA	Group identified by characteristic CPE and/or FA; type identified by neutralization with specific antiserum	CF on paired sera, ELISA HAI	Virus isolation
Arboviruses of North America	Suckling mouse intracerebral inoculation, vero, BHK-21, LLC-MK2 cell culture	Neutralization with specific antiserum	CF on paired sera, HAI, indirect FA, IgM antibody capture ELISA	CF on paired sera
Coronaviruses	Human embryo tracheal organ culture, HEK PCR	Neutralization with specific antiserum	Neutralization, CF, HAI on paired sera, ELISA, indirect FA	No practical method presently available
Rhinoviruses	WI-38, MRC-5 cell culture	Characteristic CPE: stability on exposure to lipid solvents and inactivation at pH 3	Neutralization on paired sera	Virus isolation
Enteroviruses	MK, WI-38 cell culture, suckling mouse inoculation (intracerebral and intraperitoneal)/PCR	Group identified by characteristic CPE in cell culture or illness or pathology in mice; type identified by neutralization with specific antiserum; FA for some serotypes	Neutralization, CF, HAI on paired sera	Virus isolation
Cytomegalovirus	WI-38, MRC-5, foreskin cell culture/FA, IP, PCR, hybrid capture	Characteristic CPE; FA/IP for definitive identification	CF on paired sera, ELISA, LA, indirect FA	Virus isolation; PCR
Epstein-Barr virus (EBV)	Practical method not available/PCR	Practical method not available	Indirect FA against viral capsid antigen on paired sera; indirect FA against early antigen in single serum	Infectious mononucleosis rapid slide tests; rarely, EBV-specific FA test; PCR
Herpes simplex virus	WI-38, MRC-5, primary RK cell culture/FA, IP, ELISA, PCR	Characteristic CPE; FA, IP, ELISA for definitive identification	CF on paired sera, ELISA, indirect FA, ACIF	Virus isolation; antigen detection by FA, ELISA; PCR
HIV	ELISA, PCR, bDNA	ELISA, Western blot	ELISA, Western blot, indirect FA	ELISA
Human metapneumovirus	LLC-MK2, Vero, A549, HEp-2, R-Mix, R-Mix Too cell culture PCR, FA, ELISA	FA	ELISA	PCR; virus isolation
Influenza viruses	MK, LLC-MK2, MDCK, R-Mix Too cell culture and chicken embryo (amniotic sac and aliantoic cavity) inoculation/FA, ELISA	HA or hemadsorption of guinea pig or chicken erythrocytes and inhibition with specific antiserum for type/strain identification; FA for identification of type	CF, HAI, ELISA on paired sera	Virus isolation; antigen detection by FA, ELISA
Measles virus	Primary MK, HEK, R-Mix, R-Mix Too cell culture/FA	Hemadsorption and HA of monkey erythrocytes and inhibition with specific antiserum or identification by FA	CF, HAI on paired sera identification of measles-specific IgM antibody by ELISA, indirect FA	Identification of measles-specific IgM antibody by ELISA, Indirect FA or CF/HAI antibody titer rise
Parainfluenza viruses, mumps virus	Primary MK, LLC-MK2, HEK, R-Mix, R-Mix Too cell culture/FA	Hemadsorption and HA of guinea pig erythrocytes; specific identification by FA	CF, HAI on paired sera, ELISA, indirect FA	Virus isolation; antigen detection by FA
Respiratory syncytial virus	HEp-2, WI-38, R-Mix, R-Mix Too cell culture/FA, ELISA	Characteristic CPE in absence of hemadsorption; specific identification by FA	CF on paired sera, ELISA, indirect FA	Detection of viral antigen by FA/ELISA: virus isolation
Rabies virus (animal infections)	Demonstration of Negri bodies by microscopic examination of brain or demonstration of viral antigen by FA, mouse inoculation	Demonstration of Negri bodies or antigen by FA	Neutralization, ELISA	Antigen detection by FA

TABLE 264–3 Common Laboratory Methods for Virus Isolation, Identification, and Direct Detection and Most Useful Methods for Diagnosis of Specific Viral Illnesses—cont'd

Virus	Culture/Direct Detection	Identification of Isolates	Serology	Most Useful Method for Diagnosis of Specific Viral Illness
Rubella virus	African green monkey kidney cell culture	Interference of enteroviral CPE; neutralization with specific antiserum	HAI on paired sera; identification of rubella-specific IgM antibody by ELISA, indirect FA	Identification of rubella-specific IgM antibody by ELISA, indirect FA or HAI antibody titer rise
Poxviruses	MK, WI-38 cell culture/FA, EM	Characteristic CPE; FA or appearance on EM	Not useful for diagnosis	Antigen detection by FA, EM
Varicella-zoster virus	WI-38, MRC-5 cell culture/FA, PCR	Characteristic CPE: FA for definitive identification	CF on paired sera, EIA, LA, IHA, IAHA, ACIF, FAMA	Detection of viral antigen by FA; virus isolation
Hepatitis A virus	Demonstration of antigen by ELISA, IEM, RIA	Practical method not available	ELISA, RIA, HA	Identification of HAV-specific IgM by ELISA, RIA
Hepatitis B virus	Demonstration of antigen by ELISA, RIA, HA, demonstration of DNA by hybridization, PCR	Practical method not available	ELISA, RIA, HA	Demonstration of antigen, nucleic acid
Hepatitis C virus	Demonstration of antigen by IEM, RIA	Practical method not available	ELISA, RIBA	ELISA, RIBA, determination of viral RNA
Notovirus	Determination of antigen by IEM, RIA	IEM, RIA	ELISA, RIA-BL; serology not used routinely	Demonstration of antigen
Rotavirus	Demonstration of antigen by ELISA, LA, EM	EM, ELISA	ELISA; serology not used routinely	Demonstration of antigen
Adenovirus 40/41	Demonstration of antigens by ELISA	ELISA	CF, ELISA on paired sera; serology not used routinely	Demonstration of antigen

For details, see Chapters 164-204.

ACIF, anticomplement immunofluorescence; A549, human lung carcinoma: bDNA, branched-chain DNA; BHK-21, continuous babv hamster kidney cell line; CF, complement fixation; CPE, cytopathic effect; ELISA, enzyme-linked immunosorbent assay; EM, electron microscopy; FA, immunofluorescent antibody; FAMA, fluorescent antibody to membrane antigen; HA, hemagglutination; HAI, hemagglutination inhibition; HEK, human embryonic kidney; HEp-2, human laryngeal carcinoma cells; IAHA, immune adherence hemagglutination assay; IEM, immune electron microscopy; IHA, indirect hemagglutination; IP, immunoperoxidase test; KB, oral cavity carcinoma; LA, latex agglutination; LLC-MK2 continuous line of Rhesus MK; MDKC Madin-Darby canine kidney; MK, monkey kidney; PCR, polymerase chain reaction; RIA, radioimmunoassay; RIA-BL, radioimmunoassay blocking test; RIBA, recombinant immunoblot assay; RK, rabbit kidney; R-Mix, A549 and mink lung mixture; R-Mix Too, A549 and MDCK mixture; Vero, continuous line of African green monkey kidney; WI-38, MRC-5, human total diploid lung fibroblasts.

time to detection of a positive culture. Cell lines are propagated on 12-mm round coverslips in 1-dram shell vials. An aliquot of specimen is inoculated into the vial, centrifuged at 700 × *g* for 1 hour, and incubated 1 to 3 days, depending on the virus being sought. Antigen typically is detected by IF or occasionally by IP staining with monoclonal antibodies directed against a specific virus.

SVA was described initially and evaluated extensively for HSV[88,108,188,239,244,267] and CMV,[90,102,106,107,179,233,234,249] and its use since then has been extended to the rapid identification of VZV,[103,275] adenovirus,[10,78,191,314] RSV,[26,290] influenza virus,[84,210,222,299] parainfluenza virus,[274] measles virus,[211] and human metapneumovirus[172,235] antigens in culture. Pooled antibodies directed against seven commonly isolated respiratory viruses (adenovirus; influenza viruses A and B; parainfluenza virus types 1, 2, and 3; and RSV) also have been evaluated.[197,229,248] In addition, SVA has been applied to the detection of enteroviruses[160,183] and human herpesvirus type 6.[205] Recently, the application of mixed cell lines in tube and shell vial culture has resulted in several improvements in isolation of virus. Combination cell lines in a single tube or shell vial broaden the range of culturable viruses, reduce the requirement for multiple single cell lines, and decrease the time to detection of a positive result, with sensitivity similar to that of conventional culture. Mixed cell lines are useful for rapid isolation of respiratory viruses,[13,92,135,349] human metapneumovirus,[152,284] enteroviruses,[12,95,136] and herpes group viruses.[134] The sensitivity of mixed cell versus conventional single-cell lines for virus detection ranges from 92 to 100 percent for respiratory viruses[13,92,135,349] to 85 to 97 percent for enteroviruses,[95,136] with time to detection of a positive result reduced from an average of 5 to 10 days to 1 to 2 days for respiratory viruses and 1 to 3 days for enteroviruses.

Although it is rapid, sensitive, and specific, SVA is an adjunct to and not a substitute for traditional culture. When compared with traditional culture, the sensitivity of SVA averages approximately 85 percent (range, 70-100%) and depends on numerous variables, including the cell line,[359] the age of cells,[90] the concentration of virus,[359] the type of specimen,[179,233] the number of vials inoculated,[233] and the type of reagents used.[82,108,208,239,267] Table 264–4 summarizes the typical time to detection of a positive result in traditional culture and SVA, the sensitivity of SVA versus culture, and the turnaround time for each.

Other culture modifications include hybridization[82,94] and ELISA[10,64,204,329,336] for rapid detection of viruses. A modification of cell culture for the rapid detection of HSV is the enzyme-linked virus-inducible system (ELVIS).[295,296] This system consists of a mixture of modified baby hamster kidney cells and MRC-5 cells. The modified baby hamster kidney cells contain an HSV-

TABLE 264–4 Detection of Virus in Traditional Culture and Shell Vial Assay

Virus	Traditional Culture		Shell Vial Assay	
	Usual Day Positive, Range	*Negative Turnaround Time*	*Day Stained (Range)*	*% Sensitivity vs. Culture*
Adenovirus	4-10	2-3 wk	2 (1-3)	92-100
CMV	7-14	1 mo	2 (1-3)	75-100
Enterovirus	1-7	2-3 wk	3	85-100
HSV	1-3	5-7 days	1	70-100
HHV-6	NA	2-3 wk	3 (2-3)	86
hMPV	≥14	3-4 wk	1 (1-2)	92-100
Influenza	3-7	2-3 wk	2 (1-3)	92-100
Parainfluenza	3-7	2-3 wk	2 (1-3)	92-100
RSV	3-7	2-3 wk	2 (1-3)	92-100
VZV	5-10	2-3 wk	3 (2-5)	80-100

CMV, cytomegalovirus; HHV-6, human herpes virus type 6; hMPV, human metapneumovirus; HSV, herpes simplex virus; RSV, respiratory syncytial virus; VZV, varicella-zoster virus.

inducible promoter and an *Escherichia coli LacZ* reporter gene that produces β-galactosidase only when cells are infected with HSV. After the addition of a substrate for the β-galactosidase, infected cells stain blue, whereas uninfected cells remain colorless. ELVIS appears to be comparable with culture for the detection of HSV-positive specimens (95-100% sensitivity) in a similar time frame, 1.4 to 1.7 days.[42,194] This system may have future application in antiviral susceptibility testing.[280]

DIRECT DETECTION

Cytology

Historically, rapid detection of viral infection relied on light microscopy and evaluation of tissues and exfoliated cells for viral inclusions or other CPEs. Cytologic identification of virus is most useful in illnesses with vesicular exanthems such as HSV or VZV infection. A scraping of the base of an HSV or VZV lesion (Tzanck smear) reveals multinucleated giant and balloon cells when stained with hematoxylin and eosin, Wright, or Giemsa stain. In contrast, vesicular lesions caused by enteroviral infections do not contain giant or balloon cells, and allergy-related lesions contain eosinophils. Cytologic study of urine in congenital CMV infection reveals cells with the characteristic "owl's eye" intranuclear inclusions in 25 to 50 percent of cases, and nasal or pharyngeal smears in measles may reveal typical giant cells. These types of stains no longer are performed routinely in most diagnostic virology laboratories because they have been replaced by IF, which is more sensitive and specific.[45,46] Whereas the Tzanck smear cannot differentiate HSV from VZV and the presence of multinucleated giant cells is necessary to make the diagnosis, IF can identify the causative agent specifically, and the presence of viral antigen in balloon or giant cells is diagnostic.

Antigen Detection

Antigen-detection methods are available for most commonly isolated viruses. Advantages of these methods include speed; the use of standardized reagents and kits; the ability to detect nonviable, nonculturable, or difficult-to-grow viruses; and the ability to detect antigen when culture may be negative late in the course of infection. Generally, for viruses that can be cultured, these methods are not as sensitive as is optimized culture; thus, culture backup is recommended. These tests also are approved for specific-specimen types. DFA, indirect immunofluorescent assay (IFA), and ELISA are used most commonly for antigen detection in the clinical laboratory.

Immunofluorescence

Antigen detection by IF requires collection of the appropriate cell types (i.e., those in which the virus propagates) in adequate numbers for evaluation. In some cases, the specimen is placed on the slide directly (e.g., HSV or VZV detection), but usually the sample is transported to the laboratory for processing and slide preparation (e.g., for respiratory virus detection).

DFA methods use a virus-specific monoclonal antibody labeled with fluorescein dye to detect antigen and usually require approximately 30 to 45 minutes to complete. If processing of the specimen is required and slides are prepared in the laboratory, additional time is necessary. For IFA, unlabeled monoclonal antibody is added to the sample and incubated for 30 minutes, followed by a wash and the addition of fluorescein-labeled antimouse immunoglobulin. After an additional 30 minutes of incubation has transpired and a wash step has been performed, the slide can be examined for typical fluorescence (for excellent photographic examples, see Rossier and colleagues[257]). IFA can be completed in 2 to 3 hours, depending on specimen-processing requirements and the number of viral antigens being sought. The advantage of using DFA or IFA is the ability to determine specimen adequacy and perform small-batch and demand testing. A high-quality microscope and skilled, experienced personnel are required for optimal preparation and evaluation of the specimen.

The first DFA reagent available for use in the diagnostic laboratory was for the detection of HSV[109] in genital, dermal, oral, and anal lesions. The test has not been validated for the detection of HSV in CSF, asymptomatic genital specimens, tracheal aspirates, or bronchoalveolar lavage (BAL) specimens from immunocompromised patients. The sensitivity of DFA versus culture for HSV detection ranges from 72 to 92 percent[167,243] and, like culture, depends on the stage of the lesion.[45,46] The ability to detect HSV by DFA or culture decreases with the stage and age of the lesion. DFA or culture detected HSV in 96.7 percent of vesicles, 79.2 percent of pustules, 44.7 percent of ulcers, and 16.7 percent of crusts; HSV was detected in 82 percent of lesions less than 24 hours old, 77 percent of lesions 25 to 72 hours old, 50 percent of lesions 73 to 121 hours old, and 15 percent of lesions older than 122 hours.[45]

DFA is an excellent method for detecting VZV in lesion material, and because the virus is labile, the sensitivity of DFA is superior to that of culture.[41,68,103,275,279] In a comparison of DFA

and culture for the detection of VZV in skin lesions, the sensitivity and negative predictive values were 97.5 and 96.8 percent, respectively, for DFA and 49.4 and 60.4 percent, respectively, for culture. Because of the sensitivity of DFA, culture backup is not necessary.

Rapid detection of CMV antigen in lung tissue or BAL specimens[73,118,192,331,340] and in liver tissue[232] for the diagnosis of CMV pneumonia or hepatitis also has been evaluated. The sensitivity is less than that of culture or SVA and ranges from 56 to 100 percent; results were best when a mixture of antibodies directed against early and late viral antigens was used.[331] Sensitivity may be reduced further because BAL specimens virtually have replaced lung biopsy for the diagnosis of CMV pneumonia. A comparison of the cellular portion, supernate, and whole BAL for isolation of CMV in culture suggested that in most BAL specimens, CMV is associated with the cell-free rather than the cellular component.[40]

The antigenemia assay[325,326] is a sensitive, specific, and rapid method for detecting CMV viremia. Antigenemia has been used for establishing the diagnosis of CMV infection early[76,77,173]; for monitoring patients at high risk for acquiring CMV disease, including bone marrow,[19] heart transplant,[101] renal transplant,[324] and liver transplant patients,[322] as well as those with acquired immunodeficiency syndrome (AIDS)[198]; and for monitoring the treatment of severe disease after organ transplantation has been performed.[101,323] Clinically, it has been useful in detecting infection before the onset of symptoms, and through quantitation of viral load, it has enabled differentiation of disease from asymptomatic infection.[89,170,311] The assay consists of separation of leukocytes from whole blood, spotting or cytocentrifuging of cells onto microscope slides, fixation and permeabilization, staining with monoclonal antibodies, and detection by fluorescein- or peroxidase-labeled secondary antibodies. Antigen-positive leukocytes are quantitated. Once the assay was optimized,[20,99,100] standardized IFA[173] and IP[76,77] kits became available commercially. Antigenemia is more sensitive than is traditional culture or SVA for detecting CMV viremia. Antigenemia results were positive in 91 percent (90 of 99) of confirmed active CMV infections as compared with 34 percent (34 of 99) for culture[173]; another study yielded similar antigenemia results: 91 percent sensitivity versus 66 and 57 percent sensitivity for culture and SVA, respectively.[77] Disadvantages of the assay are that it is labor-intensive, time-consuming, and subjective; the leukocyte suspension must be adjusted to 10^6/mL, and the specimen must be processed quickly because storage for longer than 6 hours results in inaccurate quantitation of positive cells.[20,170]

Finally, DFA and IFA are useful for the rapid detection of common respiratory virus antigens[200,202,251,292,301,333,335,346] in nasopharyngeal washes, aspirates, and suctions. DFA for RSV has been evaluated extensively,[35,154,200,212,251,301,312] and its sensitivity in comparison to that of optimized culture ranges from 80 to 97 percent. As is the case for VZV, RSV is relatively labile, and antigen detection actually may be more sensitive than is culture; thus, culture backup usually is not required. However, culture still may be advisable because 5 to 25 percent of specimens submitted for establishing the diagnosis of RSV contain other viruses.[18] The sensitivity of DFA and IFA for detection of influenza virus A and B, parainfluenza virus 1, 2, and 3, and adenovirus antigens varies when compared with that of culture (ranging from 29-100%[10,139,171,197,200,292,301]), so culture must be performed for optimal diagnosis.

