ATM can be associated with more widespread central nervous system (CNS) demyelinating disorders or systemic autoimmune

disorders; in such cases, the term *disease-associated transverse myelitis* has been used. Isolated ATM can be triggered by identifiable preceding infections. Alternatively, ATM can be associated with a nonspecific preceding infection or have no apparent cause; for both of these subgroups, the term *idiopathic ATM* has been used. This last group constitutes the most common category in pediatric ATM. Although the precise pathophysiology of idiopathic ATM is uncertain, the frequent association with preceding infections and vaccinations and accumulating immunologic data suggest an inflammatory cause for the disorder.[12,18,37,56]

CLINICAL PRESENTATION

Idiopathic ATM affects approximately 1.34 persons per 1 million.[12] Six published case series ranging in size from 9 to 50 patients report common symptoms in pediatric patients with ATM. Patients present at a mean age of 8 years, with a slight female predominance.[18,19,25,39,57,59] Patients universally report acute to subacute, bilateral leg weakness, which is symmetric in approximately 67 percent of patients.[18] Involvement of the arms occurs in approximately 40 percent of patients. Approximately 90 percent of patients complain of bowel and bladder dysfunction, ranging from urinary retention and constipation to incontinence. A similar percentage of patients report sensory symptoms, including paresthesias and numbness. Back pain and fever affect nearly 50 percent of patients and may prompt consideration of primary infectious etiologies, such as an epidural abscess. The symptoms of ATM develop rapidly. In one study, the constellation of weakness, sensory changes, bowel and bladder dysfunction, and back pain reached a peak at an average of 5 days (range, 1 to 14 days).[18]

The general examination, although usually unremarkable, may reveal signs suggestive of an underlying systemic infection or autoimmune disorder. Abdominal examination may reveal a distended bladder. A diffuse or dermatomal vesicular rash or its sequelae suggest concurrent or preceding chickenpox or shingles.

On the neurologic examination, the presence of any mental status changes suggests that the myelitis is a component of a more diffuse process (i.e., acute disseminated encephalomyelitis). In the acute stages, muscle tone is flaccid in affected limbs. Detailed muscle strength testing with objective grading serves as a crucial baseline to compare with serial examinations to determine whether the patient is improving. All sensory modalities should be assessed carefully. In one series, preferential involvement of pain and temperature sensation with sparing of vibration sense and proprioception led the authors to speculate that thrombosis of the anterior spinal artery led to most cases of ATM (Fig. 43–2).[59] This series was limited, however, by its retrospective nature and lack of available neuroimaging. In addition, most patients in subsequent series have had involvement of all sensory modalities.[18,25,39,57] A spinal cord sensory level usually is located in the thoracic region (80%) and less commonly in the cervical (10%) or lumbar (10%) area.[12] In the acute phase, deep tendon reflexes are depressed in approximately 70 percent of patients and later become hyperactive. Similarly, Babinski responses may be negative early in the acute phase but soon become positive, indicating upper motor neuron dysfunction.

RADIOLOGIC FEATURES

Every patient with suspected ATM should undergo emergent gadolinium-enhanced magnetic resonance imaging (MRI) of the entire spine to confirm the diagnosis and rule out alternative diagnoses, particularly compressive lesions, such as epidural abscess, epidural hematoma, and extramedullary tumors. T1-weighted and T2-weighted sagittal imaging of the entire spine can serve as an initial screen, followed by axial imaging in areas of suspected pathology.[3]

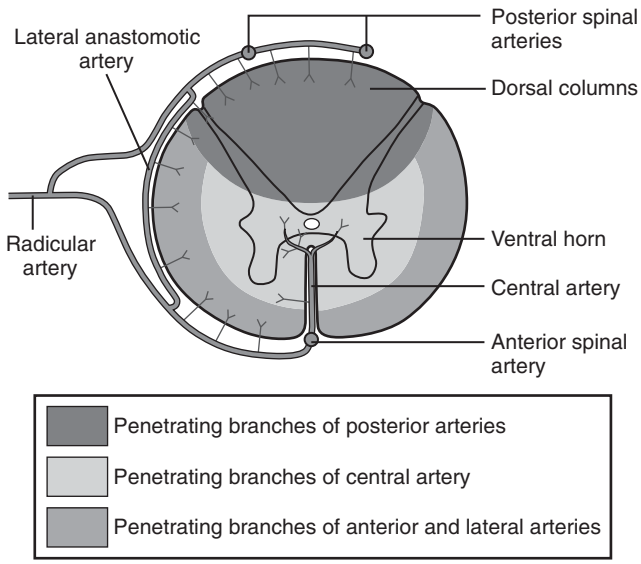

Figure 43–2 The ventral horns, which contain the lower motor neurons, and the lateral spinothalamic tract, which carries pain and temperature sensation, are supplied by the anterior spinal artery. The dorsal columns, which mediate vibration and joint position sense, are supplied by the posterior spinal arteries.

Spinal MRI in ATM typically reveals T1-isointense and T2-hyperintense signals over several contiguous spinal cord segments[18] and may involve the entire spine (Fig. 43–3).[3] This "longitudinally extensive" subtype (extending over three or more vertebral segments) seems to occur more commonly in children than in adults.[3,63] The hyperintense signal can extend into the lower brain stem.[3] Spinal cord swelling with effacement of the surrounding cerebrospinal fluid (CSF) spaces may be present in severe cases (Fig. 43–4). Axial imaging can determine whether gray or white matter or both are affected. Contrast enhancement is variably present and may appear diffuse, patchy, or nodular. In some patients with very suggestive clinical features, initial spine MRI may be normal and should be repeated several days later.[18,39,57] In rare cases, the MRI remains normal but does not rule out the diagnosis.

LUMBAR PUNCTURE

Approximately 50 percent of pediatric patients with ATM have CSF pleocytosis, typically with a lymphocytic predominance. Elevated CSF protein levels, either in isolation or in conjunction with pleocytosis, also are detected in approximately 50 percent of patients. Glucose typically is normal. A normal CSF profile does not rule out ATM because this pattern is seen in approximately 25 percent of patients. CSF cytology should be sent on all patients to assess for the possibility of neoplasm. Additional CSF testing is discussed further subsequently.

DIFFERENTIAL DIAGNOSIS

CONDITIONS THAT MIMIC ACUTE TRANSVERSE MYELITIS

Numerous disorders can affect the spinal cord and produce identical symptoms and signs that mimic idiopathic ATM (Table 43–4). Such conditions must be ruled out through a combination

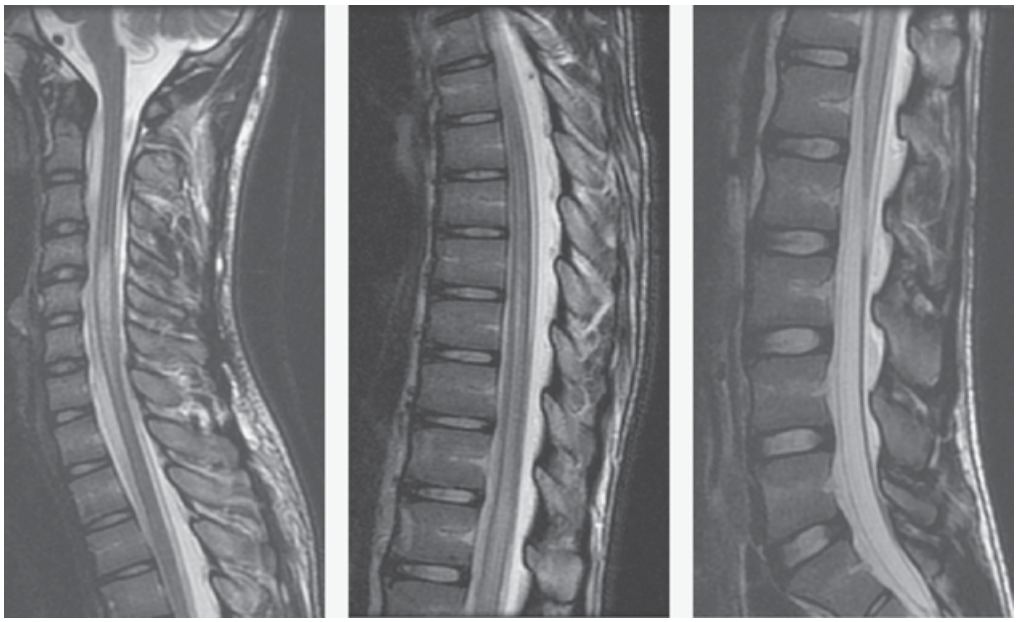

Figure 43–3 Sagittal T2-weighted MR image of the spine of a 16-year-old boy who presented with bilateral leg paresthesias that progressed to paraplegia and urinary and bowel retention. MRI shows diffuse T2-hyperintense signal extending from C4 through the thoracic region to the conus medullaris. The boy's symptoms resolved with administration of high-dose steroids.

Figure 43–4 Sagittal T2-weighted MR image of a 7-year-old boy with transverse myelitis in the setting of acute disseminated encephalomyelitis. There is T2-hyperintense signal in the cervical cord with associated swelling and effacement of the cerebrospinal fluid spaces. The abnormal signal also extends into the lower brain stem.

TABLE 43–4 Conditions That Mimic Idiopathic Acute Transverse Myelitis

of history, physical examination, neuroimaging, and laboratory evaluation.

Extramedullary compressive lesions are neurosurgical emergencies that must be diagnosed rapidly for effective treatment. Spinal epidural abscesses are rare in children. In one series of eight children compiled over a 15-year period at a major children's hospital, seven had fever, and all eight had back pain.[8] *Staphylococcus aureus*, some of which were methicillin-resistant, were the most common isolates in this and other series. Spinal epidural hematomas also are rare occurrences in children. They can occur spontaneously or may be associated with anticoagulant use, clotting disorders, trauma, or lumbar puncture.[61] Spinal epidural hematomas usually are located in the lower cervical region and extend over two to three vertebral segments, much fewer than in ATM. In one series of 1147 children with cancer, 70 (6%) developed spinal cord compression at some point during their course.[64] The most common responsible tumor types were primitive neuroectodermal tumor, soft tissue sarcoma, and neuroblastoma. When spinal cord compression is the initial manifestation of cancer, as was the case for 67 percent of the patients in this series, it can mimic ATM. Spinal MRI readily distinguishes each of these disorders from ATM.

The initial clinical presentation of ATM can be quite similar to that of Guillain-Barré syndrome. Both disorders can manifest with back pain, paraparesis, and sensory abnormalities. Although typically absent in both disorders, the presence of deep tendon reflexes would point strongly toward ATM. When deep tendon

reflexes are absent, the presence of a spinal cord sensory level and bowel and bladder involvement suggests ATM. Some patients have albuminocytologic dissociation, which is indistinguishable from Guillain-Barré syndrome. In some cases, ATM and Guillain-Barré syndrome can be distinguished only with MRI. Spinal cord, nerve root, and peripheral nerve pathology can coexist in myeloradiculoneuritis, suggesting that ATM and Guillain-Barré syndrome may share a common pathophysiologic mechanism in some cases.[48]

The most common intramedullary spinal cord tumors in children are astrocytomas (60%), followed by ependymomas (30%).[7,22,35] Although biopsy of the tumors is necessary to establish the exact histologic diagnosis, biopsy of the spinal cord rarely is needed to distinguish tumor from ATM. Despite similarities in presenting symptoms, clinical features can help to distinguish intramedullary tumors from ATM. Intramedullary spinal cord tumors manifest more subacutely or chronically than does ATM, reflecting their low cellular growth rate.[35] In one study, the mean duration of symptoms before presentation of children with intramedullary spinal cord tumors was 254 days.[22] In ATM, the symptoms peak much earlier from onset, with a mean duration of 5 days in one study.[18] On examination, the presence of scoliosis or torticollis suggests the presence of longer standing tumors rather than ATM.[22]

ATM and spinal cord tumors typically are isointense on T1-weighted MR images and hyperintense on T2-weighted images. Although intramedullary tumors display swelling, contrast enhancement, and associated syrinxes more frequently than does ATM, these features also can be seen in the latter (Fig. 43–5; see Fig. 43–4). Other radiographic features may be used to distinguish the two entities. The eccentric location of astrocytomas within the spinal cord[7] can be used to differentiate them from ATM, which usually produces symmetric findings. Although ependymomas can produce symmetric spinal cord expansion because of their origin from the central canal, these tumors usually span three to four vertebral segments,[7] whereas pediatric ATM typically involves longer areas of the spinal cord. In addition, an area of low signal intensity reflecting hemosiderin deposits from chronic hemorrhage at the edge of ependymomas also can serve as a radiographic clue.[7] Because patients with intramedullary spinal cord tumors may be diagnosed on the basis of CSF cytology, this test should be sent on all patients with suspected ATM.

Figure 43–5 Sagittal post-gadolinium T1-weighted MR image of the thoracic spinal cord of a 9-year-old girl who presented with bilateral leg weakness and urinary retention, showing patchy enhancement and a small syrinx. Although these findings raised concern for an intramedullary tumor, her spontaneous improvement and the resolution of enhancement without treatment favored a diagnosis of transverse myelitis.

Clinical features and neuroimaging also can be used to distinguish ATM from spinal cord infarction, which is an exceedingly rare finding in children. The latter diagnosis typically manifests in a hyperacute fashion with dissociated sensory loss (absent temperature and pain sensation with preserved vibration and proprioception) from thrombosis of the anterior spinal artery (see Fig. 43–2). Accompanying MRI signal abnormality in the adjacent vertebral body is highly suggestive of the diagnosis.[60] Diffusion-weighted MRI also may reveal the presence of ischemia and aid in making the differential diagnosis.

The clinical presentation of spinal cord dysfunction in the setting of prior irradiation suggests radiation-induced transverse myelitis as the most likely diagnosis. This entity typically manifests 9 to 18 months after radiotherapy, but it can occur earlier in children.[76]

Although they typically cause slowly progressive symptoms, spinal arteriovenous malformations can manifest acutely as a result of hemorrhage or venous congestion.[71] These lesions usually can be detected as abnormal, dilated vasculature on MRI of the spine; subsequent spinal angiography can confirm the diagnosis.

DISEASE-ASSOCIATED ACUTE TRANSVERSE MYELITIS

ATM with a presumed inflammatory basis can be associated with recurrent CNS demyelinating disorders and systemic autoimmune disorders. In these cases, the term *disease-associated ATM* can be applied (Table 43–5).[5,20]

The presence of changes in mental status and MRI abnormalities of cerebral white matter points toward acute disseminated encephalomyelitis as the correct diagnosis (Fig. 43–6). Spinal cord demyelination in multiple sclerosis tends to be limited to fewer than two vertebral segments and partial in the transverse plane, resulting in mild, asymmetric symptoms compared with the typically severe, symmetric symptoms in ATM.[67] In addition, the recurrence of lesions over the course of time and in different parts of the CNS is required for establishing the diagnosis of

multiple sclerosis. Previous subtle visual or sensory symptoms suggestive of a recurrent demyelinating disorder may be elicited only with detailed questioning. Oligoclonal bands are present more commonly in multiple sclerosis-related myelitis,[67] but they also have been reported in idiopathic ATM (Table 43–6).[57]

ATM is a necessary feature of neuromyelitis optica (NMO), a severe, relapsing demyelinating disorder restricted mainly to the spinal cord and optic nerves. Specific diagnostic criteria for NMO have been developed.[80] Concurrent or preceding optic neuritis suggests NMO as the correct diagnosis. NMO may manifest initially as ATM, with a future episode of optic neuritis leading to the reclassification of ATM as NMO. Some patients also can have recurrent episodes of idiopathic ATM without optic neuritis; in the literature, such patients have been considered to have a "restricted" or "limited" form of NMO.[63]

A novel biomarker (NMO-IgG) targeting the predominant CNS water channel protein aquaporin-4, which is concentrated in astrocytic foot processes in the blood-brain barrier, has been detected in 73 percent of adult patients with NMO and 52 percent of adult patients with recurrent longitudinally extensive ATM.[44,45] This antibody also has been detected in several pediatric patients with NMO.[52]

ATM also can occur secondary to a variety of systemic autoimmune disorders. Involvement of other organ systems, particularly the skin, lungs, kidneys, and joints, may point to a particular diagnosis, including systemic lupus erythematosus, sarcoidosis, and Sjögren syndrome. A personal or family history of recurrent miscarriages or hypercoagulability is suggestive of antiphospholipid antibody syndrome.

The long list of demyelinating and rheumatologic disorders potentially associated with ATM precludes diagnostic testing for every possible disorder. Table 43–7 presents a schema to guide which tests should be obtained in patients with ATM.

IDIOPATHIC ACUTE TRANSVERSE MYELITIS

Because of the numerous conditions that mimic or are associated with idiopathic ATM, establishing the diagnosis requires a systematic approach. Although all case series have emphasized the presence of bilateral lower extremity motor dysfunction and loss of voluntary bowel/bladder control, definitions of ATM have varied in the literature regarding the duration of symptoms and the necessary diagnostic testing.[18,39] To address this nonuniformity, the criteria proposed by the Transverse Myelitis Consortium Working Group[5] should be used to secure the diagnosis and guide the differential diagnosis and work-up (Table 43–8).

ROLE OF INFECTIONS IN TRANSVERSE MYELITIS

Infectious agents can cause spinal cord dysfunction by directly infecting the spinal cord parenchyma (infectious myelopathy) or by triggering postinfectious, immune-mediated processes (postinfectious ATM). In some cases, such as human T-cell lymphotrophic virus (HTLV)–associated myelitis, damage to the spinal cord may be produced by direct infection and by the immune response to the agent. Several agents, including cytomegalovirus (CMV) and varicella-zoster virus (VZV), are associated with direct CNS infection in certain patients (many of whom are

TABLE 43–8 Transverse Myelitis Consortium Working Group Diagnostic Criteria

Inclusion Criteria	Exclusion Criteria
Development of sensory, motor, or autonomic dysfunction attributable to spinal cord	History of previous radiation to spine within last 10 yr
Bilateral signs/symptoms (not necessarily symmetric)	Clear arterial distribution clinical deficit consistent with thrombosis of anterior spinal artery
Clearly defined sensory level	Abnormal flow voids on surface of the spinal cord consistent with AVM
Exclusion of extra-axial compressive etiology by neuroimaging (MRI or myelography; CT of spine inadequate)	Serologic or clinical evidence of connective tissue disease (sarcoidosis, Behçet disease, Sjögren syndrome, SLE, mixed connective tissue disorder)*
Inflammation within spinal cord shown by CSF pleocytosis or elevated IgG index or gadolinium enhancement. If no inflammatory criteria are met at symptom onset, repeat MRI and lumbar puncture evaluation 2-7 days after symptom onset meet criteria	CNS manifestations of syphilis, Lyme disease, HIV, HTLV-1, *Mycoplasma*, other viral infection (e.g., HSV-1, HSV-2, VZV, EBV, CMV, HHV-6, enteroviruses)*
	Brain MRI abnormalities suggestive of MS*
	History of clinically apparent optic neuritis*
Progression to nadir 4 hr to 21 days after onset of symptoms (if patient awakens with symptoms, symptoms must become more pronounced from point of awakening)	

**Do not exclude disease-associated acute transverse myelitis.*

AVM, arteriovenous malformation; CMV, cytomegalovirus; CNS, central nervous system; CSF, cerebrospinal fluid; CT, computed tomography; EBV, Epstein-Barr virus; HIV, human immunodeficiency virus; HHV-6, human herpesvirus-6; HSV, herpes simplex virus; HTLV-1, human T-cell lymphotrophic virus-1; MRI, magnetic resonance imaging; MS, multiple sclerosis; SLE, systemic lupus erythematosus; VZV, varicella-zoster virus.

Data from Transverse Myelitis Working Group: Proposed diagnostic criteria and nosology of acute myelitis. Neurology 59:499-505, 2002.

immunocompromised) and postinfectious ATM in others. When a specific agent is identified as a trigger of ATM, it should be indicated in the diagnostic terminology (i.e., post-varicella ATM).

Within the postinfectious category of ATM, the preceding infection usually is a nonspecific upper respiratory tract infection without an identifiable, specific microbe.[12,18,59] Approximately 50 percent of patients report having had such an infection with an intervening symptom-free interval of 5 to 10 days.[12,18,59] In instances in which the specific microbe is not identified and in cases in which no associated infection, systemic disorder, or recurrent demyelinating disorder is identified, the term *idiopathic ATM* has been applied.

Clues in the history can suggest the involvement of specific microbes. Immune status should be determined because immunocompromised patients are more susceptible to particular agents, such as CMV.[27] A history of exposure to cats or parakeets may point to *Bartonella henselae* (cats)[66] or *Chlamydia psittaci* (parakeets)[79] as rare causes of ATM. A detailed travel history may lead to the consideration of agents not typically encountered in the patient's primary residence, such as *Schistosoma*.[4]

Vaccination status also should be determined. Some cases of ATM seem to be related to recent vaccination, although causality usually is difficult to prove, given the paucity of reported cases.[18,26,38,57,81] Alternatively, unimmunized children are susceptible to particular agents, such as measles, mumps, and rubella, which have been associated with ATM.[24]

INFECTIOUS MYELOPATHIES

The etiology of an infectious myelopathy usually is established by positive CSF culture or polymerase chain reaction (PCR) results. Biopsy or autopsy results also have provided evidence of direct CNS infection in some patients. Some authors consider elevated CSF titers without positive culture or PCR results to be sufficient evidence of direct CNS infection, but this issue has not been resolved. Viruses constitute the most frequently reported category of infectious myelopathies, with bacteria and parasitic causes being less frequent (Table 43–9).

TABLE 43–9 Partial Listing of Microbes That Cause Infectious Myelopathies

- Cytomegalovirus[49]
- Epstein-Barr virus[48]
- *Echinococcus granulosus*[11]
- Enteroviruses[11]
  - Coxsackieviruses
  - Echoviruses[77]
  - Enterovirus 71[53]
  - Polioviruses (vaccine associated and wild-type)
- Herpes simplex virus-1[54]
- Herpes simplex virus-2[31]
- Human immunodeficiency virus[10,62]
- Human T-cell lymphotrophic virus-1 and -2[10]
- *Mycobacterium tuberculosis*[13]
- *Mycoplasma pneumoniae*[5]
- *Schistosoma haematobium* and *Schistosoma mansoni*[4]
- *Taenia solium* (neurocysticercosis)[11]
- *Treponema pallidum*[13,29]
- Varicella-zoster virus[29]
- West Nile virus[65]

POSTINFECTIOUS ACUTE TRANSVERSE MYELITIS

In postinfectious cases, a specific etiology can be suggested by elevated acute or rising convalescent serum titers, isolation of the agent from systemic sources in the setting of a suggestive clinical picture, or both. In such cases, the presumptive pathophysiology entails an aberrant autoimmune response to the spinal cord via mechanisms such as molecular mimicry, rather than direct CNS invasion by the microbe. A variety of bacterial and viral pathogens and vaccinations have been associated with postinfectious ATM (Table 43–10). Microbes that have been reported to cause infectious and postinfectious myelitis are listed in both Tables 43–9 and 43–10.

TABLE 43–10 Partial Listing of Microbes and Vaccines Associated with Postinfectious or Postvaccinial Acute Transverse Myelitis

Bacteria/Spirochetes	Viruses	Vaccinations
Bartonella henselae[66]	Adenovirus[47]	Hepatitis B[73]
Borrelia burgdorferi[46]	Cytomegalovirus[27]	Influenza[26]
Brucellosis[40]	Coxsackieviruses[56]	Measles, mumps, and rubella[81]
Chlamydia psittaci[79]	Enterovirus 71[33,53]	Poliovirus[38]
Mycoplasma pneumoniae[74]	Epstein-Barr virus[33]	Rabies[26]
	Hepatitis A[15,75]	Smallpox[26]
	Hepatitis B[50]	
	Hepatitis C[32]	
	Herpes simplex virus-1[28]	
	Herpes simplex virus-2[31]	
	Human herpesvirus-6[34]	
	Mumps[58]	
	Rubella[24]	
	Varicella-zoster virus[51]	

TABLE 43–11 Suggested Diagnostic Work-up for Infections Associated with Acute Transverse Myelitis

Blood	Cerebrospinal Fluid	Other
Blood cultures	Bacterial culture	Viral culture of stool and respiratory secretions
Acute and convalescent titers to	Viral culture	Consider stool ova and parasite testing and serum titers if parasitic infection is suspected
Borrelia burgdorferi	PCR testing for	
EBV	CMV	
Mycoplasma pneumoniae	EBV	
	Enterovirus	
	HSV	
	M. pneumoniae	
	VZV	

CMV, cytomegalovirus; EBV, Epstein-Barr virus; HSV, herpes simplex virus; PCR, polymerase chain reaction; VZV, varicella-zoster virus.

TABLE 43–12 Additional Diagnostic Work-up for Infections Associated with Acute Transverse Myelitis

Blood	Cerebrospinal Fluid	Other
Bartonella titers	Cryptococcal antigen	PPD placement
HIV antibody	HTLV antibody	Stool ova and parasite testing
HTLV-1 antibody	Fungal culture	
Parasitic infection titers	VDRL	
RPR		

HIV, human immunodeficiency virus; HTLV, human T-cell lymphotrophic virus; PPD, purified protein derivative; RPR, rapid plasma reagin; VDRL, Venereal Disease Research Laboratory.

The long list of potential pathogens precludes performing diagnostic testing for every possible agent. The work-up instead should focus on the pathogens that are common, treatable, or suggested by particular clues in the history or examination. Table 43–11 lists the infectious disease tests that should be sent for every patient with ATM. Additional infectious disease tests that should be considered depending on the clinical scenario and immune status are listed in Table 43–12. Although a detailed description of every infectious cause of transverse myelitis is beyond the scope of this discussion, several examples of the most commonly reported entities in the literature that highlight general features of the infectious disease aspects of ATM are described subsequently.

CYTOMEGALOVIRUS

Although reported more frequently in immunocompromised patients, CMV myelitis also may affect immunocompetent individuals.[27,75] CMV can infect the spinal cord directly and can produce secondary vasculitis in immunocompromised patients. In such cases, CSF PCR testing frequently is positive.[27] In other cases of reported CMV-associated myelitis, evidence for concurrent or recent infection has included isolation of the virus from blood or urine, detection of anti-CMV IgM in the serum, or significant increases in convalescent CMV serum titers in the absence of viral detection by CSF viral cultures or PCR.[27,75] The inflammatory process in CMV myelitis extends into the brain stem or nerve roots in some cases.[75] Treatment with ganciclovir or foscarnet should be considered.[11] The combined treatment of CMV-associated myelitis with ganciclovir and methylprednisolone was associated with marked recovery in an immunocompetent adult.[27] As illustrated by CMV, myelitis associated with viral infections may be produced by direct infection, accompanying secondary processes such as vasculitis, or postinfectious immune-mediated mechanisms. Whether optimal treatment requires antiviral agents or immunomodulation or both is uncertain.

HUMAN IMMUNODEFICIENCY VIRUS-ASSOCIATED MYELOPATHY

Infections such as HTLV, herpes simplex virus, syphilis, tuberculosis, and VZV can cause myelopathies in patients with acquired immunodeficiency syndrome (AIDS) and seem to be particularly important in developing countries.[13] In addition, human immunodeficiency virus (HIV) itself has been linked to a particular form of myelopathy termed *vacuolar myelopathy*, which is the most common cause of paraparesis in adults with HIV infection in developed countries.[62] Typically occurring in the setting of advanced disease, vacuolar myelopathy has been detected in pathologic series in 22 percent of patients with AIDS.[62] Myelopathy also can occur acutely in conjunction with seroconversion, but this form is less common than is vacuolar myelopathy.[11]

In vacuolar myelopathy, spinal cord pathology reveals noninflammatory myelin loss and spongy degeneration affecting mainly the lateral and posterior columns and producing vacuolization of the white matter, which provides the disorder its name.[62] HIV can be cultured from affected spinal cords, but the exact role of the virus in causing the disorder is unclear. The description of similar vacuolar myelopathies in patients with cancer or other immunocompromising conditions without HIV infection has cast some doubt on the central role of HIV in the disorder. Nutritional or metabolic factors in the vitamin B_{12} pathway may play a central or contributing role.[11]

The clinical presentation is similar to the presentation of other causes of chronic progressive myelopathy, and HIV-associated myelopathy may be underrecognized.[11,23] The diagnosis relies on determining a patient's HIV status and ruling out other bacterial, viral, fungal, and parasitic causes of myelopathy. No specific, effective treatments are available for vacuolar myelopathy.

Children with AIDS encephalopathy frequently develop upper motor neuron symptoms and signs, with resultant delay or regression in motor development.[23] In one series of 15 children with AIDS, only one patient had evidence of vacuolar myelopathy.[23] The most common finding in this series was demyelination with or without axonal loss in the lateral corticospinal tracts in the

spinal cord. The pathologic expression of HIV-associated spinal cord damage seems to be age-dependent.

As illustrated by HIV myelopathy, the existence of co-infections or accompanying systemic illnesses or both may confound the association of particular infectious agents with myelitis. Distinguishing these different causes clinically may be impossible, or they all may contribute to the disorder in some cases; treatment directed at multiple possible mechanisms may be warranted.

MYELOPATHY ASSOCIATED WITH HUMAN T-CELL LYMPHOTROPHIC VIRUS-1 AND HUMAN T-CELL LYMPHOTROPHIC VIRUS-2

The retrovirus HTLV-1 can cause a chronic, progressive myelopathy in immunocompromised and immunocompetent patients. Although reported less frequently, HTLV-2 infection can produce an identical clinical picture.[6] Risk factors for the acquisition of HTLV-1 and HTLV-2 include blood transfusions, intravenous drug use, and multiple sexual partners.[10] HTLV also can be transmitted from mother to infant, usually via breast-feeding. HTLV-1 is endemic to regions closer to the equator, including the Caribbean and southeastern United States.[70] Although the average age of onset is approximately 40 years,[16] rare pediatric cases have been reported.

Approximately 1 of 250 patients with HTLV-1 infection develops myelopathy.[11] Differences in the immune response to HTLV-1 seem to play a role in determining whether an infected individual develops myelopathy. Patients who also are infected with HIV seem to be at higher risk for the development of HTLV-associated myelopathy compared with other patient groups.[10]

The presence of serum and CSF antibodies to HTLV-1/HTLV-2 and of CSF HTLV-1/HTLV-2 DNA (detected by PCR) confirms the diagnosis. Immunomodulation, particularly corticosteroids, may be transiently beneficial early in the course of the disorder, but the progressive nature of the disorder nonetheless ensues.[10,11]

Pathologic specimens of HTLV-associated myelopathy reveal demyelination and degeneration of the long tracts with perivascular T-cell–predominant infiltrates and gliosis.[11] HTLV-infected $CD4^+$ and $CD8^+$ lymphocytes can be detected in the blood, CSF, and white matter of patients with HTLV-associated myelopathy.[9] Although the pathophysiology is uncertain, the evolution of an initially beneficial immune response into a self-destructive autoimmune process has been emphasized in the literature.[9] Possible mechanisms include cytotoxic T-lymphocyte–mediated killing of infected cells, bystander damage from enhanced cytokine production, and cross-reacting autoantibodies directed against CNS autoantigens via molecular mimicry. The example of HTLV-associated myelitis reveals that the boundaries between infectious and postinfectious myelitis may be unclear.

MYCOPLASMA PNEUMONIAE

Antimyelin antibodies reactive against glycolipid components have been detected in patients with *Mycoplasma*-associated inflammatory nervous system disorders, including one patient with ATM.[17,42,74] Such antibodies may be induced via molecular mimicry because of similarities in the glycolipid components of myelin and *Mycoplasma pneumoniae*.[42] Although the specificity of *M. pneumoniae* serologic testing has been questioned,[14] *Mycoplasma*-associated ATM seems to be a true entity based on the available literature, which includes cases of infectious myelopathy with positive CSF *Mycoplasma* PCR results and postinfectious cases.[1,74]

VARICELLA-ZOSTER VIRUS

After producing chickenpox, VZV survives in a latent form in cranial nerve and dorsal root ganglia, particularly in the trigeminal and thoracic regions.[30] Reactivation of the virus increases with immunosuppression and advancing age. Myelitis can occur in immunocompetent patients, often 1 to 2 weeks after the rash of varicella or zoster occurs, but it also can occur without a preceding rash.[30] In such cases, VZV DNA or antibodies can be detected in the CSF, but the virus cannot be cultured. In immunocompromised patients, invasion of the spinal cord by VZV has been described. Treatment with acyclovir or corticosteroids or both in combination may be effective.[21,29]

ROLE OF THE IMMUNE SYSTEM IN IDIOPATHIC ACUTE TRANSVERSE MYELITIS

In cases of idiopathic ATM, infections seem to provoke spinal cord dysfunction via secondary, immune-mediated mechanisms, rather than via CNS invasion. In such cases, a specific triggering agent usually is not identified. Increased peripheral blood lymphocyte responses to myelin basic protein have been shown in the research setting in patients with ATM, three of whom had a preceding viral illness.[2] The patients in this study who did not show increased lymphocyte responses were receiving steroids; reduction of autoimmune cell–mediated responses to CNS myelin antigens may underlie the beneficial effect of these medications in ATM (discussed further subsequently). None of the six patients who were tested in the recovery stage showed significant responses to myelin basic protein, suggesting that the cellular autoimmune reaction is short-lived.

In addition, the production of interleukin-6 by astrocytes seems to lead to nitric oxide–induced injury to spinal cord oligodendrocytes and axons in patients with idiopathic ATM. Interleukin-6 levels are markedly elevated in the CSF of patients with ATM and correlate with long-term disability.[37] The efficacy of corticosteroids in ATM may be due partially to their reduction of interleukin-6 production.[68]

TREATMENT

All patients with ATM should be hospitalized for further monitoring and treatment. Most patients can receive care on the regular ward, although the approximately 5 percent of patients with respiratory involvement from cervical myelitis require intensive care monitoring and may need endotracheal tube placement and mechanical ventilation.

No randomized, controlled treatment trials in ATM have been done. Based on case reports and series that have suggested a beneficial effect,[19,43,68] high-dose corticosteroids have become the standard of care in ATM. In one series of 12 children with severe ATM compared with a historical control group of 17 patients, the use of high-dose intravenous methylprednisolone (IVMP) significantly increased the proportion of children walking independently at 1 month (66% compared with 18%) and with full recovery at 1 year (55% compared with 12%).[19] Although a variety of agents and courses have been used, we use IVMP, 30 mg/kg per dose for 5 maximum 1 g. The need for a prednisone taper is controversial and may be based on whether full or partial recovery is achieved with the intravenous steroids. Most patients improve, often dramatically, with intravenous steroid treatment. Although some patients may improve spontaneously,[59] the collective data suggest that high-dose IVMP should be used in all patients with ATM. For the rare patient who does not improve with IVMP, intravenous immunoglobulins[69] or plasmapheresis can be used.

The use of antimicrobial agents in patients with ATM is controversial. Because most cases are caused by secondary, immune-mediated mechanisms, such treatment may not have significant benefit. Antimicrobial therapy is indicated, however, in cases with highly suspected or proven direct or associated infections, such as doxycycline for *Mycoplasma*,[74] ganciclovir for CMV,[27] and acyclovir for herpes simplex virus and VZV.[29] When antimicrobials are used, agents with good CSF penetration are preferred because direct invasion of the CNS may be present in some cases.

Additional treatment includes pain management, urinary bladder catheterization, bowel regimens, and peptic ulcer and deep venous thrombosis prophylaxis. The early institution of clean intermittent catheterization may improve long-term neuro-urologic outcomes in children with ATM.[72] Physical therapy should be instituted early to maximize the chance for recovery and continued in inpatient rehabilitation or an outpatient setting after the patient has been discharged from the acute care hospital.

Patients with ATM usually are fearful that they will not recover control of their legs or of their bowel or bladder, or that they will have a recurrence. Clinicians caring for patients with ATM must be attuned to their psychosocial needs. Psychiatric consultation may be necessary in some cases. Patients and their families may find the resources of the patient support group Transverse Myelitis Association (www.myelitis.org) helpful.

PROGNOSIS

DISABILITY

Although the variable definitions of recovery reported in the literature preclude a definitive assessment, the prognosis for pediatric patients with ATM generally is favorable and is better than their adult counterparts.[63] Paine and Byers'[59] degree of recovery categories have been the most widely reported outcome scale but are limited by vague terminology. Based on this scale, approximately 80 percent of pediatric patients who receive high-dose IVMP achieve full or good recovery, and 20 percent have a fair or poor outcome.[19,43] Among patients not treated with high-dose IVMP, 60 percent have a full or good recovery, whereas 40 percent have a fair or poor outcome.[59] In one series comprising 33 percent children and 67 percent adults who were not treated with steroids, approximately 33 percent each achieved good, fair, and poor recovery.[12] In a study of adult patients with ATM who were treated with high-dose IVMP and additional immunosuppressive agents if needed, approximately 67 percent were reported to have a good outcome, and 33 percent had a poor outcome. Comparisons with the aforementioned studies are difficult to make because a different outcome scale was used. Future studies in pediatric ATM may be improved by the use of the Extended Disability Status Scale, which has been used widely to assess outcomes in the adult and pediatric multiple sclerosis literature.[41]

During recovery, motor function returns first, with an average time to independent ambulation of 56 days in one study[18] and 25 days in a group of patients treated with high-dose IVMP.[19] Bowel and bladder control recovers more slowly, with an average time to recovery of normal urinary function of 7 months.[18] In one study, 86 percent of children with ATM showed evidence of bladder dysfunction on long-term follow-up.[72] Although these results likely were affected by selection bias for more severely affected patients, this study suggests that urodynamic studies should be considered in all patients after the acute phase has resolved. Based on these results, clean intermittent catheterization and anticholinergic medications may be required.[72]

Patients with hyperreflexia at presentation[57] and independent ambulation at 1 month[18] have a better prognosis. Complete paraplegia, time to maximal deficit of less than 24 hours, and younger age of onset are associated with a poor prognosis.[18,57] Levels of the intracellular neuronal 14-3-3 protein in the CSF of patients with ATM may reflect the extent of neuronal injury and correlate with outcome.[36,37]

RECURRENCES

In contrast to adult patients with idiopathic ATM, who have an approximately 25 percent likelihood of experiencing relapses,[20] most pediatric patients with idiopathic ATM do not have any recurrences. In a series of 24 pediatric patients with a mean follow-up of 7 years, there were no recurrences.[18] In another study of children with a variety of initial acute demyelinating events, only 2 of 29 patients with transverse myelitis had a later demyelinating event.[55,78] In this same study, the presence of myelitis for all patients with acute demyelinating disorders was negatively correlated with recurrence.

The detection of NMO-IgG is predictive of later recurrences and conversion to a diagnosis of NMO.[78] In adult patients with longitudinally extensive ATM, 56 percent of seropositive patients had relapses of either transverse myelitis or optic neuritis within 1 year; none of the seronegative patients had relapses.[78] Some researchers have suggested that NMO-IgG should be checked in all patients with longitudinally extensive ATM to predict more accurately the possibility of relapses.[63] In our anecdotal experience, NMO-IgG usually is not present in the serum of pediatric patients with ATM, even patients with a longitudinally extensive pattern. This finding suggests that NMO-IgG may not play a major role in idiopathic pediatric ATM and may partially explain the differential recurrence rates in pediatric and adult ATM.

CHAPTER 43c

Parainfectious and Postinfectious Disorders of the Peripheral Nervous System

Benjamin A. Ross ● Daniel G. Glaze

Guillain-Barré Syndrome

Guillain-Barré syndrome (GBS) encompasses a spectrum of acute-onset, flaccid paralytic disease involving the peripheral nervous system. The classic form now generally is referred to as *acute inflammatory demyelinating polyradiculoneuropathy* (AIDP). With the decline in the incidence of poliomyelitis, GBS emerged as the most frequent cause of acute, severe generalized human paralytic disease.[195] GBS typically occurs several weeks after an upper respiratory or gastrointestinal tract illness, but it has been associated with other factors, including immunization and surgery. It is characterized by progressive ascending motor weakness, hyporeflexia, and minor sensory disturbances.

No specific diagnostic test for GBS exists; the diagnosis is based on the clinical features supported by other data, including cerebrospinal fluid (CSF) protein elevation, electrophysiologic changes, and pathologic changes of the peripheral nerves. The consensus is that GBS is mediated immunologically; however, the specific immunologic alterations necessary to initiate the events that result in demyelination of human peripheral nerves are unclear. The primary treatment is supportive care, but the efficacy of other therapies, such as plasma exchange transfusion and intravenous immunoglobulin (IVIG) therapy, in shortening the duration of the illness has been shown.[87,96,207,208] Following is an overview of GBS and its variants, including diagnostic criteria, the role of preceding infection and immunization, immunologic aspects, and treatment modalities.

HISTORY

Although bearing the names of Guillain and Barré, GBS was recognized first by Landry in 1859.[114] Landry described 10 patients who presented first with generalized weakness, followed by paresthesia and transitory muscle cramps, and then a rapidly ascending paralysis that involved the respiratory muscles last. He named this disorder *acute ascending paralysis*, postulated that it occurred after another illness, and considered it to be a severe disease because 2 of the 10 patients died. Other reports of this disorder appeared, but in 1916, Guillain, Barré, and Strohl[72] clearly characterized it and were the first to call attention to the "albuminocytologic dissociation," or increased CSF protein with absence of cells. Barré and Guillain favored an infectious cause for the disease.

In 1955, Waksman and Adams[215] pointed out the similarity in the clinical and pathologic pictures between GBS and experimental allergic neuritis in rabbits. In 1963, Melnick[131] found antibodies to nervous tissue in 19 of 38 patients with GBS. In 1960, Osler and Sidell[149] indicated the need for exact diagnostic criteria for GBS and presented 12 diagnostic criteria restricting the definition of the disorder. Most subsequent studies arrived at a broader concept of the disorder, however.[9,13,54] After reports of an increased incidence of GBS in association with the 1976 inoculation program for swine influenza, the National Institute of Neurological and Communicative Disorders and Stroke (NINCDS) proposed a standardized inclusion and exclusion diagnostic criteria.[12,13,14]

DIAGNOSTIC CRITERIA

The diagnosis of GBS is based on the clinical history and examination and supported by clinical laboratory (i.e., CSF) and electrodiagnostic (i.e., nerve conduction velocities) evaluations. The "typical" case of GBS often occurs a few days or weeks after a recognizable, nonspecific infection that is more often viral than bacterial in origin. The paralytic stage usually begins with pain or paresthesia, followed by hypotonia, ascending paralysis without pyramidal tract involvement, and loss of deep tendon reflexes rather than hyperreflexia or pathologic reflexes. Initial weakness usually is noted in the lower extremities and less commonly in the upper extremities or the face. Many patients experience minimal to moderate sensory loss in a glove-stocking distribution. Maximal paralysis is reached in approximately 3 weeks. In 46 to 75 percent of patients, cranial nerves, including VII, IX/X, or both, may be affected, giving rise to facial weakness and difficulties in swallowing. Respiratory weakness occurs in 12 to 20 percent of patients, and some may require mechanical ventilation.

Although not part of any diagnostic criteria, pain has been reported to occur in 55 to 90 percent of patients with GBS, and it may precede weakness in some patients.[176] Approximately 79 percent of children with GBS who are younger than 6 years of age present with pain that may be present for longer than 1 week before the correct diagnosis is made.[140] Multiple pain syndromes that have been described include (1) deep, aching throbbing discomfort in the lower back that radiates to the buttock, thighs, or calves (67%); (2) dysesthesias, described as burning, tingling, or shock-like pain (20%); and (3) myalgias or muscle aches (9%). Severity of pain has not been found to be a predictor of the clinical course.[136]

Routine laboratory tests are unremarkable except for characteristic elevation of CSF protein (typical values of 50 to 200 mg/dL) without appearance of cells. The CSF protein concentration usually peaks between the second and eighth week of illness, with a slow decline occurring thereafter. Although most patients experience "complete" recovery, 20 percent have permanent residual disease (weakness, muscle atrophy), and approximately 1 to 4 percent die of respiratory failure.[19,130]

As Asbury[12] has emphasized, the problem is not with recognition of a typical case but with knowing the boundaries of the disorder. To define those limits, specific criteria were created in 1978 (Table 43–13).[14,15] These criteria consist of specific features required for establishing the diagnosis and additional features that strongly support, cast doubt on, or rule out the diagnosis entirely. The two features required for establishing the diagnosis are progressive motor weakness involving more than one limb and areflexia.

Clinical features supporting the diagnosis include the following: (1) progression of symptoms with signs of motor weakness that cease to progress after 4 weeks; (2) symmetry of symptoms; (3) sensory, cranial nerve, and autonomic dysfunction; (4) recovery; and (5) absence of fever. Laboratory features supporting the diagnosis include CSF protein elevation after the first week of symptoms or an increase in protein on serial lumbar punctures and less than 10 mononuclear leukocytes/mm^3.

Electrodiagnostic studies in GBS show evidence of an axonal, a demyelinating, or a mixed neuropathy. Features suggestive of demyelination include slowing of conduction velocity, prolongation of distal compound motor action potential latencies, prolonged or absent F-wave response, and a partial conduction block

TABLE 43–13 Criteria for Diagnosis of Guillain-Barré Syndrome

Required
Progressive motor weakness in more than one extremity
Areflexia (at least distal with hyporeflexia of the biceps and knee jerks)
Strongly Supportive
Clinical features (in order of importance)
Progression—ceases by 4 wk
Relative symmetry
Mild sensory symptoms or signs
Cranial nerve involvement
Recovery—usually 2-4 wk after progression ceases
Autonomic dysfunction
Absence of fever at onset of neurologic symptoms
CSF Features
Protein—elevated after first week of symptoms, or increasing on serial lumbar punctures
Cells—≤10 mononuclear leukocytes/mm^3
Electrodiagnostic Features
Nerve conduction slowing
Casting Doubt
Marked, persistent asymmetry of weakness
Persistent bladder or bowel dysfunction
Bowel or bladder dysfunction at onset
>50 mononuclear leukocytes/mm^3 in CSF
Presence of polymorphonuclear leukocytes in CSF
Sharp sensory level
Rule Out the Diagnosis
Current history of hexacarbon abuse
Abnormal porphyrin metabolism
Recent diphtheria infection
Evidence of lead neuropathy or intoxication
Purely sensory syndrome
Definite diagnosis of poliomyelitis, botulism, hysterical paralysis, or toxic neuropathy

CSF, cerebrospinal fluid.
Data from references 14 and 15.

TABLE 43–14 New Diagnostic Criteria for Guillain-Barré Syndrome

From Van der Meche, F. G. A., et al.: Diagnostic and classification criteria for the Guillain-Barré syndrome. Eur. Neurol. 45:133-139, 2001.

or evidence of temporal dispersion (broadening of the compound motor action potential response). Signs of axonal neuropathy include absent or significantly reduced compound motor action potential amplitudes and absence of the features suggestive of demyelination.[87] Early in the course of the disease, many of these findings may not be present, and findings may remain normal in 20 percent of cases.[12,13] The earliest electrodiagnostic signs of GBS are most likely to be decreased or absent F waves, absent h reflex, and the presence of A waves.[5,67,213]

Certain features, including persistent asymmetry of weakness, bowel or bladder dysfunction at onset or a persistence of dysfunction, elevation of cells in the CSF, or a discrete sensory level, cast doubt on the diagnosis. Features that can rule out the diagnosis entirely include (1) a purely sensory syndrome; (2) a current history of hexacarbon abuse; (3) abnormal porphyrin metabolism (increased excretion of porphobilinogen and δ-minolevulinic acid in the urine); (4) evidence of recent diphtheritic infection; (5) lead neuropathy or intoxication; or (6) a definite diagnosis of a condition such as poliomyelitis, botulism, hysterical paralysis, or toxic neuropathy (nitrofurantoin, dapsone, or organophosphorus).[12,13]

A diagnostic process has been suggested.[12] If the clinical features and temporal evolution are typical and without variant features or features that rule out GBS, the diagnosis may be made on clinical grounds alone. Laboratory findings, such as CSF protein elevation, may not appear until after 1 week, and electrodiagnostic findings may never occur. If clinical features are unusual, however, laboratory studies may provide important supportive information, and a diagnosis of GBS may have to be delayed to evaluate these test results fully. Asbury and Cornblath[15] reported that certain variant features are seen occasionally in otherwise typical cases of GBS. These variant features include fever at onset of neuritic symptoms, severe sensory loss with pain, progression beyond 4 weeks, cessation of progression without recovery or with major permanent residual deficit, sphincter dysfunction, central nervous system involvement, no increase in CSF protein 1 to 10 weeks after onset of symptoms, and cell counts of 11 to 50 mononuclear leukocytes/mm^3 in CSF.

Asbury and Cornblath[15] suggested that the presence of one of these symptoms, signs, or laboratory results should raise doubt about the validity of the diagnosis and that the presence of two or more suggest the diagnosis of GBS is incorrect. Manifestations of systemic illness or constitutional symptoms (or both) preceding or coinciding with signs and symptoms of involvement of the peripheral nervous system suggest a diagnosis of a systemic illness or intoxication and not GBS. In patients who have features consistent with GBS and who also have human immunodeficiency virus (HIV) seropositivity, CSF cell counts frequently are elevated.[15,41]

To facilitate use for poliomyelitis surveillance, the diagnostic criteria were simplified by the World Health Organization in 1993 to involve solely clinical features. Cases that fulfilled the aforementioned clinical criteria were diagnosed as GBS. If further electrodiagnostic or pathologic data were obtained, however, the terms *demyelinating* or *axonal* could be applied, and all subtypes were described independently.[219]

With further advancement in diagnostic techniques and identification of additional variant syndromes, a new set of criteria has been proposed to include a systematic approach for further subclassifications and to support future research (Table 43–14).[209] This new classification is based on four main criteria necessary for establishing the clinical diagnosis of GBS: (1) flaccid paralysis that develops subacutely, (2) bilateral onset of weakness (with a tendency for symmetry), (3) loss of reflexes, and (4) other causes

being highly unlikely (ruled out with additional testing as necessary). Electrodiagnostic studies and CSF analysis (as previously discussed) can assist in the diagnosis if the fourth criterion is in question. For all subclassifications, the main criteria first must be met.

Motor-sensory GBS requires the presence of a sensory deficit at some point during the course of the disease. In pure motor GBS, paresthesias may be present, but no sensory deficit at anytime. Miller Fisher syndrome requires weakness of the external ocular muscles and either ataxia or positive anti-G_{Q1b} antibodies in the serum. The bulbar variant requires the onset of weakness to be within the bulbar musculature: facial muscles, tongue, or muscles of deglutition. Lastly, electrodiagnostic or pathologic studies or both can be used to distinguish between the primary axonal and demyelinating forms because this determination cannot be made by clinical signs and symptoms alone.[209]

CLINICAL VARIANTS

GBS typically has an acute onset followed by rapidly ascending weakness. In some patients, the onset is stuttering with periods of progression and plateaus before reaching a nadir of involvement. In other patients, the onset is subacute, with a slow progression that can occur over a few weeks.[123] In addition to weakness and areflexia, other individual features may be observed in patients with GBS, such as total and incomplete external ophthalmoplegia[65,70]; papilledema[42]; and autonomic dysfunction, including hypertension, postural hypotension, and cardiovascular disturbances.[38,42,43,196] Hypertension may be a consequence of sympathetic nervous system hypersensitivity and increased excretion of catecholamines,[42] but it also has been associated with increased renin-angiotensin activity.[183] Cardiovascular disturbances have been reported to be more prevalent in patients with GBS who are severely paralyzed and require mechanical ventilation.[38] Autonomic dysfunction in GBS, including tachycardia and other arrhythmias, may contribute to morbidity.[43]

An axonal form of GBS was described first in 1986. This new variant syndrome seemed to have a more severe disease course with poorer recovery.[58] The pure motor axonal form, termed *acute motor axonal neuropathy* (AMAN), initially was characterized in north China[129] as a summertime epidemic pattern mostly in children and young adults after they experienced an acute diarrheal illness. When sensory symptoms are present, it is called *acute motor-sensory axonal neuropathy*. Although these axonal subtypes tend to have a more severe and rapidly progressive clinical course, the diagnosis can be made only by electrodiagnostic studies or by pathologic examination of peripheral nerves. Despite some initial conflicting reports, recovery can be either rapid or quite prolonged; however, the long-term recovery potential is similar to that of classic demyelinating GBS (AIDP).[83,152,202]

One criticism of the NINCDS Ad Hoc Committee criteria is that they are too restrictive.[12,14] The criteria initially were designed for use during field studies of GBS, and certain variants are allowed: fever at onset of neuritic symptoms; severe sensory loss with pain; occasional progression beyond 4 weeks; major permanent residual deficits; transient bladder paralysis; and, possibly, central nervous system involvement, such as ataxia (cerebellar), dysarthria, extensor plantar responses, and ill-defined sensory levels. These features need not exclude the diagnosis of GBS.[12,13]

Specific variants in which the clinical features are atypical but fall in the spectrum of GBS have been described.[12,13] Findings of ophthalmoplegia, ataxia, and areflexia were described initially by Fisher in 1956, and he postulated that it was a variant of GBS because of the areflexia and CSF findings of cytoalbuminologic dissociation. This clinical syndrome now is referred to as *Miller Fisher syndrome*.[61,172] The rapid onset of these symptoms usually indicates a benign course with fairly complete recovery occurring within weeks to months.[12,13] According to new diagnostic criteria, Miller Fisher syndrome must meet general criteria for GBS and in addition requires onset of weakness in the extraocular muscles and either ataxia or positive anti-G_{Q1b} IgG antibodies (present in 85%).[209]

Similarities with Miller Fisher syndrome occur in a subgroup of patients with Bickerstaff brain stem encephalitis. Bickerstaff and Cloake first described a syndrome of altered mental status, ophthalmoplegia, and ataxia in 1951. This syndrome was termed *Bickerstaff brain stem encephalitis* when Bickerstaff reviewed his collection of cases for the *Handbook of Clinical Neurology* in 1978. Bickerstaff's clinical criteria for Bickerstaff brain stem encephalitis include progressive external ophthalmoplegia and ataxia along with either alteration of consciousness or hyperreflexia. More recent studies have questioned these strict criteria because a subgroup of these patients may have normal or absent reflexes and varying degrees of weakness and cytoalbuminologic dissociation, indicating an overlap with GBS. In addition, 65 percent of patients with a diagnosis of Bickerstaff brain stem encephalitis have positive anti-G_{Q1b} antibodies, which suggests that all of these syndromes may be part of a clinical spectrum of disease.[145]

A rarer form of GBS, pharyngeal-cervical-brachial or bulbar, has been described in adults, and even fewer reports exist in children. This subtype has predominant weakness of the facial and bulbar musculature and weakness in the neck and upper extremities.[134] Sensory loss and areflexia without motor weakness or simultaneous onset of symmetric cranial nerve dysfunction (cranial polyneuritis) also may be accepted as variants of GBS if they are characterized by rapid onset with recovery, elevation of CSF protein, and the typical electrodiagnostic pattern of demyelination.[12,13,147] The presentation of acute sensory neuropathy characterized by symmetric glove-and-stocking sensory loss for pain and temperature (acute numbness) with normal muscle strength and tendon reflexes (acute small fiber sensory neuropathy 1) also is suggested as a variant of GBS.[5,188]

EPIDEMIOLOGY

Worldwide, the incidence of GBS has been reported to range from 0.4 to 4 cases per 100,000, with a median value of 1.3.[110,173,178] GBS can occur at any age; however, peaks occur in older adolescents or young adults and in the elderly. Overall, men tend to be affected more often than are women, at a ratio of approximately 1.25:1. Specific incidence rates do not exist for the various subtypes, although AIDP accounts for approximately 90 percent of cases compared with only 10 percent in Western countries. Approximately two-thirds of patients have had a preceding illness, typically involving the upper respiratory or gastrointestinal tracts, within 6 weeks of diagnosis.[39,100,173,178] No clear seasonal or geographic clustering of GBS has been observed, with the exception of the increased incidence of AMAN related to *Campylobacter jejuni* infection observed in children and young adults in China during the summer months.[129]

Age-related differences in the expression of GBS in children have been observed.[183] In children younger than 5 years old, a greater incidence of bulbar nerve (cranial nerves IX, X, and XII) dysfunction occurs, and muscle weakness is the most frequent initial symptom (72%). In children older than 5 years, limb pain is the most frequent initial symptom (53.4%). The interval between previous illness and onset of GBS is shorter for children older than 5 years and typically is 2 to 14 days. No statistically significant differences occurred in respiratory complications or fatal outcomes between the older and younger children with GBS.

PATHOLOGY AND PATHOGENESIS

GBS has been described as a distinctive neuropathy characterized pathologically by inflammatory lesions scattered throughout the peripheral nervous system.[143,161] Asbury and associates[13,14] studied 19 fatal cases and observed that the pathologic hallmark of this disorder is perivenular mononuclear inflammatory infiltrates, which occurs throughout the peripheral nervous system, even in cases with a short clinical course (1 to 4 days). These authors observed that the lesions were predominantly lymphocytic and that the inflammatory infiltrates tended to cluster about small endoneural and epineural vessels, particularly veins, in a seemingly random, multifocal distribution. All levels, including anterior and posterior roots, ganglia, proximal and distal nerve trunks, terminal twigs, cranial nerves, and sympathetic chains and ganglia, seemed vulnerable to attack. The site of maximal involvement correlated with the degree of premorbid clinical findings. Segmented demyelination was the predominant form of nerve fiber damage, with myelin destruction restricted to the regions of nerve trunks that were infiltrated by inflammatory cells.

Subsequent reports have confirmed the observation that primary demyelination occurs only in tissue infiltrated by inflammatory cells. These studies have shown that the destructive process is affected by macrophages in the presence of lymphocytes and directed only at the part of the Schwann cell plasma membrane forming the myelin sheath.[27,160,161,218,224] Kanda and associates[99] reported the findings of a necropsy of early fulminant GBS in an adult, however. Using semi-thin sections, they observed less extensive mononuclear infiltration than expected and found nerve fibers with myelin splitting, even in regions where inflammatory cell reaction was inconspicuous. Small myelinated fibers were involved preferentially, and no abnormalities of unmyelinated fibers occurred. Sensory roots were involved as severely as motor roots. These authors concluded that the underlying pathologic mechanism of GBS is heterogeneous. They suggested that some cases are cell-mediated, with predominant perivascular infiltration, whereas other cases are humorally mediated, with predominant demyelination without lymphocytic infiltration.

We now know that demyelinating and axonal forms of GBS exist and, as one would expect, that their mechanisms of injury to the nervous system differ. As a result of molecular mimicry, an immune attack is generated against the peripheral nerves and is mediated by immunoglobulins, macrophages, and complement factors. In AIDP, the initial target is the Schwann cell, which is responsible for myelination of the peripheral nervous system. In the axonal forms of GBS, the initial attack is targeted at the nodes of Ranvier, which allows macrophages to penetrate the basal lamina and enter the periaxonal space, causing subsequent axonal degeneration to ensue.[227]

ROLE OF INFECTION

The onset of GBS frequently follows an acute febrile infectious illness. GBS has been reported to occur after childhood illnesses such as mumps,[31] varicella,[23,44,216] measles,[50,116,156] and rubella.[48,180] These childhood illnesses rarely are associated with GBS, however.[48] Epidemiologic studies have indicated the significant occurrence of upper respiratory or gastrointestinal tract illnesses before the onset of GBS and support the concept that both of these categories of illness constitute important risk factors for GBS.[101,132] One case-control study[132] reported a higher incidence of elevated specific complement-fixation antibody titers in GBS cases compared with control cases for infectious mononucleosis and parainfluenza. Although influenza A and B infections have been observed in patients with GBS,[22,141,142,217] this case-control study found no significantly higher incidence of elevated complement-fixation titers in patients with GBS compared with control subjects for influenza A or B.[132] During outbreaks of influenza A2 in 1960 to 1961 and influenza B in 1961 to 1962, the prevalence of GBS was high; however, the greatest number of cases occurred from November 1959 to October 1960, when the prevalence of influenza was comparatively low.[132]

Infectious hepatitis has been reported in association with GBS,[154,158] and four case reports have observed hepatitis B antigenemia in patients with GBS.[60,128,139,140] Acute viral hepatitis rarely is complicated by GBS. GBS has been associated with serologically documented cases of acute A, B, non-A/non-B, and delta hepatitis.[117,199,204] Immune complexes containing hepatitis B surface antigen in the serum and CSF were found in patients with GBS. These complexes were present with acute hepatitis B during the acute phase of GBS and disappeared when the neurologic symptoms resolved.[124,199,204] A causal association has not been established, however, and the fact that many of the populations at risk for hepatitis B and A also are at risk for other acquired viral infections, such as Epstein-Barr virus and cytomegalovirus (CMV), has been emphasized.[199]

Echoviruses and various serotypes of coxsackievirus A and B isolates have been observed in patients with GBS.[17,56,63,94,102,132,153,206] Most isolates were obtained from stool, although some were obtained from CSF in a few cases.[48] Recovery of virus does not prove causation, however; some isolates were recovered when enterovirus was prevalent in the community and in one instance equaled the frequency from control subjects.[48,122] In one series investigating West Nile virus, 1 patient of 224 had a clinical diagnosis of GBS.[126] Direct isolation of coxsackievirus A4 from nerve roots and dorsal root ganglia has been reported.[56] GBS also has been reported to occur after herpes simplex virus type 2 encephalitis,[133,194] in association with HIV infection,[41] and during rabies infection.[210]

Laboratory research has suggested that an important association exists between herpesviruses and GBS. Dowling and Cook[48] reported that 15 percent of patients tested with GBS had high titers of IgM antibodies against CMV antigen in tissue culture cells. Other studies also have observed an association between CMV and GBS.[11,35,45,97,137,157,185] Dowling and Cook[48] reported a wide spectrum of antecedent illness, ranging from asymptomatic infection to typical respiratory tract and gastrointestinal tract symptoms, in CMV-positive patients. A predilection for CMV-positive GBS was found to occur in patients younger than 30 years, corresponding to the age incidence described in heterophil-negative, CMV-induced, mononucleosis-like illness.[48] Time clustering of cases was observed, with CMV antibody–positive cases appearing in 10- to 16-week clusters. Dowling and Cook[48] suggested that in cases associated with preceding surgery, GBS may be consequent to CMV, either acquired during transfusion or caused by activation of latent virus, or occurrence of nontransfusion, non-A/non-B hepatitis.

Dowling and Cook[47] also observed the frequent (8%) occurrence of IgM antibodies to Epstein-Barr virus in GBS. In contrast, less than 2 percent (1 of 75) of GBS patients showed IgM herpes simplex virus–specific antibody.[21] These studies indicate that two herpesviruses are common antecedents of the syndrome, but the precise mechanism by which they initiate destruction of myelin is unknown.

Hart and Kennedy[74] emphasized the difficulty of establishing CMV as a cause of GBS. Using serologic tests, they confirmed active CMV infection in three patients with GBS. They reported that CMV could be isolated in 1 percent of asymptomatic individuals and in 10 percent of pregnant women; hence, isolation may be coincidental. These authors suggested that other viruses may activate latent CMV, and isolation may reflect such a nonspecific phenomenon. GBS also has been observed in association

with HIV infection.[41] Elevated levels of circulating antibody to Epstein-Barr virus, CMV, and other infectious agents are common findings in these patients and may be directly responsible for some cases of GBS occurring in association with HIV infection.

Nonviral infectious agents also may precede occurrence of GBS. A preceding infection with *C. jejuni* associated with a diarrheal illness commonly occurs.[168,169,171] After two case reports,[33,162] a retrospective study was conducted to determine serologic evidence of recent *C. jejuni* infection in GBS.[98] Of 56 GBS patients, 38 percent (20 patients) were found to have serum evidence, CSF serologic evidence (including documentation of increase in titer, two or more elevated antibody titers, or positive CSF titer), or both. Preceding diarrheal illnesses were documented in 20 percent of these patients with GBS. Groups of normal control subjects and subjects with other neurologic disorders had no evidence of having had a recent *C. jejuni* infection. IgA-specific and IgM-specific antibody was found only in the CSF of patients with recent *C. jejuni* infection, suggesting production of specific antibodies by the central nervous system because passive diffusion into the CSF is unlikely.

Patients with GBS who also showed serologic evidence of *C. jejuni* seemed to have a significantly more severe illness; 90 percent of these patients required mechanical ventilation. Electrodiagnostically, GBS preceded by *C. jejuni* selectively elicits the AMAN subtype rather than AIDP.[112] One report noted mild illness in patients with GBS and positive serology and stool culture for *C. jejuni*.[162] Rees and associates,[169] in a prospective, case-controlled study in a cohort of patients with GBS (96 patients) or Miller Fisher syndrome (7 patients) who were admitted to hospitals throughout England and Wales between November 1992 and April 1994, found evidence of recent *C. jejuni* infection in 26 percent of the patients with GBS or Miller Fisher syndrome compared with 16 percent of household controls and 1 percent of age-matched hospital controls. A study in Japan has shown the *C. jejuni* serotype HS:19 to be more common in patients with GBS (67%) than in control patients with enteritis (5%).[200] Seventy percent of the patients with *C. jejuni* infection reported having had a diarrheal illness within 12 weeks before the onset of the neurologic illness. *C. jejuni* was associated with axonal degeneration, slow recovery, and greater disability after 1 year. The median interval from onset of diarrhea to the onset of symptoms for all *C. jejuni*–positive patients was 9 days, suggesting that GBS is a consequence of an immune response to *C. jejuni*, rather than a direct effect of the organism or one of its toxins.[95]

Mycoplasma pneumoniae is the second most prominent nonviral agent reported in association with GBS. One report observed that 5 percent of patients with GBS had serologic evidence of active *Mycoplasma* infection.[66] GBS has been reported rarely after infection with *Haemophilus influenzae*, *Francisella tularensis* (tularemia), *Chlamydia* (psittacosis), *Plasmodium* (malaria), *Mycobacterium tuberculosis*, *Bartonella henselae*, and *Toxoplasma gondii*.[24,69,125,132,135,138,148,184,214]

Patients with GBS frequently give a history of prodromal symptoms. An association between GBS and an infectious agent long has been considered. Isolation of a pathogen in a patient with GBS does not confer a direct correlation, however. McFarlin[127] has suggested that demyelination of peripheral nerves may result from direct infection of Schwann cells by the infectious agent, producing prodromal symptoms, or from immunologic mechanisms triggered by the infection. The second possibility is favored because epidemiologic and virologic surveys of patients with GBS have failed to identify reactivity with a single infectious agent and because the disorder can be triggered by other events, including surgery and immunizations. In addition, the clinical course may be shortened by plasmapheresis.

ROLE OF IMMUNIZATION

GBS occurs infrequently after immunization, including smallpox, diphtheria, tetanus, pertussis, combined mumps-rubella, hepatitis B, rabies, *H. influenzae* type b, and polyvalent pneumococcal vaccines.[40,64,73,92,104] A nationwide GBS surveillance conducted from December 16, 1976, until January 31, 1977, suggested that an excess risk of developing GBS was related to A/New Jersey influenza vaccine for adults 18 years or older.[28] The peak time of onset of GBS was 2 to 3 weeks after the vaccine was given. For the 10 weeks after vaccination with A/New Jersey vaccine, the risk was approximately 13.3 cases per 100,000 for vaccine recipients, which was five to six times higher than that in unvaccinated individuals (2.6 per 100,000).[186,187]

A subsequent survey of adults older than 18 years of age vaccinated in the 1978 to 1979 influenza campaign revealed that the relative risk of developing vaccine-associated GBS (individuals vaccinated within 8 weeks before the onset of GBS) was 1.4, which was significantly below the risk (6.2) associated with A/New Jersey vaccine for the equivalent 8-week period.[28,92,187] The survey of 1979 to 1980 also did not reveal an increased incidence of GBS for vaccinated versus nonvaccinated individuals.[92,100,187] The clustering of onset of GBS in the second and third weeks after the influenza vaccinations were administered in 1976 was not observed after administration of vaccinations in either 1978 to 1979 or 1979 to 1980.[187] These results suggested that A/New Jersey influenza vaccine differed from subsequent influenza vaccines in its ability to trigger GBS.[187] The neurotigenic P2 protein of peripheral nerve myelin has been shown to have been present and biologically active in the 1976 influenza vaccine.[193] P2 may have been a factor in the production of GBS after administration of the A/New Jersey influenza vaccination in susceptible individuals.[192]

Asbury[12] concluded that an "epidemic" of GBS actually occurred, but the precise cause of the illness remains undetermined. Whether a special antigenic site was present on the A/New Jersey viral product remains unknown. Patients with GBS who were vaccinated were spread throughout all 141 lots, and the problem could not be traced to individual lots or a single manufacturer. Surveillance for GBS in the subsequent (1979) influenza programs did not show any excess number of cases of GBS.[12]

GBS has occurred after the administration of rabies vaccine prepared in suckling mouse brain.[26,80] A severe protracted course with involvement of cranial nerves, increased mortality rate (20%), and increased long-term sequelae were observed. GBS occurs less commonly after immunization with sample-type vaccine prepared in brain and spinal cord of mature animals.

The prevalence of GBS cases was increased in children and adults in Finland in 1985 after institution of a mass vaccination program with oral polio vaccine.[103,205] This one-time campaign involved the entire Finnish population, and further study of the association between oral polio vaccine and GBS in Finland was impossible. This potential relationship was examined further during a retrospective epidemiologic survey in southern California.[165] No apparent temporal association between GBS and oral polio vaccine was noted. The frequency of GBS was low in the age groups during which children usually are immunized (before 2 years old and 5 years old). Researchers concluded that the failure to find a correlation between the usual age of oral polio vaccine immunization and the incidence of GBS by age coupled with the failure to find any children with GBS with onset within 1 month of receiving oral polio vaccine immunization provided strong evidence against a causal relationship between administration of oral polio vaccine and development of GBS. They suggested that the differences noted in the outcomes of these studies may be related to the fact that the entire population in the study

in Finland already was vaccinated with inactivated polio vaccine and that different types of oral polio vaccine were used in Finland and California.

In October 2005, five cases of GBS occurring after the administration of the meningococcal polysaccharide diphtheria toxoid conjugate vaccine (Menactra, MCV4) in the United States were reported to the Vaccine Adverse Events Reporting System. Following a heightened awareness, three additional cases were reported. A subsequent investigation determined that the occurrence of eight cases of GBS out of the total number of vaccines given within the time period reported is similar to what might be expected on chance alone, based on an average annual incidence rate of 1.4 per 100,000 per year. The Centers for Disease Control and Prevention and the Global Advisory Committee on Vaccine Safety (World Health Organization) have concluded that no change should be made in vaccine policies, with the exception that individuals with a history of GBS not be vaccinated unless they are thought to have an elevated risk of contracting meningococcal infection.[29]

IMMUNOLOGIC FACTORS

Current opinion strongly favors the hypothesis that GBS is an autoimmune disease. Much evidence suggests that GBS represents an aberrant immune response to peripheral nerve components.[9] McFarlin[127] suggested that the following factors support an autoimmune mechanism in GBS: (1) plasmapheresis shortens the clinical course of GBS; (2) sera from patients with GBS contain IgM antibodies against a component of peripheral nerve myelin; (3) lipid antigen reacts with these antibodies; and (4) at least one lipid, sulfate-3-glucuronyl paragloboside (SGPG), can produce an experimental disease similar to GBS. This hypothesis is supported by the similarities of GBS, experimental allergic neuritis, and Marek disease.[203,215] Serum antibodies or antibody-like factors have been shown in peripheral nervous system tissues in experimental allergic neuritis and in GBS.[28,110,115,137,167,168,190,193,199] P2, a neurotigenic component of peripheral nervous system myelin administered in complete Freund adjuvant, has been shown to induce experimental allergic neuritis,[217] and sensitization to P2 has been reported in GBS.[2-4,192] Sensitized lymphocytes capable of producing demyelination have been found in experimental allergic neuritis and GBS.[10,59,68,222] Evidence of hypersensitization to peripheral nervous system antigens by use of the technique of macrophage migration inhibition factor assay has been reported in experimental allergic neuritis[191] and GBS.[68,106,119,174]

The cause of GBS and the nature of the antigen or antigens against which the immune response is directed are not known precisely. Studies have provided evidence that an intense immunologic response is an invariable accompaniment of the disease.[4,36,93,179,181] Cell-mediated and humoral immunity have been found to be altered in GBS and may contribute to the pathogenesis and pathology of GBS.

Several lines of investigation have implicated a cell-mediated immunologic reaction to the constituent of myelin as being of primary importance in the pathogenesis of GBS.[3,4,9,68,93,106,181] Activated lymphocytes can be identified in early phases of GBS.[46] Secretion of mediators, such as macrophage migration inhibitory factor (a measure of T-cell sensitization), in the presence of P2 protein has been shown during the acute phase of GBS.[20,68,106,174,192] By means of in vitro lymphocytic transformation technique, some researchers found lymphocytes sensitized to P2 in GBS,[4] whereas others have not confirmed these results and suggest that P2 may not be the antigen in GBS.[93] Goust and associates[68] reported finding circulating immune complexes in GBS and an association between increased immune complex and decreased suppressor cell function. Abnormal T-cell subsets have been reported,[120] but other investigators have not reproduced this finding.[86,93] Additional evidence of cell-mediated immunity in GBS is suggested by studies observing demyelinization of rat peripheral nerves in tissue culture by circulating immunocytes from patients with GBS or lymph node cells from animals with experimental allergic neuritis.[10,93,182]

Activation of T cells has been reported in GBS.[4,77,78,201] Alterations in T-cell subsets, including decreased numbers of $CD3^+$ and $CD4^+$ and increased CD19, have been observed.[225] These changes normalized after plasmapheresis occurred in patients who improved. Taylor and Hughes[201] observed an increase in the levels of T cells bearing activator markers (interleukin-2 receptor and transferrin receptor) in the serum of GBS patients compared with normal control subjects. Hartung and associates[77,78] showed T-cell activation in the acute phase of GBS, as evidenced by increased interleukin-2 receptor expression on T cells, increased serum concentrations of interleukin-2 and soluble interleukin-2 receptor, and increased numbers of DR-positive circulating T cells. They reported that increased soluble interleukin-2 receptor concentrations that were found in several samples decreased with clinical improvement. The suggested role of activated T cells in GBS could include cytotoxic effect on Schwann cells, myelinotoxic effects, recruitment of macrophages in a delayed hypersensitivity reaction, or helping B cells to produce antibody against myelin. Activated T cells also may play a role in recovery.[77,78]

Protective and destructive roles have been ascribed to antibodies in GBS.[10,223] One suggestion is that the destructive effects of antibodies are mediated either directly by lysis of peripheral myelin with or without a requirement for complement or indirectly by opsonizing myelin, which then is attacked by macrophages.[93] Serum and CSF immunoglobulins of restricted electrophoretic heterogenicity have been reported to be increased in GBS, and these increased levels return toward normal with clinical improvement.[34,36,118] Autoantibodies to erythrocytes and circulating antigen-antibody complexes have been found in GBS.[34,37,46,49,68] Melnick[131] first showed anti-neural antibody in GBS sera, and anti-neural antibodies also have been reported in the CSF of patients with GBS.[179] The cytotoxic effect of GBS serum in vitro has been reported.[36,38,51] Several studies have suggested the presence of anti-neuronal antibodies in GBS patients. Indirect immunofluorescence has been used to show that sera of patients with GBS have IgG antibody to monkey dorsal root ganglia.[47]

Some findings indicate that sera from patients with GBS react with multiple antigens in peripheral nerve myelin.[49,110,163,226] Complement-fixing antibodies to peripheral nerve myelin have been detected in the sera of patients with GBS.[108,131] Increasing titers of complement-fixing antiperipheral nerve myelin antibodies (IgM) have been found during the acute phase of GBS, and decreasing titers have been observed during convalescence.[108] Koski and associates[108,109] found that some of the antiperipheral nerve myelin antibody in sera from patients with GBS binds a neutral glycolipid of human peripheral nerve myelin and cross-reacts with Forssman antigen, a cross-species antigen found in many infectious diseases. These investigators suggested that IgM antibodies, triggered by multiple infectious agents in patients with GBS, can bind to a glycolipid surface determinant of human peripheral nerve myelin and, after penetration of the damaged blood-nerve barrier, participate in the demyelination of peripheral nerves through activation of complement. Yu and associates[226] found that sera from patients with GBS reacted with antigens in peripheral nerve myelin, including one lipid, SGPG. In rabbits, immunization with SGPG produced weakness and physiologic abnormalities consistent with a demyelinating neuropathy.

PATHOGENESIS

GBS is regarded as an autoimmune disorder involving cellular and humoral immune mechanisms.[209] Immunologic studies have not resulted in a simple concept of the pathogenesis of GBS. The animal model of GBS, experimental allergic neuritis, has allowed researchers to analyze the pathogenetic mechanisms involved in the demyelinating process.[209] In the Lewis rat, GBS can be transferred by $CD4^+$ T cells reactive to neuroautoantigens P2 and P0. In the rabbit, experimental allergic neuritis serum injected intraneurally demyelinates rat nerve largely because of antigalactocerebroside antibody.[159] In humans, no peripheral nerve antigen has been identified as the responsible target.[208] Involvement of the cellular immune system also has been implicated. T and B cells become activated at the onset of GBS, as indicated by an increase of activation markers, including interleukin-2, soluble interleukin-2 receptor, and tumor necrosis factor-α, in serum and CSF.[18,76,189,208] The serum levels of these markers decrease with recovery.[18,189]

Disruption of myelin has been reported secondary to increased serum concentrations of the cytokine tumor necrosis factor-α.[189] Increased serum concentrations of tumor necrosis factor-α are detected in 50 percent of patients with GBS and in 26 percent of patients with unrelated neuropathies and other neurologic disorders. Increased serum concentrations of tumor necrosis factor-α are not specific for GBS, however. Tumor necrosis factor-α serum concentrations correlate with clinical severity, decrease as patients recover,[189] and are similar in patients with GBS whether or not preceding infections were noted. These elevations likely are not merely secondary to the antecedent infection. In contrast, soluble concentrations of interleukin-2 receptor are elevated in healthy relatives of patients with GBS and in patients with GBS. These data suggest that these concentrations may be secondary to environmental or infectious factors, rather than related to the pathogenic mechanism responsible for GBS.[189]

The involvement of complement is suggested by findings that include increased concentrations of the soluble terminal complement in serum and CSF and increases of C3a and C5a in CSF alone.[76,159,208] One study showed a breakdown of the blood-nerve barrier by activated T cells, allowing the development of focal conduction block and demyelinization in the presence of circulating anti-myelin antibodies.[159] Elevated serum concentrations of endothelial leukocyte adhesion molecule-1 have been shown in GBS during the acute phase, with serum concentrations returning to normal by 14 days. Endothelial leukocyte adhesion molecule-1 may be important by virtue of breakdown of the blood-nerve barrier.[148]

The diversity of preceding infectious factors and the observation that GBS may occur after noninfectious factors, such as surgery, trauma, epidural anesthesia, drug administration, and immunizations (Table 43–15),[9,28,57,198] have suggested that infection is not a necessary precondition for the development of GBS. A single factor, such as the release of antigen, may be the common mechanism leading to nerve damage. Also, the peripheral nervous system may possess a limited repertoire of pathologic responses and may react to diverse insults in a restricted fashion.[191] As noted, numerous reports have indicated alterations of cell-mediated immunity and humoral immunity in GBS and have suggested an immunologic basis for the demyelination in GBS. The exact mechanism and precise interaction of a preceding event and the patient's cell-mediated and humoral immune responses in causing demyelination are unknown. Whether GBS is the result of an autoimmune process or represents neural injury from an immune response to viral antigen that might be present in neural tissue is unclear.[36] Proposed mechanisms for the immunopathogenesis of GBS lesions have included antibody or cell-mediated immunity to an infectious agent with secondary neural injury, autoantibody or cell-mediated immunity to peripheral nervous system tissue, and demyelinization caused by deposition of circulatory antigen-antibody complexes in blood vessels of peripheral nerves.[36] One suggestion is that GBS is a syndrome and not a disease and that it may have several different causes.[197]

TABLE 43–15 Antecedent Factors

Strongly Suggestive Evidence
Cytomegalovirus
Epstein-Barr virus
Coxsackieviruses A
Campylobacter jejuni
Mycoplasma pneumoniae
Suggestive Evidence
A/New Jersey 1976 influenza immunization
Survey study or anecdotal reports
Viral Agents
Echoviruses
Coxsackieviruses A and B
Influenza viruses A and B
Measles
Varicella virus
Rubella
Mumps
Hepatitis viruses
Herpes simplex viruses
Rabies
Human immunodeficiency virus
Nonviral Agents
Francisella (Pasteurella) tularensis (tularemia)
Chlamydia
Plasmodium (malaria)
Toxoplasma gondii
Mycobacterium tuberculosis
Noninfectious Agents
Immunizations
Trivalent oral poliovirus
Diphtheria-tetanus-pertussis
Measles-mumps-rubella
Rabies
Influenza, other than A/New Jersey
Polyvalent pneumococcal
Hepatitis
Haemophilus influenzae type b
Surgery
Trauma
Epidural anesthesia
Neoplasm (Hodgkin)
Vasculitides (systemic lupus erythematosus)
Drug hypersensitivities
Heroin addiction
Drug (zimeldine)

Increasingly, researchers have noted that the expression of GBS varies considerably.[52,208] Although the NINCDS Ad Hoc Committee proposed criteria for the research diagnosis of GBS, this committee recognized the occurrence of the many variant subtypes previously discussed. GBS could be viewed as a family of closely related diseases that can be categorized by class of axon (motor, sensory, autonomic, or mixtures), pathologic process (inflammatory-demyelinating, antibody attack), preceding infection, associated antibody, underlying disease mechanism, or response to treatment.[208]

The clinical variability of GBS may reflect different pathogenetic mechanisms. Pathology results suggest the heterogeneity of GBS. Studies by Asbury and coworkers[12,13,15] indicated the early occurrence of inflammatory cells as the primary mechanism

resulting in demyelination. The lesions were found along the entire length of the nerve, but with variable expression among patients corresponding to their clinical deficits. The role of lymphocytic infiltration has been reappraised. Lymphocytic infiltration varies widely among patients with GBS, and severe demyelination can occur without lymphocytic infiltration. Heterogeneity is suggested further by experimental allergic neuritis models.[208] The rat experimental allergic neuritis model is a T-cell–dependent response to the antigen P2. In the rabbit model, demyelination results from a B-cell–dependent response to galactocerebroside. These models suggest that the variability of GBS may depend on the relative contribution of T-cell and B-cell responses.

Serum antibodies against such glycolipids as G_{M1}, G_{M1b}, G_{M2}, GALNAc-GD_{1a}, G_{D1a}, G_{D1b}, G_{D3}, G_{T1a}, G_{T1b}, G_{Q1b}, and L_{M1} have been reported in the acute phase of GBS.[55,75,144,211,227,228] In GBS, the specificity of anti-ganglioside antibodies varies.[31,220] The presence of anti–G_{M1} ganglioside IgG antibodies may be associated with a more severe and predominantly motor form of GBS (AMAN). Among 132 patients with GBS participating in the Dutch GBS trial and for whom suitable pretreatment serum was available, 25 (19%) showed high anti-G_{M1b} antibody titers of the IgG ($n = 15$) or IgM ($n = 14$) class or both ($n = 4$). Patients who were antibody-positive more frequently experienced preceding diarrhea and had serologic evidence of recent *C. jejuni* infection without antecedent evidence of CMV, Epstein-Barr virus, or *M. pneumoniae* infection than did patients who were antibody-negative. In the patients who were antibody-positive, the onset was more rapid, limb weakness was more severe, distal weakness was more prominent, and recovery time was more prolonged. These patients had less frequent sensory deficit or cranial nerve involvement.[229]

Serum anti–G_{Q1b} ganglioside antibodies have been observed in the Miller Fisher (and Bickerstaff brain stem encephalitis) variant of GBS.[31,95,220] Eighty-two percent of patients with the Miller Fisher variant of GBS may have IgG antibodies to G_{Q1b}. The circulating anti-G_{Q1b} IgG antibodies induce presynaptic and postsynaptic blockade. After the patients recovered, this blocking activity was lost, and sera became negative for anti-G_{Q1b} antibodies. These IgG antibodies may play a pathogenic role in the Miller Fisher variant of GBS.[25] In addition, the G_{Q1b} epitope is expressed preferentially on the paranodal regions of the oculomotor, trochlear, and abducens nerves, which correlates with the clinical picture of ophthalmoplegia.[227] Researchers also have hypothesized that the anti-G_{Q1b} antibodies may bind to 1a afferent nerve fibers within the spinocerebellar tract, leading to ataxia.[227]

These findings suggest that some association exists between antigenic specificities of anti-glycolipid antibodies and clinical forms of GBS. The exact role of these antibodies as either neurotoxic and directly responsible for the symptoms or incidental by-products is not clearly established, however.[31,208,220] A decline in anti–G_{D1b} ganglioside titers in relation to clinical recovery has been reported in patients with GBS after receiving plasma exchange.[170] Although studies confirm the activation of the immune system in GBS, whether the increase in activation markers is caused by preceding infection, why they are found only in some and not all patients with GBS, and what their role is in destruction of myelin remain unknown.

Evidence for shared antigenic determinants among certain infective agents associated with GBS and various antigens within peripheral nerve includes the following: (1) shared antigenic determinants between herpes simplex virus ribonucleotide reductase and peripheral nerve P0 glycoprotein have been shown, (2) amino acid sequence homology between CMV and varicella-zoster virus and P0 glycoprotein has been observed, and (3) antibodies to ganglioside have been detected in patients with GBS after they have had an infection caused by *C. jejuni* or *M. pneumoniae*.[7,159] Some studies indicate that molecular mimicry may contribute to the presence of antiganglioside antibodies after infection with *C. jejuni* has occurred.[55,144,228] Humoral immune mechanisms directed at an infectious agent may cross-react with antigens of the peripheral nervous system and cause an immunopathologic disease. The family of glycoconjugates, which includes gangliosides, is one of the myelin antigenic groups with which antibodies have been identified in GBS. The frequency of these antibodies may be 35 percent of patients with GBS. Nonetheless, the presence of high titers of anti-glycoconjugate antibodies is not correlated with the more severe course of this disease.[55,71,98,211]

The association of *C. jejuni* infection preceding presentation of GBS and the occurrence of antiganglioside antibodies may contribute to an understanding of pathogenesis of GBS. *C. jejuni* has a lipopolysaccharide capsule that is rich in glycoconjugates containing sialic acid that resemble human glycoconjugates.[71] A terminal tetrasaccharide immunogenically identical to the ganglioside G_{M1} in human peripheral nerve has been shown on the outer membrane of a *Campylobacter* strain cultured from a patient with GBS.[17] Serologic evidence of an antecedent *C. jejuni* infection has been shown to correlate with the presence of anti-G_{M1} antibodies.[55,95,211,228] Anti-G_{M1} IgG antibodies in GBS sera recognize surface epitopes on whole *Campylobacter* bacteria, and this recognition is strain-specific. *Campylobacter* isolated from patients with GBS and with enteritis have been found to have similar ganglioside-like moieties. This finding indicates that patients who develop GBS respond differently to the ganglioside-like epitopes on *Campylobacter* than do patients with non-GBS diarrhea.[95] The finding also suggests a role for host susceptibility as a determinant for outcome after *Campylobacter* infection.[190]

C. jejuni, but not *Escherichia coli*, bacteria can absorb G_{M1} antibodies of the IgG class.[144] Studies suggest that molecular mimicry might play a role in the pathogenesis of GBS. Molecular mimicry is suggested further by the observation that the G_{Q1b} epitope is present in the lipopolysaccharide fractions of *C. jejuni* isolated from patients with the Miller Fisher variant.[220,228] Direct infection of cells of the peripheral nervous system leading to an immune attack seems unlikely in the case of *C. jejuni* because extraintestinal infection, especially peripheral nervous system infection, probably is irrelevant. *C. jejuni* may generate toxins that directly damage peripheral nerves. Although strain-specific toxins may play a role in post–*C. jejuni* GBS, an immune mechanism remains most likely.[71] Especially appealing is that the association with *C. jejuni* provides indirect support for the shared epitope or molecular mimicry model of the immunopathogenesis of GBS.[190] One hypothesis is that an infectious agent with a specific antigenetic repertoire induces an immune response involving T-cell activation and antibodies that cross-react with gangliosides in peripheral nerves.[55]

In the motor axonal form of GBS, the nodes of Ranvier of the motor fibers are the primary targets. The earliest changes seem to be antibody-mediated and complement-mediated, and T lymphocytes are a rare finding in nerve. The axonal form of GBS has been associated with antiganglioside G_{M1}, G_{M1b}, G_{D1a}, and GalNAc-G_{D1a}, antibodies, and *C. jejuni* infection.[75,227] The epitopes for the aforementioned antibodies have been shown to be located on the nodal axolemma of motor nerves. Most of the Chinese cases are reported to be triggered by recent *C. jejuni* infection in the gut. Surface lipopolysaccharides of *C. jejuni* strains associated with GBS contain epitopes that are similar or identical to G_{M1} ganglioside that is concentrated at the nodes of Ranvier. This finding supports the role of molecular mimicry for inducing GBS.[16]

Conflicting results have been reported concerning the relationship of G_{M1} antibody to axonal degeneration.[113] Antibodies to other gangliosides have been reported to be elevated in sera of patients with GBS during the acute phase. Only a 50 percent

concordance between serologic evidence of *C. jejuni* infection and the presence of anti-G_{M1} antibody was found during large studies. GBS patients with anti-G_{M1} antibodies have had identified infections that included *C. jejuni* (23%), CMV (10%), *M. pneumoniae* (6%), and Epstein-Barr virus (3%).[146] Microorganisms other than *C. jejuni* may trigger an anti-ganglioside response and elicit axonal GBS. Whether the presence of anti-G_{M1} antibodies is associated with extensive axonal loss and poor outcome is controversial. Some patients with GBS and anti-G_{M1} antibodies recover quickly or have conduction abnormalities suggestive of demyelination.[85,113,167,212]

OUTCOME

Most patients with GBS recover spontaneously. Epidemiologic studies have indicated, however, that 10 to 23 percent of patients may require mechanical ventilation, 7 to 22 percent have some residual disability, 3 to 10 percent relapse, and 2 to 5 percent die.[12,30,62,85,105,121,164,221] Patients may be left with residual symptoms, such as facial weakness, weakness in the lower extremities with footdrop, weakness and atrophy of hands, and autonomic dysfunction (impotence and urinary retention).[123] In the North American study of the effect of plasmapheresis,[87] the median time to recovery of independent walking was 85 days for control subjects compared with 169 days for patients who received mechanical ventilation. This same study indicated that children walked at 52 days. Five prognostic factors were identified: age, requirement for respiratory support, rate of progress, abnormal physiologic characteristics of peripheral nerve function, and plasmapheresis. In children, the overall recovery and outcome generally is better than that seen in adults. Much of the literature now uses the Hughes functional disability rating scale in assessing outcome measures. This is a scale from 0 to 6: 0—healthy, 1—minor symptoms and able to run, 2—able to walk 5 m independently, 3—able to walk 5 m with assistance, 4—confined to bed (or chair), 5—requiring assisted ventilation, 6—death.[87]

Complete recovery from motor or sensory deficits after an episode of GBS has been reported in 70 percent of cases after 12 months and in 82 percent after 15 years.[177] Kleyweg and associates[105] compared the outcome of GBS in groups of children and adults. They observed that 22 percent of children compared with 30 percent of adults required mechanical ventilation, with a median duration of 21.5 days in children and 32 days in adults. Mean duration of hospitalization was 84 days for children and 86 days for adults. Two of 18 children died. At 1 year, 77 percent of children had a good outcome, and at 2 years, 83 percent had a good outcome. For adults, good outcomes at 1 and 2 years were observed in 86 percent and 92 percent. Significant slowing of motor and sensory nerve conduction or electromyographic abnormalities may persist for weeks to years after recovery.[164,177] Reported unfavorable signs for complete recovery in children included a period longer than 18 days of plateau between onset of weakness and time of greatest weakness, weakness and maximum motor deficit of greater than 3 weeks, or marked paralysis alone (need for assisted ventilation).[53,177,221]

There are different recovery patterns for demyelinating forms of GBS compared with axonal variants. The axonal varieties overall have a more aggressive and progressive course, reaching their nadir much earlier than do AIDP variants. Demyelinating or AIDP syndromes tend to have a uniform recovery, with most patients having a complete or near-complete recovery over the course of several weeks to months, as previously described. Patients with axonal subtypes (specifically AMAN) seem to have two distinct recovery patterns: a rapid recovery observed within the first few weeks or a prolonged recovery period lasting several months or longer (more often seen with acute motor-sensory axonal neuropathy). Some patients have shown improvements and regained the ability to walk years later,[81,82] which may explain earlier studies that predicted a worse outcome overall for the axonal subtypes because the evaluation period was too brief to measure their long-term recovery potential accurately. The recovery and outcome have been shown to be better and faster in children. One study in children showed similar outcomes at 1 year, regardless of subtype; however, the axonal subtypes had a more protracted course.[202]

TREATMENT

The mainstay of treatment of GBS is supportive care because there is no known cure. Intensive nursing and medical care are essential for proper management. Most deaths are related to respiratory failure, pulmonary embolism, and autonomic dysfunction.[88] Respiratory function must be monitored closely, especially during the acutely progressive phase. The need for endotracheal intubation and mechanical ventilation has been suggested if vital capacity decreases to less than 12 to 15 mL/kg, arterial Po_2 decreases to less than 70 mm Hg, or clinical signs of fatigue develop. Tracheostomy may be indicated if paralysis is prolonged.[175] Physiotherapy and preventive measures for pulmonary embolism are indicated. Because of autonomic dysfunction, electrocardiogram and blood pressure monitoring are essential. Hyponatremia is a reported complication and probably is caused by inappropriate secretion of antidiuretic hormone[155]; fluid and sodium balance and adequate nourishment must be maintained. Reassurance and attention to anxiety, anger, and depression are important during the progressive phase of GBS, especially for patients being ventilated.[88]

Pain is a very common feature of GBS, especially in children, and may be the earliest and most common symptom, occurring in as many as 90 percent of cases. Pain often is either underrecognized or underappreciated and undertreated. Although nonsteroidal anti-inflammatory drugs and opioids can be effective in pain management, they may not be optimal treatment options because of side effects or relative ineffectiveness for neuropathic pain. Gabapentin and carbamazepine have proven efficacy in a variety of neuropathic pain syndromes and in GBS as measured by a reduction in use of intravenous opiates and subjective patient reporting.[136,150,151] Carbamazepine and gabapentin were compared head to head in a randomized, prospective, double-blind, placebo-controlled study. Although both treatments were effective, gabapentin showed earlier and more profound pain relief and less sedation compared with carbamazepine.[151]

A variety of treatment modalities have been used in an attempt to hasten recovery, shorten the duration of time on a ventilator or in an intensive care unit, and decrease the incidence of residual neurologic deficits. These treatments include steroids, plasmapheresis or plasma exchange, CSF filtration, immunoadsorption, and IVIG. The Cochrane Collaboration has published separate systematic reviews of corticosteroids, plasma exchange, and IVIG therapy for GBS.[89,90,166] In 2003, the American Academy of Neurology (AAN) published practice guidelines with regard to immunotherapy in GBS, largely based on the Cochrane systematic reviews of the literature.[91]

The earliest studies investigated the effects of steroids on GBS. Limited evidence suggests that oral steroids slow the recovery process. Intravenous steroids have shown a trend toward a more rapid recovery that is not statistically significant. No effects of intravenous steroids on long-term outcome have been reported, and no significant adverse effects from intravenous steroids have been reported. Currently, corticosteroids are not recommended in the treatment of GBS.[90,91]

Plasma exchange has been shown to be beneficial in the treatment of GBS by shortening recovery time and duration of mechanical ventilation and reducing medical costs. Plasmapher-

esis may be beneficial in patients treated 30 days after the onset of disease, although it is more beneficial when started within 7 days of onset.[166] Studies in children also have shown the efficacy of plasmapheresis for treatment of GBS. In children, the benefits have included decrease in the number of days of mechanical ventilation and time to motor recovery and a decrease in the overall cost of care.[96,207] A further study suggested that two exchanges are better than none for mild GBS, four exchanges are more beneficial than are two for moderate GBS, and six exchanges are no more beneficial than are four in severe GBS.[16]

Although plasmapheresis can be a cumbersome procedure with many technical difficulties, it has been used safely in critically ill children 8 months old. Mild hypotension related to rapid fluid removal has been reported, but no major complications or deaths related to plasmapheresis have been reported in pediatric patients with GBS. Reported complications in adults include hypotension, transfusion reactions, hypocalcemia, arrhythmias, cardiopulmonary arrest, and infection caused by transmitted blood products or sepsis secondary to indwelling catheters. As the only treatment with proven benefit in randomized placebo-controlled trials, plasma exchange is the standard against which all subsequent treatments will be compared. Based on the evidence, current AAN guidelines recommend plasma exchange for nonambulatory patients within 4 weeks of onset of symptoms and for ambulatory patients within 2 weeks of onset.[91,166]

Immunoadsorption has been tried as an alternative to plasma exchange to remove immunoglobulins; however, only one small nonrandomized, unblinded trial and case reports exist suggesting efficacy. Also, CSF filtration has been used in some small studies, but no good large, randomized trials have been done. Currently, the evidence is insufficient to suggest whether or not either of these options is a valid treatment in GBS.[8,79,84,91]

Contraindications to the use of plasmapheresis in some patients with GBS, complications, and lack of universal availability led to the initial studies of IVIG as an alternative therapy to plasmapheresis. Because plasma exchange has proven efficacy in the treatment of GBS, no placebo-controlled trials have been performed of IVIG, only trials comparing IVIG with plasma exchange. IVIG has been shown to have equal efficacy to plasma exchange in speeding recovery in GBS.[89] In addition, some reports indicate that certain GBS subtypes (anti-G_{M1} or anti-G_{M1b}) may respond more favorably to IVIG than to plasma exchange.[111,229] Advantages of IVIG therapy for GBS include its wide availability, ease of administration, safety, and absence of serious complications. Therapy with IVIG generally is less expensive than is plasmapheresis.[207] Current AAN guidelines recommend IVIG for patients with GBS who lose independent ambulation within 2 to 4 weeks of onset of symptoms.[91]

No large trials of IVIG therapy have been performed exclusively in children. Small studies indicate improvement in children similar to that in adults when plasmapheresis or IVIG therapy is used. Plasma exchange and IVIG are treatment options for children with severe GBS (mostly derived from evidence in adult populations). A more recent multicenter, randomized trial[107] investigated the use of IVIG in children and compared IVIG, 2 g/kg (total dose) given over 2 days versus over 5 days, with the primary outcome measure being time required to regain ability to walk unassisted. No statistically significant difference was found between the two groups on the primary outcome measure (19 days versus 13 days). In the 2-day treatment group, early transient deterioration in the disability score before recovery occurred more often. Generally, in centers where it is available, IVIG has emerged as the treatment of choice for moderate to severe GBS in children because of its relative ease of administration, lower incidence of side effects, and overall cost-effectiveness.

Genitourinary Tract Infections

CHAPTER 44

Urethritis

Ellen R. Wald

Urethritis refers to inflammation of the urethra and periurethral tissues in males and females. It may be associated with a variety of infectious and noninfectious disorders.

EPIDEMIOLOGY

The cause of urethritis varies with the age of the patient, sexual practices, and hygienic standards.[10,45] *Chlamydia* infections and gonorrhea are common occurrences in adolescents; fecal contamination or irritation caused by physical or chemical substances is a more usual occurrence in preschool-aged children. Transmission during sexual activity is the usual means of spread of *Neisseria gonorrhoeae* and *Chlamydia trachomatis* in teenagers and in sexually abused patients; nonvenereal transmission has been described in prepubertal children.[46] Manifestations after nonvenereal spread has occurred may include vaginitis, balanitis, and conjunctivitis in addition to urethritis.[13,46]

The home and social environments of prepubertal children must be examined to identify fully the pattern of spread and infection in the patient and contacts because complex psychosocial diagnoses and therapies often are involved.[38] Children with gonorrhea and chlamydial infections are concentrated in large urban centers, usually in poor socioeconomic environments.

Gonococcal infections in children 2 to 10 years of age should be considered evidence of probable sexual abuse.[1,19,21-23] Household contacts have been found to have positive cultures in 27 to 63 percent of such cases. Prepubertal girls infected with *N. gonorrhoeae* as a result of sexual abuse outnumber boys by a ratio of at least 3 : 1 and in one report 8 : 1.[15]

PATHOPHYSIOLOGY

Infection caused by *N. gonorrhoeae* usually is localized to the urethra in boys and to the vagina in girls; however, rectal carriage sometimes occurs in the absence of urethral colonization. Gonococcal virulence factors include pili, the ability to attach to urethral epithelial cells, and production of extracellular proteases that cleave IgA. Initial attachment of gonococci to the surface of columnar epithelial cells is mediated by pili, which are filamentous outer membrane appendages composed of multiple subunits, the most important of which is pilin.[44] Local invasion involves multiple adhesins interacting with host receptors at the mucosal cell level. After attachment occurs, gonococci become engulfed in a process known as parasite-directed endocytosis.[16] The organisms are able to undergo intracellular replication within phagocytic vacuoles and columnar epithelial cells, which is a successful adaptive response promoting survival.

Chlamydia infections are the most frequent cause of sexually transmitted disease in the United States.[6,9,51] Chlamydiae are structurally complex organisms that are obligate intracellular parasites and contain DNA and RNA. Attachment, which is not understood completely, is the first step in the infectious process of the susceptible host cell. It is followed by phagocytosis and then the failure of cellular lysosomes to fuse with the phagosome containing the elementary body, which may be mediated partly by macromolecules in the chlamydial cell envelope. After these two crucial events occur, the elementary bodies undergo biologic changes, and after approximately 72 hours, they are released from the host cell as new infective elementary bodies (Fig. 44–1).

Urethritis in younger children also may be caused by the introduction of fecal bacteria or pinworms into the urethra during the early years of toilet training, particularly in girls. Inflammation may be related to bubble baths and other chemical and physical irritants. Edema of the mucosa and the presence of inflammation and red blood cells are common histopathologic features of urethritis that lead to dysuria, hematuria, and microscopic pyuria.

CLINICAL PRESENTATION

Gonococcal urethritis is characterized by a 2- to 8-day incubation period after sexual intercourse. The onset often is sudden, with dysuria and copious urethral discharge in boys and leukorrhea in girls. The urethral discharge often is thick, profuse, and yellow. The patient usually has no fever. In prepubertal girls, leukorrhea is more prominent as a sign of gonococcal infection, and urethritis occurs less commonly. This difference may be related to the method of infection and to the different sensitivity of the vaginal epithelial surface to infection in a prepubertal child. Leukorrhea may be minimal in adolescent girls, and dysuria may be absent.[1]

Diagnosis often is made earlier in adolescent boys than in girls, perhaps because of the prominence of urethral discharge in boys and misinterpretation of the significance of leukorrhea in girls. Gonococcal urethritis also may cause asymptomatic pyuria in boys. Occasionally, prepubertal patients have conjunctivitis or balanitis without significant urethritis. Clinical presentations include systemic illness with fever, arthritis, and skin lesions secondary to bacteremia in 3 percent of untreated individuals with mucosal gonorrhea.[1] These lesions often begin on the extremities as small erythematous macules that progress to circular papules with an area of central necrosis.

The clinical presentation of nongonococcal urethritis may be similar to that described for gonorrhea, but it more commonly has a longer incubation period (often 8 to 14 days after sexual intercourse) and a scanty exudate, which may be clear in character and intermittent. This condition also is called nonspecific urethritis and may be present in association with or subsequent to gonococcal urethritis. In the latter case, the scant urethral discharge may persist after the patient has been treated for

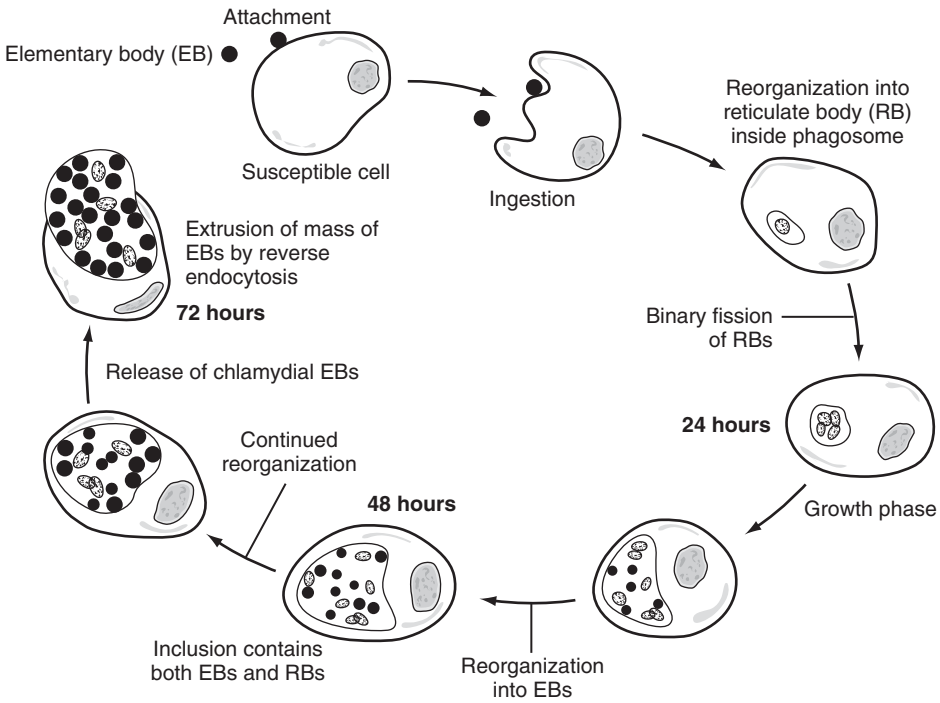

Figure 44–1 Schematic description of the growth cycle of *Chlamydia trachomatis*. *(From Batteiger, B. E., and Jones, R. B.: Chlamydial infections. Infect. Dis. Clin. North Am.* 1*:55-81, 1987.)*

gonorrhea. Asymptomatic urethral colonization with *C. trachomatis* also is reported in males.[49]

An equivalent syndrome, acute urethral syndrome, has been described in sexually active females. The patient experiences an acute onset of dysuria and increased frequency, and pyuria (≥8 white blood cells/mm^3 of midstream urine) is a common finding. Bacterial cultures of the urine often are sterile or show less than 10^5 bacteria/mL; coliform bacteria, *Staphylococcus saprophyticus*, and *C. trachomatis* are the most common causes. Clinical expression of infection with *C. trachomatis* in adolescent girls is characterized by a yellowish, mucopurulent secretion at the cervical os.[7] However, infection with *C. trachomatis* may be asymptomatic in both sexes, an important consideration in designing effective strategies for diagnosis and management of sexual contacts.

A patient with urethritis caused by trauma may have hematuria and dysuria without fever. The trauma may be obvious or related to masturbation or introduction of foreign bodies into the urethra. Patients with urethritis secondary to bubble bath or soap usually have transient dysuria and no systemic signs. Fecal contamination of the urethra may be accompanied by hematuria, dysuria, and pyuria.

DIFFERENTIAL DIAGNOSIS

Table 44–1 lists the differential diagnoses for urethritis.

NONINFECTIOUS

Trauma, bubble bath, detergents found in shampoos, masturbation, radiation, dysfunctional elimination syndrome, and caustic substances may lead to the development of urethritis.[26] Urethritis also may be a component of several systemic syndromes, including erythema multiforme (Stevens-Johnson syndrome), Kawasaki disease, and occasionally other forms of allergy. Reiter syndrome denotes the association of nongonococcal urethritis with conjunctivitis and arthritis.

TABLE 44–1 Etiology of Urethritis

Infectious	Noninfectious
Sexually transmitted infections	**Vasculitides**
Neisseria gonorrhoeae	Reiter syndrome
Chlamydia trachomatis	Erythema multiforme
Trichomonas vaginalis	Kawasaki disease
Herpes simplex virus type 2	**Mechanical**
Mycoplasma spp.	Masturbation
Non–sexually transmitted infections	Foreign body
Staphylococcus saprophyticus	Trauma
Enterobacteriaceae	**Chemical**
Gardnerella vaginalis	Soaps
Streptococcus spp.	Detergents
Enterobius vermicularis	Drugs

INFECTIOUS

The most common forms of urethritis in sexually active adolescents and young adults are gonococcal and so-called nongonococcal urethritis. They may occur together or sequentially. Nongonococcal urethritis has been related causally to infections with *C. trachomatis* in approximately 30 to 50 percent of cases and with *Ureaplasma urealyticum* (T-strain mycoplasma) in approximately 25 percent of cases of nongonococcal, nonchlamydial urethritis in males.[7,50] The remaining cases of infectious urethritis in postpubescent, sexually active patients may be caused by a variety of pathogenic microorganisms, including *Gardnerella vaginalis*, *Mycoplasma hominis*, *Trichomonas vaginalis*, *Candida albicans*, herpes simplex virus type 2, *Treponema pallidum* (syphilis), and other bacteria, such as staphylococci, Enterobacteriaceae, and occasionally streptococci including group B.[18]

Mycoplasma genitalium is a newer species, first isolated from males with urethritis.[8,28] Studies also have implicated a causative role in *Chlamydia*-negative nongonococcal urethritis for anaerobic organisms of the *Bacteroides* spp., in particular *Bacteroides urealyticus*.

In younger children, urethritis usually has noninfectious causes as outlined earlier. Gonorrhea, *Chlamydia*, and fecal bacteria may be important as well.

SPECIFIC DIAGNOSIS

A standard method for diagnosing gonorrhea in a sexually active male is to obtain urethral discharge by manually stripping the urethra or, if that is unproductive, by gently inserting a swab 2 to 3 cm into the distal urethra. The best culture technique for isolating *N. gonorrhoeae*, a fastidious organism, is immediate inoculation of this material onto a selective growth medium, such as regular or modified Thayer-Martin agar. Any delay in inoculation of the plates necessitates the use of a transport method with growth media in a carbon dioxide environment that support the gonococcus at ambient temperatures. These media protect the organism from its marked susceptibility to the effects of drying, cold, and overgrowth by other bacteria. Urethral exudate from a male patient should be Gram-stained at the same time; typical kidney bean–shaped, gram-negative, intracellular diplococci are presumptively diagnostic, with a sensitivity and specificity approaching 100 percent (Fig. 44–2).

Putative gonococcal colonies should be confirmed by oxidase reaction, Gram staining, sugar use tests, rapid enzyme tests, nucleic acid probes, or agglutination reactions with antibodies specific for *N. gonorrhoeae*. The last four tests are especially important in evaluating sites of infection (e.g., the pharynx) or populations of patients with a low prevalence of gonorrhea.

Sexually active females with urethritis also should undergo urethral culture. Although the Gram stain of cervical secretions is only 66 percent sensitive in detecting *N. gonorrhoeae* in adolescent girls, the finding of kidney bean–shaped, intracellular gram-negative diplococci is highly specific and helpful.[52] Vaginal, cervical, and rectal swabs are recommended. Asymptomatic colonization with gonococci seems to occur most commonly in female patients, although it has been described in adolescent boys.[1,25] Pharyngitis, conjunctivitis, balanitis, and other, less common, manifestations of gonorrhea may coexist with urethritis. Samples obtained from these sites should be handled as described earlier. Blood agar and other specialized media may be indicated to identify nongonococcal causes of urethritis.

Nucleic acid amplification (NAA) tests are highly sensitive and specific when used on urethral (males), endocervical swab, and urine specimens.[9] These tests include polymerase chain reaction, transcription-mediated amplification (TMA), and strand displacement assays. Only the TMA assay is approved by the U.S. Food and Drug Administration for testing vaginal swabs from postmenarcheal females. Use of urine specimens increases the feasibility of initial testing and follow-up of hard-to-access populations such as adolescents.[1] These techniques also permit dual testing of urine for *C. trachomatis* and *N. gonorrhoeae*. NAA tests are not recommended for rectal and pharyngeal swabs.[1] Although none of these tests is superior to culture, their ease of use (for urine or self-obtained specimens) renders them extremely attractive.

Gonococcal urethritis in prepubescent boys is diagnosed as described earlier for adolescent boys. Vaginal swabs are most useful in female patients, although vaginal discharge may not be prominent. Endocervical cultures are not recommended for the diagnosis of gonorrhea in prepubescent girls. The yield of vaginal swabs seems to be adequate for most diagnostic purposes; rectal swabs also may be useful in female patients. Showing kidney bean–shaped, gram-negative, intracellular diplococci in a prepubescent boy and girl is useful for establishing a presumptive diagnosis and instituting therapy. Confirmation by culture as described for a sexually active male is necessary.

Other infectious causes of urethritis may be diagnosed by specific techniques, including wet mount for *Trichomonas*, Gram stain and culture on Sabouraud dextrose agar for *C. albicans*, and culture for herpes simplex virus, used in the patients and their contacts. New culture techniques for *Chlamydia*, such as the use of microtiter cell monolayers, have increased the recovery rates, decreased the cost, and shortened the turn-around time for the isolation of *C. trachomatis*.[3] The rigorous transport conditions and the small number of laboratories with cell culture techniques have limited the availability of *Chlamydia* cultures; however, noncultural methods, including direct immunofluorescence staining of smears with use of monoclonal antibodies,[3,20,27,34,47] enzyme-linked immunosorbent assay (ELISA) techniques, and NAA testing, are available.

The use of immunofluorescence and ELISA techniques has been surpassed in sensitivity and ease of use by NAA testing.

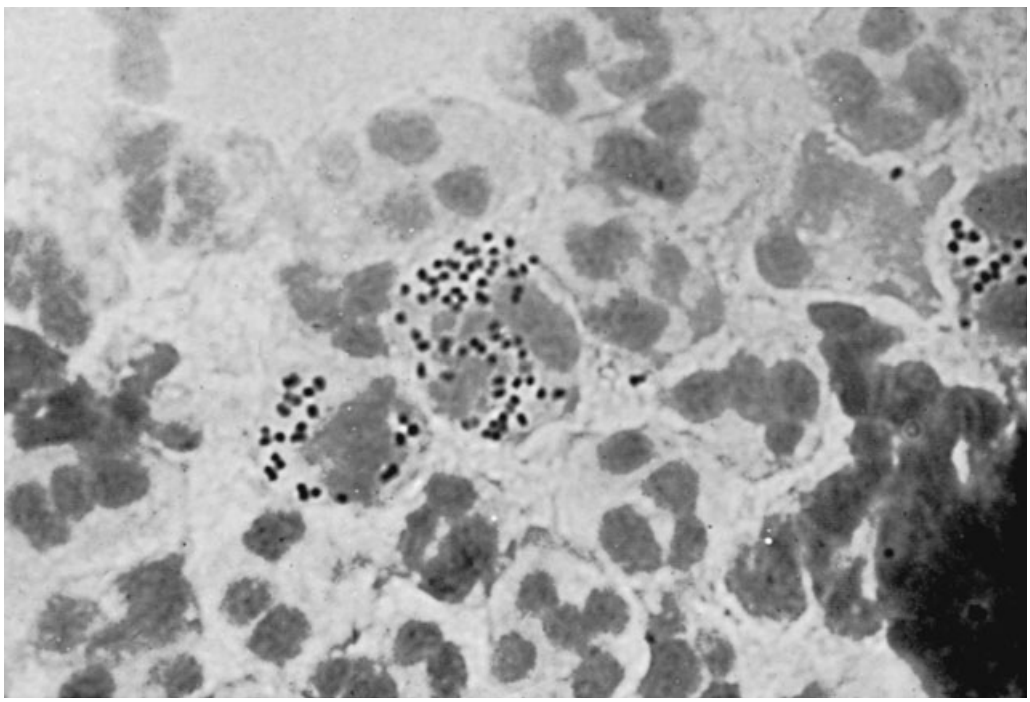

Figure 44–2 Gram-stained smear of urethral discharge from a teenage boy with gonorrhea.

NAA tests such as polymerase chain reaction, TMA, and strand displacement assays are available and are more sensitive than cell culture, DNA probe, direct fluorescent antibody tests, or ELISAs, although specificity varies compared with culture.[1] Polymerase chain reaction, strand displacement assay, and TMA are useful for evaluating urine specimens from either sex. The Food and Drug Administration has approved TMA for testing vaginal swabs from postmenarcheal adolescents. NAA tests are not recommended for specimens obtained from rectal or pharyngeal swabs or for urethral swabs from females.

When documentation of infection is being sought in cases of suspected child abuse, the performance of cultures is strongly preferred and may be the only acceptable test in certain jurisdictions.[1] When culture is unavailable, some experts support using NAA testing if a positive result can be verified by another NAA test. ELISA and fluorescent antibody tests should not be used for testing rectal, vaginal, or urethral specimens from infants and children because of low sensitivity and specificity.[1] Ligase chain reaction seems to be substantially more sensitive in children than is culture for *Chlamydia*.[17,31]

Ureaplasma and other genital *Mycoplasma* spp. can be identified only by culture at this time. This test should be reserved for the evaluation of recurrent cases of urethritis with poor response to treatment.[8,27] Specimens of urethral and vaginal discharge secondary to fecal contamination and foreign bodies can be examined by conventional diagnostic bacterial techniques.

TREATMENT

Table 44–2 presents antibiotic regimens for treatment of urethritis. The treatment of urethritis should include treatment of the sexual partners of the index case to avoid reinfection and further spread of infection. Patients with urethritis frequently have mixed infections with *N. gonorrhoeae* and the pathogens linked with nongonococcal urethritis, such as *C. trachomatis* and *U. urealyticum*. Concurrent infection with *N. gonorrhoeae* and *C. trachomatis* is documented frequently. In a survey of adolescents admitted to juvenile detention centers throughout the United States, screening for sexually transmitted infections was performed on adolescent girls with gonorrhea. Fifty-four percent were coinfected with chlamydia; of adolescent boys infected with gonorrhea, 51 percent were coinfected with *Chlamydia*.[30] A study determining chlamydia and gonorrhea co-occurrence in a high school population showed similar results: of 117 students with gonorrhea, 50 (42.7%) had chlamydia; of 451 with chlamydia, 50 (11.1%) had gonorrhea.[39] Patients with gonococcal urethritis also are at risk for development of early incubating syphilis. One must consider these factors and the possibility of systemic infection when choosing a treatment regimen for urethritis.[36]

Sexual abuse is the most common cause of gonococcal infection among children 2 to 10 years of age. Anorectal and pharyngeal infections with *N. gonorrhoeae* are common and frequently asymptomatic occurrences among these patients.[37]

In 2006, the Centers for Disease Control and Prevention (CDC) published treatment guidelines for sexually transmitted diseases, including urethritis (see Table 44–2). Every attempt should be made to ascertain the specific diagnosis. If doing so is impossible, the treatment regimen chosen always should be appropriate for nongonococcal urethritis and gonococcal infection. The emergence of penicillin-resistant and tetracycline-resistant strains of *N. gonorrhoeae* has led to the abandonment of penicillin and tetracycline for the treatment of gonorrhea.[14]

Single-dose azithromycin for nongonococcal urethritis and either intramuscular or oral single-dose regimens for uncomplicated gonococcal infections are likely to increase compliance.[23,24,32,35,40,41,48,53] Test of cure is not indicated for uncomplicated gonococcal or chlamydial infection when single-dose treatment regimens are used.[9] Emergence of resistance to quinolones initially restricted the use of these drugs in cases of gonorrhea that originated from California, Hawaii, and Asia,[1,4,9] However, in 2007, the CBC recommended that fluoroquinolones no longer be used for treatment of gonorrhea.[9a] If these regimens fail, infections with other pathogens, such as herpes simplex virus or *T. vaginalis*, or bacterial urethritis should be considered. Appropriate testing and specific treatment should be provided when indicated.

TABLE 44–2 Antibiotic Regimen for Urethritis

Nongonococcal Urethritis	
Recommended regimen	Azithromycin 1 g orally in a single dose *or* Doxycycline 100 mg orally bid for 7 days
Alternative regimen	Erythromycin base 500 mg qid for 7 days *or* Erythromycin ethylsuccinate 800 mg qid for 7 days *or* Ofloxacin 300 mg bid for 7 days *or* Levofloxacin 500 mg once daily for 7 days
Chlamydial Infection	
Recommended regimen (adults and adolescents)	Azithromycin 1 g orally in a single dose *or* Doxycycline 100 mg orally bid for 7 days
Alternative regimens	Erythromycin base 500 mg qid for 7 days *or* Erythromycin ethylsuccinate 800 mg qid for 7 days Ofloxacin 300 mg bid for 7 days *or* Levofloxacin 500 mg once daily for 7 days
Children	
<45 kg	Erythromycin 50 mg/kg/day qid for 14 days
≥45 kg and <8 years old	Azithromycin 1 g orally in a single dose
>8 years old	Use same regimen as for adults
Gonococcal Infection	
Recommended regimen (adults and adolescents)	Ceftriaxone 125 mg IM in a single dose *or* Cefixime 400 mg orally in a single dose *plus* Regimen effective for *Chlamydia*
Children	
<45 kg	Ceftriaxone 125 mg IM in a single dose
If bacteremia, arthritis, or meningitis	Ceftriaxone 50-100 mg/kg/day (maximum 2 g/day) IV for 7-14 days
≥45 kg	Use adult regimen

bid, twice a day; IM, intramuscularly; IV, intravenously; qid, four times a day.

PROGNOSIS

Gonococcal urethritis may subside and lead to asymptomatic carriage in female patients. Carriage may last for weeks to months

in adults; this period is undefined in children. Untreated gonococcal urethritis also may lead to prostatitis and epididymitis in male patients and urethral stricture. Asymptomatic genital infections in women can progress to pelvic inflammatory disease with tubal scarring and infertility. Systemic complications of asymptomatic gonorrheal infections include arthritis, endocarditis, and necrotic skin lesions.

Chlamydial infections frequently have been associated with pelvic inflammatory disease in women, resulting sometimes in infertility or ectopic pregnancy. *Chlamydia* can be transmitted to a newborn in the birth canal, which can result in conjunctivitis, pneumonia, or both.

The frequency of *U. urealyticum* is higher in sperm samples from men of infertile couples. It also has been associated in women with premature delivery and postpartum fever. In a newborn, this organism might be linked with the development of bronchopulmonary dysplasia. *Ureaplasma* infection of the central nervous system occasionally is reported in newborns.

PREVENTION

Despite substantial efforts, a specific gonococcal vaccine has not been developed. The mainstays of prevention continue to be education and screening. Prepubescent gonorrhea can be prevented from recurring only by careful family counseling and psychosocial therapy; legal intervention may be necessary.

The availability of diagnostic tests performed on urine (a noninvasive alternative to specimens obtained from the urethra or endocervix) renders extensive screening possible in nontraditional settings such as schools and recreation centers.[22] Large-scale efforts that have implemented screening for all sexually active teens attending school-based clinics have been successful in reducing the prevalence of *Chlamydia* infection in boys.[11]

Prevention of noninfectious causes of urethritis usually depends on education and specific counseling of the family. Physical agents or allergens identified as a cause of urethritis must be removed.

Acknowledgments

The author acknowledges the contribution of Dr. Melvin I. Marks and Dr. Antonio C. Arrieta to the previous edition of this chapter. Many sections required minimal changes apart from addition of more recently published information.