Enzyme-Linked Immunosorbent Assay

Standardized, well-characterized commercial kits for the detection of viral antigen by ELISA are available for HSV, RSV, influenza virus A, rotavirus, adenovirus, and hepatitis B virus (HBV). Intracellular and extracellular antigen can be detected, the method is simple technically, and suboptimal specimen handling still may yield positive results. ELISAs come in two basic formats, either a classic microtiter/tube system or the more recently developed self-contained membrane assays. The microtiter/tube format uses antibodies lining the surface of the solid phase to capture viral antigen, which in turn is reacted with an enzyme-labeled secondary antibody, followed by detection with the addition of substrate and color development. Results are read spectrophotometrically and thus are objective, thereby eliminating some of the difficulties inherent in microscopic techniques, which require technical skill and expertise for evaluation of specimens. These tests are relatively inexpensive, can be automated, are suitable for processing large numbers of specimens, and generally can be completed within 2 to 4 hours. Specimens normally are batched and cannot be tested on demand as previously described for IF. In addition, the adequacy of the specimen cannot be ascertained. In contrast, membrane assays use the membrane as the solid support to retain viral antigen. Enzyme-labeled antibodies are added to react with trapped antigen, and antigen-antibody complexes are detected via a chromogenic substrate. The results are read visually. Although they are rapid (15-20 minutes) and simple to perform, these tests are more expensive, require more hands-on time, and do not result in objective end-points. False-positive results and interpretation can be a problem.

Numerous studies have evaluated the performance of ELISA for detection of HSV in genital, dermal, oral, and ocular specimens.[44,54,105,111,149,227,283,328,330] Herpchek (DuPont Pharmaceuticals, Wilmington, Del) has been investigated most frequently and, when compared with culture, yields sensitivities and specificities ranging from 72 to 99 percent and 92 to 100 percent, respectively (the average sensitivity is approximately 90%). An automated system, VIDAS (bioMerieux, Hazelwood, Mo), also has shown promise, with a sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) of 92, 89, 83, and 95 percent, respectively.[149] Results obtained with another assay (Ortho ELISA) yielded an unacceptably low sensitivity of 35 percent, but the specificity, PPV, and NPV were 100, 100, and 85 percent, respectively,[111] thus illustrating the substantial differences among assays and the need for evaluation and validation by the laboratory. Membrane assays are less sensitive than is microwell ELISA, with a reported sensitivity, specificity, PPV, and NPV of 73, 99, 97, and 84 percent, respectively, and, therefore, they are used infrequently.[66,360]

Detection of RSV antigen in nasopharyngeal aspirates, washes, suctions, and swabs, like HSV, also has been evaluated extensively in standard[91,120,150,175,312,321,332] and membrane ELISA formats. The reported sensitivity, specificity, PPV, and NPV for standard ELISA were 71 to 91, 87 to 100, 95, and 94 percent, respectively, and for membrane enzyme immunoassay (EIA), 57 to 94, 73 to 100, 38 to 100, and 75 to 97 percent, respectively. When the results of TestPack RSV (Abbott Laboratories, Abbott Park, Ill) and Directigen RSV (Becton Dickinson) membrane EIAs were compared, TestPack appeared to be more sensitive and specific for the detection of RSV antigen; the mean sensitivity, specificity, PPV, and NPV for TestPack and Directigen were 87, 93, 89, and 92 percent and 76, 81, 63, and 89 percent, respectively. In many of these studies, antibody-blocking assays confirmed the specificity of ELISA. Other RSV rapid membrane assays include Directigen EZ RSV (Becton Dickinson), NOW RSV (Binax), RSV OIA (Biostar), XPECT RSV (Remel), QuickVue RSV (Quidel), and RSV ImmunoCard STAT (Meridian). Reported sensitivity, specificity, PPV, and NPV are similar to those mentioned earlier.[5,25,228] The recent introduction of antiviral therapy for influenza A and B has increased the demand for rapid diagnosis, thus prompting the development of several new assays. Table 264–5 summarizes the features of these assays. The assays are rapid and require less than 30 minutes to perform.

TABLE 264–5 Summary of Rapid Influenza Assays

Rapid Test (Manufacturer)	Virus Detected	Acceptable Specimens	Assay Time	Sensitivity	References
Directigen Flu A (Becton Dickinson)	A	NP wash/aspirate; NP and throat swabs	15-20 min	64-90%	148, 169, 334
Directigen Flu A + B (Becton Dickinson)	A and B	Same as Flu A and lower nasal swab, BAL	15-20 min	47-86%	264, 289, 303, 339
Directigen EZ Flu A + B (Becton Dickinson)	A and B	Same as Flu A + B	15-20 min	39%	339
Flu OIA (Biostar)	A/B*	Nasal aspirate, NP and throat swabs, sputum	15-20 min	54-88%	23, 48, 128
Flu OIA A-B (Biostar)	A and B	Same as Flu OIA	15-20 min	54-88%	48, 128
NOW Influenza A (Binax)	A	Nasal wash/aspirate, NP swab	15-20 min	53-59%	289
NOW Influenza B (Binax)	B	Same as NOW Flu A	15-20 min	53-59%	289
NOW Influenza A + B (Binax)	A and B	Same as NOW Flu A	15-20 min	47-88%	24, 289, 339
QuickVue Influenza (Quidel)	A/B	Nasal wash/aspirate, NP swab	10-15 min	73-94%	11, 264
QuickVue Influenza A + B (Quidel)	A and B	Same as QuickVue Flu	10-15 min	69-85%	3
XPECT Flu A + B (Remel)	A and B	Nasal wash, NP and throat swabs	15-30 min	94%	33
ZstatFlu (Zyme Tx)	A/B	Throat swab	20-30 min	41-87%	121, 226

**A/B does not differentiate A from B.*
BAL, bronchoalveolar lavage; NP, nasopharyngeal.

Some assays detect influenza A or B, some detect both but do not differentiate between them, and some simultaneously detect A and B and differentiate between them. Various specimen types have been validated and approved for use with these rapid assays, but accuracy may vary, even when acceptable specimens (e.g., throat swab versus NP swab versus NP aspirate) are used. In general, these rapid assays are expensive, are best suited to small-batch testing, require subjective interpretation, and are less sensitive than is culture or rapid IF detection. Sensitivity is variable (median 70-75%) and highly dependent on the type and quality of the specimen; median specificities are 90 to 95 percent.[23,48,148,169,181,265,303,334] Directigen Flu A and culture were compared for the detection of influenza A in nasopharyngeal washes, throat gargles, nasopharyngeal swabs, and throat swabs obtained from experimentally infected volunteers. Culture yielded 3.6, 1.2, 1.8, and 0.6 log of virus from these sources, respectively. The sensitivity of Directigen Flu A versus culture was 75, 22, and 64 percent for nasopharyngeal washes, throat gargles, and combined throat and nasopharyngeal swabs, respectively.[153] For optimal diagnosis, these devices should not be used when disease prevalence is low (at a 1-2% prevalence, the predictive value of a positive result is <15%) or in the off-season, adequate specimen collection must be emphasized, and negative results should be backed up by culture or IF testing.[115]

For the diagnosis of rotavirus and adenovirus 40/41 infection, ELISA is the only rapid test available in the clinical laboratory. Rotavirus antigen detection by standard ELISA has been studied thoroughly.[51,56,163,313] Many of the assays have excellent sensitivity (93-100%) and specificity (98-100%) when compared with that of electron microscopy (EM), although the best results were obtained with monoclonal (versus polyclonal) antibody-based kits (see elsewhere[57,196] for a review of available tests). Some assays can be read either visually or spectrophotometrically, so instrumentation is not always necessary. Several membrane EIAs also are available for rotavirus antigen detection (TestPack, Abbott Laboratories; ImmunoCard, Meridian Diagnostics, Cincinnati, Ohio) and, as is typical of this format, are somewhat less sensitive than is standard ELISA, with approximately 2 to 4×10^7 virions/mL required for detection of a positive specimen. The reported sensitivity and specificity versus EM are 94 to 100 percent and 90 to 100 percent, respectively.[27,37,57] An excellent ELISA for detection of adenovirus 40/41 in stool specimens is available and yields a reported sensitivity, specificity, PPV, and NPV of 96, 96, 95, and 96 percent, respectively.[127,146,347]

Latex Agglutination

Latex agglutination (LA) has been used primarily to diagnose rotavirus infection,[56,196,230,268,269] although assays also are available for detection of adenovirus[114] and HSV[300] antigens. LA is the least technically demanding of the tests described thus far, is rapid (2-5 minutes for rotavirus, 25 minutes for HSV), and is adequate for testing specimens collected early in the course of infection, but it is not as sensitive as is standard ELISA, with 10^7 virions/mL required for detection of a positive specimen. The sensitivity, specificity, PPV, and NPV for detection of rotavirus antigen by LA ranged from 70 to 93, 80 to 100, 76 to 100, and 85 to 95 percent, respectively (see elsewhere[56,196] for review); those for HSV were 73, 89, 89, and 72 percent, respectively.[300] The sensitivity and specificity of LA versus EM for detection of adenovirus were 95 and 100 percent, respectively.[114]

Nucleic Acid Detection

Molecular methods for the detection, identification, and characterization of microorganisms are being adapted increasingly for use in the clinical laboratory.[161,236-238,242,309,310,341,343,344] The two broad categories for detecting nucleic acids are direct detection via labeled DNA or RNA probes and hybridization or amplification of selected nucleic acid targets followed by detection of the amplified product. Direct hybridization formats include solid-phase (slot/spot/dot blot, microwell/bead capture, Southern/Northern blot), solution-phase, and in situ hybridization.[74,161,237,310,344] Nucleic acid amplification techniques are characterized as target (PCR), probe (ligase chain reaction), or signal (branched-chain DNA [bDNA]) amplification types.[74,237,309,344] Some of this methodology is moving from the research to the clinical laboratory for the following reasons: (1) replacement of radiolabels with enzyme, chemiluminescent, or affinity labels (e.g., biotin); (2) replacement of more cumbersome, labor-intensive detection methods with simplified, objective, ELISA-like formats; (3) simplified specimen preparation methods for releasing and exposing target nucleic acid; (4) the availability of standardized, optimized, and quality-controlled reagents and kits; and (5) the publication of guidelines and recommendations for the use of molecular testing in infectious disease diagnosis.[74] A few of these techniques are described in the following section with respect to their application for the diagnosis and monitoring of certain viral infections. Table 264–6 lists various methods and

TABLE 264–6 Comparison of Analytic Sensitivities

Detection Method	Approximate Detection Limit of Assay (Virions or Copies/mL)
Culture	1-10
Antigen	
IF-, IP-stained cells	1-10
Microwell ELISA	10^3-10^6
Membrane ELISA	10^7
Latex agglutination	10^7
Electron microscopy	10^6-10^7
Nucleic acid	
Radiolabeled oligonucleotide probes	10^6
Radiolabeled full-length probes	10^4
Enzyme-labeled probes	10^4
Chemiluminescent probes	10^4
Compound or branched probes	50-10^3
Nucleic acid amplification	≤10-10^3

ELISA, enzyme-linked immunosorbent assay; IF, immunofluorescence; IP, immunoperoxidase.

their relative analytic sensitivity for the detection of viruses, viral antigen, or viral nucleic acid.

IN SITU HYBRIDIZATION

In situ hybridization is a type of solid-phase hybridization assay in which whole cells or tissue sections fixed to microscope slides are taken through the hybridization process within the morphologic context of infected tissue. Cell suspensions and fresh-frozen and formalin-fixed, paraffin-embedded tissue sections have been used as the starting material for hybridization. The target nucleic acid is made accessible for hybridization via proteases and heat to increase availability of the target while preserving cellular architecture and morphology through the use of fixatives such as formalin, paraformaldehyde, or glutaraldehyde.[237] Detection systems include radiolabeled, as well as enzyme-, biotin-, and digoxigenin-labeled, probes. Some commercial kits are available, but methods often are optimized individually, thereby leading to variations in sensitivity among laboratories. In situ hybridization has been applied to the study and diagnosis of numerous infections,[237,316,318] particularly CMV viremia,[53,298] pneumonia,[104,217,340] hepatitis,[79,232] and HSV infection.[93,174,252,302] In some cases, culture,[104] immunocytochemistry,[302] and histopathology[79] had equivalent or superior sensitivity in comparison with hybridization. Although in situ hybridization probably is one of the first molecular techniques applied to the diagnosis of viral infections, lack of sensitivity, cost, and complexity have precluded its widespread use in diagnostic virology laboratories. In addition, the technique is related more closely to routine histologic staining and immunocytochemistry and, thus, is better suited to other areas of the pathology laboratory.[317,318]

SIGNAL AMPLIFICATION

In signal amplification, target nucleic acid is hybridized with complementary DNA or RNA probes, captured onto a solid surface such as a microtiter well or test tube, and, in an assay similar to ELISA, detected after the addition of enzyme-labeled probes and substrate. The attachment of multiple enzyme-labeled probes to each captured target molecule allows for amplification of the signal rather than the target nucleic acid itself. Thus, the signal generated is approximately proportional to the quantity of target nucleic acid in the sample, which is determined from a standard curve. Two signal amplification systems that have become commercially available are bDNA assays (VERSANT [formerly Quantiplex], Siemens-Bayer, Tarrytown, NY), and Hybrid Capture System (HCS) (Digene Corp., Gaithersburg, Md).

bDNA

Quantiplex assays have been developed for the detection of HBV,[36,124,357] hepatitis C virus (HCV),[58,186,225] and HIV[60,253] viremia. Virus is concentrated from plasma or serum; the target nucleic acid is released by disruption, hybridized with target and capture probes, and incubated overnight. The captured complex is hybridized with bDNA, incubated and washed, hybridized with alkaline phosphatase–labeled probes, and detected via a chemiluminescent substrate.[58] As many as 3000 alkaline phosphatase–labeled probe molecules can be incorporated onto each target molecule, thereby amplifying the signal and increasing the sensitivity of detection.[237] Because the signal is proportional to the quantity of nucleic acid in the specimen, the assay can be used to quantitate viral burden. Although the analytic sensitivity of bDNA is less than that obtained with PCR (10^1 to 10^5 copies/mL versus 10^1 to 10^2 copies/mL, respectively), bDNA's ability to quantitate viral burden by using a relatively simple and reproducible method has rendered it useful for establishing the diagnoses and prognoses of HBV,[34,36,124,133,357,353] HCV,[58,133,225] and HIV[14,138,176,177,273,288] infections, as well as for monitoring the response to antiviral therapy.

HYBRID CAPTURE SYSTEM

HCS assays have been developed for the detection and monitoring of human papilloma virus, HBV,[9,34,1130] HSV,[185] and CMV[14,138,140,176,187,199,209,273,288] infections. Briefly, specimens are treated to release viral DNA, target DNA combines with specific RNA probes to create RNA/DNA hybrids, hybrids are captured onto a test tube or microwell coated with capture antibody specific for the RNA/DNA hybrids, and captured hybrids are detected with multiple antihybrid antibodies conjugated to alkaline phosphatase. The bound alkaline phosphatase is detected with a chemiluminescent substrate. Similar to the case with bDNA, as many as 3000 alkaline phosphatase molecules can bind to each captured hybrid, and the signal generated is proportional to the quantity of nucleic acid in the original sample.

HCS has been evaluated for the detection and quantitation of CMV viremia; correlation to symptomatic infection; and response to therapy in renal,[14,138,176,177,273,288] liver,[176,177,187] heart,[176,177] and bone marrow transplant[176] and HIV-positive patients.[140,199,209] HCS was more sensitive than is traditional tube culture, SVA, or both, and it was useful for the early detection of CMV infections. Higher DNA concentrations correlated with clinically significant disease or progression, and quantitative DNA was useful in monitoring antiviral therapy. As with all quantitative methods, the threshold levels that predict disease must be determined in various patient populations. The lower limit of detection is 600 copies/mL, levels similar to those detected by PCR.

TARGET AMPLIFICATION BY POLYMERASE CHAIN REACTION

Of the molecular techniques developed recently, probably none has had a greater impact on basic and clinical research than has PCR. PCR has been applied to the detection and study of numerous, if not most, bacteria, fungi, parasites, and viruses. PCR is a target amplification technique in which a specific nucleic acid sequence is replicated by repeated cycles of denaturation, annealing, and extension directed by an oligonucleotide primer pair that defines the region of interest.[237,344] Target nucleic acid is produced in sufficient quantities to render it detectable by a variety of methods. The most practical and adaptable detection methods use an ELISA-like format with 96-well microtiter

plates. These methods entail the use of biotinylated primers in the amplification step, which are incorporated into the PCR product and subsequently detected via avidin-biotin interaction. In one scheme (Roche Diagnostic Systems, Indianapolis, Ind), the biotinylated PCR product is captured through hybridization with a specific probe attached to the microwell and detected with avidin–horseradish peroxidase conjugate. This system also features enzymatic prevention of carryover contamination.[156,165,186,225,253,260,281,337,354] Another system (Digene Corp.) uses solution hybridization with specific RNA probes to form RNA/DNA hybrids that are captured onto streptavidin-coated microwells. Bound PCR product then is detected by the addition of alkaline phosphatase–conjugated antibodies directed against RNA/DNA hybrids. This universal product detection system has been used to detect amplified CMV,[83,166] HBV,[320] and HIV[182] and can be adapted for the detection of numerous targets with the use of specific primer/probe sets. Issues that surround the implementation of PCR diagnostics include the production of diagnostic kits, the availability of standardized kits approved by the Food and Drug Administration (FDA), guidelines for use and interpretation, standardization and quality control of test procedures and specimen preparation, qualitative versus quantitative PCR, validation of test protocols, participation in proficiency surveys such as the College of American Pathologists survey, and re-evaluation of the gold standard. Although PCR is a powerful and sensitive technique, as with all other diagnostic tests, interpretation of results must integrate the clinical features, patient history, supporting laboratory data, and treatment records. PCR is a rapid, sensitive, and specific tool that is clinically useful for establishing the diagnosis of particular viral infections in select situations. PCR is useful (1) when culture is too insensitive, lengthy, expensive, difficult, impractical, or unavailable; (2) for confirmation of infection; (3) for early detection of infection; (4) for detection late in disease; (5) for resolution of indeterminate serology results; (6) to monitor the status of disease; and (7) to monitor response to therapy (Table 264–7). Use of PCR for diagnosing certain viral infections is addressed in the following section.