CHAPTER 45

Cystitis and Pyelonephritis

Ellen R. Wald

Urinary tract infections (UTIs) are the most common serious bacterial infections in children. In several series of children evaluated for fever, UTIs accounted for 5 to 6 percent of infections. They are more common than occult bacteremia, bacterial pneumonia, and bacterial meningitis. UTI is especially common as a cause of infection in white infant girls; UTI may explain febrile episodes in nearly 20 percent of such infants.

EPIDEMIOLOGY

UTIs occur in all age groups and may be symptomatic or asymptomatic. Factors that affect the incidence of UTIs are associated with gender, age, race, circumcision status, and general health.[93] The site of infection may be the bladder (cystitis), ureters (ureteritis), pelvis (pyelitis), and renal parenchyma (pyelonephritis). Infections in neonates and infants are common occurrences. In the first 3 months of life, infections in uncircumcised boys are most common.[116,123] Beyond 6 months, infections in infant girls are substantially more common than are infections in boys; the female predominance of UTIs is maintained throughout the remainder of childhood and adolescence.[31]

RISK OF URINARY TRACT INFECTION

The risk of developing a UTI during childhood seems to have increased since early studies by Winberg and colleagues[159] in 1960. These investigations showed that the risk of developing a UTI during the first 10 years of life was 3 percent in girls and 1.1 percent in boys. In a more recent retrospective study of a cohort of 3556 school entrants, 7.8 percent of girls and 1.6 percent of boys were found to have had symptomatic UTIs as confirmed by significant bacteriuria.[47] In approximately half of these cases, the clinical presentation was consistent with acute pyelonephritis (APN).[42] Another population-based study was performed in Göteborg, Sweden, to describe the incidence rate of first-time symptomatic UTI in children younger than 6 years old. The cumulative incidence rate during the first 6 years of life was 6.6 percent for girls and 1.8 percent for boys.[94] The apparent increase in risk most likely relates to an increased awareness of the diagnosis of UTI as an explanation for fever in children and the more frequent practice of culturing the urine of children who are ill.

Several studies have investigated systematically the prevalence of UTI as the explanation for fever in febrile young children presenting to the emergency department. Although the definition of significant bacteriuria has varied among studies, the overall prevalence of UTI is 3.3 to 5.3 percent.[52,128] White infant girls had significantly more UTIs than did black boy infants. Higher prevalences occurred in uncircumcised boys or boys with abdominal or suprapubic tenderness on examination.[128] White girls with a temperature of 39º C or greater had a prevalence of UTIs of 17 percent.[52] In a large prospective study of febrile (temperature ≥38º C) infants 3 months or younger evaluated in pediatric office settings, 54 percent of infants had urine tested, and 10 percent had UTIs.[99]

RISK FACTORS FOR URINARY TRACT INFECTION

Uncircumcised Boys

The common problem of UTIs in uncircumcised boys, although suspected in the 1970s, was first documented in the 1980s by Ginsburg and McCracken.[35] The strongest evidence of a causal link between an intact foreskin and a UTI comes from several studies conducted by Wiswell and colleagues.[161] In their series, an overall 10-fold increased incidence of UTI was found in uncircumcised compared with circumcised male infants (1.12% versus 0.11%; $p < .001$).[161] Wiswell and other investigators have continued to document this problem.[123,129,160] Where and when rates of circumcision have decreased, the frequency of UTIs in boys has increased. The presence of preputial folds in uncircumcised boys encourages a high density of bacterial growth and contamination of the urethral opening.[14] Circumcision reduces meatal contamination, decreasing the ascent of bacteria into the bladder.[160] The high risk of acquiring UTIs in uncircumcised boys diminishes with age (as the foreskin becomes more retractable) but is still present in the toddler age group.[19]

Dysfunctional Voiding

Dysfunctional voiding is a risk factor for the development of a UTI and an occasional consequence of UTI. Dysfunctional voiding refers to a lack of coordination between the two functions that are essential for normal voiding to occur—relaxation of the urethral sphincter and contraction of the detrusor muscle of the bladder. Ordinarily, the sphincter must relax as the detrusor contracts.[5] The failure of the sphincter to relax causes an obstruction to the outflow of urine. Consequently, voiding pressures and intravesicular pressure are high, the bladder becomes overdistended, dribbling instead of a good flow occurs, and residual urine remains in the bladder after the void. This dyscoordination is termed *dyssynergia*.[5]

Clinical manifestations typically appear after toilet training and include incontinence, enuresis, urinary urgency, and UTI.[29] Constipation is a common occurrence because of the inability to relax the pelvic floor musculature. The presence of dysfunctional voiding also may promote the persistence of vesicoureteral reflux (VUR) and lead to recurrence or contralateral reflux after attempts are made at surgical correction of reflux.[72]

Constipation

The distended rectum in constipated children has been suggested to press on the bladder wall and produce an obstruction to bladder outflow that may cause dysfunctional voiding. Urodynamic studies have shown instability of the detrusor muscle in patients with functional constipation and associated enuresis or UTI.[162] Loening-Baucke[86] studied a group of children referred with encopresis and constipation. The history indicated that many were incontinent of urine, and 11 percent had histories of UTIs. When a vigorous regimen to alleviate the constipation was prescribed, a dramatic improvement occurred in the enuresis and the frequency of recurrent UTI.

Wan and colleagues[151] prospectively evaluated the toilet habits of 77 girls and 24 boys diagnosed with UTIs. Parents were instructed to use a "toilet diary" to record the frequency of voiding and stooling. An abnormal voiding habit was defined as infrequent urination (four times or fewer daily when awake), an abnormal voiding pattern (>4 hours between voidings), or the practice of avoidance maneuvers (repetitive habitual squirming, crossing of legs, or sitting on heels).[149] Constipation was defined as stooling less frequently than every third day. Children with and without abnormal imaging studies were compared. Although abnormal voiding patterns and constipation were identified in both groups, only 10 percent of children with normal images were without constipation or abnormal voiding compared with 60 percent of the group with abnormal images ($p = .0001$). These data strongly suggest that evaluation of children with UTIs should include inquiry into these functional matters, especially when imaging study results are normal.

Sexual Activity

The well-recognized association in women of acute cystitis with sexual intercourse is reflected in the popular, now perhaps outdated, term *honeymoon cystitis*.[101] This phenomenon usually is related to the new onset of sexual activity or a recent change in sexual partners. A novel study of 15 patients with a history of recurrent UTIs involved daily monitoring for the presence of UTI with dipslides and calendars that recorded episodes of intercourse, menses, and the occurrence of symptoms.[101] Eleven patients experienced 16 infections; 12 infections occurred within 24 hours of engaging in intercourse. In 12 control subjects, three infections occurred, all within 24 hours of having intercourse. The authors concluded that in sexually active women, most UTIs are related to intercourse.

These results were reinforced by a large prospective study from Seattle, Washington, which confirmed that the incidence of symptomatic UTI is high in sexually active young women and that a strong and independent association exists between UTI and recent sexual intercourse, recent use of a diaphragm with spermicide, and a history of recurrent UTIs.[59] Most of these same risk factors, including frequency of sexual intercourse and use of spermicide, were documented as risk factors associated with development of APN in healthy women.[124]

Catheters

In the hospital, urinary catheters are major risk factors for acquisition of nosocomial infection. In adults, the risk of developing an infection is approximately 5 percent per day of catheterization.[100] The usual infecting strains include *Escherichia coli*, *Proteus*, *Pseudomonas*, *Klebsiella*, and *Serratia*. Many strains of bacteria that cause infection display antibiotic susceptibilities that are more resistant than usual. The route of infection may be either intraluminal or periurethral. Bacteremia is an unusual complication of nosocomial UTI. In a study of nosocomial infections in a children's hospital, catheter-associated UTI accounted for 48 percent of the UTIs. Secondary bacteremia occurred rarely, with an incidence of 2.9 percent.[21]

PATHOGENESIS

BACTERIOLOGY

Most uncomplicated UTIs are caused by members of a large family of gram-negative bacteria known as Enterobacteriaceae. In most instances, the urinary tract becomes infected by the ascending route. Bacteria derived from the fecal flora colonize the periurethral area and gain access to the urethra. The most common bacterial species in primary and recurrent infections is *E. coli*. Other gram-negative species that commonly cause UTI are *Klebsiella*, *Proteus*, *Enterobacter*, and *Citrobacter*, although virtually any enteric organism can cause UTI. Gram-positive bacterial species account for approximately 5 percent of UTIs and primarily include *Staphylococcus saprophyticus* and enterococcal species. After *E. coli*, *S. saprophyticus* is the most common cause of uncomplicated UTIs in teenagers and young adults of both sexes.

Rarely, the urinary tract may become infected hematogenously in the course of a bacteremic infection. This mechanism is thought to account for at least some cases of neonatal UTI. Increasingly, evidence indicates that even in neonates, most infections occur by the ascending route.

VIRULENCE FACTORS

The key virulence factor for isolates of *E. coli* is the mechanism by which they attach or adhere to the uroepithelial cell.[62] Bacterial adherence is an essential initiating step in all infections. So-called uropathogenic bacteria, derived from the numerous species found in the fecal flora, can attach to specific receptor sites on the uroepithelium and can bind in a nonspecific manner by electrostatic and hydrophobic bonds.[118] A principal means of attachment is through adhesins localized on specialized pili of the *E. coli*. These pili are referred to as *P fimbriae* because they can recognize and agglutinate erythrocytes of the P1 blood group; this P blood group antigen also is present on human uroepithelial cells.

Evidence to support the notion of the increased pathogenicity or virulence of the P fimbriae comes from studies of *E. coli* recovered from children with infection at different levels of the urinary tract. When *E. coli* strains recovered from patients with

pyelonephritis are examined, 76 to 94 percent are P fimbriated; in contrast, strains of *E. coli* recovered from patients with cystitis or asymptomatic bacteriuria are 19 to 23 percent and 14 to 18 percent P fimbriated, respectively.[69,147] Although P fimbriated strains of *E. coli* are common findings in patients with pyelonephritis whose urinary tracts are completely normal, their frequency decreases considerably when strains of *E. coli* are examined from patients with pyelonephritis associated with VUR. Apparently, this virulence characteristic (and others described later) is unnecessary when reflux is present.[89]

The principal adhesin on the tip of the P fimbriae that fosters adherence to the uroepithelial cell is known as the *PapG adhesin*. More recently, 153 *E. coli* organisms recovered from the urinary tracts of infants and children with pyelonephritis were analyzed by polymerase chain reaction for class I, II, and III alleles of the pyelonephritis-associated adhesin gene *papG*. Strains with any class II *papG* alleles were found significantly more often in infants with normal anatomy and function or in infants with clinically insignificant abnormalities than in infants with significant abnormalities (90 of 119 versus 14 of 34 infants; $p < .001$).[63] This virulence factor is more important when the urinary tract is structurally normal than when anatomic features predispose the individual to infection.

Other virulence factors related to the bacterial species causing UTIs are the K antigen, lipopolysaccharides, hemolysins, colicins, resistance to the bactericidal action of serum, and increased iron-binding capacity. In addition to the immunogenic activity of lipopolysaccharides (activating an intense host response), they have been shown to have direct toxic effects on renal cells via their biologically active component lipid A.[144] The K antigen is a capsular polysaccharide that constitutes an outer surface of the *E. coli* organism. The capsule has the capacity to impede phagocytosis and to shield the bacteria from lysis induced by complement.[60] Hemolysins are cytotoxic proteins that can damage renal tubular cells in vitro.

Approximately 50 percent of the types of *E. coli* isolated from the urine of patients with APN produce a pore-forming toxin, alpha-hemolysin. Alpha-hemolysin damages the cell membrane and may activate apoptosis in renal tubular cells.[16] Colicins, elaborated by "uropathogenic" strains of *E. coli*, kill other bacteria that are in their vicinity. In the presence of human serum, many bacteria are killed after activation of complement. Virulent *E. coli* organisms have the capacity to resist this bactericidal effect of serum. Another virulence factor found in bacteria is their ability to acquire and bind iron. Most bacteria require iron for optimal growth and metabolism and have developed mechanisms to acquire iron when the supply is limited. Increased iron-binding capacity, mediated by proteins such as aerobactin, which are made by some *E. coli* strains, provides additional pathogenic potential.

After reaching the bladder, P fimbriated *E. coli* organisms can colonize the ureter even in the absence of VUR.[116] Bacterial colonization of the ureter affects ureteral peristalsis, leading to dilation and a physiologic obstruction. This dilation of the ureter and calyces favors a change in the shape of the renal papillae, which facilitates intrarenal reflux of colonizing bacteria at low pressure. APN develops because the receptors for the P fimbriated *E. coli* are present in the collecting duct and proximal tubules.[102,116]

Experimental studies conducted by Roberts[116] have led to a theory of the chain of events involved in the process that ultimately leads to renal scarring. The initial event is the inoculation of the renal parenchyma with bacteria, which leads to an intense inflammatory response. Liberation of proinflammatory cytokines (interleukin-1, interleukin-6, and interleukin-8) is followed by recruitment of inflammatory cells and a second cytokine burst.[67] This inflammation results in the release of toxic enzymes within the granulocytes and tubular lumen. Superoxide is released simultaneously, generating oxygen radicals that are toxic to the bacteria and to the tubular cells.[117] The resultant death of the tubules intensifies and extends the inflammatory process into the interstitium. At the same time, focal ischemia results from the intravascular aggregation of granulocytes and edema.[66] The tissue damage that results from the toxic enzymes, oxygen radicals, inflammatory response, and ischemia culminates in the creation of renal scars.[62,116]

CLINICAL PRESENTATION

CYSTITIS

Most children with cystitis present with urgency, frequency, or dysuria. Children who have the urge to urinate may have a history of difficulty in initiating the urinary stream. Occasionally, children may complain of abdominal or suprapubic pain. If fever is present, it is low-grade. Suprapubic tenderness may be present on palpation. The urine may be foul-smelling and cloudy in appearance.

PYELONEPHRITIS

Many children who present with APN have impressive chills, spiking fevers, and complaints of back pain. They may have associated gastrointestinal complaints of vomiting and diarrhea, especially vomiting. Lower urinary tract symptoms, such as frequency, urgency, dysuria, and suprapubic discomfort, may or may not be present.

Other findings, such as irritability, poor feeding, vomiting, decreased urinary output, and clinical evidence of dehydration, vary. The youngest children with APN usually present with high fever without other localizing features.[54,93,164]

PHYSICAL EXAMINATION

Features of the physical examination that should be emphasized include (1) an accurate measurement of blood pressure (hypertension may be present in patients who have chronic renal disease), (2) general growth and development (failure to thrive may be a sign of more chronic or recurrent UTI), and (3) a careful abdominal examination (which might reveal tenderness or a mass caused by either an enlarged bladder or an obstructed urinary tract).[142] An effort should be made to elicit the finding of costovertebral angle tenderness in children of all ages. The perineum should be inspected carefully to search for signs of irritation, scars, tears, signs of trauma, labial adhesions, or evidence of vulvovaginitis. In uncircumcised infants, the foreskin may not be retractable, leading to phimosis. A rectal examination should be considered to detect masses or poor sphincter tone, which might be associated with a neurogenic bladder.[142] The lower back should be observed for any lipoma, sinus, pigmentation, or tufts of hair that may be signs of an occult myelodysplasia.

Neurologic examination of the lower extremities and evaluation of the bulbocavernosal reflex often reflect the neurologic integrity of the lower motor neuron reflex arcs. The bulbocavernosus reflex is elicited by squeezing the glans penis or clitoris and observing or feeling a reflex contraction at the external anal sphincter. Absence of this reflex suggests a possible sacral lesion.[5]

ASYMPTOMATIC BACTERIURIA

A large body of work has been produced dealing with the issue of asymptomatic bacteriuria. Data were accumulated during a

long-term study by Kunin[73] of the natural history of recurrent bacteriuria among school-age girls in a well-defined community in central Virginia. Girls were identified in the first grade and were observed prospectively for 10 years. Each year, approximately 0.5 percent of school-aged girls developed asymptomatic bacteriuria. The overall prevalence was 5 percent for the years between entrance to grade school and graduation from high school. Although it was billed as asymptomatic bacteriuria, approximately one third of the girls did have symptoms, and some were known to have had infection or, rarely, abnormalities of the urinary tract before the first screening.

Just a few years after Kunin[73] began his investigations, a similar study was conducted in Göteborg, Sweden. Beginning in 1970, 19,000 girls a year were screened routinely for bacteriuria in Göteborg schools at ages 7, 11, 14, and 16 years.[84] A significant minority had a history of previous infection or symptoms that were referable to the urinary tract.

Savage and colleagues[120] also studied covert bacteriuria in school-age girls. In the three studies, the prevalence of bacteriuria ranged from 0.7 percent[84] to 1.1 percent[73] to 1.6 percent.[120] The risks associated with asymptomatic bacteriuria are difficult to assess from these studies because patients who were truly asymptomatic were difficult to separate from patients with symptoms.

Several prospective studies of infants and school-aged girls from Scandinavia have provided important information regarding the natural history of asymptomatic bacteriuria.[42,154] Most children identified as having asymptomatic bacteriuria among a large cohort of infants (N = 3581) spontaneously cleared the bacteriuria within months. Only 2 of 45 went on to develop symptomatic bacteriuria. In contrast, none of 42 infants who developed symptomatic UTIs had been identified previously as having asymptomatic bacteriuria, suggesting that asymptomatic bacteriuria rarely is a precursor to symptomatic UTI. In addition, prophylactic antibiotics used to treat children with asymptomatic bacteriuria seemed to predispose them to the development of pyelonephritis, usually with microorganisms that had not been present at the outset.[42]

Currently, physicians have little enthusiasm for screening children of any age to discover the presence of asymptomatic bacteriuria. The absence of pyuria in these specimens of urine provides additional evidence that the host is not perturbed by the presence of asymptomatic bacteriuria. The presence of bacteria of low virulence in the urine in asymptomatic patients seems to be protective. These strains apparently prevent invasion by other bacteria and provide a kind of biologic prophylaxis.[42,70]

Rather than screening asymptomatic populations of children, an appropriate approach is vigorous evaluation for the presence of UTIs in febrile children without an obvious focus of infection. In addition, health maintenance examinations should be used as an opportunity to screen for historical information that might suggest the need to collect a urine specimen for culture (Table 45–1). Important items include frequent episodes of unexplained fever, dribbling when urinating, enuresis, encopresis, constipation, urgency, frequency, and dysuria. In addition, it is valuable to know when toilet training was accomplished; frequency of voiding; frequency of stooling; and any apparent difficulties associated with voiding, such as in initiating the urinary stream. The practitioner also should inquire about so-called avoidance maneuvers (e.g., repetitive habitual squirming, crossing of legs, or sitting on heels)[151] and family history of UTI.

TABLE 45–1 Renal-Focused History and Physical Examination

History
Age of toilet training
Characteristics and frequency of voiding (urgency, dysuria, dribbling)
Frequency and characteristics of stooling
Family history of renal disease
Habitual squirming
Color and odor of urine
Unexplained episodes of fever
Physical Examination
Temperature
Blood pressure
Abdominal tenderness
Costovertebral angle tenderness
Suprapubic tenderness
Genital examination (irritation, scars, tears)
Rectal examination (sphincter tone, bulbocavernosus reflex)
Lower back (sinus, pigmentation, lipoma, tufts of hair)

DIFFERENTIAL DIAGNOSIS

INFECTIOUS

E. coli is the most common cause of infection in the urinary tract for primary infections (in which *E. coli* causes 85 to 90% of infections) and recurrent infections (in which *E. coli* causes approximately 75% of infections). Virtually any other gram-negative enteric bacteria may cause infection. Common etiologic agents include *Klebsiella*, *Proteus*, *Enterobacter*, *Serratia*, and *Pseudomonas*. *Proteus mirabilis* is a common cause of UTIs in some series of boys and in nosocomial UTIs associated with catheterization.[71,105] In young women, *S. saprophyticus* is second only to *E. coli* as a cause of cystitis. Rarely, *Staphylococcus epidermidis* has been reported as a cause of pyelonephritis in young boys with anatomic abnormalities of the urinary tract.[40]

In the context of bacteremia or septicemia, occasionally the blood culture and the urine culture are positive for the same bacterial species. In these instances, the kidney has been seeded as part of a hematogenous dissemination. Any organism that is responsible for sepsis, such as *Haemophilus influenzae* type b, *Neisseria meningitidis*, *Neisseria gonorrhoeae*, *Staphylococcus aureus*, *Streptococcus pneumoniae*, or *Streptococcus pyogenes*, may be found in the urine.

Anaerobic infections of the urinary tract are rare occurrences in children despite the high density of gram-positive and gram-negative anaerobes in the fecal flora; this fact relates to the probable lack of adherence of these bacterial species to the uroepithelium. Anaerobic infections of the urinary tract should be suspected when organisms are seen on Gram stain but do not grow in conventional culture, or when the urine of symptomatic children shows no bacterial growth.[13] Another unusual infecting agent that should be suspected in instances in which the Gram stain of the urine shows gram-negative rods but the urine culture is negative is *H. influenzae*.[97]

Fungal infections of the urinary tract usually are caused by *Candida* spp., but they also may be caused by *Cryptococcus neoformans*, *Aspergillus* spp., and the endemic mycoses.[139] Candiduria is an increasingly common form of nosocomial infection that may involve any level of the urinary tract.[50,109] It often occurs in immunosuppressed patients, especially patients who are receiving broad-spectrum antibiotics for treatment of documented or undocumented systemic infections. In many immunosuppressed patients, the infection is complicated by the presence of an indwelling urinary catheter.

Viruses also may cause infection of the urinary tract. For the most part, these infections involve the bladder rather than the kidney, although infection of any part of the urinary tract may occur. The principal etiologic agents are adenoviruses, enteroviruses, coxsackieviruses, and echoviruses. Mumps virus and hepatitis viruses occasionally have been implicated. Type 11 adenovirus has been the most common cause of acute

hemorrhagic cystitis in school-age boys; type 21 also has been documented to be a cause of infection in this age group. In immunosuppressed patients, especially children who have undergone bone marrow transplantation or are recipients of kidney transplants, BK polyomavirus and adenovirus may cause hemorrhagic cystitis.[17,81]

Granulomatous cystitis is the histopathologic description of cystitis caused by *Mycobacterium tuberculosis* and by schistosomiasis and other parasitic infections. Granulomata formed in response to certain parasites, such as *Toxocara* and microfilariae, also may contain numerous eosinophils. *Enterobius vermicularis* infection occasionally leads to signs and symptoms of cystitis and inflammatory changes of the bladder wall.

Xanthogranulomatous pyelonephritis is a rare, chronic, suppurative renal infection. Although it can occur at any age, it typically involves middle-aged women. Cases in children have been reported across all age groups, including infants.[1,114] The patient usually presents with what appears to be an acute UTI, caused most often by *E. coli* or *Proteus* spp. Evaluation of the patient usually reveals a unilateral enlargement of the kidney, often accompanied by urolithiasis and sometimes a staghorn calculus. The differential diagnosis of the mass lesion includes neuroblastoma, Wilms tumor, tuberculosis, and renal carcinoma. The lesion is characterized histologically by granulomata, abscesses, and lipid-laden foam cells. Nephrectomy is the usual means of management.

Infectious urethritis caused by *N. gonorrhoeae* or *Chlamydia trachomatis* is a common cause of symptoms suggestive of UTI. In addition, any etiologic agents of vulvovaginitis may cause inflammation of the distal urethra, with urgency, frequency, or dysuria; they include *Candida* spp., *Gardnerella vaginalis*, *Trichomonas vaginalis*, *S. pyogenes*, *S. pneumoniae*, *H. influenzae*, *C. trachomatis*, *Shigella* spp., and *Yersinia enterocolitica*.

NONINFECTIOUS

Urethral symptoms, such as urgency, frequency, and dysuria, may be caused by any factor or process that gives rise to inflammation in the lower urinary tract. Examples include mechanical irritation (which might result from insertion of foreign bodies, migration of pinworms, or masturbation) and chemical irritation (which might arise from bubble baths or shampoos). Chemical cystitis has been reported from the inadvertent insertion of a vaginal contraceptive suppository (nonoxinol 9) into the bladder. Pharmacologic causes of urethral symptoms include cyclophosphamide and methenamine mandelate, both of which can lead to inflammatory changes in the urinary bladder. Several other agents used in the topical treatment of bladder cancer have been noted to cause cystitis.

SPECIFIC DIAGNOSIS

COLLECTION OF A URINE SPECIMEN

Proper collection of a urine specimen is crucial to facilitate interpretation of the culture. In toilet-trained children, a midstream clean-catch specimen is appropriate for evaluation. When this specimen is used, the definition of significant bacteriuria is 10^5 colony-forming units (CFU)/mL or more. The child is asked to void into the toilet. Straddling the commode in a reverse position creates a natural separation between the urethra and the vulva. Cleansing of the perineum does not result in less contamination of the specimen and is no longer encouraged.[122] The child is asked to begin voiding. A second or two after the void has been initiated, a sterile cup is passed into the stream. The hope is that the initial void succeeds in washing out the distal urethra, the site from which the urine specimen is most likely to be contaminated.

If the child is not toilet-trained, a specimen may be collected by urethral catheterization or suprapubic aspiration. When the urine is collected by urethral catheterization, the perineum is cleaned with 1 percent iodine. A properly sized catheter (10 or 12 French) or a size 5 feeding tube may be used. The catheter is lubricated and inserted into the urethra and threaded a short distance. The first few drops of urine should not be collected in the sterile container. This part of the specimen is the most likely to be contaminated with fecal flora from the distal urethra; these bacteria are not eliminated by the process of perineal cleansing. The remaining urine is collected in a sterile container and sent to the laboratory. When a urine specimen is collected by urethral catheterization, significant bacteriuria is defined as 50,000 CFU/mL or more.[57] This method is preferred when a small volume of urine in the bladder is anticipated and collecting a specimen of urine is necessary so that antibiotics can be initiated.

An alternative to urethral catheterization is suprapubic aspiration. Although some physicians might contend that catheterization is less traumatic than suprapubic aspiration,[142] little evidence supports this notion. The procedure can be done in children of any age; it has been used to obtain specimens of urine in pregnancy.[96] Urine culture specimens obtained by suprapubic aspiration are easy to interpret because the usual source of contamination, the distal urethra, has been bypassed. The presence of any bacteria in a specimen collected by suprapubic aspiration is significant, although most samples contain 10^5 CFU/mL or more.

The patient is in a supine position with the lower extremities flexed (Fig. 45–1 and Table 45–2). The suprapubic area is cleaned with iodine and alcohol. The symphysis pubis is located with the index finger. A 3-mL syringe is attached to a 1½-inch, 22-gauge needle. A spinal needle (21-gauge, 2½- or 3-inch) can be used in older patients. The needle is passed in the midline about 1.5 cm above the symphysis pubis. It is angled about 10 to 20 degrees from the vertical, pointing in a slightly cephalad direction (Fig. 45–2). Negative pressure is applied while the needle is inserted. The procedure is most likely to be successful when the infant can be encouraged to drink and the diaper has been dry for at least 60 minutes before the procedure is done. The success rate of suprapubic aspiration can be improved with the use of a portable ultrasound device.[36] If the suprapubic aspiration is unsuccessful,

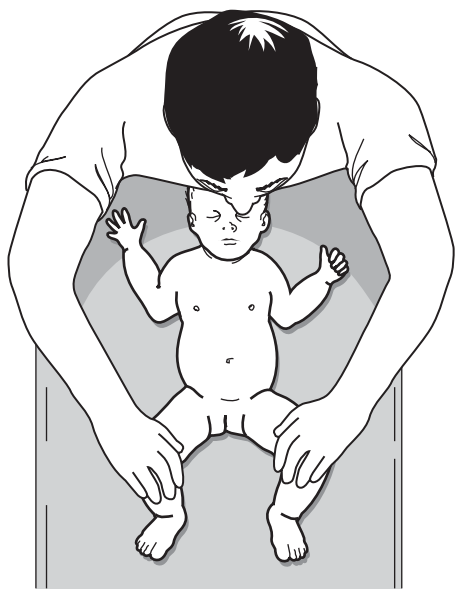

Figure 45–1 Suprapubic aspiration technique, position of patient.

TABLE 45–2 Suprapubic Aspiration Technique

Step 1	Child should not have voided within 1 hr of the procedure
Step 2	Restrain the infant in a supine, frog leg position
Step 3	Clean the suprapubic area with povidone-iodine and alcohol
Step 4	Identify the site of puncture at 1-2 cm above the symphysis pubis in the midline
Step 5	Use a 22-gauge, 1½-inch needle (with 3-mL syringe attached to it) and puncture at 10- to 20-degree angle of the true vertical aiming cephalad; a second attempt can be made at a similar angle aiming caudad
Step 6	Exert suction gently as the needle is advanced until urine enters syringe; aspirate urine with gentle suction. If urine is not obtained, further trials are unlikely to be successful

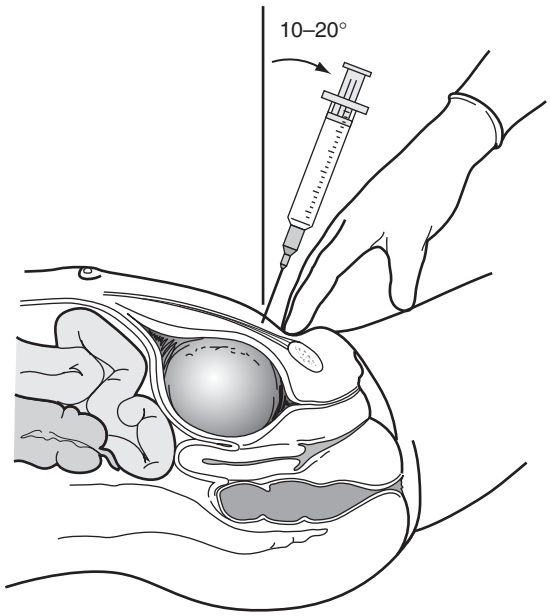

Figure 45–2 Suprapubic aspiration technique, position of needle.

a catheterized specimen should be obtained. Complications of suprapubic aspiration are rare and include formation of a hematoma, perforation of the bowel, and formation of a suprapubic abscess.[111] Suprapubic aspiration is contraindicated if the patient has a bleeding diathesis.

The last method of urine collection is the bag technique. The perineum is washed with soap and water and allowed to dry. A sterile plastic bag is attached. The bag is removed as soon as the patient voids. If the patient has not voided in 20 minutes, the bag is removed, the perineum is cleaned again, and a new bag is attached. If this procedure is followed meticulously, a reasonable specimen can be collected. This specimen is susceptible to contamination from periurethral flora,[121] however, and the technique is not recommended if the patient appears ill and antibiotics need to be started immediately after the specimen of urine is collected. The results of the culture of a bagged specimen are useful only if they are negative. If the culture is positive, a second specimen must be collected by a more reliable method.[3]

DIAGNOSIS OF URINARY TRACT INFECTION

The diagnosis of UTI hinges on the results of culture of a properly collected urine specimen. Disagreement within the literature is substantial regarding the definition of significant bacteriuria.[38] As indicated in the previous section, the definition of UTI varies according to the method by which the urine is collected. This variability in definition acknowledges that although the bladder urine is regarded as a sterile body fluid, contamination of the urine specimen may occur as it passes through the urethra. The distal urethra frequently is colonized with coliforms derived from the gastrointestinal tract. The only urine specimen that bypasses the urethra and is free of contamination is obtained by suprapubic aspiration. When a specimen is collected by this technique, any colony count of coliforms is significant.[164]

TABLE 45–3 Urinary Tract Infection—Definitions

Method of Collection	Colony Count (CFU/mL)
Clean catch	$\geq 10^5$
Catheter	$\geq 5 \times 10^4$
Suprapubic	Any

CFU, colony-forming unit.

In urine that is collected by a midstream clean-catch method, significant bacteriuria is defined, most stringently, by the recovery of 100,000 CFU/mL or more (Table 45–3). For specimens of urine obtained by catheter, significant bacteriuria is defined as 50,000 CFU/mL or more. In each of these instances, physicians recognize that although urine specimens containing lower colony counts rarely may represent true infection, for the most part, lower colony counts usually are the result of contamination of the specimen.[57]

Specimens of urine usually are inoculated onto two different kinds of solid media—one that supports the growth of only gram-negative enteric bacteria (e.g., MacConkey agar) and another that supports gram-positive and gram-negative bacteria (e.g., 5 percent sheep blood agar), with use of a 0.001 calibrated loop. Colonies are counted the next day (18 hours later), and the total is multiplied by 1000 to determine the colony count. The results of the urine culture are unavailable during the practitioner's first encounter with the ill child. Consequently, there is great interest in the development of a method that would predict the results of the urine culture so that appropriate antimicrobial therapy could be initiated presumptively at the time of the initial encounter. Microscopic methods (to evaluate pyuria and bacteriuria) and biochemical tests (which can be evaluated with a dipstick) have been evaluated.

Microscopy

Two surrogate markers for UTI on microscopic assessment are pyuria and bacteriuria. A problem in assessing pyuria and bacteriuria has been the issue of the definition of significant microscopic pyuria and bacteriuria. How many white blood cells (WBCs) in the urine are too many? Should the specimen of urine that is examined be centrifuged or uncentrifuged? How should the WBCs in a specimen of urine be enumerated? Should the number of WBCs on a centrifuged specimen be enumerated as the number per high-power field, or should they be enumerated on a counting chamber as the number of cells per cubic millimeter, as they would be in a sample of cerebrospinal fluid? If the urine is centrifuged, additional variables are introduced: the initial volume of urine, the duration of the spin, and the volume of urine used to resuspend the sediment. All of these variables influence substantially the enumeration of WBCs per high-power field, especially the volume used to resuspend the sediment.

Methods to assess bacteriuria also have raised issues of definition. Should bacteriuria be assessed on a centrifuged specimen or an uncentrifuged specimen, and should the bacteria be evaluated

on a wet mount or a Gram-stained specimen? Should bacteria be enumerated as the number per high-power field?

The standard definition of pyuria in the pediatric literature has been 5 WBCs per high-power field on a centrifuged specimen. Traditionally, microscopic bacteriuria has been expressed as the number of bacteria per high-power field on a Gram stain of a centrifuged specimen of urine. Several investigations undertaken by Hoberman and colleagues[56] have shown, however, that a so-called enhanced urinalysis has greater sensitivity, specificity, and positive predictive value than the standard urinalysis. An enhanced urinalysis is performed on an uncentrifuged sample of urine that has been obtained by catheter. The urine is placed on a counting chamber, and the cells are enumerated as the number per cubic millimeter. A Gram stain is performed in a manner that standardizes the number of drops of urine that are assessed and the number of oil immersion fields that are reviewed.

An enhanced urinalysis is considered to be positive when 10 WBCs/mm^3 or more are present and at least one gram-negative rod in 10 oil immersion fields is present. This definition of significant pyuria is much more sensitive than were previous definitions, and it has performed well for numerous investigators and in neonates and in older infants.[49,82,84,164] A systematic review of the existing literature to assess the performance of rapid diagnostic tests for UTI concluded that use of the traditional definition of pyuria (>5 WBCs per high-power field on a centrifuged specimen) is sufficiently poor that it cannot be recommended for making a presumptive diagnosis of UTI.[38] Huicho and coworkers[61] also performed a meta-analysis of urine screening tests to determine the risk of UTI in children. This more recent study concluded that pyuria of at least 10 WBCs/mm^3 and bacteriuria are best suited for assessing the risk of UTIs in children.

Automated methods to perform urinalysis are being used in many hospitals and laboratories. The most updated automated image-based urinalysis system, the iQ200 (Iris Diagnostics, Chatsworth, CA) received clearance from the Food and Drug Administration more recently. The system uses flow imaging analysis technology and so-called Auto Particle Recognition (APR; Iris Diagnostics) software to classify particles found in an uncentrifuged urine specimen based on multiple parameters. Images are stored and can be viewed later on the workstation screen, eliminating the need for manual microscopy in most cases.[148] The iQ200 provides for a rapid turn-around time, and results correlate well with manual methods, especially for red blood cells, WBCs, and squamous epithelial cells.[74,85]

Pyuria is not specific for UTI. In numerous other conditions, including fever, streptococcal infections, and Kawasaki disease, and after exercise, WBCs are found in the urine. Finding pyuria does not ensure that an infection of the urinary tract is present. Despite reports to the contrary, finding true UTI without pyuria is unusual.[150] Generally, inflammation is expected to accompany infection. The absence of pyuria in children with UTIs is rare; it may occur when a child is being evaluated so early in the clinical course of the infection that the inflammatory response has not yet developed. It also may occur when a child is experiencing an episode of asymptomatic bacteriuria.

The most likely explanation for significant bacteriuria by culture in the absence of pyuria is a contaminated specimen. In most cases when UTI has been reported to occur in the absence of pyuria, the definition of pyuria has been at fault. The requirement for 5 WBCs per high-power field on a centrifuged specimen corresponds to approximately 25 WBCs/mm^3; it is too stringent a requirement, with a low sensitivity for the detection of UTIs in infants and children.

Urine Dipsticks

Urine dipsticks (or reagent strips) have been used to indicate the presence of leukocyte esterase (as a surrogate marker for pyuria) and urinary nitrite (which is converted from dietary nitrates by the presence of gram-negative bacteria in the urine). The conversion of dietary nitrates to nitrites by bacteria takes approximately 4 hours. The test result is most likely to be positive when the urine tested is the first morning void (representing a urine that has incubated in the bladder overnight) or a urine that has been in the bladder for at least 4 hours (e.g., obtained from an older child who may hold urine in the bladder for several hours at a time).

The performance characteristics of leukocyte esterase and nitrites vary according to the definition used for a positive urine culture, the age and symptoms of the population being studied, and the method of urine collection. A nitrite test, although not a sensitive marker in children, is helpful when the result is positive because it is highly specific. A negative nitrite test result has little value in ruling out UTI, however.[25] The leukocyte esterase test has an average sensitivity of 83 percent.[26] It can have a sensitivity of 94 percent in settings in which UTIs are suspected clinically and a sensitivity of 52.9 percent when it is performed on febrile children, most of whom do not have a UTI.[57] The specificity of leukocyte esterase (average 72%; range 64 to 92%) generally is not as good as the sensitivity, reflecting the nonspecificity of pyuria in general. A positive leukocyte esterase test result should be interpreted with caution, depending largely on the population being evaluated.[25]

DETERMINING THE SITE OF INFECTION

Urinalysis is useful for detecting infection but not for determining the location of the infection within the urinary tract (i.e., upper tract versus lower tract). To determine the site of infection (i.e., kidney versus bladder), many investigations of the discriminatory ability of C-reactive protein, erythrocyte sedimentation rate, and total peripheral WBCs have been performed. Several studies have evaluated the accuracy of procalcitonin levels compared with C-reactive protein levels to predict renal involvement among children with febrile UTIs.[8,34,107,112,138] These studies showed that serum procalcitonin concentrations, measured with either an immunoluminetric quantitative test or a rapid semiquantitative test, diagnosed APN with a sensitivity of 70.3 to 94.1 percent and a specificity of 82.6 to 93.6 percent. The specificity of procalcitonin was always higher than that of C-reactive protein, and a highly significant correlation was noted between elevated procalcitonin levels and severity of renal involvement as measured by dimercaptosuccinic acid (DMSA) scintigraphic scores.[107]

IMAGING

The current standard of care is to perform imaging procedures on children with a diagnosis of UTI. The categories of children for whom imaging generally is recommended are (1) any child who experiences an episode of APN, (2) boys of any age with a first UTI, (3) girls younger than 3 years old with a first UTI, (4) girls older than 3 years of age with a second UTI, and (5) girls older than 3 years old with a first UTI if an extenuating circumstance exists (Table 45–4). The extenuating circumstances include a family history of renal disease, recognition of abnormal voiding patterns, poor growth, hypertension, known abnormalities of the urinary tract, and failure to respond promptly to therapy. The imaging studies that usually are considered are renal ultrasonography, contrast voiding cystourethrography (VCUG) to detect VUR, renal cortical scintigraphy, and magnetic resonance imaging (MRI).

TABLE 45–4 Indications for Imaging Procedures in Children with Urinary Tract Infection

Any episode of acute pyelonephritis
Boys with first UTI
Girls <3 years old with first UTI
Girls ≥3 years old with second UTI
Girls ≥3 years old with first UTI if
Positive family history
Abnormal voiding patterns
Poor growth
Hypertension
Abnormalities of urinary tract
Failure to respond promptly to treatment

UTI, urinary tract infection.

RENAL ULTRASONOGRAPHY

The renal ultrasound examination has replaced completely intravenous pyelography as a means to assess the gross anatomy of the urinary tract. Generally, ultrasonography has been performed promptly after diagnosis of the UTI has been made. It is a noninvasive test that can describe the size and shape of the urinary tract, the presence of duplication and dilations of the ureters, the presence of ureteroceles, and the existence of gross anatomic abnormalities such as a horseshoe kidney.[3] It is not sensitive enough, however, to signal consistently the presence of hydronephrosis, hydroureter, VUR, or renal scarring.[30] When ultrasonography was compared with intravenous pyelography for the detection of renal scars, wide interobserver variations were noted, with sensitivity ranging from 40 to 90 percent.[42]

Some investigators have questioned whether routine performance of renal ultrasonography is essential.[54] Given the current frequency with which fetal ultrasound examinations are performed during gestation, the likelihood that ultrasonography would disclose information that is not already known is small. In a study of 306 children younger than 2 years old with UTIs, only 1 child had a clinically important finding discovered by the routine performance of renal ultrasonography.[55] In a more recent study of 255 children younger than 5 years old with a first diagnosed uncomplicated febrile UTI, abnormalities were found on ultrasonography in 14 percent of patients; in none of these patients did the ultrasonography findings influence management.[163]

Most obstructions of the urinary tract are diagnosed in utero. Selective performance of renal ultrasonography is recommended for children with UTIs who do not respond promptly to antibiotic therapy (i.e., have persistent fever or abdominal findings) and in children who did not have a prenatal ultrasound examination performed beyond 30 weeks of gestation at a reliable center.

RENAL SCINTIGRAPHY

In patients with presumed APN, renal scintigraphy with Tc 99m DMSA or Tc 99m glucoheptonate has been shown to be the most practical and reliable method for detecting APN.[126] DMSA and glucoheptonate are amino acids that are cleared by the renal tubules. When these amino acids are labeled with technetium and injected intravenously, they can be used to create an image of the kidney, which reflects vascular flow and tubular function (Fig. 45–3). In experimentally induced APN in piglets, the DMSA scan had a sensitivity of 87 percent and a specificity of 100 percent in showing lesions consistent with APN compared with histology as the gold standard.[119]

In most patients with APN, renal scintigraphy performed during the acute phase of the illness shows a decreased uptake of DMSA (Fig. 45–4). High-resolution pinhole images of the kidney reveal focal, multifocal, or diffuse areas of decreased uptake of isotope in the kidney without loss of volume and with maintenance of the contour of the kidney.[126] DMSA renal scintigraphy can be used to localize the level at which the urinary tract is infected, specifically distinguishing between acute cystitis and

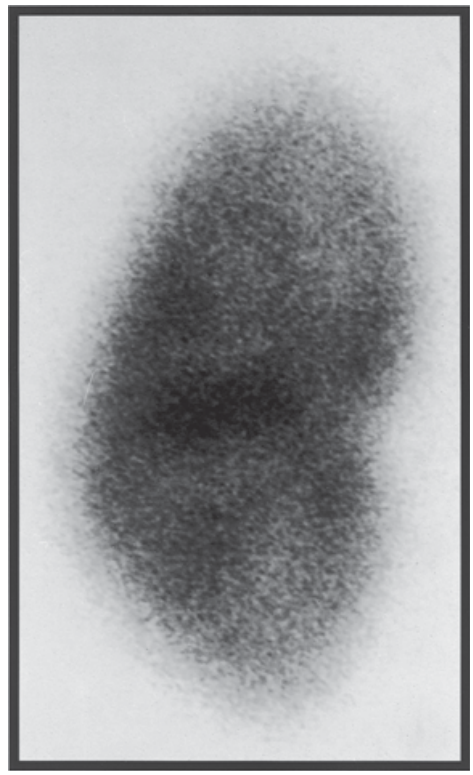

Figure 45–3 Normal renal scintigram.

Figure 45–5 Scintigram showing a renal scar with loss of the normal contour.

APN with a sensitivity of slightly less than 90 percent. Rarely, a patient may present with classic signs and symptoms of APN in whom renal scintigraphy does not show the usual findings.[32]

The DMSA and glucoheptonate scans also can be used to indicate the presence of renal scars that result from an episode of APN. The scar is indicated by an area in which uptake of the radioisotope is decreased (Fig. 45–5). In this case, the contour of the kidney is not preserved. Scarring also may be indicated by an overall reduction of the size of the kidney. Hoberman and colleagues[53] prospectively evaluated 309 children who were 1 to 24 months old with their first febrile UTI. An initial DMSA scan was performed on all children and showed that 61 percent (190 of 309) had findings compatible with APN, and only 1 child had evidence of previous scars. Repeated scintigraphic scanning was done 6 months after entry in 89 percent to detect renal scarring. A small percentage of renal parenchymal involvement (mean 8.2%) was noted in 9.6 percent of the children. All children whose initial scans were normal had normal scans at follow-up.

DMSA scintigraphy has been suggested as the preferred imaging study to evaluate a child with a first febrile UTI rather than ultrasound or VCUG.[41,46] A strategy to perform VCUG only in patients with an abnormal DMSA scan has been proposed.[41] The rationale is based on the rarity of renal scarring when the initial DMSA is normal. Reflux definitely may be present, however, when DMSA scans are normal (30 of 99 in Hoberman's data).[53] Absence of scarring may be attributable to the effect of prophylactic antibiotics. Renal scintigraphy is the most sensitive study to indicate the presence of small renal scars that may occur after APN.

MAGNETIC RESONANCE IMAGING

MRI can be used to detect the presence of APN. Two studies by Lonergan and colleagues[91,108] showed a sensitivity and a specificity of MRI that are equal to and perhaps even greater than those of renal scintigraphy with DMSA. In both instances, the best pulse sequence to show areas of APN with MRI was gadolinium-enhanced, fast spin-echo inversion recovery. These results have been confirmed by others.[78] Several investigators have urged, however, that MRI not become a screening test for children with UTIs until the detection of minor changes in the renal parenchyma (by either DMSA or MRI) has been proved to be of clinical importance.[78,90] The time and sedation requirements for MRI render it an unattractive choice for routine management.

VOIDING CYSTOURETHROGRAPHY

Two types of cystography are available for the diagnosis of VUR—fluoroscopic contrast VCUG and radionuclide cystography. Contrast VCUG has excellent anatomic resolution and provides detailed images of the bladder and the urethra. It can be used specifically to label the degree of reflux (according to the international classification);[75] to look for trabeculations, diverticula, or ureteroceles of the bladder; and to outline the urethra (which is essential to identify posterior urethral valves causing obstruction). Radionuclide cystography provides less anatomic detail and is most useful when urethral disease is not suspected and when the patient has no history of voiding dysfunction. It is used to observe patients who are known to have reflux (to assess whether reflux is still present) and can be used for screening purposes in siblings of children with reflux and in children of adults known to have had reflux. Compared with conventional contrast VCUG, the amount of radiation exposure is reduced substantially when the radioisotope is used.

The international classification of reflux is a universally used system involving five degrees of reflux.[75] Grade I is reflux into the distal ureter; grade II is reflux into the pelvis; and grades III, IV, and V are reflux with mild, moderate, and severe dilation of the pelvis and calyces (Fig. 45–6).

VCUG is performed on children who have experienced a symptomatic UTI to determine the presence of VUR. Children who have VUR are at risk for developing reflux nephropathy—permanent renal damage secondary to the reflux of infected urine into the kidney. Because reflux often resolves spontaneously over the course of several years, the purpose of identifying a child with VUR is to recommend antibiotic prophylaxis until the reflux either has resolved spontaneously or, in cases of high degrees of reflux, has been corrected surgically.

Although imaging of children with UTI is routine, little evidence exists that diagnostic imaging of children after their first UTI results in prevention of renal scarring, hypertension, or renal failure.[23] In a systematic overview of the literature using the MEDLINE database, no controlled trials or analytic studies evaluating or comparing different management strategies with regard to imaging were discovered.[23] If studies can show with certainty that antibiotic prophylaxis to prevent UTIs in children with VUR is superior to placebo in the prevention of renal scarring, the necessity and importance of performing VCUG would be established. Such a study was funded by the National Institutes of Health to begin in 2007[39a] (see the section on management of VUR).

TREATMENT

ANTIBIOTICS FOR TREATMENT OF ACUTE INFECTION

The treatment of UTI is influenced by the age of the patient, the probable site of infection (cystitis or APN), the degree of toxicity, and the likelihood of adherence to the treatment regimen. Oral antimicrobial therapy is appropriate for children with cystitis and for older children with suspected APN who are neither toxic nor

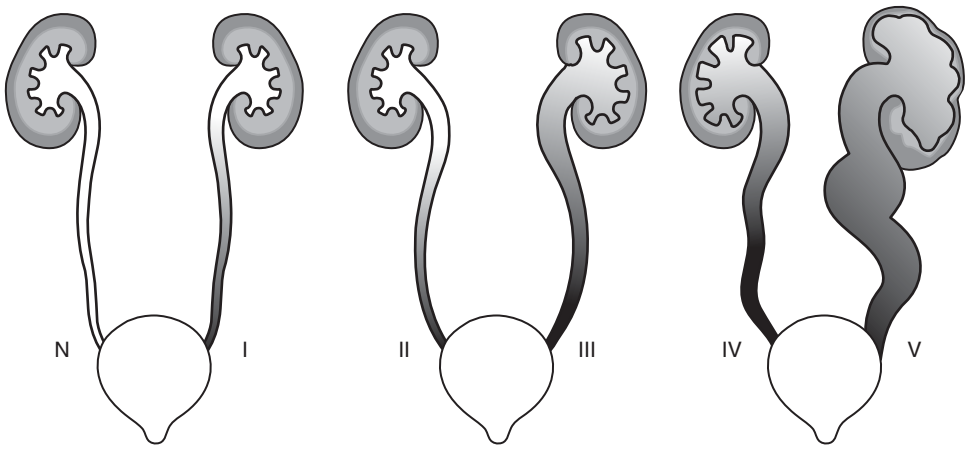

Figure 45–6 Vesicoureteral reflux, international classification.

TABLE 45–5 Antibiotic Treatment

Oral	
Amoxicillin + potassium clavulanate	45 mg/kg/day in 2 divided doses
Cefuroxime	30 mg/kg/day in 2 divided doses
Cefprozil	30 mg/kg/day in 2 divided doses
Cefixime	10 mg/kg/day in 1 dose
Cefpodoxime	9 mg/kg/day in 1 dose
Ceftibuten	10 mg/kg/day in 1 dose
Cefdinir	14 mg/kg/day in 1 dose
Trimethoprim-sulfamethoxazole	10 mg/kg/day (trimethoprim) in 2 divided doses
Parenteral	
Ampicillin + sulbactam	200 mg/kg/day in 4 divided doses
Cefuroxime	150 mg/kg/day in 3 divided doses
Cefotaxime	200 mg/kg/day in 4 divided doses
Ceftriaxone	80 mg/kg/day in 1 dose
Ceftazidime	150 mg/kg/day in 3 divided doses
Cefipime	100 mg/kg/day in 2 divided doses
Gentamicin	7.5 mg/kg/day in 3 divided doses

vomiting. The more complex issue is the management of a young infant with high fever in whom the likely diagnosis is APN. These children traditionally have been admitted to the hospital for parenteral administration of antibiotics.

Numerous choices of oral antimicrobials are available for patients who present with presumed cystitis (Table 45–5). Alternatives include amoxicillin-potassium clavulanate; second-generation cephalosporins, such as cefuroxime and cefprozil; third-generation cephalosporins, such as cefixime, cefpodoxime, ceftibuten, and cefdinir; and the combination agent trimethoprim-sulfamethoxazole. Generally, neither amoxicillin nor first-generation cephalosporins are recommended for first-line therapy because 30 to 50 percent of *E. coli* now are inherently resistant to these agents. Because of some geographic variability in the prevalence of resistance, the practitioner should check with local infectious disease specialists to verify these susceptibility patterns.

In an older patient who appears ill but is not toxic, a repeated visit or telephone follow-up is indicated to ensure that recovery is progressing as predicted. If fever is present, the patient generally becomes afebrile within 1 or 2 days, although occasionally it may take longer. If other indices of recovery, such as general well-being, appetite, and playfulness, are improving appropriately, the persistence of fever is not alarming. If susceptibility test results are available and the organism causing infection is susceptible to the antimicrobial being used, repeating the urine culture after 24 hours is unnecessary.[55] The rapid sterilization of urine is a testimony to the fact that virtually all the antibiotics that are used to treat UTIs are concentrated in the kidney and excreted in the urine.

Duration of treatment for patients who are presumed to have cystitis has been controversial. Conventional recommendations are for 7 to 10 days of antimicrobial therapy. Short courses of therapy, varying from single-dose regimens to 3- or 4-day courses, have been evaluated with mixed results. The potential advantages of short-course therapy include the likelihood of improved adherence to the drug regimen; lower cost of drug; and fewer undesirable side effects, including less alteration of normal flora.[127] A meta-analysis (and the most comprehensive review of the data) was performed by Tran and coworkers[143] after review of 22 published trials and a total of 1279 patients. Amoxicillin in a single dose and trimethoprim-sulfamethoxazole as either a single dose or a 3-day regimen were the short-course regimens most commonly evaluated. The authors found that short-course antimicrobial therapy is less effective than therapy of conventional duration, largely because of the ineffectiveness of single-dose amoxicillin. A 3-day course of trimethoprim-sulfamethoxazole was an effective alternative to the standard course of treatment.

A more recent meta-analysis evaluated 10 trials in 652 children with lower tract UTIs.[58] No significant difference was found in the frequency of positive urine cultures between short-duration (2 to 4 days) and standard-duration (7 to 14 days) oral antibiotic therapy for UTIs in children 1 to 15 months after treatment. In children with clear evidence of cystitis without APN, short-course therapy may be acceptable.[149]

Management of a young infant with presumed APN has been controversial. A study conducted by Hoberman and colleagues[55] compared oral therapy with cefixime (for 14 days) with a combination of intravenous therapy with cefotaxime (for 3 or 4 days) plus oral cefixime for 9 to 10 days. Children were eligible for this study if they were 1 to 24 months of age and presented to the physician with temperature greater than 38.3° C, and were found to have a positive enhanced urinalysis (≥10 WBCs/mm^3 and 1 organism per 10 oil immersion fields). After blood and urine cultures, complete blood count, C-reactive protein determination, and erythrocyte sedimentation rate were performed, the children were randomly assigned to treatment groups. Outcome was evaluated with regard to the short-term measures of sterilization of the urine and time to defervescence and the long-term measures of reinfection and scarring 6 months after the initial infection. No statistically significant differences in any outcome were found.

Bloomfield and colleagues[12] performed a systematic review of the treatment of APN in children. They assessed 18 trials of 2612 children aged 0 to 18 years with proven UTIs and APN. Their results suggested that children with APN could be treated effectively with oral cefixime or with a short course of intravenous therapy followed by oral therapy.[58]

MANAGEMENT OF DYSFUNCTIONAL VOIDING

If a history of dysfunctional voiding is obtained, a behavioral modification approach may be helpful. The key features include frequent volitional voiding every 2 to 3 hours until the voiding pattern has been re-established, increased water intake (1 L/day) in addition to all other fluids consumed, correction of constipation, and adequate perineal hygiene.[28] Referral to a pediatric urologist may be necessary. Children who exhibit persistent inability to relax their sphincters may require training that involves relaxation techniques reinforced with biofeedback. Pharmacologic treatment with anticholinergics may be necessary if uninhibited bladder contractions are shown with urodynamic studies.[28] Special attention must be paid to the management of constipation if anticholinergics are initiated because they would exaggerate the problem.

ANTIBIOTIC PROPHYLAXIS

Although antibiotic prophylaxis commonly is recommended for children with recurrent UTIs,[79] only limited data support this position. In a review of the literature, Le Saux and colleagues[79] found sparse data of low quality to support the use of antibiotic prophylaxis in children with a normal urinary tract. A meta-analysis by Williams and associates[156] revealed five randomized controlled trials assessing the use of prophylactic therapy. Of these, only two trials with 71 children evaluated the effectiveness of long-term, low-dose antibiotics to prevent UTIs.[87,134] The authors concluded that well-designed, randomized, placebo-controlled trials still are required to evaluate this commonly used intervention.

MANAGEMENT OF VESICOURETERAL REFLUX

The clinical significance of VUR as a predisposing factor for UTIs in general or APN in particular and its contribution to the formation of renal scarring have been questioned more recently. As a corollary to the latter, the question also has been framed as to whether long-term antibiotic prophylaxis would prevent renal damage in patients with VUR.[32] The authors concluded that the role of VUR in UTIs needs to be redefined through well-designed, multicenter, prospective, randomized, controlled studies using state-of-the-art renal imaging techniques.

Epidemiology

The incidence of VUR in the general population is thought to be approximately 1 percent.[22] Children usually are tested for the possibility of VUR in one of two clinical situations—during the assessment of prenatally diagnosed hydronephrosis and in the evaluation of a UTI. Reflux is diagnosed in approximately 10 to 20 percent of cases of prenatally identified hydronephrosis; it often is high-grade and occurs more frequently in boys than in girls in this situation.[48,146] The incidence of reflux in girls evaluated after a first UTI is 25 to 40 percent.[26]

An increased incidence of VUR within families suggests a genetic mode of transmission.[68] Rates for prevalence of VUR in identical and fraternal twins were 80 percent and 35 percent, providing evidence that this trait is transmitted in an autosomal dominant fashion. Siblings of children identified to have VUR as part of an evaluation for UTI have a much greater chance of having reflux than the normal population.[4,106] The presence of VUR in these siblings is accompanied by silent renal damage.[15] In addition, a girl who has reflux has a 65 percent risk of having affected offspring.[22] Reflux is much more common among white than black children.

Natural History of Reflux

The natural history of reflux is for spontaneous resolution to occur over time, with a longer period being necessary in more severe types of reflux. Other factors that may affect the rate of resolution include age at diagnosis, gender, unilaterality versus bilaterality, and whether there is dysfunctional voiding. Average figures for spontaneous resolution are 80 to 86 percent for grade II reflux and 40 to 46 percent for grade III reflux during a 5-year period.

In a report from Skoog and associates,[130] spontaneous resolution occurred within 1.65 years of diagnosis in patients with grade II reflux, but 1.97 years was required for resolution in patients with grade III reflux ($p < .04$). Ninety percent of patients with reflux grades between I and III who ultimately had resolution of reflux experienced this result within 5 years. The rate of resolution was approximately 30 to 35 percent per year, although the duration of reflux was shorter for patients in whom the diagnosis was made before they reached 1 year of age compared with patients who were older at the time of diagnosis.[7]

In another study of the natural history of reflux, Schwab and coworkers[125] determined the resolution rate by patient for 179 girls and 35 boys with UTIs and diagnoses of primary VUR between 1981 and 1984. Reflux spontaneously resolved in 68 percent of patients during the study. Grades I to III reflux resolved at a rate of 13 percent per year for the first 5 years of follow-up and then at a rate of 3.5 percent per year during subsequent follow-up. Grades IV and V reflux resolved at a rate of 5 percent per year. Bilateral reflux resolved more slowly than unilateral reflux and more rapidly in boys than in girls. There is no specific age in adolescence at which one can assume reflux will not resolve. Leneghan and colleagues[76] reported cessation of reflux after 14 years of age in 27 percent of patients observed without surgical intervention.

Management of Reflux

The optimal management of children with high grades of reflux (grades III to V) has been the subject of numerous retrospective and prospective studies.[64] Since 1970, two large prospective randomized trials, the Birmingham Reflux study[9-11] and the International Reflux Study in Children,[115] have been performed to compare medical therapy (antibiotic prophylaxis) with surgical therapy (reimplantation of ureters). The International Reflux Study in Children reported results from Europe and the United States. Because entry criteria were different, the results have been reported separately.

In Europe and the United States, the surgical management of VUR is neither superior nor inferior to medical treatment. In both groups, new scars were acquired during the 5-year follow-up period, some in patients who did not show scarring at the time of entry. In other children, scars present at entry worsened.[110] No detectable differences were found between study groups in either renal function or renal growth. The number of episodes of infection also was similar in both groups. The only exception was a greater frequency of episodes of febrile UTIs (presumed pyelonephritis) in children receiving medical therapy.

Wheeler and colleagues[155] conducted a systematic review of randomized trials of the effects of various interventions in patients with VUR on the development of subsequent UTI and renal parenchymal injury. The aim was to evaluate whether any intervention for reflux (surgical) is better than nonsurgical treatment. Eight trials involving 859 evaluable children were reviewed. Seven trials compared antimicrobials alone with surgery plus antimicrobial propylaxis. The risk of a UTI developing by 1 or 2 and 5 years was not significantly different between surgical and medical groups, and the risk of renal scarring or progressive renal damage occurring was similar. The choice of treatment remains a value judgment governed by such local factors as preference of the parents, availability of skilled surgeons, availability of closely supervised medical treatment, and willingness to comply with prolonged periods of prophylaxis.

Does VUR predispose to pyelonephritis? Garin and associates[32] reviewed 10 studies of children with acute UTIs who underwent DMSA scanning and VCUG. Selection of patients in at least one of the studies was biased toward the association between reflux and APN because the VCUG often was performed after the DMSA scan was reported to be abnormal. Six of 10 studies showed statistically significant results indicating that the presence of reflux definitely was associated with the occurrence of APN; all 4 of the remaining studies showed a trend in the same direction.

Antimicrobial Prophylaxis

Although the use of antimicrobial prophylaxis has become routine in the management of children with VUR, substantial controversy currently surrounds this approach, and an increasing literature challenges its benefit. In 2003, a Cochrane Review of the effectiveness of long-term antibiotics for preventing recurrent UTIs in children indicated that most studies published before this date were poorly designed without proper blinding.[157] Although Garin and colleagues[33] contributed a large study suggesting that antibiotic prophylaxis is not an effective intervention compared with no treatment in children with VUR, this study also had many methodologic flaws.[150]

Accepting for the moment that prophylaxis is the most effective medical therapy that can be offered to children with mild to moderate degrees of reflux, the duration of prophylaxis also is an issue. VUR spontaneously remits in most cases during the first 3 to 5 years of life. Conventional wisdom is that prophylaxis should be maintained until reflux ceases, either spontaneously or with surgical intervention. Greenfield and colleagues[39] suggested that two normal VCUGs performed 12 months apart are necessary before prophylactic antibiotics are discontinued. This recommendation is based on the observation that 27 percent of children exhibit VUR again after a single normal study.

Greenfield and colleagues[39] maintained that administration of prophylactic antibiotics should continue until reflux resolves, no matter what the age. They supported this position by noting that older children with reflux may have new scars evolve when they become infected. In contrast, other authors suggest that prophylaxis should be discontinued in older children, even if reflux persists.[2,7,18,141,158] The only two antimicrobial agents that are recommended for prophylaxis of the urinary tract are nitrofurantoin and trimethoprim-sulfamethoxazole. Each agent is used in half the usual therapeutic dose and given before bedtime. These two agents can be used for months to years without the emergence of antibiotic resistance. In contrast, most other agents that are used for treatment of UTIs are not recommended for prophylaxis. Invariably, if agents such as amoxicillin, cephalexin, and second-generation and third-generation cephalosporins are used for prophylaxis, infection with resistant strains emerges within weeks.

Surgery

When antireflux surgery is undertaken, a variety of approaches are available, no one of which seems to be superior. In most cases, the surgical approach is intravesicular. Interest has been gaining in evaluation of an extravesicular approach to reimplantation of the ureters.[95] The advantage of extravesicular approaches seems to be a diminution of the intensity and frequency of bladder spasms and less requirement for postoperative analgesia. This technique is indicated primarily in unilateral VUR.[44] When experienced senior surgeons embark on reimplantation of ureters, the outcome generally is successful.[22] Generally, all surgical techniques have a high success rate of 92 to 98 percent.[44] Repeated operation for persistence or recurrence of reflux seldom is required. Rarely, when children younger than 2 years old undergo surgery, ureteral obstruction may result; its persistence mandates a second operation.[115]

A newer technique for the management of VUR is endoscopic injection therapy using a variety of materials. Developed as a minimally invasive approach to the treatment of VUR in 1984, dextranomer/hyaluronic acid copolymer has emerged as the favored bulking agent since its approval by the Food and Drug Administration.[43,92] Although success is defined differently from after surgery, overall success rates range from 82 to 89 percent with initial injections of dextranomer/hyaluronic acid. The bulking agent is injected beneath the ureteral orifice and effectively closes the distal ureter. The procedure is done in the outpatient setting and is associated with less pain and a quicker recovery compared with traditional reimplantation procedures.[92] The success rates are lower, however, than those of traditional therapy, and the results have questionable durability. Long-term prospective studies are necessary to evaluate endoscopic treatments critically.

PROGNOSIS

Generally, a review of reports suggests that the short-term prognosis for previously normal children who experience an episode of UTI is excellent. In a large cohort of 306 children experiencing their first febrile episode of UTI, 40 percent were found to have reflux.[55] Only five (1.6%) of the children had grade IV reflux; none had grade V reflux. Most of the children with grades I, II, and III reflux can be expected to have spontaneous resolution of the process during the subsequent several years. Although many reports indicate that recurrent UTIs are common occurrences in children who have recovered from UTIs, recurrence during the first 6 months after recovery from the index episode of UTI was an infrequent event in this cohort of children.

Recurrence is seen most commonly in the early months after a symptomatic or asymptomatic UTI has occurred. Symptomatic reinfections (fever, pyuria, and positive urine culture) occurred in 7 children treated orally and in 11 children treated intravenously (for a total of 5.9% of children) during the 6-month follow-up period.[55] Asymptomatic bacteriuria (positive urine culture in the absence of fever and pyuria) occurred in one child treated orally and in two children treated intravenously (1%). Renal scarring occurred in 9.5 percent of all children; the average percentage of renal parenchymal involvement was 8.2 percent. In children who had an abnormal renal scintigram at the time of diagnosis, the frequency of scarring was 15.3 percent. None of the children with a normal renal scintigram at the time of diagnosis developed scars. This experience, reflecting an aggressive approach to the early diagnosis of UTI in infancy, is encouraging with regard to outcome.

When children with a diagnosis of UTI are found to have anomalies of the urinary tract, congenital dysplasias, or massive

degrees of reflux, the prognosis is less optimistic. The most profound degrees of scarring are associated with advanced degrees of reflux. Reflux nephropathy is a major cause of severe hypertension in children and young adults. It occasionally progresses to chronic renal failure,[136] which accounts for approximately 25 percent of the children in the United Kingdom with end-stage renal failure requiring regular dialysis or transplantation.[80] Although surgical correction may relieve the reflux, the overall outcome for children with reflux who have undergone surgical correction has not been shown to be materially better than that for children who have been managed medically.[103,104,137]

Smellie and colleagues[133] undertook a randomized trial of medical management versus surgical correction in 53 children with bilateral severe VUR and bilateral nephropathy. The glomerular filtration rate of the children at enrollment was 20 mL/min/1.73 m^2 body surface area. Children with this degree of severity of renal impairment are rare; recruitment to this study took 5 years. No significant differences were observed in glomerular filtration rate, renal growth, or scarring during a 10-year follow-up period. The failure to find differences may be due to the small sample size and broad heterogeneity of the study group. Nonetheless, no convincing evidence that outcome for renal function is improved by surgical correction of VUR in children with bilateral disease exists.

PREVENTION

Primary prevention of UTI can be accomplished in infant boys by promoting the practice of circumcision. Whether this procedure can be justified simply to prevent UTIs in the context of social rituals is uncertain. Circumcision should be recommended, however, for selected groups of patients, including newborns with prenatal hydronephrosis who are found to have VUR in the neonatal period, boys with high grades of VUR, and boys in whom VUR is associated with unilateral renal agenesis or multicystic kidney.[14]

Other commonly recommended strategies to prevent UTI, such as the avoidance of bathing in tubs or swimming and the instruction in correct wiping techniques, are not accompanied by convincing evidence.[45] The relationship between constipation and UTI is well known. Effective treatment of constipation results in normalization of bladder function and cessation of UTIs.[86]

The role of prophylactic antibiotics for patients with VUR is discussed in the section on treatment. Prophylaxis has not been shown in large, prospective, placebo-controlled, randomized trials to reduce effectively the frequency of UTI and subsequent renal scarring either in patients with reflux or in patients who have experienced an episode of APN.[33,157] Although definite biologic plausibility to this likelihood exists, strong evidence is lacking.

An additional preventive strategy for UTI is immunization. A small pilot study was reported from Turkey.[98] Ten otherwise healthy girls aged 5 to 11 years old with recurrent UTIs were immunized with inactivated uropathogenic bacteria intramuscularly once a week for 3 consecutive weeks. A booster injection was given after 6 months. The frequency of infection was compared with that in a group of 10 age-matched girls with UTIs who were not immunized. Immunization therapy caused a significant reduction in the frequency of infection and an increase in the concentration of the secretory component of IgA in the urine. Other mucosa, such as vaginal and oral surfaces, are alternative targets for vaccine delivery.

A vaginal mucosal vaccine composed of a mixture of heat-killed bacteria from 10 human uropathic strains (6 *E. coli* and 4 other gram-negative enteric bacteria) was developed for women with recurrent UTIs.[145] Fifty-four women completed a double-blind, placebo-controlled, phase 2 trial. Time until reinfection was longest for women who received primary and booster immunization compared with women receiving a placebo. This strategy has potential for further development.

CHAPTER 46

Renal Abscess

Edmond T. Gonzales, Jr. ✪ Sheldon L. Kaplan

Although acute pyelonephritis is a common infection in children, the primary development of a renal abscess or progression of pyelonephritis to a renal or perinephric abscess is an uncommon occurrence. In one study conducted over a 10-year period, 8 children with a renal abscess were found among 43,224 discharge diagnoses—approximately 1 case per 5400 pediatric admissions.[5] Six of the eight children were 11 years or older. Although rare, renal abscesses have been reported in neonates.[8] Renal abscess may be a primary problem—that is, one that develops in a kidney without an antecedent infection or underlying anatomic abnormality—or it may occur secondarily in a patient with previously recognized acute pyelonephritis or in a child with congenital urologic abnormalities known to predispose one to the development of pyelonephritis.

A primary renal abscess is thought to develop most often after an episode of bacteremia and frequently occurs in younger children. Hematogenous spread of bacteria to the kidney usually results in a cortical abscess.[5] The most common organisms involved in these abscesses are gram-positive cocci, primarily *Staphylococcus aureus*, and less often a streptococcus. In some cases, a cutaneous infection might have been present before development of the renal abscess, and this infection is thought to be the primary source for the bacteremia.[14] Most children in whom a renal abscess develops hematogenously are normal hosts.[5,10,18,20]

In older children and teenagers, tuberculous abscesses and caseous necrosis of the renal parenchyma also should be included in this primary classification. These infections tend to be indolent, although renal tuberculosis may be complicated by bacterial infection because of associated ureteral strictures and severe tuberculous cystitis. Pediatricians should become familiar with this "adult" malady because of the resurgence of tuberculosis and the generally older age group for which many pediatricians now provide care.

When a renal abscess occurs in association with a recognized urologic disorder, the organism responsible most often is a gram-negative bacillus or an enterococcus, bacteria usually seen in simple urinary tract infections and pyelonephritis.[17] Examples of urologic disorders that one might encounter with these infections include congenital and acquired obstructions (e.g., ureteropelvic and ureterovesical obstruction, retrocaval ureter, ureteral stricture after surgical intervention), calculous disease (obstructing and nonobstructing), infundibular stenosis, and renal dysplasia with cystic changes. Abscesses that occur as a result of infection of the urinary tract generally are found in a corticomedullary location.[5]

Anaerobic organisms also have been implicated as a cause of renal abscess. They often are present simultaneously with the more usual aerobic bacteria, but they can cause infections and abscesses alone. These anaerobic renal infections develop most commonly in association with infections complicating bowel injury or surgery, renal transplantation, malignancy, and orodental infections.[4] The genus of the anaerobic organism may provide a clue to its source. *Bacteroides fragilis* is likely to arise from an intra-abdominal source, whereas an oral site is more common for *Prevotella oralis*.[4]

Children with human immunodeficiency virus infection seem to have an increased risk for development of renal abscesses from the more common traditional organisms[3] and from unusual opportunistic fungal organisms, especially *Aspergillus*.[12] As expected, these children also tend to have a more fulminant course that often requires extensive surgical intervention and drainage.

The presence of a renal abscess implies the destruction and liquefaction of tissue in a confined space. Two other infectious disorders of the kidney, xanthogranulomatous pyelonephritis and acute lobar nephropathy (acute focal bacterial nephritis), frequently are included in this general category, although technically, true abscesses do not always develop in these disorders. Acute lobar nephropathy may progress to renal abscess, however, if not treated appropriately.

Xanthogranulomatous pyelonephritis describes a more chronic form of severe renal parenchymal destruction that often is associated with chronic stone disease. The process may involve the whole kidney or may be focal. In children, the focal form occurs more commonly. The pathognomonic histologic finding is an accumulation of lipid-laden macrophages that coalesce into discrete yellow nodules. Small abscess cavities often are studded throughout the kidney. The organism most frequently recovered from the kidney is *Proteus*, and urinary calculi are common findings. Although these patients often have acute symptoms, the symptoms frequently are superimposed on more chronic manifestations, such as weight loss, failure to thrive, and anemia. Treatment is complete or partial nephrectomy because the renal destruction generally is severe.[19]

Acute lobar nephropathy describes a focal area of intense edema at the site of infection in acute pyelonephritis.[2] It usually is recognized as a mass effect on an initial screening renal ultrasonogram. Severe nephromegaly (renal length >3 standard deviations above the mean for age) is another finding on renal ultrasound suggestive of acute lobar nephropathy.[6] Computed tomography (CT) of the kidney shows poor uptake in the involved segment, but no well-defined liquefaction (Fig. 46–1). Whether this edema is just an exaggerated response to infection or represents a pre-abscess change is unknown. Klar and colleagues[11] described 13 children, 4 months to 8 years of age, with acute lobar nephropathy in a prospective study during a 4-year period. Bacteremia was documented in only one child. Evolution to abscess formation occurred in four (31%). In another prospective study, Cheng and associates[7] found bacteremia occurred in 4 of 80 children (5%) with acute lobar nephropathy. These lesions

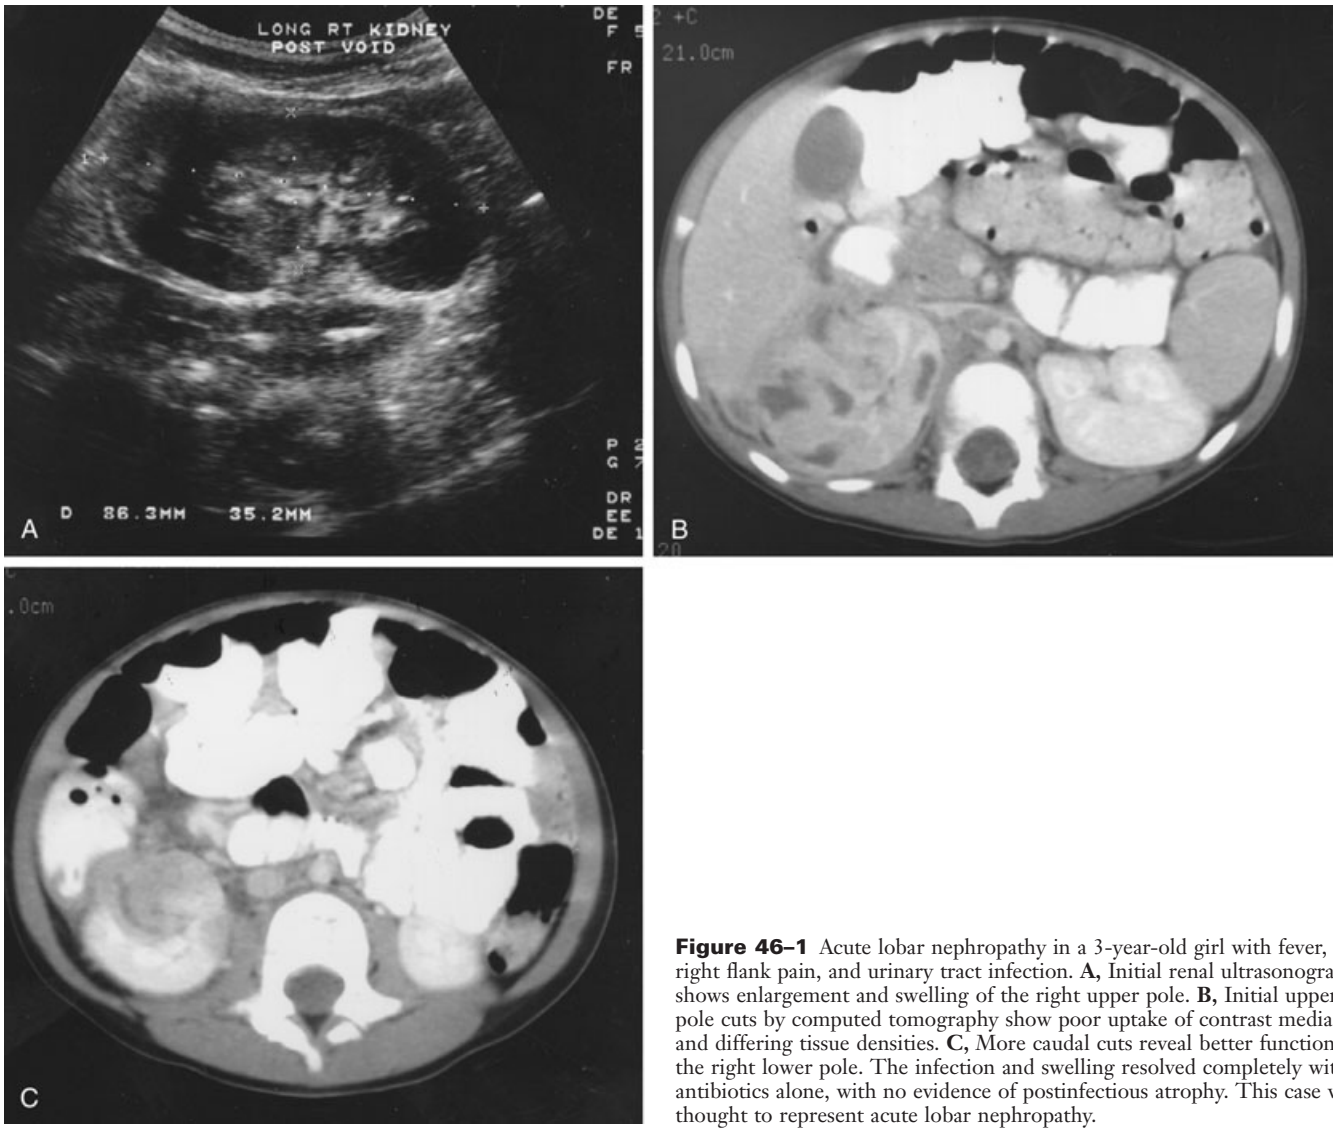

Figure 46–1 Acute lobar nephropathy in a 3-year-old girl with fever, right flank pain, and urinary tract infection. **A,** Initial renal ultrasonogram shows enlargement and swelling of the right upper pole. **B,** Initial upper pole cuts by computed tomography show poor uptake of contrast media and differing tissue densities. **C,** More caudal cuts reveal better function in the right lower pole. The infection and swelling resolved completely with antibiotics alone, with no evidence of postinfectious atrophy. This case was thought to represent acute lobar nephropathy.

generally heal satisfactorily with administration of antibiotics alone.

CLINICAL FINDINGS

Children with acute renal abscess are febrile and have localized pain in the costovertebral location. Prolonged fever is a common finding, especially in older children. Most patients are febrile for longer than 7 days before the diagnosis is established. The initial findings generally do not differentiate, however, between acute pyelonephritis with and without an abscess. If the abscess has spread into the perinephric region, one might be able to recognize psoas muscle irritation in the patient—that is, the patient is more comfortable with the ipsilateral leg in a position of flexion and experiences pain with full extension. A large abscess may be palpable as a flank mass.

Findings on urinalysis can be confusing. With a primary (hematogenous) abscess, the urine may be deceptively benign, and culture generally is negative.[14] Blood cultures may be positive, depending on the duration of the illness when blood is obtained for culture. Abscesses associated with underlying urologic disorders can be expected to contain organisms and pyuria. Generally, severe leukocytosis is present. The erythrocyte sedimentation rate typically is elevated; the same probably is true for C-reactive protein.[20] All these findings are nonspecific, however, and often further studies are needed to establish the diagnosis. If a more indolent process is encountered, one should consider performing appropriate staining and cultures for tuberculosis.

DIAGNOSTIC EVALUATION

All children admitted to the hospital with a febrile urinary tract infection should undergo renal ultrasonography as soon as is reasonable after admission. The findings on this initial study can have a significant effect on the choice of therapeutic options. If both kidneys are normal and unobstructed, organism-specific therapy is satisfactory in most patients. If significant obstruction or stones are present, antibiotic therapy may not be as effective, and interventional drainage may become necessary if the response to antibiotics is inadequate. At the time of this initial screening study, findings may suggest the presence of a renal abscess. Such findings include a mass effect within the margins of the kidney

along with a thickened wall and material of varying sonographic density within the mass (Fig. 46–2). Similar findings can be seen in infections accompanied by severe ureteropelvic junction obstruction or infundibular stenosis with isolated calyceal dilation, in which case purulent material within the dilated collecting system layers out and can mimic a renal abscess (Figs. 46–3 and 46–4).

When the diagnosis of an abscess is suspected on ultrasonography, performing CT of the involved kidney is in order.[9] CT more clearly defines the margins of the abscess, assesses whether loss of function is significant, and can screen the remainder of the kidney for small satellite abscesses.[16] If loss of function in the affected kidney seems to be significant, a dimercaptosuccinic acid renal scan should be done because it is an even more sensitive test to quantitate overall renal function. Currently, gallium 67 scintigraphy is not used frequently to diagnose an obscure inflammatory mass. If CT suggests the diagnosis, percutaneous aspiration can confirm clearly whether an abscess is present, without having to perform additional studies, and, at the same time, provide material for culture.

If a child with a urinary tract infection and a previously normal result on renal ultrasonogram is taking culture-specific antibiotics and a new fever subsequently develops, ultrasonography should be repeated. A previously small, unrecognized abscess

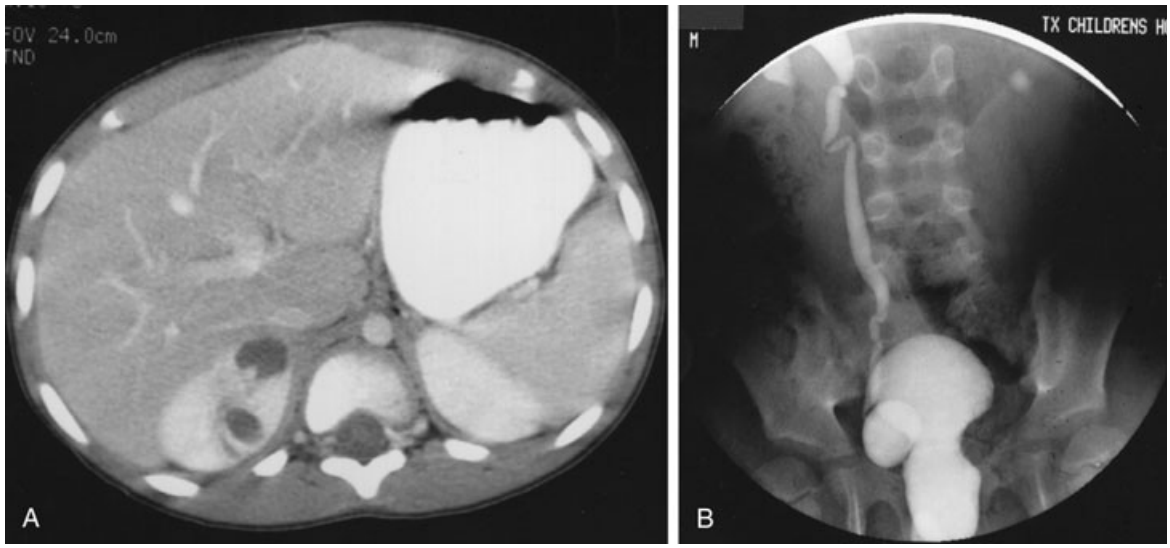

Figure 46–2 Renal abscess (secondary) in a 6-month-old boy with urinary tract infection. A screening renal ultrasonogram showed a small mass in the right kidney. **A,** Computed tomography shows two clearly defined cystic areas consistent with small parenchymal abscesses. Treatment consisted of intravenous antibiotics only. **B,** Voiding cystogram revealed the presence of vesicoureteral reflux.

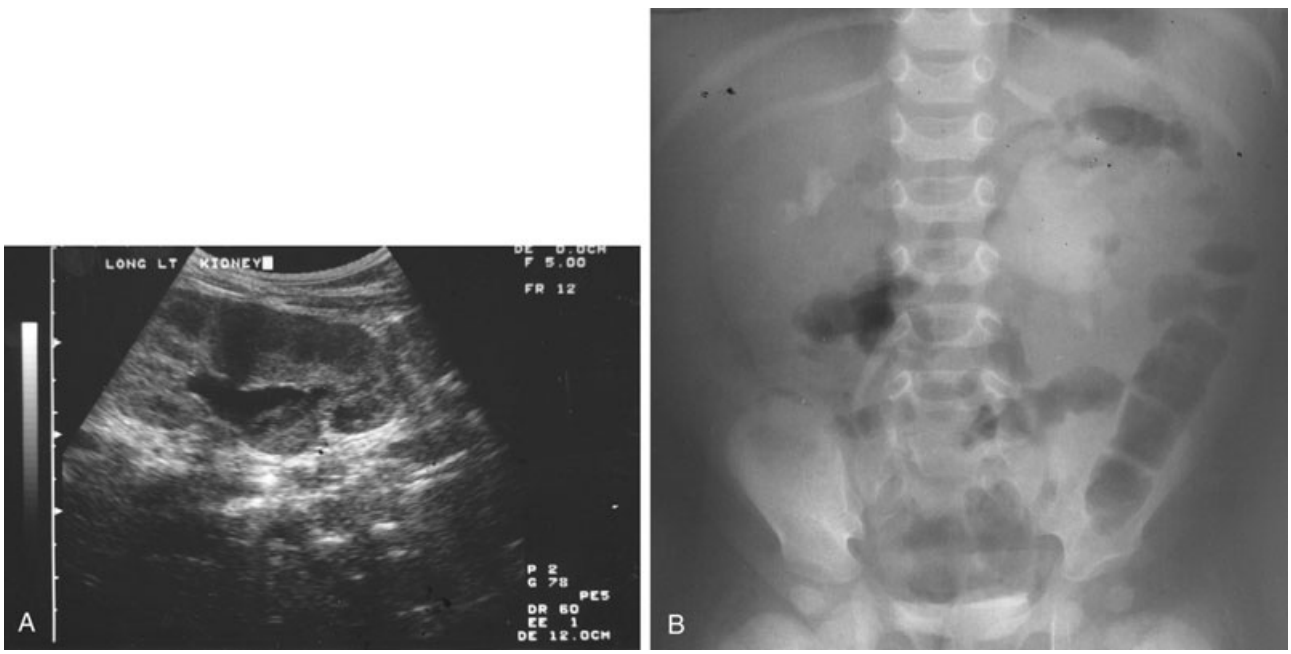

Figure 46–3 Pyonephrosis associated with ureteropelvic junction obstruction in a 3-month-old boy with fever, left abdominal and flank tenderness, and urinary tract infection. **A,** Renal ultrasonogram shows a medially placed cystic mass with layered fluids of different density consistent with purulent material. The position of the mass is most consistent with the renal pelvis. **B,** Intravenous pyelogram confirms ureteropelvic junction obstruction. This infant was treated initially with percutaneous nephrostomy drainage in addition to appropriate antibiotics.

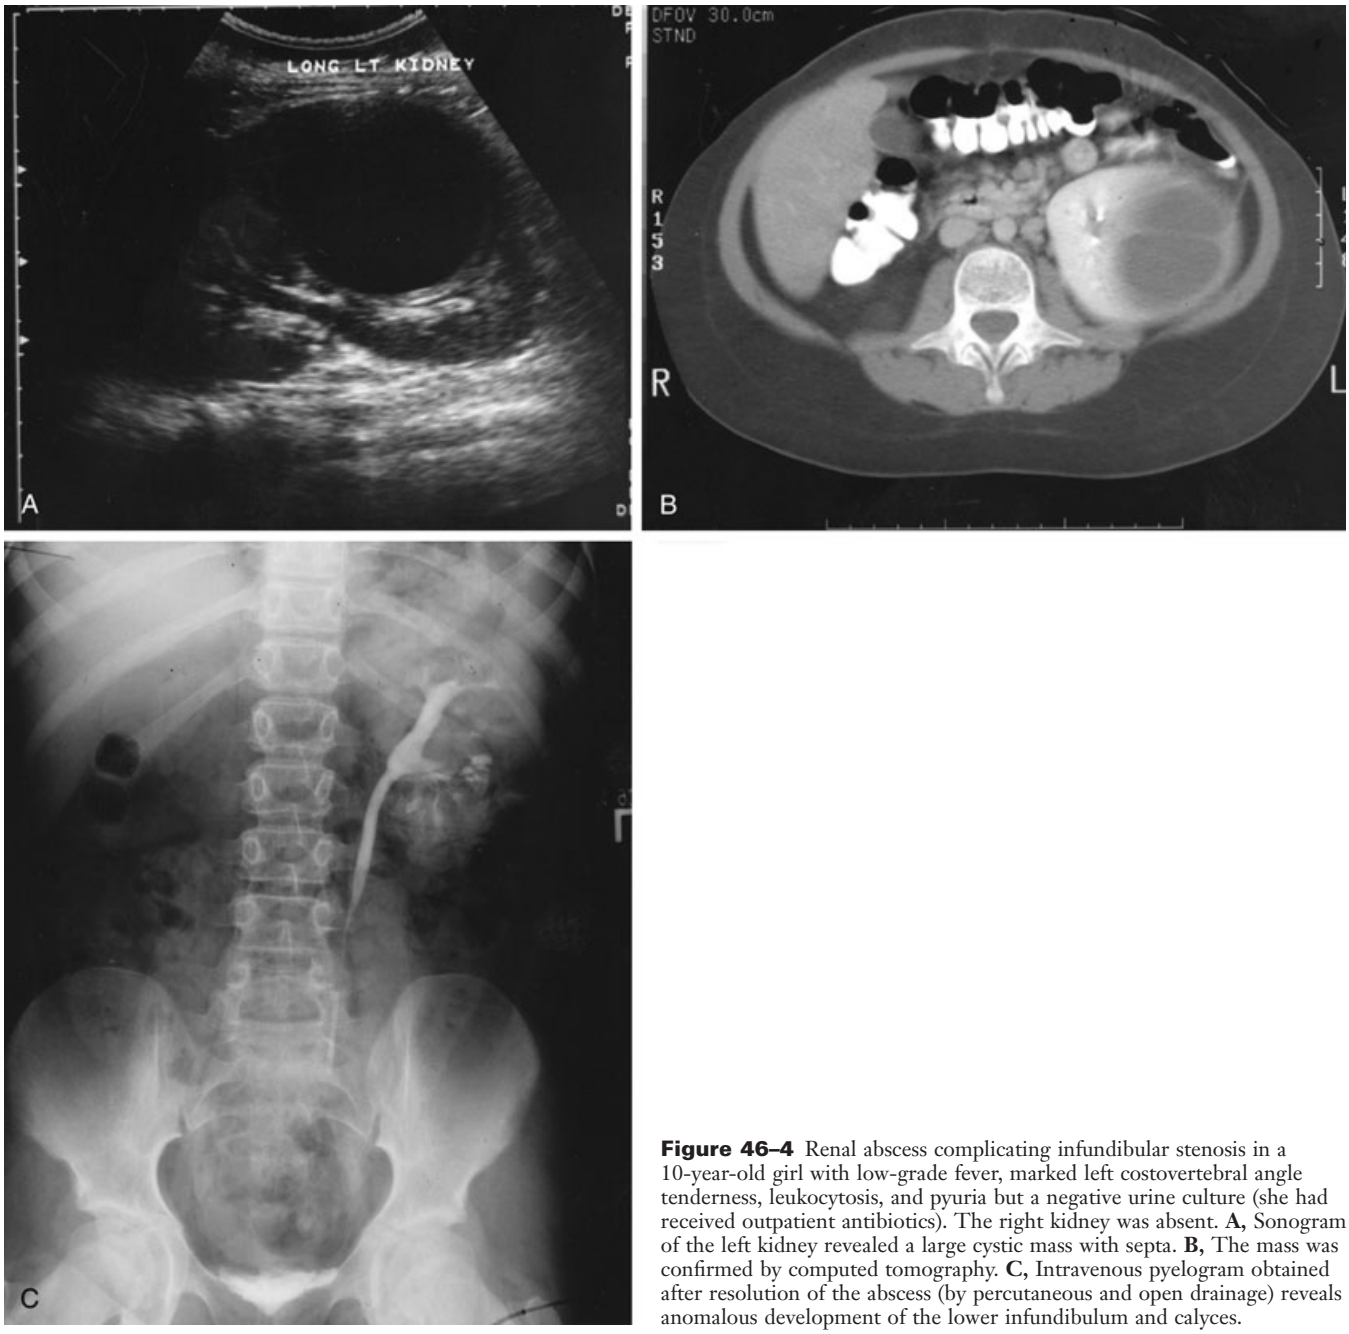

Figure 46–4 Renal abscess complicating infundibular stenosis in a 10-year-old girl with low-grade fever, marked left costovertebral angle tenderness, leukocytosis, and pyuria but a negative urine culture (she had received outpatient antibiotics). The right kidney was absent. **A,** Sonogram of the left kidney revealed a large cystic mass with septa. **B,** The mass was confirmed by computed tomography. **C,** Intravenous pyelogram obtained after resolution of the abscess (by percutaneous and open drainage) reveals anomalous development of the lower infundibulum and calyces.

may have been treated inadequately and now may be more apparent.

Occasionally, imaging studies cannot distinguish between a renal abscess and severe acute lobar nephropathy. The latter condition also may show tissues of differing density by ultrasonography or CT. In these situations, ultrasonography-guided or CT-guided percutaneous aspiration of the lesion may be necessary to determine whether purulent material can be obtained.

THERAPEUTIC CONSIDERATIONS

When the diagnosis of an abscess is confirmed, the choice of therapeutic options is dictated by several factors, including the overall status of the patient, the size and number of abscesses, whether the abscess appears to be unilocular or septate, associated uropathies, and the extent of renal function in the involved kidney. Included in these considerations is some insight into the responsible organism. If it is a solitary abscess in a child with unimpressive urinalysis findings and an otherwise normal kidney, one should suspect a staphylococcal abscess, which can be confirmed by percutaneous aspiration, Gram stain, and culture. If bacteremia caused by *S. aureus* possibly was nosocomial in origin, or if methicillin-resistant *S. aureus* isolates are found commonly in the community, antibiotics such as vancomycin or clindamycin should be included in the initial empiric regimen.

Subsequent therapy is based on the antibiotic susceptibility pattern of the organism isolated. If urinalysis reveals an obvious infection, one can assume that the urine culture reflects the organism responsible for the abscess. In this situation, empiric

therapy is directed against gram-negative enteric organisms. Cefotaxime, ceftriaxone, or ceftazidime plus an aminoglycoside would be suggested. The only caution is if the abscess is complicated by significant stone disease. In this situation, more than one organism may be in the urinary tract, and urine culture alone may be misleading. Percutaneous aspiration can identify accurately the organism responsible for the abscess. The optimal duration of antibiotic therapy for treatment of a renal abscess is not established, but 3 weeks of treatment is superior to 2 weeks for acute lobar nephropathy.[7]

Renal abscesses traditionally have been managed by open surgical drainage. With the introduction of safe percutaneous access, particularly when used with ultrasonography or CT guidance, single, unilocular lesions now can be managed effectively with percutaneous placement of an indwelling catheter that allows not only for primary drainage but also for irrigation of the cavity with appropriate antibiotic solutions.[1,11] Small renal abscesses have been treated successfully with antibiotics alone.[13,18] If the child does not improve with medical therapy alone, some type of drainage procedure is indicated. When function is insufficient to justify renal salvage and ultimate nephrectomy is planned, a short course of specific antibiotics and percutaneous drainage is initiated, if the abscess is large, to decrease inflammation in the perinephric tissues and to reduce the possibility of causing bacteremia at the time of surgery.

When required, surgical repair of associated congenital anomalies of the urinary tract generally is performed at a separate session after the abscess has resolved. Reconstructive surgery in the presence of active infection significantly increases the risk of development of surgical complications and the possibility that additional surgical procedures might be required.

CONCLUSION

Treatment of renal abscess today is multifaceted, and each case must be individualized. In addition to culture-specific antibiotics, treatment may include observation only, percutaneous drainage, or open surgical drainage. Diagnostic evaluation, including renal ultrasonography, CT, and percutaneous aspiration, generally can confirm that an abscess is present and assist in the decision regarding therapeutic options.

CHAPTER 47

PROSTATITIS

Edmond T. Gonzales, Jr. ❂ Sheldon L. Kaplan

Prostatitis, a major source of chronic infection and symptoms in men, occurs rarely in prepubertal children. Although prostatitis may develop in postpubertal teenagers, even in this age group the diagnosis is recognized infrequently. The disorder commonly called prostatitis generally is divided into three separate clinical problems: acute prostatitis, chronic prostatitis, and prostatodynia.

Acute prostatitis is a severe infection generally associated with significant toxicity (high fever, elevated white blood cell count, systemic symptoms). Marked urinary symptoms, such as frequency, dysuria, and urinary retention, may be present. The urine usually is infected. On rectal examination, the prostate is enlarged, boggy (edematous), and exquisitely tender. Care must be taken when performing the rectal examination or when inserting a transurethral catheter because bacteremia can result.

The organism responsible usually is one of the gram-negative pathogens that commonly causes urinary tract infection (UTI). The virulence factors of *Escherichia coli* strains recovered from men with acute prostatitis and women with UTIs, such as adhesins and cytotoxins, were similar in one study.[13] Johnson and colleagues[6] found, however, that prostatitis *E. coli* isolates differed significantly from *E. coli* associated with cystitis or pyelonephritis by having a higher prevalence of the genes encoding P fimbriae structural subunits, P fimbriae assembly, fimbriae tip pilins, hemolysin, and cytotoxic necrotizing factor, and a lower prevalence of the gene encoding invasion of brain endothelium virulence factor. Rarely, *Trichomonas vaginalis* can cause prostatitis.

Treatment generally begins with administration of broad-spectrum parenteral antibiotics, such as cefotaxime, and aminoglycosides that are effective against gram-negative enteric organisms, pending the availability of culture-proven sensitivity results and a satisfactory clinical response. In patients older than 17 years of age, a fluoroquinolone also is recommended.

Chronic prostatitis is a more indolent infection associated with intermittent UTI, bladder irritative symptoms, and perineal discomfort. Ejaculation may be painful. Expressed prostatic secretions usually show an increase in the white blood cell count. Chronic prostatitis generally is recognized to occur in two different patterns: bacterial and nonbacterial. The clinical features of the two disorders are remarkably similar, including an increase in the white blood cell count in expressed prostatic secretions, but patients with chronic bacterial prostatitis usually also have recurring episodes of UTI with the same organism, most often one of the gram-negative pathogens.

The diagnosis of chronic prostatitis is related partly to detecting inflammation in expressed prostatic secretions. More precise methods of determining inflammatory parameters, such as counting the white blood cells per cubic millimeter with a hemocytometer, have been proposed.[14] In a large cohort study, the severity of symptoms in men with chronic prostatitis did not correlate with leukocyte or bacterial counts, however.[17] This study suggested that the symptoms associated with chronic pelvic pain syndrome were related to factors other than leukocytes and bacteria.

E. coli isolates associated with chronic prostatitis possess urovirulence profiles similar to those of strains from women with acute uncomplicated pyelonephritis.[1] In most studies, chronic nonbacterial prostatitis occurs more commonly than chronic bacterial prostatitis.

The cause of nonbacterial prostatitis remains enigmatic. Prostatic secretions do not show a common organism consistently, and UTI does not recur. Culture of prostatic secretions is notoriously unreliable, because of the means by which this material is collected; these secretions are contaminated easily as they pass through the urethra.[12] A specific causal relationship in nonbacterial prostatitis has not been found for either *Ureaplasma urealyticum* or *Chlamydia trachomatis*, two organisms commonly implicated in urethritis.[18] Molecular studies using polymerase chain reaction have shown DNA evidence of the presence of bacteria despite negative cultures for the typical bacteria associated with prostatitis.[5] Using these new techniques may lead to greater understanding of the role of infection in the pathogenesis of prostatitis.

Treatment of chronic bacterial prostatitis is frustrating because few patients truly are cured, and relapse occurs commonly after discontinuation of antibiotic therapy. Several studies have confirmed satisfactory concentrations of most common antibiotics in prostatic tissues,[5,8,10] but no study has provided a convincing explanation for the high treatment failure rate. Levofloxacin and other fluoroquinolones penetrate well into seminal and prostatic fluids and reach concentrations equivalent to corresponding plasma levels.[3] Researchers have postulated that antibiotic concentrations may be inadequate within the acini of the prostatic glands and their secretions, but this theory has not been proved.[15]

Normal prostatic secretions exhibit an antibacterial effect that is not present in men with chronic bacterial prostatitis. Several investigators have shown this factor to be free zinc or a zinc-based compound.[16] This antibacterial factor is depressed or absent in men with chronic prostatitis, but whether it causes or results from prostatitis is unknown. The most successful antibiotic therapy has been with trimethoprim-sulfamethoxazole or one of the fluoroquinolones.[9] In many instances, low-dose maintenance chemoprophylaxis with trimethoprim-sulfamethoxazole or nitrofurantoin is the most effective means of controlling symptoms.

A final population of patients have all the symptoms described in patients with chronic (bacterial) prostatitis but no history of UTI and microscopically normal prostatic secretions. To distinguish this group of patients from patients with prostatic infection, the term *prostatodynia* is used. The etiology of prostatodynia is unknown, but most investigators think that the disorder is a form of perineal and urethral muscle dysfunction with sphincter spasm, high voiding pressure within the prostatic urethra, reflux of urine into the prostatic ducts, and, ultimately, the development of chemical prostatitis.[4,11] Treatment generally consists of the use of alpha-adrenergic blocking agents to relax the bladder neck and proximal prostatic urethra and diazepam to relax the striated muscle of the perineum. Although most patients seem to experience some benefit, the results of therapy are difficult to quantitate, and underlying psychosocial issues are thought to be responsible for the symptoms of many patients. Psychological assessment and indicated treatment are essential parts of the total management of these patients.

In the older age group still seen in a pediatric practice, symptoms similar to those of the chronic form of prostatitis also might occur with urethritis. As noted earlier, *Chlamydia* and *Ureaplasma* spp. commonly are found in the urethral discharge in these patients[2] and are thought to be responsible for these specific symptoms. These organisms also have been implicated as a cause of epididymitis in young men. The organisms are transmitted sexually and are treated effectively with a tetracycline (minocycline or doxycycline) or a macrolide (erythromycin or azithromycin).[19] To prescribe these drugs empirically for sexually active young adults with lower tract irritative symptoms and clinical findings consistent with urethritis while awaiting culture results seems reasonable.

Nonspecific urethritis is the term commonly used for the infection in men with irritative voiding symptoms and a clear mucoid discharge and in whom culture of the discharge reveals a mixture of common perineal and gram-negative organisms but without a predominant organism thought to be responsible for the infection. Some of these patients likely have undiagnosed *Chlamydia* or *Ureaplasma* infection. Although specific treatment is empiric, a tetracycline or erythromycin seems to be a prudent first choice in most cases. Finally, one must not overlook the possibility of gonococcal urethritis.

In males, ectopic ureters can drain into the prostatic urethra or the seminal vesicle. With this anomaly, the ipsilateral renal parenchyma generally is dysplastic, the ureter is highly dilated, and the seminal vesicle may be distended markedly and form a large cystlike structure behind the prostate, the bladder neck, and the trigone. If this anomaly becomes infected, pain in the perineum and on rectal examination generally is significant. Occasionally, frankly purulent material is passed at the urethral meatus or expressed from the urethra after rectal examination.

In most cases, the kidney drained by the ectopic ureter is highly dysplastic and shows little or no function. Ultimate management usually consists of nephroureterectomy (ureteroneocystostomy if the kidney works) and, if the seminal vesicle is unusually large, partial excision and decompression of the seminal vesicle. Although these abnormalities are congenital and recognized easily by fetal ultrasonography, they can occur at almost any age if not identified before birth. Unless a palpable flank or lower abdominal mass is felt, infection usually is the initial symptom. Despite the severe degree of abnormality and ureteral and seminal vesicle dilation, the development of infection can be delayed well into the adult years. Infrequently, distortion at the bladder neck can result in obstruction to urinary flow.

SUMMARY

Prostatitis as it is seen and described in adults is a rare event in pediatric patients. When it does occur, it affects pubertal adolescents. Even in these patients, distinguishing true prostatitis from simple urethritis may be difficult.

Appropriate evaluation of an adolescent boy with a lower tract urinary infection generally begins with renal ultrasonography. Special attention should be directed to the region of the bladder and prostate. With this imaging modality, one can assess the presence and normalcy of both kidneys, the degree of thickening of the bladder wall, the ability of the bladder to empty, and whether any cystic masses are located behind the bladder or prostate. Any obvious abnormality justifies obtaining a voiding cystourethrogram. A thickened detrusor or recurrence of infection suggests the possibility of urethral obstruction. Although properly performed voiding cystourethrography does image the entire urethra, other diagnostic tests might include retrograde urethrography or determination of the urinary flow rate, especially if one suspects a urethral stricture. Performing cystoscopy usually is unnecessary if all imaging study results are normal, although cystoscopy may be used to confirm, and sometimes manage, obvious urethral obstruction.

CHAPTER 48

Genital Infections

Mariam R. Chacko ✪ Mary Allen Staat ✪ Charles R. Woods, Jr.

This chapter reviews the clinical aspects of genital tract infections in children and adolescents. Genital infection in boys is limited to balanoposthitis. For details on other genital infections in boys, such as urethritis, epididymitis, and orchitis, refer to the other chapters in this section. Genital tract infections in premenarcheal girls are limited mostly to the vulva and vagina. The clinical presentations and management differ from those of similar infections in older patients. Genital infections in postmenarcheal girls include all the infections found in women; the symptoms accompanying them are similar to those in adults, and their treatment essentially is the same. Genital infections associated with pregnancy are not addressed in this chapter.

GENITAL TRACT INFECTIONS IN BOYS

Genital tract infections in boys are uncommon at any age but can be serious when they occur. Group A streptococcal proctitis and perianal skin infections have been reported.[154,180,261] Perianal pruritus, erythema, and tenderness occur commonly, and abdominal pain and rectal bleeding may be present. Penile involvement occurs rarely if at all.[261]

Balanoposthitis is a condition characterized by inflammation of the prepuce[210] and glans penis.[53] Causes of this condition have been described poorly in the literature; however, researchers have suggested that balanoposthitis results from trauma, irritation, or infection. A few cases of balanitis caused by *Streptococcus pyogenes* and *Staphylococcus aureus* have been reported.[53,60,69,105,160,205,210]

Balanoposthitis occurs more commonly in uncircumcised boys compared with circumcised boys. In one survey, the frequency of balanitis and penile irritation was determined in 272 uncircumcised and 273 circumcised boys.[124] Balanitis was defined as redness or swelling of the entire foreskin or glans, with or without pus, and irritation was defined as redness without swelling or pus. Six percent of uncircumcised and 3 percent of circumcised boys had balanitis. Four percent of the uncircumcised boys were found to have irritation alone compared with 1 percent of the circumcised boys. In another study examining penile problems in boys from birth to 8 years of age, penile inflammation

developed in 8 percent of circumcised and 14 percent of uncircumcised boys.[78]

The diagnosis of balanoposthitis is made on clinical grounds. A boy may complain of soreness, swelling, and discharge around the penis. Examination reveals redness, swelling, and discharge of the prepuce or glans penis, or both. The discharge originates from the area under the foreskin or around the glans penis and not from the urethra. Urethritis may be associated with urethral discharge, but it is not seen commonly. In a case series of 100 boys with balanitis, 100 percent had redness, 91 percent had swelling, and 73 percent had discharge on examination.[75] If an infectious etiology is suspected, Gram stain and culture of the discharge can be performed to determine the cause and guide therapy.

For nonspecific balanoposthitis, local therapy, including sitz baths, gentle cleansing, and application of hydrocortisone cream, is suggested.[244] In cases in which an infectious etiology is suspected, or local therapy has not been effective, a topical or oral antibiotic with coverage against *S. pyogenes* and *S. aureus* can be used.

Circumcision or a dorsal slit procedure may be necessary for recalcitrant or recurrent balanoposthitis. In a study reviewing the reasons for circumcision beyond the neonatal period, 23 percent of 476 boys underwent the procedure for recurrent balanoposthitis.[290] Aside from the need for circumcision, most cases of balanoposthitis seem to be uncomplicated. Cases resulting in necrotizing fasciitis and *Staphylococcus*-induced toxic shock have been reported, however.[53,132]

GENITAL TRACT INFECTIONS IN GIRLS

In this section on genital infections in girls, the normal vaginal microenvironment is reviewed first, followed by specific and nonspecific premenarcheal bacterial and fungal causes for vulvovaginitis. Issues of sexual abuse in children with genital tract infections also are addressed. The section on sexual abuse in children with genital tract infections addresses bacterial and viral sexually transmitted diseases (STDs) in sexually abused children. These sections are followed by postmenarcheal lower genital tract infections of the external genitalia, including clitoris and Bartholin ducts and glands, and bacterial, protozoal, and fungal vulvovaginitis. Vulvovaginal viral infections, granulomatous and ulcerative vulvovaginal disorders, infections of the cervix, and upper genital tract infections are reviewed for premenarcheal and postmenarcheal girls.

These sections provide information regarding infections by specific microbes and syndromes, including trichomoniasis, candidiasis, gonorrhea, syphilis, chlamydial infections, bacterial vaginosis, genital herpes, condyloma acuminatum, molluscum contagiosum, lymphogranuloma venereum, granuloma inguinale, chancroid, tuberculosis, Behçet syndrome, and vulvar vestibulitis, and infections caused by group A streptococci, *Shigella*, and other agents that occasionally cause genital tract disease. Additional information on the microbes can be found in the respective chapters.

Supplemental information concerning the principles of gynecologic infections in children and adolescents can be found in referenced sources.[22,28,29,62,73,129,234] Although the infectious complications of pregnancy are not discussed, pregnancy is a common occurrence in teenage girls. Pregnancy-related infection should be considered when confronted with a septic state in an adolescent girl.

NORMAL VAGINAL FLORA

The lower female genital tract is colonized by nonpathogenic bacteria from birth. Throughout life, this colonization is dynamic and complex. A wide range of aerobic and anaerobic species have been cultured from asymptomatic girls. The results of several modern series are summarized in Table 48–1.

Most girls harbor several organisms in the vagina at any given time. Vaginal specimens obtained for culture during anesthesia for elective surgery from 19 healthy girls aged 3 months to 5.7 years old yielded a mean of 12 bacterial species.[127] Anaerobes predominated, with a mean of 8.7 species versus 3.4 aerobic species. In a series of 25 asymptomatic girls aged 2 months to 15 years, a mean of 8.7 different species (approximately 4 aerobes and 5 anaerobes) per vaginal specimen were detected.[114] Another series of adolescents and young adults aged 13 to 21 years in which only aerobic flora were evaluated noted a mean of approximately three organisms in non-sexually active subjects versus six in sexually active patients.[249] This heterogeneity in vaginal microflora during childhood and adolescence is similar to that found in women.[164]

TABLE 48–1 Vaginal Organisms Isolated from Asymptomatic Girls 2 Months to 16 Years of Age

Organism	%*
Coagulase-negative staphylococci	35-73
Diphtheroids	14-78
Streptococcus viridans	13-39
Enterococci	29-62
Group B streptococcus	5-11
Group D streptococcus	
Staphylococcus epidermidis	
Staphylococcus aureus	
Streptococcus pneumoniae	
Micrococcus spp.	
Gaffkya (Aerococcus) spp.	
Lactobacillus spp.	10-39†
Escherichia coli	12-67
Klebsiella spp.	15-52
Enterobacter spp.	
Proteus spp.	3-5
Pseudomonas aeruginosa	5-6.5
Citrobacter spp.	
Haemophilus influenzae	
Neisseria spp. other than gonococci	
Moraxella (Branhamella) catarrhalis	
Flavobacterium spp.	
Alcaligenes spp.	
Acinetobacter spp.	
Mycoplasma hominis	
Ureaplasma urealyticum	
Gardnerella vaginalis‡	
Peptostreptococcus spp.	29-56
Peptococcus spp.	39-76
Veillonella spp.	
Eubacterium spp.	
Propionibacterium acnes	
Bacteroides fragilis	
Bacteroides melaninogenicus	
Other *Bacteroides* spp.	
Prevotella spp.	
Bifidobacterium spp.	
Clostridium perfringens	
Other *Clostridium* spp.	
Fusobacterium spp.	
Candida spp.	3-18
Other yeasts	
Actinomyces spp.	

**Percentage range when the organism was isolated from patients in at least two studies. If no range is present, the organism was isolated from 3 to 33% of patients in a single study.*

†In one series, 88% of girls were older than 11 years.

‡Isolated in numerous cases without discharge.

Data from references 72, 95, 114, 120, 127, 164, 165, 177, 230.

Different types of bacteria are isolated at various ages. The vagina and its microbial flora form an ecosystem that changes over time from infancy to childhood to adolescence and adulthood.[126] The major forces that influence these changes are fluctuations in estrogen levels and the advent of sexual activity. Hygienic practices and medications, including oral contraceptives and antimicrobial agents, also affect the complex interactions among the various flora present in the vagina in terms of persistence, predominance, and overgrowth. The vaginal flora of most healthy women is dominated by one or more *Lactobacillus* spp., but a substantial minority may harbor other predominant flora, including *Bifidobacterium*, *Gardnerella*, *Prevotella*, *Pseudomonas*, or streptococci, in the absence of lactobacilli.[135]

Gram-negative enteric bacteria and enterococci commonly are encountered in infants and toddlers before completion of toilet training, but less frequently thereafter.[114,127] Younger adolescents have a greater prevalence of anaerobic bacteria than do women. From puberty, aerobic colonization increases with age, onset of sexual activity, and parity.[165] Lactobacilli are the predominant flora in most girls by the end of adolescence and may play a protective role in limiting the overgrowth of other flora.[126] In children, lactobacilli are present more often in girls younger than 2 years than in older prepubertal girls. The increasing presence of yeast and *Gardnerella vaginalis* from puberty to adulthood, although much less common in all ages, parallels that of lactobacilli.[114]

Mycoplasma hominis and *Ureaplasma urealyticum* are present more commonly in sexually active adolescents and in girls of any age who have been sexually abused than in nonsexually active girls. Genital mycoplasmas were found in 17 percent of one series of young girls who were not known to have undergone any sexual abuse.[108,249]

Microbes that usually behave as commensals sometimes are associated with vulvovaginitis. The difference between colonization and disease is at least partially a function of the magnitude of the replication and the quantity of a given bacterial species. In women with bacterial vaginosis in which *G. vaginalis* is a predominant microbe, colony counts generally are greater than 10^7 colony-forming units/g of vaginal fluid. Asymptomatic colonization with *G. vaginalis* usually is associated with colony counts of less than 10^5 colony-forming units/g of vaginal fluid.[165] Alteration in the vaginal microenvironment by factors such as poor hygiene, foreign bodies, or hormonal fluctuations results in loss of environmental constraints on bacterial replication and facilitates the overgrowth of one or more commensals.

When bacterial vaginosis occurs, typically the numbers of lactobacilli, which produce hydrogen peroxide, are decreased. When such a decrease occurs, catalase-negative microbes, such as *G. vaginalis*, *Mobiluncus* spp., and other anaerobes, can increase in number. Lactobacilli probably have mechanisms other than hydrogen peroxide production that may help restrain the growth of other microbes present on the surfaces of the lower genital tract.[165,258]

PREMENARCHEAL VULVOVAGINITIS

Infections and inflammation of the vulva and vagina account for 85 to 90 percent of all genital problems in premenarcheal girls. These conditions are encountered most commonly in children 2 to 7 years old.[213,226] Infections of the vulva and vagina usually occur together and generally are discussed as one entity, vulvovaginitis. The various types of vulvovaginitis are differentiated by determining the presence or absence of specific agents associated with the inflammation in a particular case.

Genital discharge and perineal or vulvar discomfort are the most common symptoms that bring a child with vulvovaginitis to the physician.[133,213] The discomfort may be only minor pain or soreness, or it may be intense perineal burning or pruritus. Genital erythema is the most common sign in girls with vulvovaginitis and is noted in more than 80 percent of cases. Visible discharge is present in one third of cases.[213] The discharge may be scanty serous fluid, bloody, or profuse and purulent. Infections of the vulva and vagina are more likely to be accompanied by moderate or severe inflammation and prominent discharge than is nonspecific vulvovaginitis.[142] Infection can be present at times, however, with neither discomfort nor discharge.

In a series of 80 prepubertal girls aged 2 to 12 years old with vulvovaginitis and no suspicion of sexual abuse, probable bacterial pathogens were found in cultures of 36 percent. Group A streptococci, *S. aureus*, and *Haemophilus influenzae* (non–type b) were the most common isolates.[266] In another series of 74 girls, group A streptococci and *H. influenzae* were isolated in 47 percent and 12 percent. Most of these girls had had symptoms for 7 days or less at the time treatment was sought.[51] These bacteria, especially group A streptococci, causing vulvovaginitis may lead to more severe symptoms that result in care being sought soon after onset, whereas pathogenic bacteria generally are less likely to be found when girls present for care after several weeks of symptoms.

Genital discharge does not always indicate infection or inflammation. Most female infants have a grayish white, mucoid discharge from the vagina during the newborn period. This discharge consists of desquamated vaginal mucosa and cervical epithelium that has undergone hypertrophy because of prenatal stimulation by placental and maternal hormones. Microscopic examination of the material reveals masses of large, superficial vaginal epithelial cells (Fig. 48–1). The condition may last for several weeks, is not pathogenic, and does not require treatment. Urinary leakage from an ectopic ureter opening into the genital tract may mimic a vaginal discharge.

A pubertal girl nearing menarche may have a copious viscous, transparent secretion that fills the vagina, bathes the vulvar tissues, and soils underclothing. The parents of such a girl may be concerned that she has a vaginal infection. In this case, the vulvar and vaginal tissues are thick and moist, a sign of increased estrogen stimulation. Microscopic examination of the vaginal fluid reveals masses of estrogenized superficial vaginal epithelial cells and few leukocytes (Fig. 48–2). Test results for pathogenic bacteria are negative. The parents should be reassured that the girl does not have an infection. Frequent bathing and changes of underclothing are all that is needed.

Poor hygiene with subsequent overgrowth of a mixed aerobic and anaerobic bacterial flora is the most common cause of pre-

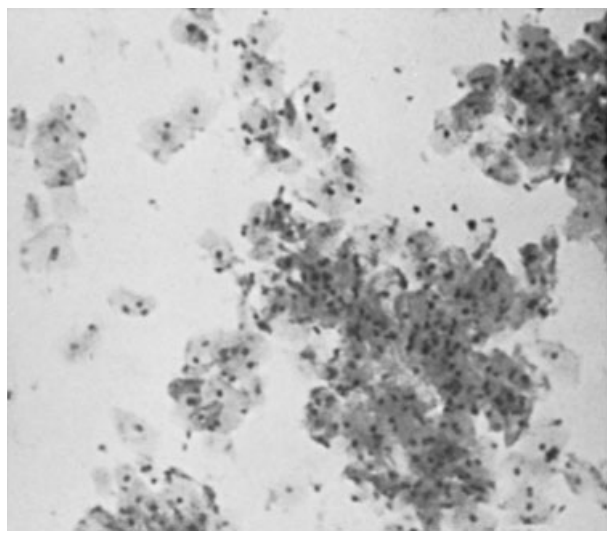

Figure 48–1 Cytosmear from the vaginal discharge of a newborn.

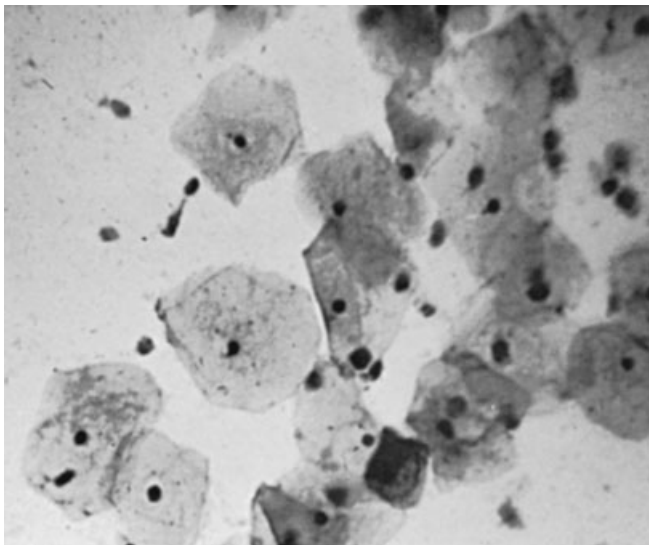

Figure 48–2 Cytosmear from the vaginal secretion of a pubertal girl. Masses of epithelial cells and few bacteria or leukocytes attest to its nonpathologic character.

menarcheal vulvovaginitis.[209] Inflammation of the lower genitourinary tract also may be caused by a variety of specific microorganisms, chemicals, and other physical agents. Contact irritation and allergic reactions induced by soaps, detergents, and medications are frequent causes of vulvovaginitis. Some systemic diseases and focal skin disorders may mimic vulvovaginitis or allow it to develop as a secondary process when these conditions involve the vulvar or perineal tissues.[80,90] Anatomic abnormalities also may be associated with vulvovaginitis. An increased incidence of vulvovaginitis and urinary tract infections has been reported in girls with high posterior commissures.[287] Drainage from an ectopic ureter into the vagina can cause chronic vulvovaginitis and lead to the formation of vaginal calculus. Labial adhesions were present in 7 percent of girls with vulvovaginitis in one series.[213] Table 48–2 outlines the causes of vulvovaginitis in premenarcheal girls.

The history should include information about the manner and circumstances surrounding the onset of the complaint, the characteristics of any discharge, the duration of symptoms, whether the problem is recurrent, and the nature of any recent treatments or medications. Information should be elicited regarding the use of bubble baths, enuresis, history of atopic dermatitis or allergies, anal pruritus (associated with pinworm infection), recent respiratory or skin infections in family members, and hygienic practices. The possibility that the child may have had or has a systemic disorder affecting the genitalia should be explored.