PCR has been used to detect HSV DNA in a variety of clinical specimens, including CSF and brain biopsy material,* skin lesions,[218,219] genital lesions,[43,61,123] and ocular samples.[143,351] The application of PCR to CSF specimens for diagnosing HSV encephalitis (HSE) has received a great deal of emphasis. Brain biopsy remains the gold standard for diagnosis. However, it rarely is performed, and patients are treated empirically. Traditional laboratory methods, including culture, antigen detection, intrathecal antibody production, CSF and serum antibodies, and the serum/CSF antibody ratio, lack sensitivity or specificity or are too slow; they are useful primarily for retrospective diagnosis. Numerous reports have documented the utility of CSF PCR for diagnosing HSE in a timely manner, with sensitivity and specificity greater than 95 and 100 percent, respectively.* Most of these studies have used some combination of traditional methods along with clinical observation and radiodiagnostic studies for case definition. Lakeman and Whitley[168] compared CSF PCR and brain biopsy in 101 patients, 54 with biopsy-proven HSE and 47 who were biopsy culture-negative. The sensitivity and specificity of CSF PCR were 98 percent (53 of 54) and 94 percent (44 of 47), respectively. The PCR-positive, biopsy-negative specimens remained PCR-positive in repeat assays with two different primer pairs and were considered true-positive; culture failures were perhaps due to sampling problems. The PCR-negative, biopsy-positive sample remained PCR-negative after DNA extraction and was not inhibitory to PCR. Patients also were monitored after receiving acyclovir treatment; 100, 98, 47, and 21 percent of CSF specimens were PCR-positive at times 0, 0 to 7, 8 to 14, and greater than 15 days, respectively, after brain biopsy was performed and therapy was initiated. The authors concluded that PCR should be the standard for establishing the diagnosis of HSE because its sensitivity and specificity were adequate for establishing the diagnosis of focal biopsy-proven HSE; its usefulness for defining the spectrum of HSV infection of the central nervous system (CNS) continues to be investigated. Detection of HSV DNA in skin and genital lesions has shown that PCR is more sensitive than culture, is able to identify asymptomatic HSV, detects the presence of HSV for a longer period of time (in older lesions and even fixed tissue), and has greater diagnostic value than culture and clinical observations for assessing genital HSV and treatment efficacy in patients with recurrent genital HSV.[43,61,123,218,219] PCR also is useful for diagnosing ocular infections caused by specific viruses or as supporting information in the clinical diagnosis of specific ocular disease syndromes.[143,351]

PCR has been used to diagnose cutaneous,[62,157,164,218,219] ocular,[222,351] CNS,[247,286] and congenital VZV infection[141] and as a tool for studying the natural history of primary and reactivated disease.[62,157,164] The principal clinical use of PCR in VZV disease is for the diagnosis of VZV CNS infection because isolation of virus rarely is successful and intrathecal antibodies cannot be used as an early diagnostic tool.[247,286]

TABLE 264–7 Clinical Use of Polymerase Chain Reaction for the Diagnosis of Selected Viral Infections

Virus	Clinical Utility
CMV	Diagnosis of CNS infection, diagnosis of neonatal/congenital infection, diagnosis of ocular infections, diagnosis and monitoring of active infection/viral load in immunocompromised hosts
EBV	Diagnosis of active EBV infection, diagnosis of CNS infection, diagnosis and monitoring of EBV-related lymphoproliferative disorders in liver and bone marrow transplants undergoing suppression
Enteroviruses	Rapid diagnosis of CNS infection
HBV	Early detection of infection, confirmation of infectivity, monitoring of viral load and therapeutic efficacy in chronic hepatitis
HCV	Detection before seroconversion, resolution of indeterminate or ambiguous serology, monitoring of viral load and therapeutic efficacy in chronic infection
HHV-6	Confirmation of infection
HIV	Detection before seroconversion, resolution of indeterminate immunoblot results, evaluation of suspected prenatal and intrapartum HIV infection, monitoring of viral load to evaluate therapeutic efficacy and disease progression
HSV	Diagnosis of HSV encephalitis, confirmation of neonatal HSV infection, detection of virus in late lesions, diagnosis of ocular infections
HTLV-I/II	Detection of HTLV-I in adult T-cell leukemia and lymphoma and tropical spastic paraparesis/HTLV-I–associated myelopathy
Parvovirus B19	Detection of infection, early detection before seroconversion
VZV	Diagnosis of CNS infection, detection of virus in late or atypical lesions, diagnosis of ocular infections

CMV, cytomegalovirus; CNS, central nervous systems; EBV, Epstein-Barr virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HHV-6, human herpesvirus type 6; HIV, human immunodeficiency virus; HSV, herpes simplex virus; HTLV-I/II, human T-cell lymphotropic virus types I and II; VZV, varicella-zoster virus.

*See references 6, 59, 116, 158, 168, 245, 246, 262, 276, 315, 319, 342.

Significant morbidity and mortality are associated with CMV infection, primarily in organ transplant recipients and patients with AIDS, and surveillance and monitoring for infection or disease by culture or antigenemia are required. Increasingly, PCR is being used to detect CMV DNA in blood,* CSF,[2,8,39,113,345] urine,[55,207] and the same spectrum of specimens submitted for culture.[207] Whole blood, peripheral blood leukocytes, serum, and plasma have been evaluated extensively for detection of infection, association with clinical disease, and therapeutic monitoring. Although PCR was positive earlier, remained positive longer, and was more sensitive than culture or antigenemia for the detection of CMV infection in whole blood or peripheral blood leukocytes, in the absence of a positive culture or antigenemia, PCR was not always associated with clinical symptoms and did not necessarily predict or correlate with the appearance of clinical disease, although it did predict a risk of relapse.[71,101,145,361] Detection of CMV DNA in serum or plasma, however, correlated with viremia, clinical disease, or both in patients with CMV infection,[28,294,337] including congenital CMV infection.[220] Detection of mRNA in peripheral blood leukocytes by reverse transcriptase PCR also has been used to assess active productive CMV infection and to identify patients at risk for symptomatic infection.[17,112] Detection of CMV viremia by PCR likewise is useful for monitoring antiviral therapy, both for the early initiation of treatment and as a predictor of treatment efficacy.[70,101,337,361] In addition, commercial kits (Roche Diagnostic Systems) are being evaluated for the qualitative and quantitative detection of CMV DNA from plasma.[21,29,287,337] PCR also is useful for diagnosing CMV CNS infection, primarily in patients with AIDS,[8,39,113,345] with reported sensitivity ranging from 79 to 100 percent.[8]

Conventional diagnostic methods generally are not useful in the evaluation of Epstein-Barr virus (EBV)-related disorders in immunosuppressed patients. Culture is not practical or useful, and serology is difficult to interpret in the setting of immunosuppression. PCR offers the possibility of rapid detection of EBV in a variety of clinical specimens and allows a semiquantitative or quantitative estimate of viral load. PCR has been used for establishing the diagnosis of AIDS-related CNS lymphoma,[7] EBV-related lymphoproliferative disorders,[49,159,193,221,297,307] and other EBV-associated diseases (e.g., infectious mononucleosis, fatal infectious mononucleosis, chronic active EBV infection, and EBV-associated hemophagocytic syndromes) in which increased DNA concentrations are associated with more severe clinical categories.[350] PCR is particularly useful for the early identification and diagnosis of lymphoproliferative disorders in pediatric patients after they have undergone liver transplantation, for monitoring EBV levels so that immunosuppression can be adjusted, and as a prognostic marker.[49,159,193,221,297,307]

PCR is useful for the early detection of HIV infection, resolution of indeterminate Western blot results, evaluation of suspected prenatal and intrapartum infection, and monitoring of the viral load for prognosis and evaluation of therapeutic efficacy.[129,156,165,203,253,254] Qualitative[156,165] (for detection of proviral DNA in peripheral blood leukocytes) and quantitative[72,75,215,253,266] (for detection of viral RNA in plasma) kits are available commercially (Roche Diagnostic Systems), and the quantitative assay has FDA approval. Quantitative PCR is useful for correlating RNA levels to disease stage, predicting clinical outcome, and monitoring response to therapy.[129,203] However, guidelines for the optimal use of PCR and other quantitative assays (bDNA, nucleic acid sequence–based amplification [NASBA]) still are evolving.[266] In a comparison of PCR, NASBA, and bDNA,[205] no significant differences in sensitivity were found for baseline measurement of HIV-1 RNA levels in the three assays. In addition, changes in RNA levels in response to therapy were comparable. The lower limit of detection for PCR, NASBA, and bDNA was 200, 4000, and 10,000 copies/mL, respectively; the turnaround time was 6 hours, 5 hours, and 1.5 days, respectively. Improvements in PCR and bDNA assays have lowered the limits of detection to 50 copies/mL.[15,72,75,215] Commercial kits (Roche Diagnostic Systems) also are available for the detection of HCV RNA in plasma.[186,225,260,281,358] Detection of HCV RNA is useful for establishing the diagnosis of acute hepatitis before seroconversion, for detection of chronic HCV in seronegative patients, for resolution of indeterminate serologic test results, and to monitor patients receiving therapy. PCR was more sensitive than was bDNA,[186,225] with approximately 11 percent of true-positives undetected by bDNA.[225] The analytic sensitivity of PCR and bDNA was 400 and 3.5×10^5 copies/mL, respectively.[225] Modifications to the VERSANT HCV version 3.0 bDNA assay have lowered the detection limit to 617 IU/mL, with a linear detection range of 617 to 7,700,000 IU/mL.[30] The unit of measure for HCV PCR assays has been converted from copies per milliliter to international units per milliliter, with lower limits of detection of 600 and 50 IU/mL for the quantitative and qualitative assays, respectively.[178] The qualitative assay is the first HCV assay to receive FDA approval.

With regard to enteroviruses, PCR has been used to diagnose enteroviral CNS[32,255,256,258,259,270,277,354] and neonatal infections[1,52,256] and to identify vaccine[352] and wild-type[38] poliovirus infections. Major emphasis, however, has been placed on developing a rapid, sensitive method for diagnosing aseptic meningitis because up to 25 to 35 percent of specimens from patients with characteristic enterovirus infection are negative and, when positive, require an average of 4 to 8 days for detection in culture.[258,270,354] CSF evaluation for pleocytosis is not always reliable because specimens with no pleocytosis also may be culture- or PCR-positive.[255,270] PCR for the diagnosing of enteroviral CNS infections has a sensitivity, specificity, PPV, and NPV of 95 to 100, 97 to 100, approximately 98, and 98 percent, respectively.[255,256,258,259,270,277] Commercial kits also have become available and yield rapid (<6 hours), sensitive, and specific results.[31,259,270,305,354,355] In addition, rapid diagnosis by PCR will have an effect on patient management with regard to number of days of hospitalization, antibiotic treatment, and, therefore, overall cost.[122,250,255,277]

Increased use of PCR for the diagnosis of disease has stimulated several recent developments, including automation of nucleic acid extraction, amplification, detection, and reporting and interpretation of results. Automation of specimen processing significantly improves the PCR process by rapidly and efficiently providing standardized, reproducible nucleic acids for amplification, comparable with those obtained with more labor-intensive manual methods.[81,215] Roche has developed numerous qualitative and quantitative PCR assays for the COBAS, an instrument that automates PCR amplification and detection and yields results similar to those of manual methods. Assays that have been developed for the COBAS include HCV,[63,98,356] HBV,[155,224] CMV,[21,29,287] and HIV.[215] In addition to increased automation is a trend to obtain more rapid, clinically relevant results through the use of real-time PCR. Amplification and detection are integrated in real-time PCR and occur simultaneously, in contrast to conventional PCR, in which these processes are separate. Turnaround time for conventional PCR ranges from 4 to 48 hours, depending on the detection system, whereas real-time PCR can be completed in 20 minutes to 2 hours, depending on the system and instrumentation used. Potential contamination is reduced in real-time PCR because amplification and detection occur in a closed system. For quantitative assays, real-time PCR also offers linearity over a broader dynamic range (5-6 logs) than possible with conventional PCR (2-3 logs). Real-time amplification methods, instrumentation, assay development, validation, and implementation in the clinical microbiology laboratory have been

*See references 28, 70, 71, 97, 101, 112, 145, 207, 220, 285, 294, 337, 361.

reviewed.[87,117,338] Although the majority of real-time amplification methods are home-brew, standardized and optimized commercial reagents are increasingly available, rendering validating and incorporating new molecular assays easier for diagnostic laboratories. Real-time PCR has been used for the qualitative and quantitative detection of CMV,[96,223,271,272,306] HSV,[80,86] VZV,[85] EBV,[159,221,297] HBV,[184,231] influenza A and B,[22,190,308,327] RSV,[22,110,190,214,308] parainfluenza viruses,[308] and human metapneumovirus[47,189] from a variety of specimens. See Espy and colleagues[87] for a complete review.

SUMMARY

Methods for the laboratory diagnosis of viral infections, including culture, SVA, antigen detection, and molecular diagnostic methods, have been reviewed. The use of these tests in some combination is most practical because a single test may not yield a diagnosis. For many viruses, culture has been the gold standard or reference method for evaluation of the new, rapid tests. However, culture is neither 100 percent sensitive nor always diagnostic of symptomatic infection. With the newer methods, particularly molecular diagnostic methods, the gold standard is changing, and evaluation of new techniques must be compared against a spectrum of laboratory and clinical data. Standards for performance and guidelines for the use and interpretation of molecular techniques are becoming available. Quantitative (versus qualitative) viral results may be useful for interpreting tests, particularly with regard to viruses causing latent infection or for monitoring therapy or disease progression. Finally, interpretation of any result requires integration of the clinical history, laboratory data, treatment records, and observation of trends over time.

CHAPTER 265

Parasitic Laboratory Diagnosis

David A. Bruckner ✪ Robyn Shimizu-Cohen

Parasitic infections usually are associated with tropical areas; however, many infections (*Dientamoeba fragilis*, *Entamoeba histolytica*, *Enterobius vermicularis*, *Giardia lamblia*, and *Toxoplasma gondii*) have worldwide distribution. With the ability of travelers to move freely throughout the world in a short time span, clinical laboratories must be able to recommend specimen collection and detection/identification methods for all types of parasitic infections. It is helpful if the physician informs the laboratory of the parasitic infection suspected or travel history of the patient because some organisms are detected more easily using specific methods (*Giardia* and *Cryptosporidium*—enzyme immunoassay [EIA] or direct fluorescent antibody [DFA] techniques) or alternative methods (microfilaria—Nuclepore filtration or Knott concentration procedure).[5,7,9] The life cycle of the parasite and the time of infection are important factors in determining the type of specimens to be collected and the techniques used to detect the infection (Table 265–1). Multiple specimens might have to be examined before the etiologic agent can be detected (e.g., colon aspirates or biopsy tissue for *Entamoeba histolytica*, blood for malaria). All specimens must be considered infectious and

must be handled with universal safety precautions using proper protective equipment.

The diagnosis of parasitic infections is dependent on macroscopic and microscopic examination of blood, feces, respiratory, tissue, and urine specimens. Specimens must be collected using methods that allow for the preservation of parasites when they are transported to the laboratory. Most stool specimens are collected at home or in a physician's office that may be a considerable distance from the laboratory performing the stool examination. Trophozoites disintegrate rapidly and do not form cysts after passage; therefore, stool specimens should be collected in containers from stool collection kits containing preservatives. The preservatives fix the specimens so that the trophozoites can be recognized easily on permanent stained slides and prevent the continued development of larvae and eggs.[3,5,9]

If questions of when and how to collect specimens to maximize the recovery of parasites occur, one's laboratory should be consulted about the collection methods of choice.

STOOL SPECIMENS FOR DETECTION OF INTESTINAL PARASITES

Liquid or semisolid stool specimens should be examined within 30 to 60 minutes, respectively, from the time of collection for protozoan trophozoites. Because most clinical laboratories cannot perform the examination in this time frame, stool specimens should be placed in preservative immediately after passage (Table 265–2). Most stool collection kits contain a combination of vials such as sodium acetate–acetic acid–formalin (SAF) and polyvinyl alcohol (PVA).[3,5,9] Specimens should be collected before radiologic examination with barium is performed, which may prevent the detection of intestinal parasites for up to 10 days after administration. Other substances or medications that also can interfere with the detection of intestinal parasites for a prolonged period of time include antibiotics (aminoglycosides, metronidazole, and tetracycline), antimalarial agents, bismuth, mineral oil, and nonabsorbable antidiarrheal agents. The specimen should be collected in a clean, wide-mouthed container and must not be contaminated with toilet water or urine. Once collected, the specimen should be transferred to a container with preservative. After being mixed with the preservative, the specimen can be stored at room temperature until it is transported to the laboratory.

Physicians recommend that three specimens be collected on alternate days within 10 days to rule out most intestinal infections. The probability of detecting stool parasites with a single stool specimen is as low as 50 percent. Multiple specimens collected from the same patient on the same day should not be accepted. Many intestinal protozoa such as *Giardia* are shed in a cyclic pattern, and the concentration of trophozoites and cysts in the stool can vary considerably from day to day.

OTHER SPECIMENS FOR DETECTION OF INTESTINAL PARASITES

Sigmoidoscopy samples may be submitted for the detection of *E. histolytica*. No fewer than six samples (slides) should be submitted

TABLE 265–2 Common Intestinal Tract Specimen Preservatives

Stool Preservative	Concentrate	Permanent Stain	Immunoassay	Advantages	Disadvantages
Formalin	Yes	No	Yes	Easy to prepare and has a long shelf life; preserves helminth eggs and larvae and protozoan cysts well; can be used with modified acid-fast and trichome stains	Does not preserve trophozoite morphology adequately; not suitable for permanent stains; specimen does not adhere to slide; cannot be used with all immunoassays
MIF*	Yes	No	ND	Has a long shelf life; fixes and stains parasite forms simultaneously	Two solutions must be mixed immediately before use; trophozoite morphology is poorly preserved; not suitable for trichrome stains; iodine interferes with immunoassays
PVA	Yes	Yes	No	Excellent preservation of trophozoite morphology; suitable for PCR assays	Contains Hg making disposal quite costly; morphology of larvae and eggs makes identification difficult; unsuitable for modified stains; PVA interferes with immunoassays
PVA, modified	Yes	Yes	No	Does not contain Hg; disposal is less expensive	Cu or Zn (substitute for Hg) does not preserve trophozoite and cyst morphology, making identification difficult; PVA interferes with immunoassays
SAF	Yes	Yes	Yes	Does not contain Hg; disposal is less expensive; has a long shelf life; permanent stain of choice is iron hematoxylin; preserves helminth eggs and larvae and protozoan cysts well; can be used with most immunoassays and special stains	Must use albumin-coated slides for permanent stains
Schaudinn	No	Yes	No	Excellent preservation of trophozoite morphology	Contains Hg, making disposal quite costly; not recommended for concentrates and has poor adhesive properties for liquid and mucoid specimens

MIF, merthiolate-iodine-formalin; PCR, polymerase chain reaction; PVA, polyvinyl alcohol; SAF, sodium acetate–acetic acid–formalin.

to the laboratory. Aspirates or scrapings can be collected and sent to the laboratory for direct wet mount observations, immunoassay, or polymerase chain reaction (PCR) (not commercially available). Preservatives such as Schaudinn fluid or PVA can be used to fix the samples to microscopic slides. Biopsy specimens should be submitted to the pathology laboratory for histologic preparation.

Duodenal aspirates and biopsies can be collected for the detection of *Cryptosporidium*, *Giardia*, and *Strongyloides*. Collection techniques similar to those mentioned for the detection of *E. histolytica* can be used. In addition, duodenal contents may be sampled using the EnteroTest (HEDECO, Mountain View, Calif). The nylon string can be sent directly to the laboratory for processing and microscopic examination for parasitic organisms.

E. vermicularis infections are detected best using the cellulose tape method. Specimens should be collected in the early morning before bathing or having a bowel movement. The adhesive side of the cellulose tape is pressed against the anal folds and after completion of sampling, the tape is placed with the adhesive side down onto a microscope slide. *Enterobius* eggs and adults may be trapped on the tape (commercial collection kits are available).[3] Multiple specimens (four to six) may be collected on consecutive days to rule out the presence of infection. Eggs from infections with *Taenia* adult worms also may be detected using this method.

STOOL PROCESSING AND EXAMINATION FOR PARASITES

All specimens should be examined using a concentration technique and performing a permanently stained slide (Fig. 265–1). If fresh, unpreserved specimens are received, a direct wet mount should be performed for the detection of motile protozoan trophozoites and protozoan cysts. Helminth eggs and larvae also may be seen. If necessary, a few drops of saline may be used to emulsify the stool and a drop placed on a microscopic slide and covered with a 22 × 22-mm coverslip. The wet mount should be examined using 100× and 400× magnification. A drop of iodine solution may be added to highlight parasite internal structures; however, parasite motility will be lost. A concentrate and a permanent stained slide also should be prepared from this fresh specimen.

Common concentration techniques include the flotation method using zinc sulfate ($ZnSO_4$) and sedimentation method. Specimens fixed in formalin, PVA, or SAF can be used. The flotation method gives a cleaner preparation to observe cysts and eggs, but the high specific gravity tends to distort cysts and eggs, rendering identification difficult. Heavier eggs (*Ascaris* or operculated eggs) will not float and will be found in the sediment; therefore, one should examine both top and bottom layers for a complete examination. The sedimentation method is used most widely in laboratories. Parasites and fecal debris are pelleted to the bottom of the tube by centrifugation. After the supernatant is discarded, the sediment is examined for parasites at 100× and 400× magnification.

Permanent stained slides should be prepared on every stool specimen that is examined for ova and parasites.[3,5,9] The stained slide is used primarily to detect and identify protozoan, trophozoites, and cysts. Gomori trichrome (Wheatley modification) and iron hematoxylin stains frequently are used in laboratories. Both stains have advantages and disadvantages that should be weighed, as should the expertise of laboratory personnel, before selecting the stain of choice for the laboratory.

Certain parasites are not detected easily by wet mount or routine permanent stained slides stained with Gomori trichrome (Wheatley modification) and iron hematoxylin. They include *Cryptosporidium* spp., *Cyclospora cayetanensis*, *Isospora belli*, and microsporidia. The oocysts of *Cryptosporidium*, *Cyclospora*, and *Isospora* can be detected easily by the modified acid-fast stain. Microsporidia can be detected using a modified trichrome stain.[6,9]

Culture of fresh stool or contents of the large intestine have been used to detect *E. histolytica;* however, this methodology is not practical for most clinical laboratories.

EIA kits are commercially available for the detection of *E. histolytica/Entamoeba dispar* group, *G. lamblia*, and *Cryptosporidium*. For *E. histolytica/E. dispar* group, only fresh or frozen stool can be used in the assay. Formalin interferes with reagents to detect

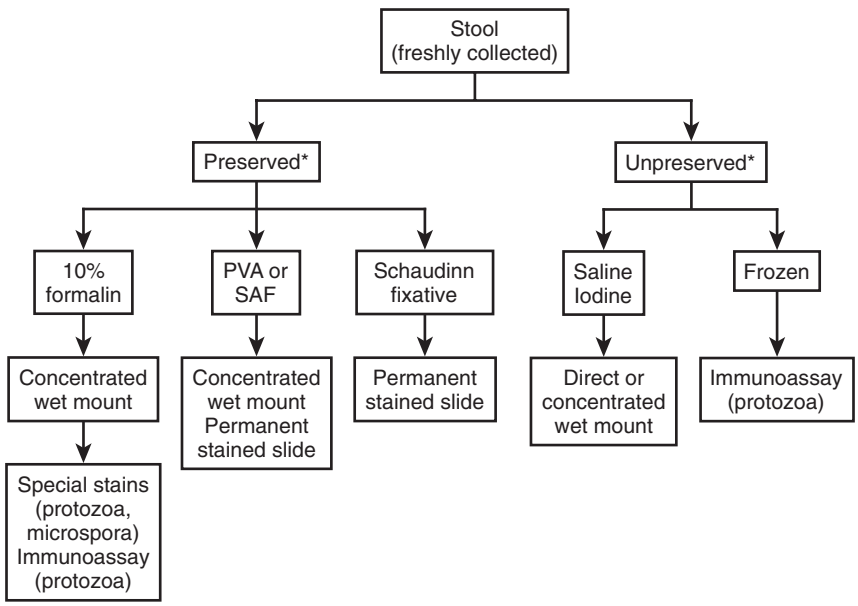

Figure 265–1 Parasite stool examination. *Worms (cestodes, nematodes, trematodes)—fix in 70% ethanol. PVA, polyvinyl alcohol; SAF, sodium acetate–acetic acid–formalin.

E. histolytica and cannot be used. EIA kits are available that will discriminate between *E. histolytica* and *E. dispar*, using fresh or frozen stool. EIA kits for the detection of *G. lamblia* and *Cryptosporidium* can be used with fresh, frozen or formalin fixed stool. Direct fluorescent antibody tests have been developed to detect *G. lamblia* and *Cryptosporidium*. Depending on the manufacturer, either fresh or formalinized specimens can be used. PCR also has been used to detect *E. histolytica*, *G. lamblia*, and *Cryptosporidium*. PCR test kits are not commercially available, whereas DFA and EIA kits are readily available. The DFA and EIA kits have excellent sensitivity and specificity compared to microscopy. The disadvantage of using DFA or EIA kits is that they detect only one or two pathogens at one time and other pathogens might be missed. Additional parasite examinations would have to be performed to detect other parasitic pathogens.

Detection of *Strongyloides stercoralis* is enhanced by culturing a small amount of fresh stool on an agar plate and looking for larval tracks across the plate as evidenced by lines of bacterial growth.[4] Other methods include the Baermann concentrate, Harada-Mori, or Petri dish filter paper slant.[3,5,9] It is possible that hookworms eggs could hatch and the larvae would have to be differentiated from *Strongyloides* larvae.

BLOOD PARASITES

Numerous important parasites can be detected in blood, although most laboratories will see these organisms only during proficiency testing (Fig. 265–2). These parasites include *Babesia*, *Leishmania donovani*, microfilaria, *Plasmodium*, and *Trypanosoma*. They may be found in macrophages, plasma, or red blood cells depending on the parasite. Maintaining proficiency to speciate *Plasmodium* or to recognize the amastigote stages of *Leishmania* is difficult for many laboratorians because these infections are seen so infrequently in the United States. A very important factor is that the physician inform the laboratory about the travel and medication history of the patient. If the patient took partial prophylaxis for malaria, a longer time should be spent examining the blood film due to low parasitemias. Similarly, differences in periodicity of microfilaria in the blood exist, and the timing of collection of specimens becomes more important. Alternative concentration techniques not normally used in most laboratories, such as Nuclepore filtration or Knott concentration procedure, can be used to detect microfilaria in low numbers in the blood, and Nuclepore filtration also may be used with urine.[3,5,9] Without the knowledge of what infection the physician may be considering, these concentration procedures are not routinely performed on blood specimens and the diagnosis of infections could be delayed or missed. Requests for the diagnosis of malaria must be considered to be STAT requests due to the morbidity and mortality mostly associated with *Plasmodium falciparum* infections.

Although some parasites (trypanosomes and microfilaria) can be detected by their motility in whole blood, identification is dependent on morphology as seen with a permanent stain. The blood film stain of choice is Giemsa, although Wright stain can also be used, or Delafield hematoxylin stain can be used, for the microfilarial sheath. Because Giemsa stains may not differentiate the microfilaria nuclei adequately, Delafield hematoxylin stain may be necessary to speciate the microfilaria.

Although blood films can be prepared in clinics or at the bedside (finger or ear lobe sticks), the recommendation is that blood be collected in EDTA (lavender top) so that multiple slides (thick and thin blood films) may be prepared in the laboratory and concentration methods be used. EDTA-collected blood provides the best overall morphology of parasites, and the tubes should be filled to the proper level to reduce distortion of the blood cells and organisms by the anticoagulant. Heparin tubes (green top) can also be used; however, these blood-filled tubes cannot be used for PCR testing. The blood should be examined for parasites within 4 to 6 hours of being collected.

Blood should be drawn immediately when a parasitemia is suspected. For malaria, blood should be drawn every 6 to 8 hours for 36 hours to rule out infection. Pediatric patients may be drawn at 10-hour intervals. A set of one negative blood films does not rule out the presence of malaria. When parasitemias are low, concentration procedures other than thick films, serology, or PCR may be the more sensitive method to detect *Babesia*, Chagas' disease, malaria, or microfilaria. Serology has not been shown to be an effective method to detect active infections of African trypanosomiasis in nonendemic areas.

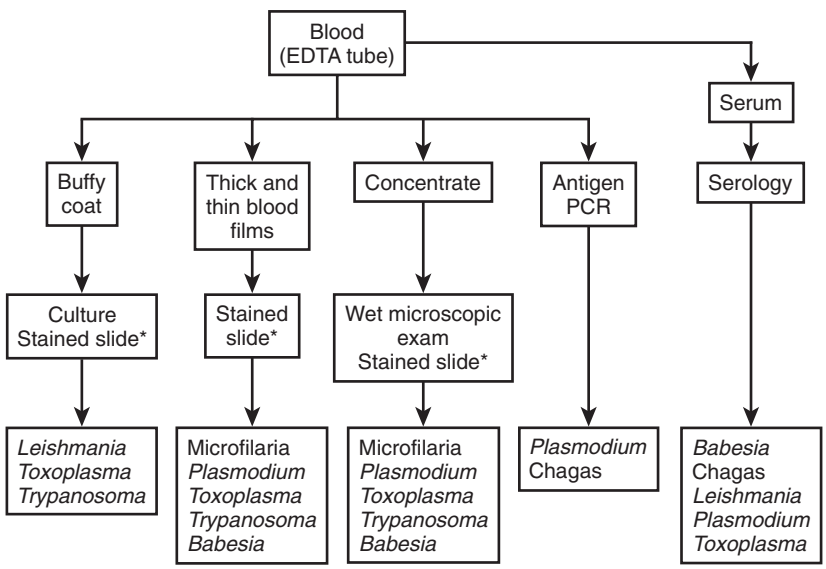

Figure 265–2 Blood parasite examination. *Preferred stain is Giemsa; however, Wright stain is also acceptable. PCR, polymerase chain reaction.

BLOOD PROCESSING AND EXAMINATION FOR PARASITES

If the physician does not indicate the specific blood parasite suspected, fresh blood should be used as a wet mount to look for the presence of microfilaria or trypanosomes by their characteristic shape and motility. If these parasites are detected, a permanent stained slide will have to be performed to identify the organisms to species. When thick and thin blood films are examined for the presence of parasites, no fewer than 300 microscopic oil fields should be examined before finalizing a result for the presence of *Babesia* or malaria. One may use lower magnification when looking for the presence of trypanosomes or microfilaria, but the entire film should be observed before finalizing a result. Thin films are used for the detection of blood parasites, enumeration of infected cells, and also to determine the species of parasite. Once the films are air dried, the film can be fixed with 100 percent methanol and stained with Giemsa stain or Wright stain without the methanol fixation process. If *Babesia* or malarial parasites (*P. falciparum* and *Plasmodium vivax*) are present, one should quantitate the number of infected red blood cells. This quantification can be expressed as the number of infected cells/100 RBC observed in the blood film. Serial specimens collected at various times during therapy can be used to monitor the success or failure of therapy. Continued presence of parasites in blood films without a marked decrease in parasitemia within the first 24 hours is an indication of therapeutic failure.

Thick films are prepared with one or two drops of blood that should be stirred in a small circle for 10 to 20 seconds at various intervals as it dries on the slide to prevent the blood from sloughing from the slide during the staining process. The thicker the film, the more likely the blood will slough. Detecting and identifying the presence of parasites on thick films is extremely difficult, particularly with inexperienced laboratory personnel. Once the thick film has dried, the blood film is laked with water or buffer before staining if Wright stain is used, or the films can be placed directly into Giemsa stain without prior laking. Laking disrupts the red cell membrane, allowing the hemoglobin to be removed and leaving parasites, white blood cells, and platelets intact. The search for microfilaria can be performed at a lower magnification, whereas the search for *Babesia*, malaria, and trypanosomes must be done with oil magnification looking at 200 to 300 oil microscopic fields.

Concentration techniques also can be used to detect *Babesia*, *Leishmania*, malaria, microfilaria, and trypanosomes. Microhematocrit capillary tubes can be centrifuged, and the parasitized red blood cells and trypanosomes can be detected near the buffy coat interface. The tube can be scored and snapped, and the buffy coat can be used to prepare a thin film. Alternatively, the tube can be observed under a microscope at the buffy coat interface for the presence of motile trypanosomes.

Microfilaria can be concentrated using the Knott procedure or Nuclepore membrane filtration technique. Normally, a 5-μm filter is used, but if *Mansonella perstans* microfilaria is suspected, a 3-μm filter is recommended. Most laboratories would not be familiar with or normally use concentration techniques unless specifically asked to do so.

Antigen tests for malaria have been developed and approved for clinical use in the United States.

UROGENITAL SPECIMENS

Trichomonas vaginalis is the most common pathogen; however, schistosome eggs, microfilaria, and microsporidium also may be recovered from urogenital specimens. Many *T. vaginalis* infections are diagnosed on clinical signs and symptoms with a specimen being collected. The detection of *T. vaginalis* usually is based on direct observation in wet mounts prepared from vaginal and urethral discharges, prostatic secretions, and urine sediment. Urine specimens should be first-voided urine in the morning. Specimens collected for the detection of *T. vaginalis* should not be refrigerated because *T. vaginalis* is susceptible to cold temperatures. Specimens can be diluted with a drop of saline and observed under low power in reduced illumination for the presence of motile flagellates. Stained slides, such as Giemsa or PAP smears, also can be used, but the majority of the infections with *T. vaginalis* are identified by the direct wet mount.

Culture can be used and is recommended by the Centers for Disease Control and Prevention (CDC) for patients suspected of harboring *T. vaginalis* infections, but no organisms were detected by the direct wet mount method.[1] Specimens can be collected with a brush, swab, or sponge. Specimens should be inoculated as soon as possible into the media. Cultures showing no organisms after incubation for 4 days can be reported as negative. Commercially available DFA, EIA, and DNA probe kits have been approved by the FDA for the detection of *T. vaginalis*.[2,3,5,9]

The Knott concentration procedure and the Nuclepore membrane filtration technique have been used for the detection of microfilaria in the urine. Microfilaria most frequently detected using these methods are *Wuchereria bancrofti* and *Onchocerca volvulus*.

Schistosoma hematobium eggs found in the urine can be concentrated by sedimentation, centrifugation, or the Nuclepore membrane filtration procedure. The preferred specimen is urine collected at midday, when the patient is most active and most likely to have eggs in the urine.

OTHER SPECIMENS

Other important pathogenic parasites, such as ocular infections with *Acanthamoeba* and *Toxoplasma gondii*, can be detected in other anatomic sites and are addressed in specific chapters.