Sexual abuse must be considered when a child has a genital infection, regardless of the nature of the infection or the socioeconomic status of the family. This concern is particularly relevant when the child has a sexually transmissible disease, but any infectious organism can be transmitted to the genitalia by digital contact. Sexual abuse does not require penile penetration of the vagina. The history of vaginal or penile discharge in other family members should be ascertained. Behavioral changes, nightmares, fears, abdominal pain, headaches, and enuresis can be indicators of abuse or other psychosocial stressors.

The characteristics of the discharge frequently do not help identify a specific cause. At the onset of an infection, the discharge likely is thick, purulent, and profuse. It may become scanty and seropurulent in later chronic stages of infection.[133] Discharges that are odorless and bloody or serosanguineous may result from noninfectious conditions, such as vulvar irritation, trauma, precocious puberty, foreign body, urethral prolapse, or tumor. Vulvovaginitis caused by *Shigella* or group A streptococci also can cause bleeding, as can an eroding foreign body. Foul-smelling discharge suggests a foreign body but also may result from a necrotic tumor. Specific diagnoses are made more often when symptoms have been present for less than 1 month.[279]

A general physical examination should precede assessment of the genital tract. The gynecologic examination begins with abdominal inspection and palpation followed by external examination of the perineum and genitalia, including the vulva, urethral meatus, clitoris, hymen, and anus. The examination should be done with the child in a supine, frog leg position. The labia can be retracted gently to visualize the anterior of the vagina. Speculum and bimanual examinations generally are inappropriate in prepubertal children.[214] Note should be made of structural abnormalities, inflammation, sores and ulcerations, and excoriations. If complaints consist only of vulvitis, and findings on external examination are limited to a scanty mucoid discharge and an erythematous introitus, further examination generally is unnecessary.[72]

If the vaginal discharge is purulent, persistent, or recurrent, a thorough gynecologic assessment is warranted. Visualization of the vagina and cervix without instrumentation is possible with the child in the prone knee-chest position.[74] This method is useful in children older than 2 years. In this position, with labial traction, the vaginal muscles relax and stretch the hymenal membrane open. An otoscope head or a magnifying lens with a good wall light is used to visualize the cervix. Because the vagina of a prepubertal child is short, a foreign body or a lesion may be seen.[71]

A rectal examination may be important when persistent discharge, bleeding, or pelvic or abdominal pain is present. The rectal examination may help express discharge from the vagina that previously was not recognized and can permit palpation of hard foreign bodies or abnormal masses.

Visualization with instrumentation (vaginoscopy) is required in some situations. General anesthesia may be required for girls who are small or unable to cooperate, or who may experience significant anxiety or discomfort during the procedure. Conscious sedation for the procedure may be an option in some situations. When a purulent, persistent, or recurrent vaginal discharge is present, samples should be obtained for culture and Gram stain. Gram stain of exudates may provide information rapidly that points toward a specific pathogen and may indicate the need for additional evaluations or interventions. Wet mount preparations may be useful if fungal infection (potassium hydroxide preparations) or pinworms are suspected. Saline wet mount may be indicated for trichomoniasis if sexual abuse is suspected. Urinalysis with microscopic examination should be performed. A complete blood cell count may be useful when pyogenic infection is suspected or bleeding has occurred.

When cultures are indicated, separate vulvar and vaginal specimens may be necessary. The type and duration of discharge and considerations of potential sexual abuse influence this decision. Vulvar specimens alone may be appropriate when etiologies such as group A streptococci are suspected. Exudates emanating from the vagina in prepubertal girls also are adequate specimens for evaluation for gonorrhea, such that vaginal swabs or aspirates are not required. Further information on types of specimens required for specific sexually transmitted infections such as gonorrhea or *Chlamydia trachomatis* is provided in Chapters 100 (gonorrhea) and 206 (*C. trachomatis*).

Options for obtaining vaginal specimens in young girls, when needed, include use of (1) a nasopharyngeal Dacron swab moistened in nonbactericidal saline, inserted carefully through the hymenal opening; (2) a catheter-within-a-catheter technique (Fig. 48–3)[214]; or (3) a sterile newborn suction catheter, with insertion 2 to 3 cm into the vagina.[266] For the catheter-within-a-

TABLE 48–2 Etiologic Factors in Premenarcheal Vulvovaginitis

Bacterial Infections
Nonspecific mixed infections secondary to
- Poor perineal hygiene
- Foreign body in vagina
- Respiratory tract infections
- Skin infections (impetigo)
- Urinary tract infection

Specific nonvenereal infection
- Hemolytic streptococci (groups A, B, F)
- *Escherichia coli*
- *Shigella flexneri*, *Shigella sonnei*
- *Neisseria meningitidis*, *Neisseria sicca*
- *Haemophilus influenzae* type b, nontypeable strains
- *Streptococcus pneumoniae*
- *Corynebacterium diphtheriae*
- *Yersinia enterocolitica*
- *Mycobacterium tuberculosis*
- *Moraxella (Branhamella) catarrhalis*
- *Staphylococcus aureus*

Specific venereal infections
- *Neisseria gonorrhoeae*
- *Treponema pallidum*
- *Chlamydia trachomatis*
- Chancroid *(Haemophilus ducreyi)*
- Granuloma inguinale

Bacterial vaginosis
- *Gardnerella vaginalis*
- *Mobiluncus* species

Fungal Infections
Candida albicans
Other yeasts
Dermatophytes

Protozoan and Parasitic Infections
Trichomoniasis
Amebiasis
Enterobius vermicularis
Hirudiniasis
Schistosomiasis
Other parasitic infections (ascariasis, trichuriasis)

Viral Infections
Venereal
- Herpes simplex
- Condyloma acuminatum (papillomavirus)
- Molluscum contagiosum

Involvement as part of systemic infection
- Measles
- Varicella
- Mononucleosis (Epstein-Barr virus)
- Coxsackievirus
- Smallpox

Infestations
Pediculosis
Scabies

Contact Irritation or Allergic Reactions
Bubble bath preparations
Hair shampoos
Vulvar deodorant sprays
Soaps, laundry detergents
Other medications

Vulvar or Perineal Skin Diseases
Local
- Seborrhea
- Lichen sclerosus et atrophicus
- Lichen planus
- Lichen simplex chronicus
- Premalignant leukoplakia
- Erythrasma (*Corynebacterium minutissimum*)
- Bartholinitis
- Skenitis

Involvement as part of a systemic disorder
- Psoriasis
- Bullous pemphigoid
- Atopic dermatitis
- Drug eruption
- Generalized pruritus with excoriation
- Chronic liver disease
- Chronic renal disease
- Metabolic errors
- Psychosomatic
- Crohn disease
- Sjögren syndrome
- Henoch-Schönlein purpura
- Histiocytosis
- Kawasaki disease
- Stevens-Johnson syndrome
- Typhoid
- Zinc deficiency

Physical Factors
Sand (sandbox)
Chemical or thermal trauma
Physical trauma (accidents, abuse, masturbation)
Nylon, rayon underclothing
Tight garments (maceration in warm climates)
Anatomic abnormalities
- Neoplasms (sarcoma botryoides)
- Polyps
- Labial agglutination, adhesion
- Prolapsed urethra
- Ectopic ureter
- Rectal fistula
- Draining pelvic abscess via fistula

Data from references 11, 12, 72, 80, 81, 134, 163, 183, 250.

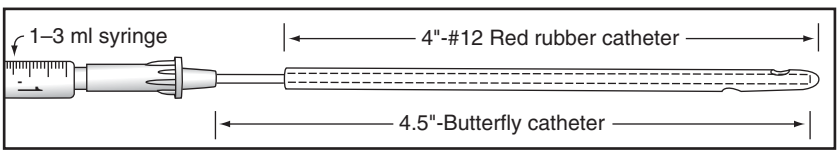

Figure 48–3 Assembled catheter-within-a-catheter for obtaining specimens from a prepubertal child. *(From Pokorny, S. F., and Stormer, J: A traumatic removal of secretions from the prepubertal vagina. Am. J. Obstet. Gynecol. 156:581, 1987.)*

catheter technique, the distal 4 inches of a soft, size 12 bladder catheter and the proximal 4 inches of butterfly needle intravenous tubing are excised from their parent devices by sterile technique. The catheter-within-a-catheter is inserted into the vagina, and fluid is flushed in and out of the upper part of the vagina several times before final aspiration into the syringe and removal of the device.

Nonspecific Vulvovaginitis

Nonspecific vulvovaginitis is identified by vaginal cultures that yield a growth of mixed bacteria not related etiologically to a specific disease. Nonspecific vulvovaginitis is the premenarcheal genital disorder most frequently encountered[133] and is responsible for 25 to 75 percent of cases of vulvovaginitis diagnosed in

this age group in referral centers.[279] In most cases, as noted in Table 48–2, identifiable secondary factors contribute to nonspecific vulvovaginitis.

Several factors other than those listed in Table 48–2 contribute to the occurrence of vulvovaginal infections in young children. The developing immature labia minora and majora flare outward as a young girl squats or sits. As a result, they do not protect the vestibular and vulvar mucosae from contamination, as occurs later in life. The nonestrogenized, prepubertal vulvar and vaginal epithelium, which consists of only a few layers of cells, is traumatized easily and infected readily; however, no evidence suggests that estrogen deficiency is a causative factor in premenarcheal vulvovaginitis. The alkaline vaginal reaction during childhood also is not as resistant to infection as is the acidic vaginal secretion of postmenarcheal girls and women. Because children frequently do not cleanse themselves properly after defecation, the perineum and vulva often are contaminated by fecal material. Nonabsorbent nylon garments or other tight-fitting clothes can lead to maceration, which predisposes to the development of infection.

VULVOVAGINITIS SECONDARY TO POOR PERINEAL HYGIENE

A vulvovaginal infection is considered to be secondary to poor perineal hygiene when bacteria native to the lower gastrointestinal tract are found in properly obtained cultures from the vagina. In a large series of cases of vulvovaginitis subjected to culture, *Escherichia coli* or other coliform organisms were found in 70 percent of patients in the series.[120] Other studies also have found a higher prevalence of *E. coli* in vaginal cultures from girls with vulvovaginitis than in asymptomatic controls.[72] The reappearance and disappearance of premenarcheal vulvovaginitis secondary to poor perineal hygiene are related directly to the appearance and disappearance of coliform organisms in vulvovaginal cultures. The primary role of vulvar and vaginal contamination with fecal material as a result of inadequate cleansing after defecation is supported by the observation that symptoms resolve in most cases when proper perineal hygiene is the only treatment recommended. Fifteen to 20 percent of children have recurrences, usually 1 month or more after resolution of the initial episode. In most instances, recurrences can be attributed to poor perineal hygiene.[120]

Children with nonspecific vulvovaginitis secondary to poor perineal hygiene do not have any uniform historical findings. If asked, the parent may be able to describe the way that the child cleanses herself after defecation. Many children wipe themselves from back to front after defecation. In girls, this practice easily results in fecal contamination of the vulvar area.

On examination, the vulvar mucosa and outer third of the vagina usually are hyperemic and covered with a scant, light gray mucoid discharge. Frequently, a clue to the cause of the infection is fecal soiling around the anus or on the perineum. Inspection of the undergarments may show fecal material in the area that comes in contact with the vulva, unless, as often is the case, the girl has been bathed and dressed in clean clothes before visiting the physician.

Instructing parents regarding perineal and vulvar cleansing when girls are bathed decreases the likelihood that nonspecific vulvovaginitis will develop in their daughters. Young girls should be taught proper hygiene and that they should wash their hands before and after urinating and defecating. Routine inspection of the perineum, vulva, hymen, and clitoris should be a part of routine physical examinations, including well-child checkups.[133]

Proper cleansing of the perineum and anus after defecation and sitz baths leads to the resolution of symptoms and infection in most cases. Sitz baths (warm water with or without Aveeno colloidal oatmeal or baking soda) 10 to 15 minutes in duration should be taken two to six times per day, depending on the severity of the vulvovaginal inflammation.[72] For intense, oozing inflammation, wet compresses with Burow's solution (1:40) or plain water applied every 3 to 4 hours may be used instead of sitz baths.[11] In mild cases, the vulva may be washed twice a day with water or a mild, unscented, nonmedicated soap (e.g., Basis, unscented Dove, Neutrogena). The perineum should be patted dry gently after baths or treatments. Complete drying may be facilitated by sitting for 10 minutes with the legs spread apart. Urinating with the labia and legs spread apart to minimize urinary reflux into the vagina may be helpful. Witch hazel pads (Tucks) may be used for cleansing after defecating and to provide mild analgesia.[252]

White cotton underpants, changed frequently to absorb discharge, and loose-fitting clothing should be worn for several days to a few weeks after the symptoms resolve. Continued wearing of such clothing also may be helpful in preventing recurrences of vulvovaginitis, especially in girls living in warmer climates.

As the inflammation and exudate subside over 1 to 2 days, sitz baths may be reduced in frequency and alternated two to four times a day with the application of either calamine lotion or protective ointments, such as zinc oxide, Desitin, Vaseline, and A and D ointment. If pruritus is a significant symptom, an oral agent such as hydroxyzine hydrochloride (Atarax) or diphenhydramine hydrochloride (Benadryl) may be administered. Topical application of 1 percent hydrocortisone cream or triamcinolone acetonide (Mycolog) cream may be used as the inflammation resolves but should be avoided in the acute phase.[252]

Shampooing the hair while sitting in a bathtub and using harsh soaps, bubble baths, or other preparations that might lead to chemical irritation of the vulvar skin and vaginal mucosa should be avoided throughout the course of vulvovaginitis.[19,32,39] The application of powders should be avoided, at least until the acute symptoms have resolved.

Patients who do not improve after 2 to 3 days of hygienic measures should be re-evaluated. Specimens taken from the vagina should be sent for aerobic and anaerobic bacterial cultures, if these were not done initially. An intravaginal triple-sulfa medication such as Sultrin vaginal cream, which consists of sulfathiazole, sulfacetamide, and sulfabenzamide, may be given.[2,90] Approximately 1 mL is inserted into the vagina with a 5-mL Luer syringe each night for 7 nights (the applicator that comes with the tube of cream is too large to insert into the immature vagina). A 5-cm piece of 12 or 14 French urethral catheter attached to the syringe facilitates application of the cream, if the patient is cooperative (Fig. 48–4). Parents must be warned against and instructed on how to avoid inserting the cream into the child's urethra and bladder.[120] Alternatively, the vagina may be irrigated with a 1 percent povidone-iodine (Betadine) solution with this same method and caveat.[72]

Intractable nonspecific vulvovaginal infections that are not caused by foreign bodies, intestinal parasites, or poor perineal hygiene are encountered occasionally. They are resistant to hygienic measures and topical antibiotics. Reducing vaginal pH from an alkaline or neutral to an acid reaction often helps in these difficult cases and may be achieved either by the local use of estrogen or by daily flushing of a solution of 1 mL of lactic acid (USP) in 250 mL of tap water into the child's vagina with a 10-mL Luer-type syringe and a section of a rubber or plastic urethral catheter, as shown in Figure 48–4.[120]

Estrogens cause thickening of the thin prepubertal vaginal mucosa, which reduces vaginal pH. These events generally are therapeutic. Estrogens are not recommended for the treatment of routine cases of premenarcheal vulvovaginitis for two reasons: the results do not seem to be superior to nonhormonal therapies in these cases,[120] and prolonged administration of topical estrogens may cause isosexual pseudoprecocity. For intractable cases, estrogen should be applied topically and not orally. A globule of estrogen cream (Premarin vaginal cream) measuring not more

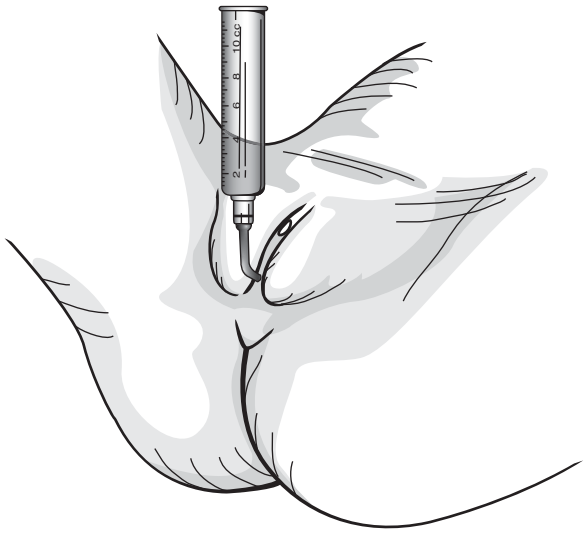

Figure 48–4 The barrel of a Luer-type syringe and attached piece of urethral catheter are used for vaginal lavage in an older child with a vaginal infection.

than 5 mm in diameter should be rubbed gently onto the inner surfaces of the labia minora and external surface of the hymen. This procedure is repeated daily for 2 to 4 weeks. After 7 to 10 days, the vulvar and vaginal tissues usually thicken, and a mucoid vaginal secretion may appear. The parents must understand clearly that the cream must be used for no longer than instructed. The cream should be discontinued if thelarche occurs.

Oral or parenteral antibiotics may be indicated if symptoms persist for 2 to 3 weeks, or if a specific pathogen that requires antibiotic treatment is isolated. When possible, selection of antibiotic agents and the route of administration should be based on susceptibility testing of organisms isolated from vaginal cultures. Nonspecific vulvovaginal infections are benign, superficial, localized mucosal inflammations that usually respond to less potent chemotherapeutic agents when they are needed. Many antibiotics are absorbed through the vaginal mucosa. The indiscriminate use of vaginal, oral, or parenteral antibiotics may result in the child becoming sensitized to them.

NONSPECIFIC VULVOVAGINITIS SECONDARY TO INTESTINAL PARASITES

Pinworms (*Enterobius vermicularis*) are the causative factor in many cases of recurrent or intractable nonspecific vulvovaginitis in children.[72] Infection occurs when the worms in the lower bowel crawl out of the anus onto the perineum and migrate into the vagina, where they deposit ova. The pinworms may carry *E. coli* and other coliform bacteria into the vagina, which may lead to vulvovaginitis. Other intestinal parasites seldom invade the vagina, although in one case *Ascaris lumbricoides* was discovered in the vagina of a child.[133]

Infestation with pinworms occurs commonly and does not indicate poor hygiene. Pinworm ova may be deposited in playground soil, on toys or books, and on the hands of infected individuals. Infection frequently is asymptomatic.

A child with a pinworm infection and vulvovaginitis usually has a history of a chronic vaginal discharge that has recurred despite repeated attempts to eradicate it. Parents may note worms on the perineum of the child and that she awakens at night because of perineal itching. Other family members or the girl herself may have had pinworms previously.

Examination reveals a low-grade inflammation of the vulva and vagina. Excoriations from scratching may be seen on the perineum. Vaginoscopy (if indicated) shows an inflammatory reaction extending to, but not including, the cervix. Vaginal cultures produce a mixed growth of nonpathogenic bacteria, with *E. coli* and other coliform bacteria generally predominating.

The diagnosis depends on finding pinworm ova on smears from the perineum or in the vaginal discharge or a report from parents that worms are visible on the child's perianal skin. A perineal smear is most likely to show the presence of pinworms, but pinworm ova may be detected in a wet smear of vaginal secretions (Fig. 48–5).

When a perineal smear for the ova of *E. vermicularis* is to be obtained, the parent is given a wooden tongue blade, a piece of Scotch tape, and a glass microscopic slide. The tape is attached to the tongue blade, adhesive side out (Fig. 48–6), and applied

firmly to several areas around the anus. It is removed and applied, adhesive side down, to the glass slide, which is sent to the laboratory for examination.

The type of discharge, the appearance of the vaginal mucosa, or the presence or absence of pruritus does not aid in establishing a diagnosis. A history of a previous pinworm infection in the patient, a member of the family, or a playmate is significant. Pinworms should be suspected when a child has recurrent episodes of intractable nonspecific vulvovaginitis.

Treatment consists of eradicating the pinworms. All members of the family are presumed to be infected and must be treated. Several highly effective drugs are available for this purpose; among them are pyrantel pamoate, given as a single dose of 11 mg/kg, not to exceed 1 g, and mebendazole, 100 mg given orally as a single dose. Either treatment should be repeated after 2 weeks. Three negative perianal smears, taken at weekly intervals, should be obtained before one can assume that the worms have been eradicated. The vulvovaginitis caused by coliform organisms carried on pinworms is treated the same as other cases of nonspecific vulvovaginitis caused by poor perineal hygiene (see earlier).

NONSPECIFIC VULVOVAGINITIS SECONDARY TO VAGINAL FOREIGN BODIES

Foreign bodies account for approximately 4 percent of cases of vaginal discharge in premenarcheal girls.[11] When a foreign body remains in the vagina for some time, it inevitably causes nonspecific vulvovaginitis. Many types of vaginal foreign bodies, including safety pins, glass beads, coins, beans, bits of crayon, and parts of toys, have been reported. The most common objects are bits of toilet paper or shreds of cloth from nightclothes or bedding (Fig. 48–7).[122,134]

The history does not contribute to the diagnosis unless the child has a record of having put objects in her vagina previously. Usually, the parent is unaware that the child has inserted something into her vagina. The child is brought to a physician because of a profuse, foul-smelling, sometimes blood-tinged discharge. The presence of such a discharge is almost pathognomonic for the presence of a foreign body. Even without a profuse discharge or bleeding, a foul odor from the vagina suggests a foreign body.

Examination reveals inflammation of the vulvar and vaginal mucosa. Although foreign material may be seen when the labia are separated, vaginoscopy often must be performed to explore the full length of the vagina. Rarely, a metallic object that has been in the vagina for some time erodes the mucosa and becomes hidden in granulation tissue. When such a condition is suspected, a radiograph should be obtained. Most foreign bodies, such as glass, plastics, paper, or cloth, are not radiopaque, however, and radiographic examination fails to detect the foreign material. Soft foreign bodies, such as toilet paper, can be flushed out of the vaginal canal.

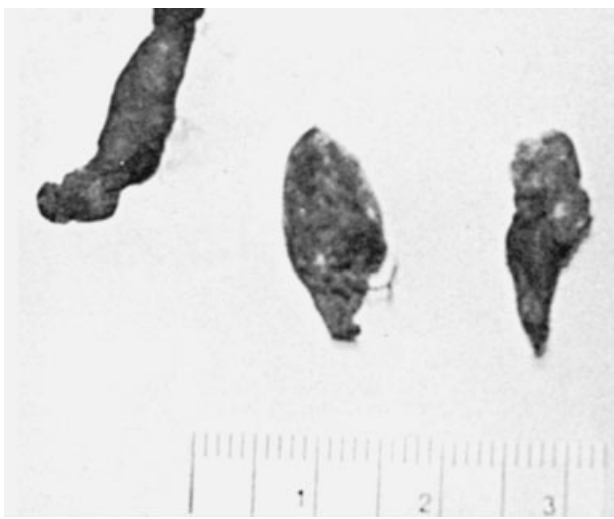

Figure 48–7 Bits of paper or cloth are the vaginal foreign bodies most frequently found in children.

The nonspecific vulvovaginitis caused by a foreign body disappears gradually after removal. Recovery can be hastened by using the hygienic treatments previously described. Repeat episodes are common.

Specific Vulvovaginal Infections

Specific vulvovaginal infections include infections of the premenarcheal vulva and vagina by bacteria that cause specific diseases in other sites.

GONORRHEAL VULVOVAGINITIS

Gonococcal infections of the prepubertal genital tract are manifested as vulvovaginitis and not the endocervicitis seen in postmenarcheal girls and women.[40,72,121,247,277,293] The alkaline environment of the unestrogenized vaginal tissues of young girls apparently limits spread of infection to the upper genital tract. Gonorrhea is found less commonly in children now than in the past but must be considered whenever a girl has vulvovaginitis.

Sexual contact should be suspected strongly and almost always is the source when a child has a gonococcal infection. Whether gonococcal infection is transmitted through nonsexual contact is controversial. Researchers have suggested that transmission may occur from freshly infected bedding, towels, or a toilet seat, or digital transmission from an infected adult. No absolute evidence exists, however, for any of these sources of infection. Gonococcal infections in nurseries have been traced to rectal thermometers, other instruments, fomites, and attendants, but before attributing a gonococcal infection to an environmental source, the possibility of sexual transmission must be considered strongly and investigated, and supportive epidemiologic evidence should be sought (e.g., cultures of potential reservoirs).

Neisseria gonorrhoeae was the most common cause of vulvovaginal discharge among prepubertal girls in Rwanda in the late 1980s. Sexual contact was considered likely in all cases because of a cultural belief that a man with a purulent urethral discharge could be cured by rubbing his penis on the external genitalia of a prepubertal girl.[25] In a prospective study of girls 12 months to 12 years of age in the mid-1990s in Cincinnati, Ohio, who had vaginal discharge and no suspicion of sexual abuse, 4 of 43 had positive cultures for *N. gonorrhoeae*.[250] Such cases should lead to investigation for probable sexual abuse.

The acute stage of gonorrheal vulvovaginitis is characterized by inflammation and a purulent discharge. The child may complain of vulvar discomfort, dysuria, frequent urination, and pain on walking. The child usually is well otherwise. Asymptomatic vaginal infection is rare. On examination, the vulvar tissues are edematous; hyperemic; and covered by a profuse, thick, yellowish discharge that exudes from the vagina. The entire vaginal mucosa is inflamed.

The urethra, paraurethral glands, and the major vestibular (Bartholin) glands rarely are involved in a premenarcheal gonorrheal infection. Vulvovaginal infections, including gonorrhea, in prepubertal children rarely, if ever, affect the upper genitalia (uterus, uterine tubes, ovaries, or pelvic peritoneum). Symptoms suggestive of pelvic peritonitis have been reported in premenarcheal children who had gonorrheal vulvovaginitis; all the patients recovered promptly after the administration of penicillin.[40,88]

The acute phase of infection lasts for a few weeks, after which most of the symptoms disappear except the discharge. The vulvar and vaginal tissues may remain hyperemic and macerated in some cases. The discharge becomes scanty and seropurulent, which may persist chronically.

The diagnosis of gonorrheal vulvovaginitis and its differentiation from other types of vulvovaginitis are established by vaginal smears and cultures. Specimens from the pharynx and rectum to test for *N. gonorrhoeae* also should be obtained. Because of the potential medicolegal use of the test results for *N. gonorrhoeae* among children, standard culture systems should be used for the diagnosis of *N. gonorrhoeae* in children. DNA probes (available for vaginal and urine specimens) and other rapid tests can be used as adjunctive evidence, but they should not be done in place of culture for the diagnosis of gonococcal infection in children. The presence of gram-negative intracellular diplococci in vaginal smears from a child with a history of exposure or with typical clinical findings is sufficient reason to start treatment, but it does not establish a definitive diagnosis. Other related species, particularly *Moraxella (Branhamella) catarrhalis* and *Neisseria sicca*, may be found in association with vulvovaginitis. A definitive diagnosis of gonorrhea is made only when *N. gonorrhoeae* is differentiated from other *Neisseria* spp. on the basis of glucose use. Additional confirmation of *N. gonorrhoeae* is recommended in children. Monoclonal fluorescent antibody tests or DNA probe confirmation tests are available. Isolates should be preserved to permit repeated or additional analyses.

Children weighing less than 45 kg with uncomplicated gonococcal vulvovaginitis and urethritis, pharyngitis, or proctitis are treated with a single dose of 125 mg of intramuscular ceftriaxone. An alternative is a single dose of intramuscular spectinomycin, 50 mg/kg (maximum 2 g), if ceftriaxone is contraindicated. Spectinomycin is not recommended for the treatment of gonococcal pharyngitis. Presently, spectinomycin is unavailable in the United States.[43] Treatment of children who are 8 years or older and weigh more than 45 kg follows the guidelines for postmenarcheal girls. In addition to ceftriaxone, 125 mg intramuscularly, single oral doses of cefixime (400 mg), ciprofloxacin (500 mg), or ofloxacin (400 mg) can be given to these girls. Local treatment is limited to gentle cleansing of the vulva and perineum. For hospitalized children, standard isolation precautions are recommended until 24 hours after effective parenteral therapy has been administered. Empiric therapy with erythromycin, azithromycin, or doxycycline to treat potential concomitant infection with *C. trachomatis* is given routinely to individuals with gonococcal infection.[42]

Follow-up cultures should be obtained from all infected sites 2 weeks after treatment to ensure that it has been effective. If not done as part of the initial evaluation, children confirmed as having gonorrhea should be evaluated for co-infection with *C. trachomatis*, *Treponema pallidum*, *Trichomonas*, human immunodeficiency virus (HIV), and hepatitis B virus.

PREMENARCHEAL CHLAMYDIAL VAGINITIS

Although *C. trachomatis* apparently is an uncommon cause of vaginitis in prepubertal girls, vaginal infection with *C. trachomatis* can occur in children with or without a known history of sexual activity and should be considered in the evaluation of a child with vaginal symptoms. Only a few studies have evaluated young children for *C. trachomatis*. These studies have involved mostly children being evaluated for sexual abuse or vulvovaginal symptoms, or both, and some have included a control group in an attempt to control either for a history of sexual activity or for vaginal symptoms.

In studies evaluating premenarcheal children with vulvovaginitis, recovery of *C. trachomatis* has been low in children with symptoms and healthy control groups. In one study, none of the 35 children with symptoms had *C. trachomatis*, whereas 1 of 35 without symptoms had *C. trachomatis* isolated.[209] In another study conducted in a pediatric gynecology clinic, 4 of 29 (14%) premenarcheal girls were found to have *C. trachomatis*.[37] All four had a homogeneous white discharge, and one had a bloody discharge. Sexual abuse occurred in two of the children and was considered possible in another. In a Cincinnati study evaluating vaginitis in girls younger than 12 years in whom sexual abuse was not suspected, none of the 87 children had a positive culture for *C. trachomatis*.[250] Similarly, in a smaller study of 11 girls with vaginitis, none was found to have *C. trachomatis*.[225]

In studies evaluating children suspected of being sexually abused, rates of recovery tend to be higher than those seen in children with vaginitis. In one study, a history of sexual abuse was discovered in two control children only after *C. trachomatis* was identified.[109] Initially, 2 percent of children with a history of sexual abuse versus 4 percent of healthy controls had positive vaginal cultures for *Chlamydia*. On further questioning, however, the two children in the control group with *C. trachomatis* were siblings who were sexually abused 3 years earlier, changing the rate of *C. trachomatis* vaginal infection in the sexual abuse group to 6 percent and decreasing the rate in the control group to 0 percent. This misclassification, if not discovered, would have changed the conclusion of the study, which suggested that similar rates of *C. trachomatis* infection occur in children with and without a history of sexual contact. This incidence illustrates the importance of thoroughly investigating the possibility of sexual abuse whenever a sexually transmitted pathogen is isolated in a young child. In a Cincinnati study evaluating children for sexual abuse, rates were low in prepubertal girls compared with pubertal girls (0.8% versus 7%),[253] whereas in a study in Raleigh, North Carolina, 6 percent of sexually abused girls younger than 12 years versus 0 percent of control children had *C. trachomatis* isolated from their vagina.[140] Four of the 10 children in the latter study had a vaginal discharge.

The highest rates of *C. trachomatis* infection were seen in a Los Angeles study, in which 47 prepubertal girls were examined for alleged sexual abuse and 17 percent had *C. trachomatis* isolated from vaginal specimens.[89] The variation in rates among studies may reflect differences in the prevalence of *C. trachomatis* in different communities. Although co-infection with *C. trachomatis* has not been studied well in prepubertal children, experience from adult populations has shown that it should be suspected in children with *N. gonorrhoeae* infection. In one study in prepubertal girls, 30 percent with *N. gonorrhoeae* also tested positive for *C. trachomatis*.[225]

One possibility is that a positive chlamydial culture in a young child, especially a child younger than 3 years, may be due to persistence of perinatal infection. Subclinical infections have been reported in 14 percent of infants of mothers with active *C. trachomatis* infection.[238] Many infants infected with *C. trachomatis* at birth remain infected for 372 days in the vagina; 383 days in the rectum; and 866 days in the conjunctiva, nasopharynx, and oropharynx.[21] Persistence of perinatal infection for 18 months and for 6 years has been reported in other studies as well.[172,237,275] Although persistence of perinatal infection can occur, when *C. trachomatis* is identified in vaginal specimens, sexual abuse still must be suspected strongly.

In contrast to premenarcheal gonorrhea infections, chlamydial vaginitis in children often seems to be asymptomatic. Because of study design issues in evaluating children with *C. trachomatis* infection, in which only children with a history of sexual abuse or vaginal symptoms, or both, are included, fully understanding the spectrum of symptoms seen in young children is difficult. In one study evaluating symptomatic children with *C. trachomatis* vaginal infection, 25 percent had a vaginal discharge and 12 percent had vaginal bleeding.[89]

Numerous diagnostic methods for *Chlamydia* are available.[23] Direct tissue culture isolation of *C. trachomatis* remains the gold standard and is the only test that should be used in prepubertal children or in cases in which sexual abuse is under consideration.[42] Culturing for chlamydiae requires isolation of the organism in tissue culture and confirmation of the characteristic intracytoplasmic inclusions by fluorescent monoclonal antibody staining.[42] Although the specificity of tissue culture approaches 100 percent, tissue culture is only 70 to 85 percent sensitive compared with DNA amplification techniques.[23] The low recovery rate in studies of prepubertal children may be due to the low sensitivity of tissue culture or the use of vaginal cultures in young children. Isolation rates from the vagina usually are lower than rates of recovery from the endocervix.[176]

Nonculture chlamydia tests, including enzyme immunoassays, direct fluorescent antibody tests,[1] DNA hybridization, and DNA amplification tests, are available and have been investigated in cervical and urine specimens and approved for use in sexually active postmenarcheal adolescents and adults. These tests have not been field-tested for large numbers of vaginal specimens from premenarcheal girls. In addition, rectal or pharyngeal specimens have not been tested. False-positive results have been reported in vaginal specimens for some of these tests in children, and these tests should not be used in premenarcheal children.[112,215] False-positive results probably are caused by cross-reactivity with common anogenital organisms, such as group A and B streptococci, *Acinetobacter* spp., *N. gonorrhoeae*, *G. vaginalis*, *E. coli*, *Proteus* spp., and *Staphylococcus* spp.[156,228,231,232,274]

The treatment of choice for chlamydial infection, including vaginitis in children weighing less than 45 kg, is erythromycin, 50 mg/kg/day in four divided doses for 10 to 14 days.[42] Because erythromycin base or ethyl succinate is only 80 percent efficacious, a test of cure should be considered 3 weeks after completion of treatment. A second course of therapy is recommended if the repeat culture is positive. Children weighing 45 kg or more but who are younger than 8 years of age should be treated with azithromycin as a single 1-g oral dose. For children 8 years and older, two regimens are recommended: azithromycin as a single 1-g dose or doxycycline at a dose of 100 mg twice a day for 7 days.[42] Because these two regimens are highly efficacious, a test of cure is recommended only if symptoms persist or re-infection is suspected.

PREMENARCHEAL VAGINAL TRICHOMONIASIS

Vaginal trichomoniasis is reported infrequently in prepubertal children. This low prevalence may be accurate or could be due to lack of appropriate testing or limitations of the diagnostic techniques used in studies in prepubertal children. Many diagnostic techniques are available; however, the diagnosis of *Trichomonas vaginalis* infection typically is made by identifying the motile, triflagellated trichomonads in urine or wet preparations of vaginal secretions or through culture of vaginal secretions (see Chapter 226).[42,72] Stained smears of vaginal discharge may reveal trichomonads, but this method is the least sensitive of the available methods. The sensitivity of wet-mount examination of vaginal secretions depends on prompt transport of the specimen to the laboratory before the organisms lyse or lose motility and on the expertise of the individual examining the specimen.[157]

Although culturing of vaginal specimens is more sensitive, this method is not widely available. More sensitive techniques have allowed for the evaluation of culture and wet-mount methods. In a study examining vaginal swab samples using polymerase chain reaction (PCR), culture and wet-mount evaluations were found to have sensitivities of 70 percent and 36 percent.[72] A urine-based PCR enzyme-linked immunosorbent assay had a sensitivity and specificity of 91 percent and 93 percent compared with wet mount or culture.[147] Such techniques may be promising for detection of *T. vaginalis* when vaginal specimens are unavailable and culture of specimens is not feasible. Because of a lower specificity than that of culture, however, these techniques probably never will be recommended for use in prepubertal children in whom sexual abuse would need to be considered.

Trichomoniasis in newborns through the acquisition of *T. vaginalis* from the mother's vagina during delivery, with recovery of *T. vaginalis* from urine, vaginal, and respiratory tract specimens, has been described in several case reports.[5,50,54,169,178,216,260] The prevalence of *T. vaginalis* in healthy, vaginally delivered infants of mothers with *T. vaginalis* is unknown. In one study, *T. vaginalis* could not be identified in any of the 14 female infants of mothers in whom *T. vaginalis* was diagnosed.[34] The overall prevalence of *T. vaginalis* in the 868 mothers was 4 percent, but the denominator of mothers of female infants was not described. In another study of 984 female infants, direct smear or culture (or both) of infant vaginal specimens identified 3 infants with *T. vaginalis*, a prevalence of 0.3 percent.[9] Two of the three infants had a vaginal discharge. The overall prevalence of infection in the mothers of the 984 infants was not reported. Of the three infants with *T. vaginalis*, one mother had a history of vaginal discharge and a negative direct smear for *T. vaginalis*, and the other two mothers had no history of *T. vaginalis*.

Numerous reports in the literature confirm the occurrence of *T. vaginalis* outside the newborn period in prepubertal girls evaluated for vaginitis. The prevalence of *T. vaginalis* in prepubertal girls with vaginitis but no history of sexual abuse ranged from 0 to 4 percent.[102,120,142,209,250] In studies with a healthy control population,[101,120,142] *T. vaginalis* was not identified in any of the children in the asymptomatic control group.

T. vaginalis has been described in varying frequency in sexually abused prepubertal girls. A case report described *Trichomonas* vaginitis in two sexually abused children with vaginal discharge.[143] In two studies conducted in Raleigh, North Carolina, which described isolated pathogens in sexually abused children with a vaginal discharge, 19 percent of 52 children at risk for being sexually abused had positive wet mounts for *T. vaginalis* in one study, whereas only 2 percent of 141 children had *T. vaginalis* in the second study.[140] The variation in detection in this high-risk population cannot be explained easily. In studies systematically evaluating children for sexual abuse regardless of symptoms, *T. vaginalis* has not been recovered. In an Australian study evaluating 160 children younger than 10 years and 95 healthy age-matched controls, none of the children had *T. vaginalis* isolated from vaginal cultures.[93] Similarly, none of the 119 prepubertal girls evaluated for sexual abuse in a Cincinnati, Ohio, study had *T. vaginalis* identified by urinalysis or wet mount of vaginal secretions.[253] Without additional studies using culture techniques and conducted in diverse populations of prepubertal girls, determing the true prevalence of *T. vaginalis* in prepubertal girls who have vaginitis, with or without a history of sexual abuse, is difficult.

A more recent case report suggests that *T. vaginalis* could be transmitted within a family without sexual abuse or contact.[3] In this report, *Trichomonas* vaginitis was diagnosed in the mother, and her three prepubertal daughters were symptomatic with a vaginal discharge. Two of the three girls had *T. vaginalis* identified on wet-mount evaluation of their vaginal specimens. They had no history or evidence of sexual abuse, the father was asymptomatic, and microscopy of an early morning urine specimen was negative for *T. vaginalis*. Although these cases may have resulted from transmission within a family without sexual abuse, identification of *T. vaginalis* in a prepubertal child outside the newborn period should prompt further medical and social evaluation for sexual abuse. Additionally, if *T. vaginalis* is recovered from a child, the child should be evaluated for other sexually transmitted infections, including syphilis, *N. gonorrhoeae*, *C. trachomatis*, hepatitis B, and HIV infection.[72]

Metronidazole (Flagyl) is effective in the treatment of vaginal trichomoniasis in premenarcheal children. The recommended dose for prepubertal girls is 15 mg/kg/day in three divided doses (maximal dose 250 mg three times a day for 7 days), 500 mg twice a day for 7 days, or 40 mg/kg (maximum 2 g) in a single dose.[72] Metronidazole can be made into a suspension for young children and has a low level of toxicity. Possible side effects are described in the discussion of trichomoniasis in adolescent girls. Metronidazole is very effective, with cure rates of 90 to 95 percent; however, if the infection does not respond to treatment, prepubertal children should be re-treated with a 7-day course as described.[4,42] A vaginal preparation of metronidazole is available, but it is not recommended for the treatment of *T. vaginalis* infection.[42]

BACTERIAL VAGINOSIS

Bacterial vaginosis is a cause of vaginal discharge in adolescent girls and women and may be seen in premenarcheal girls. Bacterial vaginosis is caused by a change in the relative proportions of bacteria in the vaginal flora: an overgrowth of anaerobes and *G. vaginalis* and a decrease in hydrogen peroxide-producing lactobacilli.[12] Although overgrowth of *G. vaginalis* often is found in bacterial vaginosis, identification of *G. vaginalis* by culture of the vaginal discharge is not diagnostic because *G. vaginalis* may be present in girls with or without bacterial vaginosis.[42]

Two methods are used to establish the diagnosis of bacterial vaginosis—Gram stain of vaginal discharge and clinical criteria,[42,72] with clinical criteria being used more commonly. The Gram stain method is used to determine the relative concentrations of bacterial morphotypes and evaluate for the overgrowth of anaerobes. This method requires an examiner with expertise in evaluating specimens for bacterial vaginosis and is less practical than is the use of clinical criteria; thus, clinical criteria are used more widely. The clinical criteria used for establishing the diagnosis of bacterial vaginosis are the presence of three of four findings: a grayish homogeneous discharge, the presence of clue cells on a wet-mount evaluation, a pH greater than 4.5, and a positive amine test result (amine or fishy odor when vaginal secretions are mixed with 10% potassium hydroxide). Although these criteria have been used routinely in studies in postmenarcheal women, use of these criteria in premenarcheal girls has been inconsistent, rendering assessment of the prevalence of bacterial vaginosis in this population difficult.

Despite the fact that the presence of *G. vaginalis* is not diagnostic of bacterial vaginosis, studies in premenarcheal girls have examined the presence of *G. vaginalis* in vaginal secretions.[18,93,114,142] In a survey of vaginal flora in children without a vaginal discharge, *G. vaginalis* was isolated from 14 percent.[114] In another study, prepubertal girls with a history of sexual abuse were more likely to have *G. vaginalis* isolated from vaginal specimens (15%) than were girls with no history of sexual abuse and either genitourinary complaints (4%) or no genitourinary complaints (4%).[18] In girls with a vaginal discharge, *G. vaginalis* was isolated from 20 percent of 25 sexually abused girls versus none of 11 girls with no history of sexual abuse. In a study examining the vaginal flora of sexually abused and nonabused 3- to 10-year-old girls, 6 percent of abused versus 1 percent of nonabused girls had *G. vaginalis* in their vaginal secretions.[93] In a study of premenarcheal girls older than 2 years with vulvovaginitis, none of the 50 girls or their age-matched controls had *G. vaginalis* isolated from vaginal specimens.[142] Because *G. vaginalis* has been isolated from symptomatic and asymptomatic girls and from girls with and without a history or evidence of sexual abuse, culture for *G. vaginalis* should not be done in the evaluation of a child with a vaginal discharge or to determine whether sexual contact has occurred.

Bacterial vaginosis is defined poorly in premenarcheal girls. No published studies using the recommended criteria to make the diagnosis exist. Some studies have used some of the criteria, however, in an attempt to examine bacterial vaginosis in premenarcheal girls. In a study examining sexually transmitted infections in girls aged 1 to 12 years who were evaluated for possible sexual abuse, 99 of the 245 girls with a vaginal discharge had an amine test and were examined for clue cells.[139] Seven of the 99 girls (7%) had clue cells or a positive amine test, or both. In a similar study, 22 of 51 girls with a history of sexual contact and a vaginal discharge had an amine test performed and were evaluated for clue cells; all of them were negative for both tests.[140] In the same study, in a second group of girls defined as being at risk for having had undetected previous sexual contact, 30 girls had a vaginal discharge, and 10 had wet-mount preparations performed. One had a positive amine test and clue cells, and one had a positive amine test only. In both of these studies, the full criteria were not used, and only subgroups of girls with vaginal discharge were evaluated.

In another study, 31 abused and 23 nonabused girls aged 2.5 to 13 years had vaginal washes performed along with amine tests and testing for clue cells.[110] The abused girls had an initial visit and a follow-up visit more than 7 days after the abuse occurred. The nonabused girls had only an initial evaluation. One of the 23 nonabused girls had a positive amine test with normal examination results and was asymptomatic. Similarly, 1 of the 31 abused girls had a positive amine test on the initial visit. On follow-up evaluation, clue cells and a positive amine test developed in 4 of the 31 abused girls, and either clue cells or a positive amine test was noted in another 4 of the 31 girls. Either a new vaginal discharge or dysuria developed in five of these eight girls. Three of the eight girls were postmenarcheal. Whether the testing itself could have been responsible for the positive results is unclear because the control group did not undergo the follow-up evaluation.

Until studies using the proper and complete criteria are done in young girls with and without a vaginal discharge, the prevalence of bacterial vaginosis will be unknown and the significance of bacterial vaginosis as a cause of vaginal discharge in premenarcheal girls will remain unclear. At this time, the presence of manifestations of bacterial vaginosis should prompt the health care provider to consider treatment of bacterial vaginosis. In addition, the possibility of sexual abuse should be contemplated because a diagnosis of bacterial vaginosis does not provide evidence of sexual abuse. Because bacterial cultures may be performed in the evaluation of a vaginal discharge in a premenarcheal girl and *G. vaginalis* may be identified, identification of *G. vaginalis* should not be considered evidence of sexual abuse or diagnostic of bacterial vaginosis.

Numerous regimens for the treatment of bacterial vaginosis exist, but no specific recommendations are available for premenarcheal girls. Probably because bacterial vaginosis is diagnosed infrequently, clinical trials evaluating treatment of bacterial vaginosis in premenarcheal girls are lacking. The drugs recommended for use in young girls are those recommended for postmenarcheal women, with dosages based on the child's body weight. In small children (<45 kg), metronidazole can be given at 15 mg/kg/day divided two times a day for 7 days (maximum dose 1 g/day).[42,72] Two intravaginal preparations also are available as alternative regimens for adolescents. Two percent clindamycin given once a day for 7 days or 0.75 percent metronidazole gel given twice a day for 5 days can be used to treat bacterial vaginosis.[42] An alternative regimen for younger girls is oral clindamycin; a dose of 10 to 20 mg/kg/day divided three times a day for 7 days is suggested.[197]

MYCOTIC (FUNGAL) VULVOVAGINITIS

Candida albicans and other fungi can cause vulvovaginitis in infants and children. Although these infections can occur in any child, children with a history of recent antibiotic use, uncontrolled

Figure 48–8 Mycotic vulvovaginitis. The child is a diabetic.

diabetes mellitus, or immunosuppression are at an increased risk for development of fungal vulvovaginitis. In children with recurrent or persistent infection, especially with no history of antibiotic use, immunosuppressive conditions, such as diabetes or HIV infection, should be considered. Mycotic infections are not considered sexually transmitted infections, but they are discussed in this section because they can cause genital infections in young children.

Children with fungal vulvovaginitis usually complain of vulvar pruritus and burning. The burning results from urine coming in contact with desquamated or excoriated areas of the vulva. A vaginal discharge also may be present. In diapered children, an erythematous rash in the child's diaper area may be noticed.

Examination reveals findings of diffuse erythema of the vulvar mucosa that may extend onto the perineal area. The involved areas are red and shiny, and whitish plaques and edema may be found. Excoriated areas, caused by scratching, can be seen as well. If the condition has been long-standing, the edema, secondary infection, and repeated scratching may produce thickened and fissured lesions closely resembling chronic eczema or lichen sclerosus et atrophicus (Fig. 48–8). If the vagina is involved, the mucosa is dusky red, and small, whitish plaques on the vaginal surface or a scant white curdled discharge may be noted. The discharge, when present, is odorless.

The diagnosis of fungal vulvovaginitis is made by finding yeast and pseudohyphae on examination of the vaginal discharge or scraped material from the vulvar skin by Gram stain or wet preparation suspended in 10 to 20 percent potassium hydroxide (Fig. 48–9).[72] Further confirmation can be obtained by identifying fungus by culture of material from the vagina or vulva on Sabouraud or Nickerson media.

C. albicans and other fungi have been isolated from the vagina in asymptomatic and symptomatic girls. In a study examining the microbiology of the vagina, yeast was cultured from 48 percent of girls aged 2 months to 2 years, from 12.5 percent of girls aged 3 to 10 years, and from 35 percent of girls aged 11 to 15 years.[122] *C. albicans* (37%) and *Candida tropicalis* (26%) were the species most frequently isolated, but *Candida parapsilosis, Torulopsis glabrata*, non-*Candida* yeast species, and other *Candida* spp. were isolated as well.

In studies evaluating prepubertal girls with vulvovaginitis, fungi have been recovered at varying rates. In one study, *C. albicans* was isolated from 25 percent of 31 symptomatic prepubertal girls with an abnormal vaginal discharge or vulvovaginitis, whereas only 3 percent of asymptomatic girls had *C. albicans* isolated.[95] Another study found different results, with none of the

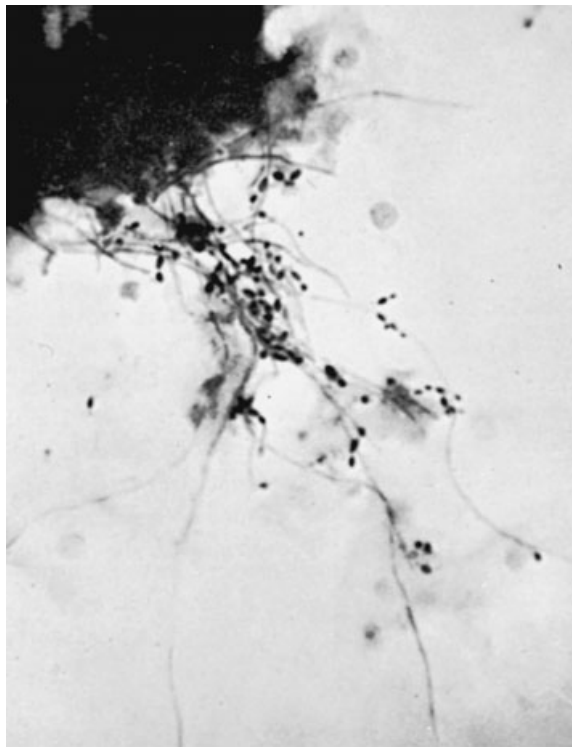

Figure 48–9 Hyphae of *Candida albicans* discovered on a wet smear of vaginal discharge.

50 asymptomatic girls and only 2 percent of the 50 girls with vulvovaginitis having *C. albicans*.[142] Similarly, in a study evaluating girls younger than 12 years with vaginal complaints, only 3 percent of the 74 girls had *C. albicans* isolated.[250] Neither of these groups of girls had a discharge on examination, and both had been treated recently with antibiotics. In a study that examined recovery of microorganisms from girls with vaginitis, 8 percent of the vaginal cultures of the 35 girls evaluated grew yeast.[101] In these latter two studies, assessing the role of yeast in the disease is difficult because there was no control population for comparison.

Several modes of therapy can be used for the management of fungal vulvovaginitis.[72] Numerous antifungal creams, including nystatin, miconazole, clotrimazole, or terconazole, are available. The creams should be applied as prescribed to the affected area after cleansing. In diapered children, the cream should be applied with each diaper change.

Curing fungal infections often is difficult in children who are taking antibiotics or who receive repeated courses of antibiotic therapy. In such cases, a 1-mL dose of nystatin suspension (Mycostatin), 100,000 U/mL, can be injected into the vagina three times a day for 10 days in infants and small children. In addition, the suspension should be administered at the same dose orally four times daily. Fluconazole (Diflucan) also can be administered as a one-time oral dose. A second dose may need to be administered for severe infections.[72] In older girls, vulvovaginal fungal infections can be treated with fungicidal vaginal creams, suppositories, or oral fluconazole as described in the section on vaginal infections in adolescent girls.[42]

NONGONORRHEAL NEISSERIAL VULVOVAGINITIS

Occasionally, other species of *Neisseria* are the causative agents in cases of premenarcheal vulvovaginitis. These gram-negative, intracellular and extracellular diplococci resemble *N. gonorrhoeae*

on stained smears. *M. catarrhalis* also is identical on Gram stain. Gram-negative diplococci should be speciated completely by the microbiology laboratory to avoid misidentifying of nongonococcal diplococci as gonococci and vice versa. Especially for pediatric patients, misidentification can result in serious medicolegal consequences for the family when unwarranted intervention is initiated, or it can result in failure to protect the child's welfare when appropriate measures are deemed unnecessary.[9]

N. sicca, generally considered nonpathogenic, has been isolated from children with vulvovaginal infections that clinically resembled gonorrhea.[283] *Neisseria meningitidis* also has been reported as a cause of vulvovaginitis.[77,102] Nongonococcal *Neisseria* spp. may be considered the cause of vulvovaginal infections when isolated as the predominant flora in the setting of vaginal inflammation and discharge.

Treatment of vulvovaginitis caused by nongonococcal *Neisseria* spp. or *M. catarrhalis* is the same as for *N. gonorrhoeae*. Most nongonococcal *Neisseria* spp. are not resistant to penicillin, but the need for therapy generally is based on the Gram stain finding of gram-negative diplococci, which for therapeutic purposes should be considered gonococci pending culture results. Although data are unavailable, a single dose of ceftriaxone probably should be as effective for these noninvasive *Neisseria* infections as it is for gonorrhea. Chemoprophylaxis, generally with rifampin, should be considered for family members and other contacts in cases of meningococcal vulvovaginitis.

GROUP A STREPTOCOCCAL VULVOVAGINITIS

Group A streptococci are a frequent cause of vulvovaginitis in premenarcheal girls and accounted for 9 to 20 percent of cases in several series.[64,67,120,265,279] Most cases occur in girls aged 2 to 7 years, but cases in infants and teenagers have been reported.[26,64,97,265] A marked seasonal variation in incidence in some geographic regions, with peak rates occurring in late fall and winter, may explain the low number of cases of vulvovaginitis caused by group A streptococci in some series.[79,182] The nasopharynx seems to be the primary reservoir for group A streptococci in these girls. Infection may occur from self-inoculation by hand to nose to the vulvovaginal area.[245] The skin also may serve as the source of group A streptococcal vulvovaginitis.[97,265] Preceding or concurrent symptoms of upper respiratory tract infection are uncommon findings, but many girls with group A streptococcal vulvovaginitis have throat cultures positive for *S. pyogenes*.[97,265] Perineal symptoms have preceded pharyngeal symptoms in some patients.[79] Group A streptococcal vulvovaginitis may occur during the course of scarlet fever.[26,119,120]

The signs and symptoms of group A streptococcal vulvovaginitis often overlap those caused by other bacterial infections, but symptoms usually are abrupt in onset. Most patients seek medical care within 1 week of onset. Vaginal discharge and dysuria are the most common complaints. These girls usually are afebrile. Localized tenderness and an intense, fiery red erythema of the vulvar tissues are frequent findings, but some cases have only mild erythema. Pruritus and excoriation may be present. The discharge usually is seropurulent but may be serosanguineous. The color may be white or green. Petechiae may be present on the vaginal mucosa, and regional papular or scarlatiniform rashes can occur.[79,97,245,265] Acute poststreptococcal glomerulonephritis has been reported in association with group A streptococcal vulvovaginitis.[193] Labial abscesses caused by *S. pyogenes* have been noted rarely in prepubertal girls.[279]

Concomitant streptococcal proctitis and perianal skin infections have been reported.[79,154,261] Perianal pruritus, erythema, and tenderness are common findings. Abdominal pain and rectal bleeding may be present. Penile involvement occurs rarely if at all.[181]

The diagnosis of *S. pyogenes* infection may be missed if vaginal secretions are not plated onto sheep blood agar or other media that readily support the growth of streptococci.[265] The vulvovaginitis caused by group A streptococci usually shows initial response to oral antimicrobial therapy within 24 hours. A 10-day course of oral penicillin, amoxicillin, or erythromycin generally is sufficient. A second course sometimes is necessary when perianal disease is present.[261] Adjunctive use of the hygienic measures discussed for nonspecific vulvovaginitis hastens clinical improvement. Group B and group F streptococci also have been isolated from girls with acute vulvovaginitis.[250]

VULVOVAGINITIS SECONDARY TO BACTERIA THAT COLONIZE THE NASOPHARYNX

Often, a history of an upper respiratory tract infection precedes the onset of vulvovaginitis by a few days. Suspicion that the two conditions are related is strengthened when vaginal cultures yield organisms that commonly colonize the nasopharynx. Vulvovaginitis is assumed to result from autoinoculation of microbes from the nasopharynx to the genitalia. The onset of vulvovaginal symptoms in these infections tends to be more acute, the inflammation and discomfort more marked, and the discharge less profuse and less purulent than in nonspecific vulvovaginitis.[133]

H. influenzae and *S. aureus* are the species isolated most frequently from cultures in this setting. *Streptococcus pneumoniae* is seen occasionally. *H. influenzae* was the organism isolated most frequently in a series of 200 girls with vulvovaginitis.[213] Acute and chronic cases of *H. influenzae* vulvovaginitis do occur, and the discharge usually is mucoid or mucopurulent, yellow, and odorless. Vulvovaginitis can be caused by serotypes a, b, and c and by nontypeable strains.[120,179] Concurrent otitis media or urinary tract infection may be present. All three of these species occasionally are found in vaginal cultures from asymptomatic children. Their isolation in pure culture from symptomatic girls is what leads to the clinical conclusion of cause and effect.

Vulvovaginitis caused by these organisms often responds to the treatment described earlier for nonspecific vulvovaginitis secondary to poor perineal hygiene. Systemic antibiotics may be required for persistent cases or may be helpful early in severely symptomatic cases. The choice of agent depends on the anticipated or known antimicrobial susceptibilities of the specific organism. The vagina is a well-recognized source of *S. aureus* colonization in cases of toxic shock syndrome (TSS) associated with this organism. Such cases generally have occurred in adolescent girls and women in association with the use of tampons. Vulvovaginitis caused by *S. aureus* in prepubertal girls has not been reported in connection with TSS. Labial abscesses caused by *S. aureus* have been described in prepubertal girls.[72]

VULVOVAGINITIS SECONDARY TO SKIN INFECTIONS

Similar to a child with an upper respiratory tract infection, a child with impetigo or an infected superficial wound may transmit bacteria from the wound to the genitalia by hand contamination. Cultures in such cases usually yield hemolytic streptococci or *S. aureus*. Treatment is the same as that described for nonspecific vulvovaginitis secondary to respiratory tract infections.

SHIGELLA VULVOVAGINITIS

Vulvovaginitis may be caused by infection with pathogens from the intestinal tract, especially when the organisms are endemic in a community. *Shigella* spp., mainly *Shigella flexneri* and *Shigella sonnei*, seem to account for most of these cases.[25,28,29,59,189] Vaginal discharge without pain, pruritus, or dysuria is the most frequent manifestation of *Shigella* vulvovaginitis. The course can be acute,

but discharge that persists for 4 weeks to several months before the diagnosis is made is common. Bloody discharge has been observed in approximately half the cases reported from developed countries, but it was not seen in any of 27 girls with *Shigella* vulvovaginitis in Rwanda between 1988 and 1991.[25] The discharge may be purulent and heavy; occasionally, it is absent. The vulvar tissues usually appear inflamed.

In most instances, *Shigella* vulvovaginitis is not associated with current or recent diarrhea.[25,189] The clinical presentation can be very similar to that of a vaginal foreign body. Local application of triple-sulfa cream (Sultrin) may clear the infection in some cases. Refractory cases have been described, however.[59,189] Systemic treatment with an antibiotic to which the *Shigella* isolate is susceptible is recommended. Single-dose therapy with third-generation cephalosporins is ineffective; 5-day courses of oral agents generally are required.[25] Amoxicillin, trimethoprim-sulfamethoxazole, and cefixime are reasonable choices for susceptible isolates; however, most *Shigella* isolates are resistant to ampicillin and trimethoprim-sulfamethoxazole. Ciprofloxacin use has been described in one case.[18] Azithromycin also may be an effective treatment option.[153] As with other causes of vulvovaginitis, adjunctive use of hygienic measures may help resolve the process and prevent recurrence.

OTHER SPECIFIC CAUSES OF PREMENARCHEAL VULVOVAGINITIS

Diphtheritic, amebic, and other types of specific vulvovaginitis in children have been reported in the literature.[84,163,212] Most such cases have had associated primary disease elsewhere.

Diphtheritic vulvovaginitis can be the primary site of infection, but most reported cases have been secondary to nasopharyngeal infection. Although diphtheria seldom occurs today, sporadic cases occasionally appear in areas where immunization coverage is inadequate. The vulva is the most common genital site involved in diphtheria,[212] but diphtheritic lesions may occur in the vagina without vulvar involvement. The diagnosis is suspected when a child has the severe systemic symptoms produced by upper respiratory tract diphtheria and a local ulceration covered by a gray adherent membrane; it is confirmed by finding *Corynebacterium diphtheriae* in discharge from the lesion.[70] Treatment of diphtheria is the same regardless of the site of the infection and is discussed in Chapter 101.

One case of vulvovaginitis with *Yersinia enterocolitica* isolated as the predominant organism was reported in a 4-year-old girl who also had a positive stool culture and associated fever and abdominal pain but no diarrhea.[281] In other members of the community in which she lived, diarrhea developed with cultures positive for *Y. enterocolitica*. The outbreak was linked to contaminated food. Infections with this organism may be missed because special culture techniques are required for isolation.

Rarely, ulcerative vulvovaginitis caused by *Entamoeba histolytica* or related to typhoid fever has been reported. Generally, specific genital infections with pathogenic organisms usually found in the gastrointestinal tract are the result of fecal contamination of the vulva and vagina. Treatment of infections caused by *E. histolytica* is described in Chapter 221.

OTHER LOWER AND UPPER GENITAL TRACT INFECTIONS OF PREMENARCHEAL GIRLS

Other specific and nonspecific infections of the premenarcheal female lower and upper genital tract genitalia, including genital herpes, condylomata acuminata, molluscum contagiosum, granulomatous and ulcerative disorders, cervicitis, and pelvic inflammatory disease (PID), are discussed in the section on genital infections in adolescents.

SEXUALLY TRANSMITTED DISEASES IN SEXUALLY ABUSED CHILDREN

Isolation of an STD in a child (especially a prepubertal child) places a health care provider in an awkward position of having to report the case to a children's protective service agency for investigation of sexual abuse. Management of children who have sexually transmitted infections requires close cooperation among clinicians, laboratories, and child protection agencies. The possibility of nonsexual transmission of these diseases often is raised, particularly when a preliminary investigation cannot elicit a history of sexual abuse. The rate of eliciting evidence of sexual abuse in prepubertal children can be 67 percent, however, in children with STDs.[15] Bacterial sexually transmitted infections are isolated more frequently than are viral infections in sexually abused children. Many challenges are involved in eliciting and validating sexual abuse in children. Verbal communication in children younger than 2 to 3 years old is impossible or difficult to interpret. Fear of disclosure by children or family members because of threats of violence may be a major barrier to validating a case in an older child.[179]

The first step in managing such situations is for a physician to assess critically the type of diagnostic test used to detect the infection. A major problem exists with inappropriate use of nonculture tests for testing for chlamydia.[8,107] The second step is for a physician to perform a genital examination on the child to look for evidence of acute or chronic vulvar and hymeneal trauma. Referral to a physician with expertise in this field is appropriate. A brief interview of the child in a nondirected manner with open-ended questions also should be done. Regardless of whether the child divulges any information, the case should be reported to the local children's protective service agency. The objective is for an agency caseworker to interview the child also in a nonthreatening manner. In addition, the caseworker should request that all household members be tested for STDs. More than one visit and interview by the caseworker may be necessary for such testing to be accomplished. Based on a review of the literature, common STDs in prepubertal children and their potential mode of transmission are summarized in Table 48–3 and discussed in this section.

GONOCOCCAL INFECTION

In infants, perinatal nonsexual transmission is considered the most likely cause of gonococcal infection. Branch and Paxton[27] found that in 1- to 11-month-old infants, all the mothers were found to have gonococcal infection, and no history of sexual contact could be elicited. The authors concluded that transmission of the infection was perinatal, from freshly contaminated hands, or through fomites.

Prepubertal children with gonococcal infection frequently are found to have a history of sexual contact.[139] The rate of eliciting a history of sexual contact in prepubertal children with gonorrhea ranges from 36 to 93 percent.[27,83,136,138] Branch and Paxton[27] reported that 93 percent of children aged 1 to 9 years with gonorrhea had sexual contact with relatives in the household. Ingram and colleagues[136,138] found that 35 percent of 1- to 4-year-old children and 100 percent of children older than 4 years with gonorrhea reported having sexual contact with an older male family member. Folland and coworkers[83] elicited a history of sexual contact from 34 percent of children with gonococcal urethritis and vaginitis.

Other infected adults and children often are found in an infected child's environment.[217] Testing of household members can detect infected adults at a rate of 18 to 29 percent.[8,192] In a retrospective study of 14 Native Alaskan children with

TABLE 48–3 Sexually Transmitted Diseases (STDs) in Prepubertal Children: Modes of Transmission and Implications for Child Sexual Abuse

Infectious Agent	Persistence after Perinatal Acquisition	STD Rate in Alleged Sexual Abuse Cases	Alleged Sexual Abuse Rate in STD Cases	Infection in Household Members of Infected Children	Survival on Fomites	AAP CCAN 2005 Guideline Recommendations for Abuse Reports	Other Comments
Neisseria gonorrhoeae	Up to 1 yr old[27]	5-7%[59]	35%, 1-4 yr old[40] 100%, >4 yr old[136] 93%, 1-9 yr old[27]	18-29% of adults in household[8,192] (abuse was thought unlikely in these series)	24 hr on wet fomites; 2 hr on dry fomites. None from public toilet seats[96,214]	Diagnostic for abuse. Report to Child Protective Services*	Although fomite transmission can occur, sexual transmission must be considered the likely mode, unless strong evidence of an alternative mode is found. Fomite or maternal nonsexual transmission plausible <1 yr old[27]
Chlamydia trachomatis	Up to 3 yr old[238] Rectal and vaginal sites up to 54 wk	6-8%[20,45,137,140] 4% cases vs. 9% controls[111]	75%		No data	Diagnostic for abuse. Report to Child Protective Services*	Perinatal acquisition likely <1 yr old; if >1 yr old, genital infection strongly suggests sexual transmission[137]
Trichomonas vaginalis	Up to 1 yr old	No data	Case report[143]	43% fathers, 72% mothers, with no history of sexual abuse elicited (Poland)[159]	Up to 6 hr on wood surface and in discharge.[149] Isolated from bathing implements[196]	Highly suspicious for abuse. Report to Child Protective Services*	If >1 yr old, genital infection strongly suggests sexual transmission. Bathing in tanks or rivers may increase infection risk in girls (India).[196] Has been isolated from mud baths, warm mineral waters, water from toilets[59,159]
Syphilis	Months to years if untreated	0-5%[59,139]	Case reports		Unlikely, based on difficulty in culturing the microbes, but no data	Diagnostic for abuse. Report to Child Protective Services*	Infection not known to be congenital should be considered sexually transmitted. Clinical manifestations (e.g., late congenital syphilis) may be helpful in discerning mode in some cases[42]
Bacterial vaginosis (*Gardnerella vaginalis*)	No systematic studies; colonization at birth potentially persists for years	7-13%[110]	28%[4]			Inconclusive; conduct medical follow-up	*G. vaginalis* can be found as part of normal flora in nonabused virginal children. Presence of clue cells in a vaginal wet mount, not culture results, is diagnostic.[42]
Haemophilus ducreyi (chancroid)	Asymptomatic persistence unlikely						Should be considered sexually transmitted

TABLE 48–3 Sexually Transmitted Diseases (STDs) in Prepubertal Children: Modes of Transmission and Implications for Child Sexual Abuse—cont'd

Infectious Agent	Persistence after Perinatal Acquisition	STD Rate in Alleged Sexual Abuse Cases	Alleged Sexual Abuse Rate in STD Cases	Infection in Household Members of Infected Children	Survival on Fomites	AAP CCAN 2005 Guideline Recommendations for Abuse Reports	Other Comments
Calymmatobacterium (Klebsiella) granulomatis (granuloma inguinale)							Should be considered sexually transmitted[42]
Herpes simplex virus (genital sites)	Symptomatic congenital infection usually develops within first 6 wk of life		Case reports only	Case report only (mother with an infected finger)[146]	2 hr on latex gloves, toilet seats; 24 hr on speculum; 72 hr on gauze[167]	Suspicious for abuse. Report to Child Protective Services*†	Autoinoculation from oral lesions is possible,[191] but fomite transmission is unlikely because it requires direct contact of viable virus with broken skin or mucous membranes
Human papillomavirus‡ (anogenital warts)	Up to at least 3 yr old and probably years longer[57]		27-90%[47]			Suspicious for abuse. Report to Child Protective Services*§	The possibility of sexual abuse should be considered when oral warts or laryngeal papillomas are found in older children
Human immunodeficiency virus (HIV)	Perinatal acquisition may not become evident for many years in slowly progressive cases	Very low in the U.S.; higher in countries with higher prevalences of HIV infection	26 of 9136 HIV cases in children were associated with sexual abuse by individuals with confirmed or suspected HIV infection[168a]	Common¶	Exposure to infected blood can lead to infection. Casual household contact alone has not been associated with transmission	Diagnostic for abuse if not perinatally or transfusion acquired. Report to Child Protective Services if mother is HIV-negative and child has no transfusion exposure*	History of maternal HIV infection suggests perinatal acquisition unless the child's presentation suggests acute HIV infection or perinatal transmission was reasonably excluded during infancy
Hepatitis B virus	Perinatal transmission can be asymptomatic for years to decades			Household transmission can occur			Nonsexual transmission can occur, so positive HBsAg tests do not necessarily indicate sexual abuse. Vaccination history for hepatitis B virus should be reviewed
Hepatitis C virus	Perinatal transmission can be asymptomatic for years to decades						Sexual transmission has been thought possible, but is currently uncertain. Maternal history may be helpful

**Or other local agency mandated to receive reports of suspected child sexual abuse.*

†Report unless there is a clear history of autoinoculation. Type of herpes simplex virus (1 versus 2) is generally not helpful in determining whether acquisition was by abuse or autoinoculation, although presence of type 1 may increase the likelihood of nonsexual transmission.

‡Laryngeal papillomas in young children are likely perinatally acquired.

§Some experts do not believe reporting is warranted in all cases. In children <3 to 4 years old for whom a thorough evaluation by an experienced child sexual abuse investigator reveals no concerns of abuse, reporting to Child Protective Services may be unnecessary. Close medical follow-up may be appropriate. Physicians must be clear when reporting that anogenital human papillomavirus is not always acquired by sexual abuse even in older children.

¶All siblings should be tested, whether perinatal or postnatal acquisition is suspected, unless perinatal infection is the known route and an older child was born during a time period in which the mother was known to be HIV-negative.

HBsAg, hepatitis B surface antigen.

Modified from Chacko, M., Staat, M. A., and Woods, C. R.: Genital infections in childhood and adolescence. In Feigin, R. D., Cherry, J. D., Demmler, G. J., and Kaplan, S. L. (eds.): Textbook of Pediatric Infectious Diseases. 5th ed. Philadelphia, W. B. Saunders, 2004, p. 577; and Committee on Child Abuse and Neglect.

gonococcal infection, 3 reported having sexual contact. Seven children slept with their parents, one or both of whom had gonorrhea; the authors assumed that these children acquired the infection by nonsexual means.[251]

N. gonorrhoeae has been shown to survive for 20 to 24 hours in infected secretions on towels and handkerchiefs.[263] Although *N. gonorrhoeae* has survived on toilet seats for 2 hours, no gonococci were recovered from toilet seats in public restrooms or in a clinic for STDs.[96,224] Nonsexual transmission to adults is rare.

Nonsexual transmission conceivably occurs in children who sleep and bathe with their parents. Sexual transmission is the more common and most likely mode of transmission, however.[112] The presence of gonorrhea should be considered diagnostic of sexual abuse. An investigation for sexual abuse must be pursued in a child with gonorrhea by reporting the case to the appropriate legal authority.[42]

CHLAMYDIAL INFECTION

C. trachomatis can be transmitted to an infant from an infected mother during the perinatal period. *C. trachomatis* has been isolated from the conjunctiva, nasopharynx, vagina, and rectum of infants born to infected mothers.[238] Perinatally acquired rectal and vaginal chlamydial infection in infants can persist for 372 and 383 days, respectively. Persistent chlamydial infection of the pharynx in infants can persist for 2 years.[21]

Sexual abuse as a potential mode of transmission of *C. trachomatis* infection should be considered in children older than 1 year.[89,111] In a retrospective study, Ingram and associates[137] found that 6 percent of girls who allegedly were sexually abused and no girls who denied sexual abuse had *C. trachomatis* infection. Except for one child, all the children in the control group were determined later to have been sexually abused. In a prospective study, Ingram and associates[139,140] found *C. trachomatis* in 8 percent of girls with a history of sexual abuse compared with 0 percent in girls with no history of sexual abuse. In the former group, three girls also were found to have rectal infection and one to have pharyngeal infection.

Perinatally acquired genital chlamydial infection is a strong possibility in children younger than 1 year. Perinatal transmission is possible in children aged 3 years. After 1 year of age, however, sexual transmission should be considered diagnostic of sexual abuse in children with genital chlamydial infection.[42] An investigation for sexual abuse must be pursued in a child in whom genital chlamydial infection is diagnosed.[42,107] Studies have evaluated the presence of *C. trachomatis* on fomites and its coexistence in family members of infected children.

SYPHILIS

The prevalence of syphilis in children suspected of having been sexually abused is lower than that of gonorrhea or chlamydia. Syphilis infections not found to be acquired congenitally should be considered sexually transmitted. Sexually acquired infection is a strong possibility in all prepubertal children with syphilis. Syphilitic lesions and positive serologic results have been detected in alleged sexual abusers of children with syphilis.[1] No data are available on the survival of *T. pallidum* on fomites. The presence of syphilis should be considered diagnostic of sexual abuse, and an investigation must be pursued.

TRICHOMONAS VAGINALIS INFECTION

T. vaginalis has been found in the nasopharynx and vagina of newborns of infected mothers. Transmission of *T. vaginalis* in infants aged 1 year probably is perinatal. The mode of transmission in children older than 1 year is controversial. Two cases of *T. vaginalis* infection in premenarcheal girls who were sexually abused have been reported.[143] Prevalence studies either do not address the mode of transmission at all or, if they do, do not address the possibility of sexual abuse. In addition, a vaginal wet mount for trichomonads is not performed routinely in children assessed for possible sexual abuse. A survey from Poland found one case of *T. vaginalis* infection in children aged 2 to 7 years and a significantly higher number of cases in 8- to 10-year-old girls. The numbers increased even further for children older than 10 years, suggesting a strong association between *T. vaginalis* and the presence of an estrogenic environment, which promotes glycogen production and decreases vaginal pH.[159]

The Polish survey tested families of women infected with *T. vaginalis* and found that almost a third of their sexual partners and 8 percent of the children (mostly girls) had *T. vaginalis*. When families of men infected with *T. vaginalis* were tested, 91 percent of their sexual partners and 13 percent of the children had *T. vaginalis*. When families of children (mostly girls) infected with *T. vaginalis* were tested, 72 percent of the mothers and 43 percent of the fathers had the infection. The investigators considered that the infection in the latter group originated from mothers and that the primary mode of transmission was nonsexual (beds, sponges, towels, overcrowding). Information regarding sharing of potentially infected fomites, sexual abuse, or physically intimate behavior between parents and children was not gathered in these cases.[159]

Although *T. vaginalis* has been known to survive on fomites in controlled experiments, its ability to spread by these means is unknown. No cases of adults being infected by fomites have been documented. *T. vaginalis* has been found to survive for 6 hours on droplets of discharge and enameled surfaces of wood blocks.[149] It has been isolated from droplets of water splashed from toilets containing the urine of an infected individual.[39] *T. vaginalis* also has been found to survive in mud baths, bathing waters, and warm mineral waters and on moist bathing implements.[159,196] In rural India, a survey found that young girls who bathed in tanks or rivers had a significantly higher risk of acquiring *T. vaginalis* than did girls who used pipe or well water.[46]

T. vaginalis conceivably is transmitted to children nonsexually. The likelihood of perinatal transmission is high in infants younger than 1 year. A child or an infant younger than 1 year with *T. vaginalis* also may have been sexually abused. In a child older than 1 year, the probability of sexual abuse must be considered highly suspicious, and the case must be investigated and reported. Perinatal transmission and transmission of infection through fomites should not be assumed without an investigation for sexual abuse.[42]

BACTERIAL VAGINOSIS

The significance of bacterial vaginosis and *G. vaginalis* and their relationship to sexual abuse in prepubertal girls are unclear and inconclusive. Data on the prevalence of bacterial vaginosis in children with vaginal discharge and suspected sexual abuse are limited. Based on the presence of clue cells and a positive amine test result in vaginal secretions, bacterial vaginosis has been diagnosed in 13 percent of sexually abused children versus 4 percent of girls who denied sexual abuse.[110,139] Similar prevalence rates for *G. vaginalis* have been reported in children who have and have not been sexually abused.[21] No data are available regarding the survival of *G. vaginalis* on fomites.

Although the prevalence of *G. vaginalis* and bacterial vaginosis is higher in sexually abused children than in nonabused children, their significance as a marker for sexual abuse is unclear. *G. vaginalis* is not the sole cause of bacterial vaginosis and is not a

suitable marker of sexual activity. The recommendation is that a child with a vaginal discharge, the presence of clue cells, and a positive amine test be questioned about sexual abuse and be followed medically. An investigation by a children's protective service agency is unnecessary, however.[42]

GENITAL HERPES

Perinatal transmission of herpes simplex virus (HSV) types 1 and 2 in the form of stomatitis occurs in infants. HSV type 2 is an uncommon finding. HSV types 1 and 2 have been isolated in the genital area in children alleging sexual abuse.[94,139] No studies have reported the coexistence of HSV genital infection in household members and infected children, however. Physical contact by a mother's infected finger has been reported.[146] Autoinoculation from the mouth to the genitals as a mode of transmission is possible, especially when oral HSV infection precedes genital herpes lesions.[191] HSV has been known to survive for 2 hours on latex gloves and toilet seats, 24 hours on a speculum, and 72 hours on gauze.[167] Transmission of HSV from fomites requires direct contact of viable virus with either a mucous membrane or a break in the skin, however, rendering fomite transmission unlikely. A child with genital herpes infection should be considered suspicious and evaluated for sexual abuse, and the case should be reported to the authorities.[42]

GENITAL WARTS (CONDYLOMATA ACUMINATA)

Perinatal transmission of human papillomavirus (HPV) from an infected mother to her infant is well-documented. The incubation period after exposure to the virus may range from 1 to 20 months.[57] Data on the presence of HPV DNA in children beyond the neonatal period are inconsistent—1.2 to 27 percent in three different studies.[166,219,282] In addition, the relationship between the presence of HPV DNA and the ultimate development of disease in children is unclear. Because the exact incubation period for the development of genital lesions is unknown, perinatal transmission has been found to be the most likely cause of genital warts in almost 96 percent of patients younger than 3 years.[57] In children 3 years or older, a history of sexual abuse has been elicited in 27 to 90 percent with venereal warts.[47,123]

Condylomata acuminata are acquired by children as a result of close physical contact with an infected individual, by digital infection of the child's genitalia by an infected individual, or by sexual contact with an infected individual.[246] A history of condylomata in other members of the family, particularly the mother or older sisters who care for the child, sometimes may be elicited. Perinatal exposure, poor hygiene, and shared bathing have been suggested sources of infection.[267,268] HPV types 6, 11, 16, and 18 are seen in adults with anogenital warts and are the most common genital types detected in children. This finding has raised questions about warts in children resulting from sexual abuse. In many cases, however, the mode of transmission is unknown.[57] Based on failure to identify sexual abuse, a report from a dermatology clinic concluded that transmission of HPV possibly occurs by fomites.[47] No reports in the literature address survival of the virus on fomites.

Sexual abuse is the most common means of acquiring anogenital HPV infection and should be considered suspicious for sexual abuse and investigated and reported in all prepubertal children older than 3 years who are infected. In children younger than 3 years, although perinatal transmission is likely, sexual abuse should be suspected and investigated.[42]

As recommended by the Centers for Disease Control and Prevention,[42] the possibility of sexual abuse should be considered strongly if no conclusive explanation for nonsexual transmission of a sexually transmitted infection has been identified. When the only evidence of sexual abuse is the isolation of an organism or the detection of antibodies to a sexually transmitted agent, findings should be confirmed, and implications should be considered carefully.

POSTMENARCHEAL LOWER GENITAL TRACT INFECTIONS

Infections of the postmenarcheal female clitoris, urinary tract, vulva, vagina, and cervix produce a variety of overlapping symptoms, including vulvar pruritus, dysuria, and increased or altered vaginal discharge and spotting.[87,175] As a result, distinguishing among various lower genital tract infections based solely on symptoms is difficult. The history, physical examination, and laboratory tests play an important role in assisting the clinician in diagnosing urethritis, vaginitis, or cervicitis.

DISORDERS OF THE CLITORIS

Cellulitis with induration, edema, and erythema, analogous to posthitis in boys, occasionally develops in the clitoral hood. Staphylococci and streptococci are the most common etiologies. Oral antibiotics with efficacy against these organisms usually are effective. Warm soaks or sitz baths also may provide symptomatic relief.[72]

Clitorimegaly with erythema can occur with vulvovaginitis of any etiology but usaully is associated with HSV infections.[67] Edematous enlargement of the clitoris and the labia without erythema has been reported in patients with Crohn disease.[188]

POSTMENARCHEAL URETHRITIS

Urethritis is manifested clinically by dysuria or urinary urgency or both. Attempting to differentiate external from internal dysuria is important. External dysuria is pain from urine flowing over the vulva. Such a history suggests vulvitis and vaginitis. Internal dysuria is pain with initiation of urination and is not associated with urine flowing over the vulva. It indicates urethritis or a urinary tract infection. A careful history and examination assist the physician in differentiating urethritis from vaginitis.

Urethritis occurs commonly, particularly in sexually active postmenarcheal girls. Urethritis with internal dysuria can occur as a result of sexually transmitted infections, such as *T. vaginalis*, *N. gonorrhoeae*, and *C. trachomatis*, and has been implicated as an important cause of dysuria in sexually active girls. It is called *acute urethral syndrome*, and clinical features include dysuria, frequency, and pyuria with significant bacteriuria.[264] Urethral infection by *C. trachomatis* may occur with or without cervical infection; such infection was associated with sterile pyuria in 50 percent of girls with acute-onset dysuria and frequency, and *C. trachomatis* was isolated in 31 percent of these cases.[264]

When a sexually active adolescent girl has internal dysuria, in addition to being tested for conventional uropathogens, she should be screened for common STDs, such as gonorrhea and *Chlamydia* and *Trichomonas* infection.[61] Urinalysis and microscopy for the presence of leukocytes and bacteria should be done in these patients as well. For treatment of urethritis caused by sexually transmitted organisms, the sections in this chapter on trichomoniasis, gonorrhea, and chlamydial infections should be reviewed.

Figure 48–10 Urethral and paraurethral duct discharge is obtained by placing downward and outward digital pressure on the distal urethrovaginal septum.

Figure 48–11 Acute Bartholin duct abscess.

PARAURETHRAL DUCT ABSCESS, BARTHOLINITIS, AND BARTHOLIN ABSCESS

The paraurethral ducts lie on each side of the urethral meatus. The Bartholin glands are small, bean-shaped glands that lie on each side of the vaginal opening, behind the hymen. Each gland opens by means of a long single duct immediately external to the hymen. Infections of the paraurethral and Bartholin ducts are found more commonly in women but occasionally occur in adolescent girls.

A paraurethral duct abscess creates a small, exquisitely painful swelling in the urethrovaginal septum. If the abscess is not incised and drained, it may rupture into the urethra and create a urethral diverticulum. Discharge for Gram stain should be obtained from the urethral lumen and the paraurethral ducts by downward and outward pressure on the urethrovaginal septum (Fig. 48–10).

Bartholinitis, or inflammation of the Bartholin ducts, causes pain, tenderness, and a linear rope-shaped swelling, best palpated by holding the vulvar mucosa and labia majora between the fingers. Purulent or mucoid exudate can be expressed occasionally from the Bartholin duct.

N. gonorrhoeae and *C. trachomatis* have been isolated from ductal exudates in women with bartholinitis.[56,223] This condition should be treated with antibiotics that provide coverage for *N. gonorrhoeae*, *C. trachomatis*, and anaerobes. Symptomatic relief may be achieved with sitz baths.

Although a Bartholin abscess is seen most often in women 20 to 29 years old, it does occur in sexually active adolescent girls. It also is the second most common urogenital complication of gonorrhea, after PID, in women. Risk factors for development of Bartholin abscess are similar to those for STDs.[4]

Infection of a Bartholin cyst results in a markedly tender abscess (Fig. 48–11). The abscess can rupture spontaneously and drain foul-smelling, purulent material externally through the skin. Multiple organisms are isolated from Bartholin abscesses. An early study using percutaneous aspirates from abscesses showed predominantly anaerobes and facultative organisms. *N. gonorrhoeae* was isolated in 8 percent of cases, and gram-negative bacilli were isolated in 16 percent. Although genital Mycoplasmataceae organisms were isolated from the duct secretions, they were not isolated directly from abscesses.[168] *Porphyromonas asaccharolytica* (a black-pigmented, gram-negative anaerobe) and *Salmonella panama* (after an attack of *Salmonella* enteritis) have been isolated from a Bartholin abscess.[52,68] Tuberculosis of the Bartholin gland has been reported.[63,133,134] Huffman[133] encountered tuberculosis of the Bartholin gland in a 14-year-old, sexually inactive girl with pulmonary tuberculosis. She had painless, unilateral swelling of the left labium majus with a brown discharge exuding from a small sinus. *Mycobacterium tuberculosis* was isolated in the discharge.

A Bartholin abscess should be incised and drained by applying a surface anesthetic, ethyl chloride, and making a 1- to 1.5-cm, full-thickness incision on the medial aspect of the labium majus. The cavity should be probed with a sterile cotton-tipped swab to break up loculations within the abscess. To allow for further drainage, one should pack the abscess cavity with sterile gauze. Alternatively, a Word catheter, a small rubber catheter with an inflatable balloon tip, can be inserted into the cavity and the balloon inflated with water. Clinical experience indicates that the packing method is far more painful to the patient, and healing takes longer.

Antibiotic coverage for anaerobes, *N. gonorrhoeae*, and *C. trachomatis* should be provided for at least 2 weeks, and a nonsteroidal medication is recommended for inflammation and pain. Frequent sitz baths help further with drainage and healing. Close follow-up during the first week is advised. The packing or the catheter may be removed after 4 days of antibiotics. Although marsupialization frequently was used to treat recurrent Bartholin abscesses, incision plus drainage and primary suture of the abscess cavity along with administration of an antibiotic (clindamycin) has been found to lead to more rapid healing and to decrease significantly the incidence of recurrent abscesses.[13]

POSTMENARCHEAL VULVOVAGINITIS

The most common types of vulvovaginitis in postmenarcheal girls are *T. vaginalis* vaginitis, vulvovaginal candidiasis, and bacterial vaginosis.

Postmenarcheal Vaginal Trichomoniasis

T. vaginalis is a triflagellated protozoan (Fig. 48–12). The organism, which is larger than a polymorphonuclear leukocyte, has a distinctive vibrating or whiplike movement when seen microscopically in fresh wet smears taken from the vagina. It quickly succumbs to reduction of the pH, drying, cooling, and changing the osmotic pressure of the fluid surrounding it. Most infections are encountered in sexually active young women; the incidence increases during the early reproductive years.

Trichomoniasis frequently is asymptomatic. When it is symptomatic, patients complain of a profuse, irritating discharge. The discharge and the pruritus tend to be more severe just before and immediately after a menstrual period. Recurrent exacerbations of the infection occur commonly. Patients occasionally report dysuria and abdominal pain.

Examination reveals diffuse vulvitis with erythema and excoriations and copious leukorrhea that covers the vulvar tissues. The discharge typically is frothy or bubbly, grayish yellow, and watery or mucopurulent. It has a pH of 5 to 7 and an acrid or musty odor. A "strawberry" or punctate vaginal eruption with hemorrhagic spots has been described as being typical of trichomoniasis. Such eruptions frequently are not present, however, even in severe cases. More often, diffuse inflammation causes the vaginal mucosa to be brilliant red.

The diagnosis of trichomoniasis usually is confirmed clinically by finding trichomonads in a wet smear of vaginal fluid. The vaginal specimen is obtained on a cotton-tipped swab and dipped into a small test tube with saline. After the solution has been stirred with the swab, one or two drops of the solution are placed with the swab on a slide. It is important that the slide be viewed under the microscope (dry high power) promptly because the organisms do not remain viable for long outside the vagina and are difficult to detect when they cease to be motile. The observer sees numerous ovoid-shaped, motile organisms. The sensitivity of this test with immediate evaluation is 60 to 70 percent. A vaginal cytosmear including a Papanicolaou (Pap) smear to detect trichomoniasis is not recommended because of the high rate of error in identifying trichomonads in stained smears. Other methods used to diagnose trichomoniasis include isolation by special culture medium, direct fluorescent immunoassay, and nucleic acid amplification test. Culture is the most sensitive, but it is not routinely available. The nucleic acid amplification test is available in some clinical settings (point-of-care test); however, a false-positive result may occur in low-prevalence populations.[42]

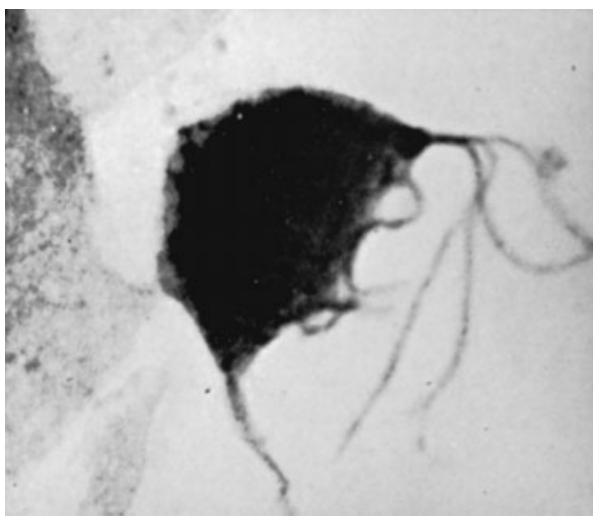

Figure 48–12 *Trichomonas vaginalis* is a triflagellated protozoan that, when motile, is identified easily in wet smears of vaginal discharge.

TREATMENT

A single 2-g oral dose of metronidazole (Flagyl) or tinidazole is the recommended treatment of choice. An alternative regimen is metronidazole, 500 mg orally twice daily for 7 days.[42] The cure rate is 95 percent in girls. If symptoms persist and wet smears from the vagina still show trichomonads, the treatment is repeated. Only in unusually persistent cases is a third course necessary. Strains resistant to metronidazole are rare. The patient should be warned of possible gastrointestinal side effects (nausea, diarrhea). Alcohol can aggravate the side effects of metronidazole therapy and cause a disulfiram-like reaction. The patient should be instructed not to consume alcoholic beverages during treatment. She should be told that trichomoniasis is an STD and that her sexual partner should be treated. Reacquisition of infection should be prevented via sexual abstinence or use of condoms. A follow-up test is unnecessary.

Metronidazole is a pregnancy category B drug, and tinidazole is a pregnancy category C drug; its safety in pregnant females has not been well evaluated. Multiple studies and data analysis subsequently have not shown a consistent association between metronidazole and teratogenic or mutagenic effects in infants.[42] Metronidazole can be given during the first trimester of pregnancy in adolescents.[42] Gentle vaginal douching with vinegar and water may relieve some symptoms but should not be encouraged during pregnancy.[134] Metronidazole gel is less effective in the treatment of trichomoniasis (<50%) and should not be used.[42] During lactation, breast-feeding can be withheld for 12 to 24 hours to reduce the exposure of metronidazole to the infant. Lactation should be withheld for 3 days when using tinidazole.

Postmenarcheal Mycotic Vulvovaginitis

Several factors play roles in causing the increased incidence of vaginal candidiasis after menarche. Menstruation, by altering vaginal pH, may offer a favorable medium for the growth of mycotic organisms. *Candida* spp. are found commonly in the intestinal tract and frequently are detected in stool cultures. Fecal contamination of the vulva during cleansing after defecation at a time when the normal vulvar and vaginal flora are depleted and not able to inhibit fungal growth would permit the development of symptomatic vulvovaginal candidiasis. Wearing tight-fitting underclothes (which keep the perineum warm and moist) is a factor that contributes to the growth of mycotic organisms. Female athletes and ballet dancers seem to be predisposed to development of candidiasis from wearing tight-fitting clothing and from increased sweating. The widespread use of antibiotics that disturb the vaginal flora and the use of oral contraceptives are additional factors that increase the incidence of candidal infection. Other predisposing factors include pregnancy, obesity, uncontrolled diabetes mellitus, immunosuppressive therapy, and heroin or other drug addiction. If a patient has a recurrent unexplainable or resistant infection, a glucose tolerance test should be done to rule out diabetes mellitus.

C. albicans and *Torulopsis glabrata* are the yeastlike fungi found most often in the vagina. *C. albicans* is responsible for 80 to 95 percent and *T. glabrata* for 3 to 16 percent of fungal infections. Other *Candida* spp. are detected less often in the vagina but can be pathogenic. *C. tropicalis*, similar to *C. albicans*, produces systemic infection in immunosuppressed hosts. Mycotic vulvovaginitis causes severe vulvar and vaginal itching; usually, the patient does not have an excessive discharge. The discharge is white,

thick, and curdled and has a yeasty sour odor. The patient may have pain during and after voiding or external dysuria as a result of urine coming in contact with excoriated areas on the urethra and vulva.

Examination in the acute stage reveals intense inflammation of the vulva and vagina that may extend to the perineal skin. Long-standing infection can cause lichenification and hyperpigmentation of the perineal skin. During acute infection, the involved areas are shiny and beefy red with linear excoriations and edema. *C. albicans* typically forms patches of mycelia that create adherent white plaques scattered over the inflamed surfaces. Superficial, red, weeping areas remain after the plaques are pulled away. Other *Candida* spp., notably *C. tropicalis*, do not form adherent plaques but produce a cottage cheese–like discharge similar to that found with *C. albicans.* Vaginal pH usually is normal (<4.5).

The diagnosis is established by wet preparation under microscopy and by finding hyphae and buds of the fungus in vaginal fluid (see Fig. 48–9), in the curdled discharge, in material scraped from the vulvar mucosa, or on the perineal skin. A wet preparation in normal saline may suffice, but debris and cellular material may render identifying the fungus difficult. If so, a smear using 10 percent potassium hydroxide solution is helpful. After one drop of potassium hydroxide has been added to one to two drops of vaginal fluid on a slide, the slide is heated gently until bubbles appear under the coverslip. The potassium hydroxide solution dissolves other extraneous material without affecting the fungus. With an experienced microscopist, this method yields a sensitivity of 86 percent in symptomatic girls; however, the yield may be only 40 percent. The diagnosis frequently is based on clinical findings, and cultural confirmation is unnecessary.

TREATMENT

Several vaginal preparations can be used. The antifungal creams commonly used are imidazoles (clotrimazole and miconazole) and polyenes (nystatin), but the polyenes should not be used because of increasing resistance of fungi to these compounds. A variety of imidazoles are available as over-the-counter vaginal creams, tablets, and coated tampons. Such agents include clotrimazole, miconazole, and terconazole. Intravaginal treatment with one 100-mg vaginal tablet of clotrimazole every night for 7 days produces a cure rate of 90 percent. Comparable cure rates are observed with 100 to 200 mg of clotrimazole or miconazole (2 tablets) for 3 days. The shorter regimen may result in better compliance. Creams and tablets are equally effective.[42]

Oral fluconazole, 150 mg as a single dose, is an effective preparation for the treatment of uncomplicated vulvovaginal candidiasis.[42] Low-dose prophylactic treatment also may be appropriate in these cases. Gentian violet, which has been used for many years, is considered an effective cheap treatment for vulvovaginal candidiasis in countries where the recommended pharmaceutical agents are unavailable.[133] Huffman[133] described painting the cervix and the vaginal and vulvar mucosa with a 1 percent aqueous solution. Care is taken to rotate the speculum so that the anterior and posterior vaginal walls are treated. The creases between the folds of the vulvar mucosa also are covered with the dye. The speculum is reinserted, opened, and left in place for 5 minutes so that all painted surfaces become dry. Treatment with gentian violet is repeated once weekly for 3 weeks and should include one treatment during a menstrual period. According to Huffman, gentian violet can cause herpes-like lesions on the vulva of some patients, and it is extremely messy.

Postmenarcheal Bacterial Vaginosis

Bacterial vaginosis is a noninflammatory polymicrobial condition caused by an ecologic change in the vagina; an overgrowth of anaerobes, especially *Bacteroides* and *Mobiluncus* spp., *G. vaginalis*, and *M. hominis*; and a decrease in the concentration of lactobacilli.[12,90,91,92,207] Bacterial vaginosis is considered an STD based on the occurrence of bacterial vaginosis with other STDs and in male partners of women with this condition. Bacterial vaginosis also has been described in adolescent girls who are not sexually active.[38]

Bacterial vaginosis has been associated with vaginal douching. It also has been noted in connection with postpartum endometritis, premature rupture of membranes, and PID.[131]

The primary complaint is an offensive odor with moderately profuse, gray-colored leukorrhea that stains the underwear. A mild pruritus or dyspareunia may be reported. A clinician often is able to identify this condition simply by the odor of the discharge. Examination shows little or no vulvar or vaginal erythema. The urethral and vulvar glands are not involved. The vagina contains a thick, homogeneous, grayish white discharge. The pH of vaginal secretions in bacterial vaginosis is 5 to 6. *T. vaginalis* tends to be associated with a vaginal pH of 6 to 8.

The diagnosis is made by the presence of any three of the following four criteria: (1) a homogeneous, gray-white malodorous discharge that smoothly coats the vaginal walls[73]; (2) a pH of nonbloody vaginal secretions greater than 4.5; (3) a fishy odor caused by the release of amines when 10 percent potassium hydroxide is added to a nonbloody vaginal specimen (whiff test); and (4) the presence of clue cells in a nonbloody specimen.[12] Microscopic examination of some of the discharge mixed with normal saline solution in a wet-mount preparation shows masses of desquamated vaginal epithelial cells and cellular debris. Clusters of bacteria adhere to the surface of many of the vaginal cells; these "clue cells" (Fig. 48–13) are characteristic of the condition.

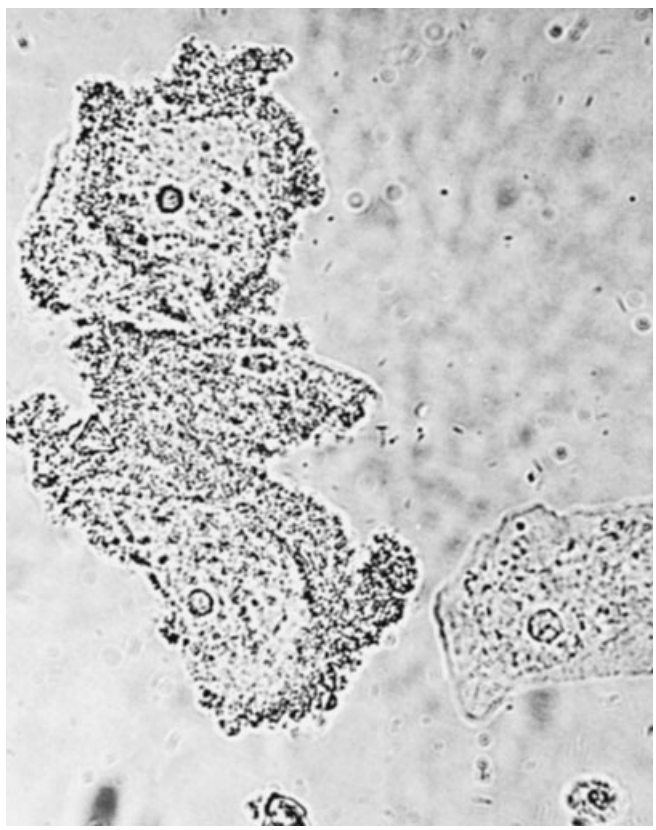

Figure 48–13 The finding of bacteria clinging to the sides of a vaginal epithelial cell ("clue cell") is significant in bacterial vaginosis. *(Courtesy of Dr. Herman L. Gardner.)*

Absence of erythrocytes and leukocytes in the discharge is another characteristic finding.

A Gram stain of vaginal secretions is considered the most reliable diagnostic test for bacterial vaginosis. A predominance of gram-variable cocci and curved rods (anaerobes) and occasional long gram-positive rods (lactobacilli) is seen.[12] A wet mount of vaginal secretions is a rapid and helpful test for clue cells in a busy clinical setting. Cultures for *G. vaginalis* and anaerobes are not useful clinically and are not recommended; Pap tests have no clinical utility for the diagnosis of bacterial vaginosis.

TREATMENT

The goal of therapy for symptomatic bacterial vaginosis is to relieve vaginal symptoms and prevent an ecologic environment that predisposes to the development of PID. Treatment of asymptomatic bacterial vaginosis may be considered before performing a surgical abortion procedure to prevent postpartum PID. In most cases, bacterial vaginosis responds to metronidazole, 500 mg given orally twice daily for 7 days,[42] or 2 percent clindamycin cream intravaginally every night for 7 days or 0.75 percent metronidazole gel intravaginally once a day for 5 days. Alternative regimens include clindamycin, 800 mg orally twice a day for 7 days, or clindamycin ovules, 100 mg intravaginally once a day for 3 days. These regimens provide effective coverage of anaerobes and *G. vaginalis.* Bacterial vaginosis that occurs during pregnancy generally is treated during the first trimester with clindamycin cream. During the second and third trimesters of pregnancy, it can be treated with clindamycin cream or metronidazole gel. Treatment of the sexual partner has not proved to be beneficial.[42]

Postmenarcheal Nonspecific Vulvovaginitis

Nonspecific vulvovaginitis has several contributory factors.[73,133] Vaginal foreign bodies cause discharges that are profuse, extremely malodorous, and sometimes bloody. The most frequent offender is a forgotten menstrual tampon, toilet paper, or a piece of condom. Improper or inadequate cleansing of the perineum after defecation also is responsible for many cases of chronic nonspecific vulvovaginitis, especially in mentally handicapped adolescent girls. If a male partner inserts his penis into the rectum first and then into the vagina or inadvertently touches the anal area before having vaginal intercourse, coliform organisms are carried into the vagina.

A tumor as the cause of a vaginal discharge is a very rare possibility. A discharge, with or without bleeding, may be one of the first symptoms of adenosis or adenocarcinoma of the vagina and cervix. These neoplasms are associated with prenatal exposure to diethylstilbestrol and related synthetic estrogens.

TREATMENT

Treating nonspecific vulvovaginitis in a postmenarcheal girl can be frustrating when no causative agent is found. Often, identifying the causative agent is impossible. In the case of a foreign body, it should be removed. Instructing the patient in proper perineal cleansing after defecation eradicates a major source of nonspecific vaginal infection in teenagers. Providing advice regarding sexual habits is necessary in some cases if coitus-related infections are to be avoided.

According to Huffman,[133] in most cases, nonspecific vulvovaginitis unassociated with chronic cervicitis responds to antimicrobial creams such as Sultrin or AVC vaginal cream inserted at bedtime for 14 days. Generally, creams are preferable because they spread over a larger area of the vaginal mucosa than is treatable with suppositories. Vaginal douching sometimes may be considered helpful in the treatment of nonspecific vulvovaginitis. More recent data suggest, however, that a causative relationship exists between vaginal douching and PID in inner-city populations at high risk for acquiring STDs.[291] Vaginal douching should be discouraged strongly.

Toxic Shock Syndrome

First recognized in the late 1970s, TSS is an uncommon, serious, sometimes fatal acute infection caused by toxin-producing *S. aureus* infection. TSS can occur in males and females of all ages; this entity is discussed fully in Chapter 71. With regard to the genital tract, more than 800 TSS cases occurred in women in 1980 in association with use of a very high absorbency tampon. This type of tampon is no longer marketed. Prolonged retention of currently marketed tampons could be a predisposing factor for TSS or other local infections, but TSS associated with tampon use is now a rare event.

VULVOVAGINAL VIRAL INFECTIONS

GENITAL HERPES

Premenarcheal Patient

HSV infection of the genitalia rarely occurs in children.[116] The mode of acquisition of the infection is not always known, but case reports describe the possibility of autoinoculation from oral lesions, physical contact by a mother's infected finger, and sexual abuse.[146] The presence of genital herpes lesions in a child or any disease that is known to be sexually transmitted in an adult should raise a question about whether the child has been subjected to some type of sexual molestation. The virus can be isolated from the pharynx or vagina of approximately 5 percent of asymptomatic adults. Such individuals are carriers and may transmit the infection to susceptible contacts. That children would have either HSV type 1 or HSV type 2 genital lesions is not surprising.[191]

Herpetic lesions on the vulva begin as small, erythematous spots. Papules quickly develop on the inflamed areas. The papules become serum-filled vesicles that rupture and leave slightly eroded red areas. The latter become covered with crusts, which remain for a few days. The lesions typically cause pruritus and burning. If they do not become secondarily infected, they heal within 2 weeks.

Herpes limited to the genitalia of a healthy child is a painful but relatively benign disease. An infection in a poorly nourished child may spread beyond the vulva and become a serious, life-threatening matter. Treatment of genital herpes is discussed later.

Adolescent Patient

HSV is the most common cause of vesiculoulcerative disease of the adult genitalia.[190] It is sexually transmitted, and its increasing frequency in teenage girls is related to their sexual activity. As noted in Chapter 170, two types of HSV exist and can be antigenically and culturally distinguished from each other. Type 1 is the causative agent in oronasal cold sores. Type 2 is responsible for 70 to 95 percent of genital herpes, but genital infections with type 1 have become more common (5 to 30%), probably related to increasing engagement in genital-oral sex play.[45]

Seroprevalence studies show that type 2 antibodies do not begin to appear until the early teens. The frequency gradually increases through late adulthood and is related to sexual activity, especially with multiple partners. Most individuals with type 2 antibodies are not diagnosed with genital herpes. Type 2 infections are highly contagious and may be transmitted by carriers who are asymptomatic. Because of its frequency and diverse clini-

cal appearance, it should be considered in the differential diagnosis of all vulvar vesiculoulcerative lesions. Because of its acute symptoms, it may mask the presence of other venereal disease acquired concurrently; a patient with genital herpes always should be examined for gonorrhea and syphilis.

Three manifestations of genital disease are recognized: primary initial, nonprimary initial, and recurrent infection. Primary initial genital herpes infection develops with no preexisting herpes antibody. A nonprimary initial infection develops in an individual for the first time with preexisting herpes antibody. Recurrent infection is diagnosed when an individual has a history of previous similar genital infection. Patients with nonprimary initial infection have fewer lesions, less pain, fewer constitutional symptoms, shorter duration of viral shedding, and an overall shorter course of illness.[48]

A primary infection begins with sexual contact with an infected individual 2 to 8 days before the onset of symptoms. The individual probably has a prodromal episode of fever, malaise, and myalgia, often accompanied by vulvar paresthesia and burning, dysuria, and tender nonsuppurative inguinal lymphadenopathy.

Primary lesions, which often involve all the vulvar tissues, the vaginal mucosa, and the cervix, occur during a 2-week period. They first appear as papules surrounded by an erythematous zone and subsequently become vesiculopustular lesions. The vesicles enlarge and rupture, and shallow ulcerations are exposed. During the acute phase of a severe infection, more or less edema and generalized erythema of the vulvar mucosa are present (Fig. 48–14).

The ulcers generally become covered with a firm yellow crust that drops off after a week or so, with a smooth, red area left behind that eventually disappears. The lesions usually are asymptomatic for 10 to 21 days, depending on the severity of the infection. Secondary bacterial infection and a coexisting immunodeficiency state, such as HIV infection, delay healing. Urethral and vesical involvement may cause severe dysuria leading to retention of urine. Proctitis may occur in adolescent girls who engage in anal intercourse, although perianal ulcers also may occur without anal intercourse. The cervical lesions are ulcerations on the exocervix and may range from erythema to severe necrotic cervicitis. Acute cervicitis may be the only manifestation of primary HSV infection.

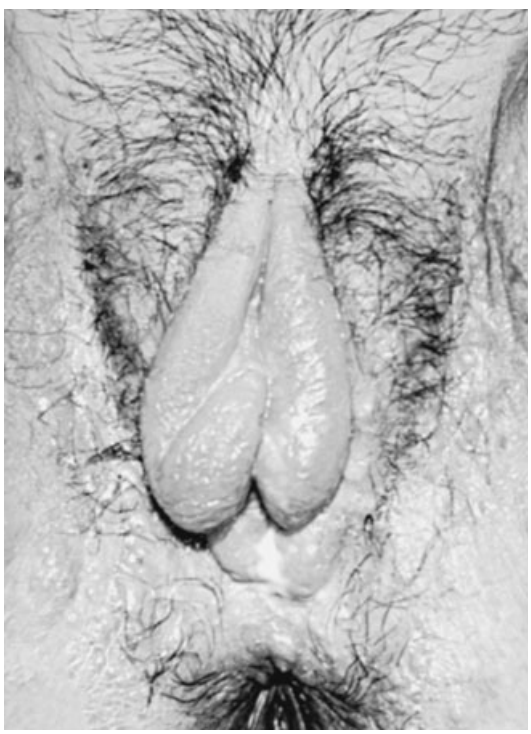

Figure 48–14 Genital herpes in an adolescent patient.

Inguinal lymphadenopathy and moderate lower abdominal pain may be present; if so, they usually occur only with the more severe first eruption. Tender inguinal lymphadenopathy is the last to resolve. If the urethra is involved, the dysuria may be sufficiently severe to cause urinary retention. Insertion of a vaginal speculum may be exquisitely painful. Extension to the perianal area may cause severe discomfort on defecation. Complete healing of lesions at all sites occurs in approximately 3 weeks. When healed, herpetic lesions rarely leave scars.

The diagnosis of genital herpes usually is not difficult to establish. The intense pain and the superficial vesiculoulcerative lesions with their irregular margins and red areolae are sufficiently characteristic to render clinical identification easy in a typical case. Laboratory confirmation should be attempted for all children and adolescents. Direct isolation of HSV by tissue culture is the preferred diagnostic method and is best when the specimen is taken from a lesion within the first 48 hours of the onset of symptoms. The virus can be cultured from the cervix in 90 percent of girls with primary type 2 infections, and the cervix appears abnormal in almost 90 percent of cases with positive cervical cultures. PCR assays for HSV DNA are more sensitive than is culture and are used in settings when available. PCR testing of genital secretions has not been approved by the U.S. Food and Drug Administration (FDA), however.[42]

Type-specific and non–type-specific antibodies to HSV develop during the first several weeks after infection occurs and persist indefinitely. Commonly available serologic tests cannot differentiate type 1 from type 2 virus. Type-specific antisera using glycoprotein G–based assays showing an increase in anti-HSV titer are useful in identifying primary type 2 infections. These tests have limited usefulness for recurrent infection, however. A variety of glycoprotein G–based assays (enzyme-linked immunosorbent assay) are available and have to be specifically requested. Point-of-care HSV tests using glycoprotein G also are available for immediate office-based testing and work best in settings with high prevalence of infection. False-positive results have been reported in individuals with low likelihood of infection.[42]

The presence of multinucleated giant cells in a Pap smear (Fig. 48–15) or in a herpetic fluid smear with a Tzanck preparation is only 40 to 50 percent sensitive compared with culture. These tests may be useful in settings where other diagnostic tests are unavailable but should not be relied on.[42]

For many weeks after the infection has subsided clinically and the patient seems to be cured, type 2 virus can be recovered from the cervix and vagina. The latent virus may infect others or cause recurrent infections in the host. Although the recurrence rate of genital herpes is unknown, recurrent episodes develop in 80 percent of patients with type 2 infection; clinical recurrence of type 1 genital infection is much less common.[48] Factors influencing recurrence rates are the severity of the initial episode and the host immune response to the disease. Emotional stress, heat, moisture, climate change, menstruation, pregnancy, oral contraceptive use, anesthesia, and trauma seem to be triggering factors. The median time from a primary infection to development of a secondary or recurrent infection is approximately 120 days.[48,256,284] Such recurrent episodes, although painful, usually are less severe than are primary infections. Some patients have recurrences immediately preceding or at the time of each menstrual period. Researchers have suggested that genital herpes and squamous cell carcinoma of the cervix are related.[36] Most of the evidence favoring this association originally came from seroepidemiologic studies. A much stronger association now has been observed

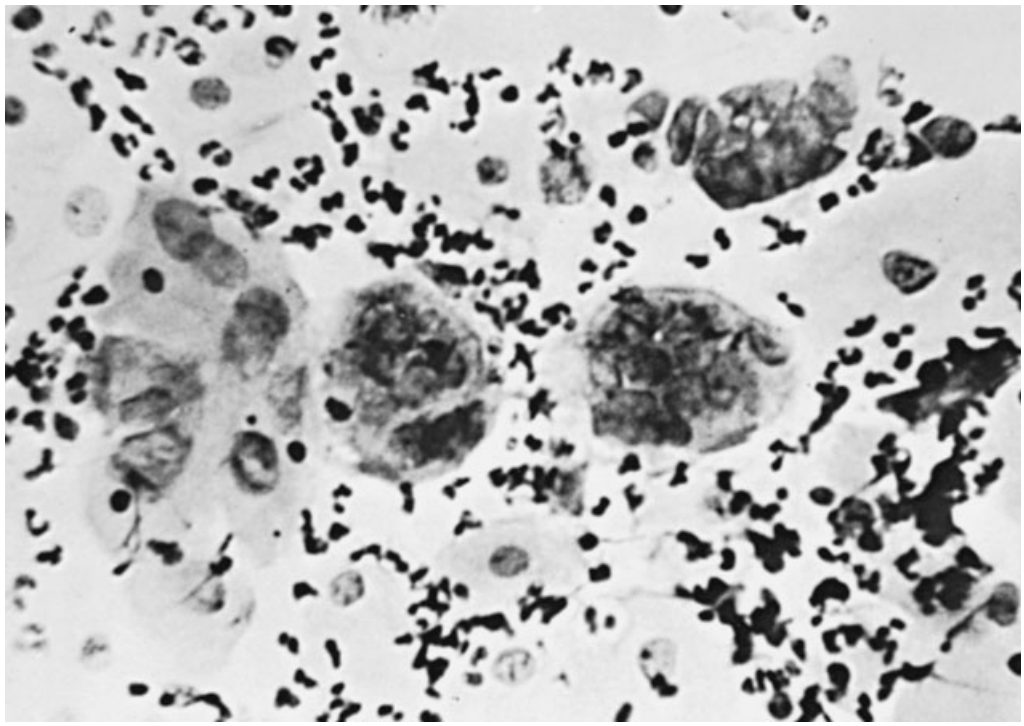

Figure 48–15 Multinucleated giant cells in a vaginal smear are characteristic of genital herpes. *(Courtesy of Dr. Herman L. Gardner.)*

between HPV and cervical cancer. At most, HSV may be causative or may be a cofactor in some cases of cervical cancer.[48]

Treatment

Several medications are available today for the treatment of genital herpes.[42] Acyclovir is the most affordable current drug on the market. For the treatment of initial genital herpes, acyclovir, one 400-mg capsule orally three times a day or one 200-mg capsule five times a day, is administered for 7 to 10 days until clinical resolution. Alternative drugs include famciclovir, one 250-mg capsule three times a day, or valacyclovir, one 1-g capsule twice a day for 7 to 10 days. These drugs are reported to shorten the time that the patient has pain, decrease the number of new lesions, hasten crusting, and reduce the time that the virus can be found in the lesions. The earlier treatment is started after the initial lesions appear, the sooner patients obtain relief.

In severe primary herpes infection with marked systemic symptoms, intravenous acyclovir, 5 to 10 mg/kg/day every 8 hours for 5 to 7 days or until clinical resolution occurs, is recommended. Frequent or severe recurrent disease may benefit from medication if it is started within 2 days of the onset of lesions or at the beginning of the prodrome. Oral acyclovir may be given at 800 mg twice a day, 400 mg three times a day for 5 days, or acyclovir 800 mg three times a day for 2 days. Alternatively, famciclovir, 125 mg twice a day, or valacyclovir, 500 mg twice a day for 3 days, or valacyclovir 1000 mg once a day for 5 days, may be prescribed. Daily suppressive treatment reduces recurrence by at least 75 percent in patients with frequent recurrences. Because of adherence problems, daily suppressive therapy may not be a practical treatment approach for adolescents. The recommended treatment is oral acyclovir, 400 mg twice a day; famciclovir, 250 mg twice a day; or valacyclovir, 500 or 1000 mg once a day for 1 year. Medication should be discontinued after 1 year to reassess the recurrence rate. The dosage regimen of medications for treating prepubertal genital herpes is unknown, and such medications are not used commonly in this age group for mild cases. In moderate to severe cases, clinicians have prescribed approximately 50 percent of the adult dose.[42]

Recurrences can be reduced in frequency in some cases if the patients can avoid stress-inducing situations. Topical anesthetics, cold wet compresses, and sitz baths with 1:40 Burow's solution frequently reduce local discomfort. Severe dysuria may be relieved by urinating when sitting in water. Local therapies used in the past, such as povidone-iodine solutions, photodynamic dye light therapy, and topical surfactant, have not been found to be beneficial and are messy and potentially toxic.

Lesions caused by HSV are common manifestations in patients with HIV infection. Immunocompromised patients benefit from an increased dosage of acyclovir. For severe disease, hospitalization may be required for intravenous acyclovir treatment.[42]

CONDYLOMATA ACUMINATA AND HUMAN PAPILLOMAVIRUS

Condylomata acuminata are encountered in premenarcheal and teenage girls. The agent causing them is HPV, a small, slow-growing virus of the papovavirus group. HPV types 6 and 11 are responsible for low-grade lesions and for 90 percent of genital warts. HPV types 16, 18, and 31 are associated with premalignant and malignant cervical carcinoma in women,[252] with HPV types 16 and 18 causing 70 percent of premalignant and malignant lesions.

Premenarcheal Patient

Warts in premenarcheal children may cover the entire vulva. Most often, however, warts in this population are single or scattered, cauliflower-like lesions (Fig. 48–16). They have a predilection for the smooth, moist mucosa covering the inner surfaces of the labia minora and for the mucosa around the urethral meatus. The vestibular mucosa may be studded with innumerable minute excrescences as well.

Condylomata in children seldom become ulcerative, but sessile condylomata arising within the vagina may become necrotic; produce a bloody vaginal discharge; and resemble, on cursory examination, a mixed mesodermal tumor (sarcoma botryoides) of the vagina. Although not tumors, condylomata acu-

Figure 48–16 Condylomata acuminata usually are single or scattered, small warts in premenarcheal children.

Figure 48–17 Condylomata acuminata may form large masses covering the vulva in postmenarcheal patients.

minata should be considered in the differential diagnosis of vaginal neoplasms. HIV infection should be considered in infants and children with severe, extensive warts.[47,57,100,252]

Adolescent Patient

Condylomata acuminata develop in adolescent girls by sexual transmission. The prevalence of HPV in adolescent girls and young women is 11 to 46 percent, depending on the method of HPV DNA detection used.[229,252] The PCR technique is more sensitive than is the dot-blot hybridization method (ViraPap; Life Technologies, Gaithersburg, MD). The prevalence of HPV in adolescents as detected by DNA isolation techniques is far higher than the prevalence of active disease. The cell-mediated or T-cell immune system seems to play an important role in whether the presence of virus results in clinically manifested disease. Cofactors of HPV infection are herpes, cervicitis, and tobacco use. Immunosuppression from a variety of conditions, including renal transplantation, Hodgkin disease, and HIV infection, is associated with a greater likelihood of development of HPV disease.[229] With regard to the natural history of HPV infection, Moscicki and colleagues[184,185] found that during the course of a 2-year period, 70 percent of cases showed regression, and low-grade squamous intraepithelial lesions (LSIL) did not develop. Daily cigarette smoking was strongly linked to the development of LSIL.[185] Regression was more likely to be seen in young women with LSIL as opposed to high-grade squamous intraepithelial lesions (HSIL). HSIL was more likely to develop in individuals with persistent positive tests showing oncogenic HPV types.

In postmenarcheal girls, condylomata usually form discrete, sessile, vegetative, wartlike growths covered with folded grayish pink epithelium. They are found most frequently on the smooth mucosa of the vulvar vestibule. Usually, they are accompanied by more or less vaginal discharge, which is increased by moisture that exudes from between the leaflike folds of the warty masses. Most often, associated pruritus and secondary infection are present. Warts are more likely to become necrotic in adults than in children. Contact lesions frequently appear on contiguous surfaces. Huge condylomatous masses (Fig. 48–17) that completely hide the introitus are common findings in adolescent patients; if not treated, these huge growths may invade the rectum. Vaginal and cervical lesions commonly accompany the lesions on the vulva.

Treatment

The goal of treatment is removal of warts and amelioration of symptoms, not eradication of HPV. No therapy has been shown to eradicate HPV. When only a few lesions are present, they can be treated in the outpatient setting with 85 percent trichloracetic acid. In infants and children with extensive lesions, Emans and colleagues[74] recommend carbon dioxide laser treatment with general anesthesia. It may be performed in an outpatient surgical setting when few lesions are present. Electrocautery, electrocoagulation, or laser treatment may result in deep scarring and distortion of the vulva. Older children and adolescents usually tolerate cryotherapy without general anesthesia if they know that some tingling or burning sensation is associated with it. Liquid nitrogen may be used in the same manner as solid carbon dioxide.

The therapeutic methods available are 22 to 94 percent effective in clearing exophytic genital warts, but recurrence rates are high, at least 25 percent within 3 months. Treatment seems to be more successful for genital warts that are small and present for less than 1 year.[42] Self-application of medication may be considered in young adults but should be discouraged for adolescents because of the risk of causing dermatologic side effects. When a few lesions are present, they can be treated with 10 to 25 percent podophyllin resin or a solution of 85 percent trichloroacetic acid. The lesions that are treated should be less than 1 cm in diameter and should not be in a confluent mass. Four hours after podophyllin has been applied, the treated area should be washed off with soap and water. The medication is applied to the wart only (not to the surrounding skin), and treatment is

Figure 48–18 The appearance of the vulva 10 days after electrocoagulation and surgical excision of the condylomatous mass shown in Figure 48–17.

repeated once weekly until the lesions have disappeared (usually 3 to 4 weeks).