CHAPTER 266

Epidemiology and Biostatistics

Eugene D. Shapiro

Clinicians care for individual patients, each of whom has certain unique problems. Clinicians base their decisions on a panoply of factors that include features of the acute and chronic medical problems of the patients, as well as features of both their personalities (e.g., How likely are they to comply with a certain therapeutic regimen?) and their private lives (e.g., Can they afford a certain medication? Are they planning to travel out of the country in the next few days?).

In contrast, epidemiologists study groups of people. They draw conclusions from studies of large numbers of patients and usually base conclusions on probabilities and biostatistical analyses of average (mean) outcomes.

Fortunately, these two approaches—the individualistic approach of the clinician and the probabilistic approach of the classic epidemiologist—are not incompatible. Indeed, each can illuminate the other. So it is that a chapter on epidemiology and biostatistics is included in a clinical textbook of pediatric infectious diseases. The goal of this chapter is not to make the reader an expert in these fields—courses and textbooks are designed for that purpose.[6-7,9-12,20-22] Instead, the goal is to summarize how selected key aspects of epidemiology and biostatistics can be applied to understand studies that will improve our ability to evaluate and treat children with infectious diseases. Chapter 7 addresses some epidemiologic issues that are specific to infectious diseases, whereas this chapter addresses more general issues related to designs of epidemiologic studies, as well as statistical analyses of such studies.

EPIDEMIOLOGY

DESIGN OF STUDIES

Overview

Epidemiologic studies generally are designed to be either descriptive or analytic. In *descriptive* studies, the goal is to describe a population (e.g., the clinical manifestations and prognosis of children with tuberculosis). In *analytic* studies, the goal is to assess associations between two or more variables (e.g., whether children who receive an experimental vaccine are less likely to develop the infection that the vaccine is intended to prevent than are controls). Indeed, analytic studies usually are designed to assess whether a causal association exists between the variables (e.g., Is a vaccine efficacious? Do children who attend daycare centers have a higher risk of acquiring infections caused by certain bacteria or viruses?). Of course, categorizing a study so easily may not be possible. In a study that is primarily descriptive, causal associations within subgroups may be assessed. For instance, in a study of the clinical epidemiology of tuberculosis in children, the investigators may compare the mortality rates of younger children with those of older children or the mortality rates of children with tuberculous meningitis with those of children who have infection at other sites.

Most studies, whether descriptive or analytic, seek to reach conclusions about the particular group that is being assessed (e.g., children with tuberculosis). However, because studying all persons with the condition of interest is not possible, investigators inevitably study a *sample* of persons and hope that the conclusions drawn from studying the sample apply to the entire population of interest (the *target population*). The *validity* of a study refers to the extent to which the results are true (accurate). The extent to which the conclusions drawn from the study sample (e.g., children with tuberculosis at Bellevue Hospital in New York City) are valid for the target population (e.g., all children with tuberculosis in New York City) is a measure of the study's *internal validity*. The extent to which the conclusions drawn from the study sample are valid for a less restrictively defined, larger population (e.g., all children with tuberculosis in the United States) is a measure of the study's *external validity*, which also is called its *generalizability*. To ensure that a study is both valid and generalizable, investigators must take steps to protect against a variety of potential biases (discussed later) that may distort the results of a study.

Elements of an Analytic Study

Epidemiologists refer to the major elements of an analytic study as the *exposure* and the *outcome*. The *exposure* is the factor that the investigator hypothesizes is related causally to the outcome of interest. In this context, the term *exposure* is not used in the classic sense of potential contact with an infectious agent; rather, it is any factor (e.g., living at a certain altitude, race, receipt of either a vaccine or a medication, smoking cigarettes) that may be associated causally with the outcome. The *outcome* is the effect (e.g., disease caused by a particular bacterium) that putatively is related causally to the exposure. The putative association may be one in which the exposure either causes or prevents the outcome of interest.

Before the specific type of study is defined, several additional elements of a study must be considered. One is how the *sample* for the study is selected. In general, investigators select a sample of the population either on the basis of exposure (e.g., patients who either received or did not receive a vaccine or who either attend or do not attend group daycare) or on outcome (e.g., patients who either had or did not have pneumococcal bacteremia or patients who either died or survived). Another key element is the *timing* of the study in relation to the timing of exposure and outcome. In studies in which the timing is *historical*, both the exposure and the outcome occurred before the study was initiated (e.g., a case-control study of a vaccine's efficacy in which cases with disease are identified from historical logbooks and antecedent receipt of the vaccine is determined from medical records). Timing may be *concurrent*—that is, both the exposure and the outcome occur after the study is initiated (e.g., a randomized clinical trial of the efficacy of a new antibiotic). Timing also may be *mixed*, a mixture of historical and concurrent (e.g., a study of the current IQ of children who previously had aseptic meningitis).

A final important element of a study is its *direction*. Direction is used to describe the order in which outcome and exposure are assessed. It may be done in a *forward* direction, from exposure to outcome (e.g., in a clinical trial of a vaccine's efficacy, the exposure [receipt or nonreceipt of the experimental vaccine] occurs first, and the occurrence of the outcome [the infection that the vaccine is designed to prevent] is determined subsequently). Alternatively, a study's direction may be *backward*, from outcome to exposure (e.g., in a case-control study, the outcome [e.g.,

pneumococcal bacteremia] is determined first, and exposure [e.g., previous receipt of pneumococcal vaccine] is determined subsequently). Alternatively, exposure and outcome may be determined simultaneously (e.g., a survey in which determination of whether subjects have sickle-cell disease and whether they are taking penicillin occurs at the same time). A study's direction can have important implications for inferences about causal associations; for example, even though a strong statistical association may exist between sickle-cell disease and the use of penicillin, concluding that the penicillin caused the sickle-cell disease would be erroneous. Although such an inference obviously is not plausible in this instance, the dangers of making erroneous inferences about causality are very real when exposures and outcomes that are less well understood are studied.

Although the terms *prospective* and *retrospective* are used widely, substantial variability exists in how they are applied. The term *prospective* is used to describe studies in which selection of the sample is based on the exposure, in which the timing is concurrent, or in which the direction of the study is forward (from exposure to outcome). The term *retrospective* is used to describe studies in which selection of the sample is based on the outcome, in which the timing is historical, or in which the direction of the study is backward (from outcome to exposure). Referring to the specific elements of the study is preferable to using the terms *prospective* and *retrospective*, which are applied so imprecisely.

Types of Studies

Epidemiologic studies may be classified as either experimental or observational. In *experimental studies*, the exposure is assigned by the investigators (e.g., in a clinical trial of an experimental vaccine, the investigator assigns subjects to receive either the experimental vaccine or a placebo). In *observational studies*, the exposure occurs naturally (e.g., rainfall in a study that assesses the effect of the amount of rainfall on rates of mosquito-borne infections), is selected by the subjects or their parents (e.g., attendance at group daycare in a study that assesses the frequency of infectious illnesses in children who attend and others who do not attend group daycare), or is assigned in the course of regular medical care (e.g., receipt of an approved vaccine in a case-control study of the effectiveness of the vaccine). Observational studies also are called *surveys*.

EXPERIMENTAL STUDIES

The paradigm for an experimental study is the *randomized clinical trial*, which is a special type of a *longitudinal cohort study* in which the exposure is assigned randomly to the subjects by the investigators. In randomized trials, the direction of the study always is forward, selection (or categorization) of subjects always is based on exposure (i.e., exposure is determined at the time of randomization), and timing always is concurrent (both exposure and outcome are determined during the real period of the study). Randomized trials are the *sine qua non* for evaluating the effect of new agents designed either to prevent (e.g., vaccines, prophylactic drugs) or treat (e.g., antimicrobials) diseases. By randomly allocating subjects to either receive or not receive the agent that is being tested, potential bias is minimized. Theoretically, if the size of the sample is adequate, the only difference between the groups is whether they received the experimental agent. Consequently, if the study is conducted properly, inferring that statistically significant differences in outcomes between the groups were related causally to the experimental agent is reasonable. For this reason, in most instances, the efficacy of new therapeutic agents or new vaccines must be demonstrated in clinical trials before the U.S. Food and Drug Administration (FDA) will approve them (although in some instances new products are approved if criteria for safety and for some surrogate end-point, such as a serologic correlate of immunity, are met).

TABLE 266–1 Randomized Clinical Trials

Advantages
Gold standard for scientific validity
Randomization ensures unbiased allocation of the exposure (e.g., a new drug or an experimental vaccine)
Blinding ensures unbiased assessment of outcomes
Disadvantages
Poor statistical power for rare diseases
Requires large samples
Requires longitudinal follow-up
Logistically complex and expensive
Impaired generalizability when the study population differs from the ultimate target population
Ethical issues
Requires informed consent
Difficult to use to evaluate approved (presumably efficacious) products

The advantages and disadvantages of randomized trials are summarized in Table 266–1. Although clinical trials are the gold standard for investigators who wish to design a scientifically valid study, they do have numerous limitations. A major problem is that clinical trials usually are expensive. Subjects need to be selected, enrolled, and monitored longitudinally to detect the outcomes. When the outcome is a disease that is relatively rare (e.g., pneumococcal bacteremia), large samples are necessary to provide adequate statistical power. Because sponsors of clinical trials usually want to test a new drug or an experimental vaccine under conditions that will maximize the chance that it will be found to be efficacious, patients with comorbid conditions (e.g., sickle-cell disease, asplenia, metastatic cancer) that might affect their response to the new agent often are excluded from the study. If the subjects who are excluded are an important part of the target population for the new agent (e.g., the patients with comorbid conditions are likely to be at high risk for serious complications of the disease and thus potentially could benefit greatly from an effective new intervention), the generalizability of the results of the clinical trial may be impaired.

Most randomized clinical trials are conducted in a double-blind manner; that is, neither the investigators nor the subjects know whether they received the experimental intervention (e.g., a new drug) or the comparison agent (e.g., either a placebo or an agent used in the standard manner). Double-blinding helps ensure lack of bias in ascertainment of the outcome because neither the subject nor the investigator can be influenced either to (or not to) seek medical care or undergo diagnostic tests on the basis of which of the interventions was received.

Randomized clinical trials may pose difficult ethical problems because the new (and potentially efficacious) agent is not given to the controls. By the time that clinical trials are begun, usually some evidence suggests that the agent is efficacious (e.g., preliminary studies showing that a new vaccine induces antibodies). Accordingly, some patients and patient advocates might suggest that withholding a potentially efficacious therapeutic agent or a vaccine from persons at risk is not ethical; consequently, it may be difficult to have persons agree to be potential controls in studies of a promising new therapy.

Problems also may arise when approval of a product for the target population is based on studies that are conducted in a different population. For example, polyvalent pneumococcal polysaccharide vaccine was approved in the United States for the elderly and for adults with chronic conditions, such as chronic obstructive pulmonary disease and congestive heart failure, that

put them at increased risk of acquiring serious pneumococcal infections. However, the data on which approval was based were derived from clinical trials conducted among young gold miners in South Africa who were at risk largely not because of their age or underlying illnesses but because of the conditions in which they lived and worked. Reports of vaccine failure and poor antibody response to the vaccine in the target population in the United States led to questions about the vaccine's efficacy.[5] However, once the vaccine was approved, conducting a randomized clinical trial in the target population was difficult ethically because it would mean withholding, on a random basis, an approved (and presumably efficacious) vaccine from patients at risk. Consequently, all but one of the postlicensure studies of this vaccine's efficacy were observational studies.

Conducting an experimental study in which the exposure is not assigned randomly is possible. For example, one might conduct an experimental cohort study in which volunteers receive a certain intervention (e.g., a new drug) while controls receive no intervention. Both groups would be monitored forward in time while undergoing surveillance for the outcome event. Although such a study incorporates some of the features of a randomized clinical trial, because the intervention is not assigned randomly, such studies are subject to significant biases.

OBSERVATIONAL STUDIES

Observational Cohort Studies

The direction of cohort studies always is forward, and the selection (or categorization) of subjects always is based on exposure; however, the timing may be concurrent, historical, or mixed. Thus, a cohort study may identify a cohort of subjects at a point (or at several points) in time in the recent or remote past, categorize them regarding their status with respect to the exposure (e.g., receipt of either a vaccine or a drug), and then monitor them forward in time for the occurrence of the outcome event (e.g., an infection) until a certain point in time, which could be in the past, present, or future. As in a clinical trial, subjects must not have the outcome at the time of enrollment in the study.

Cohort studies share many of the disadvantages of randomized clinical trials (see Table 266–1) but have the additional disadvantage that because they are not experimental, they are subject to many potential biases. On the other hand, cohort studies have many practical advantages (e.g., the timing can be historical, so conducting a 30-year follow-up study in just months is possible), and because they are observational studies, they usually have fewer potential ethical problems than does a randomized trial. In addition, for rare exposures, a critical factor is to be able to base selection of subjects on exposure.

Case-Control Studies

In both clinical trials and observational cohort studies, the selection of subjects is based on their exposures, and they are monitored in a forward direction until the outcome is determined. In *case-control studies*, the process is reversed. Subjects are selected on the basis of outcomes. The cases have the outcome, usually a disease; the controls do not have the outcome. The direction of the study is backward—the previous exposure is ascertained after the subjects are selected. The timing of case-control studies usually is historical, but it may be mixed; the timing of the exposure always is historical, but the timing of the outcome may be either historical or concurrent. For example, an investigator may conduct a case-control study of a vaccine's effectiveness in which persons who are infected (cases) are identified concurrently through active surveillance of a microbiology laboratory. Because case-control studies are nonexperimental and the exposure (and, sometimes, the outcome) occurred in the past, the potential for bias is great, both in selection of the sample and in ascertainment of both the exposure and the outcome. The advantages and disadvantages of case-control studies are shown in Table 266–2. Recently, use of "sham" outcomes and/or exposures in addition to the true outcomes or exposures of interest has been suggested as a means of assessing the internal validity of case-control studies.[24]

TABLE 266–2 Case-Control Studies

Advantages
Statistically powerful method to assess outcomes that are rare or delayed
Logistically easier and more efficient than large experimental or observational cohort studies
No longitudinal follow-up, so it can be completed relatively quickly and inexpensively
Ethically acceptable because it is an observational study
Disadvantage
Subject to many potential biases

Cross-Sectional Studies

Unlike cohort studies (both experimental and observational), in which subjects are monitored forward from exposure to outcome, and case-control studies, in which subjects are monitored backward from outcome to exposure, in cross-sectional studies, outcome and exposure are determined at the same time. In cohort studies, causal inference is made from cause to effect, whereas in case-control studies, causal inference is made from effect to cause. In cross-sectional studies, determining whether the exposure preceded the outcome may not be possible. Consequently, making valid causal inferences from a cross-sectional study also may not be possible.

Selection of subjects for a cross-sectional study may be based on outcome, exposure, or neither. However, because cross-sectional studies include only persons with prevalent outcomes, they are particularly problematic for studies of infectious diseases because patients whose illnesses (outcomes) either resolved or resulted in death before the study is conducted are not counted as having the outcome. Consequently, cross-sectional studies are more suitable to the study of chronic conditions and rarely are used in studies of infectious diseases.

ANALYSIS OF EPIDEMIOLOGIC STUDIES

The results of epidemiologic studies with dichotomous exposures and outcomes often are displayed in a 2×2 *contingency table*. However, the way that the results are analyzed statistically depends on the type of study.

Cohort Studies

Analysis of longitudinal cohort studies (both experimental trials and observational studies) is shown in Table 266–3. The measure of association between the exposure and the outcome is the *relative risk* (sometimes called the *risk ratio)*, which is an expression of the *magnitude* of this association in the study sample and represents an *estimate* of the association in the population from which the study sample was drawn. A relative risk of 1 indicates that no association exists between the exposure and the outcome, a relative risk greater than 1 indicates that the exposure is associated with an increased risk of the outcome, and a relative risk less than 1 indicates that the exposure is associated with a decreased risk of the outcome. The *attributable risk* (the risk of the outcome that is attributable to the exposure) is calculated as the risk in

TABLE 266–3 Analysis of Experimental or Observational Cohort Studies

	Outcome Present	Outcome Absent	Total
Exposed	a	b	a + b
Unexposed	c	d	c + d
Total		a + c	b + d

Risk in exposed subjects: a/(a + b).
Risk in unexposed subjects: c/(c + d).
Relative risk: (a/a + b) ÷ (c/c + d).
Attributable risk: (a/a + b) − (c/c + d).

exposed subjects minus the risk in unexposed subjects. Of course, testing the statistical significance of any association is necessary because the relative risk could be greater than 1 or less than 1 by chance (see later sections on stochastic statistics and confidence intervals).

These analyses assume that no attrition exists among the subjects in the study. However, because of death, migration out of the study area, and loss to follow-up, as well as variation in the time of enrollment (enrollment in either a clinical trial or an observational cohort study may occur over a prolonged period or, indeed, throughout a study), variation virtually always exists among subjects in the duration of time that they are at risk for the outcome. If the average time at risk among the exposed and the unexposed subjects is equal, the analysis shown in Table 266–3 is likely to be valid. However, if a great deal of irregular attrition or new enrollment occurs during the study, the denominator is expressed better as person-time at risk (e.g., person-months, person-years) rather than as the number of persons in the group. When this method is used, the rate then is called the *incidence density rate* and the index of comparison is called the *incidence density ratio*.

In studies of infectious diseases, the outcome event often is the occurrence of an infection. Frequently, persons who become infected recover and may remain at risk for the outcome event again. Nonetheless, a subject usually should be censored (i.e., removed from the study) once the outcome event occurs. The fact that the outcome occurred may indicate that the subject has an increased risk for the outcome, independent of the exposure that is being assessed. For example, consider a study of the protective efficacy of a conjugate pneumococcal vaccine in which one of the subjects (whether the subject is a vaccinee or a control does not matter) experiences three or four episodes of invasive infection caused by pneumococci (perhaps because the subject has a previously unrecognized underlying condition, such as acquired immunodeficiency syndrome [AIDS] or an immunoglobulin deficiency). The estimate of the vaccine's efficacy would be distorted substantially if each of the outcome events were counted. Certainly, in a primary analysis, only the initial event should be counted. Another reason to censor the subject is that in some instances, the outcome event may be fatal. If some subjects die of the outcome (and, therefore, must be censored), not censoring subjects with the outcome who survive is, in effect, incorporating an assessment of the exposure's effect on prognosis and not just on the risk of the outcome event.

Using a different method to adjust for unequal durations of follow-up in a study may be necessary, particularly when a long latent period exists between exposure and outcome (e.g., a condition that often is met when the study involves the effect of a potential carcinogen). In such instances, simply to sum the total person-times of exposure may be misleading because the outcome is more likely to occur many years after exposure. For example, although the total person-time at risk would be the same, the risk of an outcome developing clearly may be substantially different for 500 persons, each of whom is monitored for 2 years after exposure, than it may be for 40 persons, each of whom is monitored for 25 years. In such situations, the analyses must be adjusted for variation in the length of follow-up, which can be done with the use of *survival analysis* (also known as *life-table analysis*). The two basic methods of survival analysis, the *actuarial* method and the *Kaplan-Meier (product-limit)* method, are described in detail elsewhere.[14]

TABLE 266–4 Analysis of Case-Control Studies

	Cases (Outcome Present)	Controls (Outcome Present)
Exposed	a	b
Unexposed	c	d

Proportion of exposed cases: a/(a + c).
Proportion of exposed controls: b/(b + d).
Odds of exposure among cases: a/c.
Odds of exposure among controls: b/d.
Odds ratio: (a/c) ÷ (b/d) or (ad) ÷ (bc).

Case-Control and Cross-Sectional Studies

Analysis of a case-control study (with dichotomous outcomes and exposures) is shown in Table 266–4. Because selection of subjects is based on their outcomes, one cannot calculate the risk of development of the outcome, as one would in a longitudinal study (such as a clinical trial). Instead, one calculates the proportion of each group (cases and controls) that is exposed. The measure of association in a case-control study is the *odds ratio*. The *odds* of some occurrence means the probability that it will occur divided by the probability that it will not occur. In a case-control study, we are interested in the odds of exposure. The odds ratio is the ratio of the odds of exposure among cases (a/c) divided by the odds of exposure among controls (b/d). For rare events, the odds ratio closely approximates the relative risk of exposure that would be found in a longitudinal study of the same association. Use of a method known as *risk set sampling* allows odds ratios from case-control studies to approximate a risk ratio even if the outcome is not rare.[1] Cross-sectional studies are analyzed either like a case-control study (if the selection of subjects was based on their outcomes) or like a cohort study (if the selection of subjects was based on their exposures).

Bias

Bias occurs when the estimate of the association between the exposure and the outcome in the sample differs systematically from the true value in the population. Bias in the estimate of the association is different from bias in the measurement of individual variables. The latter bias (which may occur, for example, if an instrument such as a thermometer is calibrated incorrectly) may or may not affect the estimate of association in an epidemiologic study. Biased measurements usually affect the exposed and the unexposed groups equally. By contrast, *analytic bias* is the effect of *differential error (nonrandom error)* on the assessment of the relationship between exposure and outcome. Analytic bias can occur because of *information bias* (as a result of differential error in ascertainment of either the exposure or the outcome), *sample distortion bias* (because the joint distribution of the exposure and the outcome in the sample chosen for the study is not representative of the distribution of these factors in the target population), and *confounding bias* (because the joint distribution of one or more variables that independently are related both to the exposure and to the outcome is unequal in the groups that are being compared). Ensuring that bias does not affect a study is critical to its validity. Furthermore, although using statistical methods to adjust for certain sources of bias (particularly for confounding bias) in analysis of the results of a study sometimes is possible, adjustment for bias after the fact may be impossible.

An example of information bias is *detection bias*, which occurs when there is differential detection of the outcome in the exposed

and the unexposed groups. For example, numerous studies in which clinical scales to assess whether children with fever have a serious illness have been developed.[15] Often, however, the "serious illness" may include certain abnormal laboratory test results (such as an abnormal radiograph of the chest or a low concentration of sodium in serum). Because children with high scores on these scales were more likely to undergo diagnostic tests, detection bias may have occurred because similar abnormalities (such as a "silent" pneumonia or a mildly depressed concentration of sodium in serum) might go undetected in the "unexposed" group (children with lower scores on the clinical scale), a much smaller proportion of whom underwent a diagnostic test to detect a possible outcome. The best way to avoid having information bias is to use standardized, consistent methods to ascertain both the exposure and the outcome and to blind subjects and investigators to ensure that no differential ascertainment of either the outcome (in longitudinal studies) or the exposure (in case-control studies) occurs.

Sample distortion bias occurs when the sample in a study is not representative of the target population. However, a nonrepresentative sample does not lead to bias necessarily; bias in an assessment of the association between exposure and outcome occurs only if differential distribution of the exposure (or differential risk of the outcome) occurs in the subjects who are selected for the study versus the overall target population. This distribution can be the result of *selection bias*. For example, consider a case-control study of the effectiveness of an approved vaccine in which the control subjects (the uninfected patients) were chosen from private practices in affluent suburbs, whereas the case subjects (the infected patients) were any patients in whom a serious infection developed and who were hospitalized. The association between antecedent vaccination and infection probably is biased because the controls are not a representative sample of the population from which the cases emerged, and the proportion of them likely to have been vaccinated is higher than in the group of all uninfected persons in the population. Another possible source of sample distortion bias is differential loss to follow-up in a longitudinal study. The potential for sample distortion bias can be minimized by maximizing the probability that a representative sample will be selected, ideally by random sampling (or some other kind of unbiased sampling), and by minimizing loss to follow-up in longitudinal studies.

Confounding bias occurs when the association between exposure and outcome is distorted by a variable (a *confounder*) that is distributed unequally between the groups, is associated independently with both the exposure and the outcome, and is not in the causal pathway from exposure to outcome. One example of confounding bias is *susceptibility bias*, which occurs when the risk of the subjects (to development of the outcome) differs in the exposed and unexposed groups, independent of the exposure. For example, imagine a longitudinal study of the protective efficacy of a vaccine against *Haemophilus influenzae* type b in infants. Ensuring that an equal proportion of subjects in the vaccinated and the unvaccinated groups attended group daycare is important because attendance at group daycare is associated with an increased risk of developing infection with *H. influenzae* type b. If a substantially higher proportion of vaccinees than of controls attended group daycare, their attendance might confound assessment of the vaccine's efficacy and result in a biased (lower) estimate of the effect of the vaccine. By contrast, if a disproportionate number of controls attended group daycare, the estimate of the vaccine's efficacy might be biased in the opposite direction (it would be erroneously high because controls would have a disproportionately higher risk of acquiring infection with *H. influenzae* type b than vaccinees would).

In the previous example, adjusting for the effect of the confounder might be possible by either stratification or multivariable analysis (see later). However, identifying confounders may not always be possible. Random allocation of subjects probably is the best strategy to protect against confounding, especially potential confounders that cannot be identified.

STATISTICS

SUMMARY STATISTICS

Perhaps the most basic use of statistical analysis is to summarize data. This type of statistical analysis often is called either *summary* or *descriptive* statistics. The specific summary measures that are used depend, in part, on whether the variables being summarized are *continuous* (variables with equal distance between intervals) or *categorical* (variables with two or more discrete categories). Age, weight, height, temperature, concentration of creatinine in serum, and the number of hours spent in group daycare all are examples of continuous variables (sometimes called *dimensional* or *quantitative* variables). Race, sex, country of residence, and whether a patient is being ventilated artificially are examples of categorical variables (sometimes called *discrete* variables). Of course, continuous variables can be analyzed categorically (e.g., age can be divided into either a *dichotomous* variable [<45 years or = 45 years] or a *polychotomous* variable [20-44 years, 45-59 years, or = 60 years]).

Continuous Variables

A *frequency distribution* is classification of the values of a sample of continuous variables into successive categories (e.g., for a sample of different ages, one might place each value into different 5-year [0-4 years, 5-9 years, etc.], 3-year [0-2 years, 3-5 years, etc.], or 1-year [0 years, 1 year, 2 years, 3 years, etc.] categories) and expression of the frequency of values within each category.

A sample of values of a continuous variable also can be summarized mathematically by describing its central tendency, shape, and spread. The *central tendency* can be expressed as a *mean* (or *average*), a *median* (the middle value of the sample), or a *mode* (the most frequent value in the sample). The mean value is calculated by summing all the individual values in the sample and dividing by the number of individual values. Thus, for a sample that is composed of subjects aged 1, 1, 2, 2, 2, 3, 3, 4, 10, and 12 years, the mean age is 4 years (40/10), the median age (the age for which half the subjects are older than and half are younger than its value—if the number of subjects is even, the median is the mean of the two middle values) is 2.5 years [(2 + 3)/2], and the mode is 2 years. These summary measures provide only a limited view of the data. For example, the mean of a distribution can be shifted in the direction of extreme outlying values; in the example, the mean is 4 years even though 70 percent of the subjects are younger than 4 years. Likewise, from the median value alone, one would not know whether outlying values existed. Consequently, describing the spread of a distribution is important.

The *spread* of a sample may be expressed by its *range* and by its *standard deviation*. The range of a sample is the interval between the highest and the lowest value in its distribution. In the example, the range is from 1 to 12 years. Another useful way of mathematically summarizing the spread of a distribution is to express the interval between each individual value and the mean value of the sample. To summarize these values, one cannot simply sum all the differences because the sum always equals zero (the sum of the positive differences equals the sum of the negative differences). To avoid this problem, the standard deviation of a sample is used. This parameter is calculated by taking the square root of the *variance* of the sample. The variance is the sum of the squares of the differences from the mean of each individual value, divided by the number of *degrees of freedom* of the sample (which is equal to the number of values in the sample minus one, or $N - 1$). The

sum of the squares is divided by the number of degrees of freedom of the sample ($N - 1$), rather than by N (the actual number in the sample), because this calculation is thought to represent more accurately the true variance of the population from which a sample is taken.

To calculate the standard deviation of the sample in the example, one must determine the variance, which is the sum of the squares of the difference of each individual value from the mean of the sample:

$$(2[4 - 1]^2 + 3[4 - 2]^2 + 2[4 - 3]^2 + [4 - 4]^2 + [4 - 10]^2 + [4 - 12]^2) \div (10 - 1)$$

which equals 132/9, or 14.6667 years. The standard deviation simply is the square root of the variance, which is 3.8297 years.

In the medical literature, investigators often use the *standard error of the mean* (which is the square root of the variance divided by the square root of the number in the sample) to express the spread of the frequency distribution of a sample. However, the standard error actually is designed to be a measure of the standard deviation of the means of repeated samples from a single source population. Because the standard error always is smaller than the standard deviation of a single sample, it gives the erroneous impression that the spread of a sample is smaller than it actually is. A large sample with a large spread (and a large standard deviation) may have a small standard error. The standard error should not be used to describe the spread of a single sample.

The general shape of the frequency distribution can be inferred from the parameters given earlier. The characteristics of the most important distribution in statistics, the familiar bell-shaped curve of the normal distribution, are shown in Figure 266–1 and are discussed in a later section about diagnostic tests. The peak value of any distribution is the mode. A distribution may be bimodal, trimodal, and so on if it has two or more modes. A frequency distribution may be asymmetric, or *skewed*. If the mean is greater than the median (as in the example), the distribution is skewed to the right; conversely, if the mean is less than the median, the distribution is skewed to the left.

An investigator may want to summarize the relationship between two different continuous variables, which can be done with the use of linear regression, in which a straight line is constructed to represent the relationship between a continuous *dependent variable* (y) and a continuous *independent variable* (x). An equation ($y = a + bx$) can be created that represents the best "fit" to describe the relationship between the actual values of y and x, in which a (the *intercept*) is the value of y when x equals zero and b (the *regression coefficient*) is the slope of the line. Such an equation allows us to summarize the relationship between these variables and to extrapolate the value of each variable for conditions that may not have been observed in the sample. For example, one can calculate the incremental value of y for each interval change in the value of x.

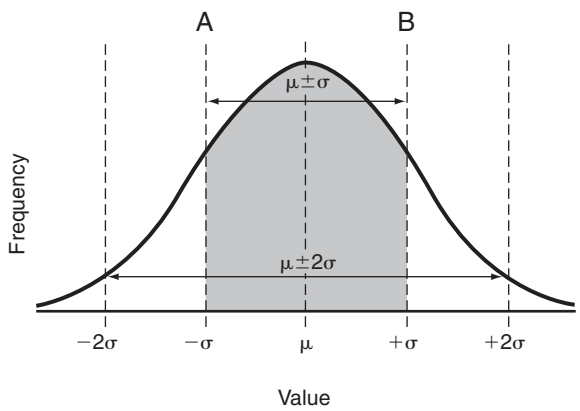

Figure 266–1 Theoretic normal (gaussian) distribution showing where 1 and 2 standard deviations (SD) above and below the mean would fall. The Greek letter mu (μ) stands for the mean in the theoretic distribution, and the Greek letter sigma (σ) stands for the standard deviation in the theoretic population. In this figure, the area under the curve represents all the observations in the distribution. One standard deviation above and below the mean, shown in dark gray and represented by the distance from point A to point B, is equivalent to 68 percent of the area under the curve, and therefore 68 percent of the observations in a normal distribution fall within this range. Two standard deviations above and below the mean, represented by the areas shown in dark and light gray, are equivalent to 95.4 percent of the area of the curve or 95.4 percent of the observations in a normal distribution. *(From Jekel, J. F., Elmore, J. G., and Katz, D. L.: Epidemiology, Biostatistics, and Preventive Medicine. Philadelphia, W. B. Saunders, 1996, p. 118.)*

Categoric Variables

The measure generally used to summarize categoric data is called a *rate* or a *proportion.* Rates consist of a numerator and a denominator. The numerator represents the actual number of persons in the sample who have the characteristic of interest (e.g., those with fever, those with tuberculosis, those who received a vaccine), and the denominator is the total number of persons in the sample. The persons in the numerator must be included in the group that the denominator represents, and the persons in the denominator must be able to have the characteristic that the numerator represents. For example, if one were interested in the rate of testicular cancer in the population, women should not be included in the denominator because they cannot have testicular cancer. Some experts believe that rates, by definition, should include a time factor (e.g., incident cases per person-months or per year). However, the term is used widely to refer to a proportion of a sample, as described earlier.

One of the most important rates that is calculated in epidemiologic studies is the *incidence rate*, which is the number of persons in whom a certain outcome develops divided by the number of persons in whom the outcome could have developed during a specified period. For example, a comparison may be made of the incidence rates of an infection over time in two groups in which the interventions given to prevent an infection differed (e.g., vaccine, placebo).

Another important rate, the *prevalence rate*, is the number of persons in whom a certain outcome develops divided by the total number of persons in the group at a specific point in time. In calculating the incidence rate, persons who at *zero time* (before the study begins) already have the outcome (e.g., prevalent cases) are excluded from both the numerator and the denominator. At time zero, the numerator of the incidence rate is zero. Thus, if one were interested in the incidence rate of lung cancer, persons who had lung cancer at the beginning of the study period would be excluded. The prevalence rate, by contrast, is measured at one point in time, and the numerator includes all persons with the outcome at that time.

Certain features of many infectious diseases affect both the prevalence rate and the incidence rate as measures of the occurrence of disease. The prevalence rate of any condition is related to its chronicity and the mortality rate associated with it; conditions that are common and chronic but are not associated necessarily with immediate mortality (e.g., atherosclerotic heart disease) have a relatively high prevalence rate. On the other hand, the prevalence rates are relatively low for conditions that either have a low mortality rate and resolve completely (such as many infectious illnesses) or have a high short-term mortality rate. To get a reliable estimate of the importance of such conditions, one must determine their incidence rates.

STOCHASTIC STATISTICS

Statistical Significance

Stochastic statistics deals with probability. Most readers are familiar with the use of "*p* values" to assess the *statistical significance* of a finding from a study. Usually, the threshold used to separate "significant" from "nonsignificant" results is a probability (*p* value) of less than 0.05, which means that (arbitrarily, by convention) if a result is likely to be observed by chance less than 1 in 20 times, the finding is considered to be "statistically significant." It must be emphasized, however, that statistical significance and clinical significance are very different. A statistically significant result means that the result is considered unlikely to be attributable to chance alone. As we shall see, the *p* value is related not only to the magnitude of the difference between the things that are being compared (e.g., a characteristic of either the exposed and the unexposed groups in a longitudinal study or the cases and the controls in a case-control study) but also to the size of the sample. Consequently, differences that are clinically unimportant (e.g., a difference in mean weight of 0.2 kg between two groups, a difference of 4% in the distribution of whites between two groups) can be statistically significant if the size of the sample is large. Of importance is to remember that a statistically significant finding may be of no clinical significance.

By the same token, the "magic" *p* value of 0.05 itself may be misleading because it is an arbitrary threshold; in fact, usually little difference exists in the results associated with a *p* value of 0.04 and one associated with a *p* value of 0.06. If the size of a sample is small, a large, clinically important difference may not be statistically significant. One should not automatically dismiss the importance of a finding for which the *p* value is 0.05 or higher.

Hypothesis Testing

In most epidemiologic studies, stochastic tests are used to check the validity of a hypothesis. By convention, one tests the validity of the *null hypothesis* that no difference exists in either the mean value of the characteristic (for continuous variables) or the frequency distribution of the characteristic (for categorical values) between the groups being compared. In essence, one is testing the probability that the two samples being compared (exposed subjects versus unexposed subjects or cases versus controls) emerged from the same population—that is, whether a difference between the groups could have been the result of chance if the two samples were selected randomly from the same population or whether the difference is so great that it probably (<1 chance in 20, or a *p* value of <0.05) did not occur by chance; that is, the samples probably actually represent a true difference in the populations of either exposed subjects versus unexposed subjects or cases versus controls.