Urethral, anal, vaginal, and cervical lesions should not be treated with podophyllin. Podophyllin and trichloracetic acid can cause severe irritation of normal skin and can cause ulcerations. Before application, the normal skin around a wart should be covered with K-Y jelly, and a thin or narrow swab should be used for small warts. If excessive medication has been applied, the area should be washed immediately with soap and water, followed by the application of talcum powder or bicarbonate of soda to soothe the area. Imiquimod 5 percent cream also is recommended for the treatment of warts in patients older than 18 years.[41] This medication is self-applied to the lesions, three times a week for 16 weeks. There are reports in the international literature regarding the successful treatment of extensive warts in children using imiquimod 5 percent cream.[171] Laser treatment or cryocautery is recommended if the lesions do not respond to chemical cautery or if they progressively increase in size. Large perianal warts may need to be removed surgically if cryotherapy does not work (Fig. 48–18). Alternative treatments for adolescents are topical 5-fluorouracil in 5 percent creams and intralesional interferon. 5-Fluorouracil is preferable for vaginal and intraurethral warts because it causes erosive dermatitis of normal surrounding skin. The use of 5-fluorouracil seems to be more effective than is the laser in treating exophytic warts in the vagina.[42,57]

An annual Pap smear is recommended in all adolescent girls 3 years after the onset of sexual activity. In an adolescent girl who has not had sex, the first Pap smear is recommended at age 21 years.[294] The quadrivalent HPV vaccine contains HPV types 6, 11, 16, and 18 and has been approved by the FDA to prevent genital warts and cervical cancer. It is recommended that females 9 to 26 years old receive the vaccine at age 11 to 12 years during their routine immunization visit. Catch-up vaccination is recommended for females 13 to 26 years old who have not been vaccinated previously, regardless of their sexual history.[174] FDA approval for a bivalent HPV vaccine containing HPV types 16 and 18, to prevent cervical cancer for a broader age range of women, is in progress.

MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum is a viral infection of the skin characterized by small, discrete, translucent, grayish pink, umbilicated, wartlike papules that sometimes are surrounded by a narrow ring of erythema. The lesions, which are asymptomatic, usually are less than 5 mm in diameter and may be missed by the patient and the examiner. The disease is transmitted by close physical contact and is encountered most often in postmenarcheal patients on the inner surfaces of the thighs and perineum. Although lesions on the lower part of the abdomen and thighs have caused this infection to be classed with venereal diseases, coitus is not necessary for transmission. Pediatricians frequently encounter molluscum contagiosum on the nongenital skin of children. It can be contracted from contaminated towels, bedding, and garments. Lesions of molluscum contagiosum on the lower part of the abdomen, pubis, thighs, or perineum of a child are tacit evidence of sexual contact.[129,170]

The appearance of the lesions usually is sufficient to establish the diagnosis. It can be confirmed by finding large, intracytoplasmic inclusion bodies in a smear or biopsy specimen from a lesion.

Treatment consists of lifting off the roof of each lesion and lightly curetting its base. Cryotherapy and topical imiquimod also give good results.[129,170] A variety of treatment approaches are available for children and adolescents. Curettage is the most efficacious treatment, with a low rate of side effects; however, the procedure requires anesthesia and is time-consuming. The roof of each lesion is lifted off, and the base is lightly curetted. Cryotherapy gives good results. Cantharadin is another useful bloodless alternative, but it can cause blisters. Topical imiquimod holds promise, but an optimal treatment schedule has not been determined.[42]

VULVOVAGINAL GRANULOMATOUS AND ULCERATIVE DISORDERS

Sexually transmitted genital ulcerative diseases occur throughout the world but are found most frequently in tropical countries. Genital ulcers are a common finding on evaluation of adolescent and adult patients with genital symptoms. They are less common findings in young children. Ulcers usually are secondary lesions that result from the breakdown of vesicles, papules, or pustules. By the time that many patients with genital infections seek medical attention for their symptoms, the primary lesion has proceeded to ulceration.[254] Microbial causes vary by geographic region and socioeconomic status: HSV is the most common cause in Western Europe and North America, whereas chancroid is the most common one in the tropics; in the United States, syphilis and chancroid are more common occurrences in urban minority groups, whereas HSV is found more commonly in more affluent groups. Complications of sexually transmitted genital ulcerative diseases also occur more commonly in developing countries and often are the reason for seeking medical care.[187]

HSV infection, syphilis, chancroid, lymphogranuloma venereum, granuloma inguinale, and tuberculosis all may have genital ulcers as a major clinical finding (Table 48–4). Although each of these diseases has a characteristic lesion and course, considerable overlap exists, so a diagnosis based on the history and physical appearance alone often is inaccurate. Herpetic ulcers, contrary to classic manifestations, can be painless, and syphilis chancres can be painful at times. Secondary infection of an ulcerated area may cause pain in lesions that characteristically are painless. In addition, more than one STD may be present in at least 3 to 10 percent of patients with genital ulcers.

Genital ulcers also may result from infestation, fixed drug eruption, mechanical or chemical trauma, autoimmune processes (e.g., Behçet syndrome and Crohn disease), and neoplasia. The presence of ulcers in sites other than the genital regions or oropharynx suggests a noninfectious etiology.

TABLE 48–4 Diagnostic Features of Genital Ulcerations Caused by Sexually Transmitted Diseases

Feature	Primary Syphilis	Genital Herpes	Chancroid	Lymphogranuloma Venereum	Granuloma Inguinale
Incubation period	9-90 days; avg., 2-4 wk	2-7 days	1-35 days; avg., 3-7 days	3 days to 3 wk; avg., 10-14 days	Precise data unavailable; probably a few days to several months
No. lesions	Usually one; may be multiple	Multiple; may coalesce, more with primary episodes than with recurrences	Usually one to three, may be multiple	Usually single	Single or multiple
Description of genital ulcers	Sharply demarcated, round or oval ulcer with slightly elevated edges; may be irregular, symmetric "kissing chancre"	Small, superficial, grouped vesicles, erosions, or both; lesions may coalesce and form bullae or large areas of ulceration; lesions have irregular borders	Superficial, shallow, sharply demarcated ulcer; irregular, ragged, undermined edge; a few millimeters to 2 cm in diameter	Papule, pustule, vesicle, or ulcer discrete and transient; frequently overlooked	Sharply defined, irregular ulcerations or hypertrophic, verrucous, necrotic, or cicatricial granulomata
Base	Red, smooth, and shiny or crusty; oozing serous exudate when squeezed	Bright red and smooth	Rough, uneven, yellow to gray	Variable	Usually friable, rough, beefy granulations; can be necrotic, verrucous, or cicatricial
Induration	Firm; does not change shape with pressure	None	Soft; changes shape with pressure	None	Firm granulation tissue
Pain	Painless; may become tender if secondarily infected	Common; more prominent with initial infection than with recurrences	Common	Variable	Rare
Inguinal lymphadenopathy	Unilateral or bilateral, firm, movable, and nontender; does not suppurate	Usually bilateral, firm, and tender; more common in primary episodes than in recurrences	Unilateral; bilateral rarely occurs; overlying erythema; matted, fixed, and tender; suppuration may occur	Unilateral or bilateral; initially movable, firm, and tender; later indolent; fixed and matted; "sign of groove" may suppurate; fistulas	Pseudobuboes; subcutaneous perilymphatic granulomatous lesions that produce inguinal swellings
Constitutional symptoms	Rare	Common in primary episode; less likely in recurrences	Rare	Frequent	Rare
Course of untreated disease	Slowly (2-6 wk) resolves to latency	Recurrence is the rule	May progress to erosive lesions	Local lesions heal; systemic disease may progress; disfiguring; late complications	Worsens slowly
Diagnostic tests	Darkfield examination, direct immunofluorescence, FTA-ABS, VDRL	Tzanck smear, culture, Pap smear, direct immunofluorescence, electron microscopy, direct immunoperoxidase staining, serology	Culture, biopsy (rarely used), Gram-stained smears have low specificity	Complement fixation, isolation of microorganism by culture	"Donovan bodies" in tissue smears; biopsy

FTA-ABS, fluorescent treponemal antibody absorption test; VDRL, Venereal Disease Research Laboratory.
From Mroczkowski, T. R., and Martin, D. H.: Genital ulcer disease. Dermatol. Clin. North Am. 12:753-764, *1994.*

In the United States, most patients with genital ulcers have genital herpes, syphilis, chancroid, or a combination thereof. Empiric treatment often must be given before diagnostic test results are available, and laboratory confirmation of a specific diagnosis is lacking in at least a quarter of patients with genital ulcer disease. Treatment of syphilis and chancroid should be considered in such circumstances, especially in geographic regions where chancroid morbidity is notable (see later).[41,203] Diagnosis and treatment of the listed infectious etiologies of genital ulcers and Behçet syndrome are discussed in this chapter and elsewhere in this text.

Genital ulcers of any etiology, but especially those caused by herpes, syphilis, chancroid, and granuloma inguinale, are associated with an increased risk of acquiring HIV infection. Serologic testing for HIV infection should be considered in the management of patients with genital ulcers.[41,188] Improved treatment of STDs can affect the rate of HIV seroconversion in a population: HIV seroconversion was reduced by 40 percent over the course of a 2-year follow-up period in rural communities in Tanzania where treatment programs were instituted compared with control communities with no programs.[103]

LYMPHOGRANULOMA VENEREUM

Lymphogranuloma venereum is an STD characterized by chronicity, indolent inflammatory infiltration, granulomatous ulceration, formation of abscesses, and fibrotic cicatrization of the inguinal, perineal, and rectal lymphatics. The infecting agent is *C. trachomatis*, subtypes L1 to L3. It occurs more often in tropical than temperate climates.

Premenarcheal Patient

Lymphogranuloma venereum has been reported in children.[17,98,285] The disease usually is acquired in childhood as a result of sexual contact, but transmission also may occur by accidental inoculation of infected material from family members, such as by handling of garments or towels that have been contaminated by drainage from ulcerative lesions or buboes. Sexual abuse always should be considered, however. Some evidence suggests that transplacental or perinatal transmission of the lymphogranuloma venereum serovars of *C. trachomatis* can occur.[98]

The primary lesion, a small papule or superficial and relatively asymptomatic ulcer, seldom is seen in either children or older patients. A prodromal episode of fever, malaise, and joint pain accompanied by leukocytosis, anemia, and an increased erythrocyte sedimentation rate may precede the local signs. These symptoms often are mild and not diagnostically significant.

The most common manifestations in prepubertal children are inguinal lymphadenopathy and proctitis. The glands may be swollen and tender for a while, and then regress spontaneously. More often, if treatment is not initiated, the lesions progress to formation of an abscess and then rupture, with the development of draining sinuses. Rectal, anal, and deep pelvic tissue infiltration with rectal and colonic strictures is an uncommon finding in children. Arthritis, usually of the knees, and erythema nodosum occasionally occur in children, as they do in older patients.[98]

Adolescent Patient

Adolescents usually acquire lymphogranuloma venereum through sexual activity. The primary lesion—a small papule, vesicle, or shallow ulcer on the vulva (Fig. 48–19), vaginal wall, or cervix—seldom is seen. Cervicitis is a more common finding in primary lymphogranuloma venereum, and the primary lesion often is asymptomatic, heals rapidly, and leaves no scar. The incubation period usually is 2 to 5 days after exposure, but several weeks may elapse before the primary lesion appears.[98,133]

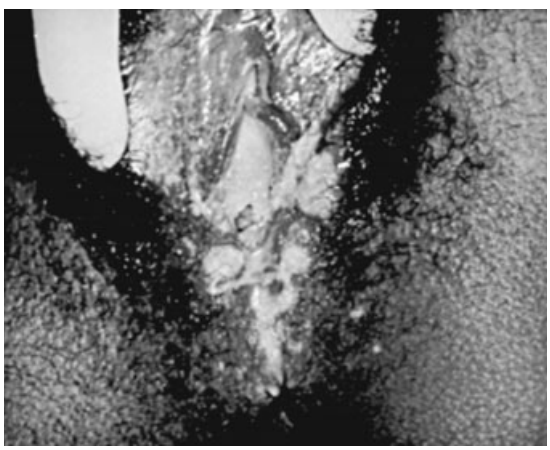

Figure 48–19 Early lesions of lymphogranuloma venereum in the form of herpetic-like ulcers in an adolescent. The diagnosis was confirmed serologically.

Painful enlargement of the inguinal lymph nodes generally occurs after the manifestation of the initial lesions. Inguinal adenitis usually is unilateral in the early stages of infection. The perirectal lymph nodes occasionally are the first to be involved; pain on defecation is an early symptom when this condition occurs. The rectovaginal septum may become involved when the posterior vaginal area is a primary site of infection.

If the disease goes untreated, it may enter a secondary stage called the *inguinal syndrome*, in which the inguinal glands and the surrounding subcutaneous tissues become a brawny mass that adheres to the indurated, purplish red overlying skin. The nodes increase in size and form abscesses (buboes). Unless aspirated, the buboes rupture and create chronically draining sinuses.[133] Enlargement of lymph nodes above and below the inguinal ligament may lead to the "groove" sign.[98] Complaints of lower abdominal pain and backache may indicate concurrent proctitis. The deep iliac nodes may be enlarged in 75 percent of cases; rupture of these nodes may cause large pelvic abscesses.

Healing of draining buboes is slow, and severe scarring occurs. In most cases, healing of buboes indicates the end of the disease, but relapses have been reported in 20 percent of untreated cases. Disseminated disease, hepatitis, pneumonia, arthritis, erythema nodosum, erythema multiforme, and ocular infection can occur in association with the inguinal syndrome.

The anogenitorectal syndrome is a subacute manifestation of lymphogranuloma venereum. It includes proctocolitis and hyperplasia of intestinal and perirectal lymphatic tissue. Perirectal abscesses often develop and lead to ischiorectal and rectovaginal fistulas, anal fistulas, and rectal stricture or stenosis. The clinical findings consist of fever, rectal pain, and abdominal cramping. Progression of the disease causes rectal bleeding and a purulent rectal discharge. Rectal strictures lead to constipation and "pencil stools." Weight loss, bowel perforation, and peritonitis may occur. Genital elephantiasis (esthiomene), a primary infection affecting the lymphatics of the scrotum, penis, or vulva, may occur with chronic infection.

The diagnosis of lymphogranuloma venereum should be considered whenever a patient has a tender, enlarged inguinal gland or an ulcerative or granulomatous lesion of the vulva, perineum, vagina, or cervix. Acutely painful, unilateral inguinal lymphadenitis strongly suggests lymphogranuloma venereum. A definitive diagnosis is made by identification of *C. trachomatis* serotype L1, L2, or L3 in tissue cultures of material from buboes or ulcerative lesions. The sensitivity of culture for lymphogranuloma venereum is only approximately 50 percent, however.[145] Serologic tests may be used when cultures are negative or buboes are not present. Complement fixation has been available since the 1930s and 1940s. In clinical settings suggestive of lymphogranuloma venereum, a complement-fixation antibody titer of 1:64 or higher is considered diagnostic. Most patients with lymphogranuloma venereum have titers of 1:128 or higher. Titers between acute and convalescent specimens may not increase because most patients seek care well after the acute phase of the infection has developed. Cross-reaction with other chlamydial serotypes does occur, but titers higher than 1: 6 rarely are seen with chlamydial urethritis. Microimmunofluorescence is more specific than is complement fixation and can detect IgM and IgG titers. This test is not widely available.[145]

Complement fixation remains the recommended test for diagnosis when the clinical findings lead to a presumptive diagnosis of lymphogranuloma venereum. If complement-fixation titers are negative, repeat testing in a few weeks may be helpful in patients who happen to be evaluated first early in the course of illness. DNA probes or monoclonal antibodies specific for lymphogranuloma venereum serovars may become available in the near future.

Lymphogranuloma venereum must be differentiated from syphilis, with which it may coexist. False-positive Venereal Disease Research Laboratory test results may occur in 20 percent

of patients with lymphogranuloma venereum. When the diagnosis is in doubt, specific tests for antitreponemal antibodies must be used to rule out syphilis. The disease is differentiated from other granulomatous and ulcerative disorders by specific tests for each, by biopsy, and by the clinical appearance of the lesions (see Table 48–3).

Treatment

The earlier the diagnosis is made and treatment is started, the better the response to therapy and the less serious the tissue destruction. Fluctuant buboes are aspirated, not incised, before they rupture. The discharge from the ulcerated areas and buboes is infectious, so precautions against transmission of the disease must be taken. The patient would be more comfortable if kept in bed. Ice-cold compresses may be applied to the inguinal areas. The vulva is cleansed gently twice daily.

The preferred treatment of lymphogranuloma venereum is doxycycline, 100 mg orally twice a day for 21 days.[42] The latter is preferred in pediatric patients younger than 8 years. The alternative regimen is erythromycin base 500 mg orally four times a day for 21 days. Either of these medications also should be given for 21 days. Because of the potential for shorter treatment courses and improved compliance, azithromycin may become a treatment option for lymphogranuloma venereum in the future. It cannot be recommended now because data are insufficient.

After treatment is initiated, patients should be monitored clinically until the signs and symptoms have resolved. Individuals who have had sexual contact with a patient during the 30 days before the onset of symptoms of lymphogranuloma venereum should be examined, tested for chlamydial infection, and treated.[41] Adolescents are likely to be treated before development of the extensive anal and rectal strictures and distorting vulvar cicatrizations occur, for which extensive surgery is sometimes necessary in older patients.

GRANULOMA INGUINALE

Granuloma inguinale is a chronic disease characterized by ulcerative granulomatous lesions of the skin and subcutaneous tissues (Fig. 48–20; see Table 48–4). Common synonyms for the infection include granuloma venereum and donovanosis. The disease most often affects the external genitalia, perineum, and inguinal regions, but the vagina, cervix, and, rarely, distant extragenital sites may be involved. The disease is caused by *Klebsiella granulomatis* (formerly known as *Calymmatobacterium granulomatis*, *Donovania granulomatis*, Donovan bodies), an encapsulated, gram-negative bacillus.[30,65,161,200] Granuloma inguinale occurs commonly in tropical and subtropical regions of the world.[191,201,203] It is relatively rare in the United States and other developed countries.[41,104] The male-to-female ratio seems to be at least 2 : 1. The disease rarely occurs in premenarcheal children, but it should be considered in the differential diagnosis of granulomatous lesions of the genitalia in adolescents.

Figure 48–20 Granuloma inguinale.

The disease is transmitted to adolescents and adults during sexual intercourse. The close physical contact of the inguinal, perineal, and genital regions that occurs during sexual activity, and not intercourse per se, probably is more important for transmission of the infection. The organism is not highly contagious; sexual partners of patients with granuloma inguinale often do not become infected. Breaches in the integrity of the skin or mucous membranes, such as with minor trauma, may be required for an inoculum to establish a successful infection.[202] The disease apparently can be transmitted to young children by contaminated clothing or towels. Close physical contact, such as sitting on the lap of an infected parent, also has been reported as a mode of transmission to young children.[295]

The incubation period usually is less than 2 weeks but may be 3 months.[202] The first manifestation of infection usually is single or multiple small, painless hard nodules on the vulva or perineum that erode the skin and form ulcers. Genital tract bleeding is the next most common finding. Ulcers are shallow and have a beefy, granular base that is friable and bleeds easily. The edges are nodular, raised, and undermined. These ulcers usually are painless, unless they become infected secondarily. Regional (inguinal) lymphadenopathy is not associated with granuloma inguinale.[200]

If left untreated, lesions progress slowly outward by eccentric expansion of the leading edge. Over time, this ulcerative stage involves large areas of the perineum, external genitalia, and surrounding skin surfaces. The central areas usually remain ulcerative but may become hypertrophic. Hypertrophic lesions consist of large, vegetating masses with overgrowth of granulation tissue. Less frequently, extensive, destructive necrosis develops in the lesions, or they are dry with sclerotic scarring, which distorts the tissues. Lymphedema of distal tissues occurs commonly during the course of the disease. Lymphatic obstruction or elephantiasis occasionally results in enlargement of the clitoris or labia.[93,149] Subcutaneous granulation develops in approximately 5 percent of cases and may mimic the appearance of bubo formation, termed *pseudobuboes*. When true regional adenopathy occurs in granuloma inguinale, it generally represents a response to a secondary infection or another associated sexually transmitted infection.

Extragenital disease may occur in 6 percent of cases and usually involves the head and neck. Autoinoculation is postulated as the means of transmission of infection of these sites.[86] Occasional involvement of the liver, thorax, and bones remote from the primary genital site suggests that hematogenous spread can occur. Systemic disease is encountered more frequently in girls with cervical lesions and is associated with prolonged spiking fever, anemia, and weight loss.[31,151,220]

Successful isolation of *K. granulomatis* rarely has proved feasible. Reliable culture techniques are unavailable. The diagnosis of granuloma inguinale is based on the presence of Donovan bodies in large, histiocytic cells on crush preparations from lesions (Fig. 48–21). A portion of the granulation tissue is removed and pressed onto a clean slide, which is allowed to air-dry. The slide then is stained with Giemsa, Wright, or Warthin-Starry

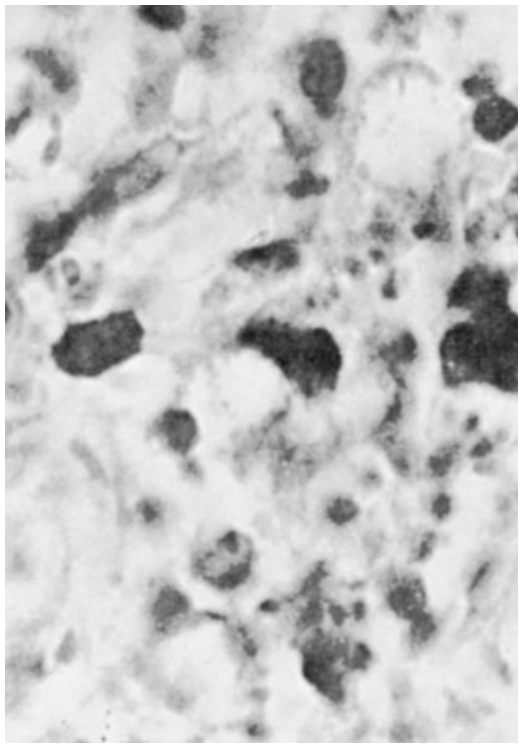

Figure 48–21 Donovan bodies.

stain. Donovan bodies, which are pathognomonic for granuloma inguinale, are vacuolar compartments within the cytoplasm that contain 20 to 30 viable organisms.[65] Histopathologic study of biopsy specimens sometimes is required for establishing a diagnosis. Biopsy specimens should be very early, very sclerotic, or heavily superinfected lesions. Specimens with a scarcity of organisms and smear or crush specimens are likely to be nondiagnostic in such circumstances. Biopsy also should be performed when malignancy is thought possible, or when antibiotic therapy does not lead to improvement.[145]

Complement-fixation and indirect immunofluorescence serologic tests have been developed but have limited specificity.[145] There are no FDA-approved, PCR-based tests for chancroid, but such testing can be performed by commercial laboratories that have developed their own test and conducted a Clinical Laboratory Improvement Act (CLIA) verification study.[41] The differential diagnosis of granuloma inguinale includes carcinoma, syphilis, tuberculosis, chancroid, lymphogranuloma venereum, condyloma acuminatum, blastomycosis, schistosomiasis, and other granulomatous diseases.[20,200,202] STDs such as syphilis may coexist with granuloma inguinale. Darkfield examination of tissue specimens and serologic tests for syphilis should be done. Biopsy may be required to rule out neoplasia or tuberculosis.[86] Chancroid ulcers tend to be deeper and more ragged and often have associated bubo formation. Physical examination alone often is insufficient to distinguish any of these processes from the others (see Table 48–4). Granuloma inguinale also is associated with the development of carcinoma within areas that have been involved in the ulcerative process.

Treatment

Doxycycline, 100 mg orally twice a day for at least 3 weeks and until all lesions have completely healed, is the recommended treatment. Alternatives include azithromycin, 1 g orally once weekly; ciprofloxacin, 750 mg orally twice a day; erythromycin base, 500 mg orally four times a day; or trimethoprim-sulfamethoxazole, one double-strength tablet orally twice a day. Each regimen should be continued until all lesions have healed completely, with a minimum course of 3 weeks.[47] Chloramphenicol and gentamicin also have been used.[227]

Vulvar lesions usually heal within 2 weeks of therapy, but cervical and pelvic lesions may require longer than 3 months. Incomplete treatment can result in recurrence with extensive fibrosis and scarring.[20] The disease recurs in approximately 10 percent of cases. Surgery may be required for complications of granuloma inguinale, such as elephantiasis, strictures, and pelvic abscesses.

Precautions regarding infections should be taken in the home or hospital until the lesions have healed. Sexual contacts of patients with granuloma inguinale within 60 days before onset of the index patient's symptoms should be evaluated and offered therapy, even if no lesions are present. The value of empiric therapy in the absence of overt clinical signs and symptoms has not been determined, however.[41] Adolescent girls who have had granuloma inguinale should be kept under clinical surveillance for many years for the potential development of carcinoma in the perineum and genital tract.

CHANCROID

Chancroid is an acute, ulcerative disease that involves primarily the external genitalia.[7,289] The causative agent, *Haemophilus ducreyi*, is a fastidious, gram-negative coccobacillus. It is a strict human pathogen, and the only known route of transmission is sexual contact. The incubation period usually is 3 to 7 days, but it may be longer. Chancroid rarely is encountered in young children, but occasionally is seen in sexually active adolescents. It occurs far more commonly in boys than in girls for reasons that are unclear, although asymptomatic carriage in girls has been hypothesized.[24,115,206,278]

Chancroid is well established as a cofactor for transmission of HIV infection.[41,42] Ten percent of patients with chancroid may be infected with HIV. Chancroid is found more commonly in tropical and subtropical regions than in developed countries, but its frequency is increasing in many parts of the world.[206] Chancroid is endemic in the United States and occurs primarily in discrete occasional outbreaks. Outbreaks caused by unrelated strains occurred in New Orleans, Louisiana, and Jackson, Mississippi, in the 1990s.[118] The disease probably is underrecognized and underreported.[41]

A recent case series described three girls 5 to 9 years old with chronic skin ulcerations on their lower legs after visiting Samoa. *H. ducreyi* was found in specimens from each child. No evidence of acquisition by sexual contact was found. Lower limb ulcerations were present among household contacts while the girls were in Samoa. Autoinoculation leading to nongenital skin lesions has been described.[278] Although the potential for nongenital transmission of *H. ducreyi* to nongenital sites exists, chancroid lesions in the genital area should be considered the result of sexual contact.

The first sign of chancroid infection of the genital tract is a small, hyperemic macule. The macule becomes a papule and then a pustule before ulceration occurs. The ulcer is painful and usually deep, with irregular borders and undermined edges. The base is gray and covered with purulent exudate laden with the *H. ducreyi* bacillus. Ulcers may occur on the vulva, vaginal mucosa, cervix, or anus but usually are found on the labia minora. Dysuria is a frequent complaint. Tenesmus and rectal bleeding may be associated with anal lesions. Single ulcers are found frequently, but multiple ulcers occur more often. They may become contiguous and form large, eroded areas. Phagedenic destruction of the external genitalia may occur when treatment is not sought early, or a secondary infection develops in the ulcers. In such cases,

scarring persists despite successful eradication of the microbe. Infection, at least experimentally, does not seem to confer protection on re-exposure to the microbe.[6]

Associated, painful inguinal adenitis occurs in 25 to 50 percent of cases. Adenitis occurs more commonly when genital ulcers have been present for more than 10 days. The skin overlying the nodes frequently is erythematous. Discharge from buboes and vulvar lesions is highly infectious. Constitutional symptoms are unusual, and invasiveness beyond regional lymph nodes does not seem to occur even in immunocompromised hosts.

Many patients with chancroid have concurrent infections with other STDs. Patients should be tested for HIV infection and syphilis when chancroid is diagnosed. Testing for both diseases should be repeated in 3 months if the initial results are negative.[42]

In the United States, a probable diagnosis of chancroid is made clinically if (1) one or more painful genital ulcers are present; (2) the individual has no evidence of *T. pallidum* infection by either darkfield examination of ulcer exudate or a serologic test for syphilis performed at least 7 days after the onset of ulcers; (3) the clinical findings, appearance of the genital ulcers, and regional lymphadenopathy, if present, are typical for chancroid; and (4) a test for HSV done on ulcer exudate is negative. When present, the combination of a painful ulcer with tender inguinal adenopathy suggests chancroid. A painful genital ulcer accompanied by suppurative inguinal adenopathy is almost pathognomonic for chancroid.[42]

Definitive diagnosis of chancroid requires isolation of *H. ducreyi* on special culture media. The sensitivity of culture is at best 80 percent.[42] When culture is performed, exudate from the purulent base of the ulcer or material aspirated from buboes should be inoculated onto appropriate media. Gram-negative coccobacilli in a "school-of-fish" grouping on Gram stain suggests *H. ducreyi*, but this pattern often is absent. The diagnosis also can be based on the histologic appearance of tissue obtained by biopsy. There are no FDA-approved, PCR-based tests for chancroid, but such testing can be done by commercial laboratories that have developed their own test and conducted a CLIA verification study.[8,243]

Treatment

Effective agents for the treatment of chancroid in adolescents and adults include azithromycin, 1 g orally in a single dose; ceftriaxone, 250 mg intramuscularly in a single dose; ciprofloxacin, 500 mg orally twice a day for 3 days; and erythromycin base, 500 mg orally three times a day for 7 days.[42] Trimethoprim-sulfamethoxazole no longer is recommended because of the frequency of resistant isolates of *H. ducreyi*. Isolates typically are resistant to penicillin and tetracyclines.

Patients should be re-examined 3 to 7 days after therapy has been initiated. If treatment is effective, ulcers should improve symptomatically within 3 days and show objective improvement within 7 days. If no clinical improvement occurs, one or more of the following should be considered: (1) the diagnosis may be incorrect, (2) co-infection with another sexually transmitted agent may be present, (3) the infecting strain may be resistant to the prescribed antimicrobial agent, (4) compliance with multiple-dose regimens may have been poor, or (5) the patient may have HIV infection. The time required for complete healing of ulcers to occur is related to their size. Large ulcers may require 2 weeks or more.[42]

Resolution of fluctuant lymphadenopathy (buboes) is slower than that of ulcers. Drainage of buboes, when present, usually is required for resolution. Needle aspiration, if adequate drainage can be accomplished, is preferred over surgical incision because it results in less cicatricial scarring. Healed ulcers frequently leave significant scarring.

Individuals who have had sexual contact with an individual who has chancroid during the 10 days before the onset of symptoms should be examined and treated for chancroid, even in the absence of symptoms. Patients co-infected with HIV should be monitored closely. Longer courses of therapy may be required, and healing may be slower. The optimal duration of therapy in these patients is unknown.[42]

TUBERCULOSIS

Even before the advent of chemotherapy for the treatment of tuberculosis, tuberculous disease of the lower genital tract was uncommon.[240,269] The lower genital tract can be affected by primary local infection of the vulvar and vaginal tissues or by scrofulous tuberculosis. Both manifestations of tuberculosis are now exceedingly rare findings. Most such cases occur in young women in developing countries. Tuberculosis of the upper genital tract also is an uncommon occurrence but frequently leads to infertility when it does occur, probably because of scarring of the uterine tubes.[235]

The primary lesions of vulvar tuberculosis may appear as painless, slowly developing, localized, nodular thickening of the skin and subcutaneous tissues or as ulcerative lesions that begin as firm, slightly raised, reddish areas. The ulcers are demarcated sharply and with progression develop undermined edges and granular, grayish brown bases with tubercles and areas of caseation studding their bases.

The scrofulous type is characterized by fistulous tracts and burrowing sinuses that extend from underlying tuberculous infection in the bowel, bladder, or pelvic viscera. Drainage from the ulcers and sinuses keeps the surrounding skin macerated and can lead to extension of the disease.

The diagnosis is straightforward if the patient is known to have visceral tuberculosis, as most often is the case. Isolation of *M. tuberculosis* from the discharge or from lesions or examination of a biopsy specimen from the base of an ulcer is confirmatory. Primary tuberculosis of the vulva must be differentiated from other granulomatous diseases, and the scrofulous type must be distinguished from syphilis, lymphogranuloma inguinale, and Crohn disease.

Treatment

The chemotherapeutic agents used to treat pulmonary and other types of systemic tuberculosis also are effective in treating the disease when it affects the genitalia. Treatment of tuberculosis is described in Chapter 107.

VULVOVAGINAL ULCERATIVE INFECTIONS

BEHÇET DISEASE

In 1937, Behçet described a syndrome characterized by recurrent genital ulcers, aphthous stomatitis, and ocular inflammation.[125,150,181,199,221] Clinical manifestations are not due directly to infection but may result from immunologic events triggered by one or more infections.[204] Arthritis, abnormalities of the central nervous system, a variety of skin lesions including erythema nodosum, and other systemic symptoms also may be associated with the disease. Ocular inflammation frequently is sight-threatening when it occurs. Deep vein thrombosis and arterial occlusion or aneurysms can develop. The onset usually is in patients who are 20 to 30 years old and more frequently in men than in women. Behçet disease is rare in children and may develop more often in girls than in boys.[150] In an international series, 15 percent of children had a family history of Behçet disease.[155]

The cause of Behçet disease is unknown, but an autoimmune basis is suspected. The HLA-B51 phenotype, and especially the B*5101 allele, is associated with Behçet disease in countries with higher prevalences of HLA-B51. Other factors also are involved because a substantial proportion of cases occur in individuals without HLA-B51. Lymphocyte reactivity with peptides derived from human heat shock protein-60 (HSP-60) has been shown. Human HSP-60 is a homologue of streptococcal HSP-65. Aberrant expression of HSP-60 has been found in oral mucosa, skin, and circulating lymphocytes in patients with Behçet disease. In addition to streptococcal species, HSV and *E. coli* antigens have been implicated as potential triggers of Behçet disease.[155,204]

The vulvar lesions take the form of destructive, deep ulcerations that, on recurrence, result in marked scarring and distortion with progressive loss of vulvar tissue (Fig. 48–22). Despite their destructiveness, the lesions are relatively painless. The oral lesions resemble common aphthous ulcers and may precede all other manifestations of Behçet syndrome by 5 to 10 years or longer. Ocular inflammation may be manifested as iridocyclitis, chorioretinitis, or other lesions of the posterior segment. Hypopyon may be seen in some cases.

The vulvar lesions of Behçet syndrome are nonspecific. Diagnosis is based on associated findings and negative test results for diseases that might resemble the vulvar ulcers, notably syphilis, herpes, granulomatous disorders, and Crohn's disease. Histologic study of a biopsy specimen from an ulcer shows only obliterative vasculitis and chronic inflammation.

Many agents have been used to treat Behçet syndrome in the past. Few have been evaluated in controlled trials. Modern treatment regimens usually have used systemic corticosteroids, with or without chlorambucil, colchicine, azathioprine, or thalidomide. More recent studies have suggested that cyclosporine and interferon α-2a may be effective.[10,208] A randomized trial reported in 1998 of the use of colchicine plus benzathine penicillin, with or without interferon α, for the treatment of adults with Behçet disease showed a decrease in the frequency of eye involvement, episodes of arthritis, vascular events, and mucocutaneous lesions in patients treated with all three agents.[155] Infliximab, a humanized monoclonal antibody against tumor necrosis factor-α, may be effective in diminishing new ocular attacks. Etanercept, a tumor necrosis factor receptor analogue, may have an impact on mucocutaneous manifestations.[204] Plastic surgery for correction of vaginal distortions is contraindicated because trauma may be followed by an exacerbation of the disease.

Figure 48–22 Vulvar lesions in Behçet syndrome. *(From Friedrich, E. G., Jr.: Vulvar Disease. Philadelphia, W. B. Saunders, 1976. Reproduced by permission of the author.)*

VULVAR VESTIBULITIS

The vulvar vestibulitis syndrome is the most common type of chronic vulvovaginal pain. Approximately 10 percent of women are affected at some point in their lives. Onset in adolescence can occur, and complaints sometimes may mimic those of sexually transmitted infections. The etiology is unknown and probably multifactorial. An exaggerated inflammatory response of the vestibule (vulvar mucosa) to injury may be involved. Vestibulitis clinically is defined by three signs and symptoms: (1) dyspareunia during intercourse, (2) vestibular tenderness to light touch (e.g., gentle palpation with a cotton swab), and (3) the presence of vestibular erythema. Pain and tenderness are distinctly limited to the vulvar vestibule. Exudates indicate another disease process. Minor ulcerations have been described, but ulceration is not a prominent feature.[27,58,182,220,230]

Debate is ongoing as to the organic versus functional nature of vulvar vestibulitis. Symptoms sometimes respond to biofeedback or cognitive behavioral therapy. Chronic inflammatory changes can be found in the vulvar mucosa of affected women, and surgical resection relieves pain in some patients. Organic and functional components seem to exist, with one or the other predominating in a particular patient.[55,173,296]

Patients with acute vulvar vestibulitis should be evaluated for STDs and treated for any that are found. A history of all medicinal agents or other treatment modalities used by the patient should be obtained. Any agent that might be contributing to the problem should be discontinued if possible. Adolescent girls who have symptoms and signs suggestive of vulvar vestibulitis should be referred for gynecologic evaluation.

CERVICITIS

PREMENARCHEAL

The cervix is not involved when a premenarcheal child has vaginitis because most vaginal infections affect only the distal half of the vagina in children; the exception is gonococcal vaginitis, which in addition usually involves the squamous epithelium over the external cervix. Cervicitis also may occur when a vaginal foreign body is present. Endocervicitis is an unusual finding in premenarcheal girls because the endocervical glands and mucosa are developed poorly before menarche, providing a poor environment for invading organisms.

Erosions of the cervix seldom are seen in children older than 1 year. So-called congenital ectopy is not the result of infection; rather, it is persistence of the fetal paramesonephric (müllerian) glandular epithelium on the outer cervix. This epithelium normally recedes into the endocervical canal as the cervix develops postnatally. Inflammation of the external cervix, which occasionally occurs with vaginitis in a premenarcheal child, need not be treated; it heals as the vaginitis improves.[133]

POSTMENARCHEAL

The structure of the cervix during the reproductive years renders it vulnerable to infections induced by numerous factors. The

long, narrow, deeply pocketed cervical canal, which is lined by open cryptic glands bathed in alkaline secretion and washed periodically by menstrual blood, is an excellent nidus for the growth of bacteria. Pathogenic bacteria in the vagina find ready access to the cervical canal. The use of oral contraceptive pills promotes cervical ectopy, increasing the vulnerability of endocervical cells to chlamydial infection.[130,229]

Early recognition and aggressive treatment of cervicitis in sexually active adolescents are important to prevent serious complications, including PID and tubo-ovarian abscess. Some confusion tends to occur, however, with regard to differentiating normal ectopic columnar epithelium on the exocervix (ectopy) from cervicitis. Ectopy is not an abnormal finding. When the squamocolumnar junction is exposed on the exocervix, it is called *ectopy*. It appears bright shiny red, in contrast to the dull pearly pink appearance of the exocervix. This area does not bleed easily when touched with a swab. During adolescence, the normal cervix may exhibit no ectopy, a small area of ectopy, or sometimes 50 percent ectopy. When the ectopy appears edematous, raised, and friable (often with marked bleeding when touched lightly with a swab), cervicitis should be suspected.[130,229]

Mucopurulent cervicitis primarily is endocervicitis associated with *C. trachomatis*, *M. hominis*, *U. urealyticum*, *N. gonorrhoeae*, *G. vaginalis*, and group B streptococci. In contrast, *T. vaginalis* causes an exocervicitis by extension of vaginitis. Because of the high prevalence of coexisting infections of the cervix, associating any one organism with the clinical signs and symptoms of cervicitis often is difficult. Although studies have shown a strong association between mucopurulent cervicitis and *C. trachomatis*, in most cases no organism is isolated.[130,230,248]

Cervicitis often is asymptomatic, but it should be clinically suspected if an adolescent reports a vaginal discharge and bleeding, especially after having sexual intercourse. Criteria for a clinical diagnosis of mucopurulent cervicitis include the presence of mucopurulent secretion from the endocervix, erythema of the cervix, friable ectopy, and bleeding from the cervix.[34] The mucopurulent secretion in chlamydial cervicitis is tenacious mucoid material mixed with yellow exudate and is difficult to remove from the endocervix. The ectopic area on the cervix may appear erythematous and friable. In chronic chlamydial cervicitis, the ectopic area may be swollen and irregular with a cobblestone appearance, a condition called *hypertrophic cervicitis*. In gonococcal cervicitis, the endocervical mucosa is swollen, intensely inflamed, and often friable as well. In contrast to the mucopurulent discharge present in chlamydial cervicitis, a profuse, yellowish green acrid discharge is present in gonococcal cervicitis.

Cervical erosions occur in sexually active adolescents. Infections other than those listed earlier as causing mucopurulent cervicitis also can involve the cervix. A chancre, the primary lesion of syphilis, may appear on the cervix, where it forms an irregularly shaped ulcer that only remotely resembles a chancre on the vulva. Tuberculosis, HSV, granuloma inguinale, lymphogranuloma venereum, chancroid, schistosomiasis, and actinomycosis also may affect the cervix. The cervical lesions of most of these infections are altered by the warmth and moisture of the vagina and are atypical in appearance. None of these lesions is a common finding, but all of them should be considered in the differential diagnosis when a patient has an unusual ulcerative or fungating lesion of the cervix.[133]

Treatment

The first step is to obtain good specimens from the endocervix. The cervix should be wiped with a large swab to remove vaginal secretions. Endocervical specimens then are obtained for detection of *C. trachomatis* and *N. gonorrhoeae* and a vaginal specimen for a saline wet-mount preparation and potassium hydroxide preparation under microscopy. The types of tests available for chlamydial and gonococcal infection are described in this section under chlamydial and gonococcal cervicitis. If an endocervical Gram stain can be performed, an endocervical specimen should be obtained. This test is useful in a clinical setting. Cervicitis is suspected when an endocervical Gram-stained smear shows more than 5 to 10 polymorphonuclear cells per field under oil immersion. The presence of at least eight pairs of gram-negative intracellular diplococci in at least three polymorphonuclear cells strongly suggests the presence of gonococcal cervicitis. The absence of gram-negative intracellular diplococci, but the presence of more than 5 to 10 polymorphonuclear cells per oil immersion field suggests nongonococcal cervicitis.[34,186] When cervical erosions or ulcers are seen, a specimen for culture of HSV should be obtained. *T. vaginalis* is identified by microscopic examination of vaginal secretions in saline.

The same guidelines for the treatment of gonococcal and chlamydial cervicitis are used for the treatment of cervicitis in nonpregnant adolescent girls or women. Current treatment of gonococcal infection is influenced by the emergence of antibiotic-resistant strains, including penicillinase-producing *N. gonorrhoeae*, fluoroquinolone-resistant strains, tetracycline-resistant strains, and chromosomally resistant strains.[42] The high frequency of chlamydial infection in individuals with gonorrhea (45% in certain populations) and the serious complications resulting from untreated gonorrhea and chlamydial infections also have influenced the treatment approach. Treatment options include intramuscular ceftriaxone, 125 mg in a single dose, cefixime, 400 mg orally in a single dose; plus azithromycin, 1 g orally in a single dose; or doxycycline, 100 mg orally twice a day for 7 days.[42]

In the case of penicillin allergy, a single dose of intramuscular spectinomycin, 2 g, instead of cephalosporins is recommended. Spectinomycin is unavailable in the United States, however.[43] Azithromycin, 2 g, can be used instead of cefixime or ceftriaxone to treat gonococcal cervicitis; however, its cost and severe gastrointestinal side effects need to be considered.[42] Pregnant adolescent girls or women should not be treated with doxycycline. Azithromycin, 1 g orally in a single dose, or erythromycin base, 500 mg orally four times a day for 7 days, is recommended for presumptive *C. trachomatis* cervicitis.[42] If pharyngeal gonorrhea is suspected, the recommended treatment is intramuscular ceftriaxone. When *T. vaginalis* vaginitis is diagnosed, or HSV is suspected strongly, the appropriate treatment for these infections should be given (see sections on trichomoniasis and genital herpes).

Integral to treating the patient is notification, examination, and treatment of the patient's sexual partners if gonococcal or chlamydial infection (or both) is confirmed. Direct notification by the patient should be encouraged, and, based on state laws, a prescription for partner therapy can be given. Written information should be provided with names of diseases and medication side effects to assist with this process. When tests are positive for gonorrhea or chlamydial infection, retesting for these infections is recommended: in 3 weeks if treated with erythromycin or if symptoms persist, and in 3 months if treated with other regimens to detect re-infection from an untreated or new partner.[42]

CHLAMYDIAL

Some of the highest rates of chlamydial cervicitis (8-25%) have been reported in adolescents.[44,82,85,233] It is three to four times more common than gonococcal cervicitis. *C. trachomatis* causes cervicitis by infecting the columnar and transitional epithelium of the cervix. Cervical ectopy seems to be a predisposing factor for acquisition of *C. trachomatis* infection.[16]

C. trachomatis cervicitis is predominantly an asymptomatic disease in adolescent girls.[44] A clinical diagnosis is made when friable ectopy with a mucopurulent cervical discharge (mucopus)

is noted. Chlamydial cervicitis is suspected when a Gram stain of an adequate endocervical smear shows more than 5 to 10 polymorphonuclear cells per oil immersion field in the absence of gram-negative intracellular diplococci.[34,185]

Numerous tests, including culture, direct fluorescent antibody tests, enzyme immunoassay, nucleic acid hybridization tests, enhanced optical immunoassays, and nucleic acid amplification tests, are available today to diagnose *C. trachomatis* infection. Material from the cervix must be obtained directly from the endocervix with a sterile swab. The tissue culture method was considered the gold standard,[236] but because of the high cost of this technique, it is not used widely for adolescents and adults. It continues to be the gold standard, however, for prepubertal children suspected of being infected. Overall, amplification tests are considered the most sensitive and specific tests today, and testing of urine specimens is expected to revolutionize screening and diagnosis. Presently, amplification tests are being used predominantly for research purposes because of their high cost, but gradually they may become available for clinical use.

In large-volume, community-based clinics, the DNA hybridization assay or DNA probe (Gen-Probe) and enzyme immunoassay (Abbot, Wampole, Kodak, Gen-Probe) can be used.[158,242] Both tests perform best in clinic populations with high prevalence rates of *C. trachomatis* infection; however, the DNA probe seems to have greater sensitivity for detection and is simple to perform. The Gen-Probe is approximately 80 percent sensitive and 100 percent specific detecting *C. trachomatis* in girls and women. It can be used as a "mail-out" specimen as well.[242,252] The direct fluorescent antibody test or MicroTrak is considered to be suited best for low-volume laboratories and requires technical expertise. It continues to be used in some hospital-based settings. This test detects *Chlamydia* elementary bodies in cervical secretions and takes 15 to 20 minutes to perform. It has a sensitivity of 75 to 90 percent and specificity of 95 to 97 percent compared with the culture method.[74,242]

The reliability of amplification tests such as PCR, strand displacement amplification, and transcription-mediated amplification in detecting *C. trachomatis* seems to be equivalent for vaginal, cervical, and urine specimens as long as the urine collected is a first-catch specimen. The sensitivity of PCR, ligase chain reaction, strand displacement amplification, and transcription-mediated amplification ranges from 87 to 99 percent, and specificity ranges from 97 to 100 percent.[23,239,252] Treatment of chlamydial cervicitis was discussed in the earlier section on cervicitis.

GONOCOCCAL

Gonococcal cervicitis may be symptomatic or asymptomatic. The risk of acquiring infection varies with the population. Adolescents seen in private practices in the suburbs have a significantly lower rate of gonococcal cervicitis than that noted in adolescents seen in large outpatient hospital clinics or community clinics serving inner-city populations. The rate of asymptomatic endocervical infection in adolescent girls seen in urban settings ranges from 3 to 12 percent. Anal gonorrhea usually is secondary to discharge from gonococcal cervicitis infecting the anus. Primary anal gonorrhea as a result of anal intercourse should be suspected in a sexually active adolescent with anal discomfort. In addition, gonococcal infection should be considered in the differential diagnosis of pharyngitis in sexually active adolescents.[218] Gonococcal endocarditis, arthritis, and dermal abscesses occur, but they are beyond the scope of this chapter.

The initial complaints in gonococcal cervicitis include vaginal discharge, dysuria, urinary frequency, and dyspareunia. Although gonococcal cervicitis is reported to be predominantly an asymptomatic condition in girls and women, many patients, after careful questioning, are found to have symptoms. The discharge is profuse and prevalent. On examination, the vulvar tissues may be inflamed and edematous. Discharge also may be seen exuding out of the urethra and paraurethral ducts in severe cases. On speculum examination, the patient has a normal-appearing cervix, or the cervix appears erythematous and friable, with a foul-smelling purulent discharge draining from the cervical os.

Laboratory diagnosis is made by detecting *N. gonorrhoeae* by culture technique, a DNA hybridization test or DNA probe (Gen-Probe), or an amplification test. Material from the cervix must be obtained directly from the endocervix with a sterile swab. Vaginal swabs that can be obtained by the adolescent also are a recommended method for amplification tests. Although the reliability of detecting gram-negative intracellular diplococci on a Gram stain of cervical secretions is low, this test can be useful in areas where more sophisticated tests are unavailable. The presence of at least eight pairs of gram-negative intracellular diplococci in at least three polymorphonuclear cells strongly suggests gonococcal cervicitis.

Hospital-based settings should continue to use the culture method in children and adolescents for medicolegal cases. The DNA probe (Gen-Probe) can be used in hospital and community-based clinics for the reasons described in the section on chlamydial cervicitis. This test has sensitivities ranging from 90 to 97 percent and a specificity of 99 percent. Amplification tests such as PCR and strand displacement amplification for *N. gonorrhoeae* from vaginal, cervical, and first-catch urine specimens have a sensitivity of 95 to 97 percent and a specificity of 99 to 100 percent.[252,257] The sensitivity of the transcription-mediated amplification test in detecting *N. gonorrhoeae* from urine specimens is poor. Treatment of gonococcal cervicitis was discussed in the earlier section on cervicitis.

UPPER GENITAL TRACT INFECTIONS

PELVIC INFLAMMATORY DISEASE

PID (i.e., infection of the uterine tubes, ovaries, and pelvic peritoneum) is an extremely rare finding in premenarcheal girls and often is undiagnosed until advanced infection occurs.[33,66,133] With the exception of gonorrhea and the inflammation caused by a foreign body, most vulvar and vaginal infections do not involve the upper third of the vagina and do not approach the cervix of premenarcheal patients. The premenarcheal cervix and endometrium apparently are barriers rather than passageways for bacteria causing all types of vulvovaginitis in children.

The causative organisms are diverse. Gonococcal pelvic infection has been reported after sexual abuse has occurred. *S. pneumoniae* serotypes 1 and 2 and *E. coli* also have been reported in pubertal girls with salpingitis and peritonitis and tubo-ovarian abscess.[33]

When intrapelvic infection has been reported in premenarcheal girls, it usually has been part of either generalized primary peritonitis or peritonitis secondary to a ruptured appendix or some other intra-abdominal infection.[72,241] Pelvic infection that is part of an intra-abdominal infection characteristically affects the surfaces of the uterine tubes, uterus, and ovaries and produces perisalpingitis and periovaritis; periappendicitis also is present even if the infection did not begin as appendicitis. An ascending infection from the lower genital tract, such as that caused by gonorrhea, involves the tubal mucosa and produces endosalpingitis and pyosalpingitis. Identical bacteria should be isolated in cultures from the lower genitalia and from the pelvic exudate before an ascending infection is considered to be the cause of a pelvic infection in a specific case in which the patient is a premenarcheal child.

PID in postmenarcheal girls is a common problem. Salpingitis has been reported in virgins, and, although the etiology is

unknown, the organisms are thought to spread hematogenously, lymphatically, or transmurally from intestines or ascending infection from the vagina.[66,74,133] PID occurs primarily in sexually active adolescents at risk for developing ascending infection acquired from STDs.[76,252]

PID is defined as an acute clinical syndrome (unrelated to pregnancy or surgery) attributed to the ascent of microorganisms from the vagina and endocervix to the endometrium, fallopian tubes, or contiguous structures that result in pelvic and generalized peritonitis. The use of terms specifically describing the anatomic sites involved is preferable (e.g., endometritis, salpingitis, salpingo-oophoritis, tubo-ovarian abscess). In most adolescents with acute severe infection, however, differentiating some of these entities is difficult; the term *PID* is used commonly.

Reasons for the development of PID are physiologic and social and include alterations in cervical mucus caused by immature and anovulatory menstrual cycles, onset of sexual activity during early puberty, and multiple sexual partners. Cervical mucus is less viscous during menses and at midcycle, rendering it more permeable to ascending infection. In vitro experiments show that *N. gonorrhoeae*, *C. trachomatis*, *U. urealyticum*, and other aerobic and anaerobic agents can adhere to spermatozoa and migrate with them.[276] Whether this event can occur in vivo is unknown. Most organisms found in nongonococcal and nonchlamydial PID also are found in bacterial vaginosis, suggesting that bacterial vaginosis may be a predisposing or a precipitating factor for the development of PID. In addition, researchers have suggested that *T. vaginalis* can act as a vector for transporting bacteria.[148] Another possible factor is upward transport of bacteria from orgasmic myometrial contractions.[288] Lastly, vaginal douching has been reported to be a risk factor in promoting ascending infection.[198,288,291]

Other factors influencing the risk of acquiring PID are the method of contraception and a history of gonococcal or chlamydial lower genital tract infection, with or without uterine instrumentation, such as the use of an intrauterine device or dilation and curettage. Oral contraceptives are used commonly by adolescents. Their possible protective effect on the development of PID has been reported. Laparoscopic studies also have shown that women with PID who were using oral contraceptive pills have significantly milder degrees of fallopian tube inflammation than those of women who do not use the pills. This finding suggests that the oral contraceptive pill may reduce potential tubal damage. Other studies report, however, that by promoting cervical ectopy, oral contraceptives are a potential risk factor for acquiring chlamydial PID.[248,273,292] In contrast, compared with other methods of contraception, women using depot medroxyprogesterone acetate (Depo-Provera) had a significantly decreased risk of developing PID.[19,292] Risk for acquiring a PID with the intrauterine device seems to be related to the individual's background risk for acquiring sexually transmitted infection.[252]

Women who have had one episode of PID have a 20 to 25 percent chance of having subsequent ones. Reasons for this susceptibility may be re-infection from untreated sexual partners, an inadequately treated first infection, or increased susceptibility of the tubal epithelium to infection.[76,288]

Endometritis

Infections of the endometrium in postmenarcheal girls and women are as rare as previously thought. The gonococcus, on its way upward to the uterine tubes, produces a fleeting asymptomatic infection of the endometrium, or the symptoms produced are overshadowed by those of the vulvar and cervical infections. Evidence also suggests that endometritis occurs in 40 percent of patients with asymptomatic endocervical chlamydial infection.[144] It also is called *subclinical PID*, and repeated episodes have been linked to infertility.[144,286] The role of HIV infection in the development of PID is unclear. An increased prevalence of endometritis in HIV-infected women compared with uninfected women has been noted, and altered immune function might contribute to difficulty clearing endometritis in these cases.[35]

Symptoms specific to endometritis are uncommon. It is commonly an asymptomatic condition. Symptoms include recurrent intermittent or acute suprapubic pain and tenderness with vaginal bleeding or spotting. On bimanual examination, the uterus is tender, and cervical motion tenderness may or may not be present. Endometritis in adolescent girls and young women also has been associated with postabortive and puerperal endometritis. Poor compliance with prophylactic antibiotics places an adolescent at an increased risk for development of endometritis after having an abortion. Young women who engage in high-risk sexual behaviors and use intrauterine devices are likely to have asymptomatic, low-grade, chronic endometritis.

Endometrial tuberculosis is a rare occurrence in the United States and is encountered most often in patients with pulmonary tuberculosis. This entity needs to be considered in HIV-infected girls and women and in geographic areas and regions where tuberculosis is endemic. In a study from a province in Iran, tuberculous endometritis was detected in 72 percent of genital tuberculosis cases in women.[194] The disease may not manifest for years after initial seeding, and the infection is thought to reach the uterus via the gastrointestinal tract through hematogenous seeding and by lymphatic spread. It is not acquired as a result of an ascending infection or through coitus with an infected man. The symptoms of endometrial tuberculosis vary from none to amenorrhea, pelvic pain, dysmenorrhea, abnormal uterine bleeding, and tuberculosis. Often, the patient has a history of healed or active pulmonary disease. Overall, 60 percent of patients with pelvic tuberculosis have tuberculous endometritis.[5,117]

Endometrial tuberculosis is diagnosed by endometrial biopsy and demonstration of acid-fast *M. tuberculosis* in cultures of curettage material or menstrual blood. Menstrual fluid has been reported to be culture-positive more frequently than are biopsy specimens.[117] Endometrial tuberculosis and the management of tuberculosis are described further in Chapter 107.

Salpingitis

The pathogenesis of salpingitis has been studied best with *N. gonorrhoeae* and *C. trachomatis*. In the fallopian tube, gonococci attach to nonciliated epithelial cells and induce sloughing of ciliated epithelial cells into the lumen.[271,288] Gonococci also enter the subepithelial space, where a local inflammatory response, predominantly polymorphonuclear leukocytic infiltrate and anaerobic bacteria, is produced and may reach the bloodstream. A purulent exudate is produced within the tube and may cause pelvic peritonitis. Chlamydial infection produces a similar picture except that it causes a predominantly lymphocytic infiltrate in the submucosa.[211,271,288]

Salpingitis also is caused by several other microbial agents that have been isolated directly from the fallopian tubes. The organisms most commonly recovered from the upper tract in salpingitis are mixed anaerobes (25-84%), followed by *N. gonorrhoeae* (25-40%) and *C. trachomatis* (25-40%). Mixed aerobic and anaerobic infections, including *Bacteroides* and *Peptostreptococcus* spp., account for 25 to 60 percent of cases. These mixed infections occur more frequently in girls and women with severe PID, chronic PID, and recurrent PID. PID develops in approximately 10 to 17 percent of girls and women with endocervical *N. gonorrhoeae* and in 10 to 30 percent with endocervical *C. trachomatis*. At first, researchers thought that *N. gonorrhoeae* initiated the infection and that superinfection with anaerobes followed. They now realize that apparently anaerobes and aerobes can initiate PID without *C. trachomatis* or *N. gonorrhoeae*.[73,74,76,252,288]

Differentiating salpingitis caused by different microbiologic organisms is difficult. *N. gonorrhoeae* has been identified most frequently within the initial 24 hours of development of symptoms. Beyond 48 hours, the most frequent isolates are anaerobes. Gonococcal and chlamydial salpingitis seem to occur most often within 1 week of menstruation.[272] The clinical presentation varies from asymptomatic to severe disease. The severity of infection depends on duration of symptoms and the etiologic agent. Chlamydial PID tends to be less symptomatic than infection from *N. gonorrhoeae*.

Diagnosis

The classic manifestation of acute PID is lower abdominal pain, which usually is bilateral and continuous and may worsen with movement. After the onset of abdominal pain, fever, nausea, and vomiting develop. The temperature may reach 39°C to 39.5°C (102°F-103°F). A chill seldom precedes the fever. Other common initial symptoms include vaginal discharge, irregular vaginal bleeding, and urinary symptoms.

On physical examination, the patient usually looks sick and uncomfortable. Abdominal examination reveals a markedly tender and often tense lower part of the abdomen. Rebound tenderness indicates generalized peritonitis. The genital examination may show a purulent vaginal discharge in the vaginal vault. Even gentle bimanual rectovaginal abdominal palpation causes great distress. Attempted mobilization of the cervix is extremely painful. The uterus is tense and tender. The adnexa may not be outlined because of discomfort produced by the examination. Palpation of the adnexa unilaterally or bilaterally may be exceptionally painful. An adnexal swelling may be palpated, but this finding is unreliable in diagnosing an adnexal mass. In a less acutely tender patient, the examination may reveal a thickened, tender tube.

Common laboratory findings in patients with PID include a peripheral white blood cell count greater than 10,000/mm^3 and an erythrocyte sedimentation rate greater than 15 mm/hr. In addition, endocervical gonorrhea and chlamydial infection may be present simultaneously in 10 to 30 percent of cases. Ultrasonography of the pelvic cavity helps exclude adnexal masses and may detect pelvic abscesses. A study involving the use of pelvic ultrasonography in adolescents with PID showed that the presence of fluid in the cul-de-sac was not helpful in differentiating patients with and without PID.[99] Almost 20 percent of patients with PID had a tubo-ovarian abscess; in the absence of a tubo-ovarian abscess, adnexal volume was significantly larger in adolescents with PID than in adolescents without it.[99] Ultrasonography (transvaginal) can be very useful in ruling out other diagnoses and defining adnexal masses.

The clinical diagnosis of PID is made by having a high index of suspicion of this entity. The clinical criteria for the diagnosis of PID were developed originally by Jacobsen and Westrom.[141] The benefits of using laparoscopy are that an accurate diagnosis can be made rapidly by direct visualization of the fallopian tubes and adjacent structures,[141] tubal exudate can be obtained for culture, and the outcome of therapy can be evaluated.[292] This diagnostic method, however, is not without risks, is not a sensitive diagnostic tool, and adds to the cost of care.[81] For practical reasons, the clinical criteria developed by Jacobsen and Westrom[141] and revised by the Centers for Disease Control and Prevention[42] are recommended to aid in making the diagnosis and subsequently to increase the index of suspicion for PID (Table 48–5). When comparing the reliability of clinical criteria using endometrial sampling as the reference test,[42] the sensitivity of using one criterion—adnexal tenderness—was 95 percent, and the sensitivity of using three criteria—abdominal pain, cervical motion tenderness, and adnexal tenderness—was 83 percent.

The minimum criteria recommended for empiric treatment include abdominal pain with uterine tenderness or cervical motion tenderness or adnexal tenderness.[42] The more criteria that can be met, the more likely that a tubal infection is present. Clinicians who use only the criteria listed in Table 48–5 to treat would miss adolescents with mild disease, however.[42,106,141,280] The differential diagnosis of PID is an acute abdomen. Conditions of the urinary tract that should be considered include cystitis, pyelonephritis, and urethritis. Gastrointestinal tract conditions include appendicitis, constipation, diverticulitis, gastroenteritis, inflammatory bowel disease, and irritable bowel syndrome. Gynecologic conditions include dysmenorrhea, ectopic pregnancy, endometriosis, endometritis, mittelschmerz, torsion or rupture of an ovarian cyst, ruptured follicle, septic abortion, threatened abortion, and pyogenic sacroiliitis. Although pyogenic sacroiliitis is very rare, it was reported in a 13-year-old girl secondary to an infected umbilical ring.[152]

As in PID, establishing an early diagnosis of acute appendicitis and ectopic pregnancy is important. In acute appendicitis, an adolescent is more likely to have nausea, vomiting, a short history of right lower quadrant abdominal pain, lower grade fever, a higher leukocyte count in relation to the fever, and little discomfort during pelvic examination. Occasionally, the appendix hangs over the pelvic brim and causes pelvic tenderness. A ruptured appendix and peritonitis may simulate PID closely. Differentiating PID from ectopic pregnancy is less difficult if the history suggests pregnancy. PID can occur during the first trimester of pregnancy. In ectopic pregnancy, the patient does not have fever or leukocytosis. The symptoms almost always are unilateral, and signs of hemoperitoneum are present if the tube is ruptured.[288] If ectopic pregnancy is suspected, a serum pregnancy test and pelvic ultrasonography (transvaginal) for detection of a gestational sac should be performed immediately.

TABLE 48–5 Clinical Criteria for the Diagnosis of Acute Pelvic Inflammatory Disease

Minimal Criteria
Lower abdominal or pelvic pain with one or more of the following: uterine or adnexal tenderness or cervical motion tenderness
Additional Criteria to Enhance Specificity
Temperature >38.3°C (>101°F)
Abnormal cervical or vaginal mucopurulent discharge
Presence of white blood cells on saline microscopy of vaginal secretions
Elevation of erythrocyte sedimentation rate
Elevated C-reactive protein
Laboratory documentation of cervical infection with *Neisseria gonorrhoeae* or *Chlamydia trachomatis* or both
Specific Criteria
Endometrial biopsy specimen with histopathologic evidence of endometritis
Transvaginal sonography or magnetic resonance imaging technique showing thickened fluid-filled or tubo-ovarian complex
Laparoscopic abnormalities consistent with pelvic inflammatory disease

From Centers for Disease Control and Prevention: Sexually transmitted disease treatment guidelines 2006. M. M. W. R. Recomm. Rep. 55(RR-11):1-93, 2006.

Treatment

The major goals of treatment of PID are preservation of fertility and prevention of other long-term sequelae, including ectopic pregnancy. Although some data suggest that women younger than 25 years old have a better fertility prognosis overall after having PID and ectopic pregnancy, no difference exists among age groups regarding tubal infertility specifically after PID.[288] The earlier the treatment is initiated, the lower the risk of devel-

oping infertility. Girls and women initially evaluated after more than 3 days of abdominal pain are found to have a 2.8-fold increased risk of having impaired fertility (tubal infertility or ectopic pregnancy) compared with those evaluated within 3 days of the onset of abdominal pain.[128] Generally, the more severe the PID, the higher the risk of future infertility occurring. In addition, the more episodes of PID, the higher the risk of future infertility occurring. After one episode, the risk of infertility ranges from 8 to 13 percent; after two episodes, the risk is 20 to 35 percent; and after three or more episodes, it is 40 to 75 percent.[252,270]

To reduce the incidence of sequelae associated with this condition, early recognition of PID, the use of broad-spectrum antibiotics to treat polymicrobial disease, careful clinical re-evaluation 48 hours after initiating antibiotic treatment to assess antibiotic response, and evaluation and treatment of sexual partners are important. Screening the patient for other STDs, such as trichomoniasis, bacterial vaginosis, and syphilis, also is important.

Patients with PID often are treated on an ambulatory basis. The primary reason to hospitalize an adolescent with PID is to ensure compliance with medication when she is unable to follow or tolerate an outpatient oral regimen because of the seriousness of the sequelae and problems with compliance in this age group. Other reasons for hospitalization are an uncertain diagnosis, the presence of a tubo-ovarian abscess, pregnancy, infection with HIV, temperature greater than 38.5°C, nausea and vomiting precluding the use of oral medications, and lack of improvement after 48 hours of oral antibiotic treatment.

The recommendations of the Centers for Disease Control and Prevention for treating PID in ambulatory and hospitalized patients address antibiotic coverage for the polymicrobial etiology of this condition (Tables 48–6 and 48–7).[42] In addition to antibiotic treatment, bed rest is recommended. Intravenous fluids are administered for hydration when necessary. When the diagnosis of PID is certain, oral analgesic agents may be prescribed. Close follow-up is recommended, with a bimanual examination performed after 48 hours of antibiotic treatment to assess the patient's response to treatment.[42] Overall, most studies show that response to antibiotic regimens is similar between HIV-positive and HIV-negative patients. The treatment recommendations for HIV-positive patients are no different.[259] Complications associated with PID are perihepatitis, tubo-ovarian abscess, hydrosalpinx (obstruction of the tube caused by scarring [Fig. 48–23]), chronic abdominal pain from adhesions surrounding the fallopian tubes and ovaries, recurrent PID, ectopic pregnancy, and infertility.[106,252]

TABLE 48–6 Ambulatory Management of Pelvic Inflammatory Disease

Ceftriaxone 250 mg IM in a single dose *or* cefoxitin 2 g IM in a single dose *plus* probenecid 1 g orally in a single dose *or* other parenteral third-generation cephalosporins (e.g., ceftizoxime or cefotaxime)
plus
Doxycycline 100 mg PO two times a day for 14 days
with or without
Metronidazole 500 mg PO twice a day for 14 days

From Centers for Disease Control and Prevention: Sexually transmitted disease treatment guidelines 2006. M. M. W. R. Recomm. Rep. 55(RR-11):1-93, 2006.

TABLE 48–7 Inpatient Treatment of Pelvic Inflammatory Disease

Regimen A
Cefoxitin 2 g IV every 6 hr *or* cefotetan 2 g IV every 12 hr
plus
Doxycycline 100 mg every 12 hr PO or IV
Regimen B
Clindamycin 900 mg IV every 8 hr
plus
Gentamicin loading dose IV or IM (2 mg/kg) followed by a maintenance dose (1.5 mg/kg) every 8 hr

Note: *The above regimens are given for at least 24 hr after the patient improves. After discharge from the hospital, the patient is continued on doxycycline at 100 mg PO two times a day for a total of 14 days.*

PERIHEPATITIS

The classic manifestation of perihepatitis, or Fitz-Hugh–Curtis syndrome,[288] is severe right upper abdominal pain that often radiates to the shoulder. Concurrent left upper abdominal pain also may be present. Lower abdominal pain and evidence of acute or subacute PID are frequent findings. The right upper quadrant pain lasts about 48 hours. Nausea, fever, and leukocytosis are common manifestations. Elevation of the erythrocyte sedimentation rate and liver enzymes may be present. The pathogenesis of perihepatitis is thought to be from direct spread of *N. gonorrhoeae* and *C. trachomatis* from the fallopian tubes into the peritoneal cavity, along the paracolic sulci. From there, they reach the subphrenic space and hepatic surface. Spread from the reproductive tract also is possible via the retroperitoneal lymphatics.[288]

The diagnosis is made by having a high index of suspicion. Perihepatitis frequently mimics cholelithiasis, hepatitis, pleuritis, subphrenic abscess, perforated peptic ulcer, nephrolithiasis, appendicitis, ectopic pregnancy, abdominal trauma, and pancreatitis. Treatment of this condition is similar to treatment of PID.

TUBO-OVARIAN ABSCESS

The formation of a tubo-ovarian abscess is a late manifestation of PID. The incidence of tubo-ovarian abscess ranges from 14 to 38 percent in hospital-based adolescents and adults with salpingitis.[99,106,162,195,255] Although tubo-ovarian abscesses rarely are seen in adolescents and young women who are not sexually active,

Figure 48–23 Large hydrosalpinx, the result of gonorrheal salpingitis in an older teenage girl who had repeated gonorrheal infections. The other tube also was diseased.

three case reports are in this group.[66] In two cases, *E. coli* and alpha-hemolytic streptococci were isolated, and in one case, *Pasteurella multocida* was isolated. The actual cause for ascending infection in these cases is unknown. Alterations in cervical secretions, which usually serve as a barrier, have been hypothesized. The abscess typically results from a mixture of facultative and anaerobic bacteria, with facultative bacteria dominating the early phase of infection, and bacterial metabolic products producing an environment of low oxygen tension that favors the growth of anaerobic bacteria.[288]

The most common organisms recovered from tubo-ovarian abscesses are *E. coli*, *Bacteroides fragilis*, other *Bacteroides* spp., *Peptostreptococcus*, *Peptococcus*, and aerobic streptococci.[222] Diagnosing the presence of a tubo-ovarian abscess clinically usually is difficult. Adolescents with a tubo-ovarian abscess tend to seek care later in their menstrual cycle (>18 days from the last menstrual period) than do girls without a tubo-ovarian abscess.[255] Bimanual examination frequently does not reveal a pelvic mass.[49] Four potentially useful clinical features that suggest the presence of a pelvic abscess are pain, persistent fever, adnexal tenderness (for >7 days), and an erythrocyte sedimentation rate greater than 30 mm/hr.[49] Ultrasonography of the pelvis is valuable in confirming the presence of an abscess.[99]

The prompt administration of antibiotics has reduced greatly the incidence of pelvic abscess. Most of those encountered today are in adolescents who have not had adequate care and have delayed seeking treatment.[106] Adolescents are far more likely to delay seeking treatment than are young women.[262]

A conservative approach is favored for the treatment of a tubo-ovarian or ovarian abscess (i.e., bed rest, supportive care, intravenous antibiotics).[252] The choice of antibiotics for treating tubo-ovarian abscess should include the following considerations: effectiveness against β-lactamase–producing anaerobes, adequate coverage against resistant *Bacteroides* spp., penetration into the abscess, and ability to remain stable in an abscess environment. The antibiotic regimens for inpatient treatment of PID fulfill these considerations and are appropriate for the treatment of tubo-ovarian abscess (see Table 48–7). As is the case with cefoxitin, cefotetan, and clindamycin, metronidazole provides good activity against anaerobes.[222] Many hospitals prefer the use of triple antibiotics: cefoxitin and gentamicin plus clindamycin or metronidazole.

A clinical response to treatment consisting of a decrease in pain, fever, and total leukocyte count should be noted in 72 hours. Pelvic ultrasonography should be repeated at this time to note any further increase in the size of the abscess. The duration of intravenous and oral antibiotic therapy for a tubo-ovarian abscess should be at least 21 days. The patient may begin oral antibiotics when she is afebrile and asymptomatic and when the size of the abscess has stabilized. The abscess either resolves without drainage or becomes an encapsulated pool of pus. The latter eventually "points" either in the cul-de-sac or anteriorly in the abdominal wall.

Surgical intervention may be needed in 25 percent of cases, either during the initial period or within a year, usually depending on the size of the abscess. An abscess larger than 10 cm has a 60 percent chance, a 7- to 9-cm abscess has a 35 percent chance, and a 4- to 6-cm abscess has a 20 percent chance of requiring surgical intervention. The fertility rate after treatment of tubo-ovarian abscesses may be 20 to 50 percent with conservative medical and surgical approaches.

OVARITIS AND OOPHORITIS

Ovaritis generally refers to inflammation of the ovaries, and *oophoritis* refers to inflammation of the substance of the ovaries, the oocytes in particular. Viral exanthems such as mumps and cytomegalovirus are complicated most frequently by ovaritis or oophoritis. Immunosuppressed children and adolescents are at risk for development of ovaritis and oophoritis. Improved immunization practices have decreased the prevalence of mumps ovaritis. The presence of an enlarged, tender, boggy, smooth mobile ovary in a child with mumps or one of the exanthems is an indication for repeated examinations and watchfulness. The ovary becomes less tender and gradually shrinks. Mumps ovaritis, in particular, may convert one or both ovaries into swellings that are 6 to 8 cm in diameter. The enlargement may persist for several months. Treatment is palliative, with analgesics given for discomfort and fever.[133]

Gastrointestinal Tract Infections

CHAPTER 49

Esophagitis

Paul Krogstad ✪ Marvin E. Ament

Infectious esophagitis is distinct from other gastrointestinal infections in that it is a rare finding in previously healthy individuals, is predominantly of fungal and viral etiology, and usually is an indicator of a primary or secondary immunodeficiency state. In normal children, infectious esophagitis frequently is associated with conditions that compromise esophageal defense mechanisms.[46]

In view of the numerous predisposing conditions, the incidence of infectious esophagitis in children is difficult to quantify. It has been reported frequently after patients have undergone chemotherapy for hematologic malignancies and after solid organ and hematopoietic stem cell transplantation. Infectious esophagitis has been reported in 3 percent of patients with ataxia-telangiectasia.[29] Before the availability of highly active antiretroviral therapy (HAART), 8 to 10 percent of children infected with human immunodeficiency virus (HIV) developed *Candida* esophagitis.[4,7,37] Despite the availability of HAART, *Candida* esophagitis remains one of the most common opportunistic infections in HIV-infected children and generally is associated with low $CD4^+$ T-cell count (<100/μL), prior episodes of oropharyngeal candidiasis, high plasma HIV-1 load, and neutropenia (<500/μL).[7,8,45]

PATHOPHYSIOLOGY AND CAUSATIVE ORGANISMS

The defense mechanisms of the esophagus against infection include motility (continuous flow of luminal contents, which discourages colonization by microbes), a mucosal lining of stratified squamous epithelium that is resistant to microbial invasion, and local and systemic immune responses. Disruption of any of these protective factors may lead to esophageal infections. Immunosuppression (as seen in patients with acquired immunodeficiency syndrome [AIDS] or after organ transplantation), chronic mucocutaneous candidiasis, malignancy, cancer chemotherapy, and prolonged corticosteroid treatment are the most common underlying etiologic factors for fungal and viral infection of the esophagus.[6-8,19,27,37] In immunocompetent children, dysmotility of the esophagus, in addition to mucosal injury secondary to gastroesophageal reflux, can render the esophagus vulnerable to infections.

Most esophageal infections are caused by fungi and viruses.[3] The esophagus can be infected by local invasion (*Candida*, herpes simplex virus [HSV], bacteria), as a result of systemic infection (cytomegalovirus [CMV], *Candida*, *Pneumocystis*), or by contiguous spread from the mediastinum or neck (tuberculosis, retropharyngeal abscess). *Candida* spp. (especially *Candida albicans*), HSV, and CMV are the major pathogens.[4,37,46] Infections with fungi such as *Pneumocystis*, *Aspergillus*, and *Histoplasma* spp.; viruses such as varicella-zoster virus (VZV), papillomavirus, Epstein-Barr virus, and HIV; and protozoa such as *Cryptosporidium* and *Leishmania donovani* are frequent, well-documented causes of esophagitis.[9,14,15,17,18,23,30,34,41] Bacterial infections of the esophagus probably are under-reported. Of esophageal infections, 10 to 16 percent can have a bacterial etiology, mostly in granulocytopenic patients and as secondary infection in fungal or viral esophagitis. Gram-positive and gram-negative oropharyngeal bacterial flora and *Mycobacterium tuberculosis* are the common pathogens causing esophagitis.[13,44] *Helicobacter pylori* has been isolated from involved tissue in Barrett esophagitis. This "infection" seems, however, to be related to gastroesophageal reflux disease, rather than to direct invasion of the esophagus by *H. pylori*.[31]

CLINICAL FEATURES

Patients with infectious esophagitis can present with esophageal, abdominal, or systemic symptoms (Table 49–1). Odynophagia and dysphagia are the most common symptoms of esophagitis, but they may not be apparent in small children.[7,8,35] In adults, only 59 to 79 percent of patients with documented esophageal infection had these symptoms.[3] Children also may describe a sensation of food "sticking" behind the sternum or a feeling of a food or liquid bolus passing through the chest.

Nearly all patients with AIDS and oral candidiasis and odynophagia have endoscopic evidence of esophageal candidiasis.[5,7,39] Some patients ultimately proven to have esophagitis have no signs or symptoms at presentation, however. Children who develop esophageal candidiasis despite being treated with HAART are less likely to have typical symptoms (e.g., odynophagia and retrosternal pain) or to have concomitant oropharyngeal candidiasis.[8] Similarly, approximately a fourth of adult patients with esophageal candidiasis are asymptomatic.[3]

Drooling is an unusual manifestation in esophagitis per se but may be present with pharyngeal involvement. Fever is caused mostly by systemic or secondary infection, such as disseminated CMV disease or tuberculosis, or complications that occur after esophageal perforation. Fever does not occur commonly in bacterial esophagitis. Cough is characteristic of tuberculosis, tracheobronchial fistulas, or high-grade esophageal obstruction.

Nausea and vomiting are associated more commonly with CMV esophagitis. The abdominal pain in esophagitis may be caused by referred pain from the distal end of the esophagus, associated gastritis (as in CMV infection), or concomitant intra-abdominal infections in immunocompromised hosts. A maculopapular truncal rash and fever may be present in patients with idiopathic esophageal ulceration during acute HIV seroconversion.[34] Diarrhea can be present in CMV infection (diffuse involvement of the gastrointestinal tract) or HIV infection (opportunistic enteral infections, HIV enteropathy). In one report of fungal esophagitis in children, hematemesis was the most common initial symptom.[46] Finally, because physicians seldom seek evi-

dence of esophagitis in the absence of dysphagia or odynophagia, infectious esophagitis may be under diagnosed in infants and children.

Oral lesions are seen in patients with *Candida*, HSV, or HIV esophagitis, but they rarely are present with CMV infection and tuberculosis. Oral thrush is a common occurrence, however, in infants and immunocompromised patients. The frequency of *Candida* esophagitis in infants with oral thrush is unknown. The presence of oral thrush and esophageal symptoms does not exclude concomitant esophageal infection with pathogens other than *Candida* or the esophageal ulcerations associated with acute HIV infection. Oropharyngeal lesions are less common findings in HSV esophagitis than in *Candida* esophagitis. Recurrent cold sores, vesicular lesions on the nasolabial folds, and esophageal symptoms sometimes are seen as initial features of HSV esophagitis in immunocompetent adults and children, but their absence does not exclude HSV infection.[3,35]

DIFFERENTIAL DIAGNOSIS

"Pill" esophagitis may be identified by history. Pathologic gastroesophageal reflux is the most common cause of esophagitis in children. In previously healthy children, esophageal symptoms are likely to be caused by reflux esophagitis, whereas in immunocompromised patients, the physician needs to rule out infectious esophagitis. Secondary bacterial or fungal infections can be present in reflux esophagitis and Chagas disease, especially with severe inflammation and obstruction. Absence of reflux symptoms (long-standing heartburn, a water brash taste in the mouth, vomiting, spitting up [in infants], pillow wetting, or coughing) does exclude reflux esophagitis. Achalasia, diffuse esophageal spasm, foreign body impaction, and mediastinal or retropharyngeal abscesses can cause esophageal symptoms and may result in secondary infection.

DIAGNOSIS

Establishing a specific diagnosis is essential for management of infectious esophagitis, particularly because fungal and bacterial superinfections occur commonly in viral esophagitis. Although the clinical profile, barium esophagogram, and endoscopic appearance can provide some clue to the etiology of esophagitis, histopathology, immunohistochemistry, and culture of endoscopic and brush biopsy specimens are essential for confirmation of specific pathogens. Serology for HSV, CMV, or Epstein-Barr virus may help establish the diagnosis in some cases by providing evidence of acute infection. DNA detection methods also may provide evidence of viremia with these herpesviruses. Detection of fungal or viral esophagitis in an ostensibly healthy host should prompt an evaluation for the presence of primary or secondary immunodeficiency states, including HIV infection.

BARIUM ESOPHAGOGRAPHY

The usefulness of an esophagogram in diagnosing infectious esophagitis is limited because it does not provide an etiologic diagnosis; normal or nonspecific findings also are found in some cases of esophagitis. These studies are useful for assessing motility and for excluding obstruction, perforation, and fistulas of the esophagus. Barium studies are not indicated if endoscopy is planned. Double-contrast barium esophagography with air and barium, which details the mucosal lining, is the radiologic investigation of choice. Children may not tolerate this procedure well, however.[25]

Candida esophagitis generally is diffuse, whereas HSV or CMV lesions are found more frequently in the mid to distal portion of the esophagus. Discrete longitudinal plaques, a grossly irregular or "shaggy" appearance, or tiny nodular lesions with a granular appearance are characteristic of *Candida* esophagitis (Fig. 49–1). The presence of discrete superficial stellate ulcers in the mid esophagus with normal-appearing surrounding mucosa is characteristic of HSV esophagitis. CMV lesions may mimic HSV lesions on barium esophagography. Oval or elongated large ulcers are found mostly in CMV infection, however, and idiopathic esophageal ulceration is found in HIV infection.[24,43] Esophagograms of patients with tuberculosis can show intramural pseudodiverticula, extrinsic compression, or esophageal displacement by mediastinal lymph nodes and sinus tracts.[10]

ESOPHAGOSCOPY

The technique for performing endoscopy with videoendoscopes miniaturized to a diameter of 4.8 mm has made the procedure far more tolerable in immunocompromised patients, requiring less sedation and anesthesia and allowing the procedure to be performed even in newborns. These new instruments have biopsy capabilities comparable to older, wider endoscopes.

Characteristic macroscopic lesions are associated with some infectious agents. Macroscopic appearances overlap considerably, however, and histopathologic or immunohistochemical analysis (or both) of endoscopic and brush biopsy specimens is essential for diagnosis. A diffuse esophageal lesion is characteristic of *Candida* infection, whereas CMV and HSV infections mainly involve the distal part of the esophagus. White, longitudinal plaques adhering to the mucosa are characteristic of *Candida* infection.[20] Plaques from oral thrush, common findings in infants and immunocompromised children, can be washed away and reveal a nonulcerated underlying mucosa. Similar-appearing plaques also may be seen in CMV, HSV, bacterial, and "pill" esophagitis, and after sucralfate ingestion.

Small, 1- to 3-mm vesicles are characteristic of HSV esophagitis, but by the time endoscopy is done, these vesicles usually slough off and reveal sharply demarcated ulcers with a raised edge, necrotic base, and normal-appearing surrounding mucosa.[35] In progressive disease, these ulcers may coalesce to resemble *Candida* esophagitis.[1] Multiple superficial ulcers in the distal portion of the esophagus often are seen in CMV esophagitis. Large elongated ulcers also are typical manifestations of CMV infection, but they may occur in idiopathic esophageal ulcerations in HIV infection as well.[24] Complete denudation of the mucosa is an unusual finding with CMV infection.[40] Endoscopy done in patients with VZV esophagitis can show vesicles, discrete ulcers, or necrotizing esophagitis, depending on the stage of the disease. Tubercular ulcers of the esophagus usually are of varying size, distinct, and shallow with a necrotic base.

BIOPSY AND BRUSHING

Endoscopic biopsy specimens should be obtained from the edge and the base of the lesions. In CMV infection, specimens from the edge do not yield diagnostic information.[40] The pathologist should be alerted to the possibility of fungal, viral, and polymicrobial infection. Appropriate fixatives should be used for routine hematoxylin and eosin stain, Gram stain, and special stains for fungi and bacteria such as *Mycobacterium*. *Candida* and *Aspergillus* can be shown by silver stain, periodic acid–Schiff stain, or Gram stain (Fig. 49–2). Diagnostic histopathologic changes, such as multinucleated giant cells, ballooning degeneration, intranuclear Cowdry type A inclusion bodies, and margination of chromatin in HSV infection (Fig. 49–3), and amphophilic intranuclear inclusions and small multiple cytoplasmic inclusion bodies in CMV infection (Fig. 49–4), can be diagnostic. Immunohistochemical studies and DNA hybridization techniques often are required to establish the diagnosis, however.

Viral culture, with or without immunohistochemical techniques, may aid in confirmation. Material obtained by endoscopy-guided brush biopsy can reveal the features of *Candida* or viral infection described earlier. Blind brushings of the esophagus may be useful for *Candida* infection when endoscopy is impossible or is unavailable.[5] If abdominal pain, fever, or other unusual symptoms are present, the possibility of disseminated or abdominal infection should be excluded by appropriate investigations.

TREATMENT

CANDIDA ESOPHAGITIS

Treatment of esophageal candidiasis requires systemic antifungal therapy. Topical therapy may produce an initial response, but early treatment failures are more common occurrences.[33] Sys-

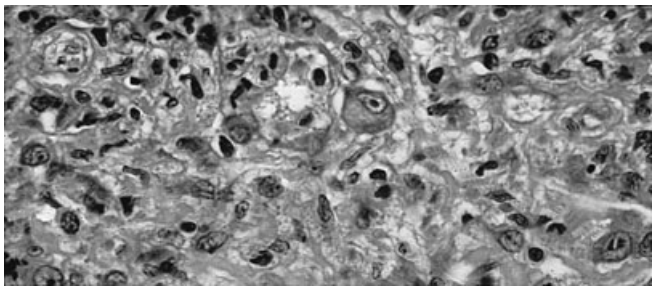

Figure 49–4 Cytomegalovirus esophagitis. Photomicrograph shows intracytoplasmic inclusion bodies in the lamina propria. Hematoxylin and eosin stain. *(Courtesy of Klaus Lewin, M.D., Department of Pathology, UCLA Medical Center, Los Angeles.)*

temic therapy with newer azole medications (fluconazole, itraconazole solution, or voriconazole) is now the preferred approach.[32] Numerous trials have been done comparing the azole agents, most often in adults with AIDS. Patients are less likely to respond and more likely to experience drug-related toxicity when treated with ketoconazole compared with fluconazole.[11] Oral fluconazole and itraconazole suspension seem comparable in efficacy for initial therapy, and some patients whose disease fails to respond to fluconazole may see improvement with subsequent itraconazole therapy.[12,36,44] Regardless of the initial severity of esophagitis, voriconazole and fluconazole seemed comparable in efficacy in one study, although toxicity occurred more commonly with voriconazole.[2,8]

Overall, experience with the azole medications supports recommendations for the initial use of oral fluconazole therapy for *Candida* esophagitis. Therapy generally is given for 14 to 21 days. Intravenous administration of azole medications may be used for patients with severe dysphagia.[26,32]

Infection with azole-resistant variants of *Candida*, including species with intrinsic or acquired resistance to fluconazole (e.g., *Candida krusei*), may occur.[2,8] Although pediatric data currently are limited, large-scale studies in adults have shown that intravenous therapy with echinocandin agents (caspofungin, anidulafungin, or micafungin) is an alternative to azole therapy.[26,32,42]

Intravenous amphotericin B deoxycholate remains an alternative for patients with disease that is refractory to treatment with azole medications.[21,32] Nephrotoxicity is a major toxic effect of amphotericin B, but brief, low-dose therapy (7 to 14 days, 0.3 to 0.7 mg/kg/day) generally is sufficient to treat esophagitis. Lipid formulations of amphotericin B also may be useful for treating refractory disease, but they are not known to be superior in efficacy or lower in toxicity than is the low-dose deoxycholate formulation for the treatment of *Candida* esophagitis.

OTHER CAUSES OF FUNGAL ESOPHAGITIS

Cases of esophagitis caused by *Aspergillus*, *Mucor*, *Cryptococcus*, and *Histoplasma* spp. have been described. Optimal therapy has not been established, but systemic therapy, as for other manifestations of invasive infection with these organisms, has been successful. Currently, this approach would involve the use of intravenous or oral azole agents or an amphotericin B preparation. Echinocandins (micafungin, caspofungin, or anidulafungin) may be useful for *Aspergillus* or *Histoplasma* infections, but they have no activity against cryptococci.

VIRAL ESOPHAGITIS

Although spontaneous resolution of HSV esophagitis may occur in some individuals, antiviral therapy for HSV esophagitis generally is advised. Immunocompromised patients usually are treated with intravenous acyclovir, but in older patients, valacyclovir and famciclovir may be useful alternatives, in view of their clinical efficacy and convenient dosing schedule.[28] Ganciclovir is used for CMV infection.[3,38] Acyclovir is the treatment of choice for VZV, and prophylaxis has reduced effectively the rate of VZV infection in post-transplantation patients. Foscarnet is an alternative treatment for patients with HSV, VZV, or CMV who cannot tolerate or do not respond to initial therapy with acyclovir or ganciclovir therapy. Therapy for 14 to 21 days usually is recommended for esophagitis caused by these herpesviruses. HIV-associated idiopathic ulcers do not respond to empiric antiviral or antifungal therapy, but they may respond to treatment with thalidomide.[16]

BACTERIAL ESOPHAGITIS

Bacterial esophagitis typically occurs in immunocompromised hosts and may involve gram-positive or gram-negative bacteria, or a mixture of both. In immunocompromised hosts, esophagitis may be associated with bacteremia. Consequently, empiric therapy should include broad-spectrum antibacterial agents active against *Staphylococcus aureus*, viridans streptococci, and aerobic gram-negative organisms. Blood cultures always should be performed to exclude bacteremia.[44]

Esophageal infections with *M. tuberculosis* or atypical mycobacteria are treated with regimens appropriate for other systemic infections with these organisms. Lack of response to appropriate therapy may indicate concomitant superinfection by other organisms or resistance to the drugs used. Repeat endoscopy is indicated for documenting eradication of infection.

PROGNOSIS

Candida esophagitis carries a poor prognosis for patients with AIDS. Survival is approximately 1 year after an episode of *Candida* esophagitis in children with untreated HIV infection, and *Candida* esophagitis is an indication for administration of antiretroviral therapy.[4,34] Fungal esophagitis, if not treated successfully, can lead to esophageal strictures, obstruction, perforation, and fistulas.[22,27] Viral esophagitis usually does not have any long-term sequelae.

CHAPTER 50

Approach to Patients with Gastrointestinal Tract Infections and Food Poisoning

Larry K. Pickering

The approach to treatment of patients with gastrointestinal (GI) tract infections begins with obtaining a thorough medical history including information about epidemiologic factors, a physical examination, and knowledge of the pathophysiologic process and clinical manifestations of various enteropathogens. GI tract infections result in a wide range of symptom complexes and can be produced by a variety of enteropathogens. Most infectious diarrheal illness can be classified into one of several categories based on the causative agent, the pathophysiologic mechanism of the agent, and the clinical response. This information then can be used to determine appropriate laboratory evaluation and therapy. All patients with diarrhea require some degree of fluid and electrolyte therapy; a few need other nonspecific support; and for some, specific antimicrobial therapy is indicated to shorten the duration of the illness and to eradicate fecal excretion of the organism. Practice guidelines for management of infectious diarrhea have been developed by the Infectious Diseases Society of America.[163] Other recommendations include a primer for physicians dealing with diagnosis and management of food-borne illnesses developed jointly by the American Medical Association, Centers for Disease Control and Prevention (CDC), U.S. Food and Drug Administration (FDA), and United States Department of Agriculture[62]; surveillance of food-borne disease outbreaks in the United States by the CDC[245]; guidelines for prevention of

opportunistic infections in patients with human immunodeficiency virus (HIV) developed by the U.S. Public Health Service and the Infectious Diseases Society of America[71]; management of acute gastroenteritis in young children developed by the CDC[66]; and guidelines on acute diarrhea in adults.[111]

EPIDEMIOLOGY AND ETIOLOGY

Establishing the cause of diarrhea often is difficult because of variations in host susceptibility and response to infection, geographic location, season, and complexity of laboratory techniques necessary to identify the wide array of causative agents. In the United States and other parts of the world, acute infectious diarrhea is caused by many enteropathogens; but on the basis of epidemiologic and etiologic considerations, major categories can be differentiated (Table 50–1): diarrhea in childcare centers, hospitals, or other institutional settings and in family members or other close contacts; food- or water-associated diarrhea; antimicrobial-associated diarrhea; diarrhea of travelers; diarrhea in immunosuppressed hosts, including patients with primary and secondary immune deficiencies; and others, which include sporadic episodes in which these categories do not apply. In addition, history of chronic diarrhea or other GI tract diseases should be obtained.

When a patient complains of moderate or severe diarrhea, a decision should be made as to whether he or she should be hospitalized or treated as an outpatient. The following patients with diarrhea should be considered for hospitalization: infants and elderly people who appear toxic, are lethargic, or have high temperatures; patients with excessive loss of fluid and electrolytes through stools, especially in association with vomiting; patients with grossly bloody stools; and patients who are immunosuppressed, including people with acquired immunodeficiency syndrome (AIDS). Once the decision has been made either to hospitalize or to treat on an outpatient basis, appropriate diagnostic procedures and therapy can be instituted.

OUTBREAKS IN CHILDCARE CENTERS

The risk for a person to acquire a GI tract infection varies with age, environment, season, exposure, and immune status. Clinical and epidemiologic data often guide classification of an episode of acute infectious diarrhea into one of the categories mentioned earlier. If predisposing factors are not present, the episode can be classified as sporadic. Most cases of sporadic diarrhea occur in children younger than 5 years old, although all age groups are affected. Infants who are breast-fed are relatively protected from contaminated food and water. Protection also is afforded by factors present in human milk.[310] During and after weaning, the risk for development of diarrhea increases. When an episode of acute infectious diarrhea occurs, an association with other cases should be sought, especially when highly contagious organisms, such as *Shigella* spp., *Escherichia coli* O157:H7, *Giardia lamblia*, *Cryptosporidium* spp., rotavirus, astrovirus, enteric adenovirus, and calicivirus, are isolated and in conditions in which close contact is facilitated, such as institutions for mentally impaired people, childcare centers, hospitals, and other institutional settings.[188,263,289,311,314,412] After respiratory tract illness, diarrhea is the second most common disease among children in childcare facilities,[188] occurring most frequently in children younger than 3 years.

FOOD-BORNE OR WATER-BORNE DIARRHEA

Reporting of food-borne and water-borne diseases in the United States began in 1923 because of concern about typhoid fever and infantile diarrhea.[245] Since 1978, food-borne and water-borne outbreaks have been published in separate annual summaries. The purposes of the outbreak surveillance include disease prevention and control, knowledge of disease causation, and administrative guidance. In 1996, the CDC established the Foodborne Disease Active Surveillance Network (FoodNet) for population-based, active surveillance investigation of food-borne disease in the United States.[362] The active surveillance includes laboratory-confirmed infections for nine pathogens (*Campylobacter* spp., *Listeria* spp., *Salmonella* spp., *Shigella* spp., Shiga toxin–producing *Escherichia coli*, *Vibrio* spp., *Yersinia* spp., *Cryptosporidium* spp., and *Cyclospora* spp.).

An outbreak of food-borne or water-borne disease is defined as an incident in which two or more people experience a similar illness, usually involving the GI tract, after ingesting common food or water.[120,236,245] Surveillance for water-borne disease and outbreaks in the United States is characterized by disease associated with recreational water and disease associated with drinking water and water not intended for drinking.[120,236] Food-borne or water-borne disease can result from ingestion of food or water contaminated with bacteria or a bacterial toxin, a chemical, a virus, or a parasite.[62,236,245] Table 50–2 outlines characteristics of food-borne and water-borne outbreaks, including outbreaks not characterized by diarrhea. Although most enteropathogens can be spread by either food or water, the epidemiology of outbreaks often suggests specific etiologic agents. A determination of the incubation period and the presence or absence of selected clinical findings (especially fever, vomiting, and bloody diarrhea) often leads a physician or other health care professional toward establishing the correct diagnosis in outbreaks of food-borne or water-borne disease.[62] As a general rule, when outbreaks are

TABLE 50–1 Major Categories of Acute Infectious Diarrhea

Category of Diarrhea	Epidemiologic Considerations	Most Commonly Involved Enteropathogens
Outbreaks usually due to person-to-person transmission	Childcare centers, hospitals, and other institutional settings	Enteric viruses, *Cryptosporidium*, *Giardia lamblia*, occasionally bacteria
Food-borne or water-borne	Other people involved after common food or water exposure	See Tables 50–2 and 50–3
Antimicrobial-associated	Recent administration of an antimicrobial agent	*Clostridium difficile*
Travelers	Recent travel to a developing country	Enterotoxigenic *Escherichia coli*, *Campylobacter*, *Shigella*, *Salmonella*, other organisms
Immunosuppressed hosts	Primary or secondary (underlying disease, including HIV infection; recent administration of an immunosuppressive drug or radiation therapy) immune deficiencies	See Table 50–4

divided by an incubation period, illnesses manifesting in less than 1 hour usually are caused by chemical poisoning; illness of 1 to 7 hours, by either *Staphylococcus aureus* or *Bacillus cereus* preformed toxins; illness of 8 to 14 hours, by *Clostridium perfringens* or *B. cereus* enterotoxins; and illness of more than 14 hours, by other infectious or toxic agents (see Table 50–2). Clinical manifestations can involve the central nervous system or be systemic with little or no intestinal tract involvement.

During the period from 1998 through 2002, a total of 6647 outbreaks of food-borne disease, which included 128,370 cases, were reported to the CDC from various regions of the United States.[245] Since 2001, reports of food-borne disease outbreaks have been submitted by state, local, and territorial public health departments through a Web application on the Internet called the electronic Food-borne Outbreak Reporting System.[245] This surveillance system has resulted in an increase in the number of reported outbreaks. Among outbreaks in which the cause was determined (33%), bacterial pathogens caused the largest percentage of outbreaks (55%) and cases (55%), with *Salmonella* serotype Enteritidis accounting for the largest number of outbreaks and outbreak-related cases.[245] *Listeria monocytogenes* accounted for most deaths from any pathogen, followed by *Salmonella* spp. Outbreaks with a known cause accounted for 54 percent of illnesses. Viruses caused 33 percent of outbreaks and 41 percent of cases, predominantly due to noroviruses, with hepatitis A being the second most common viral cause. Parasites caused 1 percent of outbreaks and 1 percent of cases, with anisakis, cryptosporidium, cyclospora, *Giardia*, and trichinella reported as causing outbreaks. Chemical agents caused 10 percent of outbreaks and 2 percent of cases, with ciguatoxin, heavy metals, mushrooms, paralytic shellfish, and scombrotoxin accounting for outbreaks caused by chemical agents (Table 50–3). The etiologic agent was not detected in 67 percent of outbreaks, indicating the need for improved epidemiologic and laboratory investigations. Factors contributing to outbreaks were classified as those that are thought to have led to contamination of a food and those that allowed proliferation of the pathogen in the food. At least one contributing factor was reported in 46 percent of outbreaks reported from 1998 through 2002.[245,438] Major contaminating factors that contributed to outbreaks were bare-handed contact

TABLE 50–2 Characteristics of Food-Borne or Water-Borne Outbreaks of Diarrhea

Usual Incubation Periods	Clinical Illness			Causative Agent	Epidemiologic and Laboratory Diagnosis
	Fever	Diarrhea	Vomiting		
5 minutes-6 hours (usually <3 hours)	Rare	Occasional (see Table 50–3)	Common	Chemical or toxin	Demonstration of toxin or chemical from food or epidemiologic incrimination of food
1-6 hours (usually <1 hour)	Rare	Occasional	Profuse	*Staphylococcus aureus* enterotoxin *Bacillus cereus* emetic toxin	Detection of toxin in food, isolation of organisms in food (>10^5/g) or in vomitus or stool
8-16 hours	Rare	Typical	Occasional	*Clostridium perfringens* enterotoxin *B. cereus* enterotoxin	Isolation of organisms or toxin from food (>10^5g) or stools of ill persons, epidemiologic incrimination of food
16-96 hours	Common	Typical	Occasional	*Shigella* *Salmonella* *Vibrio parahaemolyticus* Enteroinvasive *Escherichia coli* *Yersinia enterocolitica*	Isolation of organisms from food or stools of ill persons
12-72 hours	Clinical syndrome compatible with botulism			*Clostridium botulinum*	Isolation of organism or toxin from food (10^5/g) or stools Demonstration of toxin in serum or food
16-96 hours	Occasional	Typical	Occasional	*E. coli* enterotoxin *V. parahaemolyticus* enterotoxin *Vibrio cholerae* enterotoxin *Y. enterocolitica* enterotoxin *Listeria monocytogenes*	Isolation of organism from food and stools of ill persons Identification of toxin Epidemiologic incrimination of food Blood or cerebrospinal fluid cultures; stool culture usually not helpful
1-11 days	Occasional	Common	Occasional	*Cryptosporidium parvum* *Cyclospora cayetanensis*	Request special stool examination; may need to examine water or food
2 days-weeks	Common	Typical	Frequent	*Bacillus anthracis*	Isolation of organism from blood or contaminated meat
1-7 days	Uncommon	Typical	Frequent	*E. coli* O157:H7 and other Shiga toxin-producing *E. coli*	Isolation of organism from food or stool or identification of toxin in stools of ill persons Epidemiologic incrimination of food
1-3 days	Occasional	Typical	Common	Caliciviruses (noroviruses) Rotavirus	Antigen detection (enzyme immunoassay) in stool Immune electron microscopy of stool Serology
2-5 days	Occasional	Typical	Occasional	*Campylobacter jejuni*	Isolation of organisms from food or stools of ill persons Epidemiologic incrimination of food
7-21 days	Common	Common	Rare	*Brucella abortus*, *Brucella melitensis*, and *Brucella suis*	Blood culture and positive serology
1-4 weeks	Rare	Common	Rare	*Giardia lamblia*	Stool for ova and parasite examination enzyme immunoassay
2 days-8 weeks	Common	Common	Common	*Trichinella spiralis*	Serology, muscle biopsy

TABLE 50–3 Chemical Causes of Food Poisoning

Type of Chemical, Toxin, or Poison	Food	Clinical Symptoms	Onset of Symptoms (hr)
Heavy metals*	Water (through metallic container) and food	Gastrointestinal	1
Scombrotoxin	Fish (tuna, mackerel, marlin, mahi-mahi, bluefish)	*Due to histamine:* flushing, headache, burning of mouth and throat, urticaria, rash, paresthesia	1
Ciguatera	Fish (barracuda, amberjack, snapper, grouper)	*Neurologic:* paresthesia, reversal of cold-hot sensations *Gastrointestinal:* nausea, abdominal pain, vomiting, diarrhea	1-6
Tetrodotoxin	Puffer fish	*Neurologic:* paresthesia, numbness, loss of proprioception, ascending paralysis, death	<1
Paralytic or neurotoxic compounds	Shellfish (clams, oysters, scallops, mussels, other mollusks)	Paresthesia, weakness, respiratory difficulties, dysphasia, dysphonia, gastrointestinal	1-4
Domoic acid	Shellfish (mussels)	Gastrointestinal *Acute CNS:* headache, seizures, hemiparesis, ophthalmoplegia, abnormalities of arousal *Chronic CNS:* memory deficits, motor neuropathy or axonopathy	Within 24
Monosodium glutamate	Chinese food	Burning sensation, heavy feeling in chest, pressure over face, flushing, gastrointestinal	1
Ibotenic acid, muscimol	Mushroom	*CNS:* confusion, delirium, visual disturbances, lethargy	2
Coprine	Mushroom	*Disulfiram-like effect:* nausea, vomiting, headache, hypotension, flushing, paresthesia and tachycardia	2
Muscarine	Mushroom	*Parasympathetic:* sweating, salivation, lacrimation, blurred vision, diarrhea, bradycardia, hypotension	2
Psilocybin, psilocin	Mushroom	*CNS:* hallucinations, anxiety, mood elevation, weakness	2
Diverse, mostly unknown	Mushroom	Gastrointestinal	2
Monomethylhydrazine, gyromitrin	Mushroom	Cellular destruction, gastrointestinal, loss of coordination, convulsion, coma, death	6-12
Amatoxins, phallotoxins	Mushroom	Cellular destruction, gastrointestinal, hepatic and renal necrosis	6-24
Vomitoxin (deoxynivalenol)	Cereals contaminated with *Fusarium* species	Vomiting acutely Altered mucosal immunity with chronic exposure	<3

**Includes antimony, arsenic, cadmium, copper, mercury, thallium, tin, and zinc.*
CNS, central nervous system.

by a food handler or preparer (e.g., ready-to-eat food), inadequate cleaning of processing or preparation equipment or utensils (e.g., cutting board), handling by an infected person or carrier of a pathogen (*Salmonella* spp. or norovirus), and cross-contamination from a raw ingredient of animal origin (e.g., raw poultry on preparatory surface). Factors associated with proliferation of a pathogen in food include allowing foods to remain at room or warm outdoor temperature for several hours, inadequate cold-holding temperatures, slow cooking, insufficient time or temperature during hot holding, and preparation of foods a half day or more before serving. Most of the proliferation factors are associated with outbreaks due to bacteria. The major places where food associated with outbreaks was eaten are restaurants and delicatessens (50%) and private residences (20%); a variety of other or unknown places account for the remainder.[245]

Outbreaks of gastroenteritis caused by caliciviruses have been associated with consumption of contaminated oysters, salads, and bakery products and with transmission of the virus by food handlers.[229,272] The major causes of reported food-borne disease outbreaks due to bacteria are *Salmonella* spp., Shiga toxin–producing *E. coli*, *C. perfringens*, *S. aureus*, *Shigella* spp., and *Campylobacter jejuni*. Bacterial diseases associated with ingestion of unpasteurized milk include salmonellosis and campylobacteriosis and, less frequently, infection with *Brucella* spp., *E. coli*, *L. monocytogenes*, *Mycobacterium* spp., *S. aureus*, *Streptococcus* spp., *Streptobacillus moniliformis*, and *Yersinia enterocolitica*.[245] A nationwide outbreak of *Salmonella enteritidis* gastroenteritis involved 224,000 people in the United States and was associated with ingestion of contaminated ice cream. The origin of the outbreak was pasteurized ice cream premix that was contaminated in tanker trailers that previously had carried nonpasteurized liquid eggs containing *S. enteritidis*.[171] Consumption of raw milk has been associated with a chronic diarrhea syndrome of unknown cause,[294] initially identified in Minnesota and referred to as *Brainerd diarrhea*. It is manifested by acute onset with marked urgency and a lack of systemic symptoms. The duration of illness is at least 9 months and generally has involved adults. Clinical and laboratory data indicate that diarrhea is caused by a secretory mechanism. No evidence of secondary transmission exists. Antimicrobial therapy has not been successful.[294] In addition, an outbreak of chronic diarrhea involving 72 people who ingested untreated drinking water was reported.[297] The cause and pathophysiologic mechanism of the illness remain unknown.

Ingestion of raw fish (sushi or sashimi) has led to infection with *Vibrio parahaemolyticus* and various parasites from infected fish.[87,245] Parasites acquired through ingestion of raw fish include larval nematodes of the family Anisakidae, fish tapeworm of the species *Diphyllobothrium*, the fluke *Nanophyetus salmincola* from salmon, and many other helminths.[363,436] Most worm infections acquired from raw fish in the United States have been acquired from dishes prepared at home and not from sushi restaurants.

Symptoms in patients with chemical poisoning generally begin within 1 to 2 hours after ingestion, although certain mushroom toxins may produce symptoms for up to 24 hours (see Table 50–3). Heavy metals, such as antimony, arsenic, cadmium, copper, mercury, thallium, tin, and zinc, cause irritation of the gastric mucosa, with nausea, vomiting, and abdominal cramps, which

usually resolve 2 to 3 hours after the offending agent has been removed.[62]

The toxic syndromes acquired from fish and shellfish can be grouped clinically into two categories: the histamine-like syndrome of scombroid poisoning and the neurotoxic syndrome, which includes ciguatera, paralytic shellfish poisoning, neurotoxic shellfish poisoning, and puffer fish poisoning caused by tetrodotoxin.[121] The neurologic symptoms produced by fish, shellfish, and the Chinese restaurant syndrome agent include paresthesia, reversal of hot-cold sensations, loss of proprioception, flushing, weakness, and burning sensations. Chinese restaurant syndrome appears to be caused by excessive amounts of monosodium glutamate in foods. Fish poisoning may be caused by scombrotoxin, ciguatoxin, or tetrodotoxin. Scombroid fish poisoning is characterized by symptoms resembling those of histamine release. Shellfish poisoning can be of two types: paralytic, caused by neurotoxins including saxitoxin, and neurotoxic, caused by several poorly characterized neurotoxins. Domoic acid from contaminated mussels causes acute widespread neurologic dysfunction and GI tract manifestations followed by chronic residual memory deficits and motor neuropathy or axonopathy.[303,400]

Infectious diseases associated with consumption of raw and lightly cooked shellfish (mussels, clams, oysters, lobsters, and other mollusks) are caused by bacterial agents that are native to the marine environment and by viral and bacterial agents from sewage effluents and other sources that contaminate environmental waters. As filter-feeding organisms, shellfish amplify public health problems associated with environmental contamination because they accumulate microbial pathogens at densities many times those found in overlying waters.

Public health problems of greatest concern to consumers of molluscan shellfish are associated with viral pathogens. The numbers of cases and outbreaks caused by these pathogens far exceed those of all other infectious causes.[245] The *Vibrio* genus (specifically *Vibrio vulnificus*) presents the most serious problem in terms of the severity of human illness and death, especially in people with liver disease.[180]

Mushrooms produce several clinical syndromes, generally within 2 hours of ingestion (see Table 50–3),[167] except for poisoning caused by amatoxins, phallotoxins, amantin, monomethylhydrazine, and gyromitrin, which may produce symptoms, including death, up to 24 hours after ingestion.[167] Mushrooms also can be contaminated with other agents, including *S. aureus* enterotoxin A.[235]

PulseNet is a national network of public health laboratories that perform pulsed-field gel electrophoresis analysis on bacteria that might be food-borne.[362] This network provides rapid comparison of pulsed-field gel electrophoresis patterns through an electronic database at the CDC. PulseNet has assisted in detecting food-borne outbreaks, especially those that involve multiple states.[362] An annual listing of food-borne disease outbreaks reported to the CDC is available at *www.cdc.gov/foodborneoutbreaks/outbreak_data.htm*.

Since 1971, the number of reported water-borne outbreaks in the United States has averaged 30 per year (range, 13 to 53 years), involving approximately 7600 people annually (range, 1569 to 21,149 people).[120,236] The CDC has published recommendations for management of fecal accidents in disinfected recreational water venues contaminated with formed or liquid stool.[72]

Water-borne disease and outbreaks are reported as those associated with drinking water and water not intended for drinking and those associated with recreational water.[120,236] During 2003 through 2004, 36 water-borne disease outbreaks associated with drinking water were reported; 30 were associated with water intended for drinking, 3 with water not intended for drinking, and 3 with water of unknown source.[236] In the 30 outbreaks associated with drinking water, 4 deaths occurred among the 2760 people who became ill. Etiologic agents were identified in 25, with 68 percent involving pathogens (13 bacterial, 1 parasitic, 1 viral, and 2 mixed organisms) and 32 percent involving chemical or toxin poisonings. The major clinical manifestations in these outbreaks were gastroenteritis (68%), acute respiratory tract illness (26%), and dermatitis (7%). Organisms associated with gastroenteritis were *Campylobacter* spp., *Shigella* spp., *Salmonella typhimurium*, *Giardia*, *Cryptosporidium*, and norovirus. *Legionella* spp. were associated with all of the respiratory tract outbreaks.

Types of water systems involved community, noncommunity, individual, and mixed systems. Types of deficiencies associated with outbreaks included untreated surface water intended for drinking, untreated ground water intended for drinking, water treatment deficiencies, and deficiencies in distribution systems including storage. All water-borne disease outbreaks should be reported to the state health department.

During 2003 through 2004, there were 62 reported water-borne disease outbreaks associated with recreational water that involved 2698 people, resulting in 58 hospitalizations and one death.[120] Of the 62 outbreaks (1945 people), 48 percent were gastroenteritis outbreaks associated with enteric pathogens, chemicals, or toxins (*Cryptosporidium*, *Giardia*, *Shigella* spp., norovirus, *Plesiomonas shigelloides*, and microcystin toxin from blue-green algae); 21 percent were dermatitis; 11 percent were respiratory illness; and 13 percent were other illnesses.

Recreational water–associated outbreaks of gastroenteritis followed exposure to both treated (60%) and untreated (40%) water. In outbreaks that occurred after exposure to treated water, *Cryptosporidium* was associated with 56 percent; in exposure to untreated water, *Cryptosporidium* accounted for 8 percent of outbreaks. There also were 142 *Vibrio* illnesses associated with recreational water exposure.

The main therapeutic modality in most patients with food poisoning is supportive care because most of these illnesses are self-limited. Exceptions include botulism, paralytic shellfish poisoning, tetrodotoxin, long-acting mushroom poisoning, and Shiga toxin–producing *E. coli* (STEC) infection, all of which may be fatal in previously healthy people. Food-borne disease caused by any agent can produce fatalities in infants, elderly people, debilitated people, or people with primary or secondary immune deficiencies. Food irradiation is an important technology that can protect the public against food-borne diseases.[395] Several Web sites that provide information about food-borne disease include *www.ama-assn.org/foodborne*, *www.cdc.gov/foodnet*, *www.cdc.gov/foodsafety*, and *www.fightbac.org*.

ANTIMICROBIAL-ASSOCIATED DIARRHEA

Diarrhea associated with use of an antimicrobial agent is a common occurrence. Changes in bowel flora may result in abnormal stools in the absence of a documented enteropathogen, and discontinuation of the medication may be sufficient to eliminate symptoms. In some patients with antibiotic-induced diarrhea, a severe and potentially fatal form of colitis may develop.[31,44,184,249]

Pseudomembranous or antimicrobial-associated colitis (AAC) refers to the presence of a pseudomembrane or of multiple plaquelike lesions in the colon induced by administration of an antimicrobial agent within the preceding 8 weeks. Pseudomembranous colitis not associated with use of antibiotics also may occur with *Shigella dysenteriae* serotype 1 and STEC.[214] Toxins produced by *Clostridium difficile* are the specific cause of essentially all cases of AAC.[365] Since 2005, an epidemic of *C. difficile* infection that is more serious and more refractory to therapy has been reported.[192,241,256,424] These studies have reported a highly characterized strain designated BI/NAP1, which is responsible for most of these outbreaks. The strain is a hypersecretor of the classic toxins A and B associated with *C. difficile*, possesses an

additional toxin known as binary toxin, manifests deletion of an 18–base pair sequence in the pathogenicity locus responsible for down-regulation of toxin production, and has in vitro resistance to fluoroquinolones.[31,302]

Disease associated with *C. difficile* encompasses a range of severity from colitis, which often manifests as diarrhea, to toxic megacolon, requirement for colectomy, leukemoid reaction, and severe hypoalbuminemia that may result in sepsis, shock, and death.[44,88,134] These complications occur more commonly in older adults. In addition, nosocomial infection with *C. difficile* occurs and can result in asymptomatic carriage or diarrhea.[257] Most antimicrobial agents have been reported to cause this condition; broad-spectrum cephalosporins and clindamycin are implicated most commonly. Fluoroquinolones have emerged as a predominant risk for development of *C. difficile*–associated diarrhea.[302] Cancer chemotherapeutic agents also have been associated with AAC.

The diagnosis of AAC in a patient with diarrhea is supported by the following[29]:

1. A history of ongoing or recent antimicrobial therapy. Twenty to 40 percent of episodes occur after the drug has been discontinued.
2. Finding of leukocytes on a stain of fecal material.
3. Exclusion of other agents known to cause fecal leukocytes.
4. Identification of *C. difficile* toxins in stool specimens.
5. Endoscopy with rectal biopsy to identify pseudomembranes or plaques that contain mucin, fibrin, leukocytes, and sloughed epithelial cells.

Plaque and pseudomembranes not always are present in patients with AAC, but when they are, *C. difficile* usually can be presumed to be the cause of disease. The finding of *C. difficile* in feces suggests but does not confirm that *C. difficile* is the cause of the diarrhea. The finding of fecal toxin is a more useful method of diagnosing *C. difficile*–induced disease than is bacterial culture.[288] The enzyme immunoassay is used now by most laboratories because of ease of processing, cost, and speed of results.[31] This organism and the toxins may be found in the GI tract of some healthy people.[257,265] Approximately 15 to 63 percent of neonates, as many as 50 percent of infants younger than 1 year, and as many as 8 percent of children are asymptomatic carriers.[76,103]

The most important aspect of therapy in patients with AAC is discontinuation of the antimicrobial agent, after which symptoms usually resolve within 1 to 2 weeks; however, if symptoms persist or worsen or if the patient has severe diarrhea, specific therapy with metronidazole or oral vancomycin should be instituted.[169,260,301,399] Rifampin has been used as an adjunct to treatment with metronidazole, but it is not recommended.[230] Teicoplanin, fusidic acid, bacitracin, and nitazoxanide also have been used.[184,277,429] Metronidazole is preferred in guidelines, but vancomycin appears to be more effective in patients with severe disease.[31,276,300,441] After therapy has been initiated, symptoms generally resolve within several days, and fecal toxin disappears. Relapse of colitis after discontinuation of metronidazole or vancomycin has been documented in 10 to 20 percent of patients, generally 1 to 4 weeks after treatment has been discontinued.[32,301,399] Relapses are caused by germination of *C. difficile* spores that persist despite treatment and are not due to development of resistance. Relapses can be treated with a second course of metronidazole. Other modes of therapy include dietary reduction of carbohydrates and administration of probiotics to allow normal intestinal flora to be re-established.[184] Two meta-analyses demonstrated the benefit of probiotics in preventing antibiotic-associated diarrhea and treating *C. difficile* disease.[256,390] One study evaluated a variety of different types of probotics[256]; the other evaluated *Saccharomyces boulardii*.[390] Further research is needed to determine the optimal probiotic, the best dose and duration of treatment, and the effectiveness against specific antimicrobial agents.

TRAVELER'S DIARRHEA

Traveler's diarrhea is the most common illness encountered by people from the United States, northern Europe, Canada, or Australia who travel to Latin America, Asia, the Middle East, or Africa, where diarrhea is hyperendemic.[113,115-117,160] Half of these travelers experience diarrhea within the first few weeks after arrival. Enterotoxigenic *E. coli* (ETEC) is the most commonly identified cause of traveler's diarrhea, but the illness can be caused by a variety of bacteria, viruses, and parasites,[115,116,290,364] including *Shigella* spp., *C. jejuni*, *Aeromonas* spp., *P. shigelloides*, *Salmonella* spp., *V. parahaemolyticus* (in Asia), *G. lamblia*, enteroaggregative *E. coli*, and enteric viruses, specifically norovirus. Information from existing studies concerning pathogens associated with diarrhea among children or elderly people who travel is limited. Studies of diarrhea in travelers visiting the United States and Great Britain from developed and developing countries showed attack rates of 2 and 0.6 percent, respectively.[346]

Clinical illness varies, reflecting the diversity of causative agents. Typically, illness occurs within several weeks of arrival in a foreign country and is defined as passage of at least three unformed stools in a 24-hour period, together with cramps, nausea, fecal urgency, tenesmus, or a combination thereof. Bloody diarrhea, vomiting, and documented elevation of temperature are less frequent signs and symptoms. Approximately 50 percent of people who become ill have mild disease, 15 to 40 percent are forced to alter their scheduled activities, and 15 to 30 percent are confined to bed. Because traveler's diarrhea is caused by a variety of enteropathogens, travelers may experience more than one episode. Traveler's diarrhea is spread by many fecally contaminated vehicles; most studies implicate food, particularly uncooked food,[128,405] and untreated water and ice.[174] Careful attention given to food consumption with avoidance of foods that are not steaming hot, raw vegetables, fruit not peeled by the traveler, tap water, and ice is critical to prevention of disease.[128,174] Predisposing factors and host factors that increase susceptibility to traveler's diarrhea or complicate its course include young age, short duration of travel, eating in restaurants, season, reduced gastric acidity, chronic and active GI tract disease, and immunodeficiency disorders.[128,183]

Several studies have evaluated prevention and treatment of traveler's diarrhea in adults using either antidiarrheal compounds or antimicrobial agents.[117] Compounds that have been shown to be effective chemoprophylactic agents include doxycycline, bismuth subsalicylate, trimethoprim-sulfamethoxazole (TMP-SMX), fluoroquinolones, and nonabsorbable antibiotics including rifaximin.[4,108,113,114,117] These compounds have been shown to offer 50 to 100 percent protection against traveler's diarrhea.[4,117] Potential problems with antibiotic regimens include development of resistance against certain agents, including ETEC, *Salmonella* spp., *Shigella* spp., and *C. jejuni*, and side effects, such as nausea, diarrhea, and photosensitivity reactions. Large doses of bismuth subsalicylate can result in significant concentrations of serum salicylate.[135,316] The bioavailability of salicylate in 1 ounce of Pepto-Bismol is equivalent to that of one 325-mg adult aspirin tablet.[135] Probiotics have been shown to be only minimally effective in prevention of diarrhea.[117]

Because of the uncertain risk of widespread prophylactic administration of these antimicrobial agents, including development of resistance among enteric bacteria, and the mildness of most cases of traveler's diarrhea, prophylactic use of antimicrobial agents is not recommended in children and has limited use

in adults.[117,160] Instructing travelers with regard to appropriate dietary practices as a prophylactic measure is recommended.[128,405] If a person becomes ill in a locale where medical facilities are inadequate, self-treatment may be indicated.[4,117] Antidiarrheal compounds as therapy for traveler's diarrhea have been used in people with nondysenteric disease. Bismuth subsalicylate has been shown to be effective in decreasing the incidence of diarrhea by up to 60 percent.[116] Loperamide should not be used in infants or older children with bloody diarrhea or fever, although it may benefit older children and adults with watery diarrhea, especially when it is given in combination with an antimicrobial agent.[18,107,125] Other nonantimicrobial compounds have been shown to be ineffective or even dangerous or have not been evaluated.[18]

For self-treatment of diarrhea that occurs during travel in areas where medical care may not be available, travelers should take with them medication with expected activity against the prevalent bacteria. A 3- to 5-day antibiotic course may help children who develop diarrhea with three or more loose stools in an 8-hour period, especially if associated symptoms such as nausea, vomiting, abdominal cramps, fever, and blood in stools are present. A fluoroquinolone, azithromycin, or rifaximin for adults and azithromycin for children should be considered.[4,5,106,107,117,125,307] Problems with development of resistance by *C. jejuni* to fluoroquinolones may preclude their use in certain areas.