Hypotheses can be either *bidirectional (nondirectional)* or *unidirectional (directional)*. A nondirectional hypothesis asks whether an association exists between exposed and unexposed subjects, but it does not assume in which direction the association will occur. For example, one might ask whether an association exists between the height of fever and the outcomes of children with typhoid fever without specifying whether the association would be in the direction of better or worse outcomes (perhaps high fever indicates a more severe infection, or perhaps it indicates a more vigorous immune response). In such instances, the associated *p* value should be interpreted in a bidirectional, or *two-tailed*, manner because the distribution of the test statistic contains two "tails," one at either end of the curve; the *p* value represents the sum of the area under the two tails of the curve. In effect, one is specifying that for a result to be statistically significant, the probability of the result being in a positive direction is less than 2.5 percent and the probability of the result being in a negative direction is less than 2.5 percent. Most tables of *p* values provide results that are to be interpreted in a two-tailed manner (because this is the most conservative approach to testing a hypothesis), so the *p* value for a given test statistic can be read directly from the table.

In some instances, however, one might have good reason to suspect that an exposure is associated with an outcome in a unidirectional manner (e.g., that possession of a handgun is associated with an increased risk of sustaining a gunshot wound). If, in advance, the investigator decides to test this hypothesis in a unidirectional manner (the null hypothesis for which would be that ownership of a gun is not associated with an increased risk of incurring a gunshot wound), interpreting the results of a test statistic in a unidirectional, or *one-tailed*, manner might be appropriate. To derive a one-tailed *p* value, the two-tailed value is divided by 2. Thus, if the two-tailed *p* value is 0.06, the one-tailed value for the same result is 0.03. Clearly, obtaining statistically significant results by testing hypotheses in a unidirectional manner is easier. However, of importance is to specify before the study is conducted the *a priori* plan for how the results of statistical tests will be interpreted. Furthermore, although many hypotheses might seem to lend themselves to unidirectional analyses (e.g., one might think that an experimental vaccine that has been shown to be immunogenic could only be beneficial), in fact, unidirectional analyses are used only rarely. First, the possibility that an exposure may have an effect opposite to that expected usually cannot be ruled out in advance. For example, researchers found that persons who were immunized with a vaccine composed of inactivated respiratory syncytial virus had an increased risk for developing symptomatic infection with the virus. In addition, because two-tailed interpretation of data is more conservative, many authorities (such as editors of journals and such licensing agencies as the FDA) demand two-tailed analyses.

Type I Error, Type II Error, and Statistical Power

Two types of errors can be made when testing the validity of a null hypothesis. The first occurs when the null hypothesis is true but is rejected erroneously, which leads to an erroneous conclusion that a difference exists between the exposed and unexposed subjects; this kind of mistake is termed a *type I error*; or *alpha error*. If a test statistic with a *p* value of less than 0.05 is accepted as statistically significant (and the null hypothesis is rejected on that basis), approximately 5 percent of the time, a type I error is made because if no difference actually exists between the groups, that result will occur by chance 1 in 20 times. By contrast, if the *p* value is less than 0.001, a type I error will occur less than 1 in 1000 times if the null hypothesis is rejected.

The other kind of error, *type II error*; or *beta error*; occurs when the null hypothesis erroneously is not rejected even though a difference between the two groups truly exists. If the *p* value associated with the result is 0.05 or greater, the probability that the null hypothesis is false is not sufficiently low to reject it (even though the probability that the observed result could have occurred by chance may be only 6%).

Type I and type II errors are mutually exclusive. If one rejects the null hypothesis, one risks committing a type I error, the probability of which is equal to the *p* value. In such instances, a type II error cannot occur. If one accepts (i.e., fails to reject) the null hypothesis, one may commit a type II error (in which case a type I error cannot occur). The probability of committing a type II error is not related directly to the observed *p* value. Instead, one can estimate the probability of committing a type II error (beta error) before the study begins on the basis of an assumed (clinically important) degree of association between the exposure and the outcome. Certain assumptions also must be made about the magnitude of the effect among the exposed subjects and the

frequency of the outcome in the unexposed subjects. One is calculating a unidirectional probability that, by chance, the study will fail to detect an association equal to or greater than the magnitude that is specified for what is, in effect, an *alternative hypothesis* (i.e., that an association truly exists between the exposure and the outcome). The *statistical power* of a study (the unidirectional probability that the null hypothesis will be rejected given a specified degree of type I error—usually <5%) is equal to 1 minus beta.

In designing a study, adequate statistical power is critical to ensure that a true association between the exposure and the outcome is not missed erroneously. The probability of a type II error depends on the size of the sample, the degree of variance within the sample, and the magnitude of the association that one wants to be able to detect: the smaller the sample, the larger the variance, and the smaller the magnitude of the association that one wants to detect, the larger the beta error (type II error) and the lower the statistical power of the study to detect an association. Of these factors, the investigator usually has control over only the size of the sample (because in the population, the variance generally is a relatively fixed attribute of the characteristic being measured and the magnitude of association that is chosen usually is the minimal association that is clinically meaningful; for example, to design a study of an experimental vaccine so that it could detect as little as 30 percent efficacy would not make sense because such a product would not be approved in most instances unless the magnitude of its effect was much greater).

Exactly what constitutes adequate power is debatable. Because enrolling a large number of subjects in a study often is expensive and time-consuming, frequently the power that a study is designed to have depends on both the financial resources and the time available to conduct the study. A statistical power of 80 percent often is chosen as a reasonable compromise between ensuring that the study has a sufficient number of subjects to answer the research hypothesis and the realities of logistic and financial exigencies. On the other hand, if a pharmaceutic company has invested many years and millions of dollars to develop a new drug or a new vaccine, it may demand that a pivotal clinical trial of the product have at least 90 percent power to detect a clinically meaningful effect in an attempt to ensure that the product will be approved if it is efficacious.

Multiple Comparisons

Another more subtle problem in interpreting results arises when more than one hypothesis is assessed in a single study. If multiple tests of statistical significance are performed in a study, the probability that by chance alone the p value associated with any one variable will be less than 0.05 is substantially greater than 5 percent. In fact, the probability that by chance at least one test will be associated with a p value less than 0.05 is equal to $1 - (0.95)^k$, with k equal to the number of independent tests of statistical significance that are performed. Thus, if 10 different hypotheses are tested, a 40 percent probability exists that at least one of them will be statistically significant (i.e., that at least one of the tests will have a p value of <0.05). Of course, this matter violates the arbitrary rule that we consider a finding to be statistically significant only if it is likely to have occurred by chance less than 5 percent of the time. If multiple different associations in a study have p values less than 0.05, determining which occurred by chance and which truly are statistically significant is difficult.

On the other hand, studies often are expensive, time-consuming, and logistically difficult to conduct. Therefore, sometimes a reasonable approach is to try to increase efficiency by assessing more than one hypothesis in a single study. To address this problem, one can specify in advance the *primary hypothesis* and the *secondary* and *tertiary hypotheses.* One then might give most credence to the statistical test of the primary hypothesis. Another approach is to lower the threshold used to define statistical significance by dividing 0.05 by the number of different tests that are performed. Thus, if five independent hypotheses are tested, any one would have to be associated with a p value of less than 0.01 before the null hypothesis would be rejected. However, this approach might be too stringent because the different hypotheses that are being tested often are not truly independent, and the probability that two or more associations will be statistically significant may be greater than the product of their individual probabilities. For example, one might assess whether infection is associated both with diarrhea and with vomiting; if it is associated with one of these symptoms, usually a higher than chance probability exists that it also is associated with the other. At the least, an investigator should acknowledge this potential problem and its consequences before drawing conclusions from the study.

Tests of Statistical Significance

Going into detail about the many different stochastic tests that are available is beyond the scope of this chapter. However, several general comments, as well as descriptions of a few commonly used tests, are in order.

Tests of statistical significance are either parametric or nonparametric. The test statistic of a *parametric* test is based on the assumption that the frequency distribution of the characteristic being assessed in the source population follows certain parameters. For example, for certain tests, one assumes that the characteristic in the population has a normal distribution. If the assumption is violated (e.g., the characteristic is not distributed normally), the statistical test will not be valid. In such instances, an appropriate approach might be to use a test based on a different, skewed distribution, such as the *Poisson distribution* for rare events, which might reflect more accurately the distribution of the characteristic in the population.

Alternative approaches to assess the statistical significance of differences between groups, if the distribution of the characteristic in the population is known to be highly skewed, include transforming the data so that they are normalized, usually by converting the values to their logarithmic equivalent, or using a *nonparametric* test.[25] Nonparametric tests, such as the Mann-Whitney U test and the Wilcoxon rank sum test, do not depend directly on the numeric values of the data; instead, the individual values are ranked in order of their values, and the statistical analyses are based on the relative ranks of the values in the different groups rather than on an assumed distribution in the population or in the sample.

For large samples, parametric tests usually are valid and often are easier to calculate than are nonparametric tests. For smaller samples and for samples with highly skewed distributions, nonparametric tests or tests that use log-transformed data may be preferable.

Continuous Variables

To test the statistical significance of differences between groups in continuous variables (such as degree of fever, IQ, age, or a score on a standardized questionnaire), the mean values of the different groups can be compared.[26] The tests of statistical significance use the magnitude of the difference of the means and the variance in the sample to assess the probability that the difference could occur by chance. If more than two groups are being compared for a single variable, the procedure is called *one-way analysis of variance.* The null hypothesis is that the mean values from each group are the same (i.e., that the different groups are random samples from the same population). The total variance in all the subjects is separated into the amount that is attributable to differences between the groups of subjects (the *intergroup variance*) and the amount that is attributable to differences among the

subjects within each group (the *intragroup variance*). The greater the quotient of the intergroup variance divided by the intragroup variance (the *F ratio*), the more likely that differences between the groups are statistically significant (i.e., that they are not due to chance variation). The statistical significance of the F ratio can be determined from the *F test* table of *p* values. When this type of test is performed to assess the statistical significance of the simultaneous effects of two factors (by stratifying into additional groups), the test is called *two-way analysis of variance*.

The familiar t *test* is just a special form of one-way analysis of variance in which the means of just two groups are compared. A *one-sample* t *test* assesses whether the mean value of the study sample is statistically significantly different from the mean value in the source population. It assumes that the mean value in the source population is known and is calculated by dividing the difference of the mean of the sample minus the mean of the population by the quotient of the variance of the sample divided by the square root of the number in the sample.

A more common use of the t *test* is to assess the statistical significance of the difference between the mean values of either a characteristic or an outcome of subjects in two different samples (e.g., of the exposed and the unexposed groups in a study). The null hypothesis of this *two-sample* t *test* is that the mean values of the two samples are not statistically significantly different (i.e., that they could be random samples from the same population). The *t* test statistic is equal to the difference in the mean values of the two samples divided by the square root of the pooled variance of the samples (the standard error of the difference of the means of the two groups). The *p* value of the result (*t*) is read from the table of the *t* distribution, with the degrees of freedom equal to the sum of the number of subjects in each sample minus 2.

Categoric Values

The chi-square statistic (χ^2) commonly is used to assess the statistical significance of differences in categorical values between groups.[6] Most often, proportions of two different groups (e.g., the proportions of the exposed and of the unexposed groups in which the outcome developed) are compared. Typically, the data are displayed in a *2 × 2 contingency table* (Table 266–5). The null hypothesis is that no association exists between the exposure and the outcome (or whatever the rows and columns represent)—that is, that the two groups could be random samples from the same population. This hypothesis is tested statistically by comparing the number of subjects who would be expected to be in a given cell by chance with the actual frequency (the observed frequency). The expected frequency can be calculated from the total number of subjects in the rows and the columns (the marginal totals) and is equal to the product of the number of subjects in the row times the number of subjects in the column divided by the total number of subjects in the sample.

The value of χ^2 (with N equal to the total number of subjects) is shown in Table 266–5. The statistical significance of χ^2 can be determined by reading the *p* values from a table of the χ^2 distribution. The larger the value of χ^2, the less likely that the observed proportions could have occurred by chance. Unfortunately, assuming that the probability that the observed proportions of a random sample of subjects will follow the χ^2 distribution is not necessarily accurate if the expected frequency of any cell is small. Consequently, many experts use a *continuity correction* (sometimes called the *Yates correction*) to adjust for the deviation from the smooth, continuous theoretic distribution of χ^2 when the discrete values of small numbers of expected subjects disrupt the validity of the assumed distribution. The equation for χ^2 with the continuity correction is

$$\chi_c^2 = [(ad - bc) - (N/2)]^2 N \div [(a + b)\,(a + c)\,(b + d)\,(c + d)]$$

If the expected frequency in any cell is very small (often defined as <5), the χ^2 test, even with the continuity correction, is not a valid estimate of the probability that the observed values could have occurred by chance. In such instances, the *Fisher exact test*, which is based on a hypergeometric distribution, should be used to assess the statistical significance of differences in categoric values.

TABLE 266–5 2 × 2 Contingency Table

	Outcome Present	Outcome Absent	Total
Exposed	a	b	a + b
Unexposed	c	d	c + d
Total	a + c	b + d	N

$\chi^2 = [(ad - bc)^2 N] \div [(a + b)(a + c)(b + d)(c + d)]$

Confidence Intervals

Although the validity of a null hypothesis typically is tested by stochastic tests and the use of *p* values, construction of a *confidence interval* (usually a 95% confidence interval [CI]) has the advantage of providing information about both the precision of the estimate of the association (the narrower the confidence interval, the more precise the estimate) and its statistical significance.[4] CIs have become standard components of reports of the results of epidemiologic studies.

Analyses of studies are concerned with both estimation (of the "true" value of the association between the exposure and the outcome in the population) and hypothesis testing (i.e., what probability that any association that is observed could have occurred by chance alone). A sample of the population is enrolled in any study. The association observed in the study is hoped to be an accurate estimate of the true value of the association in the entire population. However, if an unbiased study were repeated many times, by chance alone the results would vary (because of random sampling error). A CI is a range of values, based on the estimate and the spread of the data from a single study, within which the true value of the association in the population is likely to lie with a specified probability (i.e., 95% of the time for a 95% CI, 99% of the time for a 99% CI). CIs provide information about both the magnitude of associations (so that the clinical significance of the estimate can be assessed) and their statistical significance. If the CI is calculated for a single outcome and if the 95 percent CI for the difference between two groups does not include zero, the outcome is statistically significant (i.e., <5% probability that the null hypothesis of no difference existing between the groups is true). If the CI is for a risk ratio or an odds ratio, the association will be statistically significant if the 95 percent CI for the association does not include 1 (i.e., <5% probability that the null hypothesis that no association exists is true). CIs can be calculated with both continuous and categoric data, as well as for estimates of a single proportion and for differences (or associations) between two groups.

Adjustment for Potential Confounding Variables

The effect of confounding variables on the associations between exposure and outcome may be controlled in either the design or the analysis of a study. Random allocation of subjects to the exposed and the unexposed groups is a common strategy to avoid the effect of confounding in longitudinal studies. Although randomization actually ensures only lack of bias if a confounding variable is distributed unevenly between the groups (because an uneven distribution is as likely to favor the exposed group as the

unexposed group), randomization is likely to be effective in preventing confounding if the size of the sample is large (which renders substantial inequalities between groups in the distribution of an independent variable unlikely to occur). Nonetheless, an investigator must check to ensure that confounding does not occur, even in a randomized clinical trial.

Another way to ensure that a potential confounding variable does not affect the results of a study is to *match* on that variable. Subjects in the exposed and the unexposed groups (or, in a case-control study, the cases and the controls) can be matched on certain variables that are known to be associated independently with both the exposure and the outcome. Such matching can be achieved either by matching subjects individually or by *frequency matching* (i.e., ensuring that the overall frequency distribution of the potential confounder is the same among the cases and the controls). Matching can ensure that the matched variable (e.g., race, age) does not affect the observed association between exposure and outcome.

One disadvantage of matching is that the effect of the matched variable on the association between exposure and outcome cannot be assessed as it might be if either stratification or multivariable analysis were used to control for confounding. If matching is used in the design of the study, analyzing the data with special tests for matched designs is necessary. For example, in a matched-pairs case-control study, only discordant pairs (matched pairs in which the cases and controls differ in their exposure status) provide information. Calculation of the matched odds ratio and the associated test of statistical significance (*McNemar* χ^2) is shown in Table 266–6.

Adjusting for the effect of potential confounders in the analyses also is possible. One way to accomplish this adjustment is with *stratification*, which is performed by dividing the data into different groups, or *strata*, according to the potential confounder. For example, a study may indicate that children whose parents both work were three times more likely to become febrile during the course of a study than were children whose parents both do not work. We may suspect, however, that it is not having both parents at work, per se, that results in this increased risk of fever; rather, another factor probably is related independently to the risk for fever and to the probability that both parents work. Attendance at group daycare is such a factor. If we stratified the results of the study by whether the children attended group daycare, we most likely would find that a disproportionate number of children whose parents both work also attended group daycare. When the risk ratios in the two different strata are combined (by using the Mantel-Haenszel technique), we probably would find that the apparent association between having both parents work and the risk of fever disappears when the effect of attendance of group daycare is controlled by stratification.

Advantages of stratification are that it can be understood easily and it can be performed without changing the design of the study after it is completed. One disadvantage is that it requires being able to identify and to measure accurately the potential confounders (which is not necessary if one allocates subjects to different groups randomly). In addition, if several different potential confounders exist, performing the calculations may be difficult and time-consuming, and the sizes of the individual strata may be so small that the ability to make statistical inferences is poor.

Finally, one can adjust for confounding with the use of one of many multivariable statistical techniques, such as *multiple linear regression* (if both the dependent and the independent variables are continuous) or *logistic regression* (if the dependent variable is dichotomous and the independent variables are either categoric or continuous). Providing a detailed description of multivariable techniques is beyond the scope of this chapter. However, in general, these techniques involve creating a mathematic model that fits the data and then using that model to analyze various associations.[2-3,6,22] Although multivariable techniques are a powerful tool for both assessing the effects of and controlling for potential confounding variables, they depend on mathematic assumptions that may not always be valid and use techniques that are not intuitively obvious.