Approximately 3 percent of people develop persistent diarrhea after an episode of traveler's diarrhea.[109] The differential diagnosis should include persistent infection, particularly with *Giardia*, *Cryptosporidium*, *Cyclospora*, or *Isospora* spp.; antibiotic-associated colitis; small intestinal bacterial overgrowth; transient disaccharidase deficiency; initial manifestation of ulcerative colitis or regional enteritis; postdysenteric colitis; irritable bowel syndrome; and tropical sprue.[109] An underlying immune system defect, such as occurs with AIDS, also should be considered.

HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Diarrheal disease often is a major problem in people with primary and secondary immunologic disorders.[22,356,439] The GI tract must act as the first line of defense against a wide variety of potentially harmful organisms and toxins. Immune deficiencies can result in an increased host susceptibility to intestinal tract infections or an atypical, prolonged, or disseminated course once an organism is established.

Causes of GI tract disease in children with AIDS can be grouped under the major headings of infection, malignant disease, and HIV enteropathy. The location of GI tract involvement by infectious agents determines the clinical symptoms and the ease with which these organisms can be diagnosed and treated (Table 50–4). Organisms and diseases of the GI tract that fulfill the CDC surveillance case definition of AIDS[59] are candidiasis, cryptosporidiosis, cytomegalovirus, herpes simplex, *Mycobacterium avium* complex, *Microsporidium*, isosporiasis, and *Salmonella* spp.[21,225,264] In addition, the AIDS wasting syndrome (HIV infection without superimposed opportunistic enteric infection of known cause) is part of the CDC case definition for AIDS.[59] Infection with any organism requires more attention because of malnutrition and co-morbidity.[203] Patients with AIDS have been shown to have D-xylose malabsorption and steatorrhea, and on jejunal and rectal biopsy specimens, a specific pathologic process can be demonstrated in the lamina propria of the small intestine and colon.[225] Before institution of highly active antiretroviral therapy (HAART), a significant proportion of patients with AIDS and severe small intestinal injury had enterocyte infection,[224] and infections occurred more frequently and were more likely to be severe, recurrent, persistent, or associated with extraintestinal disease.

TABLE 50–4 Organisms That Cause Gastrointestinal Tract Infections in Patients with AIDS

Area	Organisms
Esophagus	*Candida albicans**
	Cytomegalovirus*
	Herpes simplex virus*
Hepatobiliary	Cytomegalovirus

	Entamoeba histolytica
	Herpes simplex virus*
	Salmonella species*
	Shigella species

**Diseases of the gastrointestinal tract that fulfill the Centers for Disease Control and Prevention surveillance case definition of AIDS.*

The occurrence of opportunistic infections in people infected with HIV should be considered as infections that occurred before and those since the advent of HAART. In 1993, 11,285 HIV-infected children aged 18 years or younger in the United States were hospitalized, compared with an estimated 3419 in 2003 (a 71% decrease).[227] The inpatient fatality rate also decreased from 5 percent in 1994 to 1.8 percent in 2003. In Thailand, the hospitalization rate in children decreased from 31 percent during the first 24-week period to 2 percent during weeks 120 to 144 after initiation of HAART.[327] The mortality rate also decreased from 5.7 percent in the first 24 weeks to 0 to 0.6 percent in the subsequent weeks of HAART therapy.[327] In another study in the United States, the impact of HAART on the overall incidence of opportunistic infection was significant, with a decline in incidence from 14.4 to 1.1 cases per 100 patient-years.[285] A study in adults examined the annual incidence of bacterial diarrhea before and during the HAART era in a large cohort of people with HIV infection.[285] Between 1992 and 2002, the overall rate of bacterial diarrhea in people with clinical AIDS decreased (odds ratio, 0.4; 95% confidence interval, 0.2 to 0.6). *C. difficile* was the most common cause of bacterial diarrhea. HAART can result in complete clinical, microbiologic, and histologic responses in patients with AIDS infected with *Cryptosporidium parvum* and *Enterocytozoon bieneusi*[56] and in patients with HIV enteropathy.[225] Guidelines for prevention of opportunistic infections, including those involving the GI tract, have been published.[64]

ORGANISMS THAT CAUSE ACUTE GASTROENTERITIS

BACTERIA

Many bacterial, viral, and parasitic organisms produce diarrhea in humans. Tables 50–5 and 50–6 show the major bacterial enteric pathogens associated with acute infectious diarrhea.[80] These organisms are discussed here in alphabetical order for ease

TABLE 50–5 Pathogenic Bacteria Associated with Acute Infectious Diarrhea

Agent	Epidemiologic Considerations
Aeromonas hydrophila	Water, food, or animal exposure
Bacillus cereus	Food exposure
Campylobacter jejuni	Animal or food exposure
Clostridium difficile	Exposure to antimicrobial agents
Clostridium perfringens	Food exposure
Listeria monocytogenes	Food exposure
Plesiomonas shigelloides	Water, fish, or animal exposure
Salmonella species	Exposure to carrier; food and reptile exposure
Shigella species	Exposure to an infected person or to contaminated food
Staphylococcus aureus	Food exposure
Vibrio cholerae O1	Food or water exposure
Vibrio cholerae O139	Food or water exposure
Vibrio parahaemolyticus	Seafood exposure
Yersinia enterocolitica	Food or animal exposure

TABLE 50–6 Pathogenic *Escherichia coli* Associated with Acute Infectious Diarrhea

Class of *E. coli*	Abbreviation	Usual Presentation of Disease
Shigatoxigenic	STEC	Bloody diarrhea, water- and food-borne outbreaks, associated with hemorrhagic colitis and hemolytic-uremic syndrome
Enterotoxigenic	ETEC	Watery diarrhea in children living in and travelers visiting developing countries
Enteroinvasive	EIEC	Dysentery in adults and watery diarrhea, occasionally food-borne outbreaks
Enteropathogenic	EPEC	Acute and chronic watery diarrhea in infants in nurseries, diarrhea in children younger than 1 year in developing countries
Enteroaggregative	EAEC	Acute and chronic watery diarrhea in children

of reference. The relative importance of each organism as a cause of diarrhea varies in different populations.

Aeromonas hydrophila

Aeromonas spp. are gram-negative bacteria found in soil and fresh and brackish water worldwide. *Aeromonas* spp. are recognized as colonizers and pathogens of cold-blooded animals, including fish, reptiles, and amphibians.[16] *Aeromonas* spp. have been associated with a wide spectrum of human disease, most frequently gastroenteritis, soft tissue infection, and bacteremia, especially in immunocompromised hosts.[16,196] Of the 14 species in the genus, *Aeromonas hydrophila*, *Aeromonas veronii*, *Aeromonas caviae*, *Aeromonas jandaei*, and *Aeromonas schubertii* have been associated with human disease; the first three are defined as major pathogens and the species associated with gastroenteritis.[196] Because many clinical laboratories cannot perform precise identification, most species isolated are reported as *A. hydrophila*.

The role of *A. hydrophila* in human diarrhea remains uncertain. Despite the association of this organism with acute gastroenteritis and in some studies its more frequent isolation from patients with diarrhea than from healthy controls,[196] volunteers who have been fed the organism have not become ill.[270] *A. hydrophila* has been isolated from stools of less than 3 percent of healthy humans[16]; however, in Thailand, the isolation rate from healthy controls increased with age, up to 27 percent in adults.[16] *A. hydrophila* strains have been shown to produce both cytotoxin and enterotoxin, including heat-labile (cholera-like) enterotoxin and heat-stable enterotoxins.[365] Children with watery diarrhea associated with *Aeromonas* are significantly more likely to have organisms that possess genes for both a heat-labile cytotonic enterotoxin and the heat-stable cytotonic enterotoxin than are control children.[11] Other toxic or invasive properties may be important in production of disease because a fourth of patients have a dysentery-like illness.[196]

Bacillus cereus

Bacillus cereus is an aerobic, spore-forming, gram-positive bacillus that is a rare cause of food poisoning in the United States.[60,244] Although frequently present in food, *B. cereus* should be suspected as the cause of GI tract illness if appropriate symptoms are present and if incriminated food, particularly fried rice, contains 10^5 or more *B. cereus* organisms per gram.[62] Two distinct forms of GI tract illness can be produced by this organism. One is caused by production of a low-molecular-weight (1.2-kd) preformed emetic toxin, cereulide, that survives high temperatures, exposure to trypsin, and pH extremes. The other is caused by a group of three enterotoxins sensitive to high temperatures, proteolytic enzymes, and acids and is formed in vivo.[365] If the strain causing illness produces the emetic toxin, a syndrome occurs that resembles illness produced by staphylococcal enterotoxin, with nausea, vomiting, and abdominal cramps that begin within 1 to 6 hours of ingestion. Rarely, illness associated with the emetic toxin is followed by fulminant liver failure.[97] The diagnosis may be difficult to confirm because heating may kill the organism but leave the toxin intact. If the strain produces enterotoxins, profuse watery diarrhea and abdominal pain begin within 6 to 24 hours, with minimal or no vomiting. Some strains produce both toxins, whereas others produce only one toxin. Symptoms caused by either toxin usually resolve in less than 24 hours, and fever rarely occurs. Spores of *B. cereus* are resistant to heat and, therefore, may withstand a brief period of cooking or boiling. *B. cereus* can grow in temperatures ranging from 25° C to 40° C. *B. cereus* also has been associated with panophthalmitis, endophthalmitis, pneumonia, bacteremia, endocarditis, and meningitis.[105]

Campylobacter

*Campylobacte*r spp. are recognized as one of the most important causes of acute diarrheal disease in humans throughout the world[15,55,202] and are a major bacterial cause of diarrhea in the United States.[15,70] Most diarrheal illness in the United States caused by *Campylobacter jejuni* is food-borne.[245] Currently, 18 *Campylobacter* spp. and subspecies are recognized. *C. jejuni* and *Campylobacter coli* are the two predominant species, although use of selective media and lack of use of stool filtration techniques may preclude isolation of other *Campylobacter* spp.[202,231,411] Many clinical microbiology laboratories do not differentiate *C. jejuni* and *C. coli*. *Campylobacter fetus*, recognized as a cause of fever, bacteremia, and meningitis in immunocompromised hosts and of abortion, rarely causes diarrhea. People infected with *C. jejuni* may develop diarrhea, cramping abdominal pain, chills, and fever. Gross rectal bleeding may occur, and mucus and fecal leukocytes may be present, resembling the illness produced by *Shigella*. The clinical presentation also may mimic that of inflammatory bowel disease. Both a heat-labile enterotoxin and mucosal invasion have been incriminated in the pathogenesis. *C. jejuni* also has been associated with reactive arthritis and Guillain-Barré syndrome.[278,393]

Phylogenetic trees have been established for *Campylobacter* and contain three distinct clades (species groups). The first consists of *C. fetus*, *Campylobacter hyointestinalis*, and *Campylobacter mucosalis*, all generally associated with disease in farm animals, although *C. fetus* and *C. hyointestinalis* produce human disease. The second clade consists of *C. coli*, *C. jejuni*, *Campylobacter helveticus*, *Campylobacter lari*, and *Campylobacter upsaliensis*; all (except *C. helveticus*) have been associated with gastroenteritis in humans. The third clade contains *Campylobacter curvus*, *Campylobacter concisus*, *Campylobacter gracilis*, *Campylobacter rectus*, *Campylobacter showae*, and *Campylobacter sputorum*, organisms generally associated with the periodontal cavity of humans and animals.

Helicobacter pylori (formerly *Campylobacter pylori*) has been isolated from the stomach and duodenum of patients with histologically confirmed type B antral gastritis, peptic ulcer disease, duodenal ulcers, and gastric lymphoma.[46] This organism is not associated with diarrhea. *Helicobacter cinaedi* and *Helicobacter fennelliae* were identified previously as *Campylobacter* spp. but have been reclassified.

Clostridium perfringens

Clostridium perfringens types A, C, and D produce an enterotoxin that is implicated in the pathogenesis of disease caused by this organism.[365] Most food-borne outbreaks are caused by type A strains. *C. perfringens* causes a short-duration food poisoning syndrome.[251] After contaminated meat or poultry products have been ingested, in vivo sporulation occurs in the small intestine, with release of a structural spore protein that has enterotoxic and cytotoxic properties. The heat-labile, 35-kd, single-polypeptide enterotoxin induces fluid accumulation in ileal loops in animals and produces diarrhea in humans. Within 14 hours after ingesting contaminated food, patients experience watery diarrhea and abdominal pain with minimal nausea, vomiting, or fever ensuing. Illness resolves in less than 24 hours. Less than 5 percent of *C. perfringens* isolates contain the chromosomal *cpe* gene encoding this toxin. *C. perfringens* type C also is associated with a rare destructive intestinal disease called *enteritis necroticans* or *pigbel*. These strains produce three toxins (alpha-toxin, beta-toxin, and an enterotoxin) of potential pathogenetic significance.[365] Enteritis necroticans occurs after ingestion of undercooked pig at pork feasts in Papua, New Guinea. It is characterized by vomiting, abdominal pain, bloody diarrhea, and small bowel necrosis, with peritonitis, shock, and death.[275]

Escherichia coli

Several recognized categories of *Escherichia coli* produce diarrhea (see Table 50–6).[279,365] *E. coli* is among the most common cause of bacterial diarrhea in humans worldwide.[315]

Shiga toxin–producing *E. coli* (STEC) produces bloody diarrhea, usually without fever. This hemorrhagic colitis syndrome has been recognized to be caused most often by *E. coli* O157:H7 and other STEC strains, which produce large quantities of a potent cytotoxin[65,210,279,365] similar or identical to the cytotoxin produced by *S. dysenteriae* serotype 1.[210] STEC also is referred to as enterohemorrhagic *E. coli* (EHEC) and verotoxin *E. coli* (VTEC).[323] Several closely related toxins are recognized. The *E. coli* toxin that essentially is identical to Shiga toxin made by *S. dysenteriae* is called Shiga toxin 1 (Stx1, also called verotoxin 1). A structurally and functionally related toxin that is distinct immunologically is called Stx2 (or verotoxin 2). Both toxins are encoded by bacteriophages. Multiple additional variants exist that are more closely related to the second toxin. *E. coli* organisms that produce high levels of cytotoxin are important clinically because, like *S. dysenteriae* 1, they have been incriminated as etiologic agents of hemolytic-uremic syndrome.[317] Most reported outbreaks result after ingestion of contaminated food or water. Healthy cattle harbor the organism as part of their intestinal flora and are the main animal reservoir for STEC. Direct transmission from animals and their environments to humans in public settings where children come in contact with farm animals, such as petting zoos, represents a public health concern.[319] Hemolytic-uremic syndrome is characterized by the triad of hemolytic anemia, thrombocytopenia, and renal insufficiency and is associated most frequently with *E. coli* O157:H7. Approximately 8 percent of people infected with *E. coli* O157:H7 develop hemolytic-uremic syndrome; most reported cases occur in children younger than 5 years old.

Enterotoxigenic *E. coli* (ETEC) disease is caused by heat-stable (ST) and heat-labile (LT) enterotoxins.[279,328,365,398] STa and LT-I are associated with disease in humans and other animals, whereas STb is associated primarily with disease in piglets, and LT-II has been associated only with animal disease. ETEC strains from humans with diarrhea produce STa only, LT-I only, or both together. These toxins often are produced by strains that have colonization factor antigens, which are important in adherence of the organism to the GI tract.[279] ETEC strains belong to many different serogroups and cause disease in patients of all ages, especially infants and children living in developing countries and travelers from developed to developing countries, and outbreaks of food-borne disease in the United States.[328,398]

Enteroinvasive *E. coli* (EIEC) is related antigenically and biochemically to *Shigella* and causes either a dysentery-like illness or watery diarrhea. EIEC possesses 140-Md plasmids that encode invasiveness and contribute to dysenteric illness. This plasmid is related closely to the plasmids that are associated with *Shigella* virulence.[279] The watery diarrhea may be due to an enterotoxin referred to as *EIEC enterotoxin*. Infections generally occur in adults; food-borne outbreaks have been reported.

Enteropathogenic *E. coli* (EPEC) has been incriminated as a cause of both sporadic and epidemic diarrhea in infants, especially in developing countries.[100] Originally, EPEC was a term used to describe all *E. coli* organisms associated with diarrheal syndromes. Currently, the term EPEC is defined more narrowly. Volunteer studies[100] and studies comparing rates of isolation from sick and healthy infants[279] have demonstrated that EPEC organisms are pathogens, although these strains rarely cause diarrhea in older children and adults. The specific mechanisms involved in production of disease may be related to adherence, which can be demonstrated in HEp-2 cells.[101,279] The proposed three stages of EPEC infection include (1) intestinal colonization mediated by the bundle-forming pilus; (2) induction of the attaching and efficacy lesion through intimin and other secreted proteins; and (3) signal transduction, resulting in induction of a net secretory state.[95,100,102,365]

Enteroaggregative *E. coli* (EAEC) is a cause of acute diarrheal illness among many different subpopulations in both developing and industrial regions of the world,[191,192] including the United States. EAEC also has been associated with chronic diarrhea in developing countries[39,156,364] and in adults with traveler's diarrhea.[3,156] Bloody diarrhea has been described in approximately a third of patients. Chronic persistent diarrhea is especially likely to be caused by EAEC.[361,364] Pathogenicity of EAEC in humans has been confirmed in volunteer studies and outbreak investigations.[252,376] EAEC is defined by its aggregative or stacked brick pattern of adherence in HEp-2 cell assays,[279] the "gold standard" for identification. Some strains elaborate an enterotoxin (EAEC ST enterotoxin 1 [EAST1]).[279,359] However, this toxin is not uniquely present in EAEC, nor is it found consistently (only 40-45% of EAEC pathogens are EAST1-positive in some series).[279,361] A plasmid-encoded enterotoxin may be important, but its role is not fully defined.[124,282] Many EAEC pathogens have genes for aggregative adherence fimbriae (*AAF/I* or *AAF/II*).[85,334] A gene probe that appeared in initial studies to be both sensitive and

specific appears to be less useful than is the original HEp-2 cell assay.[131,334]

Listeria monocytogenes

The genus *Listeria* includes six species, of which two are potentially pathogenic, *Listeria monocytogenes* and *Listeria ivanovii*.[410] *L. monocytogenes* is a rare but serious localized and generalized infection in humans. Listeriosis is primarily food-borne. Acute febrile gastroenteritis caused by *L. monocytogenes* contamination of a variety of foods has been described.[28,67,86,161] The foods most frequently implicated are soft cheeses and dairy products; pâtés and sausages; smoked fish; and industrially produced, refrigerated, ready-to-eat products that are eaten without cooking or reheating. *L. monocytogenes* tolerates high concentrations of salt and relatively low pH and is able to multiply at refrigerator temperatures. Bacteremia may complicate diarrheal illness caused by this organism,[28,67,352] especially in immunocompromised hosts, during pregnancy, and in older people. Symptoms include fever (temperature as high as 40.3° C), chills, headache, cramps, myalgia, and diarrhea.[28,291]

Plesiomonas shigelloides

Plesiomonas shigelloides is a gram-negative bacillus that has been associated with opportunistic infections in immunocompromised hosts and with sporadic cases of diarrhea in immunocompetent hosts in a variety of countries.[187,208] In some case-control studies, the organism has been found to be associated with diarrhea, whereas in others, it has not.[12] Whether a subset of *P. shigelloides* has virulence genes that make them pathogens, whereas other members of this species do not have such genes, is unclear. Organisms produce ST and HL enterotoxins, but their associations with disease are unknown.[365] The organism has been isolated from surface water and the intestines of freshwater fish and many animals, including dogs and cats.[404] *Plesiomonas* occurs commonly in tropical and subtropical areas from which most stool isolates have been reported.[187] Patients with *P. shigelloides* infection describe self-limited diarrhea, occasionally characterized by blood and mucus. The organism is a rare cause of extraintestinal illness, such as meningitis or bacteremia.[208] Appropriate antimicrobial therapy appears to shorten the duration of diarrheal illness.[196,208] The organism has failed to produce illness when fed to volunteers, and its role as an enteric pathogen remains unknown.[173]

Salmonella

Identification of *Salmonella* spp. in the laboratory is not difficult, but the various terminologies used to classify *Salmonella* spp. is confusing. Most hospital laboratories biochemically differentiate *Salmonella* ser. Enterica and *Salmonella* ser. Typhi, although other nomenclature schemes may be used.[51] Since 1993, the *Salmonella* isolates most frequently reported have been *S. enterica* serotype Typhimurium and *S. enterica* serotype Enteritidis.[58,73] Several clinical syndromes are caused by *Salmonella*: the carrier state; acute gastroenteritis; bacteremia, enteric fever, or both; and dissemination with localized suppuration, such as abscess, osteomyelitis, or meningitis. Although *S.* ser. Typhi is the prototype of *Salmonella* able to penetrate intestinal mucosa, reach intestinal lymphatic tissue, and disseminate, other *Salmonella* organisms, particularly *Salmonella* Paratyphi A, occasionally behave in this manner.[73,185] Invasion of intestinal epithelium by *S.* ser. Typhi and occasionally by nontyphoidal *Salmonella* strains is a well-known virulence trait of *Salmonella* spp. Most nontyphoidal *Salmonella* serotypes are associated with watery diarrhea. *Salmonella* rarely causes an illness similar to pseudomembranous colitis.[190] *Salmonella* gastroenteritis occurs throughout life but most commonly in the first 5 years of life, decreases during childhood, and remains relatively constant throughout the adult years.[73] Although most episodes of *Salmonella* infection are food-borne, reptiles, including turtles, snakes, lizards, and iguanas, carry certain serotypes of *Salmonella* in their intestinal tracts and have been associated with episodes of salmonellosis.[281,319,387] Numerous outbreaks of disease caused by *Salmonella* after ingestion of contaminated food products, including eggs, milk, ice cream, peanut butter, and fresh produce, have been reported.[48,68,171,245,326] Food-borne outbreaks associated with *Salmonella* have been reported from fairs or festivals, hospitals, nursing homes, and prisons.[73]

Shigella

Four serogroups of *Shigella*, containing more than 40 serotypes and subtypes, exist.[215] *Shigella sonnei* accounts for more than 75 percent of shigellosis in the United States. *Shigella boydii* and *Shigella dysenteriae* are uncommon causes of diarrhea in the United States. In 2005, a strain of *S. sonnei* resistant to ampicillin and TMP-SMX emerged as a cause of prolonged community-wide outbreaks of shigellosis associated with childcare centers in three states.[368] In addition to person-to-person spread, shigellae can be transmitted through contaminated foods, sexual contact, and water used for drinking or recreational purposes.[120,245] Patients with *Shigella* isolated from stool may present with several clinical patterns: asymptomatic excretion,[312] enterotoxin-like watery diarrhea, bacillary dysentery,[385] arthritis similar to that seen in Reiter syndrome,[9] and hemolytic-uremic syndrome occurring after infection with *S. dysenteriae* 1. The arthritis occurs 2 to 5 weeks after the dysenteric illness, characteristically in patients with histocompatibility antigen HLA-B27. Postinfectious arthritis also occurs in patients after they have had *Salmonella*, *Campylobacter*, and *Y. enterocolitica* infections.[119] *S. dysenteriae* 1 produces Shiga toxin in high levels.[385] Infection by *Shigella* spp. rarely occurs in the first few months of life but is a common occurrence in children between the ages of 6 months and 10 years.[73]

Staphylococcus aureus

Two enteric syndromes have been associated with *Staphylococcus aureus*. Although previously it was considered a cause of AAC, whether antibiotic-associated staphylococcal enteritis actually exists as a disease entity is unclear because most antibiotic-associated colitis is associated with *C. difficile*.[33] The existence of the other major staphylococcal enteric syndrome is well established. Staphylococcal food poisoning is caused by ingestion of food contaminated with preformed *S. aureus* ST enterotoxin.[123,235] Illness usually occurs within 2 to 4 hours after ingestion of contaminated food[244] and is manifested by vomiting and diarrhea. Although multiple enterotoxins (A to F) have been described, only enterotoxin types A to E cause enteric disease. Type A has been responsible for more than half of the reported outbreaks of staphylococcal food poisoning in the United States.[186,235] All toxins are antigenically related, low-molecular-weight proteins. Illness caused by these preformed toxins begins within 1 to 6 hours after ingestion and lasts less than 12 hours. Nausea, vomiting, abdominal pain, and diarrhea occur without fever.

Vibrio cholerae

Strains of *Vibrio cholerae* are classified according to somatic or O groups. *V. cholerae* strains are separated further into two main serotypes (Ogawa and Inaba) and two biotypes (classic and El Tor).[209] *V. cholerae* responsible for epidemic cholera belong to serogroups O1 and O139; all other *V. cholerae* strains belong to serogroups other than O1 and O139 and occasionally cause diarrhea or extraintestinal infections.[197] Cholera affects people of all

ages, but children are involved disproportionately. *V. cholerae* O139 infection occurs primarily in Southeast Asia. *V. cholerae* O1 infection occurs primarily in Asia, Africa, and South America, although a focus is present in the Gulf Coast of the United States.[209,243,271] Most clinical isolates of *V. cholerae* O1 in the United States are associated with foreign travel and with ingestion of undercooked seafood,[73,271] and many are resistant to antimicrobial agents.[386] Crabs harvested from the U.S. Gulf coast are a common source of cholera.[73] After Hurricane Katrina in 2005, crabs were the source of illness for certain cases of cholera.[73,74] Epidemic cholera appeared in Peru in January 1991 and subsequently spread throughout the Americas, including the United States.[209] The epidemic strain is biotype El Tor, serotype Inaba. This strain can be differentiated from the strain of *V. cholerae* that is endemic to the U.S. Gulf coast by production of hemolysin and by molecular subtyping techniques.

V. cholerae O1 adheres to and multiplies on small intestinal mucosa. Diarrhea occurs after elaboration of several toxins, the most important of which is cholera toxin, an HL enterotoxin composed of one A and five B subunits.[365] The B subunits bind the toxin to the terminal galactose of the G_{M1} ganglioside receptors present on intestinal mucosal cells. The A subunit adenosine 5′-diphosphate ribosylates the guanosine 5′-triphosphate–binding regulatory protein of adenylate cyclase in gut epithelium.[365] The resulting intracellular increase in cyclic adenosine monophosphate causes inhibition of sodium absorption and causes chloride and fluid secretion in the small intestine. Most non-O1 strains isolated from ill people in the United States lack cholera toxin–like activity[197] and, when tested with gene probes, are found not to possess gene sequences homologous to those of cholera toxin.[209] Two additional toxins are produced by *V. cholerae*, Zot (zonula occludens toxin) and Ace (accessory cholera enterotoxin). Strains of *V. cholerae* belonging to serotypes other than O1 and O139 are much less significant pathogens, although they can cause mild and occasionally profuse, watery diarrhea. Other *Vibrio* spp., including *Vibrio fluvialis*, *Vibrio mimicus*, *Vibrio hollisae*, and *Vibrio furnissii*, have been shown occasionally to cause GI tract disease.[197]

Vibrio parahaemolyticus

Vibrio parahaemolyticus is a gram-negative, halophilic bacterium that inhabits warm estuarine waters worldwide. The organism has been found in water, shellfish, fish, and plankton[180] and has caused outbreaks of gastroenteritis after ingestion of contaminated seafood.[258,271] Although widely distributed in coastal waters, *V. parahaemolyticus* is an uncommon cause of diarrhea where consumption of raw seafood is common. Clinical manifestations of infection with *V. parahaemolyticus* are gastroenteritis in 59 percent of cases and include abdominal cramps, nausea, and, less frequently, vomiting, headache, low-grade fever, and chills; wound infections, including hemorrhagic cellulitis in 34 percent; and septicemia in 5 percent.[87] A dysentery-like syndrome has been described in India and Bangladesh.[193] Preexisting liver disease predisposes infected patients to development of septicemia and death.[180] A selective culture medium is required for isolation of the organism from stool cultures.

Yersinia enterocolitica

Yersinia enterocolitica is a gram-negative bacillus that appears to be a common cause of gastroenteritis among children in Europe and Canada but is a relatively uncommon cause of enteritis in the United States, where *Y. enterocolitica* O8 has been the predominant clinical serotype.[45] The ingestion of contaminated milk or food such as chitterlings[206,232] has been implicated as the mode of transmission in reported outbreaks. The clinical manifestations vary according to the age of the person involved. Illness in children younger than 5 years usually is self-limited gastroenteritis. Stools may contain blood and mucus or be watery. Associated symptoms consist of fever, vomiting, and abdominal pain. Older children may present with abdominal pain associated with mesenteric adenitis that mimics acute appendicitis. Adults develop diarrhea and abdominal pain less frequently than do children but may present with polyarthritis, arthralgia, or erythema nodosum. Patients with beta-thalassemia and iron overload are at an increased risk for development of severe yersiniosis.[6]

VIRUSES

Acute infectious diarrhea of viral origin generally is a self-limited disease characterized by various combinations of diarrhea, nausea, vomiting, abdominal cramps, headaches, myalgias, and low-grade fever.[254,263,289,412] Bowel movements are watery and generally do not contain mucus or blood. Vomiting is the most common manifestation of this condition. Rotavirus, enteric adenovirus, astrovirus, and norovirus are common causes of viral gastroenteritis (Table 50–7). Other viruses, including coronaviruses, Breda virus, parvoviruses, pestiviruses, picobirnaviruses, and toroviruses, have been linked to gastroenteritis in humans with varying degrees of certainty.[34,222,440]

Rotaviruses

Rotavirus is a 70-nm particle that on electron microscopy resembles a wheel with radiating spokes (Fig. 50–1). Rotavirus was associated with diarrhea in children first by Bishop and associates in 1973.[42] Since then, human rotavirus has been established as a

TABLE 50–7 Viruses Associated with Gastroenteritis

Virus	Approximate Size (nm)
Rotavirus	70
Enteric adenovirus (types 40 and 41)	70-80
Astrovirus	20-30
Calicivirus (noroviruses)	35-39
Parvovirus	20-30

major cause of acute gastroenteritis in infants, children, and various animal species worldwide. Six antigenically distinct groups of rotavirus (A through F) have been recognized. Three of these groups (A, B, and C) have been identified in humans. The group A rotaviruses are those associated with infantile diarrhea.[130] Group B rotaviruses have caused epidemics of cholera-like illness in China and sporadic cases elsewhere.[279,366] Group C rotaviruses have caused outbreaks of diarrhea in children in many countries.[286]

Group A rotaviruses have two outer capsid proteins, a hemagglutinin (VP4) and a glycoprotein (VP7), each of which induces neutralizing antibodies.[130] Fourteen different antigenic types of VP7 (which define serotype) and seven human serotypes of VP4 (also designated P serotypes because VP4 is protease sensitive), including two subtypes, are known. This number, combined with the ability of the gene segments to reassort independently, indicates that rotaviruses are complex antigenically.[130] VP7 (also designated G serotype) serotypes 1, 2, 3, 4, and 9 are of epidemiologic importance. Epidemiologic studies indicate that these serotypes are endemic in most regions, that one serotype tends to be predominant at any particular time, that predominant serotypes differ among regions in the same country, and that predictable cycles of change of the predominant serotype may occur.[254]

Rotavirus gastroenteritis affects more than 90 percent of children by the time they are 3 years of age and may cause moderate to severe vomiting that precedes diarrhea. It accounts for 10 to 50 percent of the cases of diarrhea in children and is the most common cause of diarrhea in infants and children during winter months in colder climates. Rotavirus accounts for 35 to 50 percent of infants and young children hospitalized for acute diarrhea. In the United States, rotavirus accounts for 60,000 hospitalizations per year and 37 deaths.[140] Stools usually are watery or soft, and the presence of blood or leukocytes is rare. Asymptomatic rotavirus infections occur frequently,[289,311] and re-infection appears to be a common event.[415,416] The mechanism of spread is fecal-oral; whether respiratory transmission occurs is uncertain. Shedding of virus most frequently occurs from a few days before to 10 days after the onset of illness.[311] Before licensure of the rotavirus vaccine in 2006, outbreaks of rotavirus in childcare centers occurred commonly (usually in the colder months), were caused by a single serotype,[289] and were manifested by the fact that half the infected children were asymptomatic.[30]

The incubation period of human rotavirus infection ranges from 2 to 4 days. Animal models suggest that whereas morphologic changes in the villous tip cells contribute to malabsorption and diarrhea, altered cell function, resulting in enzyme deficiencies, results from enterocyte immaturity and may account for the major part of the disordered physiologic findings. Adults with rotavirus gastroenteritis treated with nitazoxanide showed a significant reduction in time to resolution of symptoms compared with controls (1.5 versus 2.5 days).[341] In hospitalized children, nitazoxanide reduced the duration of rotavirus infection.[338]

The first rotavirus vaccine licensed in the United States was associated with an increased rate of intussusception, resulting in its withdrawal from the market within 14 months of being licensed.[274,332] In February 2006, a bovine-based pentavalent rotavirus vaccine was licensed by the FDA for use in infants in the United States[19,71] as a three-dose vaccine administered orally at 2, 4, and 6 months of age, with all doses administered by the time the child reaches 32 weeks of age. A two-dose orally administered, attenuated monovalent G1 (P8) human rotavirus vaccine is available in many countries throughout the world and is being reviewed by the FDA for licensing in the United States.[343]

Astroviruses

Astroviruses, identified in 1975, are 20 to 30 nm in diameter and have a characteristic five- to six-pointed star. The virus genome is a positive-stranded RNA of about 7500 nucleotides that encodes four structural proteins.[157,422] Eight different antigenic types have been described. Astrovirus gastroenteritis occurs worldwide and has been associated with outbreaks of mild gastroenteritis in schools, childcare centers, pediatric wards, and nursing homes.[94,157,164,263] Illness is restricted primarily to children and elderly people; 80 percent or more of adults have antibodies against the virus. The incubation period is 3 to 4 days.[157] Symptoms include fever and malaise, followed by watery diarrhea that may last approximately 3 days. Vomiting is an uncommon symptom. Short-term intolerance of monosaccharides and more prolonged intolerance of cow's milk protein have been reported after astrovirus infection.[157]

Noroviruses

Members of the genus *Norovirus* in the family *Caliciviridae* have been identified as the most common viral cause of acute gastroenteritis in humans, with an estimated 23 million cases occurring annually.[43,407] The mean incubation period for norovirus is 24 to 48 hours. The primary routes of transmission are fecal-oral, including consumption of fecally contaminated food or water; direct person-to-person contact, especially in schools, childcare centers, restaurants, summer camps, hospitals, nursing homes, and cruise ships[10,69,200,201,221,330]; and through contaminated objects or environments. A low inoculum dose is required for infection, and prolonged, asymptomatic shedding can occur in infected people. Clinical manifestations include acute onset of vomiting, nonbloody diarrhea, or both lasting 12 to 60 hours. Molecular epidemiology techniques have identified substantial diversity in strains, indicating that epidemic strains of norovirus might be more virulent or more environmentally persistent than are nonepidemic strains.[43] The identification of human histo-blood group antigens as norovirus receptors opens a new approach for evaluation of susceptibility and therapy of norovirus infection.[136] The demonstration of an in vitro cell culture infectivity assay for human norovirus may improve understanding of the pathogenesis of human norovirus infections.[389]

Enteric Adenoviruses

Human adenoviruses of subgroups A to F have been identified as etiologic agents in a wide range of human diseases, including conjunctivitis, upper respiratory tract infections, and pneumonia. A subgroup of fastidious adenoviruses (group F) with a distinct set of antigenic determinants and specific tissue culture growth characteristics have been shown to be associated with acute gastroenteritis and are referred to as *enteric adenoviruses*.[50,226,412] These agents fail to propagate in conventional cell lines used to grow adenoviruses but grow readily in 293 cells, an adenovirus type 5 transformed line.

The enteric adenoviruses in group F include serotypes 40 and 41.[226] Types 40 and 41 both appear to be widespread and endemic causes of diarrhea in children. Antibody prevalence to enteric adenovirus increases from 20 percent during the first 6 months of life to 50 percent or greater by the third or fourth year of life.[372] Seasonal shifts in the predominance of types 40 and 41, similar to those described for rotavirus, may occur. A 9-year study in Washington, DC, found that enteric adenovirus types 40 and 41 circulate simultaneously all year.[50] Infection with enteric adenovirus appears to increase in the summer, although with a less marked seasonal variation than that exhibited by rotavirus, which peaks in the winter.[50] Outbreaks of enteric adenovirus diarrhea have been described in childcare centers, where asymptomatic excretion is a common occurrence.[412]

PARASITES

The most important protozoa known to cause diarrhea in various populations in the United States are *Entamoeba histolytica*, *G. lamblia*, and spore-forming protozoa: *Cryptosporidium parvum*, *Isospora belli*, *Microsporidium* spp. (*Encephalitozoon intestinalis* and *Enterocytozoon bieneusi*), and *Cyclospora cayetanensis*. Among helminths, *Strongyloides stercoralis* and *Trichuris trichiura* may produce diarrhea. Data associating *Ascaris* and hookworm with diarrhea are lacking, but both cause abdominal pain. HIV infections stimulated renewed interest in several of these organisms, including various *Microsporidium* spp., *C. parvum*, and *I. belli*.[159] *Balantidium coli* is a cause of bloody diarrhea in humans. The roles of *Blastocystis hominis* and *Dientamoeba fragilis* as causes of diarrhea are not known.

Cryptosporidium

Cryptosporidium organisms are coccidian protozoa that invade and replicate within the microvillous region of epithelial cells lining the digestive and respiratory tracts of vertebrates.[79] *Cryptosporidium* spp. are related taxonomically to *Toxoplasma*, *Sarcocystis*, *Isospora*, and *Plasmodium* spp. Fecal-oral transmission of *Cryptosporidium* oocysts occurs from person to person, through ingestion of contaminated drinking water or recreational water, through consumption of contaminated food, or by contact with infected animals (cattle and sheep).[61,73,120,181,236] Unlike bacterial pathogens, *Cryptosporidium* are resistant to chlorine disinfection and can survive for days in treated recreational water, including swimming pools and recreational water parks.[120] Children aged 4 years old and younger appear to be at a particularly high risk for acquiring this organism.[73] Cryptosporidia have been implicated as a cause of diarrhea in travelers and of epidemics in hospitals, child-care centers, and other institutional settings worldwide. Other groups at risk include animal handlers, travelers to foreign countries with a high prevalence of *Cryptosporidium*, and hospital personnel. The largest water-borne outbreak of diarrhea documented in the United States was caused by *Cryptosporidium*.[246] Volunteer studies in adults showed that 132 oocysts cause disease.[112] The incubation period in humans has been estimated to be 2 to 14 days.

Cryptosporidiosis can be manifested with a wide spectrum of symptoms, including asymptomatic excretion, acute diarrhea, chronic diarrhea, epidemic diarrhea, severe life-threatening watery diarrhea, and biliary tract disease.[79] Watery diarrhea is the hallmark of symptomatic infections, but few if any features distinguish gastroenteritis caused by *Cryptosporidium* in the immunocompetent patient from other enteric infections. Stools do not contain blood or leukocytes. Vomiting, flatulence, abdominal pain, and low-grade fever routinely accompany diarrhea.[168] Symptoms usually subside in an average of 9 days. Patients may have cholera-like illness, transient diarrhea, relapsing episodes, or a protracted clinical course with unremitting, profuse diarrhea lasting for months accompanied by profound malabsorption and weight loss. Before HAART was instituted, enteritis caused by *Cryptosporidium* occurred in 10 to 15 percent of patients with AIDS in the United States and approximately 15 percent of patients with AIDS in the developing world.[248] The frequency with which *Cryptosporidium* and microsporidia are identified in stools of patients with AIDS is a reflection of the CD4 count; identification of the organisms and symptoms is more frequent when the count is less than 100 cells/μL.[141] Antiretroviral therapy is protective against disease.[56,248] Biliary tract infection with *Cryptosporidium* produces two syndromes: sclerosing cholangitis–type lesions, which cause progressive, irregular obstruction and dilation of the intrahepatic and extrahepatic bile ducts,[37] and acalculous cholecystitis, caused by infection of the wall of the gallbladder. Symptoms have been characterized by right upper quadrant pain, nausea, and vomiting.

Entamoeba histolytica

The life cycle of *Entamoeba histolytica* involves encystment of a trophozoite, followed by release of the trophozoite from the cyst under appropriate conditions in the GI tract (Fig. 50–2).[129] Trophozoites vary in size and are found in stools of patients with dysentery or diarrhea. The cyst is more resistant to environmental stresses and is the infective stage. Cysts are found more frequently in formed stools. The minimum period between ingestion of cysts and development of symptoms is 8 days. The incubation period ranges up to 95 days.

The genus *Entamoeba* contains many species, six of which can reside in the human intestinal lumen. *E. histolytica* is the only species definitely pathogenic. *Entamoeba dispar* and *Entamoeba moshkovskii* do not appear to be pathogenic. New approaches to identifying *E. histolytica* are based on detection of *E. histolytica*–specific antigen and DNA in stool and other clinical specimens.[142] Several molecular techniques, including polymerase chain reaction (PCR), have been developed for detection and differentiation of *E. histolytica*, *E. dispar*, and *E. moshkovskii*.

Clinical patterns that occur in patients with amebiasis consist of intestinal amebiasis, with the gradual onset of colicky abdominal pain and frequent bowel movements, tenesmus, and little or no constitutional disturbance; amebic dysentery, characterized by profuse diarrhea containing blood and mucus and the presence of constitutional signs, such as fever, dehydration, and electrolyte alterations; hepatic amebiasis, which usually presents as abscess formation without GI tract symptoms[8]; and asymptomatic

Figure 50–2 **A,** Trophozoite of *Entamoeba histolytica* with ingested material in the cytoplasm. **B,** Cyst of *E. histolytica* seen in a merthiolate-iodine-formalin–stained preparation from a stool specimen. Note two visible nuclei (×1000). *(From DuPont, H. L., and Pickering, L. K.: Infections of the Gastrointestinal Tract. New York, Plenum Publishing, 1980.)*

colonization. Patients may experience tender hepatomegaly, jaundice, weight loss, fever, and anorexia. The frequency of liver abscess in patients with amebiasis is between 1 and 5 percent. The complications of intestinal amebiasis include perforation, ameboma, stricture, hemorrhage secondary to erosion into a blood vessel, intussusception, ischiorectal abscess, fistulas, and rectal prolapse. People in the third through fifth decades of life have the highest incidence of infection and clinical symptoms, although people of all ages are susceptible.

Giardia intestinalis

Giardia intestinalis (formerly *G. lamblia*), a flagellated protozoan, is the most common intestinal parasite identified by public health laboratories in the United States.[63,146] Giardia infection is transmitted by the fecal-oral route and occurs after ingestion of *Giardia* cysts in fecally contaminated food or water or through person-to-person transmission.[120,236,245] The low infectious dose of 10 cysts places people in close contact, including children in childcare, at risk of acquiring infection.[331] The relative contribution of person-to-person, animal-to-person, water-borne, and food-borne transmission to sporadic human disease is unknown. Children appear to be more susceptible to *Giardia* than are adults. Specific conditions that predispose to giardiasis are hypogammaglobulinemia, secretory immunoglobulin A (IgA) deficiency, peptic ulcer disease, biliary tract disease, and pancreatitis. The parasite may exist in two forms: cyst and trophozoite (Fig. 50–3). After being ingested, each cyst divides into two trophozoites, which subsequently mature. The trophozoites usually are seen in duodenal aspirates and loose stools, whereas cysts can be found in formed stools and can remain viable and infectious in water for longer than 3 months. Scanning electron micrographic examination of *Giardia* reveals firm attachment to the intestine (Fig. 50–4).

People vary in their response to infection with *Giardia*, with the following clinical manifestations: asymptomatic; an acute illness with a sudden onset of explosive, watery, foul-smelling stools and flatulence, abdominal distention, nausea, and anorexia, with the absence of blood and mucus; and chronic diarrhea and malabsorption, with exacerbations and remissions of flatulence, abdominal distention, and abdominal pain often lasting for months.[309]

Strongyloides stercoralis

Strongyloides stercoralis is a nematode that infects humans through the intestinal tract or through skin if either comes in contact with soil that contains larvae. About one third of people with strongyloidiasis are asymptomatic, and the remainder may have skin, pulmonary, or, more frequently, GI tract involvement.[373] People at risk include residents and travelers to endemic areas; natives and residents of the Appalachian region in the United States; institutionalized patients; and people treated with corticosteroids, cimetidine, and antacids.[152] Epigastric abdominal pain occurs and is associated with diarrhea that contains mucus and blood. Some patients may complain of nausea, vomiting, and weight loss with

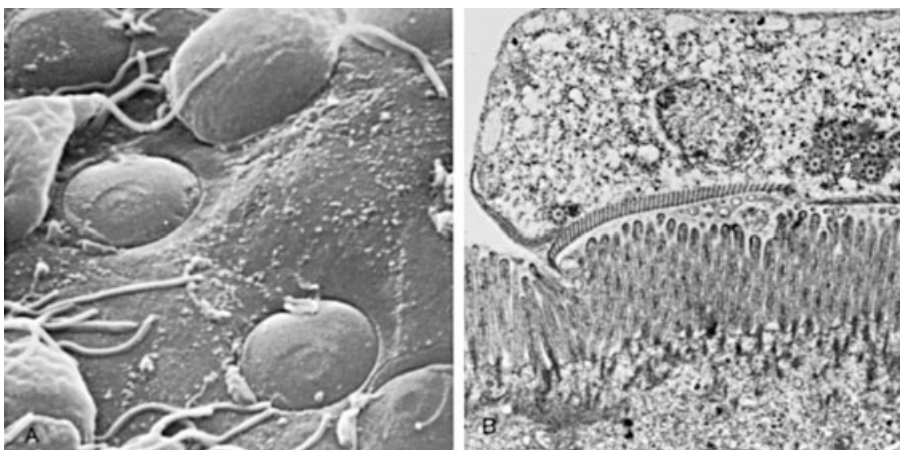

Figure 50–4 **A.** Scanning electron micrograph of an intestinal villus revealing firm attachment of *Giardia muris* trophozoites to the microvillous border. Circular dome-shaped lesions in the microvillous border are produced by attachment of the adhesive disk of trophozoite (×4600). **B.** Transmission electron micrograph of a *G. muris* trophozoite illustrating how lesions in the microvillous border are produced. Note that the edges of the adhesive disk penetrate the microvillous border and compress the microvilli centrally. The microvilli also show some vesiculation under the adhesive disk (×20,000). *(**A**, **B**, Courtesy of Dr. S. L. Erlandsen.)*

evidence of malabsorption. Eosinophilia and an urticarial rash are prominent features of infection. *S. stercoralis* hyperinfection syndrome can present in immunocompromised patients years after exposure and can result in multisystem organ involvement culminating in sepsis.[213] People infected with *S. stercoralis* should be treated with ivermectin or albendazole in an attempt to eradicate the infection.[259]

Isospora belli

Isospora was established as a cause of diarrhea in humans in the early 1900s, when sporadic cases of isosporiasis and a few clinical series were reported in the medical literature.[99] *Isospora belli* gained importance with the advent of AIDS and before HAART was shown to be an important cause of severe and prolonged gastroenteritis.[295] Humans are the only known host for *I. belli*, but the actual prevalence of this parasite is unknown. Infection can occur in adults and children and has been reported in infants with severe diarrhea.[239] This organism also has been implicated as a cause of traveler's diarrhea.[134]

Transmission is fecal-oral from one human to another, but the infective dose in humans is unknown. Oocysts may be present in stools for as long as 120 days after infection occurs. No animal reservoir of *I. belli* has been documented. Transmission is thought to occur by ingestion of oocysts contaminating food, water, or environmental surfaces.[239] *I. belli* oocysts are resistant to commonly used disinfectants and may remain viable for months in a cool, moist environment.

The clinical spectrum of disease caused by *Isospora* is indistinguishable from that described for *Cryptosporidium*. The spectrum includes asymptomatic infection, acute diarrhea in children in developing countries, and chronic diarrhea or severe protracted life-threatening diarrhea in patients with AIDS. Infection of the biliary tract in patients with AIDS by *Isospora* has been associated with acalculous cholecystitis.[36] The incubation period was 8 to 14 days in four subjects who had been exposed to the organism in the laboratory.[170] Fever, malaise, abdominal pain, and headache have been reported. Stools are watery and do not contain blood or leukocytes. Malabsorption, steatorrhea, severe weight loss, and chronic diarrhea lasting months to years are most likely occurrences in immunocompromised hosts.[92]

Microsporidia

Microsporidia are unicellular, spore-forming, obligate intracellular protozoal parasites that cause disease in a wide range of vertebrate and invertebrate hosts.[223,253] Of the more than 100 genera of microsporidia that have been identified, six cause disease in humans. The nontaxonomic term *human microsporidia* can refer to any of the microsporidia known to cause disease in humans: *Enterocytozoon* spp., *Encephalitozoon* spp., *Pleistophora* spp., and *Nosema* spp. Of these, *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis* (formerly *Septata intestinalis)* are the most important in GI tract disease of humans.[26,426] These organisms emerged as important opportunistic pathogens when AIDS became pandemic. Infections with these organisms have been documented in immunocompetent and immunosuppressed people from Africa, Asia, Europe, and North and South America.[367]

In animals, transmission occurs by ingestion of environmentally resistant, infective spores shed into the environment.[253] The person-to-person, fecal-oral route may play a role in transmission, and water-borne disease occurs.[84] The zoonotic potential has been documented for several *Encephalitozoon* species.[253] The clinical spectrum appears to depend on the immune status of the host. *E. bieneusi* and *E. intestinalis* have been detected in intestinal biopsy specimens of patients with AIDS, with a clinical picture of prolonged diarrhea and weight loss.[84] The primary location of all intestinal spore-forming protozoal infection is the small intestine, but colonic infection has been reported with *E. bieneusi*.[159] Infection of the biliary tract with *E. bieneusi* and *E. intestinalis* in patients with AIDS can cause sclerosing cholangitis–type lesions[322,371,434] and acalculous cholecystitis caused by infection of the wall of the gallbladder. *E. intestinalis* can infect lamina propria macrophages, fibroblasts, and endothelial cells and can disseminate to other organs, including liver, respiratory tract, and kidney.[159,434] Extraintestinal infection develops after infection with other species of microsporidia occurs.

Cyclospora

Cyclospora cayetanensis (formerly cyanobacteria or blue-green algae–like bodies) is a coccidian protozoon that first was diagnosed as causing infection in humans in 1977.[293] *Cyclospora* is transmitted by the fecal-oral route; direct person-to-person transmission is unlikely to occur because excreted oocysts require days to weeks under favorable environmental conditions to sporulate and to become infectious. An animal reservoir has not been described. Outbreaks of diarrhea caused by consumption of water and fresh fruits contaminated with *Cyclospora* have been described,[175,245,247] and travelers to developing countries are at increased risk for development of diarrhea caused by *Cyclospora*.[292] Most of the reported cases have occurred during the spring and summer. The mean incubation period appears to be 7 days. Clinical manifestations include asymptomatic excretion, acute watery diarrhea, and diarrhea that may be protracted for days to weeks with frequent, watery stools, which may remit and relapse.

DIAGNOSIS

Determination of the cause of an episode of acute infectious diarrhea depends on epidemiologic information, the clinical syndrome, laboratory tests, and knowledge or assessment of an organism for virulence factors. Because virulence properties determine clinical manifestations of disease, an understanding of pathophysiologic mechanisms guides the laboratory evaluation and empiric therapy. The major virulence properties of enteropathogens include adherence; production of enterotoxin, cytoskeleton-altering toxin, cytotoxin, and toxins with neural activity; and epithelial cell invasion.[365] Certain enteropathogens may produce diarrhea by other mechanisms, and enteric pathogens may possess one or several of these virulence properties. Both host and microbiologic factors ultimately determine clinical expression in the individual patient. Not all of the recognized virulence properties of a given species are obvious clinically in each episode of disease. Virulence properties of individual bacterial, viral, and parasitic enteropathogens are discussed in specific chapters.

LABORATORY EVALUATION

Proper identification of the causative agent of an episode of acute infectious diarrhea will help facilitate initiation of appropriate therapy. A gross examination of the stool specimen should be routine in all patients with diarrhea, even if no laboratory studies are performed. Diarrheal stool that is watery and without mucus or blood usually is caused by an enterotoxin, virus, or protozoan organism, or it may be caused by infection outside the GI tract. The color of stools generally conveys little information if the stool does not contain blood. Infectious causes to be considered when stools contain blood or mucus include a cytotoxin-producing bacterium; an enteroinvasive bacterium causing mucosal inflammation; and an enteric parasite associated with blood in stools, such as *E. histolytica*, *B. coli*, and *T. trichiura.*

TABLE 50–8 Laboratory Tests Used to Detect Enteropathogens

Laboratory Tests	Organisms Suggested or Identified
Microscopic examination of stool	
Fecal leukocytes	Invasive or cytotoxin-producing bacteria
Trophozoites, cysts, oocysts, or spores	*Giardia lamblia*, *Entamoeba histolytica*, *Cryptosporidium*, *Isospora belli*, *Cyclospora*, *Enterocytozoon bieneusi*, *Encephalitozoon intestinalis*
Rhabditiform larva	*Strongyloides*
Spiral or S-shaped gram-negative bacilli	*Campylobacter jejuni/coli*
Stool culture	
Standard	*Escherichia coli*, *Shigella*, *Salmonella*, *Campylobacter jejuni*
Special	*Yersinia enterocolitica*, *Vibrio cholerae*, *Vibrio parahaemolyticus*, *Clostridium difficile*, *E. coli* O157:H7, *Listeria monocytogenes*
Stool cytotoxicity assay	*C. difficile*
Enzyme immunoassay or latex agglutination	Rotavirus, *G. lamblia*, *Cryptosporidium*, enteric adenovirus, *C. difficile*, STEC, *E. histolytica*
Serotyping	*E. coli* O157:H7 and other STEC, enteropathogenic *E. coli*
Latex agglutination after broth enrichment	*Salmonella*, *Shigella*
Tests performed in research or reference laboratories	Toxin-producing bacteria, small round viruses, invasive *E. coli*, EAEC, gene probe or polymerase chain reaction for virulence genes

STEC, Shiga toxin–producing E. coli; EAEC, enteroaggregative E. coli.

When it is present, blood usually is mixed evenly into the stool, except in the case of *E. histolytica* infections, in which blood often is on the surface of the stool, and some STEC infections, in which the stool may be blood streaked. Stools that are particularly foul smelling are consistent with *Salmonella* and other bacteria as well as *Giardia*, *Cryptosporidium*, and *Strongyloides* spp. Stools with little odor suggest an enterotoxin, such as cholera toxin or ETEC, or a viral enteropathogen. Laboratory tests used to detect enteropathogens are listed in Tables 50–8 and 50–9.

MICROSCOPIC EXAMINATION

Microscopic examination of stool specimens for evidence of fecal leukocytes provides information about the cause of diarrhea and helps determine the anatomic location and presence of mucosal inflammation.[313] Fecal leukocytes are produced in response to bacteria that diffusely invade the colonic mucosa and indicate that the patient has colitis. No inflammatory bacterial enteritis exists in which results of the fecal leukocyte examination are uniformly positive.[178] Thus, results of examination are more helpful when they are positive than when negative. When results are positive, the patient probably has an invasive or cytotoxin-producing organism, such as *Shigella* spp., *Salmonella* spp., *Campylobacter* spp., invasive *E. coli*, STEC, *C. difficile*, or *Y. enterocolitica*, although ulcerative colitis and Crohn disease also are associated with fecal leukocytes. Fecal leukocytes generally are not present in stools from patients with diarrhea secondary to viruses, enterotoxin-producing bacteria, or parasites. The leukocytes seen in cytotoxin-associated and invasive bacterial diarrhea syndromes are polymorphonuclear leukocytes. The exception is infection by *S. typhi*, in which the leukocytes are mononuclear. If the fecal leukocyte examination shows evidence of inflammatory enteritis, further laboratory evaluation is indicated. The fecal lactoferrin assay has been shown to be a more accurate test than are fecal leukocytes or occult blood in patients with inflammatory diarrhea.[194]

Normally, examination of stools for ova and parasites is unnecessary unless the patient has a history of recent travel to high-risk areas, stool cultures are negative for other enteropathogens, the patient is involved in an outbreak of diarrhea, diarrhea persists for longer than 1 week, or the patient is immunosuppressed. *G. lamblia* and *S. stercoralis* can be visualized microscopically in stools, duodenal fluid, and small intestinal biopsy material. Both trophozoites and cysts of *G. lamblia* and larvae of *Strongyloides* spp. can be identified on direct smears of stool specimens (see Fig. 50–3); however, the sensitivity of stool examination for most parasites can be improved by use of a concentration technique and by placement of stools in vials containing a stool preservative. Trichrome and iron hematoxylin both are useful as permanent stains for *Giardia* spp. Pooling of preserved fecal samples is an efficient and economical procedure for detecting ova and parasites.[13] Rational use of the stool ova and parasite examination relies on communication between the clinician and laboratory personnel.[49]

For patients in whom giardiasis, cryptosporidiosis, isosporiasis, or strongyloidiasis is considered and in whom stool cultures are negative, aspiration or biopsy of the duodenum or upper jejunum may be indicated. Because these organisms live in the upper intestine, this procedure is more reliable than is examination of stool specimens.[336] Duodenal biopsy is a sensitive and specific method for diagnosing giardiasis, strongyloidiasis, and spore-forming protozoa. Small intestinal biopsy should be considered in patients with characteristic clinical symptoms, negative stool and duodenal fluid specimens, and one of the following: abnormal radiographic findings such as edema and segmentation in the small intestine, abnormal lactose tolerance test results, absent secretory IgA, hypogammaglobulinemia, achlorhydria, AIDS, or severe malabsorptive diarrhea with weight loss. Electron microscopic examination of tissue sections may be useful in identifying fine structures of a parasite (Fig. 50–5).

Medications, including antibiotics, antacids, antidiarrheal compounds, and certain enema and laxative preparations, as well as contrast material for radiographic studies can interfere with identification of an organism by altering morphologic features or causing a temporary disappearance of parasites from stool specimens. Patients should not receive these compounds for 48 to 72 hours before stools are collected for testing. *G. lamblia* and *Cryptosporidium* antigens in feces can be detected by use of one of several rapid and sensitive diagnostic tests.[148,220] *E. histolytica* can be diagnosed by microscopic examination of fresh stool specimens or bowel wall scrapings for cysts or trophozoites (see Fig. 50–2). A concentration technique may be helpful in demonstrating amebic cysts. Examination of several stool samples by an experienced technician may be necessary because excretion of cysts often is intermittent and making an interpretation is difficult. Confusion in differentiating amebic cysts from fecal leukocytes may occur. Microscopy can be used only as presumptive evidence of *E. histolytica* because the nonpathogen *E. dispar* is morphologically identical.[129] Several molecular techniques have been developed for detection and differentiation of *E. histolytica*, *E. dispar*, and *E. moshkovskii*.[142] Numerous serologic tests for amebiasis to detect different types and antibodies are available. Serologic test results for amebae almost always are positive in acute amebic dysentery and hepatic amebiasis. A liver scan may indicate the presence of a liver abscess.

Diagnosis of *Cryptosporidium*, *Isospora*, *Cyclospora*, and microsporidia is based on morphologic appearance and staining of stool or histologic examination of tissue sections.[159] Among the most widely used stains to visualize oocysts of *Cryptosporidium*, *Isospora*, and *Cyclospora* are standard acid-fast or modified acid-fast stains,

TABLE 50–9 Laboratory Evaluation of Patients with Presumed Bacterial Diarrhea

Organism	Tests
Aeromonas hydrophila	Screen colonies grown on MacConkey agar for positive oxidase test result
	Culture on modified blood agar
Bacillus cereus	Culture food (>10^5 organisms/g); demonstrate enterotoxin in food and stool by enzyme immunoassay
Campylobacter jejuni	Stool culture with special media incubated at 42° C with 5% O_2 and 10% CO_2
	Gram stain for "gull wing"–like organisms and fecal leukocytes; darkfield or phase contrast of stool for organisms with darting motility
	Nucleic acid probe
	Serology
Clostridium difficile	Culture feces anaerobically on cycloserine-cefoxitin-fructose agar
	Demonstrate toxins in stool by enzyme immunoassay or tissue culture cytotoxicity with neutralization with antitoxin
Clostridium perfringens	Culture food (>10^5 organisms/g) and feces; stools can be tested for enterotoxin
	Serotype organism
Escherichia coli	Standard stool culture for initial isolation
ETEC	
Stable toxin	Suckling mouse assay
	Gene probe hybridization assay
Labile toxin	Rabbit ileal loop
	Y-1 adrenal or Chinese hamster ovary cell assay
	Gene probe hybridization assay
	G_{M1}, enzyme immunoassay
EPEC	Serogroup, gene probe assay
	Small bowel biopsy for routine microscopy and electron microscopy
EIEC	Gene probe assay
	Biologic assays for invasiveness (Serény or HeLa cell)
STEC	MacConkey sorbitol agar for O157:H7
	Gene probe or polymerase chain reaction to detect toxin gene sequences
	Serotyping
	Toxin enzyme immunoassay
	Free cytotoxin in stool by enzyme immunoassay or tissue culture
	Serologic responses to verotoxins or lipopolysaccharide of *E. coli* O157
EAEC	HEp-2 adherence assay, DNA probes
Listeria monocytogenes	Culture on blood agar
Plesiomonas shigelloides	Culture
Salmonella species	Standard stool culture; blood, bone marrow, and urine cultures if disseminated
	Serotype
Shigella species	Examine stool for fecal leukocytes
	Standard stool culture
Staphylococcus aureus	Culture food and skin lesions of food handlers
	Phage type
	Demonstrate enterotoxin in food, stool, and vomitus
Vibrio cholerae	Culture feces on thiosulfate–citrate–bile salt agar
	Serotype
Vibrio parahaemolyticus	Culture feces on thiosulfate–citrate–bile salt agar
	Test for Kanagawa reaction (beta-hemolysis on Wagatsuma agar), which is a marker for pathogenicity
Yersinia enterocolitica	Standard stool culture with cold enrichment; blood culture if disseminated
	Serology
	Lack of rhamnose fermentation by toxin-producing strains
	Suckling mouse assay for stable toxin

EAEC, enteroaggregative E. coli; STEC, Shiga toxin–producing E. coli; EIEC, enteroinvasive E. coli; EPEC, enteropathogenic E. coli; ETEC, enterotoxigenic E. coli.

which are based on the use of reagents that enhance the penetration of fuchsin into the organism without the need for heating (modified Kinyoun acid-fast stain). In a modified acid-fast stain, *Cryptosporidium* oocysts, which are 4 to 6 μm with four crescentic sporozoites, stain red and can be differentiated readily from yeasts that stain green.[172] Enzyme immunoassays[148,211] and fluorescent monoclonal antibody–based assays[149,345] for detection of *Cryptosporidium* antigen in stool specimens are available. In a study of seven microscopy-based *Cryptosporidium* oocyst detection methods, false-positive results were detected by acid-fast and auramine-rhodamine stains but not by monoclonal antibody–based methods.[23] Oocysts of *I. belli* often are visualized by wet-mount preparations because of their size, which is 20 to 30 μm with four sporozoites in two sporocysts. *Cyclospora* oocysts are 8 to 10 μm in diameter and are nonrefractile spherical organisms containing two sporozoites in two sporocysts that are seen easily on wet-mount preparations and are variably acid fast.

Microsporidia are difficult to differentiate from bacteria and debris because of the small size of the spores, which measure 1 to 2 μm. For detection, formalin-fixed stool or duodenal fluid can be stained with a calcofluor stain, a modified trichrome stain, or a fluorescent stain.[96,425] Gram, acid-fast, periodic acid–Schiff, and Giemsa stains also have been used to stain the organism.[367] A nonspecific fluorescence method or enzyme immunoassay may enhance speed and sensitivity. Small bowel biopsy may be more sensitive than is stool examination for establishing the diagnosis of intestinal microsporidiosis.[35] Spores are gram positive, and parts of the internal structure are positive for acid-fast or periodic acid–Schiff stains. After preliminary identification by these stains has been achieved, further examination by electron microscopy is needed to classify adequately the microsporidia into an appropriate genus. Routine histopathologic studies can provide presumptive identification in infected biopsy tissue; diagnostic confirmation requires electron microscopy. Reliable serologic

tests are not available. Sensitive PCR assays are being evaluated for *E. bieneusi* and *E. intestinalis*.[89,133]

DIAGNOSTIC STOOL CULTURES

Obtaining of stool cultures cannot be justified in all patients with acute diarrhea.[178] Patients with mild, self-limited illness do not need to have stool specimens cultured. When culture is indicated, the specimen should be inoculated onto culture plate media adequate to isolate *E. coli*, *Shigella*, *Salmonella*, and *C. jejuni*. Fecal specimens can be transported to the laboratory in a non-nutrient holding medium, such as Cary-Blair, when culture cannot be performed immediately. This medium prevents drying or overgrowth of specific organisms.

E. coli grown in a hospital microbiology laboratory usually is considered to be normal flora. Proving pathogenicity is difficult because gene probe and PCR assays generally are available only in reference or research laboratories.[279,280] All stool specimens should be evaluated with sorbitol MacConkey medium for *E. coli* O157:H7.[47] *Shigella* organisms are identified in the standard evaluation of stool cultures. However, volunteer studies have shown that these organisms are not always isolated in culture from patients ill with shigellosis.

Salmonella organisms are isolated routinely by clinical microbiology laboratories. Speciation is important in salmonellosis because *S.* ser. *choleraesuis* and *S.* ser. *typhi* cause more severe disease than do other *Salmonella* spp. *S.* ser. *enteritidis* is more variable in severity. Serotyping of *S.* ser. *enteritidis* usually is not helpful in the individual case, although serotyping is crucial in evaluation of an outbreak. Because so many *Salmonella* serotypes exist, isolation of an unusual serotype can be of use in the investigation of a food-borne epidemic or identification of a potential reptile source of infection. As with *Shigella*, isolation of a *Salmonella* spp., even without demonstration of virulence properties, is considered adequate to make an etiologic diagnosis. Serologic studies are of no value in the individual patient.

Some bacterial enteropathogens require modified laboratory procedures for identification.[178] If these agents are suspected, the laboratory should be notified so that appropriate culture methods can be used. *Listeria* is cultured on blood agar plates rather than on the usual enteric media.[410] *Y. enterocolitica* can be isolated from routine media, but a differential selective medium, such as cefsulodin–triclosan (Irgasan)–novobiocin agar, is more effective.[45] If routine enteric media are inoculated, recovery of organisms is optimized by plating them onto MacConkey agar, followed by incubation at 25° C for 48 hours. Cold-enrichment techniques may increase the yield of the organism from contaminated specimens, such as feces. Stool cultures positive for *Y. enterocolitica* only after prolonged cold enrichment may represent environmental strains of low virulence, unrelated to human disease. Biotyping and serotyping for O3, O8, and O9 are helpful in determining the clinical relevance of such isolates.

V. cholerae strains can be isolated from stool with use of thiosulfate–citrate–bile salt–sucrose agar, which is the most convenient and frequently used selective medium. This medium is suitable for most enteropathogenic *Vibrio* spp., except *V. hollisae*. Placement of the specimen into an enrichment broth, such as alkaline peptone water with 1 percent sodium chloride (pH 8.5) for 5 hours before placement on thiosulfate–citrate–bile salt–sucrose agar enhances the isolation of vibrios. Serotyping is necessary to classify organisms into those that cause typical epidemic cholera (i.e., O1 and O139 serotypes) and those that cause less severe disease (i.e., non-O1, or nonagglutinating vibrios).[209]

V. parahaemolyticus, like other vibrios, can be cultured on thiosulfate–citrate–bile salt–sucrose agar. Strains associated with diarrhea are Kanagawa-positive on Wagatsuma agar (i.e., show hemodigestion resembling beta-hemolysis), which is a marker for pathogenicity. *V. parahaemolyticus* can be serotyped on the basis of the O and K antigens.[87]

A. hydrophila can be overlooked easily on standard stool cultures. A specialized blood agar has been suggested for isolation.[16] Oxidase testing of organisms that resemble *E. coli* can select organisms as possible *Aeromonas* spp.[16] If oxidase-positive colonies are found, they can be evaluated biochemically to determine species.

C. difficile can be isolated by anaerobic stool culture on agar containing cycloserine, cefoxitin, and fructose. For establishing a definitive diagnosis, demonstration of the presence of cytotoxin in stool specimens and neutralization with antitoxin or by use of enzyme immunoassay or PCR-based assays are necessary.[14,324,355]

C. perfringens is isolated commonly from feces of well people. Diagnosis of *C. perfringens* food poisoning requires isolation of the organisms from epidemiologically implicated food in a significant quantity (more than 10^5 organisms/g) or demonstration of 10^6 organisms/g of stool from two or more ill people or demonstration of enterotoxin in stools of two or more ill people.[245]

S. aureus may be isolated from food and may not be the cause of illness because not all strains of *Staphylococcus* produce enterotoxin. Conversely, the absence of *S. aureus* from food that has been reheated just before being eaten does not exclude staphylococcal food poisoning because heating may destroy the organism without inactivating the toxin. Confirmation as a cause of food-borne disease requires isolation of the same phage type *S. aureus* from stools or vomitus of two or more ill persons or detection of enterotoxin in epidemiologically implicated food or isolation of 10^5 organisms/g from epidemiologically implicated food, provided the specimen is properly handled.[245]

B. cereus can be diagnosed by demonstration of greater than 10^5 organisms/g in the incriminated food or isolation of the

organism from stool of two or more ill people and not from stool of control patients.[245]

SEROTYPING AND TOXIN DETECTION

Certain serotypes have been associated with ETEC, EIEC, EPEC, and STEC. Studies of somatic *E. coli* antigens are not helpful in establishing the diagnosis of ETEC because more than 50 different serogroups of *E. coli* have been shown to produce ST enterotoxins, HL enterotoxins, or both. Diagnosis of the various pathotypes of diarrheogenic *E. coli* is by assays that identify phenotype directly as well as with genotypic assays. Bacteria initially attach to epithelial cells that respond by forming cuplike pedestals composed of cytoskeletal protein and can be seen on electron micrographic examination in patients infected with EPEC (see Fig. 50–5). Identical lesions can be induced by human STEC strains.

VIRUS DETECTION

Rotavirus has been identified by examination of stool specimens for 70-nm particles by electron microscopy (see Fig. 50–1). Commercially available enzyme immunoassay and latex agglutination kits are available to detect rotavirus antigen in stool specimens. Assay procedures using monoclonal antibodies have improved the sensitivity and specificity to greater than 95 percent.[93,219] Other diagnostic methods less suitable for routine use include gel electrophoresis, PCR, and viral culture. Non–group A rotaviruses are not detected by the commercially available assays.

After the Norwalk virus was cloned and sequenced in 1990,[199] two major types of assays for diagnosing human noroviruses were developed. One type detects the viral antigens or antibodies against the antigens by recombinant enzyme immunoassays, and the other detects the viral RNA by reverse transcriptase–PCR.[269] The report of an in vitro cell culture infectivity assay for human norovirus may improve diagnostic abilities as well as understanding of the pathogenesis of norovirus.[388]

Diagnosis of enteric adenovirus can be established by immune electron microscopy of stool specimens, enzyme immunoassay of stool specimens, or propagation in a line of human embryonic kidney cells transformed by adenovirus type 5 (293 cells).[226] Restriction enzyme analysis is the definitive method for classifying individual enteric adenovirus isolates. Commercially available assays for detection of enteric adenovirus are available.[412]

Astroviruses grow well in human embryo kidney cells in the presence of trypsin. Electron microscopy, immune electron microscopy, immunofluorescence on cell culture, enzyme immunoassay, and PCR can be used as detection methods.[157]

PROCTOSIGMOIDOSCOPY

When symptoms of colitis are severe or the cause of an inflammatory enteritis syndrome remains obscure after laboratory evaluation, proctoscopic examination may help establish the diagnosis. Table 50–10 shows the usual proctoscopic findings in the various enteric syndromes that are characterized by fever, abdominal pain, and diarrhea with mucus and blood. Inflammatory bowel disease enters the differential diagnosis when symptoms of inflammatory enteritis become chronic. Proctitis with or without diarrhea may be related to milk allergy in infants, child abuse, or sexual practices. The etiology of proctitis includes all of these causes as well as *Neisseria gonorrhoeae*, herpes simplex virus, lymphogranuloma venereum, and *Chlamydia trachomatis*.

TREATMENT

Enteric infections generally are self-limited conditions, but nonspecific therapy can provide relief for some patients, and specific therapy may shorten the duration of the illness and eradicate fecal shedding of the organism. In caring for patients with diarrhea and dehydration, the major therapeutic considerations include fluid and electrolyte therapy, dietary manipulation, nonspecific therapy with antidiarrheal compounds, and specific therapy with antimicrobial agents. Increasing numbers of isolates resistant to antimicrobial agents and the risk for worsened illness (e.g., hemolytic-uremic syndrome occurring with Shiga toxin–producing *E. coli*) complicate antimicrobial and antimotility therapy.

TABLE 50–10 Proctoscopic Findings of Persistent Inflammatory Colitis

Organism or Disease	Gross Findings	Microscopic Findings
Shigella species	Diffuse erythema with loss of vascular pattern, mucopurulence, mild friability, occasional aphthoid ulcers	Edema, capillary congestion, focal hemorrhages, crypt hyperplasia, goblet cell depletion, mononuclear and polymorphonuclear leukocyte infiltrate, loss of epithelial cells with microulcerations
Salmonella species	Hyperemic, friable mucosa with petechiae and ulcerations; occasional pseudomembranous changes	Edema, inflammation, microabscesses, ulcerations
Campylobacter jejuni	Diffuse exudative edema	Inflammatory infiltrate with polymorphonuclear leukocytes, eosinophils, mononuclear cells, degeneration, loss of mucus, crypt abscesses, ulcerations
Clostridium difficile	Pseudomembranous colitis with 1- to 5-mm white-yellow nodules or plaques, minimal friability, sometimes nonspecific colitis	Fibrin, mucus, necrotic epithelial cells, leukocytes adherent to the underlying inflamed tissues
Clostridium perfringens	Rarely pseudomembranous colitis	Findings similar to those produced by *C. difficile*
Entamoeba histolytica	Discrete ulcers (millimeters to centimeters in diameter) with undermined edges amid normal mucosa	Trophozoites in flask-shaped ulcers that extend into submucosa, inflammatory cells near periphery but not near trophozoites; wet mount shows motile ameba containing erythrocytes
Ulcerative colitis	Friability, inflammatory polyps on heaped-up granulation tissue, deep linear ulcers	Mucosal ulceration extending to lamina propria, diffuse inflammation, vascular engagement, microabscesses in crypts
Crohn colitis	Hyperemic mucosa with linear ulcers	Inflammation involving all layers of bowel, with lymphocytes, histiocytes, and plasma cells forming granulomas

FLUID AND ELECTROLYTE THERAPY

Patients who develop diarrhea lose fluid and electrolytes through the GI tract by several mechanisms: vomiting, loss of fecal fluid caused by the infecting enteropathogen, and fecal water loss in excess of sodium caused by the intraluminal osmotic effect of unabsorbed nutrients.[179] The composition and amount of lost fluid depend on the rate of stool loss and the causative agent. The higher the rate of stool loss, the greater the sodium loss, probably as a result of rapid passage of intestinal contents through the colon, where sodium-potassium exchange occurs. Stools from patients with cholera or ETEC infection contain sodium in a concentration of 80 to 120 mEq/L, whereas stools from patients with rotavirus infection have sodium concentrations of less than 50 mEq/L.[357] In secretory diarrheal disorders, loss of fluid generally is derived from the small intestine, and colonic reabsorption is overwhelmed. In viral gastroenteritis, small bowel absorptive capacity primarily is impaired, and in dysenteric or invasive diarrhea, reabsorptive capacity of the large intestine is reduced. If vomiting also is a manifestation, this loss is compounded. Continued loss of fluid or electrolytes may lead to dehydration, with potentially severe sequelae. Children, especially infants, are more susceptible to dehydration because they have greater basal fluid and electrolyte requirements per kilogram and because they depend on others to meet these needs.

Important factors to be considered in evaluating patients with diarrhea and possible dehydration include an estimation of deficiency, ongoing daily requirements, continued losses and their replacement, and correction of the underlying cause.[18,179] The clinical signs and symptoms that may help in estimating deficiencies and determining the severity of dehydration include thirst, dryness of the mucous membranes, decrease in urinary output, tachycardia, loss of skin elasticity and turgor, and mottling and coolness of the skin.[18,66] These signs may be misleading in patients who are malnourished or in patients with hypertonic dehydration.

Fluids should not be withheld in treatment of any patient with diarrheal disease. Oral therapy should consist of rapid rehydration with replacement of ongoing losses during the first 6 to 12 hours of therapy with a glucose-electrolyte solution,[18,66,78,357] followed by early initiation of a modified diet.[66,250] If fluid and electrolyte deficits are significant, priority should be given to rehydration as rapidly as possible with oral electrolyte solutions. Ondansetron, an antiemetic, as a single dose reduced vomiting and facilitated oral rehydration in a study of children in an emergency department in the United States.[144]

Intravenous therapy is required only if the patient is in shock, is obtunded, or has ileus; otherwise, fluid and electrolyte therapy should be administered orally. Once the patient is rehydrated, an orally administered maintenance solution containing approximately 50 mEq/L of sodium should be used. Patients with mild diarrhea without clinical dehydration (<3% weight loss) can be managed at home by supplementing their diets with oral electrolyte solutions containing glucose. The glucose in these solutions is necessary to promote intestinal absorption of sodium and water in the small intestine.[370]

Commercial preparations of ready-to-feed glucose-electrolyte solutions are available in the United States and should be used in preference to homemade solutions. The sodium and potassium contents of various commercially available preparations are outlined in Table 50–11. Gatorade and other sports drinks do not supply the quantity of electrolytes necessary to replace those lost with the continued stool losses of severe diarrhea, and they are high in carbohydrate content. High concentrations of sugar are not tolerated well because high osmotic activity may exacerbate diarrhea. The carbohydrate concentration should not exceed the sodium concentration by more than 2:1. If it does, the excess carbohydrate produces osmotic retention of water in the intestine, with subsequent loss in stool.[18] The preparation of glucose and salt solutions at home is not recommended because errors in preparing the solutions may result in hypertonic dehydration in infants.[234] The use of rice-based oral rehydration solutions that contain glucose polymers and amino acids has been shown to increase the absorption of salt, water, and glucose from the intestine and may be more beneficial than are glucose-based oral rehydration solutions.[358,375] In a randomized, controlled trial in an emergency department in the United States, oral rehydration was as effective as intravenous rehydration of moderately dehydrated children.[384]

Other fluids that may be consumed at home include decarbonated soda beverages, fruit juices, and Jell-O. All contain inadequate amounts of sodium and potassium and excessive carbohydrate concentrations, which may exceed the absorptive capacity of the intestine[370] and, therefore, should not be used if rehydration requires more than one or two feedings. Kool-Aid and tea are not recommended because they are low in both sodium and potassium and thus have little advantage over sugar and water. Soon after the child has begun drinking a fluid and electrolyte solution, feeding should be restarted.[18,52,66]

DIETARY MANIPULATION

Of all common childhood illnesses, diarrhea has the most significant adverse nutritional effect. Restoration of feeding is important to reduce the nutritional defects caused by diarrhea.[18,66] However, optimal conditions have not been defined in nutritional management of different diarrheal states.[52] Once rehydration is complete, food may be reintroduced while the oral electrolyte solution is continued to replace ongoing losses from stools and for maintenance. Breast-feeding in infants should be resumed as soon as possible, preferably immediately after rehydration. Some

TABLE 50–11 Content of Representative Solutions Used for Oral Rehydration

Solution	Sodium (mmol/L)	Potassium (mmol/L)	Carbohydrate (mmol/L)	Osmolarity (mOsm/L)
Rehydration				
World Health Organization solution*	90	20	111	310
Reduced osmolar ORS (WHO/UNICEF)	75	20	75	245
Rehydralyte (Ross)	75	20	140	301
Maintenance or Prevention				
Infalyte (Mead Johnson)	50	25	70	200
Naturalyte (Unlimited Beverage)	45	20	140	265
Pedialyte (Ross)	45	20	140	250
Pediatric electrolyte (NutraMax)	45	20	140	250

**Packets of oral rehydration salts are available in the United States from Cera Products (410-997-2334) and Jianas Brothers (816-421-2880).*

infants experience temporary lactose intolerance after having diarrheal illness,[29] although most young children with acute diarrhea can be managed successfully with continued feeding of undiluted nonhuman milk.[18,53,250] Routine dilution of milk and routine use of lactose-free milk formula are not necessary, especially when oral rehydration therapy and early feeding are part of the approach to the clinical management of acute diarrhea.

In some children and infants, the carbohydrate fraction of milk may exacerbate diarrhea because of disaccharidase deficiency acquired as a result of diarrhea.[29] Development of lactase deficiency during a diarrheal illness may require some alteration in diet. In children with moderate or severe acute diarrhea, reduction or elimination of lactose from the diet early in the illness may be necessary to minimize the effects of lactose intolerance. Relative lactose tolerance has been shown to persist for 2 to 6 weeks after some episodes of diarrhea. Other disaccharidases may be reduced during infection, influencing the absorption of other sugars. Soy-based, lactose-free formulas can be used safely during the acute phase of diarrheal illness in infants.[358] If diarrhea persists for more than 3 weeks, conditions that should be considered include not only disaccharidase deficiency but also celiac disease, cystic fibrosis, parasitic disease, allergic gastroenteropathy, bacterial overgrowth syndrome, congenital diarrhea disorders, EPEC or EAEC disease, and chronic nonspecific diarrhea.[41,240]

NONSPECIFIC THERAPY WITH ANTIDIARRHEAL COMPOUNDS

Many compounds are available for symptomatic treatment of patients with diarrhea. These substances are prescribed by physicians, administered by parents, or taken by patients who are eager to relieve the symptoms. Their purpose is to decrease the volume of diarrhea by increasing absorption of water and electrolytes, to decrease intestinal secretion, or to decrease intestinal motility. These over-the-counter and prescription preparations act on the GI tract by one or more of these mechanisms. Table 50–12 lists some commercially available antidiarrheal agents and their mechanisms of action, major value, and toxicity. Most of these compounds are not approved for children younger than 2 to 3 years old.

Drugs that alter intestinal motility can be classified into antimuscarinics and synthetic or natural opium alkaloids.[18,110,321] These compounds usually have a rapid onset of action. They decrease the volume of stool output and relieve abdominal cramps and pain, probably by producing segmental contractions of the intestine, which retard movement of intestinal contents responsible for diarrhea and restrict the intestinal distention that normally causes abdominal pain. Drugs that affect intestinal motility may worsen the symptoms of *Shigella*, STEC, or other invasive and cytotoxin-producing bacteria by inhibiting intestinal transit and allowing the enteropathogen to be in contact with the intestinal mucosa for a longer time.[110,437] These agents may accelerate development of AAC.[287] Drugs that have central opiate–like effects can lead to overdose; fatalities in children have occurred.[152,153,321,344] Two to four doses of these compounds during a 24-hour period may be used in adolescents or adults to treat severe cramps, but prolonged therapy is not advised, and use in children is not recommended. The combination of TMP-SMX plus loperamide and the use of loperamide alone were effective in treating adults with traveler's diarrhea[54,127] and resulted in the shortest mean duration of diarrhea compared with that in patients taking placebo or TMP-SMX alone. In infants, loperamide can cause ileus, emesis, and drowsiness.[273] The practice parameter of the American Academy of Pediatrics does not recommend this class of compounds for treatment of diarrhea in children.[18]

Numerous chemically inert agents are used internally as adsorbents to bind toxins and water to reduce the number and to improve consistency of bowel movements. When these substances are given by mouth, they can adsorb not only bacteria and toxins but also drugs, nutrients, and enzymes. The only agents currently used widely are compounds containing activated attapulgite, which have been shown to be effective in animals by reducing diarrhea and producing formed stools,[139,329] but studies in humans are lacking. Disadvantages include nonspecific changes in adsorption of nutrients, enzymes, and antibiotics, particularly if the absorbent is used for a prolonged time.

TABLE 50–12 Antidiarrheal Compounds Used as Nonspecific Therapy for Patients with Acute Diarrhea

Mechanism of Action	Generic Name	Trade Name	Value	Comments
Alteration of intestinal motility	Loperamide	Imodium advanced, Imodium A-D, Maalox Antidiarrheal, Pepto Diarrhea Control	Decreases diarrhea, rapid onset of action	Numerous side effects and contraindications Not recommended or licensed for use in infants and young children
	Difenoxin and atropine	Motofen*		May potentiate *Shigella*, *Salmonella*, or STEC infections or accelerate the course of antimicrobial-associated colitis
	Diphenoxylate and atropine	Lomotil*		
	Tincture of opium	Paregoric*		
Alteration of secretion	Bismuth subsalicylate	Pepto-Bismol	Decreases diarrhea and cramps of travelers	Potential for salicylate or bismuth overdose, darkens stool
	Octreotide	Sandostatin*	Decreases diarrhea in patients with vasoactive intestinal peptide–secreting and metastatic carcinoid tumors	Used for relief of refractory AIDS-associated diarrhea; not licensed by the Food and Drug Administration for this condition
	Racecadotril	Not available	Decreases diarrhea	Decreases intestinal hypersecretion, enkephalinase inhibitor
Adsorption of toxins and water	Attapulgite	Diasorb, Donnagel, Kaopectate, Rheaban	Increases form of stool	Safe, minimally effective, decreases absorption of nutrients and drugs, causes abdominal fullness
Alteration of intestinal microflora	Probiotics (*Lactobacillus*, *Bifidobacterium*)	Pro-Bionate, Superdophilus	Value unproven	Safe, contraindicated in those with lactose tolerance

**Requires a prescription.*
STEC, Shiga toxin–producing Escherichia coli.

Probiotics are live, nonpathogenic microorganisms that have been studied for prevention and treatment of a variety of disorders including diarrhea, irritable bowel syndrome, and inflammatory bowel disease. When given orally, these organisms recolonize the intestine with saccharolytic flora and alter the intestinal pH as a way of deterring potential pathogens.[17,318] Ingestion of probiotics results in an increased production of short-chain fatty acids and a decrease in pH in the intestine, which may inhibit the growth of *Salmonella* and *Shigella*. Feeding of selected microorganisms, including *Bifidobacterium bifidum*, *Saccharomyces boulardii*, *Lactobacillus acidophilus*, and *Streptococcus thermophilus*, to children and adults has been shown to be effective in prevention against and treatment of intestinal disease. Several meta-analyses have shown moderate clinical benefit of probiotics in treatment and prevention of diarrheal disease in children.[205,360,391,392] There is a need to better define and standardize the optimal probiotic for prevention and treatment of diarrheal disease caused by specific enteropathogens.[318]

Indomethacin, aspirin, chlorpromazine, and imidazole decrease intestinal secretion of fluid and electrolytes. Indomethacin has been shown to be effective in treating radiation-induced diarrhea, and chlorpromazine is effective in managing diarrhea caused by *V. cholerae;* however, the usefulness of these compounds in patients with various forms of acute infectious diarrhea is unknown. Laboratory studies showed that bismuth subsalicylate (Pepto-Bismol) inhibited intestinal secretion caused by *E. coli* and cholera enterotoxins,[126] reduced diarrhea in adult students who became ill in Mexico,[116] and prevented diarrhea among U.S. students traveling to Mexico.[113] Studies supporting its use in children are limited.[382,383] Potential problems with this compound relate to the absorption of salicylate[135,316] and bismuth.[262] Octreotide (Sandostatin) is a long-acting synthetic somatostatin analogue with pharmacologic actions mimicking those of the natural hormone somatostatin. Octreotide has been used in patients with AIDS who have severe refractory secretory diarrhea.[57]

Racecadotril (acetorphan) is an enkephalinase inhibitor that decreases intestinal hypersecretion but not motility in animals and humans by preventing breakdown of endogenous enkephalins in the GI tract. Racecadotril has been shown to decrease 48-hour stool output, median duration of diarrhea, and intake of oral rehydration solution in children with watery diarrhea.[354] The mechanisms and development of effective antisecretory drugs for diarrheal disease have been reviewed.[132] The potential immunomodulatory mechanisms involved in the interrelationships between micronutrients, including zinc and vitamin A, and infectious diseases, including diarrhea, have been reviewed.[7,189,396,419]

SPECIFIC THERAPY WITH ANTIMICROBIAL AGENTS

Antimicrobial therapy is administered to selected patients with gastroenteritis to abbreviate the duration of the clinical course and to decrease excretion of the causative organisms. A stool culture specimen should be obtained when antibiotic treatment is anticipated, and antibiotic susceptibility testing of any suspected pathogen should be performed to ensure optimal therapy. Changing susceptibility patterns renders the initial selection of an antimicrobial agent difficult. Antimicrobial agents should not be used routinely or liberally for gastroenteritis of unknown cause.

Shigella

Several antimicrobial agents have been used successfully in eradicating clinical symptoms and fecal shedding of *Shigella*, but a high prevalence of antimicrobial resistance in the United States limits treatment options.[374] Of the *Shigella* isolates reported in the National Antimicrobial Resistance Monitoring System (NARMS) of the CDC in 2003, 88 percent were *S. sonnei* and 10 percent were *S. flexneri*. Among the 495 shigella isolates, 91 percent were resistant to one or more antimicrobial agents and 23 percent to five or more antimicrobial agents. Resistance to ampicillin occurred in 79 percent of isolates, to TMP-SMX in 38 percent, and to tetracycline in 29 percent. None of the isolates was resistant to ceftriaxone, imipenem, gentamicin, or ciprofloxacin. Susceptibility testing against azithromycin was not performed. Table 50–13 outlines suggested antimicrobial therapy for children and adults who are presumed to have shigellosis or from whom *Shigella* organisms are isolated from stool.

The history of resistance among *Shigella* strains has shown progressive acquisition of multiresistance, first to sulfonamides, shortly after their commercial availability; then to tetracycline, chloramphenicol, and streptomycin less than 10 years after they were introduced; and subsequently to ampicillin, kanamycin, and TMP-SMX.[308,333,394] In children with known ampicillin-susceptible or TMP-SMX–susceptible strains, either drug can be given, but neither should be used as empiric therapy because of increasing resistance. Amoxicillin is not as effective as is ampicillin in the treatment of shigellosis and should not be used.[283] Parenterally and orally administered, extended-spectrum cephalosporins have been used successfully in the treatment of children with shigellosis.[25,122,414] Two-day[122] and 5-day[414] courses of ceftriaxone were effective in eradicating *Shigella* from stool and reducing the duration of diarrhea, but a single parenteral dose of ceftriaxone produced only a moderate reduction in diarrhea and failed to eradicate *Shigella* strains from stools.[207] Cefixime and ceftibuten, orally administered extended-spectrum cephalosporins, have shown good in vitro activity against various enteric pathogens and promising clinical efficacy in patients with shigellosis; cefixime, however, no longer is manufactured in the United States.[25,325]

Ciprofloxacin, norfloxacin, and enoxacin have been used successfully to treat adults and children with shigellosis[217,251,369] and appear to be safe in children.[162] In a study evaluating dosing of ciprofloxacin in adults, 5 days of therapy were effective for patients infected with *S. dysenteriae* type 1. For other *Shigella* spp., a single 1-g dose was sufficient. Ciprofloxacin is approved by the FDA for treatment of GI tract infections caused by *S. sonnei* and *S. flexneri*. In a randomized, double-blind study of 120 children aged 2 to 15 years with shigellosis, ciprofloxacin and pivmecillinam given for 5 days were successful in providing a clinical cure and eradicating the organism from stool.[251] Ciprofloxacin was not associated with development of arthropathy in children in this study. A comparative study of a 5-day course of either azithromycin or ciprofloxacin in adults with shigellosis showed compa-

TABLE 50–13 Antimicrobial Therapy for Patients with Shigellosis

Strain Susceptibility	Antimicrobial Agent
Strain of unknown susceptibility	Ceftriaxone *or* azithromycin *or* ciprofloxacin* *or* ofloxacin*

rable clinical and bacteriologic responses.[217] Patients who are transient asymptomatic carriers may be managed without antimicrobial therapy if they understand and employ excellent standards of personal hygiene. Treatment of these patients, however, reduces fecal shedding of the organism and prevents spread of infection.

Salmonella

Table 50–14 shows antimicrobial therapy for patients with various clinical manifestations of *Salmonella* infection.[260] The type of syndrome produced by *Salmonella* influences the selection and duration of antimicrobial therapy. Antibiotics should not be used in the treatment of patients who are nontyphoid *Salmonella* carriers or in most patients with mild gastroenteritis. Antimicrobial therapy may, on occasion, convert intestinal carriage into systemic disease with bacteremia,[337] prolong excretion of *Salmonella*,[24] produce a bacteriologic or symptomatic relapse,[24] or encourage development or selection of resistant strains. Antimicrobial agents should be considered for patients with enterocolitis if the disease appears to be evolving into one of the systemic syndromes and for patients with a condition that impairs host resistance to infection, including neonates, young infants, and patients with hemoglobinopathies including sickle-cell anemia, AIDS, leukemia, lymphoma, immunosuppression, congenital heart disease, valvular heart disease, prostheses, and uremia.[163] Antibiotic treatment of *Salmonella* infection should be given to all patients with typhoid fever, bacteremia caused by nontyphoidal strains, and dissemination with localized suppuration.

Selection of antimicrobial agents for therapy is complicated by the emergence of *Salmonella* strains that are resistant to multiple antibiotics[2,427] and by increased risk of acquiring *Salmonella* infection associated with prior antimicrobial exposure.[298] Rates of antibiotic resistance among certain serotypes have been increasing, with a substantial proportion of serotypes of Typhimurium and Newport isolates being resistant to multiple drugs.[58] In 2003, 23 percent of non-*typhi Salmonella* isolates tested by NARMS were resistant to one or more antimicrobial agents and 11 percent were resistant to five or more agents.[58] Only 2 percent of isolates were resistant to TMP-SMX, 0.4 percent to ceftriaxone, and 0.2 percent to ciprofloxacin. Azithromycin was not tested.

Several outbreaks of multiresistant *Salmonella* infection in the United States have been traced to animal sources.[91,151,158,266] Resistant strains of *Salmonella* are common findings in retail ground meats, possibly because of use of antibiotics in animals used for food.[432] Human isolates of *Salmonella* should have susceptibility testing performed to guide therapy. Recommended antimicrobial agents include ampicillin, chloramphenicol, TMP-SMX, ceftriaxone, cefotaxime, ceftazidime, and a fluoroquinolone, which is approved only for people older than 17 years.[260,381] Ciprofloxacin, ofloxacin, and azithromycin are active in vitro against *Salmonella*, including *S.* ser. *typhi*, and have been used clinically with success.[27,237,378,418]

Because of the high rate of *S.* ser. *typhi* transmission together with widespread indiscriminate use of antimicrobial agents in some areas of the world, an increase in resistance patterns to ampicillin, chloramphenicol, and TMP-SMX has occurred.[58,342] Of the *Salmonella typhi* isolates reported by NARMS, 26 percent were resistant to one or more antimicrobial agents. One isolate was resistant to ceftriaxone and ciprofloxacin.[58] Because of this high rate of resistance in *S.* ser. *typhi* strains imported by travelers, empiric treatment of *S.* ser. *typhi* should be provided with ceftriaxone or a fluoroquinolone if the patient is older than 17 years. Ampicillin, chloramphenicol, and TMP-SMX should be reserved for patients in whom susceptibility testing of the causative organism has shown susceptibility. Development of resistance of *S.* ser. *typhi* to ceftriaxone and fluoroquinolones needs to be monitored. In areas of the world where *S.* ser. *typhi* strains with reduced susceptibility to fluoroquinolones have been reported, azithromycin was effective for treatment of people with enteric fever,[77,145,155] as was cefixime.[261,306] In a prospective, randomized study of children and adults with confirmed typhoid fever, ceftriaxone administered for 5 days was as effective and safe as a 2- to 3-week course of chloramphenicol,[195] but in another study, short-course therapy failed.[40]

Corticosteroids can be beneficial in treating patients with typhoid fever in whom prompt relief of manifestations of toxemia might be lifesaving,[83] but corticosteroids may increase the relapse rate.[182]

Antibiotics listed in Table 50–14 can be used for treatment of *Salmonella* infections. Patients with defective host defense mechanisms, such as people with AIDS, should be treated with ampicillin or an expanded-spectrum cephalosporin.[380] Ciprofloxacin has been reported to be effective in treating acute diarrhea caused by *Salmonella*,[118,127,128] recurrent *Salmonella* sepsis,[81] and brain abscesses in a neonate.[430] Duration of therapy is influenced by the site of infection and by the host. Patients with bacteremia without a localized infection should be treated for 14 days, whereas those with localized infection, such as osteomyelitis or endocarditis, or patients with AIDS and bacteremia should receive at least 4 to 6 weeks of therapy.[40] In most cases, chronic carriage of *S.* ser. *typhi* is associated with gallbladder disease. The presence of cholelithiasis may significantly affect the efficacy of therapy. When gallbladder disease is present, the failure rate of ampicillin is approximately 75 percent.[204] In patients without gallbladder disease, ampicillin with probenecid or amoxicillin administered for 6 weeks is the treatment of choice for chronic enteric carriers.[305] Ciprofloxacin[137] has been reported to be successful in eradicating *S.* ser. *typhi* in adult chronic carriers. Resistance of clinical isolates and failure of treatment with ciprofloxacin have been noted in patients infected with *S.* ser. *typhi*.[320]

TABLE 50–14 Antimicrobial Therapy for Patients with *Salmonella* Infections

Clinical Manifestation	Antimicrobial Agent
Acute gastroenteritis*	None
Bacteremia or enteric fever†	Ceftriaxone *or* cefotaxime *or* fluoroquinolone† *or* ampicillin‡ *or* chloramphenicol‡ *or* trimethoprim-sulfamethoxazole‡ (TMP-SMX)
Dissemination with localized suppuration (osteomyelitis)† or bacteremia in patients with AIDS	Same as for bacteremia
Meningitis or ampicillin-chloramphenicol–resistant and TMP-SMX–resistant organisms	Cefotaxime or ceftriaxone

**Patients with hyperpyrexia and systemic signs or symptoms should be treated empirically until bacteremia is excluded. Although of unproven efficacy, antimicrobial therapy for children in the first 3 months of life also is recommended by most authorities; a 7- to 10-day course of therapy probably is sufficient.*

†Ciprofloxacin or ofloxacin can be used to treat resistant organisms in patients 18 years of age and older. Both are available for intravenous as well as oral use. Neither is recommended for pregnant women. Azithromycin has been used with success in developing countries.

‡Can be used if the organism is susceptible.

Two typhoid fever vaccines for children older than 2 years, adolescents, and adults are available commercially in the United States for specific situations.[75] A *S. typhi* Vi conjugate vaccine has been shown to be safe, immunogenic, and 90 percent effective in children 2 to 5 years of age,[238] but this vaccine is not available commercially.

Campylobacter

Campylobacter jejuni isolates generally are susceptible to a wide variety of antimicrobial agents, including erythromycin, quinolones, furazolidone, aminoglycosides, tetracycline, chloramphenicol, imipenem, and clindamycin, whereas penicillin, ampicillin, cephalosporins, and TMP-SMX are relatively inactive. Isolation of *Campylobacter* from stool does not imply the need for antimicrobial therapy. In a meta-analysis of eight randomized, controlled trials of antimicrobial therapy versus placebo, antimicrobial therapy shortened the duration of intestinal symptoms by 1.32 days.[402] The decision concerning therapy should be individualized, but therapy should be considered in patients with high temperatures, bloody diarrhea, and severe diarrhea and in immunocompromised hosts. In patients with *Campylobacter* enteritis, erythromycin or azithromycin is the agent of choice when a decision has been made to initiate therapy.[260] Data from NARMS from 1977 to 2003 showed that less than 2 percent of the isolates were resistant to erythromycin and azithromycin.[58,165] In these and other studies, a higher frequency of erythromycin resistance was noted in hog isolates, most of which were *C. coli*.[147,198,285] Strains of *C. jejuni* and *C. coli* that show high-level resistance to erythromycin also appear to be resistant to clarithromycin and azithromycin.[397]

Ciprofloxacin has been licensed by the FDA for treatment of *C. jejuni* enteritis in patients older than 17 years. Development of resistance to ciprofloxacin in *Campylobacter* spp. has been reported.[58,165,347] Data from NARMS show that the rate of *C. jejuni/coli* isolates resistant to ciprofloxacin was 13 percent in 1997 and 18 percent in 2003.[58,165] These high rates of resistance have been related in part to introduction of fluoroquinolones in animal feed.[284,377] In double-blind, placebo-controlled trials of erythromycin for treatment of patients with enteritis caused by *C. jejuni*, erythromycin was shown to eradicate *C. jejuni* promptly from feces but not to alter the clinical course when begun 4 days or more after the onset of symptoms.[20] Studies in which therapy was started early showed that *C. jejuni* was eliminated rapidly from stools, but studies gave conflicting results with regard to resolution of clinical illness.[353,433] The treatment of choice for patients with septicemia caused by *C. jejuni* or *C. fetus* infection is gentamicin or imipenem.[260]

Other Bacterial Agents

Antimicrobial agents have been employed frequently in attempts to treat infantile gastroenteritis caused by EPEC and as a means of controlling the spread of EPEC strains in hospital nurseries (Table 50–15). Although no definitive studies support the effectiveness of these drugs, they may be useful in certain situations, particularly when life-threatening infection occurs or when epidemic spread of the strains continues, despite the use of strict handwashing and appropriate isolation. Agents used in the treatment of EPEC diarrhea include TMP-SMX, but strains may be resistant. If systemic infection is suspected, parenteral therapy should be started and modified according to antimicrobial susceptibility of the organism isolated.

Diarrhea caused by ETEC usually is limited, but studies in adults have shown that antimicrobial agents such as TMP-SMX and ciprofloxacin are effective treatments. The treatment in patients with diarrhea caused by EIEC is similar to that in patients with shigellosis (see Table 50–13). Travelers infected with EAEC have shown response to ciprofloxacin.[156] Antimicrobial therapy of infants and children with hemorrhagic colitis caused by STEC has been reported to increase development of hemolytic-uremic syndrome,[437] but other studies have not supported this observation for STEC[348] or for *S. dysenteriae* type 1.[38]

TABLE 50–15 Antimicrobial Therapy for Bacterial Pathogens Causing Gastroenteritis

Organism	Antibiotic Therapy
Campylobacter jejuni	
Gastroenteritis	None, or if colitis is present, erythromycin or azithromycin or ciprofloxacin
Sepsis	Aminoglycoside
Clostridium difficile (antimicrobial-associated colitis)	Metronidazole or vancomycin
Escherichia coli	
Enteropathogenic	None or TMP-SMX or fluoroquinolone*
Enterotoxigenic	TMP-SMX or fluoroquinolone* or cefixime
Enteroinvasive	Same as for shigellosis (see Table 50–13)
STEC	None
Vibrio cholerae	Doxycycline or tetracycline or TMP-SMX
Vibrio parahaemolyticus	None
Yersinia enterocolitica	
Gastroenteritis	Probably none
Sepsis	TMP-SMX or an aminoglycoside or cefotaxime or ceftizoxime or ciprofloxacin*

**Approved only for patients 18 years of age or older.*
STEC, Shiga toxin–producing E. coli; TMP-SMX, trimethoprim-sulfamethoxazole.

Antimicrobial agents decrease the duration of diarrhea associated with cholera by eradicating the vibrios from the GI tract[420] and thus reducing the volume of fluid loss. Doxycycline is the drug of choice in most instances for O1 and O139 infections, including those in children, in whom the benefits of a 1- to 2-day course outweigh the risk for dental staining.[259,261] TMP-SMX can be used in children younger than 8 years for *V. cholerae* O1, but O139 strains often are resistant. Ampicillin probably is the safest agent for use during pregnancy. Other effective antimicrobial agents are the fluoroquinolones and azithromycin. Single-dose azithromycin has been effective in both children[218] and adults.[350] Single-dose ciprofloxacin has been successful in treatment of adults,[216,349] but resistance was reported in a study from Bangladesh.[350] Diarrhea caused by *V. parahaemolyticus* is self-limited, so antimicrobial therapy shortens neither the clinical course nor the duration of excretion.[87] Antimicrobial therapy has not been proved efficacious in the treatment of uncomplicated enterocolitis caused by *Y. enterocolitica*.[45] Patients with *Y. enterocolitica*–induced septicemia or extraintestinal focal infection or compromised hosts with enterocolitis should receive TMP-SMX, a fluoroquinolone if they are older than 17 years, an aminoglycoside, cefotaxime, or cefotaxime. Table 50–15 outlines the antimicrobial therapy of these bacterial pathogens.

Protozoal Agents

Several drugs have been shown to be effective in the treatment of patients with giardiasis (Table 50–16).[90,150,259,340] Metronidazole may be better tolerated than is quinacrine, is not approved for the treatment of patients with giardiasis in the United States, and is carcinogenic in animals. Quinacrine hydrochloride may produce a yellow discoloration of the skin that disappears after

TABLE 50–16 Antimicrobial Therapy for Patients with Giardiasis

Antimicrobial Agent	Comments
Furazolidone (Furoxone)	Nausea, vomiting, disulfiram-like reaction with alcohol, mild hemolysis in glucose-6-phosphate dehydrogenase–deficient people, hypoglycemia, allergic reactions
Metronidazole (Flagyl)*	Metallic taste, nausea, headache, dry mouth, mutagenic in bacteria, carcinogenic in animals, disulfiram-like reaction with alcohol
Quinacrine HCl	Dizziness, headache, vomiting, diarrhea, yellow-orange skin color; not available commercially but can be obtained†
Nitazoxanide	Abdominal pain, vomiting, and headache uniformly reported; data minimal for children younger than 12 months or older than 11 years and for patients with immune deficiencies
Paromomycin*	Not highly effective, proposed for use in pregnancy
Albendazole*	Anorexia, constipation; clinical trials have shown mixed results
Tinidazole	Given as one dose

**Not a U.S. Food and Drug Administration–licensed indication.*
†Medical Center Pharmacy (203-688-6816) or Panorama Compounding Pharmacy (800-247-9767).

the drug is stopped. Quinacrine is not available commercially but as a service can be compounded (see Table 50–16). Furazolidone is the only one of these three compounds available in liquid form; like quinacrine, it is less expensive than metronidazole. Furazolidone can be used in children if compliance is a problem with quinacrine and metronidazole, both of which have an objectionable taste. Clinical trials using albendazole to treat people with giardiasis have produced mixed results.[150] Treatment of children with albendazole for 5 days,[166] but not 3 days,[166,299] has been effective. Toxicity of albendazole is low, and this compound is effective against many helminths, rendering it useful for treatment when multiple intestinal parasites are identified or suspected. Nitazoxanide has been licensed by the FDA for treatment of children with diarrhea caused by *Giardia* or *Cryptosporidium*. Tinidazole, a nitroimidazole drug similar to metronidazole, is given as a single dose. Paromomycin is not absorbed and is not highly effective but has been proposed for use during pregnancy.[228]

In a review of comparative drug trials for the treatment of giardiasis, Davidson[90] reported that metronidazole cured 92 percent of 219 patients and furazolidone cured 84 percent of 150 patients. Approximately 7 percent of the metronidazole-treated patients and 10 percent of the furazolidone-treated patients had side effects that were serious enough to report. The drugs available in a liquid preparation are furazolidone and nitazoxanide.

In treatment of patients with amebiasis, iodoquinol and paromomycin are the recommended luminal amebicide drugs that are available in the United States.[259] Paromomycin may be used during pregnancy. Diloxanide furoate is an alternative, but it is not available commercially in the United States. These drugs are effective against both cysts and trophozoites in the lumen of the gut, but they are ineffective against tissue forms of the disease. Invasive amebiasis of the intestine, liver, or other organs necessitates the additional use of tissue amebicides, such as metronidazole or tinidazole. Liver abscess or other extraintestinal forms of disease should be treated with metronidazole or tinidazole in the dose recommended for intestinal disease. Table 50–17 lists the recommended drugs for the treatment of children and adults with various forms of amebiasis.

TABLE 50–17 Antimicrobial Therapy for Patients with Amebiasis

Asymptomatic amebic cyst	Iodoquinol (Yodoxin) or paromomycin (Humatin) or diloxanide furoate*
Mild to moderate intestinal disease	Metronidazole (Flagyl) followed by iodoquinol or paromomycin
Severe intestinal disease, liver abscess, or other extraintestinal disease	Metronidazole followed by iodoquinol or paromomycin

**Available in the United States from Panorama Compounding Pharmacy (800-247-9767) or Medical Center Pharmacy (203-688-6816).*

Patients with intestinal strongyloidiasis should receive ivermectin for 1 to 2 days or thiabendazole every 12 hours for four doses. Immunosuppressed patients with disseminated disease may require continued therapy for 2 to 3 weeks, but the mortality rate is high despite administration of therapy. A thorough examination should be performed before immunosuppressive therapy is given to a patient with a past history of infection with *S. stercoralis*.

Therapeutic agents generally have not proved consistently beneficial for treatment of patients with cryptosporidiosis, and only one drug (nitazoxanide) is approved by the FDA for this purpose.[1,143] Infection generally is self-limited in immunocompetent patients, and therapy usually is not warranted.[1,176] In patients with persistent disease, an underlying immunodeficiency should be considered. Spiramycin has been used but is ineffective.[435] Paromomycin may be effective in rapid resolution of chronic diarrhea.[138,421,431] In a prospective, randomized, double-blind, placebo-controlled trial in the treatment of adults with AIDS and symptomatic cryptosporidiosis,[176] paromomycin was not effective. Azithromycin has been shown to be effective in treatment of two children with cancer and four children with HIV infection who had severe diarrhea caused by *Cryptosporidium*.[177,413] Combination therapy with paromomycin and azithromycin has been effective in some patients with AIDS and chronic cryptosporidiosis.[379] In a prospective, randomized, double-blind, placebo-controlled study of 50 children and 50 adults, treatment with nitazoxanide reduced the duration of diarrhea and oocyst shedding.[339] A meta-analysis of immunocompromised people treated with nitazoxanide or paromomycin showed no evidence of effectiveness.[1] Evidence of cyst reduction was not significant for HIV-seropositive people. Nitazoxanide showed a significantly higher rate of achieving parasite clearance.[1] Nitazoxanide is licensed for treatment of children with diarrhea caused by cryptosporidiosis and giardiasis. The best approach for prevention of cryptosporidiosis in HIV-infected patients is maintenance of the immune system function by use of HAART because chronic cryptosporidiosis occurs only in severely immunocompromised individuals.

Hyperimmune bovine colostrum has been used with some success in a child with agammaglobulinemia[408] and in a patient with AIDS.[409] Immune bovine colostrum has been shown to neutralize *C. parvum* sporozoites and partially to protect mice against oral challenge with *C. parvum* oocysts,[304] and oral bovine transfer factor has been used for treatment of cryptosporidiosis.[242] Nonspecific therapy with octreotide may control the severe diarrhea that occurs in patients with AIDS but has no effect on the infection[57] and is not approved for this use by the FDA.

For isosporiasis, TMP-SMX is effective and is the drug of choice.[259] In immunosuppressed patients, TMP-SMX, at a dose of 160 mg TMP and 800 mg SMX four times a day for 10 days, followed by the same dose twice a day for 3 weeks, is recommended for adults. In immunosuppressed children, TMP 5 mg/

kg with SMX 25 mg/kg four times a day for 10 days, followed by the same dose twice a day for 3 weeks, should be used. Ciprofloxacin can be used when TMP-SMX cannot be tolerated, although it is slightly less effective. Other drugs, including pyrimethamine-sulfadoxine (Fansidar), metronidazole, and furazolidone, have been reported to be successful for treating patients with isosporiasis.[296,428] Pyrimethamine has been an effective alternative in patients allergic to sulfa drugs.[296] Problems in the treatment of isosporiasis have been encountered in patients with AIDS, in whom a high incidence of recurrence has been reported after treatment has been stopped. Continuation of therapy indefinitely with either pyrimethamine-sulfadoxine or TMP-SMX in adults has been shown to be effective in preventing recurrence of disease.[296]

On the basis of in vitro studies, several drugs have been used to treat microsporidial infections in humans, but successful treatment with any of them in humans is limited. Therapy with antiparasitic drugs, diet alteration, and antidiarrheal medications often fails to relieve diarrhea and malabsorption associated with microsporidiosis, although octreotide may provide symptomatic relief,[57] and diet modification to include medium-chain triglyceride–based diets has produced clinical improvement.[423] *E. intestinalis* is susceptible to albendazole,[82,212,335] which has been reported to stop diarrhea and weight loss as well as to promote weight gain in patients infected with *E. intestinalis*,[104,267,406] although improvement has not been uniform. Infections caused by *E. bieneusi* are more difficult to treat, but oral fumagillin has been effective.[268] The use of HAART may lead to microbiologic and clinical response in HIV-infected patients with diarrhea due to microsporidia.

Patients with HIV and *Cyclospora* infection respond to TMP-SMX, but relapses are common occurrences.[247,259,417] As few as 7 days of treatment may be adequate in immunocompetent children. HIV-infected patients may need higher doses and long-term maintenance. Although ciprofloxacin is not as effective as is TMP-SMX, it is acceptable for patients who cannot tolerate TMP-SMX.[417]

Patients infected with *S. stercoralis* should be treated with ivermectin or, alternatively, thiabendazole.[260] In disseminated strongyloidiasis, ivermectin or thiabendazole therapy should be continued for at least 5 days. In immunocompromised patients and patients with *Strongyloides* hyperinfection, longer duration of therapy may be necessary[233]; however, the mortality rate is high despite therapy. A thorough examination should be performed before immunosuppressive therapy is given to a patient with a history of infection with *S. stercoralis*.

The clinical significance of *B. hominis* remains unclear, few studies have considered the treatment of large numbers of patients, and case-control studies are lacking.[388] Use of metronidazole or iodoquinol in the same dose as for mild to moderate intestinal disease from *E. histolytica* has been reported to be effective in uncontrolled studies,[388] and they are the recommended drugs of choice. TMP-SMX or paromomycin may be the most appropriate second-choice drug.[259] Treatment should be provided with caution, only after a thorough clinical review of other possible causes of symptoms has been performed.

CHAPTER 51

Antibiotic-Associated Colitis

George D. Ferry ✪ James Versalovic

Clostridium difficile colonization and infection accounts for 10 to 25 percent of antibiotic-associated diarrhea and is the major cause of antibiotic-associated pseudomembranous colitis.[8] Diarrhea and colitis develop when antibiotics, especially those with a broad spectrum of activity, disturb the bowel microbiota and allow overgrowth of *C. difficile*. Production of toxins then leads to inflammation and secretion of fluids from the colon, resulting in watery diarrhea. If inflammation progresses and pseudomembranous colitis develops, the diarrhea becomes bloody. Colitis induced by *C. difficile* has been reported without prior use of antibiotics, but it is an uncommon occurrence.

HISTORY

Pseudomembranous colitis was recognized as early as 1893[38] and derives its name from the numerous plaquelike lesions in the colon. The plaques are membranes of epithelial debris containing fibrin, mucus, and polymorphonuclear leukocytes overlying necrotic glands.[96] Not until the early 1950s was an association with antibiotics suggested. The organism that initially received the most attention as a possible cause was *Staphylococcus aureus*.[103] Stool cultures frequently were positive for *S. aureus* after antibiotic use, and autopsies showed enterocolitis with ulcers and pseudomembranes in both the small and the large bowel. The association with *C. difficile*, a gram-positive anaerobic bacillus, was shown in 1977 and 1978 with the reports of production of toxins related to pseudomembranous changes in the colon.[9,10,61] *C. difficile* can colonize the intestine without causing diarrhea and was identified as part of the normal microbiota of infants and newborns in 1935.[47] Early studies suggested that *Clostridium sordellii* might be related to pseudomembranous colitis, but subsequent investigation has shown that *C. sordellii* antitoxin neutralizes *C. difficile* cytotoxicity but is not a cause of colitis.[10]

ETIOLOGY AND PATHOGENESIS

C. difficile can be cultured in 7.6 percent of healthy adults,[34,51] but in hospitalized patients, the incidence of colonization and positive cultures reaches 20 percent or more.[74] *C. difficile*–associated diarrhea appears to have significantly increased in incidence in the United States, especially among the elderly,[70] and outbreaks with a more virulent and a more antibiotic resistant strain have been reported in the United States and Canada.[87] The specific *C. difficile* isolates responsible for some of these outbreaks have been characterized as restriction endonuclease analysis group BI, with an increased production of toxins A and B and also positive for the binary toxin CDT, a possible virulence factor.[4,67,71,72]

C. difficile spores are viable for long periods, up to 5 months,[54] and can be cultured from flooring, toilets, and bedding as well as from the stool and hands of carriers (Table 51–1).[34,54] Numerous studies have shown that neonates frequently are colonized with *C. difficile*.[47,49,117] In a London study, 2 to 52 percent of infants in three postnatal wards had positive cultures, but none developed diarrhea or colitis, and no evidence was found that infants were colonized from their mothers.[60] The rate of colonization appears to be related to the length of time infants are hospitalized.[100] In those older than 1 year, colonization decreases significantly.[46] Not only is *C. difficile* a common contaminant in hospitals,[34,54] but person-to-person transmission among children in daycare centers also has been reported.[53] A hospital outbreak of *C. difficile* in children 18 months to 18 years was reported from a pediatric orthopedic ward.[37]

Infection with *C. difficile* occurs commonly and accounts for 10 to 25 percent of cases of uncomplicated antibiotic-associated diarrhea.[8,109] Most infections cause watery diarrhea, but 5 to 10 percent progress to pseudomembranous colitis.[8,55] Pseudomembranous colitis can occur sporadically or in epidemics.[85,91] In daycare centers, the incidence of *C. difficile* infection not related to antibiotics may be as high as 50 percent.[8,53] Community-acquired diarrhea caused by *C. difficile* studied in a health maintenance organization population identified 51 cases, with an incidence of 7.7 cases per 100,000 person-years.[48] Half of these cases occurred after antibiotic use. Increased age and exposure to more than one antibiotic within a 42-day period increased the risk. *C. difficile* diarrhea was an uncommon occurrence in patients younger than 20 years. Risk factors included inflammatory bowel disease, infection with human immunodeficiency virus, and chronic treatment with antibiotics. In a report of 200 Canadian children with *C. difficile*–associated diarrhea, underlying factors such as chemotherapy, Crohn disease, transplantation, immunodeficiency, and Hirschsprung disease were found in 19 percent of patients.[79] A history of antibiotic exposure in the previous 2 months was present in 74.5 and 55.5 percent of children who had been hospitalized. Elemental diets have been reported to increase the growth of *C. difficile*,[50] and both community- and hospital-acquired *C. difficile*–associated diarrhea are associated with the use of proton pump inhibitors.[26,27]

TABLE 51–1 Distribution of *Clostridium difficile* Isolates Taken from the Environment of Two Pediatric Units

From Kim, K.-H., Fekety, R., Batts, D. H., et al.: Isolation of Clostridium difficile from the environment and contacts of patients with antibiotic-associated colitis. J. Infect. Dis. 143:44-50, 1981.

Virulence may differ among strains of *C. difficile;* some are highly toxigenic, and others have low virulence.[57] This difference may be related to S-layer proteins covering the surface of *C. difficile* serotypes known to cause disease.[94] Production of toxins by the organism and clinical illness are absent in 25 percent of patients with positive cultures.[35] Most toxigenic strains produce both toxin A and toxin B. Toxin B initially was thought to be a cytotoxin with little clinical effect[68,93]; however, more recent studies have shown that it has a significant effect once tissue damage has already occurred.[94] Toxin A produces necrosis and increased cell permeability, and both toxins lead to the production of tumor necrosis factor–α and other cytokines.[94] The increased permeability is responsible for the watery diarrhea.

Studies on the epithelial cell barrier have shown two additional pathways of cell injury.[86,92] *C. difficile* toxins disaggregate actin microfilaments in colonocytes, leading to cell destruction and opening of tight junctions. Toxin A also has a significant chemotactic effect on neutrophils, leading to local inflammation and release of inflammatory mediators.[93] Figure 51–1 illustrates these pathways. In experimental models, injection of toxin A into rabbit ileal loops results in increased fluid secretion, inflammation and necrosis of epithelial cells, and release of prostaglandin E_2 and leukotriene B_4 into the lumen.[113] Another mechanism for diarrhea may relate to decreased anaerobic microbiota and, subsequently, a decreased digestion of carbohydrates, leading to a decreased production of lactic acid and short-chain fatty acids and disturbed function of the colonic mucosa.[12]

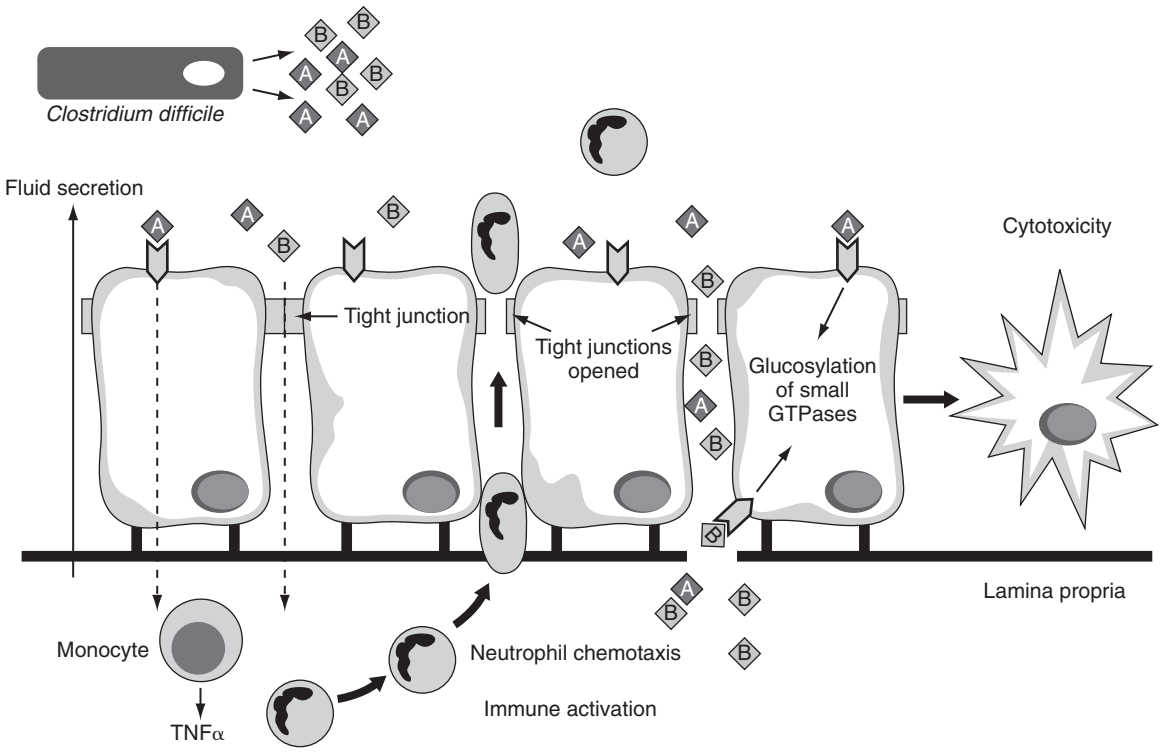

Figure 51–1 Actions of *Clostridium difficile* toxins A and B on intestinal epithelium. *(Courtesy of Ian R. Poxton, Professor of Microbial Infection and Immunity, Medical Microbiology, University of Edinburgh Medical School.)*

Serum antibodies to *C. difficile* toxins A and B occur commonly, being found in 60 to 70 percent of patients older than 3 years.[116] In adults, specific serum IgA and IgG antibodies to toxin A have been detected in 57 to 60 percent of patients.[52] Antibodies also have been found in colonic mucosa and duodenal aspirates in 10 percent of patients. Binding of toxin A was inhibited significantly by colonic aspirates with high-IgA antitoxin-A antibody. These antibodies appear to persist throughout life, and they may have a protective role against recurrence.[58]

Protection against diarrhea and pseudomembranous colitis in newborns may be due to a lack of the intestinal receptor for toxin A[30] or prematurity of the toxin receptor. A study by Enad and colleagues[32] showed that 87 infants colonized with toxin A–positive *C. difficile* had more days of diarrhea than did those who were toxin negative. Although breast milk contains antibody against *C. difficile*, whether it influences disease activity is unclear.[118] *C. difficile* has been suggested to be a causative agent in rare cases of necrotizing enterocolitis, but this suggestion remains controversial.[16,32]

In the normal host, many bacteria, especially lactobacilli, *Bacteroides*, enterococci, and *Escherichia coli*, inhibit growth of *C. difficile*.[99] Treatment with any antibiotic can result in overgrowth of *C. difficile* and lead to pseudomembranous colitis. Oral antibiotics are associated with colitis more often than are parenteral antibiotics, and broad-spectrum antibiotics are responsible for most cases. Multiple antibiotics, including clindamycin, ampicillin, cephalosporin, penicillin, chloramphenicol, gentamicin, trimethoprim-sulfamethoxazole, and rifampicin, have been implicated in antibiotic-associated diarrhea in children.[1,83,111] Fluoroquinolone administration was the most prominent risk factor for *C. difficile*–associated diarrhea (n = 5619 patients) during an epidemic in eastern Canada caused by a hypervirulent strain.[89] Proton pump inhibitors were not associated with disease in this study. Cefixime also has been associated with pediatric pseudomembranous colitis.[45] Long-term antibiotic treatment of acne has been complicated rarely by diarrhea or colitis.[33]

C. difficile infection has been reported in pediatric patients during chemotherapy.[31] The spectrum of illness has been mild to fulminant colitis, just as in antibiotic-associated disease. *C. difficile* also has occurred as an outbreak with associated diarrhea in patients with acquired immunodeficiency syndrome who were admitted to the same hospital ward.[5] In a study in 2005 of 75 pediatric outpatients presenting with diarrhea, positive bacterial isolates were found in 48 percent of patients, and eight children were positive for *C. difficile* toxin.[25]

CLINICAL MANIFESTATIONS

The spectrum of clinical signs and symptoms related to *C. difficile* infection ranges from the asymptomatic carrier state to a fulminant colitis and toxic megacolon.[112] Most patients have watery diarrhea, but 10 to 15 percent have bloody stools.[55] Diarrhea most often begins 3 to 21 days after the use of antibiotics. Most children with diarrhea have a self-limited illness with watery stools, fever, and abdominal pain.[105,111] Patients with pseudomembranous colitis present with cramping abdominal pain and fever, and watery, green, foul stools progress to bloody diarrhea.[29] Colitis often is a mild, self-limited illness once antibiotics are stopped, but it may be severe and require intensive antibiotic and supportive therapy.

Fulminant colitis is an uncommon occurrence but can lead to perforation and colectomy and a high mortality rate (35%).[56] Toxic megacolon, or toxic dilatation of the small bowel, may develop without preceding diarrhea. In these critically ill patients, colitis may lead to perforation and peritonitis. In a series of 201 surgical patients, toxic megacolon developed in five, and four of the five died.[95] Confirmation of the diagnosis may depend on finding the typical pseudomembranous ulcers on colonoscopy. Response to treatment generally is rapid; symptoms clear in 50 percent of patients within 6 to 14 days and in 100 percent by 1 month.

The role of *C. difficile* infection in inflammatory bowel disease has been controversial. Some studies have shown no significant association,[77] whereas others have implicated *C. difficile* in the relapse of Crohn disease and ulcerative colitis.[18,59] The organism has been found in 8 percent of patients in remission,[28] the same as in the general population. The presence of toxin seems to correlate with the degree of bleeding and disease activity.[44] In studies of 59 and 54 patients, toxin was found in 19 and 16 percent of individuals, respectively.[76,114] The majority, 64 and 90 percent of patients, respectively, had received antibiotics previously. These patients responded promptly to treatment with targeted antibiotics, suggesting that the flare of colitis was related to *C. difficile*.

LABORATORY STUDIES

The established standard for diagnosis of *C. difficile* infection is detection of enterotoxins A or B by immunoassays or cell culture–based cytotoxicity tests.[120] Because not all organisms produce toxin, a causative role for *C. difficile* in diarrhea and colitis is based on detection of toxin in the stool rather than a positive anaerobic culture.[42,62] Fresh, liquid stools are the specimens of choice for toxin testing,[24] and all specimens should be tested for both toxins A and B.[69] Production of *C. difficile* toxin can be diagnosed by a variety of techniques. Immunoassays, including laboratory-based enzyme-linked immunosorbent assays and point-of-care immunocard tests, are most commonly used for detection of toxigenic *C. difficile*. Although published sensitivities of these assays exceed 80 percent,[2,35] the reality is that most immunoassays have lower sensitivities when they are used in routine clinical practice. Repeated immunoassay testing usually is recommended when initial testing is negative for *C. difficile* toxin A or toxin B. An alternative and effective approach is the combination of *C. difficile* common antigen testing with toxin detection.[120] This two-pronged approach uses immunoassays to detect a species-specific antigen, glutamate dehydrogenase (GDH or *C. difficile* common antigen), and both enterotoxins A and B. GDH is found in both toxigenic and nontoxigenic strains. Commercial GDH tests are more sensitive than is direct toxin detection, and GDH-positive stools are evaluated subsequently by toxin A or B testing. This approach may detect stools positive for *C. difficile* that may be missed entirely by toxin screening. An enzyme immunosorbent assay test kit combining detection of toxin A and GDH has a negative predictive value for infection with *C. difficile* of 99.6 percent.[24]

Cell culture–based cytotoxicity assays were used widely before the introduction of commercial immunoassays and continue to be a useful approach for detection of *C. difficile* directly in stool specimens. Cell culture testing is tedious and time-consuming for the laboratory, but it may have superior sensitivity for toxin detection if technical expertise is available.[24,35] Fecal material is diluted, and cytopathic effects are evaluated with human fibroblast cell lines to assess the presence of toxin (primarily toxin B). Molecular methods show promise as next-generation methods for direct *C. difficile* enterotoxin gene detection. Polymerase chain reaction amplification, including real-time polymerase chain reaction methods, has demonstrated the ability to detect toxin A (*tcdA*) and toxin B (*tcdB*) genes (DNA) directly in human stool specimens. Published molecular studies described excellent concordance with toxin immunoassays[11,115] while enabling antigen-negative specimens to be detected.[63] Latex agglutination for *C. difficile* antigen is less sensitive than is culture and not as specific as the toxin assay.[42,90] Anaerobic culture of *C. difficile* from human stool specimens, although infrequently practiced in the United States today, may be coupled effectively with immunoassay-based or molecular detection of *C. difficile* enterotoxins. *C. difficile* can be cultured on selective media, such as cycloserine-cefoxitin-fructose agar.[41] Stool culture alone does not determine the presence of toxigenic *C. difficile*, and this approach requires the tedious practice of anaerobic bacteriology for a test that frequently is performed at high volumes.[42]

Peripheral blood leukocytosis of 15,000 cells/mL or more is a common finding in hospitalized patients and may occur with diarrhea or with systemic symptoms of fever and toxicity before the onset of diarrhea.[20] In the appropriate setting, leukocytosis may be an early marker of *C. difficile* infection, with as many as 58 percent of patients being positive for toxins and responding to metronidazole.[119] Stool examination may show evidence of blood and mucus, but fecal leukocytes lack utility for screening because they are present in only 50 percent or less of patients.[35,98]

Endoscopic diagnosis of *C. difficile* is useful when urgent diagnosis is needed before laboratory confirmation of a positive assay for toxin is obtained (Fig. 51–2). Flexible sigmoidoscopy is a rapid diagnostic tool, but in one study of 29 patients with a positive toxin assay, only 55 percent had typical pseudomembranous colitis, 14 percent had nonspecific colitis, and 31 percent were normal.[13] In cases with a typical endoscopic appearance, *C. difficile* toxin is positive in 95 percent.[40] Flexible sigmoidoscopy will detect 90 percent of patients with colitis.[109]

The colon typically appears red with raised, circular, yellow plaques.[40,108] These pseudomembranous plaques vary from 2 to 5 mm in diameter and are scattered throughout the involved area. In the earliest stage, 1- to 2-mm ulcers may be seen but may not have an obvious membrane. Biopsy specimens of these small lesions show the same endothelial degeneration and pseudomembrane as larger lesions do.

Plain radiography of the abdomen in patients with colitis may show a variety of abnormalities, including colonic ileus, small bowel ileus, ascites, and nodular haustral thickening.[17] Colonic findings on computed tomography of the abdomen in adult patients show segmental wall thickening, but this finding is nonspecific.[3] Abdominal ultrasonography also has been used to diagnose cases of *C. difficile* infection.[97] In severely ill patients with pseudo-membranous colitis, leukocyte scintigraphy has demonstrated a constant and diffuse pattern of intense radiotracer.[84] Although not specific, this test may be useful whenever endoscopy cannot be performed.

The presence of *C. difficile* toxin A or toxin B may establish the etiology of diarrhea and colitis; the absence of toxin may not be conclusive. If symptoms are suggestive of antibiotic-associated diarrhea or colitis, studies of stools should be repeated several times before this diagnosis is ruled out.[73]

DIFFERENTIAL DIAGNOSIS

Bloody diarrhea occurring after recent use of antibiotics should suggest the possibility of pseudomembranous colitis. Stool specimens should be obtained for *C. difficile* toxins A and B, along with routine cultures for *Salmonella*, *Shigella*, *Campylobacter*, and enterohemorrhagic *E. coli*. Routine parasitologic testing for *Giardia lamblia* and *Cryptosporidium parvum* by ova and parasite examination or stool immunoassays should be performed. Enteric viruses such as rotaviruses may be an important consideration, especially in children, and may be evaluated with stool antigen immunoassays. The possibility of inflammatory bowel disease, either ulcerative colitis or Crohn disease of the colon, always should be considered, especially if treatment fails to resolve the colitis. A hemorrhagic colitis related to penicillin has been described, but no pseudomembranes were seen on colonoscopy, and studies for *C. difficile* yielded negative results.[80]

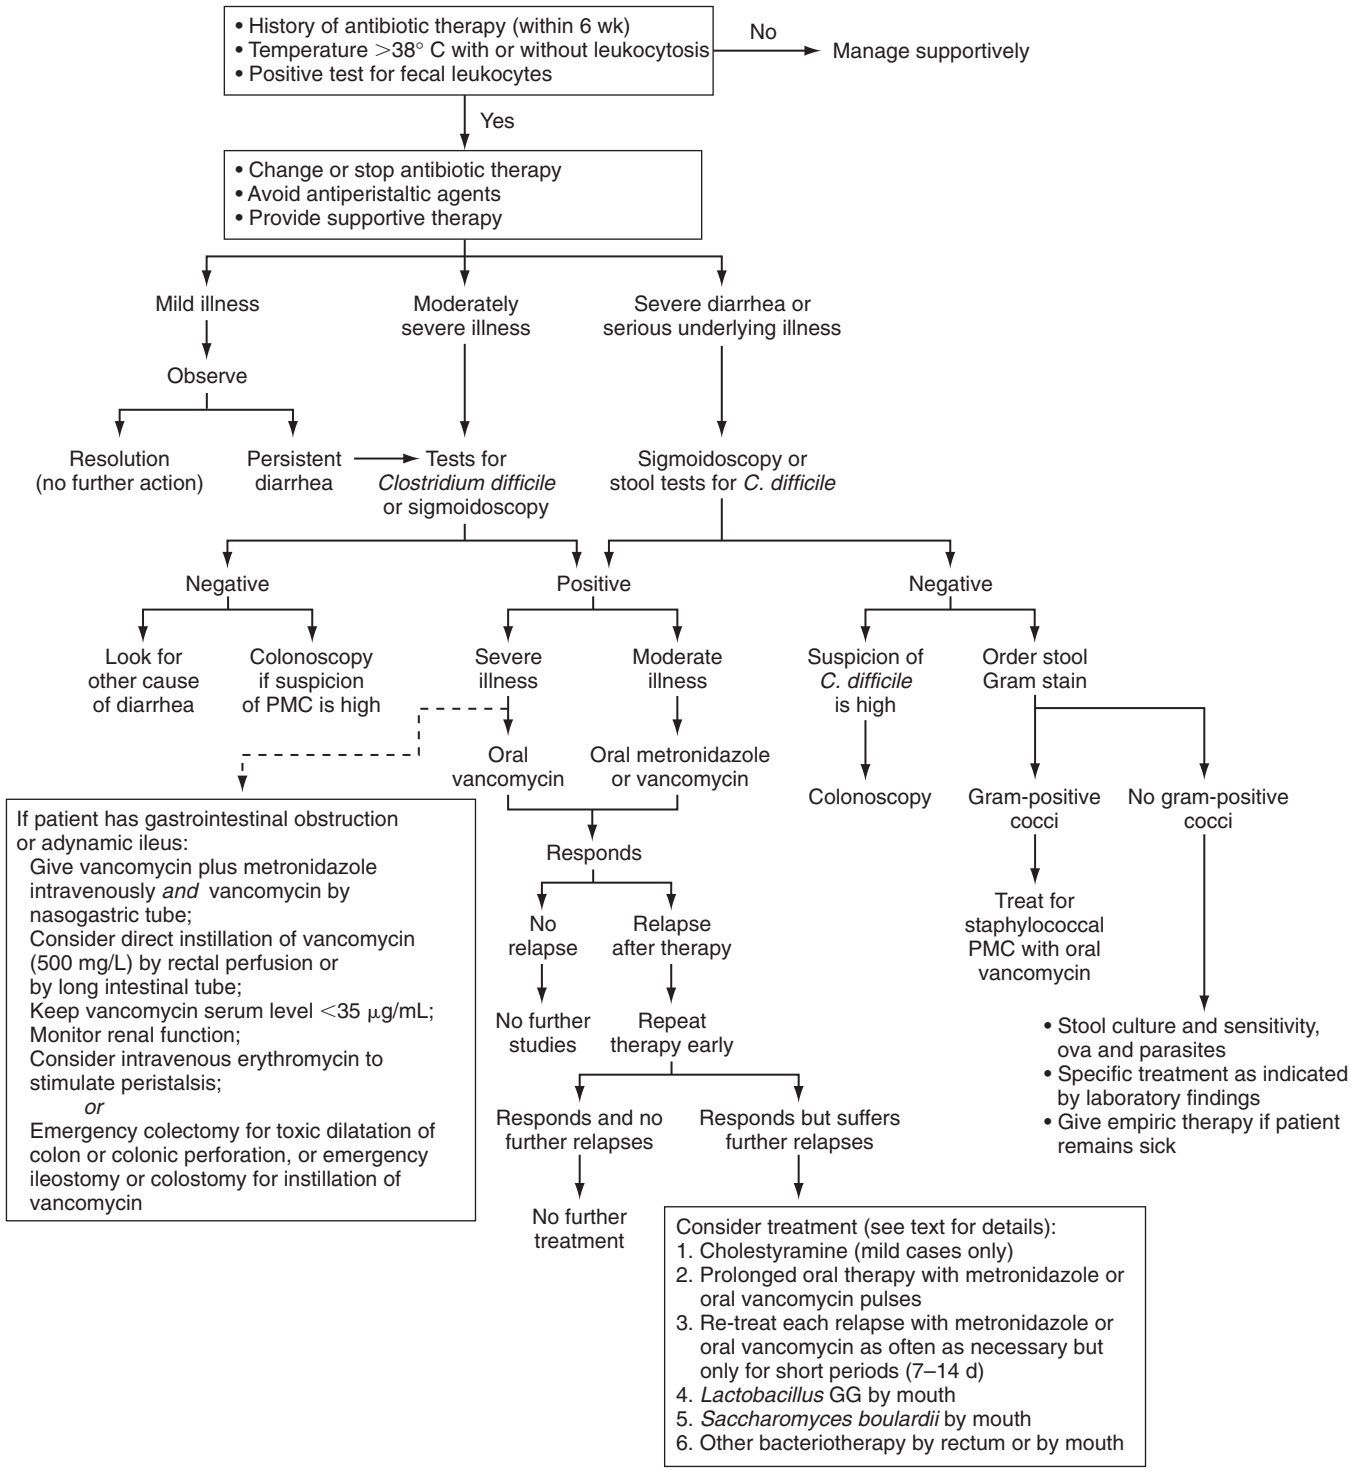

Figure 51–2 Algorithm for management of antibiotic-associated diarrhea and colitis. PMC, pseudomembranous colitis. *(From Fekety, R., and Shah, A. B.: Diagnosis and treatment of Clostridium difficile colitis. J. A. M. A. 269:72, 1993.)*

TREATMENT

In mild cases, discontinuation of antibiotics and implementation of supportive measures alone may lead to gradual resolution of symptoms.[19,108] In a study of 250 hospitalized children aged 5 to 12 years who developed diarrhea while receiving antibiotics, 45 (18%) children had stools positive for toxins A and B.[43] Although bloody diarrhea was a frequent occurrence in these patients, 68.9 percent of cases resolved with discontinuation of antibiotics. Antiperistaltic agents should be avoided because they may cause retention of toxins and complications.[23] Vancomycin has been the accepted treatment of choice for pseudomembranous colitis, but both vancomycin and metronidazole clear 80 to 100 percent of infections (Table 51–2), and metronidazole is considerably less expensive.[6,7,123] The effective oral dose of vancomycin is 40 to 50 mg/kg/day for 7 to 10 days. The adult dose is 125 mg four

times daily for mild cases and up to 500 mg/dose for severe cases.[7,36] Intravenous vancomycin is not effective. Metronidazole is effective in doses of 20 to 40 mg/kg/day; adult doses range from 250 mg four times daily up to 500 mg three times a day. One report of intravenous metronidazole, 500 mg three times daily as initial therapy, showed an excellent clinical response in 10 patients.[39] Oral bacitracin, 25,000 units four times daily, has been used in some adult patients. Systemic signs of infection generally clear within 24 to 48 hours, and diarrhea gradually subsides in 7 to 10 days.

Resistance to metronidazole is being reported, but most of these patients will respond to vancomycin.[15,78,81] Fusidic acid and nitazoxanide both have been shown to be as effective as is metronidazole.[82,121] In a series of 14 adults with severe and recurrent *C. difficile*–associated diarrhea, 64 percent of cases resolved after receiving intravenous immunoglobulin (150-400 mg/kg).[75] Relapse is a major problem and occurs in 5 to 33 percent of patients treated with either vancomycin or metronidazole (see Table 51–2).[106,107] If a relapse produces severe symptoms, retreatment generally is required.[107] In mild relapse, patients may be watched to see whether they clear the infection spontaneously. Other therapeutic regimens to treat relapse have included weaning to the point at which vancomycin or metronidazole is administered every other or every third day.[110] In some patients, administration of cholestyramine has helped clear recurrent diarrhea.[35] One study in children showed an excellent response to immune globulin given intravenously.[64]

Probiotics also have been of interest, especially in patients who relapse. *Saccharomyces boulardii* given daily for 2 weeks produced resolution of symptoms within 1 week in 18 of 19 children with diarrhea caused by *C. difficile*.[21] Relapse occurred in 11 percent of the patients. *Lactobacillus rhamnosus* GG also has been effective in clearing *C. difficile* diarrhea.[14] A combination of oral vancomycin and *S. boulardii* also has been effective in curing relapsed infection.[104] The use of prebiotics has had variable results. Oligofructose has been reported to be beneficial in prevention of relapse,[65] but it is not useful in protecting adult patients while they are receiving antibiotics.[66]

Response to treatment is poor with ileus, toxic megacolon, or colonic perforation. In these cases, instillation of vancomycin by clamped nasogastric tube or direct colonic instillation can be tried.[101] The colonic vancomycin dose for adults is 2000 mg initially, followed by 100 mg every 6 hours.[88]

PREVENTION

To date, no effective means have been implemented to prevent the spread of and colonization with *C. difficile* or to prevent antibiotic-related pseudomembranous colitis. Private rooms and enteric precautions usually are used, but their efficacy is unknown. Bactericidal activity against *C. difficile* spores has been shown with both peracetyl ions and acidified nitrite, both environmentally safe materials.[122] In one study from Turkey of 151 hospitalized patients given antibiotics, prophylactic *S. boulardii* given twice daily reduced *C. difficile*–positive stools from 9 percent in the placebo group to 1.4 percent in the treatment group.[22] A very small number of patients with recurrent *C. difficile*–associated diarrhea have received a vaccine containing toxoid A and B with resolution of diarrhea.[102]

CHAPTER 52

Whipple Disease

Roberto A. Guerrero ❂ Mark A. Gilger

Whipple disease is a rare, systemic bacterial infection that can be potentially fatal without therapy. In its most common form, Whipple disease affects white, middle-aged men, causing diarrhea, weight loss, abdominal pain, arthralgias, and fever. Although it is extraordinarily rare in children, its recognition may be crucial. Simple treatment with appropriate antibiotics may be curative and lifesaving.[28] Despite successful cultivation of the bacterium *Tropheryma whipplei* (formerly *Tropheryma whippelii*) in 2000,[56] little progress has been made in the development of improved diagnostic tests.

HISTORY

Whipple disease was described in 1907 by George Hoyt Whipple,[77] at that time an Instructor in Pathology at The Johns Hopkins University.[6] Whipple's description probably was not the first; Allchin and Webb apparently described a patient with "Whipple disease" in 1895.[48]

In Whipple's account, a 37-year-old medical missionary was admitted to the Johns Hopkins Hospital with low-grade fever, steatorrhea, and an abdominal mass. The patient had a 5-year history of sporadic migratory polyarthritis. These attacks of arthritis were associated with a gradual loss of weight and strength. His skin was pigmented with a brownish hue. Laboratory evaluation found severe anemia and an enormous number of fatty acid crystals in the stool. Explorative laparotomy revealed large, firm mesenteric lymph nodes, and a diagnosis of either Hodgkin disease or tuberculosis was made. The patient died 1 week later, and autopsy revealed marked fatty deposition within intestinal mucosa and the mesenteric and retroperitoneal lymph nodes. Other findings included polyserositis (peritonitis, pleuritis, and pericarditis) and endocarditis. Histologic examination revealed infiltration of the lamina propria of the small intestine by large,

foamy mononuclear cells that did not stain for fat. Fatty acids and triglycerides were found in dilated lymph channels. Silver stains of the mesenteric lymph nodes showed "great numbers of rod-shaped organisms" that resembled the tubercle bacillus. Whipple suggested that these bacillus-like organisms in the nodes could be the cause.

Whipple[77] reported "a hitherto undescribed disease characterized anatomically by deposits of fat and fatty acids in the intestinal and mesenteric lymphatic tissues." He concluded that the patient had "an obscure disease of fat metabolism," and proposed the term *intestinal lipodystrophy*.[18] Whipple recognized the most important features of this disease except for the involvement of the central nervous system (CNS). In 1949, Black-Schaffer showed that macrophages within the intestinal mucosa of patients with Whipple disease are stained intensely by the periodic acid–Schiff method,[35] proving that the macrophages contained glycoprotein or mucopolysaccharide, not fat, as Whipple had suggested.

In 1992, Relman and colleagues[59] identified a gram-positive bacillus in association with Whipple disease by use of polymerase chain reaction (PCR). They reported a unique 1321-base pair, 16S ribosomal RNA sequence amplified by PCR on intestinal and lymph node tissue from five unrelated patients with Whipple disease. They suggested that the responsible bacillus is a member of the actinomycetes. Relman and colleagues[59] concluded that the phylogenetic relationships of the Whipple disease bacillus, the features of the illness, and its distinct morphologic characteristics provided sufficient grounds to propose a new genus and species name, *Tropheryma whippelii* (from the Greek *trophe*, or "nourishment"; *eryma*, or "barrier," because of the malabsorption it causes; and *whippelii*, in honor of Whipple).

EPIDEMIOLOGY

Whipple disease characteristically occurs in white middle-aged men. Its true incidence and prevalence are unknown because fewer than 1000 cases have been reported worldwide. It is an extremely rare disease in children,[1,2,4,10,34,73] with fewer than 10 cases reported. The youngest patient was a newborn,[15] and the oldest was 83 years old.[42] The peak age at presentation is 40 to 49 years.[24] In a literature review of 114 patients,[42] 88 percent were men and 12 percent were women. Most of these patients were white. Most patients reported as having Whipple disease are from continental Europe or the United States.[13] In an extensive review of 741 cases, Dobbins[20] found that most academic centers in the United States had records of three or four unreported cases. He estimated that for every published report, at least two or three unpublished cases exist, and approximately 1500 to 2000 individuals probably have had Whipple disease.[18]

ETIOLOGY AND PATHOGENESIS

Whipple disease is caused by an organism known as Whipple bacillus or *T. whipplei*.[24,42,56,77] Despite Whipple's account of "great numbers of rod-shaped organisms,"[77] culture of the organism was unsuccessful until more recently. In 2000, Raoult and associates[56] reported that the bacterium *T. whipplei* had been cultured successfully from an aortic valve vegetation in a patient with prolonged endocarditis. The bacteria were isolated after inoculation in a human fibroblast cell line (HEL). Analysis by PCR confirmed that the 16S ribosomal RNA gene of the cultured bacterium was identical to the *T. whipplei* sequence. Subcultures of the bacterium also were obtained, and high-titer polyclonal antibodies against *T. whipplei* were produced. Such antibodies potentially may allow serologic diagnosis to become a reality.

T. whipplei may be a member of the actinomycetes,[59] which are gram-positive bacteria with DNA rich in guanine and cytosine.[78] The genus consists of actinomycetes, streptomycetes, and the nocardioforms.[14] *T. whipplei* seems to be related most closely to the four actinobacteria *Dermatophilus congolensis*, *Arthrobacter globiformis*, *Terrabacter tumescens*, and *Micrococcus luteus*.[59] Using so-called bootstrap analysis, some researchers have argued that the Whipple bacillus is only 67 percent associated with actinobacteria, far from the level needed for scientific conclusion.[67] The Whipple bacillus may represent another, separate, fourth line of descent with the actinomycetes. Amplification, cloning, and sequencing of a 620-base pair fragment of *T. whipplei* heat shock protein led to the conclusion that *T. whipplei* is a member of the actinobacteria.[49]

Scant support exists for a primary humoral immunodeficiency in Whipple disease,[27] but stronger evidence exists for a distinct defect in the cell-mediated immune function. Dobbins[19] reviewed data of 30 patients with HLA-A and HLA-B locus typing and 47 patients with HLA-B27 typing. He found an increased incidence of patients who were positive for HLA-B27 (28%), even with absence of concomitant sacroiliitis. Other reports have failed to confirm the increased association with the HLA-B27 antigen.[3] Marth and associates[44] studied 27 patients with Whipple disease. They found a significantly reduced number of cells expressing the complement receptor 3 L-chain (CD11B), a reduced proliferation to phytohemagglutinin and to sheep red blood cells, and a hypoergic skin reaction. These findings indicated a defect of cell-mediated immunity.

In patients with active disease, the number of $CD8^+$ cells is increased, which results in a reduced CD4/CD8 ratio. Such defects of cellular immunity seem to persist in patients for several years, despite complete remission of the disease. Schoeden and associates[65] were able to culture *T. whipplei* in mononuclear phagocytes deactivated with interleukin-4 (IL-4), IL-10, and dexamethasone. IL-4 was found to be the crucial deactivating signal that rendered monocytes permissive for intracellular multiplication of *T. whipplei*. IL-4 is an immunoregulatory cytokine. Schoeden and associates[65] suggested that host factors, such as an imbalance in the T-helper 1 and T-helper 2 immune response, may contribute to the pathogenesis of Whipple disease.

Desnues and colleagues[17] reported a specific gene expression pattern associated with replication of *T. whipplei* in macrophages. *T. whipplei* organisms are killed by monocytes. The addition of exogenous IL-16 enabled *T. whipplei* to replicate in monocytes and increased bacterial replication in macrophages. *T. whipplei* replication in macrophages was completely prevented after blocking IL-16 activity with the use of anti-IL-16 antibodies. Untreated patients with Whipple disease were noted to have significantly higher circulating IL-16 than that of control subjects and patients treated for Whipple disease. They concluded that response of monocytes and macrophages to IL-16 likely is crucial for replication of *T. whipplei* to occur, in patients with Whipple disease.

Oral acquisition of the Whipple bacillus seems most likely,[24] emphasizing greater involvement of the duodenum and proximal jejunum than the more distal small intestine. Only three reports of siblings with this disease exist; contagious spread of Whipple disease seems unlikely.[32] *T. whipplei* has been identified free in the small intestine next to the glycocalyx of the enterocyte's microvilli, in epithelial cells, and in the lamina propria.[24] Even in patients with extraintestinal Whipple disease, the organism usually is identified in the small bowel.[24] The bacillus seems to spread through the lymphatics and through the systemic circulation[24,36,50] and then can involve several extraintestinal organs.

T. whipplei can be seen faintly by light microscopy. The bacilli are seen best by transmission electron microscopy, which reveals a rod-shaped organism 0.2 μm wide and 1.5 to 2.5 μm long (Fig. 52–1). The ultrastructure of the wall of *T. whipplei* is similar to that of other gram-positive bacteria, with the exception of an

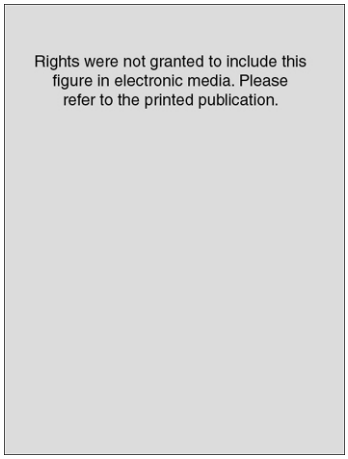

Figure 52–1 Electron micrograph of the invasion of enterocytes by Whipple bacilli. There are numerous bacilli within the lamina propria. (Magnification ×25,000.) *(From Tyor, M. P.: Whipple's disease: The Duke connection. N. C. Med. J. 55:237-240, 1994.)*

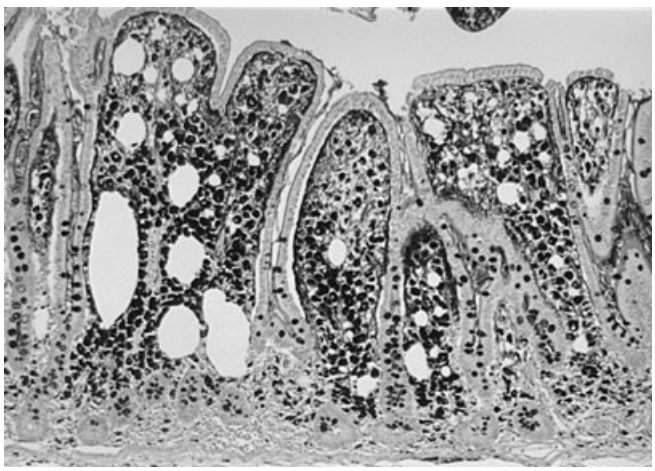

Figure 52–2 Light microscopic photograph of intestinal mucosa from the proximal jejunum of a patient with untreated Whipple disease. The villi appear blunted and swollen with periodic acid–Schiff-positive macrophages stuffed in the lamina propria. *(Courtesy of Kenneth P. Batts, M. D., Mayo Clinic, Rochester, MN; Jeffrey Craver, M. D., DePaul Health Center, Bridgeton, MO; and Milton J. Finegold, M. D., Baylor College of Medicine, Houston, TX.)*

additional surface membrane. This membrane is different from the outer membrane of gram-negative bacteria because it is thinner, has a symmetric profile, and has no periodic acid–Schiff-positive components.[67] After the bacillus has been ingested by the macrophage, the degenerative process that occurs leads to the accumulation of bacterial remnants that are resistant to degradation. The polysaccharide-containing portion of the bacillus wall correlates with these remnants, and its progressive accumulation leads to the typical intramacrophagic inclusions. These inclusions are periodic acid–Schiff-positive and one of the key features in the histologic diagnosis of Whipple disease.[67]

Biopsy specimens from the small intestine in patients with Whipple disease usually show characteristic changes. The intestinal villi are preserved,[24] but distortion of the architecture occurs.[27] A clubbed appearance of the intestinal villi[42] usually is present caused by the accumulation of foamy macrophages in the lamina propria.[24] The enterocytes may appear normal,[21,42] or they may show flattening and vacuolization and occasionally appear cuboidal (Fig. 52–2).[21,42] Lipid accumulation, with large fat droplets within the lamina propria and smaller droplets within and between the absorptive cells, occurs commonly.[42] In some instances, prominent, dilated lacteals are present.[24] Ectors and associates[21] reported reduced and absent lactase and major histocompatibility complex class II (HLA-DR) expression. Lactase and major histocompatibility complex class II expression normalized within 3 to 6 months of starting antibiotic therapy.

Figure 52–3 Electron micrograph illustrating numerous rod-shaped bacilliform bodies within the cytoplasm of a macrophage. (Magnification ×13,750.) *(From Tyor, M. P.: Whipple's disease: The Duke connection. N. C. Med. J. 55:237-240, 1994.)*

The characteristic feature of Whipple disease is the presence of periodic acid–Schiff-positive, diastase-resistant macrophages.[32] These findings are not pathognomonic, however, because intestinal periodic acid–Schiff-positive macrophages can be found in other conditions,[24] such as histiocytosis, melanosis coli, and *Mycobacterium avium-intracellulare* infection, and even within macrophages in healthy individuals. The macrophages in Whipple disease do not stain with Ziehl-Neelsen.[21,32] A sickle-shaped appearance of the periodic acid–Schiff-positive granules often is present in the macrophages of patients with Whipple disease.[42]

Sieracki and Fine[66] observed systemic involvement in the autopsies of five patients with Whipple disease. The sickle-shaped, periodic acid–Schiff-positive macrophages were thought to be specific for Whipple disease, showing involvement of the entire gastrointestinal tract and the pancreas; diffuse involvement of the retroperitoneum and lymph nodes, the adrenals, the liver with sickle-form particles in Kupffer cells and in histiocytes, the brain, the heart, and the visceral pleura of the lungs; and minimal involvement of the genitourinary tract, skeletal muscles, and bone marrow. James and associates[36] examined the vessels of the gastrointestinal system and found abundant bacilli in the arteries of the small intestinal serosa and liver. They noted focal degeneration and fibrosis in the tunica media with arteritis and intimal proliferation. Rickman and coworkers[60] reported a case that confirmed the presence of *T. whipplei* in the vitreous of the eye.

T. whipplei produces a predominantly histiocytic inflammatory reaction, with infiltration by macrophages.[23] Noncaseating, epithelioid cell, sarcoid-like granulomata are located preferentially in peripheral lymph nodes and the liver.[16,23] These granulomata occasionally can be seen in different tissues, including three reports of granulomata in the intestinal tract.[23] Mesenteric lymph nodes often are strikingly enlarged.[13]

Electron microscopy can be useful, often revealing the presence of the rod-shaped bacterium (see Fig. 52–1).[28] Electron microscopy also shows intestinal macrophages containing bacteria with signs of lysis.[67] Silva and associates[67] described steps of a degradative process of the bacillus that starts with disorganization of the surface membrane and the thick outer wall. With the loss of intracellular material, bacterial ghosts composed of the three inner layers of the envelope are present. The two electron-dense layers of the cytoplasmic membrane become disorganized and solubilized, leaving the inner dense layer of the cell wall as the final bacterial remnant (Fig. 52–3).

CLINICAL MANIFESTATIONS

Whipple disease is viewed best as a multisystem illness. It usually manifests with arthralgias and then progresses to involve the gastrointestinal tract.[5] Malabsorption is the key feature of clinical disease, but no specific signs or symptoms for Whipple disease are known. Table 52–1 lists the major symptoms and signs of Whipple disease. In children, failure to thrive, malnutrition, and chronic diarrhea appear most frequently. Abdominal distention, abdominal pain, and generalized lymphadenopathy may be found.[2] Response to antibiotic treatment may be dramatic, with rapid weight gain and resolution of symptoms.[4]

GASTROINTESTINAL TRACT

One of the most common symptoms is weight loss, which is found in 65 to 100 percent of patients.[13,22,24,28,42] Weight loss may be the only symptom.[10] Diarrhea is reported in 60 to 85 percent of patients.[13,24,28,42] The diarrhea usually is watery or fatty in nature.[42] Several mechanisms have been proposed to explain the malabsorption and steatorrhea in Whipple disease.[24] Direct infection and secondary enterocyte dysfunction may prevent the esterification of fatty acids to triglycerides and inhibit the uptake of carbohydrates and amino acids. Blockage of transport of triglyceride-rich chylomicrons into lacteals may result from the deposition of foamy macrophages in the lamina propria. Lymphatic obstruction may occur by involvement of the mesenteric lymph nodes. Malabsorption and diarrhea tend to resolve within a few days after initiation of antibiotic treatment, whereas the lacteal dilation and periodic acid–Schiff-positive macrophages can remain for months to years. Occult gastrointestinal bleeding frequently is found, but melena and gross gastrointestinal bleeding are rare. Hematemesis was reported more recently.[11] Endoscopy revealed diffuse hemorrhagic duodenitis with bleeding on contact.

Abdominal pain is experienced by 60 percent of patients.[13,24,28,42] The pain is nonspecific, is generally epigastric, and may be worse after meals.[42] Abdominal pain and anorexia may lead to reduced calorie intake and further weight loss.[24] Abdominal distention occurs commonly and may be secondary to intra-abdominal lymphadenopathy or to thickening of loops of diseased intestine.[24,42] Ascites occasionally is seen and may be chylous, secondary to lymphatic obstruction.[10,28]

TABLE 52–1 Major Symptoms and Signs in Whipple Disease

Symptoms	Cases (%)
Weight loss	65-100
Chronic diarrhea	60-85
Arthralgia	65-80
Abdominal pain	60
Fever	10-55
Central nervous system–related complaints	10-40
Signs	
Malnutrition	90-95
Hypotension	70
Lymphadenopathy	55
Hyperpigmentation	45-55
Abdominal tenderness	50
Edema	30
Abdominal mass	20
Hepatomegaly	1-14
Splenomegaly	5-10
Ascites	8

Data from references 10, 23, 24, 35, 38.

JOINTS

Arthralgia, the most frequent nongastrointestinal symptom in Whipple disease,[24,42] is present in 65 percent of adult cases.[42] Arthralgia may precede manifestation of gastrointestinal symptoms by many years or decades[24,39] and occurs less frequently in children. Generally, joint symptoms continue unchanged with the onset of gastrointestinal symptoms.[24] Acute migratory arthralgia or arthritis may last days or weeks[28,32,42] and may persist as the disease progresses. The involved joints, in decreasing order of frequency, are knees, ankles, hips, fingers, wrists, elbows, hands, and spine.[24] Examination may reveal joint pain, swelling, limited range of motion, and warmth.[63] Fever sometimes is present.[24] Spondylitis, with or without sacroiliitis, may develop.[4] Permanent joint destruction and deformity are uncommon occurrences, but can be severe.[24,63] Arthrocentesis may reveal an inflammatory arthritis, with cell counts of 6000 to 75,000, often with a polymorphonuclear leukocyte predominance.[24] Synovial biopsy may show periodic acid–Schiff-positive macrophages.[24]

CENTRAL NERVOUS SYSTEM

Whipple disease can be confined to the brain[61] but usually is accompanied by other manifestations.[28] CNS and neurologic manifestations, such as headache, diplopia, meningoencephalitis, depression, confusion, and personality changes, are uncommon manifestations[13,24,42] but may be significant.[13,24,27,42,51,53] Table 52–2 lists the spectrum of potential CNS involvement.

TABLE 52–2 Central Nervous System Symptoms and Signs of Whipple Disease

Ataxia
Confusion
Convulsions
Dementia
Depression
Diplopia
Dizziness
Facial pain
Headache
Hearing loss
Hemiparesis
Hyperphagia
Hyperreflexia (± Babinski sign)
Incoordination
Lethargy, coma
Loss of vibratory and position sense
Meningoencephalitis
Mental and personality changes
Motor weakness
Muscle jerks and twitches
Muscle rigidity
Numbness
Nystagmus
Ophthalmoplegia
Papilledema
Polydipsia
Ptosis
Pupillary abnormalities
Sensory loss
Sleep disorders
Slurred speech
Stiff neck
Tinnitus
Visual difficulties (diplopia, blurring)

EYE

Indirect involvement of the CNS and direct involvement of the eye can produce visual problems.[24] Ophthalmoplegia and diplopia can occur with involvement of cranial nerves III, IV, and VI.[24] Reduced visual acuity and papilledema can occur with compromise of the optic nerve.[24] Numerous ophthalmologic findings, including vasculitis, vitritis, optic atrophy, uveitis, chorioretinitis, vitreous opacities, glaucoma, keratitis, retinal hemorrhages, disk edema, and lacrimal duct obstruction, have been reported.[24,75,76] Rickman and associates[60] reported a case of ocular disease without marked CNS or gastrointestinal disease.

SKIN

Hyperpigmentation of the skin in sun-exposed areas occurs in roughly half of cases.[27,42] The mechanism of hyperpigmentation is uncertain but is not related to adrenal insufficiency.[24] Subcutaneous nodules may be found and can reveal periodic acid–Schiff-positive macrophages and bacilli on electron microscopy.[31]

HEART

The heart frequently is involved in Whipple disease. Endocarditis, myocarditis, pericarditis, pancarditis, and coronary arteritis have been found.[24,46,74] A blood culture–negative endocarditis may be caused by Whipple disease.[24] Chronic aortic regurgitation is the most common clinical finding of endocardial involvement.[24] Pericarditis with polyserositis (pleuritis, peritonitis) has been found.[26] The abnormalities on electrocardiogram are nonspecific but include first-degree atrioventricular block, left ventricular hypertrophy, sinus tachycardia, left bundle branch block, intraventricular conduction delay, old inferior wall infarct, and short PR interval.[27] Sossai and associates[69] reported a case of regression of a right bundle branch block after treatment with antibiotics, but the block spontaneously recurred 2 years later.

SKELETAL MUSCLE

Skeletal muscle may be involved, diagnosed by electromyography or muscle biopsy.[71] Proximal muscle weakness occurs most commonly. Muscle biopsy reveals a nonspecific myopathy.

LYMPH NODES AND SPLEEN

Whipple disease may involve any lymph node in the body.[24] Mesenteric lymph nodes frequently are involved, and splenomegaly is found in 5 to 10 percent of cases.[42]

PULMONARY

Cough, pleuritic chest pain, and dyspnea have been reported.[72] Pleural involvement may appear as a pleural rub. Pleural adhesions and granulomata have been reported at autopsy.[4,72] Chest radiography often reveals pleural thickening, parenchymal shadowing, and elevation of the diaphragm.[72] Lung function tests may show decreased lung volumes.[72]

KIDNEY

Renal involvement in Whipple disease is rare.[24] Granulomata have been found, however, as has focal glomerulonephritis.[38]

HEMATOLOGIC

Anemia occurs commonly and usually is of a hypochromic, microcytic variety.[24,27,28] Macrocytic anemia caused by malabsorption of folate also may be seen. Leukocytosis, thrombocytosis,[52] and bone marrow involvement may be found.[57] Low serum iron concentration and an elevated erythrocyte sedimentation rate frequently are seen.[27] A single case of extraintestinal lymphoma in association with Whipple disease found at autopsy has been reported.[30]

DIAGNOSIS

Despite the successful culture of the organism in 2000,[56] no specific diagnostic tests have been developed. Anemia and low albumin probably are most common, being found in approximately 90 percent of patients. Low serum iron and folate concentrations are seen in approximately 30 percent of cases. Hypokalemia, hypocalcemia, low cholesterol and carotene, prolonged prothrombin time, and increased transaminases are less common findings. Elevated fecal fat is found in more than 90 percent of cases. The D-xylose malabsorption test result frequently is abnormal.

Barium x-ray studies of the small bowel may show marked thickening of the mucosal folds and separation of bowel loops, suggesting a malabsorptive disease. These findings usually resolve completely with successful antibiotic therapy. For CNS Whipple disease, characteristic abnormalities seen on computed tomography scans of the brain include atrophy, focal gray matter lesions, hydrocephalus, and white matter alterations.[73]

A key feature in the histologic diagnosis of Whipple disease is the accumulation of periodic acid–Schiff-positive, diastase-resistant macrophages in the lamina propria of the small intestine.[4,27,43] These findings are not pathognomonic, and infection with *Mycobacterium avium-intracellulare* must be excluded.[43] *T. whipplei* does not stain acid-fast,[43] whereas mycobacteria are identified readily. Small bowel involvement by *M. avium* complex can have endoscopic, histologic, and radiographic findings similar to those of Whipple disease.[55] Periodic acid–Schiff-positive macrophages occasionally can be seen in the mucosa of the large bowel and rectum in unrelated diseases, such as histiocytosis, and in benign conditions, such as melanosis coli and pneumatosis intestinalis.[43] Electron microscopy can confirm the diagnosis by visualization of the characteristic bacillus.[28,67]

Endoscopy of the small bowel may be helpful because characteristic lesions may be seen, and biopsy specimens can be obtained. No clear data suggest where the intestinal specimens should be taken[43] because intestinal involvement usually is patchy. Random biopsy samples of the small bowel are suggested, beginning at the ligament of Treitz.[47] Endoscopic findings include yellow-white plaques and an erythematous, erosive, friable mucosa.[29]

PCR amplification may be used to detect and identify bacterial pathogens. To set up a PCR, the only prerequisite information is the nucleotide sequences flanking each end of the target.[58] PCR has become an important method for establishing the diagnosis of Whipple disease. It may be especially helpful if the histopathologic examination findings are normal or in patients with unusual extraintestinal involvement. Specific identification of *T. whipplei* can be achieved by amplification of the 1321-base pair bacterial, 16S ribosomal RNA gene isolated from infected tissue.[59] Muller and associates[50] applied this PCR technique to show *T. whipplei* in peripheral blood mononuclear cells and cells derived from pleural effusion in a patient with Whipple disease. PCR techniques have been used to detect *T. whipplei* in erythrocytes,[41] cerebrospinal fluid,[6] and resected heart valves with infective endocarditis.[10,12,50]

Sloan and colleagues[68] reported in 2005 another real-time PCR method using a 213-base pair target sequence of the heat shock protein (hsp65) gene of *T. whipplei*. The sensitivity, specificity, and positive and negative values of this LightCycler real-time PCR were compared with the conventional 16S rRNA gene sequence PCR assay and were 98 percent (sensitivity), 99 percent (specificity), 94 percent (positive), and 100 percent (negative). The completion time of the LightCycler assay was approximately 5 hours, which was significantly less than the 2 to 3 days required for the traditional PCR assay.[68]

The diagnostic utility of PCR in Whipple disease is clear, but it cannot be taken as the sole basis for diagnosis. Ehrbar and associates[23] studied the specificity of PCR for *T. whipplei*. They performed elective gastroscopy on patients without known Whipple disease. PCR analysis was positive in 4.8 percent of duodenal biopsy specimens and 11.4 percent of gastric juice samples. Compared with the gold standard of histology and clinical signs, the specificity of PCR for *T. whipplei* was 95.2 percent for duodenal biopsy specimens and 88.6 percent for gastric juice. These findings suggest that *T. whipplei* or a closely related bacterium may be present in some people without known Whipple disease. Street and colleagues[70] detected *T. whipplei* DNA by PCR in the saliva of 35 percent of 40 healthy adults tested, which suggests that this organism can be an oral commensal.

TREATMENT

Antibiotics are the mainstay of therapy for Whipple disease.[13] In vitro antibiotic susceptibility testing using real-time PCR has identified penicillin, doxycycline, macrolides, ketolides, rifampin, aminoglycosides, teicoplanin, chloramphenicol, and trimethoprim-sulfamethoxazole (TMP-SMX) with activity.[7,8,45] Current antibiotic treatment strategies are empiric, based only on the accumulated anecdotal experience, although controlled trials are under way. Generally, response to antibiotics is good and often dramatic. Symptoms such as diarrhea quickly resolve, and weight gain is rapid. Several antibiotics that have been tried alone or in combination include chloramphenicol, penicillin, streptomycin, ampicillin, TMP-SMX, erythromycin, and doxycycline.[13,24,25,28] Keinath and associates[37] analyzed the antibiotic response rate of 88 patients with documented Whipple disease. Thirty-one patients experienced relapse, with a mean time to relapse of 4.2 years after initial diagnosis. CNS relapse occurred in 13 of 88, and all CNS and cardiac relapses were late (Table 52–3). In addition to diagnosis, PCR may prove useful in the monitoring of response to antibiotic therapy.[33,54]

All patients with Whipple disease should receive antibiotics that penetrate the blood-brain barrier.[37,62] Tetracycline and penicillin do not penetrate the blood-brain barrier well, unless the meninges are inflamed.[62] The preferred treatment in adults and children is TMP-SMX given orally twice a day for 1 year.[62] If the small bowel is involved, repeated small bowel biopsy is suggested at least 6 months to 1 year after treatment to document the disappearance of the bacillus. For patients who do not tolerate TMP-SMX, penicillin or ampicillin is recommended. Levy and associates[40] described a case of acquired resistance to TMP-SMX that responded to oral penicillin. Feurle and Marth[25] noted that TMP-SMX was more efficacious than tetracycline in inducing clinical remission of Whipple disease. They observed the development of aqueductal stenosis with hydrocephalus in a patient receiving TMP-SMX treatment, however, and indicated that even TMP-SMX is no safeguard against cerebral recurrence.

CNS relapse has a poor prognosis.[9,24,25,28,37] Feurle and Marth[25] suggested an experimental therapy for CNS recurrence with a highly active bactericidal compound, such as a third-generation cephalosporin, a quinolone, or intrathecal antibiotic therapy, that readily crosses the blood-brain barrier. In adult patients, Keinath and associates[37] recommended treatment with parenteral penicillin (1.2 million U daily) plus streptomycin (1 g daily) for 10 to 14 days, followed by TMP-SMX (1 double-strength tablet twice daily) for 1 year. Because of the extreme rarity of the occurrence of Whipple disease in children, prudent management dictates long-term surveillance after resolution of symptoms.

Because Whipple disease is a malabsorptive disorder, the patient's nutritional needs must be assessed carefully. Specific attention must be paid to replacement of any vitamin or mineral deficiencies. Iron, folate, vitamin D, and calcium typically are given until the steatorrhea resolves.

TABLE 52–3 Treatment of Whipple Disease: Initial Antibiotic Regimen and Relapse

Antibiotics	No. Patients	Total No. Relapses	CNS Relapses
TCN* alone	49	21	9†
PCN + STM + TCN*	15	2	0
PCN/PCN*	8	3	2
PCN + STM	5	2	0
TMP-SMX*	3	0	0
Other	8	3	2
Totals	*88*	*31*	*13*

**Oral therapy.*

†Includes two patients treated with TCN only in whom CNS relapse was the second relapse.

CNS, central nervous system; PCN, penicillin; STM, streptomycin; TCN, tetracycline; TMP-SMX, trimethoprim-sulfamethoxazole.

Data from Keinath, R. D., Merrell, D. E., Vlietstra, R., et al.: Antibiotic treatment and relapse in Whipple's disease: Long-term follow-up of 88 patients. Gastroenterology 88:*1867-1873, 1985.*

CONCLUSION

Whipple disease, despite its rarity, warrants diagnostic consideration in any child with failure to thrive, malnutrition, and chronic diarrhea. Such findings, especially with CNS manifestations or arthralgias, should raise the specter of Whipple disease. Diagnosis of Whipple disease can be made by histology, PCR, and clinical signs. PCR should not be the sole basis of diagnosis because *T. whipplei* DNA has been detected in samples from healthy individuals without Whipple disease.[64,70] Simple antibiotic treatment with oral TMP-SMX can result in dramatic resolution of symptoms, whereas failure to consider this rare disease can lead to catastrophic events.

SECTION VII

LIVER DISEASES

CHAPTER 53

HEPATITIS

Gail J. Demmler-Harrison

Hepatitis, or inflammation of the liver, may be caused by a variety of infectious agents. Some agents, such as hepatitis A, B, C, D, and E viruses, are primarily hepatotropic and produce disease almost exclusively in the liver, whereas other agents, such as cytomegalovirus (CMV), Epstein-Barr virus (EBV), adenovirus, and the hemorrhagic fever viruses, produce hepatitis as part of a systemic or disseminated illness. With many infectious agents, hepatitis may be subclinical or silent, with very few, if any, signs or symptoms manifested in the patient. Symptomatic or clinical hepatitis may be acute or chronic at initial evaluation, and it may be associated with mild to severe or even fulminant or fatal disease.[64] Children of all ages, from neonates to young adults, both immunocompetent and immunocompromised, may contract infectious hepatitis, and the age and immune status of the host, as well as the history of exposure, may provide clues to identification of the most likely etiologic agent. Noninfectious causes such as autoimmune, genetic, and metabolic disorders, as well as exposure to toxins and idiosyncratic or hypersensitivity reactions to medications or drugs, also are important causes of hepatitis in children. Hepatic steatosis associated with childhood obesity and type 2 diabetes is a growing public health concern for our youth. Severe hypoxia also may damage the liver.

A general approach to an infant or child with hepatitis or hepatic dysfunction, from the perspective of an infectious disease specialist, is presented in this chapter. Detailed information regarding the diagnosis and management of each particular pathogen can be found in the respective chapters in the section of this textbook dedicated to infections with specific microorganisms.

HISTORY

Originally described by Hippocrates in the second century BCE, hepatitis has an ancient historical perspective. The earliest descriptions of outbreaks of hepatitis in the ancient world most likely involved hepatitis A virus (HAV), and it was known as *epidemic jaundice* and *catarrhal jaundice*, or *acute yellow atrophy of the liver* if the disease was severe or fulminant.[21] The earliest recorded outbreak in the United States occurred in Norfolk, Virginia, in 1812.[10] During wartimes, outbreaks of "camp jaundice" or "field jaundice" occurred and probably were caused by HAV, yellow fever, or leptospirosis. Not until 1973 was the cause of "infectious hepatitis" determined to be a 27-nm, nonenveloped viral particle, originally designated enterovirus 72 and now known as HAV.[39] Infection with hepatitis B virus (HBV) has a relatively more recent history. It probably was described originally in the late 1880s in an epidemiologic study published by Luerman in 1885 in Germany, where an outbreak of hepatitis in shipyard and warehouse workers who received smallpox vaccine contaminated with human material was associated with a prolonged form of hepatitis.[74] Other outbreaks of "serum hepatitis" associated with percutaneous therapies, such as gold used for rheumatoid arthritis or contaminated vaccines that were stabilized with human serum have been described.[1,13,58] In the early 1970s, the complete HBV infectious particle identified in serum was called the *Dane particle*, and a specific serologic marker, originally called the *Australian* (*Au*) *antigen* because it was discovered first in the blood of an Australian aborigine and later designated hepatitis B surface antigen (HBsAg), also was characterized and subsequently used to diagnose serum hepatitis caused by HBV.[15,73,109] Not long thereafter, in the mid-1970s, parenterally transmitted "non-A, non-B hepatitis" was described and subsequently identified in 1989 as hepatitis C virus (HCV).[19,59,110,128] The 1970s also marked the discovery of hepatitis delta virus (HDV), a "defective helper virus" that replicates only in the presence of HBV and is associated with chronic or fulminant hepatitis.[114,115] In the 1990s, another enterically transmitted non-A, non-B hepatitis virus was found to be associated with outbreaks of infectious hepatitis in developing parts of the world.[11,52] It was characterized originally as a calicivirus-like particle and subsequently named hepatitis E virus (HEV).[113] No doubt, as our medical knowledge evolves, even more viruses and other infectious agents associated with hepatitis will be discovered and named.

CLINICAL MANIFESTATIONS AND EVALUATION

PATIENT HISTORY

The clinical approach to evaluating and managing a child with hepatitis includes careful attention to the age when first seen; evolution of the initial signs and symptoms; history of exposure to potential pathogens, toxins, or medications; the presence of underlying conditions; and a family history of liver or metabolic disorders. Initial symptoms in older children with acute hepatitis are nonspecific and may include fever, vomiting, poor feeding, anorexia or aversion to specific foods, indigestion, change in taste and smell, lethargy and malaise, mild weight loss, dark urine, pale stool, or jaundice, often with pruritus. Abdominal pain also is a common complaint, and it usually is mild, dull, or aching in quality; located in the right upper quadrant; and unaffected by meals, body position, or bowel movements. Often, an antecedent viral syndrome or "flulike" illness is noted 7 to 14 days before the onset of hepatitis. Rarely, a "serum sickness–like syndrome" may occur at the onset of the illness, before jaundice occurs, and is characterized by fever, rash, and arthritis. In contrast, neonates rarely have signs and symptoms from infection with the hepatotropic viruses and are more likely to have clinical disease with agents that cause congenital or perinatal infection, such as CMV, herpes simplex virus (HSV), rubella virus, parvovirus B19, or *Treponema pallidum*, especially if extrahepatic signs such as splenomegaly, skin lesions, microcephaly, or hearing loss are present. Newborns and young infants may become seriously ill with disseminated HSV, enteroviruses, or adenoviruses and show signs of acute, massive hepatocellular necrosis. A history of administration of blood products at any age suggests hepatitis B, C, or D

or CMV, whereas previous attendance at summer camp or an institutional environment suggests HAV. A history of administration of antimicrobials such as the antifungal azoles, antibiotics, or isoniazid or medications such as acetaminophen suggests drug-induced hepatitis.[133] Exposure of older children to feral kittens is suggestive of infection with *Bartonella henselae* or *Toxoplasma gondii*. Children receiving cancer chemotherapy may have drug-induced hepatitis, and those who have experienced prolonged neutropenia may have fungal disease of the liver. Children with fulminant hepatitis are critically ill and initially may have persistent fever, protracted nausea and vomiting, severe abdominal pain, worsening jaundice, fluid retention with ascites, impaired clotting, and encephalopathy with seizures or coma. Patients with chronic hepatitis, on the other hand, often are clinically asymptomatic unless complications such as cirrhosis, chronic liver failure, or primary hepatocellular carcinoma develop.

PHYSICAL FINDINGS

Physical examination of a child with hepatitis should focus on the abdomen and liver, but it also should include a careful evaluation for extrahepatic manifestations of systemic disease. Tender hepatomegaly, with or without ascites, scleral icterus, and jaundiced skin, often is noted on physical examination of patients with acute hepatitis. Percussion or tapping over the right lower part of the thorax may produce right upper quadrant pain. Fever may or may not be present. Extrahepatic physical findings associated with the hepatotropic viruses, especially HAV, HBV, and HCV, include systemic vasculitis with rash or urticaria, polyarthralgia, and polyarthritis, similar to serum sickness or polyarteritis nodosa. A generalized papular rash, called *infantile papular acrodermatitis* (also known as *Gianotti disease* or *Gianotti-Crosti syndrome*), may accompany HBV infection, especially in young children. Rarely, a patient with acute viral hepatitis may exhibit the Raynaud phenomenon, bullous lesions, or erythema nodosa. Skin excoriations may be present if the jaundice-associated pruritus is severe, and older children and adolescents may have vascular spiders or exacerbation of acne. A child who also has conjunctivitis, pneumonitis, and a maculopapular rash may have a disseminated adenoviral disease. Generalized lymphadenopathy accompanied by pharyngitis and splenomegaly, in contrast, suggests systemic infection with CMV or EBV. Idiosyncratic reactions involving the liver may occur at any time; however, drug-related hypersensitivity hepatitis occurs 1 to 5 weeks after exposure to the agent and usually is accompanied by rash and fever on examination and evidence of nephritis, eosinophilia, and neutropenia. Neonates with acute fulminant hepatitis from disseminated infection with HSV, enteroviruses, or adenoviruses will have fever or hypothermia, respiratory distress, coagulopathy, and a sepsis-like syndrome. Physical examination of a child with fulminant hepatitis and liver failure may actually reveal a small liver or one that is shrinking in size and a child who is confused or has had personality changes. As hepatic failure ensues, the patient may be deeply jaundiced and encephalopathic or comatose, with hyperreflexia, decerebrate posturing, involuntary movements, and asterixis. A distinctive sweetish smell (also called *fetor hepaticus*) from the patient also may be appreciated by an astute observer. Physical examination of a child with chronic hepatitis, on the other hand, may be normal or reveal minimal enlargement of the liver. If the child is obese, fatty infiltration of the liver should be considered as a cause of liver inflammation and dysfunction.

LABORATORY DIAGNOSIS

Laboratory evaluation of a child with acute hepatitis should include a complete blood count and differential, urinalysis, tests of hepatic function, and specific serologic tests, cultures, or detection assays for specific pathogens of interest according to the patient's history or physical findings. In patients with severe or fulminant hepatitis or hepatic failure, serum albumin, electrolyte, and glucose levels also should be determined, in addition to performing a coagulopathy panel with fibrinogen, as well as determination of blood ammonia if encephalopathy is present. In many forms of viral hepatitis, the white blood cell count may be low, usually between 3000 and 4000/mm^3. Atypical lymphocytes also may be seen. Eosinophilia suggests a drug hypersensitivity reaction. If significant leukocytosis is present, sepsis or fulminant hepatitis should be considered. Urinalysis may reveal dark urine and the presence of urobilinogen. In a neonate with jaundice or hepatic dysfunction, an infectious agent such as a gram-negative enteric organism (*Escherichia coli*, for example) may be identified in urine or blood, or evidence of viral infection may be detected in blood, cerebrospinal fluid (CSF), or body secretions. Hematuria with casts or other signs of nephritis in an older child may signify an autoimmune disorder or a drug-induced process as the cause of the hepatitis. Liver enzymes, especially aspartate aminotransferase and alanine aminotransferase, will be elevated in all patients with acute hepatitis, and frequently they are elevated before the onset of clinical symptoms occurs. Most forms of acute hepatitis will be accompanied by elevations of 500 IU/mL or greater. A neonate, however, with transaminase levels higher than 1000 IU/mL is likely to have a potentially life-threatening infection with HSV, enteroviruses, or adenoviruses. Similarly, older children with fulminant hepatitis or hepatic necrosis may have significantly elevated transaminase levels, which gradually fall to less than 500 IU/mL as the disease progresses. Prothrombin levels usually are normal in cases of uncomplicated acute viral hepatitis, but if they become prolonged, severe liver necrosis or fulminant hepatitis should be considered. Levels of alkaline phosphatase and gamma-glutamyltranspeptidase will be elevated in patients with acute hepatitis as well. Serum bilirubin, both conjugated and unconjugated, may be elevated, but it is rarely higher than 4 mg/dL unless fulminant hepatitis with hepatic failure is present. Exceptions to this rule include patients with underlying hemolytic states such as glucose-6-dehydrogenase deficiency or sickle-cell disease; such patients may exhibit marked jaundice and high indirect hyperbilirubinemia, even if the viral hepatitis otherwise is mild. Serum albumin often is normal in acute hepatitis, but it may be low in chronic hepatitis. Some patients will have low levels of nonspecific autoantibodies, such as an elevated homogeneous pattern of antinuclear antibodies, decreased complement levels, or false-positive VDRL (Venereal Disease Research Laboratory) test reactions. The erythrocyte sedimentation rate usually is normal or slightly increased in acute viral hepatitis.

Laboratory investigation to determine the specific etiology of the patient's hepatitis includes detection of HBsAg and anti–hepatitis B core antigen (HBcAg; IgM) in serum, anti-HAV (IgM) in serum and HAV RNA in saliva and serum by polymerase chain reaction (PCR), anti-HCV and HCV in serum by PCR, and anti-HDV antibody (especially if the hepatitis is fulminant) and anti-HEV antibody (if the travel history suggests exposure).[3] Many of the non-hepatitis viruses may be identified by serologic tests that detect virus-specific IgM antibody or by fourfold rises in viral-specific IgG antibody. However, isolation of the specific viral agent in cell culture or detection of viral nucleic acid by PCR in blood, CSF, body fluids such as saliva or stool, or liver tissue provides the most convincing evidence. Bacterial pathogens may be detected by culture or, for agents associated with granulomatous hepatitis, such as *Brucella* and *Mycobacterium*, by culture, serology, or appropriate skin tests. Non-infectious causes such as autoimmune hepatitis may be identified by persistent hypergammaglobulinemia and the presence of autoantibodies, such as positive lupus erythematosus cell tests and anti–liver-

kidney-microsome antibodies (anti-LKM). Metabolic diseases may cause hepatic dysfunction that may mimic acute hepatitis. Laboratory tests that may help differentiate these diseases include sweat chloride or genetic screening for cystic fibrosis, α_1-antitrypsin levels, serum amino acids, and urine-reducing substances and organic acids for metabolic diseases. Serum ceruloplasmin and urine copper levels may help establish the laboratory diagnosis of Wilson disease. Acute hepatotoxicity from overdose of acetaminophen may be predicted from elevated acetaminophen levels. Anatomic causes of hepatic dysfunction, such as biliary atresia in infants and hepatic tumors or steatosis in older children, usually require diagnostic imaging such as ultrasound or liver biopsy for diagnosis.

INFECTIOUS CAUSES

VIRUSES

Hepatitis Viruses

Five hepatotropic viruses are known to cause infectious viral hepatitis in children: hepatitis A, B, C, D, and E. (Table 53–1).

HEPATITIS A VIRUS. HAV is a member of the *Picornaviridae* family and formerly was known as enterovirus 72.[78] A small, nonenveloped RNA virus with icosahedral symmetry (Fig. 53–1), HAV is transmitted by the fecal-oral route, and transplacental transmission has been documented on rare occasion.[27,44] It is transmitted most commonly among young and school-aged children receiving care in group settings such as daycare, summer camp, schools, and institutions.[60] The incubation period generally is 30 days but ranges from 15 to 50 days. HAV infection in young children often is asymptomatic, and usually outbreaks in children are recognized first when symptoms occur in adult caretakers. Older children are more likely to have the classic symptoms of nausea, malaise, jaundice, and tender hepatomegaly. Rarely, HAV causes fulminant hepatitis. Acute infection with HAV is diagnosed serologically by detecting the presence of HAV IgM antibody in serum. No licensed, specific antiviral treatment is available. However, prevention may be accomplished by passive immunization with immune globulin or active immunization with licensed inactivated HAV vaccines.

HEPATITIS B VIRUS. HBV, also known as *Dane particle* and *hepadnavirus type 1*, is a member of the *Hepadnaviridae* family and is a DNA virus that is a 42-nm, nonenveloped spherical particle (Fig. 53–2).[78] It is transmitted through close contact with blood or blood-contaminated secretions, objects, or products.[44] It also has been transmitted by organ transplantation, intravenous drug use, and sexual contact. The incubation period is prolonged, usually 90 days, with ranges of 45 to 160 days reported. Neonates may acquire HBV vertically from mothers who are actively infected with HBV, especially if the mothers also are positive for hepatitis B e antigen (HBeAg). Whereas newborns rarely are symptomatic, children and adults may have mild to moderate symptoms of acute hepatitis or progress to fulminant or fatal disease. HBV also is a common cause of chronic hepatitis in children. Chronic hepatitis will develop in approximately 10 percent of older children and adults infected with HBV; the figure rises to approximately 30 percent if the infection occurs during infancy or early childhood and reaches a striking 90 to 95 percent in infants born to infected mothers who are HBeAg-positive. Acute hepatitis B is diagnosed serologically by the presence of HBsAg or IgM antibody to HBcAg. HBV DNA also may be detected and quantified in serum by PCR during acute hepatitis. Individuals with HBeAg in their serum are highly infectious. Diagnosis of chronic hepatitis B requires a combination of

TABLE 53–1 Causes of Hepatitis in Children

Infectious

Viral

Primary hepatotropic
- Hepatitis A virus
- Hepatitis B virus
- Hepatitis C virus

Fungal

Aspergillus species
Candida species
Cryptococcus neoformans
Histoplasma capsulatum

Non-infectious

Anoxic liver damage
Autoimmune hepatitis
Biliary atresia
Drugs and toxins
Hemophagocytic syndrome
Histiocytosis
Kawasaki disease
Lymphoma
Metabolic and genetic disorders
Obesity with hepatic steatosis (fatty infiltration)
Reye syndrome
Sarcoidosis
Sickle-cell crisis
Toxic shock syndrome
Tumors

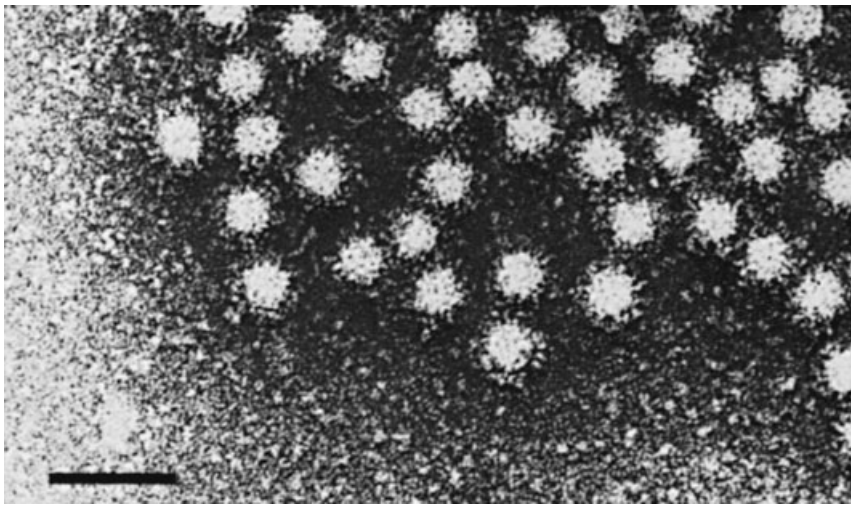

Figure 53–1 Twenty-seven-nanometer hepatitis A virus (HAV) isolated from the stool filtrate of a patient with acute HAV infection. The HAV particles are aggregated by convalescent serum containing anti-HAV antibodies. The *line* represents 100 nm. *(Courtesy of Dr. Jules Dienstag, taken at the Laboratory of Infectious Diseases, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Department of Health, Education, and Welfare, Bethesda, MD.)*

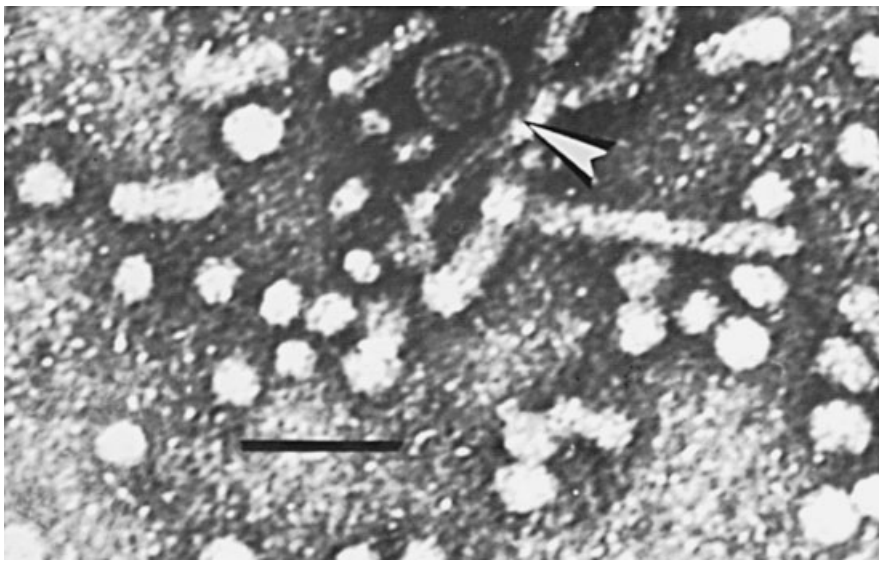

Figure 53–2 Electron micrograph of hepatitis B virus particles. Most particles are 20 to 25 nm in diameter and consist of both spheres and tubules. A larger, 42-nm Dane particle also is present (*arrowhead*). Hepatitis B surface antigen determinants are present on the surface of all three forms.

persistent clinical symptoms and laboratory abnormalities, persistence of specific serologic markers such as HBsAg over a period of at least 6 months, and histopathologic characteristics on liver biopsy. Primary hepatocellular carcinoma also is a long-term complication of infection with HBV. Successful resolution of infection with HBV is marked serologically by the presence of antibody to HBsAg. No licensed specific antiviral therapy is available for acute hepatitis caused by HBV; however, lamivudine and interferon-α may be helpful in treating chronic hepatitis. Famciclovir also has documented activity against HBV and has been used clinically in certain patients. Liver transplantation has been attempted in patients with end-stage HBV-associated cirrhosis, with variable results. Prevention is achieved by passive immunization with hepatitis B immune globulin (HBIG) and active immunization with licensed recombinant vaccines.[57]

HEPATITIS C VIRUS. HCV is a member of the *Flaviviridae* family. It is a small RNA virus with multiple genotypes that appear to have a variable effect on the development of clinical disease and response to antiviral therapy. It is transmitted most commonly to children and adolescents who have been exposed to blood products, clotting factor concentrates before 1987, hemodialysis, organ transplantation, intravenous drug use, cocaine snorting, or tattoos and piercing procedures performed at parlors that do not practice sterile technique. Perinatal transmission from an HCV-seropositive mother to her infant also occurs at an estimated risk of 5 percent, especially if the mother is HCV RNA–positive at delivery.[92,97] Infection with HCV usually does not cause acute hepatitis; however, chronic hepatitis develops in more than 50 percent of children infected with HCV.[24] In adults, cirrhosis, end-stage liver failure, and hepatocellular carcinoma also may develop. Infection with HCV is diagnosed serologically by detecting the presence of HCV IgG antibody and by detecting and quantifying HCV RNA by PCR.[69] Treatment with ribavirin plus interferon may be beneficial in some patients. Liver transplantation may be performed in patients with end-stage liver disease. Currently, no biologic products or vaccines are licensed for prevention of infection with HCV.

HEPATITIS D VIRUS. HDV, also known as the *delta agent*, *delta virus*, *helper virus*, and *defective virus*, is a small, 37-nm RNA virus that requires the presence of HBV, especially HBsAg, to replicate.[107] HDV can co-infect a patient simultaneously or subsequent to infection with HBV. Like HBV, HDV is acquired by exposure to blood products or clotting factors, intravenous drug use, or sexual contact. It also may be transmitted by liver

transplantation, and vertical transmission has been reported. Infection with HDV occurs more commonly in Europe, South America, Africa, and the Middle East and appears to be less common in the United States. The incubation period after superinfection occurs is 1 to 2 months, but it is similar to that for HBV (90 days) if co-infection occurs simultaneously. Co-infection with HDV is associated with more severe disease or progression to fulminant hepatitis in HBV-infected patients.[107] Laboratory diagnosis includes detection of antibody to HDV (anti-HDV) by commercial assays and reference laboratories that can detect IgM-specific HDV antibody, HDV antigen, and RNA by PCR. No specific antiviral therapy is available for HDV. Because HDV cannot be transmitted to or infect humans without HBV, prevention of HBV infection by vaccination prevents the acquisition of HDV infection. HDV co-infection of individuals already infected with HBV, however, cannot be prevented by any licensed biologic product or vaccine.

HEPATITIS E VIRUS. HEV is a small RNA virus that is transmitted by the fecal-oral route.[11,113] HEV infection in U.S. residents is a rare occurrence, but it may be a common cause of acute, self-limited viral hepatitis in developing countries and has been linked to outbreaks associated with contaminated water supplies.[52,101,108] The incubation period is unknown. HEV appears to cause a mild to moderate, acute hepatitis, especially in adults, and may have a high case-fatality in pregnant women. Similar to HAV, HEV does not appear to cause chronic hepatitis. Laboratory diagnosis is established by detection of IgG and IgM antibody to HEV in serum or detection of HEV RNA by PCR in serum or feces performed in reference laboratories or the Centers for Disease Control and Prevention (CDC). No antiviral agent is licensed for HEV, and prevention by immunoprophylaxis is not available. However, the results of clinical trials evaluating the efficacy of a new HEV vaccine may be available soon.

Herpesviruses

Herpesviruses are large DNA viruses with icosahedral symmetry and a glycoprotein envelope, and they share the biologic properties of latency and reactivation. Infections with this family of viruses, the *Herpesviridae*, may be primary or recurrent. All the human herpesviruses (HHVs) and one of the primate herpesviruses (herpes B virus) can cause acute hepatitis during the course of a systemic illness, but primary hepatitis with these viral agents is an unusual event.[42]

HERPES SIMPLEX VIRUS. HSV-1 and HSV-2 most often cause mucocutaneous vesicles or ulcers, and dissemination usually occurs during periods of relative immune compromise, such as pregnancy, the neonatal period, malnutrition, congenital or acquired immunodeficiency syndromes, or organ transplantation. Transient, subclinical hepatitis may occur during acute mucocutaneous HSV disease, but fulminant hepatitis with hepatic necrosis rarely has been documented in a normal host.[38,45,65,83] A special exception to this observation is HSV-associated primary hepatic necrosis and disseminated HSV disease in pregnant women.[45] Most cases occur during the late second or early third trimester, and most, but not all, cases are associated with primary infection with HSV-2.[132,134] Obvious skin lesions may not be present. This disease is associated with high mortality rates in both the mother and infant. Neonates, both term and preterm, are at risk for the development of neonatal HSV hepatitis as part of a disseminated HSV disease that includes viral sepsis–like syndrome, coagulopathy, pneumonitis with respiratory distress, and meningoencephalitis.[62] Skin lesions often are absent in this form of HSV disease. Neonatal HSV hepatitis develops most often in the child's first 2 weeks of life, and transaminase levels may be more than a thousand times higher than normal. Recipients of solid organ, bone marrow, and stem cell transplants may have HSV infection with dissemination within the first 3 weeks after undergoing transplantation, most often as a result of reactivation.[43] Patients with hepatitis secondary to HSV infection may be shedding HSV from a mucocutaneous source or may be viremic, but some may require liver biopsy for confirmation. Acyclovir therapy is recommended for HSV-associated hepatitis, and post-transplant prophylaxis is very effective in preventing post-transplant HSV disease.[132] At least one neonate with HSV-induced fulminant hepatic failure successfully treated by liver transplantation combined with acyclovir therapy has been reported.[31]

VARICELLA-ZOSTER VIRUS. Varicella-zoster virus also causes mucocutaneous vesicles in both immunocompetent and immunocompromised hosts. Primary infection is known as *varicella* (also chickenpox) and is associated with primary and secondary viremias that often seed the visceral organs. Approximately a fourth of healthy children experiencing varicella will have silent hepatitis with transaminase levels at least twice normal.[41,91,105] Fulminant hepatitis with varicella occurs rarely, however, and generally is seen in immunocompromised hosts.[5,89,102,124] Patients have severe abdominal pain with little nausea or vomiting, skin lesions may or may not be present, and transaminases levels may be more than a thousand times higher than normal.[88,119,121] Zoster in a normal host is not associated with fulminant hepatitis, but immunocompromised hosts may experience disseminated zoster with hepatitis and hepatic necrosis.[40] The diagnosis often is based on clinical findings, but viral culture of cutaneous lesions, if present, or blood and liver biopsy also may help establish the diagnosis. Treatment with acyclovir is recommended. Varicella may be prevented or attenuated by passive immunization with varicella-zoster immune globulin (VZIG) or immune globulin intravenous (IGIV) or by active immunization with a licensed live virus vaccine.[17,25]

CYTOMEGALOVIRUS. CMV infection usually is asymptomatic or "silent." However, CMV in a normal host may cause gastroenteritis, pneumonitis, or a mononucleosis-like syndrome that consists of fever, lymphadenopathy, and atypical lymphocytosis. Hepatitis occurs as part of these syndromes but often is silent or mild and rarely is accompanied by jaundice.[67,82] Granulomatous hepatitis also may be associated with CMV.[28] Infants born congenitally infected with CMV frequently have hepatosplenomegaly, elevated transaminase levels, and direct hyperbilirubinemia.[29,129] The hepatitis that newborns and infants experience is self-limited and generally resolves within the first few months of life. If hepatitis with cholestasis persists, other diseases such as extrahepatic biliary atresia should be considered. Solid organ and marrow transplant recipients and patients with acquired immunodeficiency syndrome (AIDS) and other immunodeficiency states may experience persistent fever, malaise, leukopenia, and hepatitis caused by primary or recurrent infection with CMV. Severe liver disease can occur in transplant recipients and may be associated with graft-versus-host disease or graft rejection.[35,36] CMV-associated hepatitis may be diagnosed clinically and supported by virologic evidence of positive cultures, CMV viremia (or a viremia surrogate marker such as CMV antigenemia or CMV DNAemia), or demonstration of involvement of the end-organ by liver biopsy.[34,94] Treatment with ganciclovir, valganciclovir, foscarnet, or cidofovir appears to be beneficial in immunocompromised hosts, and prophylaxis or preemptive therapy with antiviral agents or CMV hyperimmune globulin may prevent the development of severe CMV disease in transplant recipients.[34,37,46]

EPSTEIN-BARR VIRUS. EBV infection also usually is asymptomatic or "silent," but it may cause a mononucleosis-like syndrome with mild hepatitis. However, in rare patients with a

genetic X-linked predisposition, a severe, often fatal lymphoproliferative syndrome with prominent liver involvement may develop. Transplant recipients also may be susceptible to post-transplant lymphoproliferative disease (PTLPD), in which the liver may be involved.[8,22,116] In addition, patients with tumors associated with EBV, such as lymphoma, may have hepatic involvement. The diagnosis of mononucleosis usually is clinical and supported by a positive heterophile or "Monospot" test or by specific EBV serologic tests such as detection of IgM antibody to viral capsid antigen (VCA).[12] The immune response to EBV in immunocompromised hosts may be unusual, and the diagnosis of PTLPD generally is suspected by an increase in EBV DNA genome copies in peripheral blood, generalized adenopathy, or the presence of histopathologic features on biopsy. Treatment involves a reduction in immunosuppression, administration of rituximab (anti-CD20 monoclonal antibody), or adoptive immunotherapy.[26,51,99,120] Antiviral therapy with acyclovir also may be administered, but its effectiveness is controversial.

HUMAN HERPESVIRUSES 6, 7, AND 8. These viruses may involve the liver, especially in immunocompromised patients.[42] Hepatitis associated with HHV-6 may occur in solid organ transplant recipients. In recipients of liver transplants, infection with HHV-6, mostly reactivation, also has been associated with acute rejection, portal lymphocyte infiltration, and impaired function of the grafted liver. However, because HHV-6 is ubiquitous and commonly can be detected in blood and tissue, the role that the virus is playing in the liver disease observed in these patients is not entirely clear.[100] Normal hosts experiencing primary HHV-6 infection may have silent hepatitis with mild elevation of aminotransferase levels. Rarely, severe disseminated disease with fulminant hepatitis has been linked to HHV-6 and HHV-7.[2,9,54,79] HHV-8 (also known as *Kaposi sarcoma virus*) causes a complex neoplasm involving the skin, mucous membranes, and internal organs, most often in patients with severely compromised immune systems. It rarely is seen in children but has been reported in human immunodeficiency virus (HIV)-infected children with advanced AIDS. Recipients of solid organ transplants may be infected with HHV-8. The liver is a common site of visceral disease caused by HHV-8, which most often is associated with tumors rather than hepatitis.[23] Diagnosing infection with HHV-6, HHV-7, or HHV-8 is difficult because of the ubiquity of these viruses and their viral DNA in humans, but the diagnosis is supported by serologic evidence and by detection of viral DNA in blood, in secretions, or more specifically, in tissue.[100] No licensed specific antiviral therapy is available, but these viruses may be inhibited by ganciclovir, foscarnet, and cidofovir. Response also may be noted after withdrawal or reduction of immunosuppression, and with HHV-8, chemotherapy may be indicated.

HERPES B VIRUS. Also known as *herpesvirus simiae* or *cercopithecine herpesvirus 1*, herpes B virus is an alpha-herpesvirus of monkeys that causes severe disease in humans.[131] It can be transmitted from Asian monkeys, such as rhesus and cynomolgus monkeys, to humans through bites or contact with mucous membrane secretions from infected monkeys. The human disease associated with herpes B virus involves skin vesicles at the portal of entry, regional lymphadenitis, and hemorrhagic encephalitis. The virus also may disseminate to the liver and lungs and produce hemorrhagic necrosis, with a high mortality rate. The diagnosis is made by isolation of virus, and the virus is inhibited by acyclovir and ganciclovir.

Adenoviruses

Adenoviruses are small DNA viruses that are members of the viral family *Adenoviridae*. They usually are respiratory or enteric pathogens, but they also can cause disseminated disease with hepatitis and hepatic necrosis in both immunocompetent and immunocompromised hosts and neonates.[56,81,96] Patients often have fever, malaise or lethargy, conjunctivitis, pharyngitis, cough, respiratory distress, vomiting and diarrhea, and a viral sepsis–like syndrome. Hepatitis is marked by hepatomegaly and by elevated aminotransferases and bilirubin. A specific viral diagnosis is made by isolation of adenovirus or detection of adenoviral DNA by PCR from respiratory secretions, blood, stool, or tissue. Adenovirus serotype 5 generally is associated with severe hepatitis, followed in frequency by types 1 and 2.[90] Viral surveillance cultures, blood DNA PCR testing, and virus serotyping and genotyping in immunocompromised patients, such as bone marrow and stem cell transplant recipients and liver transplant recipients at high risk for acquiring severe or fatal adenovirus-associated disease, may allow early intervention before severe, disseminated disease develops.[18,50,81] No licensed antiviral therapy is available, but the virus is inhibited to some extent by antiviral agents such as ribavirin and ganciclovir, and case reports suggest a potential clinical benefit in some patients with severe adenoviral hepatitis treated with cidofovir, an antiviral agent with broad-spectrum activity against many DNA viruses.[16,72]

Erythrovirus—Human Parvovirus B-19

Erythroviruses (i.e., human parvovirus B19) are small DNA viruses. They are members of the family *Parvoviridae* and are responsible for a variety of illnesses, including fifth disease (i.e., erythema infectiosum), arthritis, and anemia. Liver involvement, often severe, may be seen in intrauterine infection with hydrops fetalis.[4,80] Fulminant liver failure with massive hepatic necrosis associated with erythrovirus also has been reported in patients with aplastic anemia.[68] Persistent infection is seen in immunocompromised hosts. Parvovirus infection can be diagnosed by detection of virus-specific IgM antibodies or detection of viral DNA in blood, serum/plasma, bone marrow, secretions, urine, or tissue. No specific antiviral therapy is available, but immunocompromised patients with chronic infection may benefit from receiving IGIV. Severe fetal hydrops usually requires in utero and neonatal blood transfusions for anemia.

Enteroviruses

Enteroviruses are small RNA viruses and members of the *Picornaviridae* family, along with polioviruses and rhinoviruses. The non-polio enteroviruses usually are associated with mild respiratory or gastrointestinal illnesses, myocarditis, or aseptic meningitis, most often occurring in late summer or early fall. Significant hepatitis with hepatic necrosis, however, can occur, especially in neonates with disseminated disease. It often is accompanied by hepatomegaly, thrombocytopenia, viral sepsis syndrome, elevated aminotransferases, and elevated serum bilirubin.[84-86] Although any serotype can cause severe liver disease, echovirus 11 is associated most commonly with severe hepatitis or hepatitic necrosis, especially in neonates.[84] Coxsackie B and echoviruses 9 and 30 also are associated with fatal disease. Enteroviruses may be transmitted to neonates perinatally from the mother or through contact with ill family members. Nosocomial nursery outbreaks with enteroviruses also have been reported.[85] The diagnosis is established by isolation of the virus or detection of viral RNA by PCR in throat, stool, urine, blood, CSF, or tissue samples. Treatment is supportive; however, case reports suggest that IGIV, the investigational drug pleconaril, and even liver transplantation may have some clinical benefit in severely ill neonates.[6,20,63,112]

Measles Virus

Measles virus is an RNA virus that is a member of the *Paramyxoviridae* family, along with parainfluenza viruses, respiratory syn-

cytial virus, metapneumovirus, and mumps virus. Of all the paramyxoviruses, measles virus is associated most often with hepatitis. Approximately 10 to 20 percent of children with measles will have subclinical hepatitis, and severe disease of the liver, lungs, and brain may occur in immunocompromised patients.[47,93,122] Rare reports of severe giant-cell hepatitis, often leading to liver failure, have implicated paramyxoviruses of undetermined type.[106] Measles and other paramyxoviruses may be identified by detection of virus-specific IgM antibody in serum and by isolation of virus in secretions, blood, or tissue. No specific antiviral therapy is licensed for measles virus; however, ribavirin, a broad-spectrum antiviral agent, may have some activity against the virus. Prevention is achieved by vaccination with the live measles vaccine or by postexposure administration of immunoglobulin or IGIV.

Rubella Virus

Rubella virus is a member of the *Togaviridae* family of RNA viruses. Clinical disease associated with infection by rubella virus generally is mild, but as many as 10 percent of children with rubella may have subclinical hepatitis with transient elevation of aminotransferase levels.[126] Congenital rubella syndrome caused by intrauterine infection with rubella virus is, however, associated with significant liver involvement, with hepatomegaly and jaundice being noted at birth.[33,87,125] Congenital rubella syndrome also is associated with intrauterine growth retardation, cataracts, congenital heart disease, thrombocytopenia, purpura, and hearing loss.[66] Because isolating the virus is difficult technically, the diagnosis of rubella most often is made serologically by detection of virus-specific IgM antibody. No specific antiviral therapy is available. Rubella can be prevented, however, by vaccination with the live rubella virus vaccine.

Hemorrhagic Fever Viruses

The hemorrhagic fever viruses are a diverse group of RNA viruses from a variety of different virus families. They include arenaviruses such as Lassa fever virus, bunyaviruses such as hantavirus, filoviruses such as Marburg and Ebola, and flaviviruses such as yellow fever virus and dengue. Hemorrhagic fever is characterized by fever, malaise or lethargy, headache, retroorbital pain, myalgia, conjunctivitis, rash, and intravascular coagulation with hemorrhage. Liver involvement with hepatitis is a very common event, and elevation of aminotransferase levels to 500 IU/mL occurs in almost every patient, with a thousand times the normal range seen in patients who are severely ill.[32] Jaundice is a significant component of yellow fever.[61] The diagnosis is established by serologic means or by detection of the viral agent with electron microscopy or PCR techniques, which in most cases should be attempted only in biosafety level IV reference laboratories. Treatment of most hemorrhagic fevers is supportive; however, intravenous ribavirin reduces the mortality rate associated with Lassa fever and also may be of benefit to patients with hemorrhagic fever caused by other arenaviruses.[74,77]

BACTERIA

Nonviral acute hepatitis can be caused by bacterial illnesses (see Table 53–1).[95] Sepsis with gram-positive organisms, especially pneumococci, or with gram-negative organisms, particularly gram-negative enteric bacteria, can produce hepatic dysfunction, primarily from the cholestatic effects induced by bacterial endotoxins.[95,137] In this form of hepatic dysfunction, the patient will appear jaundiced with mild hepatomegaly, and conjugated bilirubin levels will be elevated out of proportion to the modest elevation in aminotransferase or alkaline phosphatase levels. Neonates also may have jaundice secondary to urinary tract infection with gram-negative enteric organisms. The diagnosis is made by isolating the offending bacteria from blood, urine, or other usually sterile site. Treatment involves specific antimicrobial therapy.

Other bacterial diseases may cause chronic or granulomatous hepatitis, including actinomycosis, brucellosis, listeriosis, nocardiosis, bartonellosis (cat-scratch disease), and tuberculosis.[7,98] Diseases caused by atypical mycobacteria, especially *Mycobacterium avium-intracellulare* complex (MAC complex) or *Mycobacterium mucogenicum*, may be seen, particularly in patients with congenital or acquired immunodeficiency states.[48] Rarely, disseminated disease with hepatitis may occur as a complication of vaccination with bacille Calmette-Guérin (BCG) in children or, in adults, as a complication of bladder irrigation for bladder carcinoma.[7,49,71] A diagnosis of hepatitis caused by these unusual or indolent bacterial pathogens usually is accomplished by isolating the organism from blood or the affected organ. The diagnosis may be supported by positive skin test results in the case of tuberculosis or atypical mycobacterial disease, serologically by elevated titers to *Bartonella quintana* or *Bartonella henselae*, and by positive imaging studies that show hepatic microabscesses, as in the case of hepatic involvement with cat-scratch disease. Antimicrobial therapy is guided by the susceptibility of the offending pathogen.

Bacterial toxins, such as the emetic toxin of *Bacillus cereus*, also have been linked to fulminant hepatic failure in some patients.[75]

Spirochetes

Acute infection with *T. pallidum*, the agent of primary or early secondary syphilis in adolescents or adults, may cause acute or granulomatous hepatitis with serum aminotransferase levels up to 5 to 10 times normal.[70] Jaundice rarely develops, but a chancre of primary disease or a rash of secondary disease often is present. Congenital syphilis also is associated commonly with hepatosplenomegaly in the newborn, along with elevated aminotransferase and bilirubin levels. Other clinical manifestations of congenital syphilis include petechiae or purpura, thrombocytopenia, osteitis, and meningitis. Laboratory diagnosis is confirmed by reactive VDRL and positive fluorescent treponemal antibody tests. Treatment with penicillin is recommended.

Leptospirosis, or infection with the pathogenic bacterium *Leptospira interrogans*, can cause acute hepatitis.[55] Leptospirosis usually is an abrupt, anicteric, flulike illness, but approximately 10 percent of patients will have an icteric or septicemic syndrome with a biphasic clinical course. Patients with the icteric or severe form will exhibit jaundice, hepatomegaly, and characteristic conjunctival injection. Usually, levels of serum bilirubin are elevated out of proportion to the more modest elevations in serum aminotransferases, suggesting a defect in excretion of bilirubin rather than direct hepatic necrosis as the pathogenesis of the jaundice. Meningitis, renal failure, and even liver failure may occur in some patients. The diagnosis should be considered in older children and adolescents with a history of exposure to wild and domestic mammals, especially dogs, rats, and livestock, which may excrete *Leptospira* organisms in their urine, or with a history of exposure to contaminated water in ditches, lakes, or streams. The diagnosis is established by isolating the organisms on special media during the acute phase of illness. Serologic and PCR tests also are available in reference laboratories. Treatment with penicillin or doxycycline is recommended.

Rickettsiae

The rickettsial organism *Coxiella burnetii* causes Q fever, both the acute and chronic forms, in which hepatitis is a prominent feature along with persistent fever, malaise, weight loss, and pneumoni-

tis.[14] Clinical jaundice is a rare finding, and most often the hepatitis is subclinical. A history of exposure to mammals or birds suggests the diagnosis, which can be confirmed serologically by reference clinical laboratories. Treatment with antibiotics, usually doxycycline, is recommended.

PARASITES AND FUNGI

A variety of parasites may invade the liver and occasionally cause hepatic dysfunction or disease.[95,135] Such parasites include *Plasmodium* spp. (malaria), *Entamoeba histolytica* (liver abscess), *Toxoplasma gondii* (toxoplasmosis), and *Toxocara canis* (visceral larval migrans). *Ascaris lumbricoides* (roundworms) may invade the common bile duct and cause acute obstructive jaundice.

Fungi also may invade the liver, usually with only minimal elevation of aminotransferase levels and rarely causing jaundice or elevated levels of bilirubin. Patients with a compromised immune system may have hepatic abscesses with *Candida* spp. or abscesses or necrotic lesions with *Aspergillus* spp., as well as other unusual fungal species. Both immunocompromised and normal hosts may have liver involvement with *Histoplasma capsulatum* or *Cryptococcus neoformans*.[95]

NONINFECTIOUS CAUSES

An important noninfectious cause of acute hepatitis is drug-related hepatitis (see Table 53–1).[133,136] It can range in severity from mild, with subclinical elevation of aminotransferase levels, to severe, with fulminant hepatic failure.[64] A careful history of ingestion of prescription or over-the-counter medications, as well as exposure to toxins or herbal remedies, should be elicited. Although almost any drug can cause acute hepatitis, the most common agents associated with hepatitis in children include acetylsalicylic acid (i.e., aspirin), acetaminophen, isoniazid, rifampin, phenytoin, valproic acid, phenobarbital, β-lactam antibiotics (e.g., oxacillin, nafcillin, and third-generation cephalosporins), sulfa drugs, and antifungal agents such as ketoconazole and fluconazole. The anesthetic drug halothane also can cause acute hepatitis with jaundice.[111] Gold and other metals used to treat arthritis have been associated with hepatitis as well. Carbon tetrachloride is a direct hepatic toxin. The *Amanita* mushroom, if ingested, causes severe liver injury. In addition, chronic hepatitis can develop in children, especially premature infants, who receive prolonged total parenteral nutrition.

Anoxic liver injury also can resemble acute viral hepatitis. It occurs in critically ill children after a period of hypotension, heart failure, or cardiopulmonary arrest. A history of such an inciting event supports the diagnosis. Anoxic liver injury is characterized by an abrupt onset of markedly elevated levels of aminotransferases, often hundreds of times higher than normal, without jaundice, and rapid recovery of enzyme levels to normal or nearly normal after the event has resolved.

Other diseases such as Kawasaki syndrome and toxic shock syndrome, which have been linked to or associated with infectious pathogens, may have hepatitis as part of their manifestation. Similarly, Reye syndrome, characterized by hepatomegaly with fatty infiltration of the liver and often fatal encephalopathy, may occur after a viral syndrome such as varicella or influenza.

Metabolic and genetic disorders may be manifested as hepatitis, especially in infants. Such disorders include cystic fibrosis, α_1-antitrypsin deficiency, galactosemia, glycogen storage disease, urea cycle deficiencies, organic acidemias, tyrosinemia, and lipid storage diseases such as Gaucher and Niemann-Pick disease.[103,127] Of note, cystic fibrosis in neonates may be associated with cholestatic jaundice in the absence of pulmonary disease.[123] Disorders of metal metabolism, such as Wilson disease, may cause acute, chronic, or even fulminant hepatitis in older children.[104,117] In addition, patients with congenital disorders of bilirubin metabolism, such as Gilbert disease, may become jaundiced without significant elevation of aminotransferase levels, especially during an intercurrent viral illness. Sickle-cell crisis also may be manifested as hepatitis.[118]

Tumors of the liver and infiltrative diseases such as lymphoma, histiocytosis, and hemophagocytic syndrome may have hepatitis or hepatic failure as part of the initial manifestation.[53] Another multisystem disorder that may produce chronic granulomatous hepatitis is sarcoidosis.[30]

Anatomic causes of hepatic dysfunction in infants include extrahepatic biliary atresia, which usually develops in the first 2 months of life.[76,129]

Autoimmune hepatitis or other autoimmune disorders with liver involvement also may cause acute or chronic hepatitis, especially in older children and adolescents.[130] In autoimmune hepatitis, hypergammaglobulinemia and autoantibodies usually are present, as are other symptoms such as rash, arthritis, inflammatory bowel disease, thyroiditis, malaise, and persistent fever. Autoimmune hepatitis may respond to steroids or other immunosuppressive agents.

Hepatic steatosis (fatty infiltration) recently has been documented to occur in obese children, especially if they also have type 2 diabetes. These children may have enlarged or tender livers on examination, elevated transaminase levels in serum, abnormal imaging studies showing fatty infiltrates of the liver, and liver biopsies that show inflammation, fibrosis, and even cirrhosis in some cases. Treatment currently includes diet and lifestyle changes with weight loss and exercise.

CHAPTER 54

CHOLANGITIS AND CHOLECYSTITIS

Valérie A. McLin ❂ Jason S. Soden ❂ Saul J. Karpen

CHOLANGITIS

The term *cholangitis* refers to any inflammation of the extrahepatic or intrahepatic biliary system. Clinically, it is seen most often as a consequence of infection in the setting of biliary tract disease or obstruction. The diagnosis of cholangitis implies microbial colonization of the biliary tract, increased biliary pressure, and systemic signs of infection, although all of these findings are not present in all patients. Generally, the etiology and

treatment of infectious cholangitis are similar in adults and children. One specific pediatric population—children with biliary atresia and a hepatic portoenterostomy (HPE)—is particularly susceptible to cholangitis and its sequelae. This population and other patient groups at high risk of developing infectious cholangitis, such as patients with immunodeficiency states, congenital or acquired bile duct abnormalities, or liver transplants, are highlighted in this chapter. Biliary tract obstruction secondary to gallstone disease is discussed in the section on cholecystitis.

ETIOLOGY AND PATHOGENESIS

The central mechanisms leading to biliary tract infection are biliary colonization and stasis. Bile typically is sterile, implying that bactibilia develops either hematogenously via the portal venous system or directly via ascending infection from the gut lumen.[27]

Much is unknown regarding the route of bacterial infection of the biliary tree. Bacterial ascent may occur from the duodenum, most commonly in the presence of abnormal function of the sphincter of Oddi. In addition, bacterial invasion may occur hematogenously via increased gut translocation across the intestine into the portal circulation.[205] Earlier research indicates that infection of bile likely occurs via direct hematogenous spread of bacteria from portal venous flow across the gallbladder wall.[43] Although this mechanism has not been firmly established, the consensus is that transient episodes of bactibilia combined with biliary obstruction may lead to higher concentrations of bacteria in the biliary tract. As biliary pressure increases, bacteria likely migrate from the bile ducts into lymphatic and blood vessels, resulting in bacteremia and clinical signs and symptoms of cholangitis.[27]

In adults, cholangitis typically occurs in the presence of biliary tract obstruction secondary to impaction of gallstones in the common bile duct, leading to bile stasis and secondary infection. In approximately 85 percent of cases of cholangitis in adults, evidence of a common bile duct stone is present.[14] In adults with documented gallstones in the common bile duct (choledocholithiasis), the incidence of positive bile cultures is 30 to 90 percent.[119] Other potential causes of biliary obstruction in adults, possibly leading to a more chronic or recurrent presentation, include neoplasm of the biliary tree or head of the pancreas, other intrinsic or extrinsic strictures, parasitic disease, inflammatory conditions (e.g., primary biliary cirrhosis, primary sclerosing cholangitis [PSC]), and congenital bile duct anomalies. More recently, with improved imaging modalities and a better understanding of the pathogenesis of biliary lithiasis, it has become accepted that biliary sludge or microcalculi may be at the root of nonobstructive cholangitis and recurrent biliary infections.

In children, acute cholangitis occurs most frequently in patients with biliary atresia who have undergone HPE surgery. The HPE, also known as a *Kasai operation*, provides a permissive setup for cholangitis: poor bile flow combined with damaged intrahepatic bile ducts and obligate bacterial colonization with enteric flora in the intestinal conduit.[79,80,103,116,176] In this setting, cholangitis is thought to arise from reflux of jejunal flora through the HPE (Roux-en-Y loop), directly contiguous with the hepatic porta. Cholangitis tends to occur more frequently within 1 year after surgery, usually in patients with evidence of good biliary flow. Decreased biliary and duodenal motility generally are accepted as being associated with a higher incidence of cholangitis,[47,207] but most predictors and exacerbants for the development of cholangitis remain unknown.

Microbiologic evidence of biliary tract infection ideally should involve at least 10^5 organisms per milliliter of bile.[43] Gram-negative rods, primarily *Escherichia coli* and *Klebsiella pneumonia*, are found in infected bile, but *Enterococcus* and *Enterobacter* spp. also often are encountered. Many cases of cholangitis are polymicrobial, lending support for use of broad-spectrum antibiotic treatment regimens. *E. coli* is the organism most commonly isolated, accounting for 20 to 68 percent of infections. Table 54–1 summarizes the frequencies of specific organisms found in adult and pediatric studies.[79,98,141] Anaerobes, such as *Bacteroides fragilis* and *Clostridium perfringens*, also may play a significant role and have been identified in 40 percent of biliary tract infections.[20] Specifically, the latter organism has been implicated in acute emphysematous cholecystitis. Despite these findings in bile, many patients with cholangitis have negative blood cultures, requiring clinicians to have a low index of suspicion for cholangitis in selected circumstances and patient populations.

In addition to bacterial infection, other pathogens—viral, fungal, and parasitic—have been reported in cases of pediatric cholangitis, particularly in immunodeficient patients (primarily patients with human immunodeficiency virus [HIV]; see later) and patients with environmental exposure to parasites in endemic settings. Cholangitis has been reported with viral disease; although most commonly associated with hepatocellular disease, hepatotropic viruses, primarily cytomegalovirus (CMV), hepatitis C, and hepatitis B, have been associated with pathologic findings of bile duct injury with apparent clinical significance.[24,67,110] Depending on the clinical setting and age of the patient, CMV can have a markedly varied presentation, ranging from bile duct paucity seen in congenital CMV infection to hepatomegaly and jaundice in infants and children with primary CMV infection. The role of CMV hepatitis and cholangitis is significant in immunocompromised patients and solid organ transplant recipients (see later).

Fungal cholangitis, specifically with *Cryptococcus neoformans* or *Candida albicans*, has been reported in immunocompromised and immunocompetent patients, although more commonly in the former than the latter population.[53] Although *Cryptosporidium* spp. typically are known to cause cholangitis in the immunocompromised host, one case of a child without a documented immunodeficiency has been reported.[65]

TABLE 54–1 Bacterial Pathogens Isolated from Bile Cultures in Cholangitis*

**Pediatric and adult data used.*[15,79,98,114]

The biliary tree also is susceptible to parasitic infections in normal hosts. Nematodes—*Ascaris* and, rarely, *Strongyloides*—commonly cause biliary disease in endemic regions. Migrating *Ascaris* larvae may cause either a direct inflammatory response if they pass through the biliary system or a secondary pyogenic cholangitis secondary to obstruction via the worms themselves or eggs. Liver flukes, such as *Clonorchis* (now *Opisthorchis*) *sinensis*, *Opisthorchis viverrini*, and *Opisthorchis felineus*, also may pass through the biliary system through their life cycle. Of these trematodes, *Clonorchis* is found frequently in cases of recurrent pyogenic cholangitis in Asian children.[148] Similar to the worms, the migration of the flukes (*Fasciola hepatica*) through the biliary tree may induce primary inflammation and, later, a secondary bacterial infection. Echinococcal cholangitis has been described in the setting of obstruction secondary to cyst formation from infection with either *Echinococcus granulosus* or *Echinococcus multilocularis*.[27,70,101] A thorough travel history should be obtained in all children presenting with new-onset cholangitis, in particular in patients in whom the most common causes are ruled out rapidly.

Finally, several cases of *Mycobacterium tuberculosis* cholangitis mimicking cholangiocarcinoma in immunocompromised and immunocompetent hosts have been reported in the adult literature.[12,50,104,155,163,219]

CLINICAL PRESENTATION

The classic presentation of cholangitis first described by Charcot in 1877 and known commonly as the *Charcot triad* is reported in 70 percent of patients with cholangitis (Table 54–2). It combines the clinical findings of fever, right upper quadrant pain, and jaundice.[94] The Reynold pentad adds septic shock and altered mental status to the Charcot triad.[115] Studies in children show that fever is the most common presenting symptom, occurring in 100 percent of 105 patients with cholangitis after undergoing HPE.[47] In addition, either acholic stools or an increase in serum bilirubin concentration occurs in 68 percent of patients. Older children and teenagers with cholangitis typically report abdominal pain that may or may not be associated with meals or localize to the right upper quadrant. Patients may report new-onset pruritus as a consequence of retained biliary constituents.

The findings of cholangitis may be markedly attenuated in infants and immunocompromised patients, suggesting that a low index of suspicion be employed in the evaluation of these children at risk. The presentation of cholangitis in an infant with biliary atresia, status post Kasai portoenterostomy, may be as varied as lethargy, increasing jaundice, abdominal tenderness, or fever alone. Finally, patients with ongoing hemolysis (e.g., patients with hemoglobin SS disease) are at high risk for developing cholecystitis and cholangitis from bilirubin stones, yet the symptoms may readily overlap with other causes of abdominal pain.

DIAGNOSTIC EVALUATION

Physical examination may reveal a varied range of toxic appearances, with vital signs suggesting serious systemic infection in more advanced cases (fever, tachycardia, hypotension). Physical examination typically reveals icteric sclera and a distended abdomen, with tenderness localized to the mid or right upper quadrant. Palpation of the liver edge may reveal tenderness. Laboratory studies may reveal an elevated erythrocyte sedimentation rate (81%), leukocytosis or leukopenia (56%), and increased serum levels of conjugated bilirubin.[47] Laboratory evaluations in children should include a standard complete blood count with differential and liver panel (alanine aminotransferase, aspartate aminotransferase, alkaline phosphatase, gamma-glutamyltransferase, and fractionated bilirubin [unconjugated and conjugated]). The differential diagnosis of fever, abdominal pain, and jaundice also should include sepsis and hepatitis. No single laboratory test or combination of tests can establish a diagnosis of cholangitis.

TABLE 54–2 Charcot Triad and Reynold Pentad

Charcot Triad	Reynold Pentad
Fever	Fever
Right upper quadrant pain	Right upper quadrant pain
Jaundice	Jaundice
	Septic shock
	Altered mental status

Attempts at identifying a microbiologic agent should be made, and blood cultures should be drawn before antimicrobial therapy is initiated. Most cases are polymicrobial, with a predominance of gut-derived organisms (see Table 54–1). Blood cultures may be positive in 50 percent of pediatric patients with cholangitis, as reported by Ecoffey and colleagues,[47] but this typically is not the case in routine pediatric practice. Other investigators have reported identification of organisms in blood in approximately 10 to 25 percent of patients, which is in keeping with our experience.[227] In patients with a history of hepatobiliary surgery, aerobic and anaerobic cultures should be considered, and in virtually all cases of young children with abdominal pain and jaundice, a urine culture should be considered.

A role for direct testing of hepatic tissue by percutaneous biopsy is controversial, but occasionally this testing may have a place in the setting of negative blood cultures. When used along with blood cultures, hepatic cultures have been shown to increase the diagnostic yield of identifying a microbiologic organism to 75 percent of patients, whereas histologic confirmation of cholangitis may be the only firm evidence of biliary tract infection in some cases.[47]

In practice, liver biopsy rarely is done, and patients are treated empirically. In cases of gallstone-associated biliary tract obstruction with cholangitis that requires endoscopic or surgical decompression, bile should be obtained and cultured at the time of the procedure. In an adult study, 22 of 23 patients with gallstone-associated cholangitis were found to have positive bile cultures.[114]

The initial and principal radiologic evaluation for suspected cholangitis is transabdominal ultrasound, with the primary goal being to search for evidence of biliary tract obstruction, usually associated with dilation of the common bile duct or intrahepatic ducts. Ultrasound examination may reveal anatomic biliary tract abnormalities (choledochal cyst), intrahepatic cysts, and hepatic or other intra-abdominal masses. Other noninvasive imaging modalities include computed tomography (CT) and magnetic resonance cholangiopancreatography (MRCP), which provide increasingly detailed images of the intrahepatic and extrahepatic biliary anatomy.[137,172]

Taken together, these noninvasive imaging techniques should be able to detect the presence of biliary tract obstruction and some congenital anatomic anomalies, although even experienced ultrasonographers still may miss small stones and sludge, especially in the common bile duct. It is important to recognize the technical limitations of the methodology and the possible presence of undetected stones or sludge in the gallbladder or common bile duct (choledocholithiasis) as a cause of biliary tract dilation. Ultrasound misses 40 percent of biliary tract stones.[191] Finally, ultrasound is only 51 to 85 percent sensitive in identifying biliary tract obstruction, which improves to approximately 90 percent with CT, and 95 to 99 percent with endoscopic retrograde cholangiopancreatography (ERCP).[164]

Newer modalities, including endoscopic ultrasound, laparoscopic ultrasound, and helical CT cholangiography, may improve detection in certain patient populations. The 2002 National

Institutes of Health State-of-the-Science Consensus conference regarded endoscopic ultrasound, MRCP, and ERCP to have comparable sensitivity and specificity in detecting common bile duct stones.[146] In the hands of an experienced echoendoscopist, endoscopic ultrasound has been shown in adults to be the procedure of choice to identify small stones and sludge in the common bile duct. This method may prove useful in children as well, and may prevent the unnecessary use of ERCP and the risk of its associated complications.[54,173,191]

After HPE has been performed, imaging may be able to identify lakes of retained bile (bilomas), which may be a source of infection, in a patient with biliary atresia. Because of the inherent risks associated with invasive procedures in these infants, percutaneous drainage of bilomas for culture or other purposes rarely is performed. Similarly, ERCP is not indicated for patients with biliary atresia after HPE, for anatomic reasons.

Nuclear medicine (hepatobiliary iminodiacetic acid [HIDA]) scans have a limited role in the evaluation of cholangitis. HIDA scans may be most helpful in determining if a patient has a complete obstruction of the common bile duct, or if an isolated obstruction of the cystic duct (cholecystitis; see later) is present. Because most pediatric cases of cholangitis occur in patients with biliary atresia after HPE, involvement of the cystic duct rarely is a concern.

Invasive imaging has a role, especially when it may be coupled with therapeutic decompression of an obstructed, and potentially infected, biliary tree. ERCP has proved to be extremely useful in the evaluation and management of biliary tract obstruction and should be considered in the management of a child with evidence of an obstructed common bile duct (see later).[3,26,121,194,195,200,211,237] The role of ERCP in infants and small children is limited by the lack of experience of most pediatric gastroenterologists and should be considered in tertiary care centers that have the requisite expertise. ERCP is the most direct means of obtaining bile for microbial and chemical analysis and provides detailed imaging of the biliary tree.

Practically, ERCP may detect (and remove) small stones and sludge that are missed by ultrasound, CT, or MRCP. ERCP is helpful in establishing the differential diagnosis of biliary tract diseases, such as PSC, which may manifest in a fashion similar to that of infectious cholangitis but have a characteristic radiographic appearance. In the future, as the use of endoscopic ultrasound in pediatrics increases, ERCP may be reserved for those patients in whom stones or sludge have been found by endoscopic ultrasound or in patients with a high pretest probablility of having choledocholithiasis (e.g., patients with sickle-cell conditions).[54,191] One more recent study showed that 34 percent of pediatric patients undergoing ERCP had a normal study.[89] Limiting the indications for ERCP could prevent complications such as pancreatitis and iatrogenic ascending cholangitis. Any child with a first episode of cholangitis warrants a detailed investigation of a possible underlying biliary tract anatomic abnormality.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for an acutely ill child with fever and clinical evidence of hyperbilirubinemia is broad; a thorough work-up must include consideration of infectious and noninfectious etiologies (Table 54–3). A thorough investigation for hepatic and biliary tract pathology with blood and radiologic studies must be initiated to evaluate for stones or other obstructive processes that may cause symptoms characteristic of the Charcot triad.

Acute viral hepatitis may manifest in numerous ways but often begins with nonspecific signs: fever, headache, anorexia, and jaundice. Laboratory studies typically reveal a greater elevation of serum aminotransferase levels (alanine aminotransferase and aspartate aminotransferase) than the biliary tract enzymes alkaline phosphatase and gamma-glutamyltransferase. In a child with no other evidence of biliary tract obstruction, screening assays for hepatitis infection are warranted.

TABLE 54–3 Differential Diagnosis of Fever, Abdominal Pain, and Jaundice

Cholangitis
Cholecystitis
Cholelithiasis
Sepsis
Hepatitis
Choledochal cyst
Pancreatitis
Urinary tract infection
Leptospirosis and other systemic infections with hepatic involvement
Spontaneous perforation of common bile duct
Biliary cyst
Appendicitis

Pyogenic liver abscesses and amebic abscesses tend to manifest with fever, abdominal pain, hepatomegaly, and focal right upper quadrant tenderness.[148] Laboratory findings vary. CT is considered to be the most sensitive technique for evaluation of these diagnoses.[137] Numerous bacterial, parasitic, and spirochetal infections also should be considered in the differential diagnosis, including, but not limited to, typhoid fever, brucellosis, leptospirosis, borreliosis, amebiasis, and malaria. It is beyond the scope of this chapter to expand on the systemic infections associated with hepatic involvement.[154] Recurrent pyogenic cholangitis is another consideration, although it is rare in the Western Hemisphere and even more so in the pediatric population.[182]

Jaundice may occur with sepsis of any etiology, more commonly in a critically ill infant or child. Clinical evaluation may show a predominantly direct (conjugated) hyperbilirubinemia usually accompanied by a modest elevation of gamma-glutamyltransferase, although serum transaminase levels may not be elevated. These findings are caused by a hepatocellular cholestasis, owing to humoral mediators of sepsis (i.e., endotoxin and proinflammatory cytokines), but they can be exacerbated by biliary sludging that accompanies septicemia. Although sepsis-associated cholestasis historically was linked primarily to gram-negative sepsis, it can be seen in all forms of infection. In some cases, radiologic work-up or biopsy is warranted to rule out ductal obstruction or biliary tract pathology. Jaundice may occur as the sole presentation of sepsis in infants and children, however.[45] Evolving research into sepsis-induced cholestasis points to a complex, multifactorial etiopathogenesis.[30,59,138,215]

Drug-induced cholestasis tends to occur acutely with the onset of jaundice, pruritus, and other symptoms that may mimic cholangitis. It rarely is associated with fever, however. Among the main classes of drugs commonly used in pediatric practice that may lead to significant hepatotoxicity are antimicrobials (mainly trimethoprim-sulfamethoxazole [TMP-SMX], amoxicillin/clavulanate, clindamycin, minocycline, nitrofurantoin, erythromycin, cephalosporins, isoniazid, rifampicin, fluconazole), anticonvulsants (phenytoin, carbamazepine, valproate, felbamate), nonsteroidal anti-inflammatory drugs (aspirin, ibuprofen), antihypertensive agents (propranolol, diltiazem),[21,34] and herbal remedies such as kava kava. Although rarely used in pediatric patients, statins also lead to significant hepatotoxicity.[125] If the offending agent is identified in time, removing it typically leads to rapid improvement. Ceftriaxone warrants special mention because it has been linked directly to cholangitis and cholecystitis, possibly as a result of its biliary concentration and precipitation, leading to sludge and stones.[102,145]

Other systemic illnesses may occur with fever and evidence of biliary tract pathology, and their presentations may overlap with

presentations of infectious cholangitis. PSC is defined as a chronic inflammation of the intrahepatic or extrahepatic ducts leading to a range of biliary tract pathologies, from dilation to obliteration and periductular fibrosis. PSC is seen most commonly in patients with inflammatory bowel disease and affects adolescent boys with inflammatory bowel disease more commonly than girls. Symptoms include systemic findings, such as fatigue, malaise, and weight loss, and evidence of cholangitis, including fever. PSC must be suspected in a jaundiced patient with inflammatory bowel disease or in an adolescent boy presenting for the first time with jaundice. Diagnosis is established best by ERCP or magnetic resonance cholangiography showing irregular narrowing and stricture of the hepatic and common bile ducts and the intrahepatic ducts.[124,169] Patients with PSC are at risk of developing intrahepatic and common bile duct strictures, with subsequent obstruction, sludge or stone formation, cholangitis, and ultimately cholangiocarcinoma.[112]

TREATMENT

Therapeutic goals in the treatment of cholangitis should include general support of the patient, early initiation of appropriate antibiotic therapy, and, in cases of obstruction by stones or stricture, decompression of biliary obstruction via ERCP or surgery. Consulting pediatric surgeons early in the course of evaluating a patient with suspected cholangitis generally is helpful. The importance of decompression and drainage of the bile tract in the face of systemic infection secondary to cholangitis cannot be overemphasized. Other potential etiologies of obstruction, such as choledochal cysts, ultimately require surgical consultation and repair.

Initial and conservative management should include appropriate inpatient monitoring, cessation of oral intake with intravenous fluid support, parenteral antibiotic therapy, and supportive management as warranted by the child's clinical status. Because blood cultures tend to have a low diagnostic yield in cholangitis, antibiotics should be selected empirically, and selection should not rely on culture results.

Selection of a drug or combination of drugs should be based on appropriate coverage of suspected or documented organisms (based on sensitivities) and ability to achieve adequate serum and tissue concentrations. Currently, no single antibiotic or combination is recognized universally as being the definitive therapy for cholangitis in children. Typically, antibiotic therapy is initiated before obtaining culture results. In the past, the goal was to achieve sufficient biliary concentrations, although adequate serum levels are probably a satisfactory surrogate.[43,115] Parenteral antibiotics are indicated in almost all cases of children with suspected biliary tract sepsis. Primary antibiotics should cover gram-negative enteric organisms—*E. coli*, *Klebsiella*, and *Enterococcus*. In the case of a child with clinical sepsis, it is reasonable to add coverage for anaerobic species, particularly *Bacteroides*.[20]

Previously, a combination of ampicillin or penicillin with an aminoglycoside was considered appropriate therapy. Studies in adults suggest, however, that the use of some antipseudomonal penicillins, such as mezlocillin, is more effective alone than is the ampicillin-gentamicin combination.[61] The general recommendation for treatment of a pediatric patient with suspected cholangitis is a semisynthetic penicillin (e.g., piperacillin or mezlocillin) or a third-generation cephalosporin (e.g., cefoperazone) in combination with an aminoglycoside for adequate coverage of *Pseudomonas* spp.[107,227] The addition of metronidazole helps to cover anaerobic gut flora.