TABLE 266–6 Analysis of a Matched Case-Control Study

	Cases	
Controls	**Exposed**	**Unexposed**
Exposed	a	b
Unexposed	c	d

Matched odds ratio: b/c.
McNemar χ^2*:* $(b - c)^2/(b + c)$.
McNemar χ^2 *(with continuity correction):* $(b - c - 1)^2/(b + c)$.

META-ANALYSIS

The term *meta-analysis* refers to a number of different types of analysis. The common feature of all meta-analyses is that they summarize the results of two or more different studies. The term often is used to refer to a quantitative technique in which the results of different studies are combined after they are weighted in the calculations according to the sizes of their samples and the variances of their results. The term also sometimes refers to a qualitative analysis of a group of studies, including critical analyses that rate the methodological soundness of different studies but do not combine their results quantitatively. For example, one might review a group of studies that reached different conclusions about a topic. If the methodologically rigorous studies had similar results that differed from those of the weaker studies, one might conclude that the results of the more rigorous studies were more likely to be valid.

The concept of producing a single, statistically valid result by combining the results of different, often contradictory, studies has great appeal. However, quantitative meta-analysis has many shortcomings. Perhaps chief among them is that no distinction is made between studies that are sound methodologically and those that are not. Thus, the results of a meta-analysis may be dominated by a large, but methodologically questionable, study, whereas a superbly performed, but smaller study may fail to override the impact of the larger study in the meta-analysis. Another major problem is the selection of studies to include in a meta-analysis. Should only published, peer-reviewed studies be included? Clearly a bias exists that studies with positive results are more likely to be published than studies with negative results? Imagine that many small studies with poor statistical power are conducted and submitted to journals for publication. If the study found no association with the putative risk factor, it likely would not be published, on the grounds that the statistical power of the study is poor (i.e., the risk of making a type 2 error and erroneously concluding there is no association when such an association truly exists is great). On the other hand, if the study did find a statistically significant association with the risk factor, it might be published and could be included in a meta-analysis. If many such small studies that found an association were published, but even more small studies that did not find an association were not published, this kind of *publication bias* could lead to erroneous conclusions in a meta-analysis. Should the analysis be limited to only those studies that meet certain basic criteria for methodological rigor (and who should decide on the criteria and whether they are met), or should only randomized clinical trials be included? What formula should be used to weight the different studies? Is combining the results of methodologically different

studies valid? Results of meta-analyses should be interpreted with great circumspection.[27]

DIAGNOSTIC TESTS

Although clinicians typically order diagnostic tests many times each day, misinterpretation and misuse of diagnostic tests are extremely common occurrences.[19] The widespread practice of interpreting continuous values (e.g., the total white blood cell count) in a dichotomous manner (so that the result is either "normal" or "abnormal") and failure to appreciate fully the difference between the accuracy of a diagnostic test (i.e., its sensitivity and specificity) and its predictive value are major factors in the misuse of diagnostic tests.

WHAT IS NORMAL?

In most instances the "cutoff" for an abnormal test of a continuous variable, such as the total white blood cell count or the concentration of antibodies against an infectious agent, is based on the distribution of the results of the test in the population. One usually assumes that the distribution of most such results in the population will follow a gaussian (or "normal") distribution, which is illustrated by the bell-shaped curve in Figure 266–1. Gauss and other statisticians used the term *normal* to refer to the shape of this curve. However, in medicine, the term *normal* long has been used to mean something very different—the dichotomy between a state of health *(normal)* and one of disease *(abnormal)*. Unfortunately, the different meanings of these terms often have been used interchangeably, which has added to confusion in the interpretation of diagnostic tests.

In a normal distribution, the mode (the most frequent value) is the mean value, and 68.3 percent, 95.4 percent, and 99.7 percent of the values lie within (plus or minus) 1, 2, and 3 standard deviations (SD) from the mean value, respectively. The cutoff for an abnormal test result often is defined arbitrarily as any value that is more than 2 SD from the mean of a normally distributed population; thus, 5 percent (actually 4.6%) of the population would be categorized as abnormal. Half the people with abnormal results will be 2 SD below the mean, and half will be 2 SD above the mean. Thus, 2.5 percent (actually 2.3%) of the population will have abnormally high values. In some instances, 3 SD (or some other arbitrary parameter) is used to determine the cutoff. However, of importance is to realize that these definitions of normal and abnormal are merely statistical models that should not necessarily be translated to mean that 2.5 percent of the population is "diseased." As noted earlier, with this kind of statistical logic, the diagnosis of disease may be related to the number of tests performed because if multiple tests are conducted, the likelihood that the result of any one will be abnormal is increased. If 15 independent tests are performed on a patient, the probability that any one of the test results will be abnormal by chance is 54 percent.

Other statistical models might be more appropriate for assessing a diagnostic test. For example, interpreting diagnostic tests would be relatively easy if two separate, nonoverlapping normal distributions of diseased and disease-free patients existed. Unfortunately, although this model may apply for some rare conditions (such as genetic disorders in which affected persons are missing an enzyme that metabolizes certain substances, which leads to uniquely high concentrations of the substance in persons with the disorder), the model rarely is applicable. A model that is more appropriate for most infectious illnesses is shown in Figure 266–2. In this model (the example of which uses levels of serum calcium), the diseased and nondiseased populations have separate, partially overlapping distributions. The specificity of a diagnostic test is related directly to the degree to which the two distributions overlap.

ACCURACY OF A DIAGNOSTIC TEST

Two important characteristics of a diagnostic test—its *reproducibility* and its *validity*—are the key components of its accuracy. The reproducibility (sometimes called *reliability* or *precision)* of a test simply is the degree to which retesting yields the same result. A test that provides results that are not reproducible is of little diagnostic value. The validity of the results of a diagnostic test may be divided into two components: *sensitivity* and *specificity* (Table 266–7). The *sensitivity* of a test is the proportion of persons

TABLE 266–7 Statistical Indices of a Diagnostic Test

Result of Test	Disease	No Disease
Positive	a	b
Negative	c	d
True positives: a	Sensitivity = a/(a + c)	
False positives: b	Specificity = d/(b + d)	
True negatives: d	Positive predictive value = a/(a + b)	
False negatives: c	Negative predictive value = d/(c + d)	

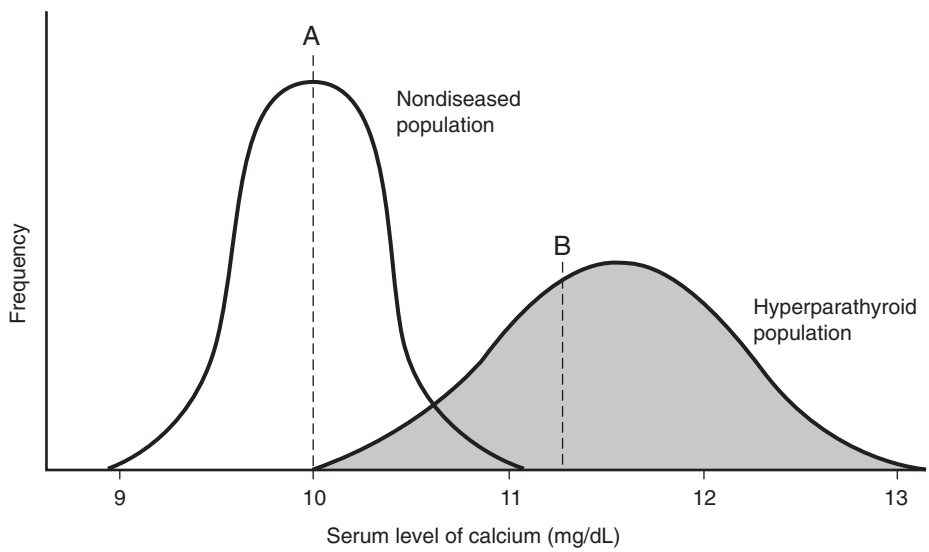

Figure 266–2 Overlap in values of randomly performed tests in a population in which most of the people are healthy (curve on the *left*) but some of the people are diseased (curve on the *right*). A person with a level of calcium below point A would be unlikely to have hyperparathyroidism. A person with a level of calcium above point B would be likely to have an abnormality in calcium metabolism, possibly hyperparathyroidism. A person with a level of calcium between point A and point B may or may` not have an abnormality in calcium metabolism. (*Note:* The normal range of calcium depends on the method used in a specific laboratory. In some laboratories, the range is from 8.5 to 10.5 mg/dL. In others, as in this illustration, it is from 9 to 11 mg/dL.) *(From Jekel, J. F., Elmore, J. G., and Katz, D. L.: Epidemiology, Biostatistics, and Preventive Medicine. Philadelphia, W. B. Saunders, 1996, p. 88.)*

with disease who are identified accurately by the test as having disease (true positives/[true positives + false negatives]). The *specificity* of a test is the proportion of persons without disease who are identified accurately by the test as not having disease (true negatives/[true negatives + false positives]). The ideal test has both a specificity and a sensitivity of 1. Of course, no diagnostic tests are that accurate. Indeed, a tradeoff exists between sensitivity and specificity—usually, the more sensitive a test is, the less specific it is, and vice versa.

Although the sensitivity and specificity of a given test often are considered to be absolute characteristics of a test, in fact, these characteristics do depend on the types of patients included in the studies in which the indices of the test were developed. Indeed, tests that appear to be both highly sensitive and highly specific in preliminary studies commonly prove to be much less so when used in actual clinical practice because the preliminary studies that establish a test's sensitivity and specificity frequently are affected by problems of spectrum and bias.[18] If the patients enrolled in studies used to assess the test (both those with disease and those without disease) have a relatively narrow spectrum of clinical manifestations, both the sensitivity and the specificity of a diagnostic test may appear to be better than they actually are. For example, if one were to assess the sensitivity of a differential heterophile test to diagnose infection with Epstein-Barr virus (EBV), its sensitivity would appear to be far better if all the subjects infected with EBV were teenagers with severe pharyngitis (a high proportion of whom will have a positive heterophile test result) than if it included subjects with a broader spectrum of manifestations of EBV infection (such as toddlers with symptoms of an infection of the upper respiratory tract, who are much less likely to have a positive heterophile test result when infected with EBV). Likewise, the specificity of a diagnostic test may appear to be better when only asymptomatic, healthy persons are used as nondiseased subjects instead of including patients with other illnesses that produce symptoms similar to those of the target illness. The effects of spectrum of the illness on sensitivities and specificities of a diagnostic test also have been reported for dipstick urinalyses as a diagnostic test for urinary tract infections.[13]

In addition, of importance is to realize that the cutoffs for classifying results as either normal or abnormal usually are somewhat arbitrary and may depend on how the test is used, as well as the nature of the disease that one is trying to detect. If a diagnostic test is being used to screen a population for a relatively mild disorder with a low prevalence, one would want to use a cutoff that results in high specificity to avoid having a large number of false-positive results, even at the expense of lower sensitivity. On the other hand, if the diagnostic test is for a serious disorder or is used not for screening but for diagnosis in a targeted population with at least a moderate prevalence of the disorder (e.g., a white blood cell count in cerebrospinal fluid to detect possible bacterial meningitis in febrile children), one might want to err on the side of overdiagnosis and, therefore, use a cutoff with a high sensitivity at the expense of lower specificity.

PREDICTIVE VALUE OF A DIAGNOSTIC TEST

Sensitivity and specificity are important characteristics of a diagnostic test, but to calculate them, one must know whether the patients do or do not have the disease; clearly, if a physician already has this knowledge, the test does not need to be performed in the first place. From the perspective of a clinician who is caring for an individual patient, the key characteristic of a diagnostic test is its *predictive value* (see Table 266–7). That is, if a test result is positive, what is the probability that the patient has the disease *(positive predictive value)*? Conversely, if a test result is negative, what is the probability that a patient does not have the disease *(negative predictive value)*? However, unlike sensitivity and specificity, the predictive value of a test depends critically on the prevalence of the disease among the subjects who are tested.

This concern is illustrated by the example in Table 266–8. In example *a*, the prevalence of the disease in the sample is 1 percent and the positive predictive value of a positive test result is only 8.8 percent. By contrast, as shown in examples *b* and *c*, when the prevalence of disease in the sample rises to 10 percent and to 50 percent, respectively, the positive predictive value of a positive test result rises to 51.4 percent and to 90.5 percent, respectively, even though the sensitivity and the specificity of the test are constant. By the same token, as the prevalence of disease in the sample that is tested rises, the predictive value of a negative test result falls, although the negative predictive value remains reasonably good until the prevalence of disease becomes high.

Of importance for clinicians is to be aware of these epidemiologic truths when ordering diagnostic tests for patients. Sometimes a physician orders tests to "rule out" the possibility that a patient's symptoms are caused by a disease that, based on the patient's history, physical examination, and previous laboratory tests, is unlikely to be the cause of the problem (i.e., the "prior probability" that the patient has the disease is low). Unless the specificity of such tests approaches 100 percent (which is unlikely for most serologic tests), in such situations the great majority of positive test results will be falsely positive; the physician then will be in the unfortunate position of ignoring the result, ordering

TABLE 266–8 Predictive Value of a Diagnostic Test with 95% Sensitivity and 90% Specificity with Different Prevalence of Disease in the Sample

	Test	Disease	No Disease	Total
a*	Positive	95	990	1,085
	Negative	5	8910	8,915
	Total	100	9900	10,000
	Positive predictive value = 8.8%	Negative predictive value = 99.9%		
b†	Positive	950	900	1,850
	Negative	50	8100	8,150
	Total	1000	9000	10,000
	Positive predictive value = 51.4%	Negative predictive value = 99.4%		
c‡	Positive	4750	500	5,250
	Negative	250	4500	4,750
	Total	5000	5000	10,000
	Positive predictive value = 90.5%	Negative predictive value = 94.7%		

**Prevalence of disease: 1%.*
†Prevalence of disease: 10%.
‡Prevalence of disease: 50%.

additional diagnostic tests, or treating the patient for a disease that probably is not the cause of the symptoms.[23] Consequently, clinicians should be selective in ordering diagnostic tests.

ASSESSMENT OF THE PROTECTIVE EFFICACY OF A VACCINE (OR OF ANY INTERVENTION)

This section will discuss assessment of the protective efficacy of a vaccine, but the same methods (with different outcomes specified, of course) can be applied to any intervention such as a drug or physical therapy. The protective efficacy (PE) of a vaccine may be assessed with either experimental or observational studies. The classic way to assess a vaccine's efficacy is in an experimental, randomized, double-blind clinical trial. The major observational designs available are cohort studies and case-control studies—although a large variety of hybrid designs such as household exposure studies and indirect cohort studies are available—but complete descriptions of them are beyond the scope of this chapter.[16,17] Table 266–9 illustrates calculation of the PE of a pneumococcal vaccine with data from clinical trials, cohort studies, and case-control studies.

CLINICAL TRIALS

In a randomized clinical trial, subjects at risk of acquiring the infection in question would be assigned randomly either to receive the vaccine (vaccinees) or not to receive the vaccine (controls). Subsequently, all subjects would be observed for occurrence of the infection during an appropriate period of follow-up. At the conclusion of the study, the *protective efficacy* of the vaccine, an index devised by Greenwood and Yule[8] to indicate the proportionate reduction in the frequency of disease attributable to the vaccine, would be calculated. PE is defined as follows:

$$PE = (\text{Risk of infection in controls} - \text{Risk of infection in vacciness}) \div \text{Risk of infection in controls}$$

A PE of 100 percent indicates complete protection against infection, a PE of 0 percent indicates no protection, and negative values indicate that a greater risk of acquiring infection existed among vaccinees than among controls. By rearranging terms, PE equals 1 minus the risk of infection in vaccinees divided by the risk of infection in controls. Because the ratio in this equation is the relative risk of infection developing in vaccinees versus controls, PE is, by definition, equal to 1 minus the relative risk.

TABLE 266–9 Calculation of Protective Efficacy (PE) of Pneumococcal Vaccine

Clinical Trial or Cohort Study	Pneumococcal Infection	No Pneumococcal Infection	Total
Vaccinated	a	b	a + b
Not vaccinated	c	d	c + d

$PE = [(c/c + d) - (a/(a + b)] \div (c/c + d) = 1 - [(a/(a + b) \div (c/c + d)]$*

	Pneumococcal	No Pneumococcal Infection
Case-Control Study	Infection (Cases)	(Controls)
Vaccinated	a	b
Not vaccinated	c	d

$PE = 1 - [(ad) \div (bc)]$†

**The expression $[(a/(a + b) \div (c/c + d)]$ also is known as the relative risk of infection in vaccinated versus unvaccinated persons.*

†The expression $[(ad) \div (bc)]$ is the odds ratio relating vaccination to infection. In a case-control study, the odds ratio approximates the relative risk if the outcome is rare.

OBSERVATIONAL COHORT STUDIES

In a cohort study, subjects at risk would be selected on the basis of whether they had been vaccinated or had been left unvaccinated during routine clinical care. The vaccinated and unvaccinated groups then would be monitored longitudinally to assess frequencies of infection. The analysis of a vaccine's PE for cohort studies is similar to that for clinical trials, but because the study is nonexperimental, the results are more subject to bias than are those of a well-conducted, randomized clinical trial.

CASE-CONTROL STUDIES

In a case-control study, patients with antecedent conditions that place them at high risk for pneumococcal infection would be eligible to be subjects. Patients with serious pneumococcal infection would become subjects in the case group. The control group would consist of subjects with similar high-risk conditions but without pneumococcal infection. The two groups then would be compared for the frequency of antecedent vaccination with pneumococcal vaccine.

In a case-control study, the strength of the relationship between vaccination and subsequent infection is measured by an odds ratio (the ratio of the odds of vaccination in the case subjects to the odds of vaccination in the controls). Because the odds ratio in a case-control study closely approximates the relative risk of pneumococcal infection in a longitudinal study and because PE is defined as 1 minus the relative risk, the value (1 – odds ratio) closely approximates the PE that would be calculated from a longitudinal study.