Rothenberg and colleagues[176] reported a 62.7 percent success rate after treatment with imipenem-cilastatin or third-generation cephalosporins with or without aminoglycosides and a 58.2 percent success rate using semisynthetic penicillins with aminoglycosides. A prospective trial involving 131 adults with biliary tract infections showed a "cure" in 85 percent of patients treated with ampicillin and tobramycin after a surgical procedure.[141] Although it is limited, a 1987 report of three patients suggests favorable results can be achieved using ciprofloxacin in pediatric patients with cholangitis after they have undergone a Kasai procedure.[84] TMP-SMX, which achieves a high biliary:serum concentration, has been used successfully in similar clinical settings.[80]

As mentioned previously, ceftriaxone probably should be avoided because it has been associated with biliary sludging and cholecystitis.[90] Currently, certain centers have reported the use of broad-spectrum antibiotics, such as meropenem, to cover optimally the enteric organisms most frequently associated with bacterial cholangitis.[201] Meropenem and other broad-spectrum β-lactam antibiotics with a β-lactamase inhibitor may be a good choice because many cholangitis episodes are polymicrobial.[221]

In clinical practice, the choice of antibiotic therapy often is empiric despite attempts to isolate a pathogenic organism. Antibiotic efficacy is determined by clinical and laboratory parameters, such as defervescence and improvement in biliary excretion. Antibiotic resistance is encountered more often in patients with repeated episodes of cholangitis.[47] The duration of antibiotic treatment varies, but a shorter course may result in recurrence.[176] The recommended course of therapy is 14 to 21 days, with longer duration recommended in special cases, such as recurrent or refractory cholangitis, and in the case of intrahepatic abscesses or hepatic surgery. Although oral antibiotic therapy generally has no place in the treatment of cholangitis in children, oral ciprofloxacin has been used in some adult populations.[227]

Ultimately, cholangitis or the risk thereof will not resolve in the presence of ongoing biliary obstruction. Although antibiotic therapy may treat septicemia, timely establishment of biliary drainage is imperative.[48] In 25 percent of adults with cholangitis, medical therapy is insufficient, and decompression via ERCP (or laparotomy) is indicated.[48,98,180] ERCP and percutaneous transhepatic cholangiography generally are recommended as first-line approaches because they pose a lower risk than does open surgical intervention.[157] These procedures can be diagnostic in the case of biliary obstruction and therapeutic, with sphincterotomy or stent placement.

Treatment of parasitic cholangitis should include appropriate treatment of biliary parasites based on regional sensitivities in addition to antibiotic coverage of secondary bacterial infections. Endoscopic or surgical intervention may be required to remove worms or cysts from the biliary tree.[35]

COMPLICATIONS OF CHOLANGITIS

Regardless of the patient's age at the time of presentation, cholangitis can be life-threatening. Other morbidities associated with cholangitis include pancreatitis. Because pediatric patients who present with cholangitis typically have underlying biliary or liver pathology, cholangitis may precipitate a rapid exacerbation of the underlying disease. In diseases such as biliary atresia, cholangitis may hasten the patient's course toward requiring organ replacement.

SPECIFIC POPULATIONS AND CHOLANGITIS

CHOLANGITIS AND BILIARY ATRESIA

In pediatrics, cholangitis is encountered most frequently in the setting of a patient with biliary atresia who has undergone a Kasai procedure. In 1959, Kasai and Suzuki[96] first reported relief of biliary obstruction in children with biliary atresia by HPE. The

procedure, a Roux-en-Y hepatic portoenterostomy, is considered to be standard first-line surgical therapy for infants with biliary atresia, and it is associated with the highest success rates and long-term survival when performed early, usually by 60 days of life. Without this procedure, 90 percent of patients with biliary atresia die before reaching age 3 years, at an average age of 19 months.[95,199]

Cholangitis remains the most frequent complication of the Kasai procedure, occurring in 40 to 60 percent of patients.[152] A subgroup of patients with the pathologic finding of cystic dilation of the intrahepatic bile ducts seems to have the highest risk of developing postoperative cholangitis.[81] The development of cholangitis has been associated with a worsening in long-term prognosis of children with biliary atresia.[85] Complications of cholangitis are severe, ranging from inflammation and scarring, to alterations in biliary flow, and, eventually to biliary cirrhosis. Repeated bouts of cholangitis are associated with worsening liver function, impaired growth, and need for early transplantation. For this reason, early detection, appropriate management, and prompt intervention and treatment of cholangitis are important in this population.

Most cases of post–Kasai procedure cholangitis occur within 1 year postoperatively. In a 1976 review of 49 cases of children who underwent the procedure, 31 achieved good bile flow restoration. Of these, 20 subsequently developed cholangitis, 15 occurring within the first postoperative month and 3 within the second month.[149] Likewise, in a study of 105 cases of cholangitis developing in 101 children after they underwent hepatic portoenterostomies, Ecoffey and colleagues[47] showed that 63 percent of the cases occurred within 3 months after surgery, and 93 percent occurred within 1 year. Rarely, late cholangitis may occur; this has been reported to occur several years after HPE.[66]

The generally accepted mechanism for development of cholangitis after a Kasai procedure is ascending bacterial colonization. This theory is reinforced by reports of a higher incidence of cholangitis developing in patients with good or partial bile flow after the Kasai procedure (78%) than in patients with no obvious bile flow (13%).[47] A 1978 study of 19 patients concluded that all bilioenteric conduits after the procedure were colonized within 1 month, correlating with the high incidence of symptomatic infection at this early stage.[80] The retrograde bacterial colonization may be enhanced by overall changes in intestinal motility after the Roux-en-Y loop.[207] Over time, the intestinal conduit from hepatic porta to jejunum seems to "mature," and the number of episodes of cholangitis diminishes. How this adaptation happens is unknown. Late episodes of cholangitis, occurring 1 to 2 years after a Kasai procedure, likely are related to mechanical obstruction, such as adhesions, and warrant investigation.[116]

Gram-negative enteric organisms constitute most organisms causing ascending cholangitis after HPE. *E. coli* has been found in 50 percent of the first and second cholangitis episodes and in decreasing frequency in subsequent episodes.[47] Anaerobes also are common findings and should be considered when selecting antibiotic treatment.[20] Refractory or recurrent cases occurring after surgery may warrant consideration of fungal disease, principally *Candida*.[33] Attempts to isolate an organism generally are made, but blood cultures typically have a low yield.[176] Bile cultures tend to reflect the multiple enteric organisms that colonize the conduit, but may not specify the true pathogens. Percutaneous liver biopsy has been used successfully to obtain cultures, but it rarely is used for this indication in pediatric patients.[150]

In the intraoperative and postoperative management of children with biliary atresia, attempts have been made to prevent the incidence of cholangitis. Various modifications in the surgical configuration of the intestinal conduit have been suggested to reduce enteric reflux. Initial studies have documented a reduced incidence of ascending cholangitis in the presence of a surgically placed antireflux valve. Despite the reduction of intestinal reflux in these cases, cholangitis continues to occur.[18] Cases of refractory cholangitis may require surgical intervention, especially if obstruction of the conduit or porta hepatis is suspected. The absolute indications for reoperation after HPE are unclear, however.

The role of corticosteroids in improving biliary drainage is controversial and has not been the subject of rigorous controlled trials. Perioperative steroid pulses, typically a 3- to 5-day course of intravenous methylprednisolone, have been shown, however, to be clinically beneficial by decreasing temperature, increasing bile flow, and improving liver function tests.[142,176] A multicenter, randomized, double-blind, placebo-controlled study sponsored by National Institutes of Health has been under way in 10 centers in the United States, to assess the safety and efficacy of using corticosteroids after the Kasai procedure (http://clinicaltrials.gov/ct2/show/NCT00294684?term=basitrank=3). The forthcoming results of this study should yield definitive information regarding the postoperative management of these children. The incidence of cholangitis in the treated and untreated arms is one of the outcomes.

In addition, some centers advocate the use of prophylactic antibiotics, typically TMP-SMX. The benefits of this practice are not well established, however.[32] In adults with recurrent cholangitis secondary to fixed obstruction, as in the case of malignancy, TMP-SMX and ciprofloxacin have been shown to be helpful in preventing episodes.[220] In our practice, TMP-SMX is used as a first-line agent. In selected patients with recurrent episodes of cholangitis on TMP-SMX and a functional HPE, we have used oral ciprofloxacin successfully.

In patients with post–Kasai procedure biliary atresia, each episode of cholangitis is associated with a 1 percent mortality risk. Some studies suggest that no significant clinical difference exists in overall survival rates between patients who have undergone the Kasai procedure and have or have not had cholangitis.[151] Previous studies suggest, however, an 88 percent mortality rate among patients who develop cholangitis within 1 month after undergoing the Kasai procedure, and 16 percent in patients who develop it more than 1 month later. More recent studies suggest that the occurrence of cholangitis is related to early postoperative mortality, and the number of repeated episodes is inversely related to survival.[231] Practically, because cholangitis can be life-threatening, patients with recurrent episodes frequently are considered for liver transplantation.

CHOLANGITIS AFTER LIVER TRANSPLANTATION

Infection remains the most common reason for morbidity and mortality after pediatric liver transplantation, accounting for 20 to 30 percent of postoperative deaths.[178,202,204] Bacterial infection that develops after transplantation tends to occur within the first 2 months postoperatively and generally is of either respiratory tract or intra-abdominal origin. Among patients with severe bacterial infections of intra-abdominal origin, cholangitis and biliary tract infections commonly develop. Gram-negative aerobic bacteria are encountered most commonly in this setting.[183] One adult study showed that 18 percent of 284 patients receiving liver transplantation had confirmed episodes of cholangitis.[222] Pediatric data suggest that the rate of cholangitis after liver transplantation for biliary atresia is 5 to 11 percent.

Biliary tract disease frequently occurs after the post–liver transplantation complication of hepatic artery thrombosis.[122,130] This complication was prevalent in the early days of pediatric liver transplantation. Although it remains a concern, the incidence has decreased owing to the use of microsurgical techniques. Hepatic artery thrombosis eventually leads to damage of the bile duct because the biliary blood supply is exclusively arterial, whereas the hepatic parenchyma is vascularized by the portal

vein and the hepatic artery. Biliary injury leads to altered biliary anatomy and drainage, increasing the risk of development of infection in these patients. Although most pediatric liver transplant recipients have a Roux-en-Y biliary-enteric anastomosis from the donor bile duct to the recipient bowel, ascending cholangitis is rare in this population.

Cholangitis that develops after liver transplantation may manifest with fever, jaundice, elevated liver enzymes, and bacteremia. The variable nature of an immunocompromised patient's response to infection renders the reliability of each of these signs and symptoms suspect, however. Distinguishing these symptoms from the presentation of post-transplant rejection or infection (e.g., with CMV or Epstein-Barr virus) is important. For this reason, liver biopsy often is a necessary part of the evaluation of a post-transplant patient with fever and elevated liver tests.

CHOLANGITIS IN IMMUNOCOMPROMISED PATIENTS

Although biliary disease related to acquired immunodeficiency syndrome (AIDS) may be considered the most common cholangiopathy of immunocompromised hosts, it is not the most frequent one in pediatric practice. Cholangitis also may occur in children with non-AIDS immunodeficiency. Sclerosing cholangitis has been reported in cases of primary immunodeficiency, including familial T-cell deficiency, IgA/IgG deficiency, and X-linked hyper-IgM syndrome.[69,113] Patients with sclerosing cholangitis often present with superimposed bacterial cholangitis because of poor biliary drainage. Hepatobiliary infection also has been reported in children with leukemia.[58,105,189,197]

AIDS-related cholangitis is a well-known complication of AIDS. It tends to occur late in the course of the illness and is more common in adults than in children. With the decline in the number of new AIDS cases in the United States, especially in pediatric patients, this diagnosis has become rare. In 1989, Cello[29] described four distinct patterns of disease in AIDS-related cholangitis as seen on cholangiography—papillary stenosis, sclerosing cholangitis, combined papillary stenosis and sclerosing cholangitis, and long extrahepatic bile duct strictures. The pathogenesis of these changes is unknown and may be related to biliary inflammation secondary to immunodeficiency, infiltration of the mucosa by HIV itself, or opportunistic infection by known gut culprits in AIDS infection.

Opportunistic agents most commonly responsible are CMV, *Cryptosporidium*, *Microsporida*, and, uncommonly, *Mycobacterium avium-intracellulare* and *Isospora*.[144,235] One report of unexplained cholangitis in a small cohort of HIV-positive men identified *Enterocytozoon bieneusi* in the bile of all of the patients.[159] Although AIDS cholangiopathy is extremely rare in children, these pathogens can be found in pediatric patients with primary immunodeficiencies and associated PSC, and with secondary immunosuppression after undergoing solid organ transplantation.[1,40,132,170,228]

Clinical presentation is similar to that in non-HIV patients, with the exception of jaundice, which tends to be less common. In a series of 45 adults with AIDS-related cholangitis, abdominal pain was reported as the most common presenting symptom, occurring in 64 percent of patients, followed by diarrhea (22%), fever (20%), and jaundice (7%). A 1997 review reported that 90 percent of adults present with right upper quadrant or epigastric pain. Twenty percent of patients were asymptomatic and identified by routine blood work alone.[44] Cholangitis has been reported as the initial presentation of HIV infection in a few patients.[17,140]

Diagnostic steps include noninvasive imaging with sonography and CT, and ERCP. Abdominal ultrasound is abnormal in 75 percent of patients and typically shows dilation or wall thickening of the common bile duct. These findings, along with liver function studies, may be suggestive of the disease even in children.[177] ERCP can show further characteristic changes in the biliary tract and has the added advantage of obtaining specimens for biopsy and culture and the possibility of therapeutic intervention.[232] Although AIDS-related cholangitis typically is not directly associated with mortality, most patients with AIDS-related cholangitis die within 1 year of being diagnosed because cholangitis usually occurs in patients with end-stage disease.[120] Therapy generally is symptomatic and should include coverage of bacterial cholangitis, which often is associated because of impaired biliary drainage.

CHOLANGITIS IN ASSOCIATION WITH CONGENITAL ANATOMIC ABNORMALITIES: CHOLEDOCHAL CYSTS AND CAROLI DISEASE

Choledochal cysts occur in 1 in 15,000 births in Western nations and 1 in 1000 live births in Japan.[148] Typically, presenting signs suggest cholestasis and may include jaundice, dark urine, and acholic stools, or patients may present with abdominal masses with or without jaundice. If diagnosed late or untreated, choledochal cysts may result in severe complications secondary to biliary tract obstruction, including cholangitis and pancreatitis. One series of 36 Indian patients reported 13 patients, more frequently children than infants, who presented with cholangitis.[158] Cholangitis is more likely to be the presenting sign for choledochal cyst in adult patients.[31]

Treatment of cholangitis associated with choledochal cysts involves supportive treatment of the patient, including appropriate antibiotic treatment. In the past, cyst-enteric drainage procedures were used as temporizing treatments, and this type of repair was associated with high rates of complications, including recurrent bouts of cholangitis, stones, and cholangiocarcinoma in the remnant duct.[168] The current surgical goal is complete surgical excision; compared with internal drainage procedures, this approach is associated with lower rates of postoperative cholangitis and mortality.[181] Five types of choledochal cysts have been identified, with solitary extrahepatic cysts (type I) being encountered most frequently. After this type of cyst has been excised, reconstruction of the biliary tract may involve a Roux-en-Y choledochojejunostomy or hepatojejunostomy.

Patients who undergo this surgery also are at risk for developing postoperative ascending cholangitis, with an incidence of 8 to 19 percent.[52,185] Although recurrent cholangitis may lead to chronic liver disease in the long-term, antibiotic prophylaxis is not recommended routinely.[92]

Caroli disease describes congenital dilation of the intrahepatic and extrahepatic biliary tree characterized by pure ductal ectasia.[37,38] More commonly, dilation of the intrahepatic ducts is attributed to ductal plate malformation in association with congenital hepatic fibrosis. The association of ductal ectasia with congenital hepatic fibrosis is more common than without and is termed *Caroli syndrome*. Both of these diseases may manifest with clinical signs of liver disease or renal disease secondary to the associated condition of autosomal recessive polycystic kidney disease, or both.[93,118,153] Dilation of the intrahepatic bile ducts results in biliary obstruction and places the patient at increased risk for development of intrahepatic stones and cholangitis, which significantly increases morbidity and mortality rates in Caroli disease and congenital hepatic fibrosis. Diagnosis is suspected in the case of recurrent cholangitis or portal hypertension of unknown etiology, and can be confirmed by ultrasound, cholangiography,[49] or MRCP.

Portosystemic shunting is considered the treatment of choice because this condition typically does not progress to liver failure. Suspicion of cholangitis, whether owing to signs of infection or sepsis or laboratory results suggesting inflammation, should be confirmed via a diagnostic liver biopsy for culture. Treatment of cholangitis in the setting of Caroli disease may be difficult.

Recurrent episodes may occur even after administration of intensive intravenous antibiotic therapy.[224] In some cases, drainage procedures may be used for refractory or recurrent infections. Orthotopic liver transplantation is the treatment of choice in recurrent, life-threatening episodes of cholangitis.[76,224]

Typically, patients with Caroli disease or Caroli syndrome present with cholangitis because the biliary malformation communicates with the extrahepatic biliary tree. Rarely, patients are seen with hepatic cysts associated with autosomal dominant polycystic kidney disease. These lesions are noncommunicating lesions and as such are not prone to infection. In the absence of a history of cholangitis, it is advisable that these rare patients not undergo invasive procedures of the biliary tree because of the risk of microbial seeding and subsequent suppurative cholangitis.[5,100,234]

CHOLANGITIS AFTER ENDOSCOPIC AND OTHER BILIARY PROCEDURES

Although at this point, experience in the use of ERCP in pediatric patients is limited, it is growing, and cholangitis is a known complication of this procedure in adults. In a series of 50 pediatric patients, low-grade fever, abdominal pain, nausea, and vomiting were reported as the most common complaints after undergoing ERCP; one patient was treated for mild cholangitis.[211] Another group reported three cases of sepsis in adults caused by multiresistant *Pseudomonas aeruginosa* after ERCP, ascribed to nosocomial transmission from the endoscope despite negative surveillance cultures.[41] In adults, and rarely in children, biliary stents are used to alleviate a common bile duct obstruction, most frequently malignant.

The major complication of these stents is obstruction and subsequent upstream infection. Clinicians have looked at ways to prolong stent patency. A meta-analysis of randomized or quasi-randomized studies examining the role of antibiotics or ursodeoxycholic acid to maintain stent patency showed no conclusive evidence in favor of either one in the prevention of stent occlusion. In certain children and adolescents with a history of recalcitrant cholangitis, percutaneous transhepatic biliary drainage is used by experienced centers to decompress the biliary tree upstream of the stricture or to dilate the stricture. This procedure is used primarily in patients with PSC and in transplant patients with biliary stenoses secondary to ischemia or rejection.[10,36,56,62,74,209] These patients also benefit from oral antibiotic prophylaxis, frequently ciprofloxacin for its excellent biliary penetration.

CHOLECYSTITIS

Gallstones are the prime initiating factor in cholecystitis. Gallstone disease is a common entity in adults, with more than 700,000 cholecystectomies performed each year in the United States among approximately 20 million adults with gallstones.[109] In children, gallstones and gallstone-related complications occur much less frequently than in adults. In certain pediatric populations, such as patients with hemolytic conditions, gallstone and gallbladder diseases are more common, however, and need to be considered in appropriate clinical settings.[192] In addition, because gallstones are associated with obesity, an increase in pediatric-onset cholelithiasis may occur soon owing to the epidemic in childhood obesity.[193]

The term *cholelithiasis* refers to the presence of gallstones, which may occur silently or in association with clinical symptoms. Biliary colic occurs in the setting of obstruction of either the cystic duct or the common bile duct secondary to gallstones and is associated with characteristic episodic, postprandial right upper quadrant pain. Acute cholecystitis involves inflammation of the gallbladder and can be seen with cholelithiasis (calculous) or in the absence of gallstones (acalculous). In adults, acute cholecystitis almost always is associated with gallstones—90 percent of adult cases occur secondary to gallstones. In contrast, 30 to 50 percent of pediatric cases are acalculous.[216] Acalculous cholecystitis is discussed separately at the end of this section.

ETIOLOGY AND PATHOGENESIS

Gallstones generally are classified as either pigment stones or cholesterol stones. Pigment stones can be divided further into either black or brown pigment stones. Black pigment stones occur in the face of a superabundance of unconjugated bilirubin in the bile and are seen most commonly in hemolytic disease, leading to increased biliary concentration of bilirubin and to calcium-bilirubinate stones. Brown pigment stones are less common and are associated with biliary infection or parasitic infestation, or with the presence of a foreign body (e.g., retained suture material) or biliary obstruction. Cholesterol stones are the end result of biliary cholesterol supersaturation secondary to an imbalance in the cholesterol : phospholipid : bile salt equilibrium or other precipitating factors.[42] These stones tend to occur in the face of either elevated cholesterol production or decreased bile salt pool.

In pediatric practice, pigment stones are seen more frequently than are cholesterol stones, in direct contrast to adult populations, in which cholesterol stones are more prevalent. Friesen and Roberts[55] described 693 pediatric cases of gallstone disease, of which 72 percent involved pigmented stones. The greatest experience with pigmented gallstones in children is in children with hemolytic diseases, primarily sickle-cell anemia and thalassemia, but also in patients with hereditary spherocytosis and other red cell membrane defects, pyruvate kinase deficiency, glucose-6-phosphate dehydrogenase deficiency, and autoimmune hemolytic anemia.[77,167,190] The prevalence of pigment gallstones in hemolytic disease increases with age. In children younger than 10 years old, the frequency is 12 to 14 percent; the frequency increases to 36 to 42 percent in individuals 10 to 20 years old.[16,188]

Total parenteral nutrition predisposes children to develop biliary tract disease, and in particular gallstone formation.[165] This condition occurs more commonly in premature neonates, especially neonates with enteral diseases, in which prolonged fasting, sepsis, immaturity of the enterohepatic circulation of bile acids, small bowel bacterial overgrowth, and prolonged duration of total parenteral nutrition contribute to biliary stasis and increased prevalence of gallstones and sludge.[6,99,106,187,208,226] The occurrence of gallstones secondary to total parenteral nutrition does not lead to increased prevalence of complications, however, because many of these gallstones are clinically silent.

Cholesterol stones are found most frequently in adults and have an increased prevalence in women from puberty to menopause and in obese patients.[184] Some of these characteristics may translate to pediatrics as well. Although boys and girls exhibit an equal incidence in gallstones at young ages, the incidence in girls increases significantly after puberty, and female predominance of gallstone disease continues through menopause.[147] Related risk factors for the presence of cholesterol stones in children and adolescents include obesity, pregnancy, and the use of oral contraceptives. In addition, conditions that are associated with decreased ileal bile salt resorption predispose to stone formation. This association includes patients who have undergone ileal resection or bypass and patients with Crohn disease.[174]

Gallstones are found in 28 percent of adults with cystic fibrosis at the time of autopsy.[196] The presence of gallstones in children with cystic fibrosis is well documented, but the pathogenesis likely is multifactorial.

TABLE 54–4 Patient Populations Predisposed to Gallstone Formation

Pigment Stones	Cholesterol Stones
Hemolytic disorders	Pregnancy
Total parenteral nutrition	Obesity
Biliary tract anomalies (e.g. Caroli disease)	Rapid weight loss
Parasitic disease (*Ascaris lubricoides*)*	Malabsorption (e.g., Crohn disease, ileal resection)
Ceftriaxone use	Genetic predisposition (e.g., *ABCB4* homozygosity)
Solid organ transplantation (heart, lung, kidney)	Cystic fibrosis and other cholestatic liver diseases

**Brown pigment stones.*

Finally, children with chronic liver disease, and in particular cholestasis, are at increased risk for gallstone formation, owing to a deficit of biliary excretion.[229] Table 54–4 summarizes the pediatric patient populations at risk for development of gallstones.[57]

The genetics of biliary stone formation has been the focus of intense research. The consensus is that biliary stone formation, affecting the gallbladder and the common bile duct, is the product of genetic predisposition and environmental risk factors. In adults, a distinction is made between the "common" polygenic predisposition to gallstones and the rarer oligogenic predisposition. Briefly, the first, polygenic group refers to patients with evidence of increased risk of developing biliary stone formation, probably associated with numerous factors, including lithogenic (*LITH*) genes. The oligogenic group refers to a small group of patients with known mutations in genes involved in bile synthesis and export.[72,229] The clearest examples to date are defects in the *ABCB4* transporter in humans[175] and the *Mdr2* homozygous null mutant in mice.[108] Both conditions lead to an increased propensity toward cholelithiasis and choledocholithiasis; however, whether these subjects have a profile of biliary tract infections different from that of the polygenic group is unknown.

The most likely cause of calculous cholecystitis is gallstone obstruction of the cystic duct, which leads to increased intraluminal pressure with gallbladder distention, mucosal damage, and release of inflammatory mediators. The end result is acute inflammation of the gallbladder. Any bacterial infection probably is a secondary occurrence to biliary obstruction.[109]

CLINICAL PRESENTATION

Acute cholecystitis typically manifests with abdominal pain and vomiting. Pain may be localized to the right upper quadrant; however, in pediatric patients, this making distinction can be difficult, and it may be difficult to differentiate from other causes of acute abdominal pain in children. As in the model of appendicitis, initial pain with obstruction of the cystic duct tends to be visceral pain that may be epigastric and poorly localized. With gallbladder inflammation, the pain becomes parietal—more localized to the right upper quadrant and associated with some peritoneal signs, such as pain with movement. With regard to the duration of pain, cholecystitis should produce pain that is more long-standing than uncomplicated biliary colic. Although obstruction of the cystic duct is associated with the acute onset of pain followed by resolution within 3 to 6 hours, true gallbladder inflammation may produce a more persistent pain, lasting 6 to 12 hours or longer.

The presence of jaundice with right upper quadrant pain and emesis in a patient without hemolysis or increasing jaundice in hemolytic patients warrants a thorough investigation for the possible presence of choledocholithiasis and cholecystitis. Fever, although classically described in the presentation of cholecystitis, is not universally present. In a retrospective study of 198 adults who presented to an emergency center with acute cholecystitis, 59 percent were afebrile.[71] Physical examination may show a tender right upper quadrant. The examiner should try to elicit Murphy's sign, for which tenderness on palpation of the right upper quadrant worsens with palpation of the liver edge or gallbladder and may be most apparent with deep inspiration. The patient may exhibit voluntary guarding or peritoneal signs. A palpable mass, representing the inflamed gallbladder with adjacent omentum, may be present.

EVALUATION

Laboratory evaluation may show leukocytosis, although this finding is not universally present in adults or children with cholecystitis.[71,165] Bilirubin levels may be elevated, especially in the setting of hemolysis. A conjugated hyperbilirubinemia should cause one to be concerned about choledocholithiasis, or sepsis-associated cholestasis. Transaminases and amylase and lipase are ordered frequently on initial evaluation to investigate for other causes of epigastric or right upper quadrant pain with vomiting or fever or both, such as pancreatitis and viral hepatitis. As in the evaluation of cholangitis, early consultation with a pediatric surgeon is appropriate.

Abdominal ultrasound is the test of choice in establishing the diagnosis of cholecystitis. Findings on ultrasound include a thickened or irregular, hyperreflexive gallbladder wall with or without the presence of gallstones. Experienced sonographers may be able to elicit tenderness over the gallbladder, the "sonographic Murphy sign." Ultrasound is useful for detecting gallstone disease, showing 90 percent in some cases, although in other studies, ultrasound has a markedly lower sensitivity to detected common duct stones.[54] Without suspicion of gallbladder inflammation, however, the finding of gallstones alone by sonogram does not indicate cholecystitis. Other false-positive studies may occur with the finding of thickened gallbladder walls in patients with hypoalbuminemia, renal failure, or heart failure.[156] The inability to visualize the gallbladder by ultrasound may indicate the finding of a diseased, chronically obstructed gallbladder.[68]

Hepatobiliary scintigraphy (HIDA scan) can be useful in confirming the diagnosis of acute cholecystitis. The study employs a technetium-labeled iminodiacetic acid agent that is excreted into the bile ducts. Subsequent images are taken, which in a normal study should fill the gallbladder, extrahepatic ducts, and duodenum. In the case of cystic duct obstruction, a positive study fails to show the gallbladder filling. The sensitivity and specificity of this study are high, with results approaching 90 to 100 percent and 90 to 95 percent.[143,166] The test may be augmented by attempts to stimulate gallbladder contraction using a cholecystokinin analogue. Plain abdominal radiographs and oral cholecystography are infrequently used in the current clinical environment.

ACALCULOUS CHOLECYSTITIS

Acalculous cholecystitis is a rare but important cause of cholecystitis in pediatric patients. Generally, acalculous gallbladder disease in children occurs in various clinical settings, ranging from congenital gallbladder abnormalities, to idiopathic gallbladder distention without inflammation (acute hydrops of the gallbladder), to acute or chronic cholecystitis. The exact pathogenesis of acute acalculous cholecystitis is unclear; however, stagnation of the bile may be an important factor, as suggested by several predisposing clinical conditions that lead to bile stasis. In addi-

TABLE 54–5 Conditions Associated with Acalculous Gallbladder Disease

Biliary tract anomaly (e.g., choledochal cyst)
Bone marrow transplant
Burns
Chemotherapy in oncology patients
Critical illness in ICU patients
Crohn disease, Kawasaki disease, systemic lupus erythematosus
Infectious agents (atypical microbes)
Postoperative state (e.g., cardiac surgery)
Sepsis
Sludge
Systemic inflammatory states
Total parenteral nutrition
Traumatic spinal cord injury

ICU, intensive care unit.

tion, sphincter of Oddi spasm or dysfunction, as occurs after administration of opiates, could lead to retrograde reflux of inflammatory enzymes or infectious agents. Alternatively, changes in the gallbladder vascular supply may weaken the gallbladder mucosa and allow biliary components to damage the gallbladder wall.[64] Acalculous cholecystitis has been associated with many infectious and noninfectious clinical scenarios. Bacterial, viral, and parasitic agents have been implicated in the setting of acalculous cholecystitis. Frequently, gallstone or biliary microlithiasis missed by standard diagnostic evaluations may lead the clinician to the presumptive diagnosis of acalculous cholecystitis. One adult study revealed that 33 of 35 patients with abdominal pain and a negative transabdominal sonogram had gallbladder sludge and stones, and 21 of those patients also had common bile duct involvement.[136]

Reports of true acalculous disease have been described with systemic infection from *Salmonella* spp., *Mycoplasma pneumoniae*, *Leptospira interrogans*, *Brucella* spp., Rocky Mountain spotted fever, group A streptococci, group B streptococci, and *Staphylococcus aureus*.[8,9,39,78,82,131,198,212,230] Examination and culture of cholecystectomy specimens from patients with acalculous cholecystitis have revealed positive cultures for *Helicobacter* spp. and *Campylobacter jejuni*.* Associations with viral disease include CMV, mumps virus, Epstein-Barr virus, and hepatitis A virus.[2,11,12,13,19,28,60,161] Acalculous cholecystitis has been associated with *Plasmodium falciparum* infections (malaria).[46,126,179,186,233] In immunosuppressed hosts, acalculous cholecystitis also has been described in fungal infections with *Candida* or *Aspergillus*, or parasitic infections with *Giardia* and *Cryptosporidium*.[144]

Noninfectious systemic diseases associated with acalculous cholecystitis or hydrops include neoplastic disease (i.e., leukemia), Henoch-Schönlein purpura, lupus erythematosus, and Kawasaki disease.[25,83,129] Table 54–5 lists several conditions with which acalculous cholecystitis has been reported.[86,88,171,203,213,214]

Clinical presentation is similar to that of patients with calculous disease, with right upper quadrant pain, nausea, vomiting, anorexia, and fever being the most common symptoms. Leukocytosis, jaundice, or a palpable right upper quadrant mass also may be present.[216] The most common setting for acalculous disease is in critically ill or chronically ill patients with concurrent acute or chronic symptoms. A high degree of clinical suspicion is crucial in making the diagnosis in these populations because often the findings suggestive of cholecystitis are obscured by the patient's systemic disease. The most common sonographic finding is a thickened gallbladder wall and a possible sonographic Murphy sign. Gallbladder distention, sludge, or pericholecystic fluid also may be found on transabdominal ultrasound.[87] In addition to ultrasound, the HIDA scan is an important tool in the evaluation of acalculous cholecystitis. Failure to visualize the gallbladder on scintigraphy and a low ejection fraction in response to a cholecystokinin analogue are suggestive of acalculous disease.[127,143,162,236]

MANAGEMENT

Management strategies of gallstone disease in children vary, contingent on individual clinical scenarios. Silent gallstones, which are asymptomatic and often detected incidentally by ultrasound, can be followed conservatively and sonographically without emergent or elective surgery. Although conservative management of adults with asymptomatic stones is described in multiple reports, no such guidelines exist for children. Patients with hemolytic disease in whom gallstones are detected should be considered for early cholecystectomy, although this plan is controversial.[4,73,91,135,225] In patients with sickle-cell anemia, the benefit of timely surgery may outweigh the morbidity of associated abdominal pain crises and the overall morbidity and mortality of surgery in these patients, which increases with age.

In acute calculous cholecystitis, surgery is the mainstay of therapy. Patients should be admitted to the hospital for monitoring, intravenous hydration, and pain control. Antibiotic therapy often is initiated, even without clinical evidence of sepsis or perforation. The choice of antibiotics is similar to that for cholangitis and typically covers gut luminal flora (e.g., a synthetic penicillin plus an aminoglycoside with or without the addition of mezlocillin).[75,227] Surgical treatment may be limited to cholecystotomy, especially in chronically ill children with a high risk of developing complications. Generally, early cholecystectomy should be performed in patients with acute cholecystitis secondary to gallstone disease. Laparoscopic procedures are becoming more widely used in experienced pediatric surgical centers and are associated with positive outcomes in children and adults.

Optimal management of acalculous cholecystitis has not been investigated fully, primarily because of the lack of a diagnostic standard and varied patient population base. This situation leads to an individualized approach that typically starts conservatively with observation but may involve removing oral feeds and placing the patient on intravenous hydration and antibiotics, or it leads to more invasive management with cholecystectomy or biliary manometrics via ERCP.[63,87] Attempts should be made to diagnose and treat any underlying condition in the patient. A more recent treatment protocol supports the close monitoring of these patients with frequent examinations, ultrasonography, and blood tests to determine if the need for cholecystectomy or ERCP seems likely. If ultrasound shows improved findings, conservative management is continued with close follow-up. If biliary dyskinesia is suspected secondary to sphincter of Oddi dysfunction, ERCP offers a diagnostic and therapeutic option at experienced centers.[51,160,218]

COMPLICATIONS

Acute cholecystitis may lead to complications, even if it is recognized in a timely fashion. An inflamed, obstructed gallbladder may wall off to form an intraluminal abscess or empyema. Perforation of the gallbladder is the most frequent complication. A localized perforation may develop into a pericholecystic abscess that is palpable as a tender right upper quadrant mass on examination. Free perforation with peritonitis is associated with a 30 percent mortality rate, but it is found in only a few patients, estimated at 1 to 2 percent of adult patients.[109] In each of these

*See references 7, 22, 23, 53, 97, 111, 117, 128, 133, 134, 210, 223.

situations, prompt surgical intervention and intravenous hydration and antibiotic therapy are crucial in management.

Aside from gallbladder inflammation, complications of gallstone disease may include pancreatitis and choledocholithiasis. Gallstone pancreatitis was a frequent complication of gallstone disease in a series of 50 pediatric patients.[165] Choledocholithiasis with ascending cholangitis, a well-known complication of gallstones, is a rare cause of cholangitis in pediatric patients. Secondary common bile duct stones, usually originating from the gallbladder, can be found in patients with acute cholecystitis by ultrasound, ERCP, MRCP, or intraoperative cholangiography. The possible presence of choledocholithiasis should be considered in any patient with known gallstone disease who presents with increasing jaundice, fever, and right upper quadrant pain, and requires urgent clinical investigation and decompression, typically via ERCP.[206]

BILIARY TRACT INFECTIONS AFTER CARDIOTHORACIC SURGERY

In adults, the association between cardiothoracic surgery and biliary complications is well known and covered extensively in the literature.[123,139,217] These complications frequently manifest as cholangitis or cholecystitis, commonly with stone or sludge formation. The high incidence of biliary complications that develop after cardiothoracic surgery is ascribed to prolonged fasting, metabolic disturbances, vagotomy, and hypoperfusion. The last, in particular, is thought to predispose the biliary tree, which is exquisitely reliant on adequate arterial perfusion, to development of focal ischemia and secondary strictures. In pediatrics, although it is commonly accepted by clinicians as a frequent association, no studies have been published. The clinical implications of the adult studies and unpublished pediatric observations is that patients may present after cardiothoracic surgery with acute biliary disease warranting aggressive empiric management occasionally in immunosuppressed hosts who have undergone thoracic organ transplantation.

Infections of the intrahepatic and extrahepatic biliary tree in children differ from infections in adults by the nature of the populations they affect. First, patients with biliary atresia and portoenterostomy are subject to ascending cholangitis and the risk of developing sepsis and rapidly progressive liver disease. Second, children with hemoglobinopathies are prone to developing cholecystitis because of their increased incidence of cholelithiasis. In these two groups and in other pediatric patients, the same principles of management apply: Biliary obstruction must be sought and alleviated when possible, and aggressive parenteral antimicrobial therapy must be initiated promptly because of the risk of developing sepsis and worsening liver disease.

CHAPTER 55

Pyogenic Liver Abscess

Sheldon L. Kaplan

Pyogenic liver abscesses are encountered infrequently in healthy children and generally have been reported more commonly in the compromised pediatric host. The rarity of liver abscesses may be explained partly by the rich blood supply, unique architecture, and extensive reticuloendothelial system of the liver, all of which present an effective barrier against bacterial invasion.

The precise incidence of pyogenic liver abscesses in children is unknown. Adult patients with hepatic abscesses constitute approximately 8 to 20 cases per 100,000 admissions; a 0.29 to 0.57 percent incidence of liver abscesses has been found in autopsies of adult patients.[11,48] In an early large series of liver abscesses in children, Dehner and Kissane[10] reported a 0.38 percent

incidence at autopsy in patients younger than 15 years old; 11 of 27 (41%) patients were younger than 2 years, and 18 of 27 (67%) patients were younger than 6 years. In a review of admissions to Milwaukee Children's Hospital, Chusid[9] found five children (four of whom were <6 months old) with at least one hepatic abscess, and estimated an incidence of 3 cases for every 100,000 admissions. Pineiro-Carrero and Andres[43] estimated an incidence of approximately 25 cases per 100,000 admissions in their pediatric population (11 patients >14 years old). Pyogenic liver abscess in children is encountered more frequently in developing countries compared with developed countries.

PATHOGENESIS

Bacteria can establish an inflammatory focus in the liver by four major routes. Direct extension from contiguous structures is the most common mode in adults and precedes up to 60 percent of hepatic abscesses in adults.[7,24,44,48] Biliary tract infection (cholangitis, cholecystitis), pancreatitis, and penetrating gastric or duodenal ulcer are examples of diseases associated with liver abscesses caused by extension from a contiguous focus of infection. In a review of this problem at St. Louis Children's Hospital, 3 of 27 children (11%) were considered to have a liver abscess secondary to inflammation of contiguous organs.[10] Although biliary tract disease occurs infrequently in children, ascending cholangitis is a particularly frequent complication of the hepatic portoenterostomy procedure for congenital biliary atresia and may lead to infections of the liver in such patients.[14] Liver abscesses also may develop as a complication of liver transplantation, especially if technical problems related to vascular supply or biliary drainage develop.[30]

The portal system is the second most common route by which bacteria may reach the liver in adults; 6 to 27 percent of liver abscesses in adults derive from this source.[24,32,48] In newborns, solitary liver abscesses, especially abscesses caused by gram-negative organisms, have complicated the use of umbilical vein catheterization or have been secondary to omphalitis.[6] Prematurity and necrotizing enterocolitis also are important predisposing conditions.[13]

Portal vein inflammation and bacteremia can be associated with infections within the abdominal cavity. Appendicitis, diverticulitis, perirectal abscesses, regional enteritis, ulcerative colitis, and omphalitis are possible sources of portal vein sepsis.[10] A pyogenic liver abscess may be an unusual complication of an ingested foreign body, with subsequent development of portal venous bacteremia.[38] Since antibiotics have been available, portal vein inflammation and pyelophlebitis have become less common sources of hepatic infection in children.

Systemic bacteremia with hematogenous spread of bacteria to the liver through the hepatic artery seems to be the most common source of liver abscess in children, but it is implicated in less than 20 percent of adult patients. In the St. Louis series, the systemic hematogenous route was responsible for 21 of 27 (78%) cases of liver abscesses.[10] In five of the patients examined before 1940, the bacteremia was associated with infection that would be considered manageable today (pneumonia, cellulitis, and osteomyelitis). Seven of 13 patients encountered after 1940 had bacteremia associated with leukemia. Anaerobic bacteremia associated with retropharyngeal or peritonsillar abscesses presumably has preceded development of anaerobic liver abscesses in several children.[8] Likewise, liver abscesses in neonates may be preceded by a systemic bacteremia without evidence of portal or biliary tract involvement.[35]

Liver abscesses occur more frequently in compromised pediatric hosts than in healthy children. Johnston and Baehner[25] reported that hepatic or perihepatic abscesses were present in 41 of 92 (45%) patients with chronic granulomatous disease. In a registry of 368 patients with chronic granulomatous disease from the United States, a liver abscess occurred in 27 percent of patients.[57] Over the course of 10 years, 15 children were diagnosed with pyogenic liver abscess in a large referral center for pediatric liver disease in the United Kingdom.[36] Three children (20%) had chronic granulomatous disease. In addition to functional disorders of phagocytes, chronic neutropenia predisposes to the development of liver abscesses.[42] Wintch and colleagues[58] noted that 5 of 10 children with hepatic abscesses in their institution had an underlying defect in host defense. Primary hemochromatosis predisposes to multiple liver abscesses caused by *Yersinia enterocolitica* in particular.[54] Pyogenic liver abscesses also are associated with Papillon-Lefévre syndrome, a rare autosomal recessive disease characterized by palmoplantar keratoderma and periodontitis.[1]

Penetrating and nonpenetrating trauma to the liver may lead to liver abscesses, presumably caused by bacterial proliferation within small collections of blood and bile that result from the trauma. Hepatic abscess may be a rare complication of ventriculoperitoneal shunts after penetration of a peritoneal catheter into the liver.[39] This mode of infection has been reported in seven children.[22] Liver abscess also is a complication of percutaneous liver biopsy.[16]

Unexplained or cryptogenic hepatic abscesses are encountered in most series and accounted for 40 to 50 percent of cases in many series.[24] Lee and Block[33] have proposed that these cryptogenic liver abscesses "originate from anaerobic bacterial invasion of hepatic infarcts." This theory is supported by reports that describe pyogenic liver abscesses as a complication of hepatic infarction in patients with sickle-cell anemia.[50] Normal gastrointestinal bacterial flora were isolated from 9 of 11 patients with liver abscesses at the Mayo Clinic. This finding suggested to Lazarchick and associates[32] that unrecognized intra-abdominal collections of pus were responsible. Although the reasons are unclear, diabetes mellitus also predisposes to the development of liver abscesses.[21,44] Nematode infection with larvae migrating through the liver is thought to be another predisposing factor for the development of pyogenic abscesses in children. The larvae induce liver granulomata that trap bacteria, leading to formation of an abscess.[41] In one study from Brazil, positive serology for *Toxocara canis* was significantly more frequent for patients with pyogenic liver abscess (10 of 16) than for the 32 age-matched controls (4 of 32).[46]

Biliary tract disease generally predisposes to the development of multiple liver abscesses. In contrast, blunt trauma to the liver or portal system inflammation most commonly predisposes to a single abscess. In neonates, liver abscesses may be solitary or multiple because of systemic bacteria.[35,37] Solitary abscesses are the most common findings in the right lobe of the liver.[32]

Hepatic and splenic abscesses caused by *Candida* spp. are well described in patients with cancer.[52] Multiple abscesses are typical findings. These organs presumably are infected hematogenously, usually when the host is neutropenic.

MICROBIOLOGY

Gram-negative organisms have been the predominant isolates from liver abscesses in adults. *Escherichia coli*, *Klebsiella*, *Aerobacter*, *Pseudomonas*, and *Proteus* spp. have been implicated most frequently. *Klebsiella* spp. were the most common organism isolated from children with pyogenic liver abscess in Taiwan.[53] *Klebsiella* spp. also predominated in adult Asian patients in a report from New York.[45] Anaerobic organisms also are important; anaerobic organisms were recovered from 45 percent of patients with liver abscesses in the UCLA series.[49]

In contrast to the adult experience, Dehner and Kissane[10] reported that 33 percent of liver abscesses in children were caused

by *Staphylococcus aureus*, whereas gram-negative organisms were found in only 32 percent. Two or more organisms were recovered from liver abscesses in 52 percent of children. In a review of 96 children (no neonates) with pyogenic liver abscesses, *S. aureus*, gram-negative enterics, and anaerobes were the organisms isolated most commonly, in that order.[28] *S. aureus* is the most common isolate that causes pyogenic liver abscess in patients with chronic granulomatous disease. In neonates, gram-negative enterics are isolated most commonly. Anaerobes, particularly *Fusobacterium necrophorum*, have been isolated from liver abscesses in children without underlying disease.[15] Human rotavirus–like particles were identified in the material aspirated from a liver abscess, but they were considered a secondary phenomenon and not the primary etiology of the liver abscess.[19] Fungi, particularly *Candida albicans*, have been associated with liver abscesses in children with leukemia and neutropenia who have received parenteral hyperalimentation.[3] Liver or splenic abscesses also may be an unusual complication of brucellosis.[55]

CLINICAL MANIFESTATIONS

The clinical manifestations of pyogenic liver abscesses are nonspecific. A high index of suspicion and an awareness of this illness are necessary to establish the diagnosis. A history of preceding abdominal surgery or trauma is helpful when present, as is the knowledge that the hosts response to infection is compromised.

Fever, nausea, vomiting, anorexia, weakness, and malaise are prominent symptoms that may last several weeks. Abdominal or pleuritic pain, weight loss, and diarrhea are less common manifestations. A history of abdominal pain and fever of unknown origin in an otherwise healthy child suggests the diagnosis of pyogenic liver abscess.[27] In contrast, fever often is not observed in neonates.[13] Patients with a macroscopic or single abscess frequently experience a subacute to chronic course. In contrast, patients with multiple abscesses generally experience a more acute febrile illness.

Hepatomegaly occurs in 40 to 80 percent of patients; abdominal tenderness occurs less frequently. Right upper quadrant tenderness or even a mass may be subtle and not appreciated, unless the physician specifically and carefully examines this region. Other physical findings include jaundice (generally associated with biliary tract disease and not liver abscesses), abdominal distention, and evidence of pleuropulmonary involvement (i.e., elevated or fixed hemidiaphragm, rales, and pleural effusion).

DIAGNOSIS

Routine laboratory studies are of little help in attempting to establish a diagnosis. Anemia, leukocytosis, and an elevation in C-reactive protein are common findings. Liver function tests generally reflect underlying disease of the liver itself and usually are not caused by the abscess. When abscesses occur secondary to biliary tract obstruction, alkaline phosphatase and bilirubin concentrations generally are elevated. Transaminase concentrations usually are normal to mildly elevated in most cases. A rapidly enlarging, tender liver in a patient with normal transaminase concentrations should alert the clinician to the possibility of liver abscess. Lazarchick and colleagues[32] found that the serum albumin concentration was the most important test with regard to prognosis; 14 of 16 patients with a serum albumin level of less than 2 g/dL died.

Blood cultures are positive more commonly in patients with multiple abscesses than in patients with solitary abscesses. Overall, however, blood cultures usually are sterile in children with pyogenic liver abscess.

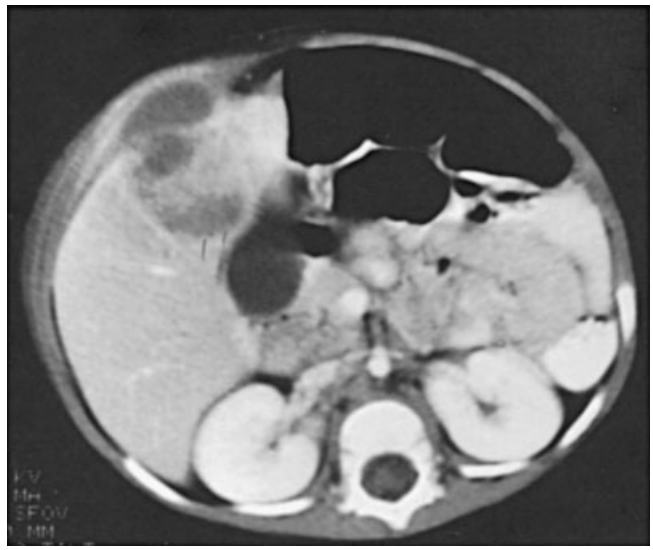

Figure 55–1 Abdominal computed tomography scan showing a 4-cm × 5-cm encapsulated, septate, circular mass within the liver. A low-density soft tissue mass is noted in the abdominal wall from apparent extension from the intrahepatic mass.

More than 50 percent of adult patients have abnormalities on chest radiography. Atelectasis, pulmonary infiltrates, pleural effusion, and elevated or fixed right hemidiaphragm are the most common findings.

Computed tomography (CT) currently provides the most accurate information concerning the size, location, and number of abscesses within the liver parenchyma (Fig. 55–1).[26,31,43] Lesions measuring 1 cm in diameter can be detected by CT. Multiple small abscesses may appear in clusters in a pattern suggesting early coalescence of the abscesses.[23] Liver abscesses appear as areas of low attenuation. The "target" lesions of hepatic candidiasis are not visualized by CT when the patient is neutropenic, and scans may need to be repeated before these characteristic lesions are observed.[52] Structures contiguous with the liver also are shown by CT; this information is important when a surgical approach to drainage is being planned.

Magnetic resonance imaging does not have any major advantages over CT for detecting or characterizing liver abscess but may show characteristic features to distinguish an abscess from other focal liver lesions in selected patients.[2,34] Ultrasonography also is a sensitive technique for detecting liver abscesses, and because it is noninvasive and does not require exposure to radiation, it is recommended for initial evaluation.[29,31] Hepatic angiography defines the vascular anatomy in the area of the liver abscess further and may provide information necessary for surgical management in selected cases. Nuclear medicine techniques rarely are indicated as a diagnostic method if liver abscess is suspected.

TREATMENT

Numerous reports have documented that patients with undiagnosed and untreated liver abscesses generally die and that surgical drainage of the solitary pyogenic liver abscess is the key to successful treatment. The choice of extraserous or transperitoneal open drainage or percutaneous closed aspiration depends on the location and size of the abscess and the experience and preference of the surgeon.[18,24,40,48]

Numerous groups have described percutaneous catheter drainage of liver abscesses in adults.[4,5,17,29] A catheter is placed

into the cavity under CT or ultrasound guidance; material is aspirated, and when an abscess is documented, a draining catheter is placed. The cavity can be irrigated with saline initially. Criteria for the selection of patients for percutaneous drainage have been established.[17] Generally, percutaneous drainage is not indicated for patients with multiple large abscesses or multiloculated abscesses.[24] The optimal route of percutaneous aspiration is directly into the abscess cavity and does not involve any uninfected organs or space. Drainage may proceed for 2 weeks or more, or until drainage from the cavity is decreased, the patient is afebrile and improving, and radiography shows that the cavity is becoming smaller.[20] Surgical backup is mandatory when this drainage technique is used because spillage of abscess material into the peritoneal cavity, hemorrhage, and other complications may occur. Percutaneous drainage of liver abscesses in children has been performed successfully, and this technique should be considered an alternative approach to surgical drainage of such abscesses, especially in the right lobe of the liver.[12,43]

Appropriate antibiotic therapy initially is based on knowledge of the organisms most commonly involved, Gram stain of the purulent material, and culture and susceptibility to antibiotics of the organisms that are recovered. If a hematogenous source of infection is suspected or the host has an immunodeficiency disease, *S. aureus* and streptococci are more likely. Biliary tract disease and blunt trauma are associated more frequently with gram-negative aerobic and anaerobic organisms. A logical antibiotic combination for the initial therapy of children with liver abscesses includes a penicillinase-resistant penicillin, such as nafcillin, plus an aminoglycoside. Vancomycin or clindamycin is selected if strains of *S. aureus* resistant to methicillin are present in the community.

The optimal duration and route of administration of antibiotics for a child with a solitary pyogenic liver abscess that has been drained have not been determined. Generally, 2 to 4 weeks of antibiotic therapy administered parenterally, followed by an appropriate oral antibiotic to complete a minimum 4-week total course, should be adequate. Penicillin, ticarcillin-clavulanate, piperacillin-tazobactam, clindamycin, cefoxitin, or metronidazole is administered for anaerobic isolates, depending on susceptibility. Meropenem is useful for polymicrobial infections, including infections caused by gram-negative aerobic and anaerobic rods.

Multiple liver abscesses are more difficult to treat because achieving complete surgical drainage usually is impossible. Prolonged antibiotic therapy plus treatment of any underlying illnesses is the keystone to effective management. Duration of treatment can be modified, depending on the evidence for resolution of the abscesses as determined by repeated ultrasound examination or CT.

Fungal liver abscesses are difficult to document by culture of the abscess material; histologic evidence of a fungal infection of the liver must be sought.[3] Amphotericin B, with or without flucytosine, is administered in the treatment of fungal liver abscesses.[52] In a neutropenic rabbit model, combination therapy with amphotericin and flucytosine was superior to amphotericin B alone in clearing disseminated candidiasis.[51] The optimal duration of therapy is unknown, but prolonged therapy, guided by repeated CT scans and biopsies, should be provided until the lesions have resolved.[52] Liposomal preparations of amphotericin B or other antifungal agents, such as caspofungin, may be beneficial for selected children with hepatosplenic candidiasis who are intolerant of or failing treatment with traditional amphotericin B.[56]

COMPLICATIONS AND PROGNOSIS

Complications of hepatic abscesses vary and are relatively common. Twenty-eight percent of the patients described by Rubin and associates[48] and 44 percent of the patients studied by Pitt and Zuidema[44] had one or more complications. Possible complications include pleural and pulmonary inflammation, peritonitis, subphrenic or subhepatic abscesses, and hemobilia.[10,48]

Polymicrobial bacteremia, hypoalbuminemia, multiple liver abscesses, or the presence of any complication is associated with increased mortality rates in patients with liver abscesses. Overall mortality rates depend largely on underlying pathologic processes and are difficult to interpret. Mortality figures from more recent reports range from 2.5 to 11 percent in adults.[24,45] In children, the prognosis for pyogenic liver abscess is excellent, generally with a low chance of mortality.[36] An increased awareness and suspicion of liver abscesses, in conjunction with ultrasound or CT of the liver, substantially reduces the mortality rate of this disease.

CHAPTER 56

Reye Syndrome

Eugene S. Hurwitz

A syndrome involving the acute onset of encephalopathy associated with fatty metamorphosis of the liver and occurring primarily in children was described first by Reye and colleagues[8] in Australia and by Johnson and associates[7] in the United States. The similarities of these two descriptions in separate countries led to the common designation of this clinicopathologic entity as *Reye-Johnson* or *Reye syndrome*. Reye syndrome occurs most frequently after a viral illness and is characterized by the onset of severe vomiting followed by the development of encephalopathy and hepatic dysfunction. The recognition in the early 1980s that the syndrome is associated with the ingestion of aspirin during the antecedent viral illness led to public awareness of this association, a decline in aspirin use for such illnesses in children, and a dramatic decline in the occurrence of this disease in the United States.[1]

EPIDEMIOLOGY

In the United States, national surveillance for Reye syndrome was conducted first during the 1973 to 1974 nationwide outbreak of influenza B and influenza A (H1N1). Such surveillance led to the recognition of outbreaks of Reye syndrome regionally and nationally that were associated with outbreaks of influenza in these and subsequent years.[2] During the first 5 years of surveillance, 250 to 550 cases were reported nationally—an underestimate because it was based on voluntary reporting.[9] Population-based studies conducted in several geographic locations showed that the average annual incidence of the syndrome was one or two cases per 100,000 children younger than 18 years old. Adults rarely were affected. Case-fatality rates reported through national surveillance, initially 40 percent, declined to 20 to 30 percent in later years when the syndrome was prevalent, although this rate undoubtedly was an overestimate because of the tendency to report more severe and fatal cases through this system.

Between 1980 and 1982, four case-control studies reported an association between Reye syndrome and the ingestion of aspirin during an antecedent respiratory or chickenpox illness.[3,11,12] The results of these studies subsequently were confirmed in the Public Health Service Pilot and Main Studies of Reye Syndrome and Medications.[4,5] In these studies, more than 90 percent of patients with Reye syndrome compared with 40 to 70 percent of controls had received aspirin for the antecedent respiratory or chickenpox illness; reported odds ratios were 11.5 to 40. After these studies were reported, publicity and recommendations from various expert panels, including recommendations issued by the Food and Drug Administration in 1985, led to a decline in the use of aspirin and a decline in the incidence of Reye syndrome, particularly in the age group that had been affected most—children 5 to 15 years old.[1]

CLINICAL ILLNESS AND LABORATORY FINDINGS

Reye syndrome is described classically as an illness characterized by the abrupt onset of severe vomiting and progressive encepha-

lopathy in a child who is just recovering from a viral illness, the most common of which are influenza and chickenpox. The onset of these symptoms typically occurs within several days after the onset of the viral illness and commonly during a period when the child seems to be recovering from this illness. In association with severe—often projectile—vomiting, which occurs for a transient period, are progressive encephalopathic changes that may follow stages from delirium through confusion, agitation, and lethargy to coma if untreated.

The definition used by the Centers for Disease Control and Prevention (CDC) and widely adopted for clinical purposes includes (1) evidence of acute encephalopathy manifested by alterations in consciousness and documented, when available, by cerebrospinal fluid with less than 9×10^6/L leukocytes or by biopsy or autopsy evidence of cerebral edema without perivascular or meningeal inflammation in histologic sections of the brain; (2) evidence of liver involvement, including either biopsy or autopsy findings of fatty metamorphosis of the liver if available or, in the absence of such specimens, elevations in liver enzymes (alanine aminotransaminase, aspartate aminotransaminase, or serum ammonia) that typically are more than three times normal levels; and (3) no other more reasonable explanation for the cerebral or hepatic abnormalities. The last requirement emphasizes that Reye syndrome is a diagnosis of exclusion, and that every effort should be undertaken to identify other possible causes for the clinical and laboratory abnormalities.

Liver biopsy or autopsy findings are considered characteristic and include panlobular microvesicular fat and mitochondrial abnormalities on electron microscopic examination showing peroxisome swelling and enlarged pleomorphic mitochondria with loss of dense granules. Additional findings include normal bilirubin levels and absence of jaundice. Most patients also have hypoglycemia and a prolonged prothrombin time. The typically elevated cerebrospinal fluid pressure in patients leads to progressive stages of coma.

Staging criteria for Reye syndrome have been used to define the level of encephalopathy. Patients have been reported with liver involvement, but without evidence of encephalopathy. These patients have been described as having stage 0 encephalopathy and, although they do not meet the Centers for Disease Control and Prevention criteria for Reye syndrome, are considered to have mild disease. Patients with stage I encephalopathy are difficult to arouse and lethargic, whereas patients with stage II are delirious and combative with some movement. Patients with higher stages of encephalopathy (III to V) cannot be aroused and have progressively deeper stages of coma. These patients have a poor prognosis, with a mortality rate approaching 50 percent for patients admitted with stage III or greater and 90 percent for patients admitted with stage V.

Exclusion of other diseases that may resemble Reye syndrome, such as salicylate toxicity, is essential in patients with symptoms resembling this entity. Intensive laboratory investigations should be undertaken to exclude such disorders. In young children, particularly children younger than 3 years of age, inherited metabolic disorders frequently may mimic Reye syndrome and must be excluded. Such metabolic disorders include disorders of fatty acid oxidation, urea cycle disorders, carnitine transport defects, and organic acidemias. Laboratory studies must be performed for the younger age group to exclude these disorders before a diagnosis of Reye syndrome is made, particularly because some of these disorders can be treated effectively. With the declining incidence of Reye syndrome in the typical age group (5 to 15 years) after virtual elimination of the use of aspirin in children, an increasing number of patients with features of Reye syndrome are in this younger age group and ultimately are found, after careful evaluation, to have one of the many metabolic disorders that mimic this syndrome.

TREATMENT AND PREVENTION

The mainstay of treatment of Reye syndrome is early recognition of disease and supportive care focusing on various measures to control intracranial pressure and electrolyte and other abnormalities. Patients should have glucose levels monitored, and early infusion of glucose is considered by many physicians to improve outcome. Comatose patients should be transferred to tertiary care centers that have experience in caring for such patients and can monitor and treat elevated intracranial pressure. When such measures were undertaken before the decline in incidence of this disease, they were associated with improved outcome and decreased mortality. Other therapeutic measures that have been used include efforts to reduce ammonia levels, such as exchange transfusions, peritoneal dialysis, and total-body washout via cardiopulmonary bypass. With advances in supportive care, the mortality rate declined to 10 to 20 percent in later years before Reye syndrome became extremely rare.

Since the association between Reye syndrome and aspirin has been recognized, aspirin no longer is recommended or used for the treatment of febrile illnesses in children. Alternative antipyretics, including nonsteroidal anti-inflammatory drugs and acetaminophen (Tylenol), have replaced aspirin as the primary therapy for such illnesses. These medications have not been associated with an increased risk for development of Reye syndrome. Children with some disorders, including juvenile rheumatoid arthritis and Kawasaki disease, continue to be given aspirin to treat these disorders. Efforts to reduce the risk of development of Reye syndrome in these children have included influenza vaccination annually and vaccination against chickenpox. Careful monitoring of these children also is necessary to ensure early recognition and treatment of Reye syndrome should it occur.

CHAPTER 57

APPENDICITIS AND PELVIC ABSCESS

Thomas L. Kuhls

The ability to diagnose appendicitis accurately in a child is one of the most fundamental skills that a pediatric surgeon has to master, although establishing the diagnosis often is difficult in young patients. The surgeon ultimately is responsible for deciding whether a child is taken to the operating room for an appendectomy; however, a primary care physician often is the first person to evaluate a patient who complains of abdominal pain. Pediatricians with expertise in infectious diseases frequently are involved in the care of children who present with subtle or atypical manifestations of appendicitis; have unusual microorganisms recovered from their appendices; or have complications as a result of appendiceal rupture, such as the development of wound infections, sepsis, peritonitis, intra-abdominal abscesses, and pelvic abscesses.

HISTORY

In the 16th century, physicians began describing patients with clinical manifestations suggestive of perforated appendicitis. Until the late 1800s, the inflammatory process was called *typhlitis* or *perityphlitis* because the illness was thought to originate from the cecum. In 1886, Fitz[52] recognized that the source of the inflammation was the appendix and suggested that a laparotomy be performed early in the course of the illness. Shortly afterward, McBurney[114] reported that in patients with appendicitis, tenderness was greatest 2 inches from the anterior iliac spine on a line drawn to the umbilicus. Despite intensive research and refinement of understanding of appendicitis during the 20th century, the rates of removing nondiseased appendices or finding already perforated appendices at laparotomy remained at approximately 20 percent until more recently when ultrasound and computed tomography (CT) examinations have been used routinely in children with suspected appendicitis, resulting in a possible decrease in misdiagnosis of the disease.

Despite the continued difficulties in diagnosing appendicitis, the mortality rate from appendicitis has decreased greatly since Fitz reported a 40 percent operative mortality rate. In 1936, Bancroft and Skoluda[16] reported a mortality rate of 8 percent and a complication rate of 11 percent for appendicitis, most likely because of the availability of general anesthesia and better aseptic surgical techniques. The second major improvement in outcome occurred in the 1940s, when sulfonamides and banked blood became widely available.[112] In the 1970s, anaerobes such as *Bacteroides fragilis* were found to cause postoperative infections frequently in patients with appendicitis, and treating these microorganisms was found to reduce further the rate of postoperative complications.[99] Currently, death from appendicitis is a rare occurrence in the United States.

EPIDEMIOLOGY

Reported incidences of acute appendicitis vary widely, depending on where the studies were performed and what methodologies were used. The consensus is that the number of cases of acute appendicitis has been decreasing during the past few decades.[86,115] Investigators have estimated that more than 70,000 children are diagnosed with appendicitis each year in the United States.[71] In 1997, appendicitis-related hospitalizations accounted for 0.6 percent of all hospitalizations in the United States, resulting in approximately 1 million hospital days and $3 billion in hospital charges.[40] Although appendicitis occurs in all age groups, the highest incidence occurs during the second decade of life.[3,107] Appendicitis is an uncommon event in children younger than 5 years of age and occurs extremely rarely in infants younger than 6 months. Researchers have suggested that patients with acquired immunodeficiency syndrome (AIDS) have a higher incidence of appendicitis than the normal population.[95]

Numerous studies have shown that the peak rates of appendicitis occur during the summer months, whereas the lowest rates occur during the winter months.[3,107] A study from Italy found a higher rate of pediatric appendicitis in winter, whereas appendicitis in adults was observed more frequently during the summer.[56] The reasons for these seasonal patterns are unknown, but changes in diet and exposure to allergens have been suggested as explanations.[107] Also, enteric infections occur most frequently during the summer and may play a role in increasing the incidence of appendicitis in summer.

Most studies show a modest increase in incidence of appendicitis in males compared with females.[3,107] An estimated lifetime risk for developing appendicitis is 8.6 percent for males and 6.7 percent for females.[3] In a study of acute appendicitis in California, the rate of appendicitis in whites was twice that of blacks and Asians.[107] More recently, Hispanics were shown to have the highest rate of appendicitis-related hospitalizations in the United States.[40] Whether the reported racial differences are due to errors of measurement, sociodemographic factors, environmental factors, factors related to body constitution, or genetic factors is unknown. Children with appendicitis more frequently have a history of having family members who previously have had appendicitis, suggesting that genetic background plays a role in the susceptibility to appendicitis.[18] Decreased dietary fiber and ingestion of refined carbohydrates also have been suggested to increase the risk for developing appendicitis.

The rates of perforation with appendicitis are significantly higher in Asian, Hispanic, and black children compared with non-Hispanic white children.[64,78,145,179] Similarly, children without health insurance or Medicaid have rates of perforation higher than those of children with private health insurance.[145,178]

Researchers have suggested that the pediatric rupture rate is a good candidate for inclusion in the National Healthcare Disparities Report.[78] Already, studies at local institutions have found no differences in perforation rates based on socioeconomic status, showing improved access to early medical care in their communities.[133,171]

PATHOPHYSIOLOGY

The initial event in the development of most cases of appendicitis is thought to be obstruction of the appendiceal lumen.[174] Microorganisms rarely invade the appendiceal mucosa and initiate the inflammatory process. Appendiceal obstruction can be caused by inspissated feces (fecalith), hypertrophied lymphoid tissue that develops during a systemic viral infection or bacterial enterocolitis, parasitic infestation, appendiceal wall hemorrhage associated with anaphylactic purpura, inspissated barium, or ingested seeds. Continued production of mucus by the appendiceal mucosa distal to the obstruction causes the appendix to distend. Vascular congestion and ischemia occur as the increased intraluminal pressure of the appendix becomes greater than the venous pressure, and edema develops as lymphatic flow becomes obstructed.

Stasis of intestinal flow and intestinal ischemia allow the microorganisms in the appendix to invade the tissues, enhancing the already developing inflammatory response. Bacteria may translocate across the appendiceal wall and reach the peritoneal cavity.[17] If the process is severe and arteriolar blood flow to the appendix is obstructed, transmural infarction occurs and the appendix ruptures. Microorganisms are liberated into the peritoneal cavity, causing generalized peritonitis and formation of an abscess. Animal studies have suggested that synergism occurring between enteric aerobes, such as *Escherichia coli*, and anaerobes, such as *B. fragilis*, is important in the development of intra-abdominal and pelvic abscesses after perforation.[62] An association between the development of an abscess after appendiceal perforation and the presence of *Streptococcus milleri* also apparently exists.[69]

As the appendix distends in the early stages of appendicitis, the visceral afferent autonomic nerves that enter the spinal cord at T8 to T10 are stimulated, referring the pain to the epigastric and periumbilical areas of the abdomen.[174] When the inflammatory response reaches the serosal surface of the appendix, the parietal peritoneum is stimulated, and the pain intensifies in the right lower quadrant. If perforation occurs, the peritoneal inflammatory response causes more generalized abdominal tenderness.

Although appendiceal obstruction may play an important role in the early stages of most cases of appendicitis, not all obstructed appendices become inflamed. Ten percent of normal appendices removed during abdominal surgical procedures contain inspissated fecal material. Also, children may develop recurrent, crampy abdominal pain, possibly from intermittent appendiceal obstruction.

The classic description of the pathophysiology of appendicitis does not explain easily many epidemiologic features of this disease, including its higher incidence in males and in certain races. The amount and reactivity of the lymphoid tissue in the wall of the appendix have been suggested to be key determinants to the development of appendicitis. The amount of lymphoid tissue in the appendix is greatest during adolescence, when the disease process is most prevalent, and the amount most likely is controlled genetically.

In a case-control study from Italy, prolonged breast-feeding during infancy was associated with a decreased risk for developing acute appendicitis later in life.[144] The investigators hypothesized that breast-feeding may have decreased the amount of stimulation to intestinal lymphocytes by microbial and food antigens early in life, so that appendiceal lymphoid tissues were less reactive to antigenic challenge during adolescence and adulthood. Appendicitis may be observed less frequently during infancy and the newborn period because the appendix is more funnel-shaped, the diet is primarily liquid, recumbent posture is maintained for prolonged periods, and gastrointestinal and respiratory infections develop less frequently during this time.[101]

CLINICAL MANIFESTATIONS

In school-aged children and adolescents with appendicitis, the median duration of symptoms before hospital admission is 24 to 28 hours.[151] Pain in the right iliac fossa is the most common sign of appendicitis, occurring in 88 to 99 percent of patients.[151,156] Pain shifts from the periumbilical area to the right lower quadrant of the abdomen in approximately two thirds of children with appendicitis. In three fourths of children, the pain worsens during movement. The characteristics of the abdominal pain do not always predict accurately which children have appendicitis. Of children found to have mesenteric adenitis at laparotomy, 25 percent report a shift in abdominal pain to the right iliac fossa and 33 percent experience worsening of pain during movement.[151]

Nausea and vomiting are found in 86 to 96 percent of children with appendicitis.[151,156] Vomiting usually occurs after the onset of abdominal pain but may precede pain in nearly 20 percent of cases. If only nausea or vomiting is present, it is less likely the child has appendicitis.[151] Anorexia occurs less commonly in children than in adults, occurring in 47 to 91 percent of cases of appendicitis. Because 50 percent of children found to have normal appendices at surgery complain of anorexia, differentiating appendicitis from other causes of right iliac fossa pain is not always helpful. Similarly, complaints of diarrhea (9-16%), constipation (5-28%), and dysuria (7%) occasionally can be elicited from children with appendicitis.[151,160] Fever may be helpful as a clinical sign of appendicitis if it is present (>37.5º C in 68-96% of cases), but absence of fever does not exclude the possibility of acute appendicitis. Very high temperatures (>39º C) suggest that perforation already has occurred or that another intra-abdominal process is present.[174] Rarely, children present with erythema and tenderness of the scrotum as the only manifestation of acute appendicitis.[216]

During the physical examination, the child frequently lies quietly on the examination table with the right hip flexed. Tenderness in the right iliac fossa is the most sensitive sign of appendicitis, occurring in 93 to 100 percent of cases of appendicitis.[151,156] The psoas muscle may become irritated from the inflamed appendix, causing the child to feel increased pain when the right hip is flexed actively. Likewise, if the obturator internus muscle is involved, pain is elicited when the flexed thigh is rotated internally.[174] Guarding is found in 80 to 91 percent of cases of appendicitis compared with 50 percent of cases of mesenteric adenitis and 8 percent of cases of nonspecific abdominal pain.[151] Similarly, rebound tenderness is found in 56 to 83 percent of cases of appendicitis, 33 percent of cases of acute mesenteric adenitis, and 1 percent of cases of nonspecific abdominal pain.[151]

The development of diffuse abdominal tenderness and the absence of bowel sounds usually indicate perforation. Extremely hyperactive bowel sounds suggest that the patient may not have appendicitis. Occasionally, a mass can be palpated in the right lower quadrant of the abdomen in children with appendicitis who are relaxed or well sedated. Rectal tenderness is present more commonly in children with appendicitis (44-68%) than in children with other causes of abdominal pain (12%); however, findings during the rectal examination seldom alter the clinical decision of the surgeon.[151]

In preschool-aged children, the diagnosis of appendicitis is more difficult to establish because of the inability of young children to express their symptoms and because they often do not cooperate during the physical examination.[210,211] Young children with appendicitis often are seen early in the course of their symptoms and are prescribed antibiotics, antihistamines, or antipyretics. By the time one realizes that the child has appendicitis, the appendix usually is perforated (50-90%).[210,211] In contrast to older children, in preschool-aged children vomiting is the initial symptom of appendicitis most frequently observed, and abdominal pain may be absent or may never localize in the right iliac fossa.[151] Sleep disturbances, irritability, restlessness, and crying are common manifestations of appendicitis in this age group. A preschool-aged child is more likely to have a palpable inflammatory mass at presentation.[174]

During the newborn period, appendicitis is an extremely rare occurrence.[101,164] Symptoms of neonatal appendicitis include abdominal distention; vomiting; irritability; diarrhea; erythema, edema, or cellulitis of the abdominal wall; gastrointestinal hemorrhage; abdominal rigidity; lethargy; and jaundice. Usually, the symptoms of neonatal appendicitis are indistinguishable from the symptoms of necrotizing enterocolitis. Underlying conditions, such as total colonic Hirschsprung disease, meconium plugs, or hernias, may predispose a newborn to developing this condition.

In children who are undergoing chemotherapy for leukemia, acute appendicitis may manifest with only vague abdominal pain, abdominal distention, lack of abdominal guarding, fever, dehydration, diarrhea, or unusual symptoms such as gastrointestinal bleeding.[8] Symptoms of appendicitis in immunocompromised patients may be identical to the symptoms of typhlitis.

The differential diagnosis of acute abdominal pain in children is extensive. Table 57–1 outlines conditions that can manifest with symptoms suggestive of acute appendicitis.

TABLE 57–1 Differential Diagnosis of Acute Appendicitis in Children

Cecal and Colonic Diseases
Constipation
Crohn disease
Infectious colitis (bacterial, parasitic)
Intestinal obstruction
Necrotizing enterocolitis (newborns)
Typhlitis (leukemia patients)
Small Intestinal Diseases
Duodenal ulcers (acute and perforated)
Gastroenteritis (including mesenteric adenitis)
Intestinal duplication
Intestinal obstruction
Intussusception
Meckel diverticulitis
Volvulus
Hepatobiliary and Pancreatic Diseases
Cholecystitis
Hepatitis
Hydrops of the gallbladder
Pancreatitis
Other Diseases
Omental torsion
Pneumonia
Psoas abscess
Spontaneous peritonitis
Reproductive Tract Diseases
Intrauterine and ectopic pregnancy
Ovarian torsion
Ovarian cysts
Pelvic inflammatory disease
Testicular torsion
Urinary Tract Diseases
Hydronephrosis
Pyelonephritis
Urachal abscess
Urolithiasis
Wilms tumor
Systemic Illnesses
Anaphylactoid purpura
Cytomegalovirus infection (in patients with AIDS)
Diabetic ketoacidosis
Kawasaki disease
Lymphoma (Burkitt)
Porphyria
Rocky Mountain spotted fever
Sickle-cell disease
Tuberculosis

AIDS, acquired immunodeficiency syndrome.

DIAGNOSIS

The diagnosis of acute appendicitis should be established without laboratory studies when a child complains of abdominal tenderness in the right lower quadrant that initially started in the periumbilical area, develops nausea and vomiting, and has rebound tenderness in the right lower quadrant with guarding during an abdominal examination.[21,174] The child should be taken to the operating room for an appendectomy as soon as possible before perforation occurs.[92] One third of children do not have all of the classic clinical manifestations of appendicitis, however; great emphasis has been placed on using various laboratory tests to help clinicians diagnose the disease accurately. Similarly, patients who have received prior oral antibiotics may have milder symptoms and signs of classic appendicitis, necessitating further diagnostic studies.[49]

For decades, physicians have valued peripheral blood leukocyte counts, neutrophil counts, C-reactive protein concentrations, and erythrocyte sedimentation rates to help them distinguish appendicitis from other causes of abdominal pain. When properly evaluated, these tests have been found, however, to be too insensitive to use as reliable tools for diagnosing appendicitis.[46,77,140,159] Normal results do not rule out the possibility that the child has appendicitis, although these tests help to confirm a physician's suspicions when results are positive. These nonspecific tests usually have elevated findings, however, during advanced disease, such as when perforation occurs.[5,136,142] Certain groups of patients commonly have normal leukocyte counts despite having acute appendicitis. Black patients with acute appendicitis frequently do not develop leukocytosis.[100,106] Patients with AIDS who develop appendicitis also frequently do not have elevated white blood cell counts.[24,124]

Routine radiographic studies for the diagnosis of appendicitis in children no longer are suggested. A chest radiograph often was obtained because right lower lobe pneumonia can cause severe abdominal pain in children. Radiographs of the abdomen are neither sensitive nor specific enough for diagnosing childhood appendicitis. Abnormalities described in association with acute appendicitis include an abnormal bowel gas pattern, a mass, a fecalith, and obliteration of normal fat planes in the right lower quadrant. Gas in the appendiceal lumen is thought to be diagnostic of acute appendicitis, but it may occur rarely in its absence. Most children do not have radiographic findings of appendicitis, or findings are nonspecific.

Graded compression ultrasonography has become the diagnostic procedure of choice in some institutions when evaluating

a patient with possible appendicitis.[57,58] A transducer is used to apply gradual pressure to the abdomen. The technician must ensure that all gas and fluid contents from the loops of bowel are expressed for the examination to be adequate. A noncompressible, enlarged (>6 mm in diameter in adolescents) appendix or a fecalith is the major criterion used for diagnosing appendicitis by ultrasonography. Interruption in the continuity of the echogenic submucosa suggests necrosis of the appendiceal wall and impending perforation. An echogenic periappendiceal mass indicates inflammation of the mesenteric or omental fat. Loculated or generalized fluid collections suggest that perforation already has occurred.

Pooled studies of graded compression ultrasonography have shown that the procedure is 88 percent sensitive and 94 percent specific in diagnosing acute appendicitis in children.[44] False-positive ultrasound results occur in obese patients who have noncompressible appendices because of overlying fat and in children who have inflamed appendices caused by Crohn disease, ulcerative colitis, or adjacent salpingitis. False-negative results occur if retrocecally located appendices are not visualized properly; if the cecum is filled with gas or feces and is not compressed adequately; or if perforation has occurred, allowing the appendix to be compressible. In one study, a noncompressible appendix was identified in only 38 percent of pediatric patients with perforated appendicitis, rendering the other ultrasound findings of appendicitis important in diagnosing the disease.[146] The examination should be directed to diagnose other causes of abdominal pain that can mimic appendicitis when a normal appendix is found during the ultrasound evaluation.

The advantages of using ultrasonography over CT are that it is inexpensive, safe, and widely available. It is especially useful in adolescent girls with abdominal pain because gynecologic causes of the pain can be evaluated easily at the time of appendiceal examination.

Most North American pediatric surgeons prefer CT over ultrasonography as the diagnostic procedure of choice for appendicitis.[122] High-resolution CT has higher sensitivity (94%) and similar specificity (95%) than ultrasonography in diagnosing appendicitis, and it is less operator dependent.[44] Intravenous contrast agents and high-resolution, thin-section scanning techniques must be used to visualize the appendix adequately. An enlarged appendix with a circumferentially and symmetrically thickened bowel wall is the most common CT finding in appendicitis. Periappendiceal inflammatory reaction or fluid collections may be identified. If the appendix is not well visualized, the presence of a fecalith, along with pericecal inflammatory changes, strongly suggests appendicitis. Fecaliths can be visualized in normal appendices by CT, however, and are of no clinical significance unless other inflammatory changes are present.

In recent years, helical CT scanning techniques that are focused only to the right lower quadrant using rectal or no contrast material have been shown to be accurate in diagnosing appendicitis in children.[50,105] By using a focused approach, CT scans may be completed within 5 minutes. Because of the high accuracy rates of CT in diagnosing appendicitis, some physicians have suggested that all children with suspected disease should have a focused CT scan.[141] In most community hospitals and medical centers, waiting for results of a CT scan may delay a surgical consultation and increase the rate of perforation before surgery.[98] Also, CT scanning is expensive and uses significant amounts of ionizing radiation in children, who have greater radiosensitivity of organs and tissues than adults do.

Whether the increasing use of ultrasound and CT scans to diagnose appendicitis in children has decreased the misdiagnosis of the disease and subsequent negative appendectomy rate in hospitals is unclear.[53,82,84,110,111,218] In a single study, the misdiagnosis rate was lower in hospitals that perform frequent pediatric appendectomies.[178] Most children with appendicitis have surgery in nonchildren's hospitals, however.[37] Radiolabeled autologous leukocyte scans also have been used to diagnose appendicitis in children; however, this modality should be reserved for atypical presentations of disease when localizing signs are not present.[72]

MICROBIOLOGY

Numerous microorganisms have been implicated as a cause of acute appendicitis; considerable debate has ensued as to whether simply isolating an organism from the appendiceal lumen is sufficient proof to define causation (Table 57–2).[2]

BACTERIA

In most cases of appendicitis, bacteria do not seem to be involved directly in the initial stages of the inflammatory process. Microorganisms that normally inhabit the appendix are liberated into the peritoneal cavity when appendiceal perforation occurs or when translocation through the inflamed tissues is present, and polymicrobial infections develop as a complication of the disease process.[19,195] In a study of 30 adolescents and adults with nonperforated and perforated appendicitis, 223 different anaerobes and 82 aerobes were recovered from cultures of the appendiceal tissues, peritoneal fluid, and contents of abscesses.[19] An average of 10 different organisms were isolated per specimen collected.

In most microbiologic studies of appendiceal tissues and peritoneal fluid specimens from patients with appendicitis, *B. fragilis* is the strict anaerobe isolated most frequently, occurring in more than 70 percent of patients.[19,153] Other anaerobes that are isolated frequently include *Bacteroides* spp., *Bilophila wadsworthia*, *Peptostreptococcus* spp., *Fusobacterium* spp., and *Clostridium* spp.[201,213] A gram-negative anaerobic rod that develops a pigment in culture and is bile resistant also has been identified frequently.[152,153] Other anaerobes, such as *Turicibacter sanguinis*, continue to be newly described in patients with appendicitis.[23]

E. coli are the aerobic or facultative anaerobic bacteria isolated most frequently from children with appendicitis. *E. coli* are found in more than 75 percent of patients.[19,153] Researchers have suggested that certain *E. coli* strains with type 1C fimbriae may contribute to the development of appendiceal inflammation.[167] Enterohemorrhagic *E. coli* O157:H7 and O111:H have been isolated infrequently from the stools and peritoneal fluid of children with appendicitis.[199,205]

Viridans streptococci of the *S. milleri* group, including *Streptococcus anginosus*, can be found in more than 60 percent of cultures from children with appendicitis.[79,153] Group D streptococci are isolated in approximately 20 to 30 percent of patients with appendicitis, whereas *Pseudomonas* spp. are isolated slightly less frequently.[153] Other aerobes or facultative anaerobes that can be isolated from appendiceal tissues, abscesses, or blood include *Citrobacter* spp.; *Klebsiella* spp.; *Enterobacter* spp.; *Proteus* spp.; *Morganella morganii*; *Providencia rettgeri*; *Eikenella corrodens*; groups C, F, and G beta-hemolytic streptococci; and staphylococci.[45,70,81,148,153,195]

Rarely, encapsulated organisms, such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Haemophilus segnis*, have been isolated from appendiceal tissues or peritoneal fluid of young children with appendicitis, and often these organisms have been isolated in pure culture.[13,117,127] Very rarely, organisms such as *Pasteurella multocida*, *Streptococcus pyogenes*, and *Actinomyces* spp. have been cultured from patients with appendicitis.[149,162,169,198] *Shigella*, *Salmonella*, *Campylobacter*, and *Yersinia* spp. also have been isolated occasionally from appendiceal tissues or peritoneal fluid of patients with nonperforated and perforated appendicitis; whether they played a role in the pathogenesis of disease is

TABLE 57–2 Microorganisms Associated with Acute Appendicitis in Children

unknown.[20,29,88,96,118] Much more commonly, these organisms cause enterocolitis or mesenteric adenitis, with symptoms mimicking those of appendicitis.[203]

In recent years, appendicitis has occurred during systemic infections caused by *Brucella melitensis* and *Ehrlichia chaffeensis*.[7,173] Rarely, *Kluyvera ascorbata*, *Arcobacter butzleri*, and *Chromobacterium violaceum* have been isolated from patients with appendicitis, as have newly described aerobes and facultative anaerobes, such as *Corynebacterium appendicis*.[31,33,97,215]

Rarely, isolated primary tuberculosis can occur in children.[66,147] The progression of disease usually is rapid. The clinician should be suspicious when caseating granulomas are observed in histopathologic sections of the appendix.

Adults and children with appendicitis usually are not bacteremic at the time they are diagnosed, especially if the appendix is not perforated. Occasionally, *Klebsiella pneumoniae*, *E. coli*, *B. fragilis*, and *B. wadsworthia* are isolated from the blood of patients with nonperforated appendicitis.[22,138,161] In a review of 1000 children and adults with appendicitis, 10 percent of patients with perforation had positive blood cultures, whereas none of the patients without perforation had bacteremia.[100] A higher rate of bacteremia may occur when laparoscopic surgery is done because of the air that is forced into the peritoneum, although the clinical significance of the induced bacteremia is unknown.[132]

In immunocompromised patients who develop appendicitis, the microorganisms that are isolated from appendiceal tissues or peritoneal cultures usually are identical to the microorganisms found in immunocompetent patients.[124] In adults infected with human immunodeficiency virus, appendicitis has been caused by cytomegalovirus infection and neoplastic obstruction of the base of the appendix by Kaposi sarcoma.[34,129] Patients with AIDS who have gastrointestinal *Mycobacterium avium* complex or *Mycobacterium tuberculosis* infections may develop symptoms that mimic appendicitis.[41,204] Atypical mycobacteria have been isolated from an appendiceal abscess from a child with AIDS.[48]

PARASITES

Roundworms, such as *Ascaris lumbricoides*, plausibly may obstruct the appendiceal lumen occasionally and initiate the cascade of inflammatory events leading to perforated appendicitis.[108,134] Parasites such as *Enterobius vermicularis* can be identified in the lumen of 1 to 12 percent of surgically removed appendices obtained from patients living in highly endemic areas.[10,38] Pinworms have been found more frequently, however, in appendices with no evidence of appendiceal inflammation in some studies, suggesting that pinworms probably are a part of the normal appendiceal flora and do not play a role in the pathogenesis of appendicitis.[38,163,217] Whether some parasites may cause abdominal pain that mimics the symptoms of appendicitis necessitating surgical intervention is unclear.

Scattered reports from mostly developing nations describe other worms, including *Taenia* spp., *Anisakis* spp., *Trichuris trichiura*, *Strongyloides stercoralis*, *Schistosoma* spp., and *Angiostrongylus costaricensis*, that have been identified in the lumina of appendices from patients with appendicitis.[11,55,65,91,165] Similarly, protozoa such as *Balantidium coli*, *Entamoeba histolytica*, and *Cryptosporidium parvum* have been found in inflamed appendices of immunocompromised and immunocompetent patients, but whether they play a role in the pathogenesis of disease is unknown.[27,43,67,150]

VIRUSES

The role that viruses play in causing appendicitis also has been debated. One suggestion is that a systemic viral infection may induce hypertrophied lymphoid aggregates that obstruct the appendiceal lumen. In the 1960s, elevated levels of antibodies against coxsackieviruses B and adenoviruses were found in the sera of some children with appendicitis.[196] A later study could not confirm this finding, however.[120] Six adolescents with infectious mononucleosis have developed appendicitis, and cytomegalovirus

has been observed occasionally in immunodeficient and otherwise healthy patients' inflamed appendices.[85,104,129,194] Other children have had histologic evidence of measles virus or adenovirus infection.[137,155] Because of the rarity of documented simultaneous viral infections and appendicitis, whether these viruses play a major role in the pathogenesis of acute appendicitis is doubtful.

FUNGI

Rarely, *Candida albicans* is isolated from inflamed appendices or abscess cultures, but its role in the pathogenesis of disease is unknown. Perforation of the appendix from intestinal mucormycosis has occurred in granulocytopenic patients and premature newborns.[130,193] Also, appendicitis has been described in individuals with histoplasmosis.[94]

TREATMENT

NONPERFORATED APPENDICITIS

In previously healthy children with signs of acute appendicitis and no clinical evidence of perforation, nasogastric suctioning should be established and imbalances in fluid and electrolyte concentrations should be corrected quickly. The child should be taken to the operating room as soon as possible for exploratory laparotomy and appendectomy. Many teaching hospitals now perform appendectomies only during day and evening hours, because of limitations on resident work hours and decreased services available at night.[122] No differences have been noted to date in perforation rates, lengths of stay, or complication rates in children who are diagnosed with appendicitis at night and given analgesics until a scheduled morning surgery.[1,191,214] Morphine can be used to reduce the severity of abdominal pain in children with appendicitis until the child is taken to the operating room and does not impede establishing the diagnosis in children under observation for suggestive symptoms and signs of appendiceal disease.[63]

Prophylactic antibiotics given perioperatively decrease the rate of postoperative wound infection, even in noncomplicated cases of childhood appendicitis.[4,175] No consensus exists concerning the appropriate antimicrobial agent or agents that should be used or the appropriate duration of treatment required after surgery to reduce the complication rate. Although some surgeons continue the antibiotics after surgery, prospective, randomized studies show that a single perioperative dose of appropriate antibiotic with antimicrobial activity against *E. coli* and enteric anaerobes is as effective as continuing the antibiotic for 1 to 5 days after surgery.[125,197]

Few data support the routine intraoperative collection of peritoneal fluid or appendiceal cultures in children with nonperforated appendicitis, although 5 to 20 percent of cultures grow enteric aerobes, anaerobes, or both.[32,60] Immunocompromised patients should undergo intraoperative cultures, including cultures for mycobacteria and cytomegalovirus.

Interest in performing laparoscopic appendectomies in children with nonperforated and perforated appendicitis has been increasing.[30,122,143] Advantages of the procedure are a reduction in wound infection, reduction in scarring, shorter hospital stay, and earlier return to normal activity, although the procedure must be done by a surgeon experienced in laparoscopic techniques.[14] The mean total cost of a laparoscopic appendectomy is similar to that of the more commonly performed open appendectomy, and more recent studies in pediatric patients have determined that no differences exist in postoperative pain, time to self-ambulation, and risk of developing a postoperative abscess.[175] In the future, the use of smaller laparoscopic instruments may improve the speed of recovery of children.[121]

PERFORATED APPENDICITIS

Most surgeons advocate early intervention when perforation has occurred to prevent severe complications, such as fistula formation, abscess rupture, and death, despite the high chance of developing postoperative complications.[122] If a laparotomy is done, debate ensues as to whether the wound should be closed primarily and whether transperitoneal drains should be placed at the time of surgery. Surgeons increasingly are performing primary closures without placing drains in children.[47,116,122] A randomized prospective trial of appendiceal drains in children with perforated appendicitis showed no benefit in using drains compared with primary wound closure.[188] Laparoscopic surgery has been used for perforated appendicitis; nonetheless, caution, good surgical judgment, and a low threshold for conversion to an open procedure are advised.[102]

During the surgical procedure, most surgeons irrigate the peritoneal cavity with copious amounts of saline or antibiotics to reduce the quantity of bacteria in the abdomen.[122] To obtain sterile cultures of the lavage fluid, 6 L of lavage fluid per m^2 surface area of the child is required.[135] It is unclear whether the lavage fluid or the addition of antibiotics to the lavage fluid decreases the rate of postoperative complications in children with perforated appendicitis who are receiving systemic antibiotics.[113]

Controversy remains as to whether immediate appendectomy should be done in a child in whom a palpable mass is associated with the appendicitis or evidence of appendiceal rupture with or without abscess formation exists at the time of presentation.[174,207] Greater than 70 percent of children with palpable masses respond to conservative, nonoperative management consisting of administration of intravenous fluids and antibiotics.[174] If the child does not improve, or a walled-off abscess develops, drainage of the area and appendectomy should be done. If the child responds to conservative management, an interval appendectomy should be done 6 to 8 weeks after resolution of the symptoms. Proponents of initial conservative management consider that the complication rate after interval appendectomy is significantly lower than when a procedure is done during the acute stage of disease.

Antimicrobial agents should be administered routinely to children when perforation or appendiceal abscess is suspected or discovered during surgery. Antibiotics active against aerobes and anaerobes that normally inhabit the intestinal tract have been effective in treating children with perforated appendicitis. Treatment failures occur most commonly when *B. fragilis* or *Pseudomonas* spp. are isolated from intraoperative cultures and antimicrobial agents without activity against these organisms are used.[73] Controversy continues regarding the value of obtaining routine intraoperative peritoneal cultures in cases of perforated appendicitis, although most studies show that culture results seldom change the clinical management of patients.[32,60,87,90,182]

The antimicrobial combination of ampicillin, gentamicin, and clindamycin has been the gold standard of therapy since the 1970s. The importance of including ampicillin in the regimen for adequate enterococcal coverage continues to be controversial. Animal studies and clinical trials using antibiotics with poor enterococcal activity have shown that ampicillin probably is not required in the treatment of perforated appendicitis.[62] Because of the increasing problem of ampicillin resistance in enterococci, ampicillin probably should be reserved for the rare child with enterococcal bacteremia or with persistent intra-abdominal infection in which enterococci have been isolated. Some medical

centers use metronidazole instead of clindamycin because of its broader activity against enteric anaerobes, whereas other institutions substitute cefotaxime or ceftriaxone for gentamicin.[170,186]

Efforts have been made to determine whether single antibiotics are effective in treating perforated appendicitis. The only agents that have been shown to be effective in treating children with perforated appendicitis are cefoxitin, imipenem-cilastatin, ticarcillin-clavulanate, piperacillin-tazobactam, ampicillin-sulbactam, meropenem, and ertapenem.[51,109,126,176,177,192,200,212] In a few medical centers, nearly 50 percent of *B. fragilis* isolates are resistant to cefoxitin, raising the question as to whether cefoxitin should be used routinely as a single agent in these institutions.[54] Generally, the convenience of monotherapy does not outweigh the potential development of resistance to these broad-spectrum agents and their associated increased costs.[87] They may be useful in the treatment of appendicitis in children with renal disease or hearing loss when avoiding the use of gentamicin is prudent.

Most patients with perforated appendicitis are treated with intravenous antibiotics for 5 to 10 days; however, limiting the duration of antibiotic use to 3 days does not lead to higher rates of wound infections or intra-abdominal abscesses.[122,180] Efforts have been made to shorten the hospital stay of children with perforated appendicitis. Some institutions have set criteria for hospital discharge and discontinuation of antibiotics, such as absence of fever for 24 hours, ability to eat well, and less than 3 percent band forms on the white blood cell differential.[74] Many surgeons switch to oral antibiotics at home after 3 to 5 days of intravenous antibiotics in the hospital, although the benefit of adding prolonged oral antibiotics to a short course of intravenous antibiotics has not been shown.[157,190] Providing home single intravenous antimicrobial therapy also can reduce costs and hasten hospital discharge in selected children with perforated appendicitis.[51,87,185]

PROGNOSIS AND EARLY COMPLICATIONS

Currently in the United States, the risk of dying as a result of appendicitis is very low. The estimated mortality rate for nonperforated and perforated appendicitis in California during the 1980s was 0.02 percent.[106] In smaller series of children and adults reported in the 1990s, the mortality rate was 0 percent.[112] It has been stated that the risk of death from appendicitis should be the risk of death from general anesthesia.[112] The mortality rate seems to be higher, however, in the rare newborn or premature infant who develops appendicitis. Also, factors contributing to the death of children rarely may include delay in establishing the diagnosis, inadequate fluid replacement, immunodeficiency, and postoperative vascular or infectious complications.

The most predictive factor of postoperative morbidity occurring from appendicitis is perforation.[154] Age, obesity, duration of the surgical procedure, and nutritional status also are risk factors for the development of complications. Wound infection rates in children who receive perioperative antibiotics should be less than 7 percent; infections generally are caused by the same organisms that are isolated in cultures obtained during appendectomy.[175,197] Occasionally, children develop peritonitis, intra-abdominal abscesses, psoas abscesses, fistulas, pyelophlebitis of the portal vein, scrotal abscesses, or pneumoperitoneum during treatment of appendicitis.[15,68,75,158,216] CT scans can be used successfully to detect postoperative abscesses in the first week after surgery.[9] If complications occur, another surgical procedure often is performed, and antibiotic treatment is prolonged. Abscesses may be treated successfully with antibiotics alone and without surgical drainage in stable patients after appendectomy.[42] The next section focuses on pelvic abscess as an early complication of appendicitis because the topic is not discussed elsewhere in this textbook.

PELVIC ABSCESS

The pelvic area is a common site for development of abscesses because it is the most dependent portion of the peritoneal cavity. Pelvic abscesses most commonly occur in children who have had intestinal perforations after appendicitis, have had penetrating abdominal or retroperitoneal injury, or have undergone an abdominal surgical procedure. Occasionally, adolescents with pelvic inflammatory disease or Crohn disease develop a pelvic abscess.[61]

In children with perforated appendicitis, a coexisting pelvic abscess often is diagnosed at the time of laparotomy. In patients who recently have had penetrating trauma to the abdomen, have had pelvic inflammatory disease, or have undergone gastrointestinal surgery, a pelvic abscess should be suspected when they have continued fever or complain of abdominal pain despite receiving adequate treatment of the initial disease process. Symptoms may not develop until days to months after therapy is ended. No characteristic physical findings are associated with a pelvic abscess, although abdominal palpation or rectal examination may elicit tenderness, or signs of intestinal obstruction may be present.

If a pelvic abscess is suspected, contrast-enhanced CT evaluation of the pelvis should be completed. The bladder should be filled before the procedure so that it can displace bowel loops from the pelvis, act as an anatomic marker, and act as a standard of fluidity against which an abscess cavity can be compared. Walled-off fluid collections in the pelvis can be identified, and sometimes the rectum, sigmoid colon, or bladder is compressed because of mass effect from the abscess cavity. Because most pelvic abscesses develop as complications of intestinal or pelvic infections, enteric aerobes and anaerobes are the organisms most commonly isolated from the abscess cavity. Yeasts only rarely cause pelvic abscesses.[202,209] An *Actinomyces*-related pelvic abscess developed in an adult who had an intrauterine device.[139] Rarely, tuberculous abscesses can develop as a complication of genital tuberculosis.[208]

When a pelvic abscess is identified, antibiotics covering intestinal aerobes and anaerobes, such as clindamycin and gentamicin, should be started, and the abscess contents should be drained. In most situations, reaching the abscess cavity by an anterior approach is difficult. Considerable interest has developed in using CT or ultrasonography to guide percutaneous drainage of pelvic abscesses by transgluteal, transrectal, transparacoccygeal, or transvaginal approaches.[28,59,80,103,131] Although placement of a transgluteal catheter is easiest, the sciatic nerve and gluteal vessels must be avoided. Also, an increased risk for development of a wound infection may occur because microorganisms may track along the outside of the catheter to the skin. Many surgeons prefer the transrectal approach because it often is the most direct route to the abscess. Transvaginal drainage has been used with good results in young women, however. Most often, drainage catheters can be removed after 7 to 10 days of treatment.

Abscesses also may develop within the muscles of the pelvic girdle, including the psoas and internal obturator muscles.[25,168,181,183,184,187] Similar to true pelvic abscesses, they usually cause fever and occasionally abdominal complaints in children. Most children begin to limp, refuse to walk, or complain of pain in the buttocks, thigh, or groin. Often, a suppurative hip infection is suspected initially. A pelvic muscle abscess usually is diagnosed by CT or magnetic resonance imaging. Labeled leukocyte scans sometimes are useful in localizing the infection to within the pelvis, especially when the child has no symptoms other than fever or refusing to walk.

Pelvic muscle abscesses can develop as a complication of Crohn disease or appendicitis; however, they often develop after an episode of bacteremia.[166] *Staphylococcus aureus* is the most common cause of a primary pelvic muscle abscess.[25,168,181,183] *S. pneumoniae*, *H. influenzae* type b, *E. coli*, *Enterococcus faecalis*,

S. milleri group, *Yersinia enterocolitica*, *Salmonella* spp., *Proteus mirabilis*, and *Actinomyces* spp. also have been reported to cause hematogenously acquired abscesses.[25,26,35,39,76,83,89,172] Bacteremia secondary to intravenous drug abuse or the presence of central lines occasionally predisposes patients to developing this type of infection.[93,206] Rarely, tuberculous psoas abscesses have been reported, often as a complication of vertebral osteomyelitis.[189]

Pelvic muscle abscesses usually are drained by a percutaneous or surgical approach, and antibiotic therapy is based on Gram stain and culture results. Successful therapy with antibiotics alone has been reported.[184] Duration of treatment is individualized and depends on the child's response and the drainage techniques that were used.

LATE COMPLICATIONS

Most children who have undergone appendectomy or drainage of a pelvic abscess do not have late complications. Occasionally, patients develop signs of bowel obstruction from peritoneal adhesions later. Some studies have suggested that the future risk for infertility is greater in women who have perforated appendices or pelvic abscesses, presumably because of adhesion formation that impairs the migration of ova in the reproductive tract.[123] Although some retrospective studies have suggested that patients with appendectomies have a higher rate of developing malignancies later in life, prospective and controlled studies have failed to show this association.[36,119] Patients who have had appendicitis have been reported to be three times more likely to develop right inguinal hernias than individuals who have not had the appendix removed.[12] It has been suggested that women have a higher long-term risk of developing Crohn disease if they had nonperforated appendicitis earlier in life, whereas patients with previous perforated appendicitis have a more severe course of inflammatory bowel disease.[6]

CHAPTER 58

Pancreatitis

Thomas L. Kuhls

Pancreatitis previously was thought to be an uncommon cause of abdominal pain in children and a disease primarily of adults. Because of better recognition of symptoms in children and the more frequent use of medications that cause pancreatic inflammation, acute pancreatitis currently is being diagnosed more frequently in institutions specializing in pediatric care.[90,169]

Compared with causes of acute pancreatitis in adults—primarily alcoholism, cholelithiasis, and trauma—causes of childhood pancreatitis are more diverse. Microorganisms account for a significant proportion of cases of pancreatitis in children. In addition, antimicrobial agents have been associated with severe and occasionally fatal episodes of pancreatitis, and bacterial infections may complicate the natural history of acute and chronic pancreatitis. Pediatricians who care for children with pancreatitis must have expertise in the diagnosis and treatment of infectious diseases.

CLINICAL MANIFESTATIONS

More than 80 percent of children with acute pancreatitis complain of abdominal pain.[16,169] Only 30 percent of pediatric patients have epigastric pain as usually described by adults, however.[165] In children, other sites of focal tenderness or diffuse pain include the right upper quadrant of the abdomen, the periumbilical area, the entire abdomen, and, less commonly, the right lower quadrant of the abdomen. The onset of pain usually is rapid and increases to a maximal intensity in a few hours, but occasionally

the onset may be slow and gradual. Most often, the pain is sharp and excruciating in nature. Only one third of children complain of pain that radiates to other areas, including the back, lower part of the abdomen, upper abdominal quadrants, and anterior chest wall. In school-aged children, the pain often intensifies after meals.

Two thirds of children with acute pancreatitis have vomiting.[16] Children younger than 5 years old occasionally experience vomiting without abdominal tenderness.[176] Fever is present in only 30 percent of children with pancreatitis, but temperatures greater than 38.5° C are observed occasionally.[165]

On physical examination, children classically are found lying quietly on their sides with their knees flexed. They usually have epigastric tenderness to palpation and decreased or absent bowel sounds. Abdominal distention is found in 30 percent of children with pancreatitis and occurs more commonly in preschool-aged children.[165,176] Occasionally, rebound tenderness, guarding of the epigastrium, jaundice, an abdominal mass, or ascites is detected. Rarely, ecchymoses of the flanks (Turner sign) or the umbilical area (Cullen sign) can be identified, but usually only when life-threatening hemorrhagic pancreatitis is present. In severe pancreatitis, children may present with evidence of shock and multiorgan failure.

Chronic pancreatitis occurs when irreversible damage in the pancreatic architecture causes abnormalities in the function of the pancreas.[91] Children with chronic pancreatitis often have lengthy or recurrent bouts of abdominal pain and vomiting.

LABORATORY DIAGNOSIS

The most common useful laboratory test for the clinical diagnosis of pancreatitis in children is measurement of serum amylase, but the level correlates poorly with the severity of the disease.[58] In most studies of childhood pancreatitis, the diagnosis is confirmed when the serum amylase is greater than three times the normal level for the particular laboratory completing the test. The serum concentration increases quickly within hours after symptoms develop. High serum amylase concentrations can be observed, however, in numerous other illnesses, including acute cholecystitis, intestinal obstruction, perforated abdominal organs, appendicitis, salpingitis, ruptured ectopic pregnancy, and salivary gland disease. The serum amylase concentration can return to normal in 24 to 72 hours after the onset of symptoms, and the diagnosis of pancreatitis can be missed. In this situation, the urine amylase concentration can remain elevated for at least 1 week.

Serum amylase concentrations occasionally are not elevated during the course of pancreatitis in children.[133] In a series of children with pancreatitis, 83 percent of patients had elevated serum amylase levels.[169] In addition, marked hyperlipidemia may interfere with the laboratory measurement of amylase.[17] Serum lipase is useful in these situations; high serum concentrations often are not detected until 24 hours after the beginning of the illness. Because lipase is produced only in the pancreas and intestinal cells, measurement of the serum concentration helps distinguish children with high serum amylase concentrations of pancreatic as opposed to salivary origin. Measurement of serum trypsinogen may be the most sensitive and specific way of detecting acute pancreatitis, but it is unavailable in most clinical laboratories.[165]

Laboratory findings in children with severe acute pancreatitis may include leukocytosis with increased immature polymorphonuclear leukocytes, an elevated erythrocyte sedimentation rate, and elevated C-reactive protein level. In children with fulminate hemorrhagic pancreatitis, anemia develops quickly. Other associated findings include hyperglycemia, hypertriglyceridemia, hypoalbuminemia, and hypocalcemia. A new scoring system for children with pancreatitis has shown that severe pancreatitis is more likely when the child who presents is younger than 7 years of age, weighs less than 23 kg, has a total white blood cell count greater than 18,500 cells/mm^3, has an admission lactate dehydrogenase greater than 2000 U/L, has a 48-hour calcium level less than 8.3 mg/dL, has a 48-hour albumin level less than 2.6 g/dL, has a 48-hour fluid sequestration greater than 75 mL/kg/48 hr, or has a 48-hour increase in blood urea nitrogen greater than 5 mg/dL.[32] Elevated transaminases and alkaline phosphatase generally are observed only when the episode of pancreatitis is caused by biliary obstruction, such as in gallstone-related disease.

The radiographic features of childhood pancreatitis also are nonspecific. Radiographs of the abdomen may show localized ileus of the jejunum in the midepigastric or left upper quadrant region adjacent to the pancreas (sentinel loop), a distended transverse colon without visualization of the descending colon because of adjacent pancreatic inflammation (colon cutoff sign), duodenal distention with air-fluid levels, or loss of the left psoas shadow.[63] Occasionally, chest radiography reveals an elevated left hemidiaphragm or pleural effusion.

In recent years, the ability to diagnose pancreatitis in children has been improved greatly by ultrasonography.[169] The echodensity of the pancreas normally is equal to or greater than that of the left lobe of the liver. During acute pancreatitis, edema causes the gland to enlarge and become less dense than the liver. These two findings can aid in establishing the diagnosis of pancreatitis, and complications such as abscesses and pseudocysts can be identified. Also, ultrasonography may delineate dilations of the pancreatic ducts caused by obstruction or ductal stones. Visualization of the pancreas by ultrasonography may be obscured because of overlying bowel gas. In such cases, computed tomography (CT) is useful to detect pancreatic size and density.

CT of the pancreas should be performed in complicated cases of pancreatitis after a few days of treatment to determine the severity of disease and extent of pancreatic necrosis. It is especially useful when surgery is being considered for drainage of abscesses and pseudocysts.

Endoscopic retrograde cholangiopancreatography (ERCP) is being used increasingly in children with pancreatitis to exclude or treat gallstones, pseudocysts, strictures, or *Ascaris* infection.[126,131] In recent years, magnetic resonance cholangiopancreatography has been used as a noninvasive technique for evaluating children with chronic pancreatitis.[11,99]

NONINFECTIOUS ETIOLOGIES

An etiology for pancreatitis in children can be determined now in more than 90 percent of cases if diagnostic evaluation is thorough, especially in children younger than 6 years of age.[90,176] The frequency of each specific cause depends on the patient population of the particular medical center. At Children's Hospital of Michigan, 33 percent of children with pancreatitis have biliary tract–related disease because of the large patient population with sickle-cell anemia.[176] At Yale–New Haven Hospital, drug-related pancreatitis accounts for 30 percent of the total cases of childhood pancreatitis because of the frequent use of immunosuppressive and cancer chemotherapeutic agents in this hospital.[63] Table 58–1 outlines the most common noninfectious causes of pancreatitis in children.

TRAUMA

In many older series of patients, trauma is the leading cause of acute pancreatitis in children. Because the highly vascular pancreas is immobilized by the stomach, duodenum, and vertebrae, it is susceptible to blunt and penetrating trauma. The less developed abdominal wall musculature in pediatric patients may

TABLE 58–1 Noninfectious Causes of Childhood Pancreatitis

Trauma
Blunt
Brain injury
Penetrating
Postoperative
Drugs
Antimicrobials—pentamidine, antimonials, sulfonamides, tetracycline, macrolides, metronidazole, dapsone, nitrofurantoin, isoniazid, ceftriaxone, gatifloxacin, nucleoside analogue reverse transcriptase inhibitors, interferon-α, liposomal amphotericin B
Atypical antipsychotics
Diuretics—thiazides, furosemide
Ethyl alcohol
Growth hormone
Immunosuppressives—azathioprine, steroids, asparaginase, mercaptopurine, tacrolimus
Metformin
Nonsteroidal anti-inflammatory drugs
Propofol
Proton pump inhibitors
Statins

Chronic fibrosing pancreatitis
Lymphoma
Orthotopic liver transplantation
Reye syndrome
Scorpion stings
Tropical chronic pancreatitis

enhance their susceptibility to pancreatic injury after episodes of blunt trauma. Child abuse has been recognized increasingly as a cause of trauma-related pancreatitis. Postoperative pancreatitis occurs most commonly after abdominal or cardiac surgery.[43] Pancreatitis also may be associated with traumatic brain injury in children.[159]

MEDICATIONS

Medications used in pediatric practice increasingly are causing episodes of pancreatitis in children. In most recent pediatric studies, the anticonvulsant valproic acid is the most common medication associated with the development of pancreatitis.[169] The risk of developing pancreatitis does not depend on the serum level of valproic acid, and it is not related to the length of therapy.[142,168] Azathioprine, steroids, mercaptopurine, and asparaginase have been associated with cases of childhood pancreatitis, and other immunosuppressive agents most likely play a role in post-transplantation pancreatitis.[80,135,143,167,171] Acute pancreatitis has been associated rarely with the use of diuretics, including hydrochlorothiazide and furosemide[96]; growth hormone[33,97]; sulfasalazine[49]; atypical antipsychotics[56,82]; statins[73]; propofol[20]; nonsteroidal anti-inflammatory agents, including ibuprofen[92,93]; metformin[46]; and proton pump inhibitors.[174] Alcohol consumption is an uncommon cause of pancreatitis in younger children; however, it can cause illness occasionally in adolescents.

Physicians with expertise in the management of infectious diseases are becoming more aware of drug-induced pancreatitis because many antimicrobial agents can cause pancreatic inflammation. Pentamidine isethionate is used in the treatment of *Pneumocystis carinii* pneumonia, African trypanosomiasis, and leishmaniasis. It may cause hypoglycemia because of toxicity to pancreatic islet cells and is associated with severe and occasionally fatal episodes of pancreatitis.[104,177] In children and adults, aerosolized pentamidine prophylaxis for *P. carinii* pneumonia also has been associated with severe cases of pancreatitis in patients with acquired immunodeficiency syndrome (AIDS).[59,104] Similarly, pentavalent antimonials, such as sodium stibogluconate and meglumine antimonate, used for the treatment of visceral leishmaniasis can induce pancreatic inflammation.[86,173]

Sulfonamides, including trimethoprim-sulfamethoxazole, have been implicated occasionally as a cause of acute pancreatitis in adults.[6,162] Symptoms have recurred when patients have been re-exposed to the medication. The abdominal pain often is accompanied by a hypersensitivity-type rash. Tetracycline-induced pancreatitis has been described in children with and without overt liver disease.[42,154] In addition, clarithromycin,[51,136] erythromycin,[149] rifampin,[125] roxithromycin,[129] dapsone,[31] nitrofurantoin,[112] isoniazid,[71] and metronidazole[116] have been added to the list of agents that can cause pancreatitis in previously healthy individuals when given in routine doses or when high amounts are consumed. Although uncommonly used in children, quinolone antibiotics, such as gatifloxacin, have been associated with hepatotoxicity and acute pancreatitis.[29] An adolescent who was receiving ceftriaxone also developed pancreatitis secondary to obstruction of the biliary tract from gallstones.[100]

Pancreatitis has been a major dose-limiting toxic effect of the human immunodeficiency virus (HIV)–inhibiting nucleoside analogue reverse transcriptase inhibitor class of medications, especially dideoxyinosine, in adult and pediatric patients.[21,22] Most episodes of pancreatitis occur when the dose is 360 mg/m^2/day or more, and usually the pancreatic inflammation resolves when the medication is discontinued. Concomitant administration of pentamidine or another nucleoside analogue reverse transcriptase inhibitor, such as ribavirin, used in the treatment of hepatitis C infection with dideoxyinosine may increase the risk of developing pancreatitis.[108] In pediatric patients with AIDS, serum amylase concentrations often are elevated in patients without pancreatic symptoms, whereas children with pancreatitis can have normal serum amylase concentrations. The serum lipase concentration is useful in evaluating HIV-infected children for possible pancreatic inflammation.[22,104] Increased liver transaminase or lipase concentrations before the administration of dideoxyinosine may be helpful in predicting the children in whom pancreatitis would develop.[22] In all children with symptoms consistent with pancreatitis, dideoxyinosine should be withheld pending the results of a lipase assay, and it should be discontinued if the concentration is elevated. Similarly, dideoxyinosine should be discontinued for 1 week after treatment with pentamidine for *P. carinii* pneumonia.[47]

Interferon-α, which is used in the treatment of chronic hepatitis and malignancies, also has been associated with the development of pancreatitis.[26] Liposomal amphotericin B treatment rarely causes pancreatic toxicity.[147]

OBSTRUCTIVE DISEASES

Obstruction of the common bile duct, pancreatic duct, or sphincter of Oddi may cause pancreatitis.[7] Gallstones or congenital anatomic malformations, including an annular pancreas, pancreas divisum, choledochal cysts, and intrapancreatic duplication cysts, can cause pancreatitis by obstructing normal pancreatic flow. Pancreatitis observed in children with sickle-cell anemia may be caused by obstruction from stones, biliary sludge, or pancreatic microvascular occlusion and ischemia during crises.[3]

GENETIC AND METABOLIC DISEASES

Metabolic diseases often are associated with chronic recurrent episodes of pancreatitis. Such diseases include hyperlipoproteinemias, cystic fibrosis, diabetes mellitus, hyperparathyroidism, aminoaciduria, and glycogen storage disease type I.[54,63,75,160] Recurrent hereditary pancreatitis usually occurs in an autosomal dominant pattern, with onset occurring between infancy and adolescence.[76] It has been linked to chromosome 7q35. The mutation allows trypsinogen to become activated to trypsin within the pancreas. Other children and adults with chronic pancreatitis have been shown to have mutations in the cystic fibrosis transmembrane regulator (*CFTR*) gene similar to individuals with cystic fibrosis,[26] or to have a mutation causing a deficiency of trypsin-specific inhibitor that inactivates low levels of trypsin within acinar cells.[76]

VASCULITIC AND AUTOIMMUNE DISEASES

Pancreatitis also can occur in syndromes in which vasculitis is a major component of the disease process. It has been associated with common pediatric disorders, including Kawasaki syndrome, Henoch-Schönlein purpura, and systemic lupus erythematosus.[28,124,128,146] Increasing data suggest that numerous children with idiopathic chronic pancreatitis may have inflammation from an autoimmune process.[110] Pancreatitis has been a presenting manifestation of Crohn disease.[84]

MISCELLANEOUS CAUSES

Although no longer common, Reye syndrome has been associated with acute pancreatitis.[50] The venom of the scorpions *Tityus trinitatus*, *Tityus asthenes*, and *Leiurus quinquestriatus* can cause pancreatitis in patients who have been stung; however, these species do not live naturally in the United States.[15,121,144] The gastrointestinal symptoms observed in children with anticholinesterase insecticide poisoning may be caused by pancreatitis.[166] Also, tropical chronic pancreatitis seen in developing countries most likely is related to malnutrition and dietary intake of toxins, such as those from the tuber cassava.[14] Rarely, primary pancreatic lymphoma may manifest in children as acute pancreatitis.[41] Chronic fibrosing pancreatitis in which the pathogenesis of the disease process remains unsolved occurs only rarely in the United States.[57]

Although a much less common occurrence than in adults, acute pancreatitis after orthotopic liver transplantation is severe in children and often results in death.[152,153] The cause of pancreatitis in liver transplant recipients most likely is multifactorial but probably involves traumatic injury, biliary obstruction, and immunosuppressive therapy.

INFECTIOUS ETIOLOGIES

Infections caused by various microorganisms have been shown by culture, histologic examination, or elevation of antibody titer during the course of acute pancreatitis in humans (Table 58–2). A true causal relationship usually is not shown, however. Although not all of the following infectious agents have been shown to be associated with childhood pancreatitis, they must be considered as possible etiologic agents because adults with infectious pancreatitis have been described. Compared with previous decades, infectious agents are being encountered less as a cause of acute pancreatitis, most likely because of mumps vaccination.

VIRAL INFECTIONS

Group B coxsackieviruses and mumps virus are the best documented causes of pancreatitis in children. Group B coxsackieviruses usually cause pancreatitis along with other clinical manifestations, including aseptic meningitis, mild diarrhea, rash, and myocarditis.[23,67] They rarely have caused death in young

infants with myocarditis and pancreatitis.[36] How commonly these enteroviruses cause pancreatic inflammation is unknown. In one epidemiologic study, 31 percent of patients with aseptic meningitis during an epidemic of group B coxsackievirus infection had increased serum amylase concentrations.[111] Numerous studies have shown coxsackievirus-induced damage to pancreatic acinar cells in mouse models of infection.[65] Coxsackievirus B strains have been isolated from pancreatic biopsy samples of patients with chronic pancreatitis.[140]

Usually, mumps pancreatitis occurs in the presence of parotitis; however, abdominal pain and vomiting may occur for days before salivary swelling develops.[164] Rarely, mumps virus can cause pancreatitis without other common clinical manifestations.[109] Because more than 80 percent of children with mumps parotitis have elevated serum amylase concentrations, ultrasonography and serum lipase concentrations should be obtained to aid in establishing the diagnosis of pancreatitis.[55] An estimated 15 percent of children with mumps virus infection have abdominal tenderness and vomiting suggestive of pancreatitis.[63] In only a single report has the pancreatitis been hemorrhagic and severe.[44] Occasionally, chronic or recurring pancreatitis develops after mumps infection.[172]

Researchers previously thought that acute pancreatitis occurred in cases of viral hepatitis only when fulminate liver disease developed. Increasingly, children with mild hepatitis A infection and pancreatitis are being described, however.[2,105] In addition, a 16-year-old patient with acute hepatitis A infection died as a result of severe pancreatitis with multiorgan failure.[79] Individuals with acute hepatitis and pancreatitis also have been found to have hepatitis E viral infection.[69,105] Hepatitis B viral antigens have been detected in the pancreatic glandular cells of patients with severe acute hemorrhagic pancreatitis.[138] The role of hepatitis B virus in the pathogenesis of pancreatic inflammation in these patients is unknown; however, a young adult developed three episodes of acute pancreatitis during acute exacerbations of chronic hepatitis B infection that resolved after lamivudine therapy was given.[27]

Human herpesviruses are uncommon causes of childhood pancreatitis in immunocompetent patients. Occasionally, pancreatitis develops in children and adolescents with infectious mononucleosis.[83,107] Acute pancreatitis and occasionally pseudocyst formation also have been reported in previously healthy individuals with varicella infection.[95,155] In addition, adults have developed pancreatitis during a period in which seroconversion to cytomegalovirus was documented, or when antigens were identified in biopsy specimens obtained during ERCP.[78,119]

Viral pancreatitis also occurs in immunocompromised patients. Cytomegalovirus has been identified in pancreatic specimens from autopsies of patients who had AIDS, transplant recipients, and patients who had undergone cancer chemotherapy.[68,72] The symptoms of pancreatitis have resolved in a few patients with AIDS treated with ganciclovir or foscarnet.[30] Adenovirus has caused hemorrhagic pancreatitis and death in a child who received a bone marrow transplant, whereas an infant with disseminated adenoviral infection and pancreatitis survived with cidofovir therapy.[25,115] Varicella-zoster and herpes simplex viruses have caused pancreatitis and death in patients with various immunodeficient conditions.[45,139] A disseminated parainfluenza virus infection in an infant with severe combined immunodeficiency was associated temporally with the development of pancreatitis; however, no attempt was made to culture the virus from postmortem pancreatic tissue.[48]

Whether HIV directly causes pancreatitis is unclear. Laboratory-diagnosed episodes of pancreatitis in adults and children with AIDS do occur, but whether the pancreatic inflammation is caused by HIV or an unrecognized opportunistic pathogen is unknown.[175] HIV-infected children frequently have elevated amylase and lipase levels with no correlation to antiviral therapy.[24] Also, increasing numbers of adults with primary manifestations of HIV infection have presented with acute pancreatitis, suggesting a role of HIV in the pathogenesis of the disease.[157]

Interstitial pancreatitis occurs commonly in children with congenital rubella syndrome.[106] In addition, severe pancreatitis has been identified in immunocompetent and immunocompromised patients with fatal measles virus infection.[161] An adolescent has been described with measles encephalitis and pancreatitis that responded to steroids.[148] One case of an adolescent with rotavirus gastroenteritis in whom pancreatitis developed has been reported.[35]

PARASITE INFESTATIONS AND INFECTIONS

Ascaris lumbricoides can migrate in the intestines to the ampulla of Vater and subsequently to the pancreatic duct or common bile duct. Obstruction of the biliary or pancreatic duct can cause acute pancreatitis.[1,11] Ascariasis is diagnosed when adult roundworms are identified in the duodenum by radiographs of the upper gastrointestinal tract (Fig. 58–1), or more commonly by ultrasonography or ERCP. Often, a history of seeing worms in the feces can be elicited. The flukes *Clonorchis sinensis* and *Fasciola hepatica* and the cestode *Taenia saginata* also can migrate to the pancreatic and biliary drainage systems and cause pancreatitis.[40,89,141] Rarely, hepatic hydatid cysts caused by *Echinococcus* can obstruct biliary drainage and cause pancreatic inflammation.[122] *Wuchereria bancrofti* occasionally has been found to cause chronic pancreatitis.[70] Parasitic infestations should be considered as a cause of pancreatitis, particularly in immigrant children and patients who have traveled to developing nations.

Figure 58–1 An ascaris close to the ampulla of Vater, the body and tail lying in the second and third parts of the duodenum. The patient is a 9-year-old girl with acute pancreatitis.

The protozoan *Cryptosporidium parvum* has been identified in the bile of a patient with AIDS with elevated serum amylase and right upper quadrant abdominal pain.[52] ERCP showed biliary and pancreatic ductal disease, but no other opportunistic pathogens were isolated. Cryptosporidia also have been observed in the interlobular pancreatic ducts of experimentally infected immunocompromised mice.[158] Whether cryptosporidial infection causes pancreatitis in immunocompetent patients is unknown; however, a previously healthy adolescent developed pancreatitis after having cryptosporidial diarrhea.[60] *Toxoplasma gondii* cysts have been found in the postmortem pancreatic tissue of patients with AIDS.[4,64] Rarely, pancreatitis occurs during acute episodes of falciparum malaria.[74] Other systemic manifestations of malaria that often are present include high fever, hepatitis, intestinal malabsorption, encephalitis, and pulmonary insufficiency.

MYCOPLASMAL AND BACTERIAL INFECTIONS

In older children and adults, moderately severe symptoms of pancreatitis have occurred just before or during the course of atypical pneumonia.[5,62] In these cases, most patients have had cold agglutinins in their sera, and all have had significant changes in *Mycoplasma pneumoniae* antibody titer. Some controversy has ensued over whether *M. pneumoniae* can cause acute pancreatitis without evidence of pneumonia. Although complement-fixing IgM antibodies against *M. pneumoniae* often increase significantly during the course of acute pancreatitis, researchers have argued that pancreatic cellular antigenic components similar to *Mycoplasma* lipid antigens are exposed during the disease process and that the antibodies elicited cross-react in *Mycoplasma* serologic assays.[88]

Along with *M. pneumoniae* infection, legionnaires' disease must be considered when acute pancreatitis develops along with pneumonia.[103,170] Miliary tuberculosis also can cause symptoms of pancreatitis.[132] Occasionally, pancreatitis may be the only manifestation of tuberculosis and usually is diagnosed by fine-needle aspiration of the pancreas.[58,113]

Common pyogenic bacteria usually do not cause acute pancreatitis. Secondary invasion of inflamed pancreatic tissue does occur. Some evidence exists that circulating endotoxin from *Escherichia coli* can cause extrahepatic cholestasis and pancreatitis.[37] Acute pancreatitis also has been seen in children with hemolytic-uremic syndrome.[130,134] Pancreatitis can occur during acute episodes of enteritis. *Salmonella typhimurium*, *Salmonella typhi*, *Campylobacter jejuni*, *Yersinia enterocolitica*, and *Yersinia pseudotuberculosis* all have been reported to cause clinically evident and laboratory-confirmed cases of pancreatitis.[10,34,137,145] A single case of *Moraxella catarrhalis* causing severe pancreatitis and death in a 4-year-old child has been reported.[118]

Pancreatitis has been reported in children with leptospirosis.[81,117] *Brucella melitensis* also has been added to the list of uncommon causes of acute pancreatitis.[123] *Helicobacter pylori* has been suggested to influence the clinical course of pancreatitis in humans, but data are still lacking to imply a role in pancreatic pathology.[98]

FUNGAL INFECTIONS

Fungal infections have not been reported to cause acute pancreatitis in immunocompetent patients. *Aspergillus* has caused fatal hemorrhagic pancreatitis, however, in an adult patient with cancer who was undergoing chemotherapy.[53] *Candida* spp. and *Cryptococcus neoformans* have been isolated from the pancreatic tissue of patients with AIDS, but whether they cause clinical symptoms of pancreatitis is unknown.[175]

PATHOGENESIS

Enzymes for polysaccharides, fats, and proteins are produced and stored in pancreatic acinar cells. They exist intracellularly in an inactive precursor form. After cholecystokinin stimulation, the proenzymes are released into the pancreatic ducts and flow into the duodenum. The enzymes normally do not become enzymatically active until they reach the intestinal lumen.

When trypsinogen is activated prematurely to trypsin within the pancreatic acinar cells, autodigestion occurs within the pancreas.[17] The mechanisms that activate trypsinogen and other proteolytic enzymes during specific pathologic processes have not been well elucidated. Drug-induced and infectious causes of pancreatitis are thought to be caused by direct toxic effects on acinar cells. Gallstones, *Ascaris* infection, and congenital abnormalities are thought to damage acinar cells by obstructing pancreatic flow. Traumatic pancreatitis probably occurs as a result of direct injury to the glandular cells, whereas vasculitis may cause changes in pancreatic blood flow, causing ischemia.

Autodigestion of the pancreas causes edema of pancreatic tissue, and microcirculation may be compromised, leading to ischemia, hemorrhage, or necrosis. An inflammatory response develops, which may be mild, as occurs commonly in episodes of infectious pancreatitis, or may be more severe with hemorrhagic necrosis. Major mediators of the intense immune response include tumor necrosis factor, interleukin-1, interleukin-6, interleukin-8, and platelet activation factor.[94] If an imbalance of the proinflammatory response occurs within the pancreas, a systemic inflammatory response including shock may occur, leading to high morbidity and mortality. Also, sepsis may occur because of extensive necrotic tissue within the pancreas and translocation of microorganisms from the intestines.

TREATMENT

Despite increasing recognition of cases of childhood pancreatitis, no major pharmacologic advances have been made in the treatment of the disease since the mid-1970s. Animal data have shown that medications such as glucagon, aprotinin, gabexate mesilate, 5-fluorouracil, octreotide, and somatostatin may be useful in the treatment of pancreatitis; however, trials in adults have not substantiated their efficacy.[38] The continuing main objectives of treatment are to relieve abdominal pain and treat aggressively systemic manifestations, such as shock, electrolyte abnormalities, and anemia. Meperidine continues to be the medication most commonly used for controlling pain.

In the past, children were kept in the fasted state and nasogastric suction was applied to decrease duodenal acid–stimulated secretin release. Feeding with carbohydrate solutions was not restarted until all symptoms had resolved. More recent studies in adults have shown, however, that feeding with a low-fat elemental diet decreases the complication rate of patients with acute pancreatitis and now is considered the treatment of choice over total parenteral nutrition.[101,151] A study has shown that patients with severe pancreatitis can be fed by slow infusion by the nasogastric route without worsening of pain or changes of nutritional status compared with being fed by a nasojejunal tube.[85] Intravenous fluids and colloids are used during the acute episode to maintain intravascular volume. During the entire course of acute pancreatitis, the hematologic and biochemical parameters of the child must be monitored closely.

If the episode of pancreatitis is drug-induced, use of the medication should be curtailed immediately. Often, the symptoms recur if the medication is restarted. Pancreatitis caused by *M. pneumoniae* or bacteria should be treated with proper antimicrobials. Obstructions to pancreatic flow (e.g., gallstones,

roundworms, congenital abnormalities) may have to be excised or altered either by surgery or by endoscopy.[18,77,126]

COMPLICATIONS

During an acute episode of pancreatitis, the systemic inflammatory response syndrome may develop, leading to renal, hematologic, central nervous system, pulmonary, and cardiovascular complications. In 12 percent of children with pancreatitis, an inflammatory mass develops in the first weeks after the onset of illness; however, these masses more commonly occur after trauma.[163] Continued or increasing abdominal pain, nausea, or vomiting often accompanies the development of a phlegmon, abscess, or pseudocyst. An inflammatory phlegmon usually develops into a thin-walled pseudocyst of the lesser sac but may become secondarily infected and induce the formation of an abscess. Patients in whom an inflammatory mass develops must be monitored closely with frequent physical examinations and serial CT scans. In children with pseudocysts, acute abdominal pain accompanied by hypotension often signifies bleeding into the pseudocyst or rupture of the pseudocyst into the peritoneum. Slowly leaking pseudocysts may cause pancreatic ascites. Pseudocysts are resected surgically, drained externally, or drained by endoscopy when complications occur.[9] Approximately 33 percent of pseudocysts resolve spontaneously within 6 weeks.[127]

The development of fever and leukocytosis during pancreatitis should suggest the presence of an infected pseudocyst, pancreatic abscess, or sepsis. In adults, infectious complications account for 80 percent of deaths associated with acute pancreatitis.[19] Isolates from pancreatic abscesses have yielded intestinal flora, including anaerobes, in more than 90 percent of cases, but *Candida* spp. are being isolated more frequently in many medical centers.[8,39] Rarely, *Streptococcus pneumoniae* can be isolated from infected pancreatic tissues of adults with chronic pancreatitis.[150] Carbapenems, such as imipenem and meropenem, are used commonly to treat adult patients with suppurative complications of pancreatitis because these antibiotics penetrate well into pancreatic tissues and have activity against intestinal flora.

Even with early diagnosis and proper antibiotics and surgical intervention, the death rate from pancreatic abscesses is 22 to 57 percent in adults.[63,66] Performing percutaneous catheter drainage under CT guidance may reduce the mortality rate associated with treating pancreatic abscesses.[13] Rarely, fistulas from pseudocysts or abscesses to other abdominal organs may develop.[61]

The role of prophylactic antibiotics in preventing the suppurative complications of acute pancreatitis remains controversial despite 3 decades of debate.[120] Prophylactic antibiotics should be considered only when pancreatic necrosis is significant; however, antimicrobial trials have yielded conflicting results in adults.[87] A more recent meta-analysis on the subject concluded that prophylactic antibiotics do not prevent pancreatic necrosis from being infected and do not prevent death.[102] Infections, when they do occur after the administration of prophylactic antimicrobials, often are caused by multiresistant bacteria or by fungi.

Osteolytic lesions resembling osteomyelitis may develop weeks to months after an acute episode of pancreatitis.[114] Elevated systemic levels of lipase activity possibly may cause intramedullary fat necrosis in the bone. Usually, the lesions are asymptomatic and resolve spontaneously without therapy.

CHAPTER 59

Peritonitis and Intra-abdominal Abscess

Judith R. Campbell ✪ John S. Bradley

Intra-abdominal infection can be a life-threatening condition that occurs spontaneously or as a result of intra-abdominal disease, injury, or surgery. Given the compartmental anatomy and physiology of the abdominal cavity, intra-abdominal infection frequently is categorized as peritonitis, intraperitoneal abscess, retroperitoneal abscess, and visceral abscess.[3] This chapter reviews peritonitis and intra-abdominal abscess; liver abscess and retroperitoneal abscess are reviewed in Chapters 55 (liver abscess) and 60 (retroperitoneal abscess).

PERITONITIS

ANATOMY

Knowledge of the anatomic relationships within the abdomen is important for understanding the source and routes of spread of infection. The peritoneal cavity extends from the undersurface of the diaphragm to the pelvis. In males, it is a closed space, whereas in females, the ends of the fallopian tubes penetrate into the peritoneal cavity. The transverse mesocolon and greater omentum separate the upper and lower peritoneal cavity. Peritoneal reflections divide the intraperitoneal space further into several compartments: the lesser sac, the paracolic gutters, and the subhepatic and subphrenic spaces (Fig. 59–1). The most dependent area of the peritoneal cavity is the pelvis. Exudate can extend to any of the recesses within the peritoneal cavity distant from the original source, however, and cause diffuse inflammation.[3] When inflamed, the anterior parietal peritoneum, which is supplied by somatic afferent nerves, gives the sensation of localized pain. Stimulation of the visceral peritoneum causes dull, poorly localized pain.

PATHOGENESIS

Peritonitis is defined as inflammation of the serosal lining of the abdominal cavity or the peritoneum and may be caused by any chemical or infectious agent that irritates the peritoneal surfaces. Noninfectious peritonitis is caused by extravasation of irritants, such as gastric juice, bile, urine, blood, pancreatic secretions, or the contents of a ruptured cyst, into the peritoneal cavity. Although chemical peritonitis generally is aseptic, it may be an important antecedent event to the development of infectious peritonitis.

After peritoneal contamination by bacteria has occurred, the first mechanism of host defense is lymphatic clearance. In experimental peritonitis, this clearance is so efficient that peritonitis and abscess formation occur only if adjuvant substances, such as hemoglobin or necrotic tissue, are present.[23,24,46] In the first hours after bacterial contamination occurs, local resident macrophages are the predominant phagocytic cells. The macrophages then are cleared by the lymphatic system. After bacterial proliferation occurs, polymorphonuclear leukocytes become more numerous in the peritoneal cavity, and inflammation ensues. These peritoneal defense mechanisms also have adverse effects. Fibrin is deposited, which potentially entraps bacteria into a sequestered environment. An increase in splanchnic blood flow causes exudation of fluid into the peritoneal space, further impairing host defenses by diluting important peritoneal opsonins.[23,24] These host responses serve as a means of containing infection, but they also may contribute to the formation of abscesses.

Infectious peritonitis is subdivided into primary and secondary peritonitis based on the pathophysiology of the infection. Peritonitis that is associated with peritoneal dialysis or the presence of a ventriculoperitoneal shunt is a unique form of peritonitis that also is reviewed in this chapter. The microbial etiologies of peritonitis vary with the underlying cause and are summarized in Table 59–1.

PRIMARY PERITONITIS

Primary, or spontaneous, bacterial peritonitis is a rare infection defined as bacterial peritonitis in the absence of intra-abdominal findings, such as intestinal perforation. The incidence of spontaneous peritonitis in children is unknown; however, in the early 20th century, 8 to 10 percent of abdominal emergencies requiring surgical intervention were due to spontaneous peritonitis.[17,70] Freij and colleagues[29] conducted a 22-year review of children with primary peritonitis in Dallas, Texas. Primary peritonitis was diagnosed in 7 previously healthy children compared with 1840 cases of appendicitis during the same period. Currently, 1 to 2 percent of abdominal emergencies requiring surgical intervention are due to primary peritonitis.[37,40]

Now that this condition frequently is recognized clinically with the assistance of computed tomography (CT), the diagnosis often is made without exploratory laparotomy. The peak incidence of spontaneous peritonitis in children occurs when they are 5 to 9 years of age. In children, the most common predisposing factor is nephrotic syndrome, but this form of peritonitis also occurs in children with postnecrotic cirrhosis.[3,17,31,37,41,45,70,71] Spontaneous peritonitis rarely develops in previously healthy individuals without underlying conditions.[32,47]

The exact pathophysiologic mechanism for primary peritonitis is unknown; however, hematogenous inoculation is thought to be the most likely mechanism because the same organism frequently is recovered from cultures of blood and peritoneal fluid.[17,31,37] Alternative mechanisms include peritoneal seeding via the lymphatics, transmural migration through edematous bowel, and ascending infection from the female genitourinary tract.[31,37] In certain cases, impaired host defenses allow proliferation of bacteria that invade the peritoneal cavity, but a few children with primary peritonitis have no apparent impaired defense. Ascitic fluid from patients with nephrotic syndrome or cirrhosis contains lower levels of complement and immunoglobulin than does

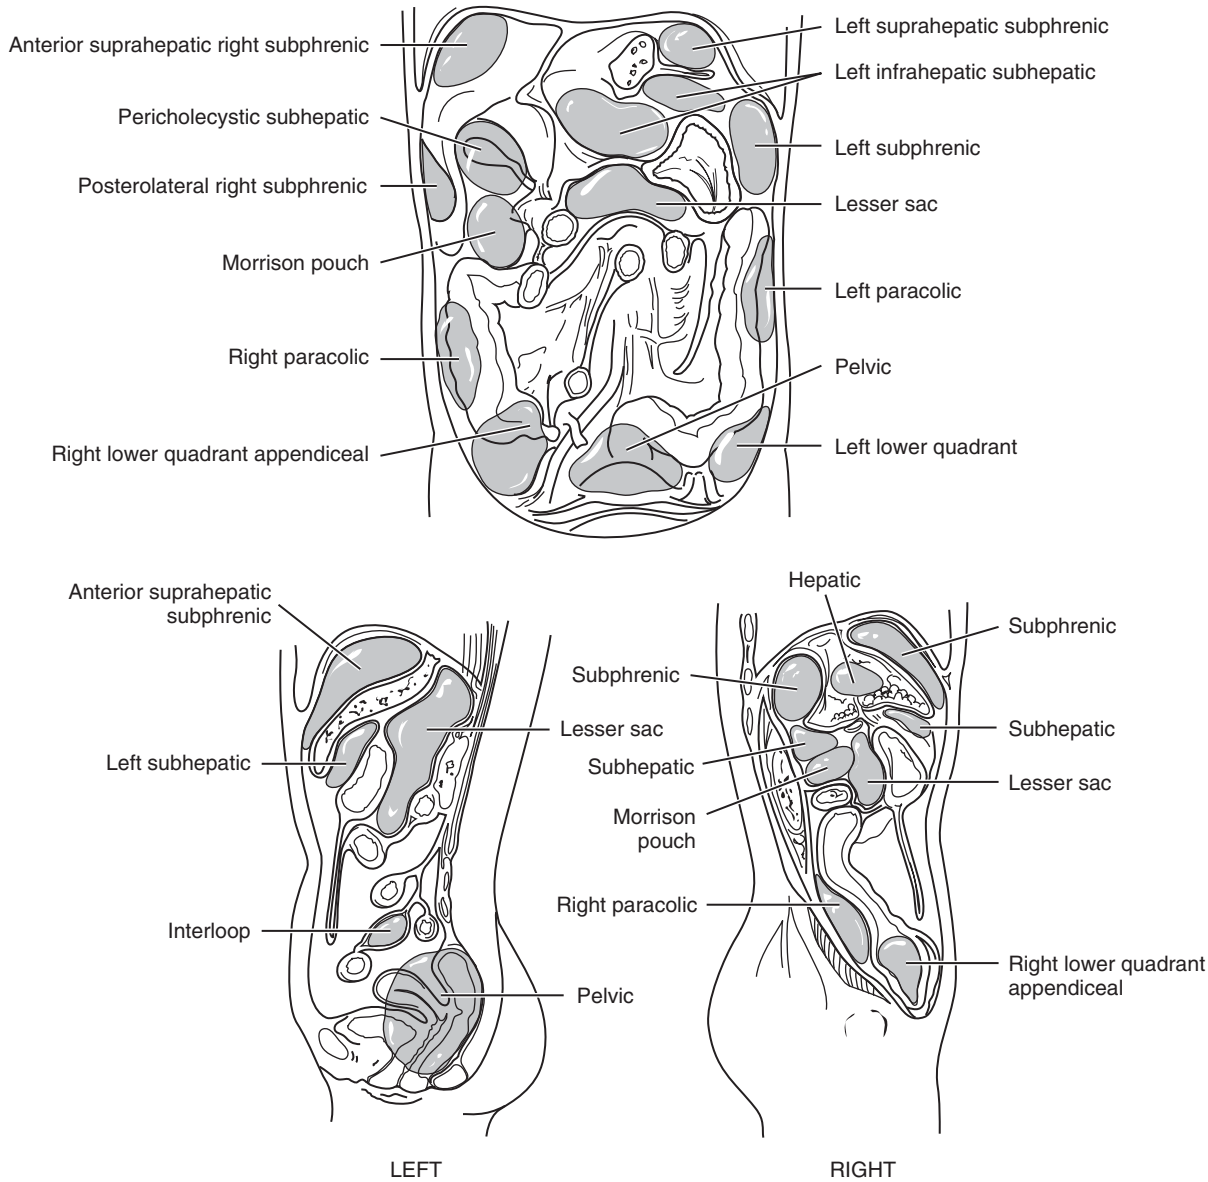

Figure 59–1 Anterior and sagittal views of the peritoneal cavity. *(From Altemeier, W. A., Culbertson, W. R., and Fullen, W. D.: Intra-abdominal sepsis. Adv. Surg. 5:281-333, 1971.)*

peritoneal fluid from a healthy host.[17,70] Deficiency of these important opsonins diminishes the natural clearance of organisms from the peritoneal cavity. Proliferation of organisms triggers the influx of phagocytes, release of inflammatory mediators, and localized or diffuse peritoneal irritation that gives rise to symptoms of abdominal pain and fever.

Since the pre-antibiotic era, researchers have recognized that primary peritonitis frequently is caused by *Streptococcus pneumoniae*,[31] *Streptococcus pyogenes*,[32] and *Staphylococcus aureus*.[17] Rarely, primary peritonitis in prepubescent girls is caused by extension of upper genital tract *S. pneumoniae* infection.[37,66] Since the 1960s, the bacteriology of primary peritonitis has shifted to include an increased proportion of infections caused by gram-negative enteric organisms, such as *Escherichia coli* and *Klebsiella* spp.[17,37,41,71] In some instances, primary *E. coli* peritonitis may occur concurrently with bacteremic urinary tract infection.

Tuberculous peritonitis may be caused by *Mycobacterium tuberculosis* or *Mycobacterium bovis*. It may occur as a complication of primary mycobacteremia or be caused by reactivation of latent intra-abdominal infection within lymphoid tissue, but only rarely does it seem to occur as a function of the ingestion of swallowed organisms from a pulmonary primary focus.[35,65,75] Peritoneal infection with *M. bovis*, which is clinically similar to *M. tuberculosis* peritonitis, is acquired from unpasteurized dairy products and has been reported in children living along the border between the United States and Mexico. These organisms may cause peritonitis from either mycobacteremia or erosion of organisms through the mesenteric lymph nodes or bowel wall into the peritoneal cavity.[20] *Salmonella* spp. rarely cause primary peritonitis and have been reported primarily in patients with underlying conditions.[47]

SECONDARY PERITONITIS

Secondary peritonitis, the most common form of peritonitis, arises as a complication of intra-abdominal injury or disease when microorganisms, secretions, and the particulate material of an

TABLE 59–1 Most Commonly Identified Etiologic Agents

Primary Peritonitis	Secondary Peritonitis
Escherichia coli (25-40%)	Aerobes
Haemophilus influenzae type b	*Enterobacter*
Klebsiella	*Enterococcus*
Mycobacterium bovis	*E. coli*
Mycobacterium tuberculosis	*Klebsiella*
Neisseria meningitidis	*Pseudomonas aeruginosa*
Other enteric gram-negative bacilli	*Serratia*
Other streptococci (alpha-hemolytic and beta-hemolytic)	Anaerobes
Staphylococcus aureus (2-4%)	*Bacteroides fragilis* group
Streptococcus pneumoniae (30-50%)	*Peptostreptococcus*
CAPD-Associated Peritonitis	**VP Shunt–Associated Peritonitis**

S. aureus	
Stenotrophomonas	

CAPD, continuous ambulatory peritoneal dialysis; VP, ventriculoperitoneal.

intra-abdominal organ enter the peritoneal cavity. Congenital or acquired conditions that result in ischemia, inflammation, or perforation of abdominal viscera may be complicated by secondary peritonitis.[46] In premature infants, necrotizing enterocolitis is the most common cause of secondary peritonitis.[51] In infants and children, appendicitis is the most common cause; however, it also may occur with volvulus, intussusception, incarcerated hernia, or rupture of a Meckel diverticulum.[51] Although less common in children than in adults, peritonitis also occurs as a complication of mucosal diseases, such as peptic ulcer, ulcerative colitis, Crohn disease, and pseudomembranous colitis.[51]

Rupture of or injury to an intra-abdominal viscus results in spillage of the luminal contents and contamination of the peritoneal cavity with bacteria, gastrointestinal secretions, and debris. Chemical and infectious sources of inflammation are introduced. The stomach and upper gastrointestinal tract contents contain only 10^3 to 10^4 or fewer organisms per gram because of the low pH of gastric secretions. Gram-negative aerobic organisms colonize the upper gastrointestinal tract. In contrast, the colonic contents have predominantly anaerobes, with 10^{11} anaerobes and 10^8 aerobes per gram.[11,37,64]

Secondary peritonitis usually is a polymicrobial infection, with 5 to 10 different bacterial species of anaerobes and facultative gram-negative bacilli. Synergy among the various bacterial species enhances bacterial proliferation.[11] Members of the *Bacteroides fragilis* group and *Peptostreptococcus* spp. are the anaerobic organisms reported most commonly in secondary peritonitis. Of the aerobic organisms, *E. coli*, *Klebsiella* spp., *Pseudomonas aeruginosa*, and *Enterococcus* spp. are isolated most often. More recently, *P. aeruginosa* has been noted to be present in 20 to 30 percent of children with complicated ruptured appendicitis.[8,38] When secondary peritonitis occurs in patients with a history of prolonged hospitalization, underlying chronic conditions, or recent antibiotic therapy, the etiology may include nosocomial pathogens that have colonized the gastrointestinal tract, such as *P. aeruginosa*, *Enterobacter* spp., *Acinetobacter* spp., or other antibiotic-resistant organisms.

Focal suppurative infection may be present within an intra-abdominal or retroperitoneal solid organ or within intra-abdominal lymphoid tissue. Organisms spread from this purulent focus through the capsule of the organ or lymphoid tissue and enter the peritoneal cavity, with the subsequent development of peritonitis. The intra-abdominal organ or lymphoid tissue may be inoculated via bacteremia (e.g., *S. aureus* and renal infection) or be inoculated as a complication of the normal function of the organ (e.g., *E. coli* and renal infection or *Yersinia* and mesenteric adenitis).[13,36,42]

PERITONITIS AND IMPLANTED DEVICES

Peritonitis is the most significant infectious complication of long-term peritoneal dialysis. Contamination of the dialysis tubing, migration of skin flora from the exit site, or contamination of the dialysate may lead to peritonitis in patients undergoing continuous ambulatory peritoneal dialysis (CAPD). In each instance, a single pathogen usually is isolated.

Gram-positive organisms, coagulase-negative staphylococci, and *S. aureus* account for 30 to 45 percent of peritonitis episodes in children undergoing CAPD. Of CAPD-associated peritonitis episodes, 20 to 30 percent are caused by Enterobacteriaceae.[26] In these instances, contamination of the catheter site with fecal material most often occurs in young children who wear diapers and children with incontinence, an open urogenital sinus, or nephrostomy tubes. The water-borne pathogens *Pseudomonas* and *Acinetobacter* account for 6 percent and 4 percent, respectively, of peritonitis episodes in children receiving CAPD. *Pseudomonas* peritonitis is especially difficult to treat with the dialysis catheter in situ and may recur despite administration of appropriate antimicrobial therapy.[26]

Fungal peritonitis is another complication of CAPD that is difficult to treat successfully without removal of the catheter. Although fungal pathogens have accounted for only 2 percent of peritonitis episodes in children undergoing CAPD, this problem is occurring more commonly.[15,25,26,48,56,76] Most patients with fungal peritonitis have had previous episodes of bacterial peritonitis and antibiotic therapy. The most common fungal pathogens are *Candida* spp.[25,26]; however, rare fungi, such as *Curvularia* spp.,[15] *Fusarium* spp.,[26] *Trichosporon asahii*,[48] and *Aspergillus* spp.,[26] have been reported.[56,76] Other rare causes of CAPD-associated peritonitis include *Mycobacterium fortuitum* and *Mycobacterium chelonae*.[77]

Intra-abdominal infectious complications develop on average in less than 5 percent of infants and children who undergo ventriculoperitoneal shunt placement or revision for hydrocephalus.[43,55,68] Peritonitis, peritoneal pseudocyst, or perforation of the bowel by the abdominal catheter rarely occurs in children with such shunts.[5,30,33,60,61,63,67,72] Cerebrospinal fluid (CSF) in the peritoneal cavity may be seeded during transient bacteremia or a febrile illness or after abdominal trauma. In addition, peritonitis may develop as a complication of infection within the ventricles being drained[68] as organisms descend into the peritoneal cavity via the distal tubing.

A peritoneal pseudocyst containing CSF is the most common manifestation of peritoneal inflammation in patients with ventriculoperitoneal shunts. These patients often have a history of symptoms compatible with a shunt infection before the formation of a pseudocyst and may have signs of peritoneal inflammation and a palpable abdominal mass. The microbial etiology of ventriculoperitoneal shunt–associated peritonitis varies and reflects the pathogenesis of infection. Infections occurring within months of surgery often are caused by skin flora, *Staphylococcus epidermidis*, other coagulase-negative staphylococci, and *S. aureus*.[30,60] The microbiology of late shunt-associated peritonitis is similar to that of spontaneous bacterial peritonitis and may include gram-negative enteric organisms and gram-positive cocci.[60] Peritonitis caused by colonic flora also rarely has been associated with bowel perforation by the distal end of the ventriculoperitoneal shunt.[33,60,67]

CLINICAL MANIFESTATIONS

The initial signs and symptoms of primary bacterial peritonitis include nausea, vomiting, diarrhea, and diffuse abdominal pain.[37,40,41] These signs and symptoms are similar to those of secondary peritonitis caused by a ruptured appendix.

Rupture of the appendix is the most common cause of secondary peritonitis in children; the initial symptoms of anorexia, vomiting, and localized abdominal pain frequently precede the signs and symptoms of diffuse peritoneal inflammation. In primary and secondary peritonitis, patients typically lie very still because any movement exacerbates the abdominal pain. Physical findings include fever, tachycardia, abdominal distention, hypoactive bowel sounds, abdominal tenderness, rebound tenderness, abdominal wall rigidity, and tenderness on rectal or vaginal examination. Peritoneal inflammation is associated with an increase in splanchnic blood flow, capillary permeability, and a shift of fluid into the peritoneal space, which may lead to intravascular hypovolemia and shock, in addition to systemic absorption of endotoxin and bacteria.[46]

Fever and abdominal pain in any child undergoing peritoneal dialysis should be evaluated carefully. Turbid dialysate fluid raises the suspicion of CAPD-associated peritonitis. Similarly, symptomatic children with ventriculoperitoneal shunts should be evaluated for shunt-associated peritonitis.[61,68,80] In a retrospective report of 19 children with ventriculoperitoneal shunts and peritonitis, Reynolds and associates[61] noted that fever and abdominal pain were the most common symptoms in 14 of their patients. Stamos and colleagues[68] found that fever, lethargy, nausea, and vomiting were the most frequently reported symptoms in a review of 23 children with gram-negative infection of ventriculoperitoneal shunts.

Primary tuberculous peritonitis usually is gradual in onset and associated with weight loss, malaise, and nightsweats.[35,37,65] The degree of tenderness is less than that present with acute pyogenic peritonitis and may be nonexistent. Palpation of the abdomen may reveal an extensive, irregular collection of masses, often described as "doughy," caused by widespread granulomatous inflammation.[37]

DIAGNOSIS

Laboratory findings in a child with peritonitis often are nonspecific. The white blood cell count usually is elevated (16,000 to ≥25,000 cells/mm^3), with a predominance of polymorphonuclear leukocytes and an increase in immature forms.[37] The hematocrit may be elevated because of dehydration and hemoconcentration. Mild pyuria is noted occasionally because of irritation of the urinary bladder or ureters.

Diagnostic imaging studies can be useful in evaluating intra-abdominal infections. Upright and lateral decubitus radiographs of the abdomen may show distended adynamic loops of bowel suggestive of ileus and obliteration of the peritoneal fat lines and psoas shadows. Free intraperitoneal air below the diaphragm indicates a ruptured viscus. The presence of a fecalith or right lower quadrant mass may be consistent with appendicitis. Abdominal ultrasound and CT may reveal an underlying cause of the peritonitis.[47,51]

Analysis of peritoneal fluid aspirate or lavage material may be helpful in differentiating primary from secondary peritonitis. Free air, blood, or bile indicates peritonitis secondary to intestinal perforation. In peritonitis, the leukocyte count in peritoneal fluid usually is greater than 250 to 300 white blood cells/mm^3 and sometimes 3000 to 5000 white blood cells/mm^3, with granulocytes predominating in 80 percent of cases.[37,45,70] A total protein content greater than 1 g/dL, a glucose level less than 50 mg/dL, or an elevated lactate dehydrogenase concentration (>25 mg/dL) is consistent with secondary peritonitis.[17,31,37,70]

If a Gram stain of peritoneal fluid shows only gram-positive cocci, primary peritonitis is most likely. The presence of gram-negative bacilli is consistent with primary or secondary peritonitis, but the presence of many different organisms on Gram stain is diagnostic of secondary peritonitis. Bacteremia occurs in 75 percent of patients with primary peritonitis. Specimens of peritoneal fluid and blood should be sent for culture.[37] Similarly, secondary peritonitis also can be associated with bacteremia, suggesting the need for obtaining cultures of blood in addition to peritoneal fluid. Specimens of peritoneal fluid should be processed to optimize the recovery of aerobic and anaerobic organisms, and the use of specific transport tubes or an airless, capped syringe is required.[11,37] The wide variety of pathogens isolated from intra-abdominal infections along with the variable antibiotic susceptibility of these pathogens supports taking an aggressive approach to obtaining samples for microbiologic evaluation.

A child undergoing CAPD who is suspected of having peritonitis should have dialysate sent for cell count, Gram stain, and culture for bacterial, mycobacterial, and fungal pathogens. If a child with a ventriculoperitoneal shunt is suspected of having peritonitis, CSF from the proximal portion of the shunt should be sent for culture, cell count, and determination of glucose and protein levels in addition to Gram stain and culture of peritoneal fluid.[30] Abdominal imaging by ultrasound or CT is useful in identifying a peritoneal pseudocyst and the location of distal tubing.

DIFFERENTIAL DIAGNOSIS

Other infectious diseases that may mimic primary or secondary bacterial peritonitis include mesenteric adenitis, gastroenteritis, hepatitis, streptococcal pharyngitis, lower lobe pneumonia, pyelonephritis, and pelvic inflammatory disease. Noninfectious diseases to be considered in the differential diagnosis are pancreatitis, diabetic ketoacidosis, Henoch-Schönlein purpura, ovarian torsion, sickle-cell pain crisis, and lead poisoning.[51]

TREATMENT

Optimal management of peritonitis involves prompt and aggressive physiologic support, surgical consultation, and antimicrobial therapy. Correction of fluid and electrolyte imbalances and hemodynamic stabilization should be initiated as soon as the diagnosis of peritonitis is suspected. Spontaneous bacterial peritonitis usually is managed medically, unless the diagnosis is uncertain, in which case exploratory laparotomy or laparoscopy is performed. Before resistant strains of *S. pneumoniae* emerged, primary peritonitis in children was treated with aqueous penicillin G.[17,31] Given the increased prevalence of *S. pneumoniae* with reduced susceptibility to penicillin, third-generation cephalosporins such as cefotaxime or ceftriaxone are recommended until susceptibility results are available.[45,71] If primary peritonitis is caused by gram-negative organisms, appropriate empiric therapy includes cefotaxime or ceftriaxone, with or without an aminoglycoside, a carbapenem, ticarcillin-clavulanate, or piperacillin-tazobactam, pending completion of culture and susceptibility testing.

Patients with secondary peritonitis may require either immediate surgery to control the source of contamination and to remove necrotic tissue, blood, and intestinal contents from the peritoneal cavity or a drainage procedure if a limited number of large abscesses can be shown.[43,47,52,79] In cases of phlegmon, or extensive inflammatory edema, surgery usually is not performed acutely because of the child's unstable metabolic state and friable

intra-abdominal tissues. Surgery is delayed for several hours or weeks to allow the inflammation to resolve. Surgery also may be postponed indefinitely.[6,14,74]

Empiric antimicrobial therapy for secondary peritonitis should have activity against anaerobes, especially the *B. fragilis* group, and enteric gram-negative aerobes.[7] Although controversial, some regimens also include an antibiotic effective against enterococci. The gold standard for antimicrobial therapy historically has been clindamycin or metronidazole, gentamicin, and ampicillin.[7,11,27,43,46,52,62] Alternative efficacious regimens, as single or combination therapy, include aztreonam, cefotaxime, cefoxitin, imipenem-cilastatin, meropenem, piperacillin-tazobactam, and ticarcillin-clavulanate.[7,43,46,52,79] Rates of resistance to cefoxitin and clindamycin among the *B. fragilis* group have increased and are reported to be 49 percent; in some institutions, alternative regimens are used routinely.[2,46]

Other studies have examined the use of a single broad-spectrum antibiotic, which allows a portion of the therapy to be delivered less expensively on an outpatient basis. Fishman and coworkers[27] prospectively evaluated the clinical outcomes of 150 children with perforated appendicitis treated postoperatively with a 10-day course of piperacillin-tazobactam. They compared the outcome with that of historical controls treated with a 10-day course of ampicillin, gentamicin, and clindamycin. Rates of postoperative infectious complications were similar in both groups. Bradley and colleagues[8] prospectively identified 87 children with complicated appendicitis in five pediatric centers, also comparing costs and outcomes with historical controls. Although inpatient treatment courses were reduced by an average of 42 percent in meropenem-treated children, outcome measures were equivalent to those of historical controls.

Table 59–2 summarizes randomized trials of monotherapy versus combination therapy for ruptured appendicitis in children. Although no differences in outcome were observed, the potential of emerging resistance to broad-spectrum agents versus the convenience of monotherapy must be considered and balanced against the possible decreased risk of developing nosocomial infection among children who can receive a substantial component of parenteral therapy in the home.[38]

Empiric antibiotic treatment of CAPD-associated peritonitis should be effective against gram-positive and gram-negative organisms until culture results are available. Intraperitoneal antibiotics, with or without concomitant intravenous antibiotics, achieve adequate serum and dialysate concentrations. Vancomycin is used for empiric therapy for gram-positive infections, but if staphylococcal organisms are susceptible to β-lactam agents, treatment with cefazolin is effective.[26] Aminoglycosides (gentamicin or tobramycin) or cephalosporins are used for gram-negative infections; however, because most intraperitoneal antibiotics are absorbed into the systemic circulation, serum aminoglycoside or vancomycin concentrations should be monitored for possible toxicity. Therapy for fungal peritonitis usually is intravenous amphotericin B, although successful use of fluconazole or intraperitoneal amphotericin B has been reported.[26,56] Indications for removal of a dialysis catheter include persistent infection with *S. aureus* or *Pseudomonas*, tunnel infection, or fungal peritonitis.[26]

Treatment of peritonitis associated with ventriculoperitoneal shunts usually requires externalization of the distal end of the catheter in addition to institution of antibiotic therapy.[30] Empiric antibiotic therapy should include an antistaphylococcal agent active against coagulase-positive and coagulase-negative staphylococci. Coagulase-negative staphylococci are a common cause of ventriculoperitoneal shunt infection; vancomycin should be administered pending culture and susceptibility results. If Gram stain of ventricular CSF or peritoneal fluid reveals gram-negative organisms, cefotaxime, ceftriaxone, ceftazidime, or meropenem should be added.[5,61]

The duration of antibiotic therapy for peritonitis should be dictated by the clinical course of the patient because no single regimen or treatment course is accepted universally.[37] Indicators of sufficient therapy include resolution of fever and abdominal pain and return of the leukocyte and differential counts to normal.[37,52,69] Primary peritonitis caused by streptococci is treated successfully with a 10- to 14-day course of antibiotics.[17,37] Primary peritonitis with gram-negative organisms may require 10 days to 3 weeks of antibiotic treatment.[17] The duration of therapy for secondary peritonitis after adequate surgery usually is 5 to 10 days, but it depends on the clinical response to therapy.[37,52,69] Short-course therapy for 5 days has been shown to be efficacious in some patients,[37,52] but longer courses are required if fever persists, or abdominal signs and symptoms are present. Standard therapy for tuberculous peritonitis consists of a minimum of two antituberculous drugs. As with other forms of extrapulmonary tuberculosis in children, empiric therapy with isoniazid, rifampin, and pyrazinamide is advised pending culture and susceptibility results. Although *M. bovis* is resistant to pyrazinamide, most strains are susceptible to isoniazid and rifampin and to ethambutol.

COMPLICATIONS

Acute complications associated with peritonitis include septic shock, adult respiratory distress syndrome, septic thrombophlebitis of the portal vein, acute renal failure, and multiorgan system failure.[46] Postoperative complications include wound infection, adhesions, bowel obstruction, formation of a fistula, and formation of an intra-abdominal or retroperitoneal abscess.

Recurrent peritonitis (tertiary peritonitis) is an entity described as occurring late in the course of therapy for secondary peritoni-

tis.[37,44,79] Patients with this condition continue to have symptoms despite receiving appropriate antimicrobial therapy, and peritoneal fluid reveals persistent inflammation. Bacterial cultures often are negative or may yield an organism of low virulence. Multiorgan system failure and a poor outcome frequently are associated with tertiary peritonitis. The mechanism of ongoing peritoneal inflammation is unknown; however, some investigators have proposed that immunoregulatory dysfunction and poor nutrition are contributing factors.

INTRA-ABDOMINAL ABSCESS

Intra-abdominal abscesses often are categorized as intraperitoneal, visceral, or retroperitoneal (see Chapter 60).[4,10] In children, intraperitoneal abscesses are most common. The most common underlying conditions associated with an intra-abdominal abscess in children are appendicitis and trauma.[10,51] Reviews of gangrenous or perforated appendicitis in children indicate that 2 to 20 percent of cases are complicated by the formation of an abscess.[52,62]

Two basic mechanisms exist for the development of an intraperitoneal abscess. In the first mechanism, diffuse peritonitis may cause loculations of purulent material to form in the areas anatomically most dependent—typically the pelvic, subphrenic, and paracolic regions (see Fig. 59–1). The second mode of formation of an abscess involves a localized focus related to contiguous disease or injury in which host defenses and the inflammatory response prevent diffuse spread and peritonitis.[4] The microbiology of intraperitoneal abscesses is polymicrobial and reflects that of the intestinal flora. In a review of intra-abdominal abscess in 36 children, Brook[10,11] noted that the predominant organisms were the *B. fragilis* group, *Peptostreptococcus*, *E. coli*, and other Enterobacteriaceae.

The most common sites of visceral abscess in children are the liver (see Chapter 55), pancreas, and spleen. Underlying conditions that may lead to the development of a pancreatic abscess include pancreatic injury, pancreatitis, and biliary obstruction. Pancreatitis or surgical or accidental injury to the pancreas causes the release of pancreatic enzymes and focal necrosis.[28] Reflux of contaminated bile into the pancreatic duct is hypothesized to be the mechanism by which enteric organisms gain access to the injured pancreas and proliferate. A pancreatic abscess usually is a polymicrobial infection caused by aerobic (*E. coli*, *Klebsiella pneumoniae*, group D streptococci) or anaerobic (peptostreptococci, *B. fragilis* group) organisms that inhabit the gastrointestinal tract. Rare instances of *S. aureus* pancreatic abscess occur as a result of bacteremia.[12,13]

Splenic abscesses are unusual findings in infants and children. Before the 1970s, most reports involved solitary pyogenic abscesses. Since then, the number of reports of multiple splenic abscesses has increased.[16,39,58] Splenic abscess usually is associated with one of five underlying conditions: endocarditis, injury, hemoglobinopathy, immunodeficiency, or adjacent infection. Given the filtering function of the spleen, an abscess can form as a result of any metastatic hematogenous infection, such as endocarditis. Although rare, splenic abscess can be a delayed complication of the nonoperative management of splenic injuries. Splenic infarcts associated with hemoglobinopathies such as sickle-cell disease may become secondarily infected and form an abscess.[16] Immunodeficiency, such as malignancy or acquired immunodeficiency syndrome, is another significant risk factor for the development of multiple splenic abscesses.[39,53,58]

Rarely, infection or disease in a contiguous focus may extend to the spleen. In a review of 56 children with splenic abscesses, 7 (12.5%) were cryptogenic with no apparent cause.[39] In most instances, a single pathogen is isolated, with *S. aureus*, streptococci, *E. coli*, and *Salmonella* spp. being the most common. Fungi, most often *Candida* spp., have been isolated from splenic abscesses primarily in immunocompromised hosts.[39,53,58]

CLINICAL MANIFESTATIONS

The typical clinical features of an intra-abdominal abscess include fever, abdominal pain, and tenderness over the involved area. Subphrenic abscesses also may be manifested as referred pain or pulmonary or pleuritic symptoms. Pancreatic abscess may be associated with a palpable epigastric mass and elevated serum lipase and amylase.[12] Splenomegaly or a splenic mass may be noted in approximately half of patients with splenic abscesses.[39] In postoperative patients, persistence of abdominal symptoms or fever warrants evaluation for an intraperitoneal abscess.[3] Leukocytosis (20,000 to 50,000 cells/mm^3) frequently is present in children with an intra-abdominal abscess.[3,37]

DIAGNOSIS

Imaging studies are helpful in diagnosing an intra-abdominal abscess. Plain radiographs are useful as an initial procedure and may show an extraintestinal air-fluid level, right lower quadrant mass, or localized ileus.[1] Chest radiographs should be obtained because subphrenic abscesses often are associated with a pleural effusion. In a series of 27 children with splenic abscesses, chest radiographs were abnormal in 20 cases, with the most common findings being left pleural effusion and an elevated left hemidiaphragm.[39] Ultrasonography is a useful noninvasive technique that can detect abdominal and pelvic abscesses. The quality of the images depends on the examiner, however. In addition, conditions such as ileus, postoperative drains, or dressings may hinder ultrasound detection of an abscess.[1,47,50] CT is the most sensitive tool for detecting an intra-abdominal abscess, and it provides good anatomic resolution. Disadvantages of CT are the radiation and, if used, exposure to intravenous, oral, or rectal contrast material.[1,47,50]

Although more recent experience with the use of magnetic resonance imaging for detecting an intraperitoneal abscess has been described in the literature,[54] this modality should be considered in children only when an abscess may not be detected more easily by other methods or in patients who should not have exposure to radiation.[54] Gallium scanning is a sensitive technique for diagnosing an abscess, but it is nonspecific, particularly in the abdomen.[1]

TREATMENT

Management of an intra-abdominal abscess includes physiologic and nutritional support, antimicrobial therapy, and drainage. After blood cultures have been obtained, empiric antibiotic therapy should be instituted with agents effective against anaerobes, Enterobacteriaceae, and other enteric flora as discussed earlier for peritonitis. Antibiotic therapy usually is begun before surgery is done to minimize any complications of bacteremia during the procedure. Abscess material should be obtained for culture of aerobic, anaerobic, fungal, and mycobacterial pathogens. Effective surgical management depends on accurate localization of the abscess, discrimination between single and multiple abscesses, and early and adequate drainage.[3,4,46] Traditional therapy for intraperitoneal abscesses has relied on open surgical drainage, although drainage of intraperitoneal abscesses percutaneously under ultrasound or CT guidance now is used often.[1,18,21,46,50,59]

In instances of multiple intraperitoneal abscesses or if the source of peritoneal contamination has not been controlled, laparotomy is indicated.[46] Pancreatic abscesses require intensive surgical and medical therapy. Antimicrobial therapy for mixed aerobic and anaerobic infection is suggested,[12] but splenectomy remains the definitive treatment of bacterial splenic abscesses. In selected patients, percutaneous drainage or splenotomy has the advantage of preserving splenic function, however.[39,53,58] Multiple small splenic abscesses and fungal lesions generally are treated medically.[39] Antibiotic therapy for a pyogenic splenic abscess should be guided by the pathogens associated with the child's underlying condition. Therapy should include antibiotics effective against *S. aureus*, streptococci, and gram-negative enteric bacilli. Specific therapy should be revised after culture and susceptibility results are available.

COMPLICATIONS

Intraperitoneal and visceral abscesses, if not adequately drained, may be associated with significant complications, including ongoing spread of the infectious process and, for splenic or pancreatic abscesses, a high mortality rate. Fistula formation, adhesions, and bowel obstruction may be late complications of intra-abdominal infection.

CHAPTER 60

Retroperitoneal Infections

Alice Pong ❂ John S. Bradley

Retroperitoneal infections consist primarily of suppurative bacterial infections that originate within the retroperitoneal structures or as an extension from another primary site. In children, these infections are much less common than are intra-abdominal infections; however, they can lead to significant morbidity if missed. Establishing a diagnosis can be difficult because symptoms often are indolent and poorly localized.

The retroperitoneal structures are separated from the intra-abdominal organs by the posterior peritoneal fascia (Fig. 60–1). Structures posterior to this fascia layer, in the anterior retroperitoneal space, include the duodenum, pancreas, and parts of the colon. The kidneys and ureters are encased further by the renal fascia. The iliopsoas and psoas muscles lie at the posterior aspect of the retroperitoneal space and are separated from the other retroperitoneal structures by the transversalis fascia. Pelvic structures, including the bladder, uterus, and rectum, that lie inferior to the pelvic peritoneum constitute the pelvic portion of the retroperitoneal space. The fascial layers limit the spread of retroperitoneal infections. However, the deep location can be difficult to assess by physical examination.

ETIOLOGY AND PATHOGENESIS

Retroperitoneal infections in children arise in numerous anatomic structures. Brook[6] reviewed cases of retroperitoneal infections from five U.S. hospitals from 1974 to 1994. Of 41 children identified, 21 had infections in the anterior retroperitoneal space related to the pancreas (4) and intestines (13), 6 had perinephric abscesses, 7 had iliopsoas abscesses, and 7 had pelvic retroperitoneal abscesses (Fig. 60–2).

Primary infection of the retroperitoneal space can be hematogenous in origin or complicate an ascending urinary tract infection. Secondary infections occur as a direct extension from gastrointestinal perforations, such as ruptured appendices or those related to Crohn disease.[6,19,20] Greenstein and associates[19] reported retroperitoneal abscesses in 12 of 231 patients with Crohn disease. Retroperitoneal infections also can develop secondary to primary infections of the vertebral spine, pelvic bones, and sacroiliac joint.[21,33,36] Suppurative iliac or retroperitoneal lymph nodes are another source of retroperitoneal infections. Prior surgery has been reported as a predisposing factor in perinephric abscesses[7,16] and in vascular grafts in adults.[8] Pancreatic abscesses are seen more frequently in adult patients and are associated with underlying biliary tract disease, alcoholism, surgery, and trauma.[9]

Infections of the perinephric retroperitoneal space include those involving the kidney and adrenal glands. Perinephric abscesses can result from bacteremic inoculation of renal tissue or as a consequence of an ascending urinary tract infection. Nephronia (i.e., focal renal cellulitis) is thought to be an intermediate stage of renal infection between pyelonephritis and renal abscess, resulting from an ascending infection of the urinary tract.[31] Adrenal abscesses are reported more frequently in neonates than in older children and are thought to be related to adrenal hemorrhages that become secondarily infected.[28]

Iliopsoas abscesses may be a consequence of hematogenous seeding of the muscle, with trauma as a predisposing factor (see Fig. 60-2).[20,32] Although primary infection occurs most commonly,[5] the iliopsoas muscle extends from the ribs and lumbar vertebrae to its insertion on the femur and is exposed to the risk of extension of infection from numerous adjacent structures.

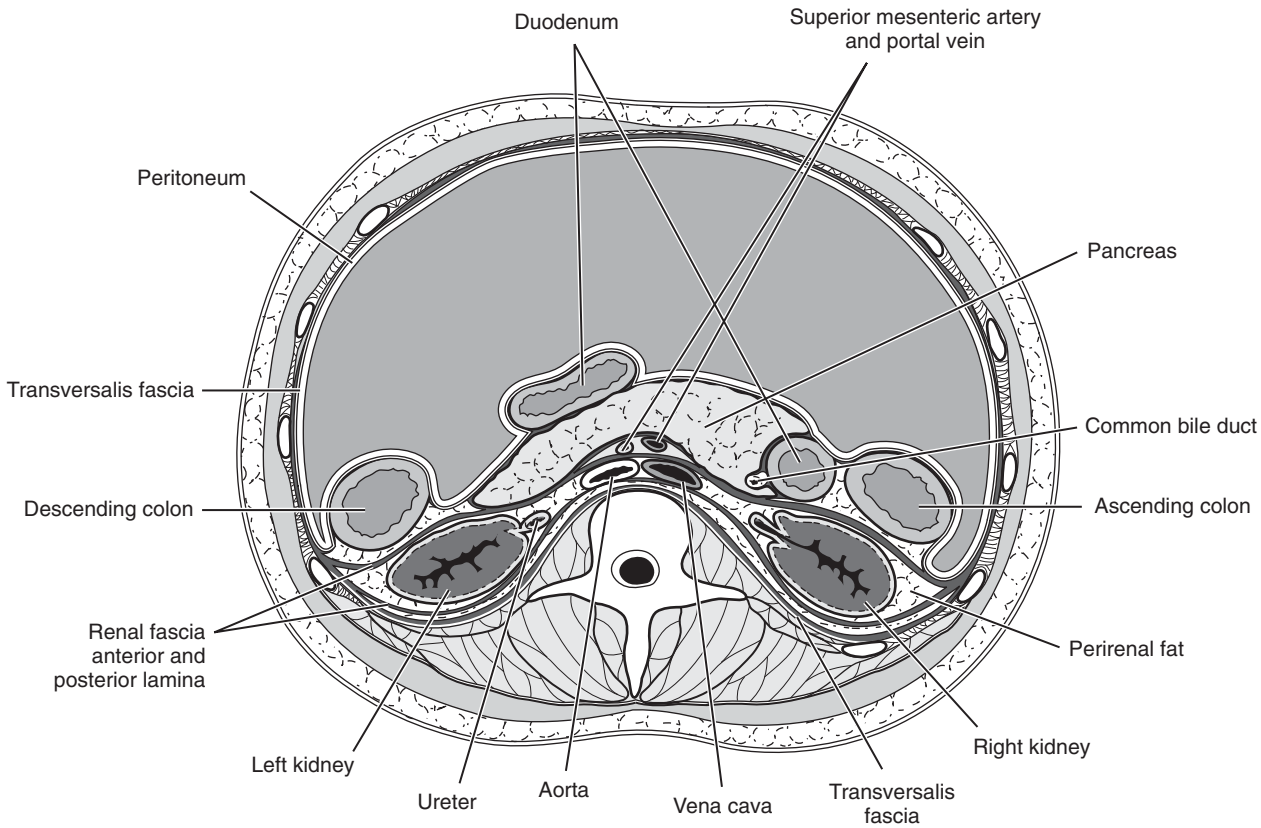

Figure 60–1 A cross section of abdomen at L2 shows the structures within the retroperitoneal space. *(From Altemeier, W. A., and Alexander, J. W.: Retroperitoneal abscess. Arch. Surg. 83:515, 1961, with permission.)*

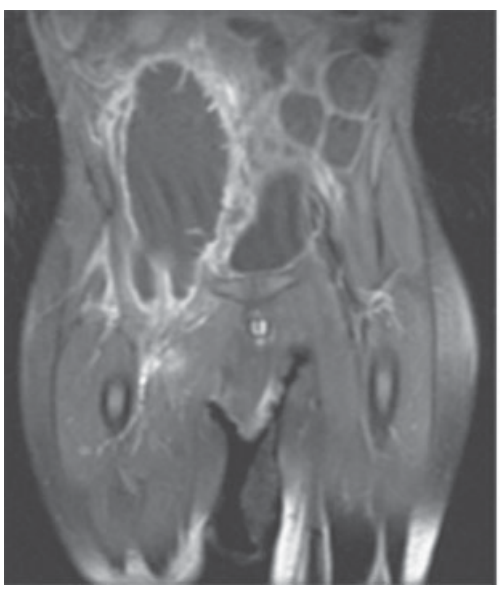

Figure 60–2 Large iliopsoas abscess seen on magnetic resonance imaging. Coronal view with contrast enhancement.

Psoas abscesses have developed as a consequence of vertebral infections, intestinal perforations, and genitourinary sources and as an extension of primary pelvic osteomyelitis.[20,22,31,33] Neonatal iliopsoas abs-cesses also have been reported and present with symptoms similar to those of a septic hip.[14,17,30]

Complications of retroperitoneal abscesses include both rupture into the intraperitoneal space and extension of the infection along fascial planes to adjacent muscles that extend from origins in the pelvis and trunk to insertion sites on the femur. Rupture into the thoracic cavity also has been reported.[1] Other reported complications include pneumonia, recurrent abscess, renal failure, and venous and arterial thrombosis.[12]

MICROBIOLOGY

The microbiology of retroperitoneal infections is determined by the source of the infection and the retroperitoneal compartment involved. Most primary infections thought to result from bacteremia are caused by *Staphylococcus aureus*. Secondary infection related to the gastrointestinal tract is caused by mixed bowel flora including *Escherichia coli*, other gram-negative enteric bacteria, *Pseudomonas* spp., and gastrointestinal anaerobes, particularly *Bacteroides fragilis* and *Peptostreptococcus*.[6] Most infections in the anterior retroperitoneal space are associated with a gastrointestinal source and may be polymicrobial.[4] *Actinomyces* infections, although seen more commonly in the cervicofacial area, also can present as retroperitoneal infections.[3,25]

Ascending infections from the urinary tract usually are caused by *E. coli*. However, perinephric abscesses also are reported as a complication of renal infection caused by *S. aureus*, group B streptococcus, and *Salmonella*.[16,38,39]

S. aureus is the leading pathogen isolated in iliopsoas abscesses unless the infection is secondary to erosion of a primary gastrointestinal focus. In that situation, gram-negative enteric bacteria and anaerobes are more likely to be the causative agents.[5,32] Retroperitoneal necrotizing fasciitis from group A streptococcus also has been reported.[13]

Tuberculosis caused by *Mycobacterium tuberculosis* or *Mycobacterium bovis* may involve the retroperitoneal space as an extension of vertebral tuberculous osteomyelitis.[1,15,22] Abdominal tuberculosis usually is manifested as an intraperitoneal infection but can produce retroperitoneal adenopathy.

CLINICAL PRESENTATION

Children with retroperitoneal infections present clinically in a variety of ways, ranging from nonspecific fever to overwhelming sepsis. The most common clinical symptoms associated with retroperitoneal infections include fever and pain in the hip, back, and abdomen.[12,26] Psoas abscesses often are manifested with the child's limping or refusing to walk.[5] Neonates with a retroperitoneal abscess may present with an abdominal mass.[34] Symptoms often are vague, and pain is not well localized. Patients often have been evaluated previously for fevers and have been treated with antibiotics before a diagnosis has been made.[5,24,33] A delay in establishing the diagnosis is not uncommon.

DIFFERENTIAL DIAGNOSIS

Retroperitoneal infections can be confused with a variety of other infections. Limp and fever caused by pyogenic arthritis of the hip and infection of the sacroiliac joint and pelvic bones occur more commonly than do retroperitoneal infections. Abdominal pain and fever are seen more frequently in patients with intra-abdominal infections, including appendicitis and intra-abdominal abscesses. Trauma and malignant disease are more frequent causes of retroperitoneal masses compared with infectious causes and should be considered.

SPECIFIC DIAGNOSIS

Laboratory tests often are nonspecific and of minimal benefit. Sedimentation rates and leukocyte counts often are elevated.[5,6,32,33] Pyuria often is absent in children with perinephric and renal abscesses, and the urine culture may be negative.[7,16,37,38] However, in patients with nephronia, pyuria and positive urine cultures are more likely.[24,31] Blood cultures may be helpful in identifying a bacterial pathogen. Brook[6] reported that 40 percent of blood cultures were positive for the same organism isolated from abscesses in children with retroperitoneal infections who had blood culture specimens collected. For children with psoas abscesses, Santaella and colleagues[32] reported that 71 percent of blood cultures were positive.

Imaging studies are the most useful diagnostic tools. Ultrasonography can be used to diagnose perinephric infections[7,37] and has been used to diagnose abscesses of the iliopsoas muscle.[20] Computed tomography (CT) with contrast enhancement appears to be the most helpful[11,12,32] because of superior delineation of organ involvement and the extent of infection as well as wide availability and rapid imaging times compared with magnetic resonance imaging (MRI). CT also can provide clues about the primary focus of the infection, thereby helping guide empiric antibiotic therapy. Abscess fluid is seen on CT as areas of low attenuation, often with an enhancing rim.[11,23,38] Percutaneous drainage and biopsy of the lesions also may be accomplished with CT. Although alternative diagnoses also can be evaluated with CT,[35] hematomas and certain tumors may not be distinguished easily radiographically from infection. These noninfectious entities may be identified better by MRI. Another advantage of MRI over CT is superior visualization of bone and inflamed muscle tissue, although calcifications may not be as well identified.[29]

TREATMENT

Percutaneous or open surgical drainage should be considered for all retroperitoneal infections for both diagnostic and treatment purposes. Culture of the aspirated fluid for aerobic and anaerobic bacteria, mycobacteria, and fungi is vital to selection of appropriate antimicrobial therapy. Reports of percutaneous drainage of perinephric abscesses and iliopsoas abscesses are increasing in number.[5,22] These procedures usually are performed with ultrasound or CT guidance. Treatment of patients with antibiotics alone without surgical drainage may not be effective, particularly in cases involving larger abscesses.[1,11]

Initial antimicrobial therapy for retroperitoneal infections should be directed by the presumed source of the infection, with definitive therapy guided by microbiologic culture results. Infections related to gastrointestinal perforation should include coverage directed primarily against enteric gram-negative bacteria and gastrointestinal anaerobes such as β-lactamase–producing *B. fragilis*. Coverage for *Pseudomonas* and *Enterococcus* spp. also should be considered. Historically, antibiotic combinations such as ampicillin for enterococcus, metronidazole or clindamycin for anaerobes, and a third-generation cephalosporin or aminoglycoside for gram-negative bacteria have been used. However, carbapenems such as meropenem, imipenem, and ertapenem as single agents may be more cost effective, particularly if any outpatient antibiotic therapy is being considered. The β-lactam and β-lactamase inhibitor combinations (e.g., ticarcillin-clavulanate, piperacillin-tazobactam), with or without an aminoglycoside, also are likely to be effective.

Infections of renal origin, usually caused by *E. coli* or other gram-negative enteric organisms, can be treated with extended-spectrum cephalosporins such as ceftriaxone or, if abscesses have been drained successfully, with aminoglycosides such as gentamicin and tobramycin. The activity of aminoglycosides may be compromised by the acidic environment of abscess cavities and may lead to clinical failures despite in vitro susceptibility of the organism.[10] Increasingly, resistance to ampicillin is seen in *E. coli*,[2,4] rendering it unreliable for empiric use in severe urinary tract infections. *Pseudomonas* is not an uncommon pathogen in children with recurrent infections caused by anatomic genitourinary abnormalities.[2] *Pseudomonas* spp. usually are resistant to ceftriaxone; extended-spectrum cephalosporins, such as ceftazidime and cefepime, or carbapenems may be needed. Urine culture and susceptibility results help focus the choice of an antibiotic to the narrowest spectrum agent required.

Psoas abscesses and primary perinephric abscesses caused by *S. aureus* should be treated with an antistaphylococcal agent such as nafcillin (or oxacillin or methicillin) or a first-generation cephalosporin such as cefazolin. The prevalence of community-acquired methicillin-resistant *S. aureus* (CA-MRSA) has increased significantly as a soft tissue pathogen, particularly in children.[18,27] Vancomycin or clindamycin should be considered as empiric therapy for serious infections in areas with high rates of CA-MRSA (>5% of all invasive *S. aureus* infections) until culture results are available. These agents also may be effective in treating the patient who is unable to tolerate penicillin or cephalosporin antibiotics.

Infections originating in the vertebrae usually are caused by *S. aureus* or may result from tuberculosis. Empiric antistaphylococcal therapy can be started, but culture and histologic examination of tissue are needed to direct appropriate therapy. For the child with risk factors for acquiring tuberculosis, a positive tuberculin skin test result, and a negative Gram stain result, empiric therapy with three or four antituberculous antibiotics should be considered. A chest radiograph should be obtained to look for evidence of pulmonary tuberculosis.

After adequate drainage is achieved, the duration of antimicrobial therapy depends on several factors, including the organ-

ism, the site and extent of infection, and the clinical improvement. Most drained retroperitoneal bacterial abscesses of renal or muscle origin are treated for 2 to 3 weeks with initial parenteral and follow-up oral antibiotics. Infections involving bone may require 6 to 8 weeks or longer, depending on how quickly the infection responds to treatment. Radiographic studies, erythrocyte sedimentation rate, and C-reactive protein measurements can be helpful to monitor recovery. Tuberculous infections are treated for 6 to 12 months, depending on the presence of bone involvement. *Actinomyces* infection can be difficult to treat because of lack of susceptibility to many antibiotics and the need for prolonged courses of antibiotic therapy, preferentially with penicillin.

PROGNOSIS

Historically, retroperitoneal abscesses are reported to have high morbidity and mortality rates. However, with modern imaging techniques enabling physicians to make more timely diagnoses, the overall prognosis is good, and most children with no underlying disease recover without sequelae.

SECTION IX

MUSCULOSKELETAL INFECTIONS

CHAPTER 61

OSTEOMYELITIS

Paul Krogstad

The term *osteomyelitis* denotes inflammation of bone and marrow but generally implies the presence of infection. Osteomyelitis is considered acute if diagnosed within 2 weeks of the onset of symptoms, or subacute if symptoms have been present for more than 2 weeks at the time of presentation. Although bacteria are the most common cause, fungi, parasites, and other microorganisms also may cause osteomyelitis.[108] Acute osteomyelitis may evolve into a chronic process, especially if not treated adequately, leading to extensive necrosis of bone.

The incidence of osteomyelitis in normal children has been examined in several populations. Estimates have varied from 1 in 20,000 adolescent girls in New Zealand to 1 in 1000 Australian Aboriginals.[26,45,82] Boys seem to be at greater risk and contract the disease 1.2 to 3.7 times more often than do girls.[82,158,189] Osteomyelitis occurs most often in the first 2 decades of life. Approximately 25 percent of children with osteomyelitis are younger than 2 years old, and 50 percent are younger than 5 years old.[83,121,154,214] The incidence is increased in patients with sickle-cell disease and in some other immunocompromised patients (see the section on special populations).

Microorganisms can be introduced into bone in three ways: (1) by direct inoculation, usually traumatic, but also during surgery; (2) by local invasion from a contiguous focus of infection; and (3) by hematogenous delivery. In children, osteomyelitis generally is of hematogenous origin. Regardless of the route of infection, the common denominator is microscopic bone death. The goal of treatment is to arrest the infection and limit the extent of the injury to bone.

USUAL MICROBIAL ETIOLOGY

Although cultures frequently fail to identify bacterial pathogens in osteomyelitis, most microbiologically confirmed infections are caused by single organisms.[5,154,162] Gram-positive bacteria are responsible for most cases of osteomyelitis in children. *Staphylococcus aureus* is incriminated in 89 percent of cases of osteomyelitis in immunocompetent children.[83,171,207,211] Group A streptococci are next in frequency (Table 61–1). Historically, *Streptococcus pneumoniae* has been a frequent cause of osteomyelitis, but protein conjugate vaccines are likely to diminish markedly the incidence of pneumococcal osteomyelitis. In contrast, *Kingella kingae*, a fastidious gram-negative organism, is being identified increasingly in children as a cause of osteoarticular infection, including osteomyelitis, diskitis, and septic arthritis, and may explain many cases of culture-negative osteoarticular disease.[46,88,134,215,228] Even in more affluent countries, *Salmonella* spp. frequently are a cause of osteomyelitis in immunocompetent patients. *Salmonella* spp. are the most common organism found in cases of osteomyelitis in patients with sickle-cell disease (discussed later). (The microbiologic peculiarities of osteomyelitis in other immunocompromised patients and special populations are discussed in later sections.)

Other aerobic gram-negative bacteria are less common causes of osteomyelitis. Before the development of protein conjugate vaccines, *Haemophilus influenzae* was reported consistently in pediatric case series and caused approximately 5 to 8 percent of cases.[121,154,171,211] As with other invasive *H. influenzae* infections, osteomyelitis caused by this organism usually occurs in children 3 months to 6 years of age.[62,71,89,199] With the advent of effective immunization, cases of *H. influenzae* osteomyelitis are noticeably absent from more recent case series.[5,83,114] Osteomyelitis caused by other gram-negative organisms is an uncommon finding but generally occurs in neonates and young infants. Hematogenous osteomyelitis caused by *Pseudomonas aeruginosa* has been associated with injection of illicit drugs.[102,128,223]

Four distinct clinical entities of infection caused by anaerobic bacteria are recognized: (1) bacteremic seeding of previously normal bones in children and young adults; (2) superinfection of a fracture site already infected with *S. aureus*; (3) indolent (months to years after surgery) infection of a prosthetic device; and (4) contiguous chronic infection,[201] which most often occurs in the skull and the extremities. *Bacteroides* spp. are found most commonly and are associated with paranasal, sinus, or mastoid infection. In most cases, a foul odor is noted when the bone is incised or the focus is opened; trauma often has been an inciting influence.[129]

As noted previously, most cases of osteomyelitis in children develop after an episode of bacteremia and are caused by a single organism. Polymicrobial infections generally reflect the spread of infection from contiguous infectious foci and most often occur in the skull, face, hands, or feet. Distal extremities compromised by vascular insufficiency or immobilized because of peripheral neuropathy also are sites of polymicrobial osteomyelitis (including paraplegia caused by spina bifida). Osteomyelitis caused by fungi and atypical bacterial pathogens occasionally occurs in children and is discussed in greater detail later.

HEMATOGENOUS OSTEOMYELITIS

PATHOGENESIS

In long tubular bones, hematogenous osteomyelitis generally begins in the metaphysis, the broad cancellous end of the bone shaft adjacent to the epiphyseal growth plate. The cartilaginous epiphyseal growth plate (the physis) is nourished by diffusion of nutrients from a narrow plexus of capillaries fed by the metaphyseal branches of the nutrient artery; these capillaries drain into a large sinusoidal plexus that ultimately joins the large sinusoidal veins in the bone marrow (Fig. 61–1).[100] Trauma or emboli lead to occlusion of the slow-flowing sinusoidal vessels, establishing a nidus for infection. Blood-borne bacteria can seed the poorly perfused area and proliferate.[40,111,209]

The high frequency of *S. aureus* in osteomyelitis may reflect specific pathogenic properties of the organism. It has the ability

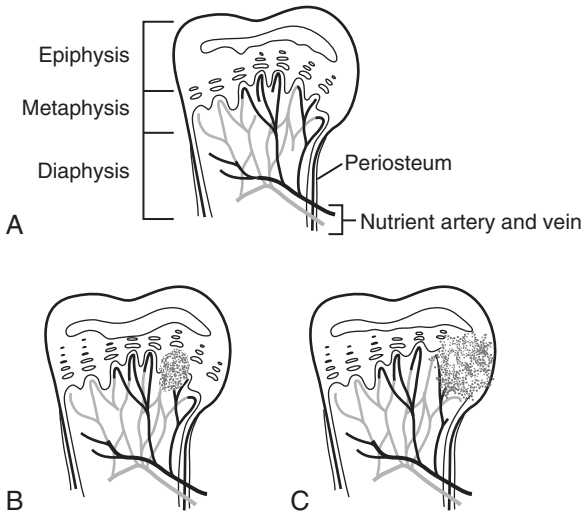

Figure 61–1 **A,** The sluggish blood flow in the sinusoidal venous connections located at the metaphyseal-epiphyseal junction predisposes to the development of traumatic thrombosis and infarction. **B,** Bacteremic seeding of the avascular area initiates the infection, which spreads through the Volkmann canals and the haversian systems and causes septic thrombosis. **C,** Infection tends to spread laterally through the cortex and elevates or ruptures through the periosteum.

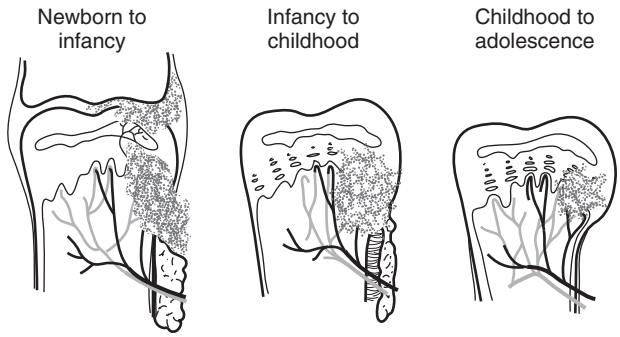

Figure 61–2 In young infants and neonates, particularly in the hip where the epiphyseal growth plate is traversed by nutrient vessels terminating in the distal ossification center, septic thrombophlebitis of the nutrient vessels can lead to growth discrepancies. With the capsule of the joint extending to the metaphysis, rupture of the infection through the cortex leads to the development of septic arthritis. Because of the thin cortex and loose periosteum, the osteomyelitis may come to medical attention as a deep soft tissue abscess. In older infants and young children, the thicker cortex and denser periosteum are a greater barrier to infection. Local tenderness from subperiosteal edema or abscess is the rule. In late childhood and adolescence, the lesion is extremely well localized and rarely penetrates the bony cortex. In this age group, invasive procedures, such as windowing or drilling, are necessary to obtain infected material.

to adhere to type I collagen of bone fibrils.[32] When *S. aureus* binds to collagen, bacterial replication gives rise to microcolonies surrounded by a glycocalyx.[94] Continued injury, elicited by *S. aureus* exoproducts and the host cellular inflammatory response to the injury, causes the accumulation of exudate under pressure. The pressure compresses blood vessels of bone and produces focal bone necrosis. The low ratio of surface area to mass, combined with the blood vessel anatomy described earlier, interferes with reabsorption of necrotic cortical bone[40,111] and the effectiveness of host defense mechanisms.

Since the late 1990s, community-acquired methicillin-resistant *S. aureus* (CA-MRSA) isolates have become a common cause of musculoskeletal infections in the United States and other countries. As described further later, most of these CA-MRSA isolates carry genes encoding the Panton-Valentine leukocidin (pvl).[22] Pvl-positive CA-MRSA has been associated frequently with sepsis, venous thrombosis, and polyostotic disease, suggesting that this or other factors contribute to the development and severity of hematogenous osteomyelitis.[26a,140] The very early stages of osteomyelitis may be aborted by administration of appropriate chemotherapy. In the absence of therapy, necrosis of cortical bone and marrow continues. The exudate under pressure is forced through the haversian systems and Volkmann canals and into the cortex (see Fig. 61–1).

SIGNS AND SYMPTOMS

The bacteremic phase of hematogenous osteomyelitis may be entirely subclinical and associated only with malaise and low-grade fever, or it may be characterized by severe constitutional symptoms with a temperature of 40º C. The subsequent clinical manifestations of osteomyelitis are not related to the severity of initial constitutional signs of infection but are influenced by the age of the child and the etiologic agent (Fig. 61–2).

In newborns, the thin cortex and loosely attached periosteum are poor barriers to the spread of infection. Consequently, the purulence rapidly ruptures through both of these structures into the contiguous muscle bed. With progression of the infection, the purulent material often dissects the muscle bundles, with the

swollen, discolored limb taking the appearance of a sausage. In addition, nutrient metaphyseal capillaries perforate the epiphyseal growth plate in newborns, and the capsule of the diarthrodial joints frequently extends to or is slightly distal to the epiphyseal plate. These anatomic characteristics permit an infection arising in the metaphysis to involve the epiphysis and to extend into the adjacent joint cavity.

In older infants, the cortex (see Fig. 61–2) is thicker and the periosteum is slightly more dense. Consequently, the infection spreads less often to the soft tissues of the extremity. Subperiosteal abscess and contiguous edema readily develop, however. The nutrient metaphyseal capillaries in older infants are atrophic, which, although more recently disputed,[159] is thought to decrease the risk of spread of infection into the adjacent joint space. The subperiosteal purulence almost always is at the metaphysis, the area in which the cortex is the thinnest.[91]

In children and adolescents (4-16 years old), the metaphyseal cortex is considerably thicker, with a dense, fibrous periosteum. The pathogenesis of the infection is the same in this age group, but the infection rarely ruptures and spreads to the outer cortical lamellae. As a result, the signs and symptoms of osteomyelitis in these older children and adolescents usually are more focal.

A newborn with osteomyelitis usually is irritable and displays evidence of pain when the affected extremity is touched or moved. Pseudoparalysis may occur, and if the disease remains untreated, massive swelling of the extremity may be seen. Obtaining a plain radiograph is invaluable in this age group; most of these patients have changes consistent with osteomyelitis on the initial radiograph.[118,147,220] In infants and young children, pain usually is present, as is a limp because osteomyelitis occurs more commonly in the lower extremities. The child refuses to use the affected extremity and displays variable constitutional symptoms.

In older children and adolescents, less restriction of function of the extremity is found compared with infants and young children. The point tenderness is circumscribed more sharply and may be found only as a small area of discomfort at rest. This disease most often affects the lower extremities and produces a mild limp. Most commonly, tubular bones are involved, but osteomyelitis occurs throughout the skeleton (Table 61–2). The hallmark of the disease is the focal nature of symptoms; point tenderness and well-localized pain suggest the diagnosis. Percussion of the long bone away from the area of point tenderness often elicits pain at the site of osteomyelitis in older children and adolescents.

The clinical features of osteomyelitis are influenced by the organisms involved. Osteomyelitis caused by CA-MRSA seems to be more complex and severe than are infections caused by methicillin-susceptible *S. aureus* (MSSA). Life-threatening infections caused by CA-MRSA have been reported in adolescents, and polyostotic disease is more common (15% in one more recent series compared with 2% in a large series that preceded the emergence of CA-MRSA).[22,154] Myositis, pyomyositis, intraosseous and subperiosteal abscesses, and septic thrombophlebitis also seem to occur more frequently with CA-MRSA than with MSSA.[5,86,87,140] In contrast, osteoarticular infections caused by *Kingella* spp. generally have an indolent course, with limb pain often present for longer than a week before initial medical evaluation is made.[134,227] Osteomyelitis caused by *H. influenzae* seems to occur primarily in the upper extremities.[61,62,89,199]

Culture-negative osteomyelitis generally is mild. In one series comparing 45 culture-positive patients with 40 patients with culture-negative osteomyelitis, symptoms were of longer duration, and overlying skin changes were seen less frequently in patients with negative disease. Treatment with β-lactams generally was successful and associated with skeletal sequelae in only one case.[69] Whether these features of culture-negative osteomyelitis suggest a more effective host defense or infection by a less virulent and more fastidious pathogen, such as *K. kingae*, which has been identified in culture-negative disease, is unclear.[215]

Data from Nelson, J. D.: Acute osteomyelitis in children. Infect. Dis. Clin. North. Am. 4:513-522, 1990.

DIFFERENTIAL DIAGNOSIS

Osteomyelitis can be confused with many other conditions associated with fever, pain, and tenderness in an extremity, including fractures, rheumatic fever, septicemia, septic arthritis, cellulitis, Ewing sarcoma, leukemia, reflex neurovascular dystrophy, thrombophlebitis, bone infarction secondary to sickle-cell or Gaucher disease, and toxic synovitis.

DIAGNOSIS

The diagnosis of osteomyelitis generally is suspected based on typical findings, such as fever, focal skeletal pain, warmth, and swelling, and a limp or refusal to use an extremity. The diagnosis is confirmed by an organism shown by culture or Gram stain in an aspirate of bone, or by histopathologic analysis of surgical specimens. In an otherwise healthy individual, the diagnosis is probable when a patient has fever, leukocytosis, elevated acute-phase reactants (elevated C-reactive protein [CRP] or erythrocyte sedimentation rate [ESR]), or a positive blood culture plus one or more of the following: abnormal imaging studies (plain radiograph, magnetic resonance imaging [MRI], or computed tomography [CT]), scintigraphy, or physical findings consistent with osteomyelitis.

Microbiology

The cornerstone of the diagnosis of osteomyelitis is isolation of bacteria or other microbes from bone or from anatomic structures contiguous to bone. Overall, such cultures (bone, subperiosteal exudate, or joint fluid) provide a bacteriologic diagnosis in 66 to 76 percent of cases. Blood cultures yield an organism in about half of cases (36-74% of patients in three series).[154,207,212,215]

In neonates, needle aspiration of soft tissue or incision and drainage of bone may yield the offending organism. In infants and young children, subperiosteal needle aspiration can be done if the point tenderness is localized. In older children and adolescents, noninvasive culturing of the bone is less rewarding. In this age group, windowing or drilling to drain pus from the bone yields valuable material for culture but is controversial; some orthopedic surgeons consider the risk of causing epiphyseal damage and subsequent length discrepancy secondary to the procedure too great. Consequently, blood cultures and imaging methods often represent the extent of the diagnostic evaluation. Nonetheless, it is important to attempt to obtain bacterial cultures early in the evaluation of suspected osteomyelitis because decisions about the type and duration of antimicrobial therapy are greatly facilitated by knowing the susceptibility profile of the etiologic agent.

Radiology

PLAIN RADIOGRAPHS

Conventional radiographs are crucial in establishing the diagnosis of pediatric osteomyelitis and always should be obtained.[26a,39,96] Because bone density must decrease 50 percent to be detected by radiographs,[8] changes in the less ossified bones of neonates are detected more readily than are changes in older children. In contrast, Waldvogel and Papageorgiou[216] found in adults that plain radiographs were of no diagnostic value in 23 percent and were misleading in an additional 16 percent.

Radiographic changes occur in three stages.[34] The first stage, which occurs approximately 3 days after the onset of symptoms, is the formation of a small area of localized, deep soft tissue swelling, usually in the region of the metaphysis (Fig. 61–3). When diagnosis of osteomyelitis is sought early, examination of the radiograph should be directed to the soft tissue rather than the bone. During the second stage, which occurs 3 to 7 days after the onset of symptoms, swelling of the muscles with obliteration of the interposed translucent fat planes can be noted. It is caused by continued spread of edema fluid and can progress, particularly in neonates and young infants, to superficial soft tissue edema; the skin may acquire an orange-peel texture.

Radiographic evidence of bone destruction usually is not detected until 10 to 21 days after the onset of symptoms. The first changes detected include subperiosteal bone resorption, areas of bone destruction, and periosteal new bone formation. The variability depends on the specific bone involved; generally, long tubular bones tend to show bony changes 2 to 3 weeks earlier than membranous or irregular bones.

MAGNETIC RESONANCE IMAGING

MRI is becoming the imaging modality of choice when additional imaging is needed.[39] The major advantages of MRI are that it accurately delineates subperiosteal or soft tissue collections of pus that might require surgical drainage without using ionizing

Figure 61–3 **A,** The left knee of an infant shows diffuse soft tissue swelling around the proximal ends of the tibia and fibula. **B,** Six weeks later, the subcutaneous fat lines between the muscles and the skin can be seen, as can an involucrum involving almost all of the tibia.

radiation, and it can identify sinus tracts for removal (Fig. 61–4).[26a,68,164,197] MRI often provides more specific anatomic information than CT or plain radiography.

In acute osteomyelitis, bone marrow edema caused by the accumulation of purulent material leads to decreased signal on T1-weighted images. On T2-weighted images of the same area, increased signal is seen. With commonly used sequences, the sensitivity of MRI for the detection of acute osteomyelitis may approach 100 percent.[141] Fat-suppression sequences, including short-tau inversion recovery, decrease the signal from fat. Inversion recovery sequences allow more sensitive detection of bone marrow edema. MRI may have a particular advantage in establishing the diagnosis of spinal osteomyelitis because a clear distinction can be made between the vertebral body and the adjacent disk. Loss of this border is one of the first abnormalities detected by MRI in spinal osteomyelitis.

The need for sedation in most infants and children and the cost of MRI are the major disadvantages that continue to limit its use. In addition, infarction and other processes can alter the appearance of bone marrow and lower the specificity of MRI and must be considered in the interpretation of the imaging study.

RADIONUCLIDE IMAGING

Radionuclide scanning has been used for decades in the evaluation of suspected osteomyelitis. Despite the fact that bone scanning involves exposure to ionizing radiation, it continues to be used widely because of its ready availability and utility in detecting multifocal disease.[56] Bone imaging employing technetium 99m (Tc 99m) diphosphonate scintigraphy is used most frequently. After being injected, the phosphate adduct is adsorbed to the surface of the hydroxyapatite crystal in bone, and Tc 99m becomes concentrated in the cement line located at the junction of osteoid and mineralized bone.[204]

Most institutions perform a three-phase bone scan for evaluation of infection. Shortly after injection (2-5 seconds), a nuclear angiogram (flow phase) of the area of suspected osteomyelitis is obtained. The second phase (the blood pool phase) consists of a single image obtained 5 to 10 minutes after injection. The third image is obtained 2 to 4 hours after injection. In this later phase, specificity of the diphosphonate compounds for the bone is revealed. Anything increasing local blood flow to the area, particularly if accompanied by inflammation, results in increased general uptake in the first two phases, but osteomyelitis results in focal uptake in the third phase, with the intensity of the signal detected reflecting the level of osteoblastic activity.[36,48,50,56,80,119,180]

Acute osteomyelitis in children is often diagnosed by a Tc 99m scan and treated successfully before bone changes are detected by plain radiographs (see Fig. 61–4).[206] With sensitivity reported to be as high as 95 percent, bone scanning has until recently been a reliable tool in establishing the diagnosis of osteomyelitis.[34] Unfortunately, in one recent report, bone scintigraphy detected only osteomyelitis caused by community acquired-MRSA cases in 53 percent (26/49) of children.[26a] This apparent lack of sensitivity for CA-MRSA may reflect the acuity of disease caused by this pathogen, as changes in radionuclide scans are more characteristic when patients have had an illness of longer duration.[182]

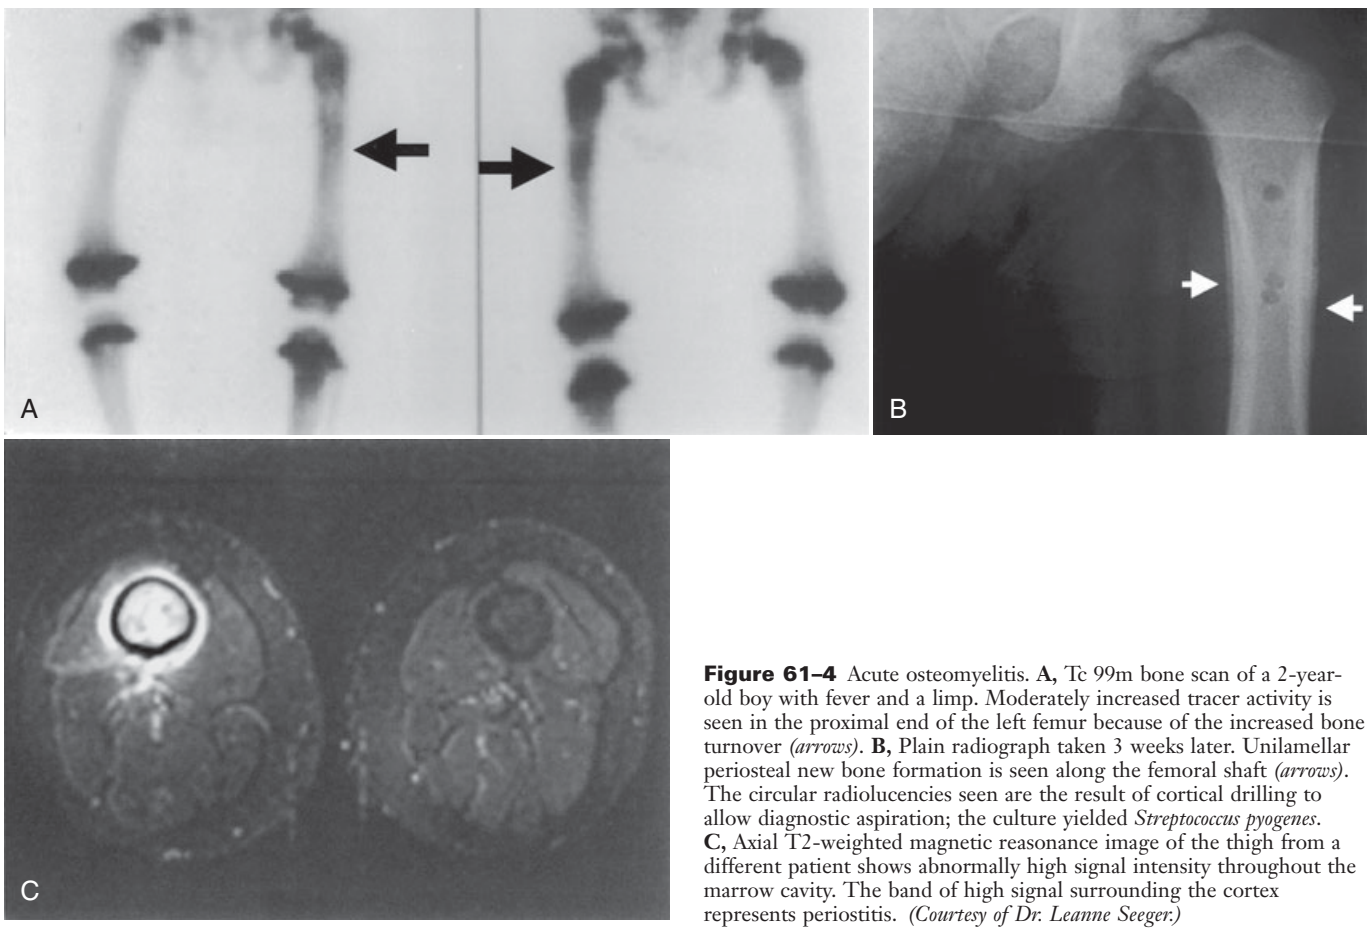

Figure 61–4 Acute osteomyelitis. **A,** Tc 99m bone scan of a 2-year-old boy with fever and a limp. Moderately increased tracer activity is seen in the proximal end of the left femur because of the increased bone turnover *(arrows)*. **B,** Plain radiograph taken 3 weeks later. Unilamellar periosteal new bone formation is seen along the femoral shaft *(arrows)*. The circular radiolucencies seen are the result of cortical drilling to allow diagnostic aspiration; the culture yielded *Streptococcus pyogenes*. **C,** Axial T2-weighted magnetic reasonance image of the thigh from a different patient shows abnormally high signal intensity throughout the marrow cavity. The band of high signal surrounding the cortex represents periostitis. *(Courtesy of Dr. Leanne Seeger.)*

In addition, bone scans that use Tc 99m may be nondiagnostic in neonates.[6,71] Destruction of cortical bone occurs, and periosteal new bone formation often is present on plain-film radiographs of bones with normal Tc 99m uptake. The false-negative result of bone scans probably is due to the paucity of mineralization in neonates' bones. Ischemia of bone, probably caused by infarction, also has been noted on the initial bone scan.[147] Overall, the sensitivity of bone scans in neonates is uncertain, but may be only 30 percent.[71]

Older infants with osteomyelitis and a nondiagnostic Tc 99m bone scan also have been described.[17,95] In such instances, a gallium 67 (Ga 67) scan may be valuable. Ga 67 is a transition metal that, similar to iron, is bound to plasma proteins; the unbound portion (10-25%) is excreted in urine. It localizes in inflammatory foci because of increased capillary permeability (leaking plasma proteins), in vivo leukocyte labeling, binding to lactoferrin in the lesion, and perhaps direct bacterial uptake. Because of the slower elimination of gallium from blood, its uptake in an inflammatory focus depends less on blood flow. Delayed elimination often results in poor contrast of bone to soft tissue, however, and delays making a reliable interpretation for 24 to 72 hours after injection.[101] In one study, 15 of 16 cases of osteomyelitis with a nondiagnostic Tc 99m scan had changes on Ga 67 scan typical of osteomyelitis.[188] Combined evaluation with Ga 67 imaging and Tc 99m bone scanning may lead to greater diagnostic certainty when the studies are not conclusively diagnostic.[185,226] Despite these successes, Ga 67 scans are seldom employed because MRI, repeating plain radiographs, and clinical improvement during therapy usually are sufficient to resolve initial diagnostic uncertainties.

Numerous studies have been conducted to examine the utility of indium 111–labeled leukocyte scans for the diagnosis of osteomyelitis. This method involves removing leukocytes and injecting them back into the patient after in vitro labeling. It has a sensitivity of approximately 86 percent.[177] The sensitivity seems to be best for the detection of lesions in long bones. False-positive scans can result from a variety of processes, including fracture and infarction. Enthusiasm for this modality also is limited by the higher organ absorption of the radiation dose.[73] Numerous other scintigraphic methods for the detection of osteomyelitis, including Tc 99m hexamethylpropyleneamine oxime–labeled leukocytes and monoclonal antibodies, have been examined. At present, these alternative methods do not offer any advantage over MRI and older radionuclide imaging approaches.

COMPUTED TOMOGRAPHY

CT is used occasionally in the diagnosis and management of osteomyelitis because it provides excellent definition of cortical bone and high spatial resolution. CT abnormalities commonly found in osteomyelitis include increased density of bone marrow caused by the accumulation of purulent material and periosteal new bone formation and purulence. CT is particularly useful in detecting sequestra and delineating subperiosteal abscesses. It previously has been used to define infections of the spine; however, MRI has replaced CT for this indication.

TREATMENT OF ACUTE OSTEOMYELITIS

The need for surgical therapy must be considered immediately when osteomyelitis is diagnosed. Reports of soft tissue, subperiosteal, and intramedullary abscesses are becoming more common in the early 21st century, mirroring the increased prevalence of skin, soft tissue, and musculoskeletal infections caused by CA-MRSA.[5,112,140] MRI, ultrasound, and CT imaging may prove useful in assessing these purulent foci.[26a] Drainage of these sites by surgical or interventional radiology techniques also provides the opportunity to obtain cultures to confirm a microbiologic diagnosis. Sequestra, if present at presentation, should be removed. If contiguous infectious foci are present, they should be débrided adequately and treated with effective antimicrobial therapy. Immobilization of the affected extremity or splinting may afford relief from pain and sometimes is used to prevent the development of pathologic fractures when extensive bone involvement is detected by plain radiography.

Although the choice of antimicrobial agents used often is modified during a course of therapy, the therapy initially chosen always should have potent activity against *S. aureus* and group A streptococci because these pathogens represent the primary causes of osteomyelitis. Acute bacterial hematogenous osteomyelitis should be treated initially with parenteral anti-infective agents, in view of the high mortality rate in *S. aureus* osteomyelitis seen in the pre-antibiotic era and more recent reports of fulminant disease with CA-MRSA.[86,87,91,140] The choice of initial therapy has become more complex with the marked increase in prevalence of CA-MRSA in the United States and other countries.

In areas where most (≥90%) *S. aureus* isolates remain methicillin-susceptible, initial therapy may consist of a penicillinase-resistant, semisynthetic penicillin, such as nafcillin or oxacillin, administered parenterally in a dosage of 150 to 200 mg/kg/day in four divided doses.[90,105,171] Cefuroxime, a second-generation cephalosporin, also has been used for empiric therapy, with good results.[154] In areas where CA-MRSA is common, either vancomycin or clindamycin (if >90% of CA-MRSA isolates are susceptible) should be included in the initial empiric therapy for CA-MRSA.[112,139] Currently, most isolates of CA-MRSA remain susceptible to clindamycin, but clinical laboratories should screen for inducible macrolide-lincosamide-streptogramin resistance using the D-test or similar methodology[5,112,127]

Although protein conjugate vaccines have rendered invasive *H. influenzae* infections rare occurrences in the United Sates, antimicrobial coverage for this possibility may be considered for younger children who have not yet completed their immunization series. In these circumstances, addition of a third-generation cephalosporin (ceftriaxone or cefotaxime) to the empiric anti-staphylococcal agent (vancomycin, clindamycin, oxacillin, or nafcillin) might be warranted. Other agents may be administered when epidemiologic factors suggest the possible presence of other pathogens: third-generation cephalosporins or chloramphenical for *Salmonella* osteomyelitis, ceftazidime and aminoglycosides for *P. aeruginosa* or for enteric gram-negative organisms, and clindamycin for suspected anaerobic infections.[63,170]

When an organism is isolated or identified by other means, antimicrobial therapy can be chosen with greater specificity. Staphylococci should be treated with penicillin G if the organisms are susceptible to this antibiotic. In most cases, staphylococci must be treated with a penicillinase-resistant penicillin (oxacillin or nafcillin), clindamycin, or vancomycin. Ceftriaxone also has proved successful in the treatment of most cases of MSSA. Oxazolidinone (linezolid) and streptogramin (quinupristin-dalfopristin) drugs have been used successfully for the treatment of osteomyelitis in some adults with MRSA and MSSA[54] and for the treatment of vancomycin-resistant enterococci. They may prove useful in cases of pediatric osteomyelitis caused by *S. aureus* with decreased susceptibility to vancomycin, but experience with these agents is still limited.

Trimethoprim-sulfamethoxazole and the lipophilic tetracyclines (minocycline and doxycycline) have been used successfully in the treatment of osteomyelitis in children and adults and are readily absorbed by the oral route. Experience with these agents in treating CA-MRSA infections in which pneumonia and bacteremia seem to be common is limited, however, and the potential

for dental staining should be considered with the tetracyclines. Daptomycin, a bactericidal lipopeptide antimicrobial agent, has excellent activity against CA-MRSA, but pediatric pharmacokinetic data and clinical experience also are limited. Daptomycin seems to have poor activity in lung tissue. Reports of pneumonia and sepsis in association with osteomyelitis add to concerns about the utility of daptomycin for the treatment of osteomyelitis.[86,87,112]

Osteomyelitis caused by *S. pneumoniae* strains with decreased susceptibility to penicillin have been managed successfully with a variety of agents, including ceftriaxone, vancomycin, and clindamycin.[24] β-Lactam antibiotics, including oxacillin, nafcillin, and cephalosporins, have been used successfully in the treatment of *K. kingae* infection.[46,88,227,228]

Decades of experience and clinical investigation have led to wide acceptance of sequential use of the intravenous and oral routes of administration of antibiotics to treat pediatric osteomyelitis, which previously was controversial. Completing treatment with oral therapy avoids the cost, pain, inconvenience, and well-known complications of long-term administration of intravenous antibiotics. Central venous catheters have not obviated these concerns. To the contrary, local skin infections, bacteremia, and malfunctions of the catheters seem to be common occurrences, especially among young children.[175]

Oral therapy is most likely to succeed, and oral therapy is an acceptable option when the following criteria are met: An organism has been identified, the patient has the ability to swallow and retain an appropriate medication, the laboratory is able to monitor the degree of antibiotic absorption, and the patient has a clear clinical response to intravenously administered antibiotics.[154,156] In most series in which oral therapy has been evaluated,[29,52,154,203,217] treatment was continued with intravenous antibiotics until the patient was afebrile, until local signs and symptoms of infection were reduced considerably, and until the patient was maintaining caloric and fluid balances by the oral route. In severe or complicated cases, an advisable approach is to delay switching to the oral route until the peripheral leukocyte count has normalized, and the ESR has decreased by 20 percent or more, or until a marked decrease in the concentration of CRP has occurred.[171,212] A review of case series employing sequential therapy affirmed these recommendations and found no evidence that a fixed period of intravenous therapy is beneficial or essential. A transition to oral therapy within 7 days of diagnosis seemed to be equal in outcome to therapy with a fixed initial period of parenteral therapy.[126]

When oral therapy is begun, most antibiotics administered orally for osteomyelitis must be given in doses higher than the doses used for the treatment of other infections.[8,155,203] Specific antibiotics and the recommended starting doses are listed in Table 61–3. Dosages of β-lactams often can be increased to 200 mg/kg/day without having serious adverse side effects. Diarrhea, an infrequent complication of high-dose, oral β-lactam therapy, can be mitigated by a reduction in dose and the administration of probenecid (40 mg/kg/day every 6 hours; maximal dose 2 g/day).[29,154,203] Clindamycin readily achieves high bone levels and does not require higher dose therapy when given orally.[113,139]

TABLE 61–3 Initial Antibiotic Doses for Oral Treatment of Osteomyelitis

Drug	Dose (mg/kg/day)	Interval between Doses (hr)
Amoxicillin	100	6
Cephalexin	150	6
Chloramphenicol	75	8
Clindamycin	40	8
Cloxacillin	125	6
Dicloxacillin	100	6
Penicillin V	125	4

Data from references 29, 76, 154, 203.

The assumption implicit in successful oral therapy is that the antibiotic reaches an effective concentration at the focus of infection. Compliance with the prescribed dose and frequency and absorption into the bloodstream are necessary to fulfill this assumption. Patient (or parent) education and a continuing time commitment by a physician or nurse are essential to maintaining the compliance required for successful treatment. Although eschewed by some physicians,[137,158] therapeutic drug monitoring is recommended by some specialists to show that adequate absorption of orally administered antibiotics is occurring.[155] Rare patients have inadequate serum levels despite receiving high oral dosages.[203] If bacteria have been isolated from the patient, a peak serum bactericidal titer of 1:8 or greater is sought.[165,203]

A disadvantage of assessing serum bactericidal activity is the difficulty of performing the test when other antibiotics are present in the serum sample. Nafcillin administered intravenously would interfere with evaluating the bioactivity of dicloxacillin. Chemical assays of a specific agent circumvent this problem. Dicloxacillin can be administered orally and the dose adjusted based on dicloxacillin measurements before the intravenous administration of another β-lactam has been discontinued. This procedure avoids several days of inadequate therapy should the dosage of the oral agent need to be adjusted.

In most cases, clinical improvement is evident within 3 to 7 days of the initiation of appropriate therapy. To help show that effective therapy is under way, it is helpful to monitor acute-phase reactants. Although CRP and ESR typically increase during the first 3 days of therapy, CRP then begins to decrease rapidly, and typically returns to normal in 7 to 10 days. CRP returns to normal levels in blood more rapidly in children with an uneventful clinical course than in children who ultimately require repeated surgical drainage.[171] A slow decline in serum CRP to normal levels has been associated with more extensive radiographic changes or persistent symptoms 1 to 2 months after discharge from the hospital. Similar to CRP, ESR generally increases during the first several days but declines in the weeks that follow.[212] Failure of ESR to decrease during the second week of treatment may indicate a need for surgical drainage or the development of chronic osteomyelitis.[196]

The outcome of acute osteomyelitis depends heavily on the duration of therapy. In one early report of 45 cases of osteomyelitis, four treatment failures occurred; all had been treated for 10 days or less.[97] Likewise, Dich and colleagues[52] noted a 19 percent failure rate in 37 patients treated for 3 weeks or less; the rate was 2 percent in 48 patients treated for 21 to 50 days. Blockey and Watson[21] provided similar data. The minimal duration of therapy for hematogenous osteomyelitis to minimize the risk of recurrence seems to be more than 3 weeks. A conservative but individualized approach is to administer antibiotics until ESR and CRP are within the normal range, which usually requires 4 to 6 weeks of treatment.[112,154-156,196]

SPECIAL MANIFESTATIONS OF HEMATOGENOUS OSTEOMYELITIS

EPIPHYSEAL OSTEOMYELITIS

Rarely, hematogenous osteomyelitis may arise in the epiphyses of the tubular bones of young children.[78,133,208] Although the pathogenesis is unclear, it may involve delivery of microorganisms to the epiphyses by transphyseal vessels. After the child

reaches 15 to 18 months of age, these vessels are lost, and the physis acts as a physical barrier to the spread of infection from the metaphysis. The vascular anatomy of the epiphysis is very similar to that of the metaphysis, however, and in some cases infection may occur when bacteria are delivered to venous sinusoids by terminal branches of the epiphyseal arteries.

Hematogenous epiphyseal osteomyelitis may be acute or subacute. In the acute manifestation, septic arthritis initially may be diagnosed when joint swelling occurs, and abnormal fluids are removed by diagnostic aspiration. In cases with a more indolent course, pain, limp, or other symptoms prompt an evaluation for the possibility of an osteoarticular infection. The correct diagnosis typically is established when a radionuclide bone scan or plain radiographs taken weeks later show evidence of increased bone turnover or the lytic changes characteristic of osteomyelitis. Administration of appropriate therapy for epiphyseal osteomyelitis has been followed by complete recovery without apparent sequelae 2 to 6 years after diagnosis.

INVOLVEMENT OF NONTUBULAR BONES

Less than 20 percent of all cases of osteomyelitis involve nontubular bones. Infection of the calcaneus seems to be the most common.[154] In patients with hematogenous infection, destruction occurs just under the epiphyseal line in the metaphysis posteriorly and medially, where the blood supply is greatest. It is present in all patients, in addition to destruction of the adjacent epiphysis, particularly in its middle to superior portion. Periosteal new bone formation occurs very late, with 3 to 4 months required for reossification. Osteomyelitis in the other cuboidal bones rarely occurs.

Almost equal in frequency to infection of the calcaneus is infection of the bones of the pelvis.[154] Of the bones of the pelvis, the ischium is involved most commonly. The next most frequently involved bone is the ilium, followed by the sacroiliac joint. The pubis is involved in only 20 percent of cases of pelvic osteomyelitis.[99,152] Pelvic osteomyelitis causes an increase in the ESR in nearly all patients, and two thirds have a peripheral leukocyte count greater than 10,000 cells/mm^3.[152] The most common organism causing pelvic osteomyelitis is *S. aureus*, which is isolated from either blood or an aspirate from the bone lesions in approximately 80 percent of cases.

Establishing the diagnosis of pelvic osteomyelitis often is difficult. Most patients are judged to have disease in the hip at the time that medical attention is sought. Most often, patients with pelvic osteomyelitis have hip pain and a gait abnormality but allow their hips to be put through a passive range of motion. Point tenderness at the site of the lesion can be elicited in approximately 50 percent of these patients. Sacroiliitis frequently is difficult to identify by clinical examination. Pressing down on the pelvis, which stresses the sacroiliac joint, produces local pain. Tenderness in the buttocks or the sciatic notch, if present, is an invaluable diagnostic finding.[1,38,55,148,221] Pelvic osteomyelitis can mimic appendicitis and urinary tract infection[221]; it occurs more frequently in individuals with inflammatory bowel disease. In most patients, plain films of the pelvis are not rewarding, whereas Tc 99m bone scans indicate the diagnosis in approximately 90 percent of cases.[135,152] CT may reveal infection not evident by bone scanning. MRI also is likely to identify pelvic osteomyelitis.[210]

Antibiotic therapy alone is adequate in most cases of pelvic osteomyelitis. Surgery is indicated only when a lack of response to antimicrobial therapy occurs. Osteomyelitis in the pelvic bones has a uniformly good prognosis; chronic infection and sequelae are rare events.

Hematogenous osteomyelitis of the flat bones occurs rarely. It has been described in the skull, ribs, sternum, and scapula.[83,149,154,211]

SPINAL OSTEOMYELITIS

Spinal osteomyelitis can involve either the intervertebral disk or the vertebral bodies per se. Conceptualizing these infections as different entities is worthwhile because of the different pathophysiology and prognosis.[65]

DISKITIS

The intervertebral disk consists of three components: the paired cartilaginous articulation, the fibrous ring (annulus fibrosus), and the nucleus pulposus.[23,65] The axial vessels that parallel the fetal notochord are atrophied by birth, with the avascular, mucilaginous nucleus pulposus remaining. The disk has two arterial supplies: periosteal vessels and vessels descending from the central portion of the vertebral body.[42,64] The vessel from the central portion of the adjacent vertebra begins to atrophy in the first year and is obliterated completely by the time the child is 10 years old. This condition leaves only the capillary network in the annulus fibrosus, which is derived from the terminal radial ramifications of the periosteal vessels. If loss of this vascular supply is precipitous, idiopathic disk necrosis ensues, usually manifested as asymptomatic calcification.[178,194,200] If bacteremia occurs during loss of the blood supply, however, infection of an intervertebral disk may occur.

Infection of an intervertebral disk has no sex preponderance, and most children are younger than 5 years old.[65,184] It occurs almost exclusively in the lumbar region (the L4 and L5 disks are involved most frequently, followed by L3 and L4). The disease comes to medical attention with the patient's refusal to walk. Backache and a progressive limp may be present. Nonambulatory infants often become irritable and refuse to sit. On examination, the most striking feature is percussion tenderness over the contiguous spine; hip pain and stiffness with loss of lordosis of the lower part of the back are observed. Occasionally, compression of the spine produces pain at the infected disk. The mean duration of symptoms before diagnosis is established ranges from 1 day to 18 months. Most patients have had symptoms for several weeks.

Lesions in higher locations (T8 to L1) can mimic gastrointestinal disease with abdominal pain, ileus, and vomiting, but the most important entities in the differential diagnosis are vertebral osteomyelitis and spinal or paraspinal tumors. Most patients have a history of a recent upper respiratory infection.[116,122,169,174,187] Fever generally is absent or low-grade. Peripheral leukocytosis is present in one third of patients, and virtually all have an increased ESR. A few patients undergoing biopsy have cultures that grow microorganisms. Most commonly, *S. aureus* is recovered, along with rare isolates of pneumococci and gram-negative organisms, including *K. kingae*. Evaluation for suspected diskitis usually involves careful elicitation of the history and physical examination, a complete blood count, determination of the ESR, a blood culture, and plain lateral radiographs of the lumbosacral spine.[65]

Typical plain radiographic findings are shown in Figure 61–5. The first finding is narrowing of the disk space, usually not detectable until 2 to 4 weeks after the onset of symptoms. Frequently, this narrowing is overlooked if loss of the normal progressive (from cephalad to caudad) increase in disk width is not appreciated. It is followed by destruction of the adjacent cartilaginous vertebral end-plates and, subsequently, by herniation of the disk into the vertebral body. Rarely, compression or wedging of the vertebral body is noted. In older children, anterior spontaneous fusion is a common finding. In all individuals, reactive bone proliferation is a rare finding, as are paravertebral soft tissue masses.

Because of overlap of this syndrome with noninfectious disk necrosis, investigators in the earlier literature advocated treating

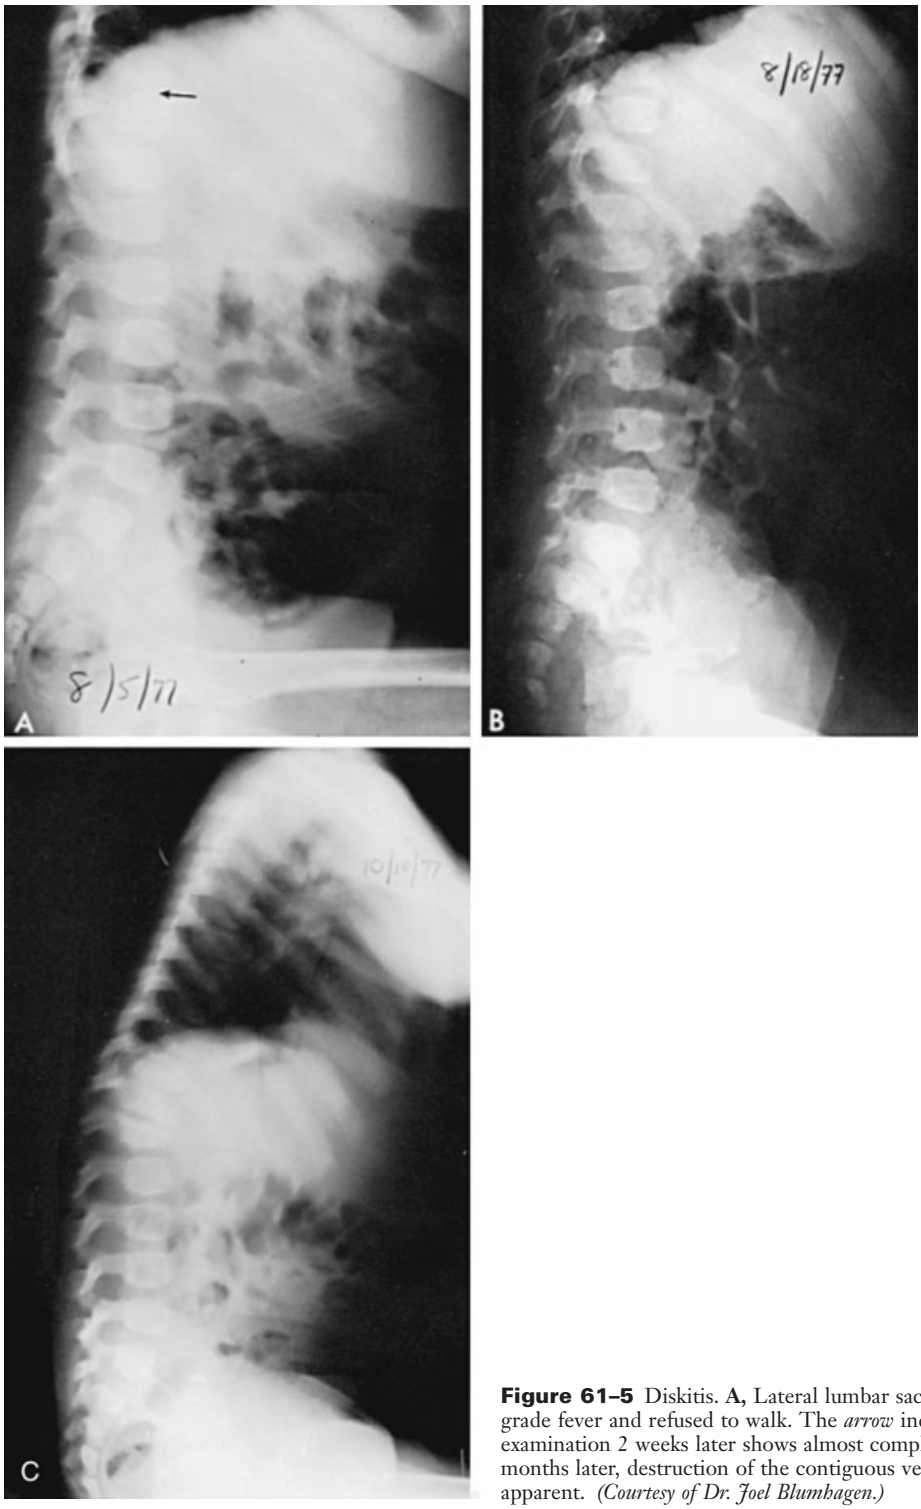

Figure 61–5 Diskitis. **A,** Lateral lumbar sacral spine of a 13-month-old child who had low-grade fever and refused to walk. The *arrow* indicates the narrow disk space. **B,** Follow-up examination 2 weeks later shows almost complete collapse of the intervertebral body. **C,** Two months later, destruction of the contiguous vertebra with marked kyphosis was apparent. *(Courtesy of Dr. Joel Blumhagen.)*

this disease solely by bed rest. In view of the low yield and generally favorable prognosis of diskitis, biopsy or aspiration for culture generally is unnecessary. Although controversial, oral antistaphylococcal therapy often is administered for a prolonged period (5-6 months).[65] Other physicians have suggested giving 5 to 7 days of intravenous antistaphylococcal therapy, followed by 7 to 14 days of a similar oral agent.[44] Very young children generally do well, and the disk space is preserved; spontaneous spinal fusion occurs commonly in older individuals.

VERTEBRAL OSTEOMYELITIS

The intervertebral disk loses its vascular supply with age, a process usually completed by 30 years of age. As a result, bacteremic pyogenic infections of the spine occur most often in the vertebral bodies. The venous drainage of the vertebral bodies is composed of three different freely communicating, but valveless, systems. Intraosseous vertebral veins drain the center of each body and form a large channel that exits through the nutrient

foramen. They anastomose with the anterior and posterior internal plexus (between the dura mater and the vertebral body). The internal venous plexus has anastomotic connections with the external venous plexus through the vertebral ligaments. The external venous plexus communicates freely with the segmental veins on the ventral surface of the body wall (Batson plexus).

Reversal of blood flow or thrombosis in the sluggishly flowing vertebral veins is thought to be the first event in the development of vertebral osteomyelitis. Because of the vascular communication, osteomyelitis usually involves two adjacent vertebral bodies, with the interposed disk initially skipped. The same process of septic thrombophlebitis involving the internal venous plexus can produce an epidural abscess (with cord compression) and infarction of the vertebral body. Spread along the external venous plexus can lead to a paraspinous mass. In the thoracic area, it may produce mediastinitis,[47] and in the cervical area, a retropharyngeal abscess can occur. The lumbar area is involved much more frequently than is the thoracic area, which is involved more frequently than is the cervical region.[2,110,193]

Children with vertebral osteomyelitis usually are older than 8 years of age and seek medical attention because of constant back pain. They may appear toxic and have a low-grade fever (>39º C) after an indolent course (2 weeks to several months).[65] Percussion of the spinal dorsal process frequently elicits exquisite tenderness. Usually, the paraspinous muscles around the involved vertebrae are in spasm, with rigidity of the area. Radiographic examination of a patient with vertebral osteomyelitis shows the earliest change to be localized rarefaction of one vertebral plateau, followed by involvement of adjacent vertebrae. Marked destruction of the bone, usually anteriorly, is followed by abundant anterior osteophytic reactions with bridging and bone sclerosis (Fig. 61–6).

Obtaining an MRI study is useful in establishing the diagnosis of vertebral osteomyelitis[146] because the vertebral disk and the vertebral body are clearly discernible. Most cases of vertebral osteomyelitis begin at the margin between the disk and the anterior part of the vertebral body. In some cases, MRI has detected evidence of osteomyelitis when radionuclide imaging studies were normal.[205] Distinguishing pyogenic osteomyelitis from tuberculous lesions radiologically is impossible, but the latter usually are characterized by less bone destruction, less bone proliferation, and less sclerosis. The osteophytic bridging between adjacent vertebrae is extremely rare in spinal tuberculosis.

Tc 99m and Ga 67 are taken up by the lesion in vertebral osteomyelitis. A possible advantage of scanning with both isotopes is identification of paraspinous abscess with Ga 67,[176] but MRI probably would accomplish the same goal.

Most cases of vertebral osteomyelitis are caused by *S. aureus.* Organisms causing urinary tract infection can cause osteomyelitis, presumably by local spread through Batson plexus.[27,98,124] Urinary tract infection rarely precedes the development of vertebral osteomyelitis, however, and only approximately 2 percent of all cases can be shown to be related to infection of the urinary tract.[77] The best method of establishing the diagnosis is through examination of bone biopsy specimens and cultures.[153] *P. aeruginosa* also has been recognized as a pathogen in vertebral osteomyelitis. All patients were intravenous drug abusers, and the organisms presumably were inoculated along with the illicit drug. Young heroin addicts have been found to have *P. aeruginosa* infection in their intervertebral disks.[28,181] In areas of the world where brucellosis is endemic, spinal osteomyelitis caused by *Brucella* spp. needs to be considered.[130] Fungal pathogens causing vertebral osteomyelitis include *Coccidioides immitis* in endemic areas and *Candida* spp. (often in immunocompromised patients).[144] *Bartonella henselae* also has been found to cause vertebral osteomyelitis.[65]

Therapy for spinal osteomyelitis includes immobilization. Whether immobilization should be accomplished by simple bed rest or with a body cast is controversial. Administration of an antibiotic always is indicated. The average duration of treatment of bacterial vertebral osteomyelitis is 2 months; however, no data are available that can be used for determining the most appropriate duration of therapy. The need for surgical drainage in some cases should not be overlooked because spinal cord compression caused by an epidural or subdural abscess can lead to permanent paraplegia. A paraspinal mass may rupture into the abdominal cavity or erode the aorta; both events are catastrophic complications.[72] The optimal therapy for fungal infection of the vertebra is unclear.

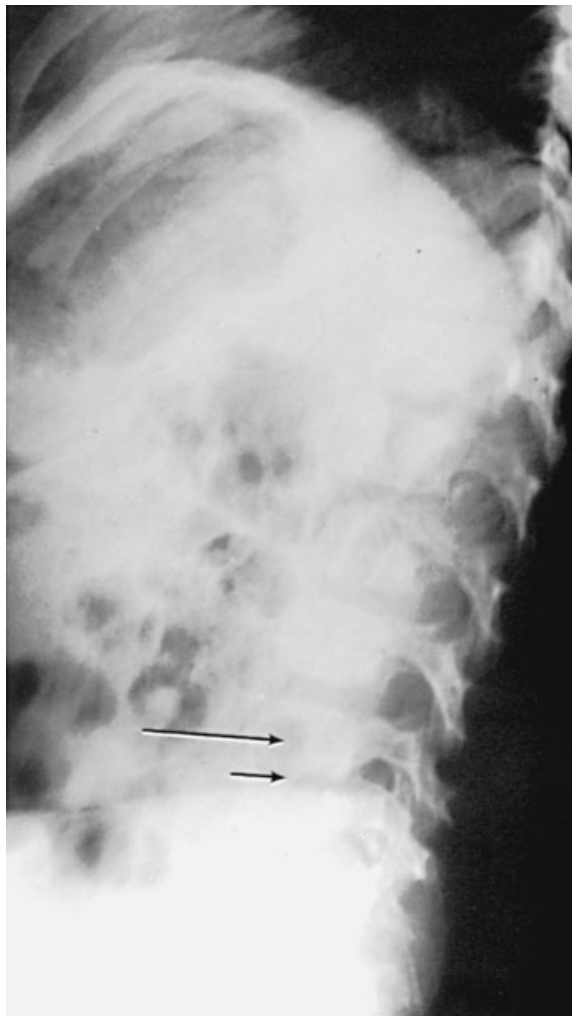

Figure 61–6 Vertebral osteomyelitis. The *large arrow* indicates the lytic lesion with some anterior sclerosis in the lumbar vertebra. The *small arrow* indicates involvement of the adjacent lower vertebra and narrowing of the disk space. *(Courtesy of Dr. Joel Blumhagen.)*

BRODIE ABSCESS

Osteomyelitis occasionally is indolent in presentation. Perhaps the best defined example is subacute osteomyelitis with the development of an intraosseous abscess (Brodie abscess).[191] These patients most often are adolescents with complaints of long bone pain and tenderness. A bony defect with sclerotic margins is detected by plain radiography in most patients. A distinctive "target" lesion has been described in MRI studies of

Brodie abscesses.[138] Concentric layers are seen and reflect a central abscess cavity surrounded by an inner ring of granulation tissue, an outer ring of fibrotic reaction, and a peripheral rim of endosteal reaction that is hypointense on T1-weighted images.

ESR usually is normal. Treatment consists of surgical drainage and curettage followed by antimicrobial therapy, as for other forms of hematogenous osteomyelitis. A variety of organisms, including *H. influenzae*, have been isolated from these lesions,[120] but *S. aureus* and other gram-positive cocci are the pathogens usually involved. The prognosis generally is good, although deformities occur in some cases.

HEMATOGENOUS OSTEOMYELITIS IN SPECIAL POPULATIONS

OSTEOMYELITIS IN NEWBORNS

Infection of the bones of newborns has distinct physiologic and clinical features that warrant emphasis.[7,49,226] Although it is rare, neonatal osteomyelitis may occur in newborns with certain risk factors, such as prematurity, skin infections, and complicated delivery.[72,118] As indicated earlier, the epiphyseal-metaphyseal junction frequently is within the joint capsule, and blood vessels that penetrate the epiphysis are common findings, particularly in the hip, shoulder, and knee of the newborn.

In newborns, osteomyelitis in the long tubular bones frequently (50-70% of cases) is accompanied by contiguous septic arthritis. Fever is present in one third to one half of the newborns; of these, half have a septic or toxic appearance. Half of infants have multiple bones involved. Antecedent infections are present in half of the cases and usually are nosocomial; infections of heel puncture sites, arterial cannulas, lungs, and cut-down sites and cephalhematoma have been described.[7] *S. aureus* is the etiologic agent in more than 90 percent of cases; gram-negative bacilli cause a few cases. Osteomyelitis often is identified when a search is instituted for the source or focus of bacteremia.[226] As noted earlier, plain radiographs often reveal evidence of osteomyelitis at the time of diagnosis, whereas bone scanning may be negative. Bone scanning may be useful, however, in excluding the diagnosis of osteomyelitis; in one study, the negative predictive value was estimated at 82 percent.[226]

Although staphylococci seem to be the most common cause of osteomyelitis in infants, group B streptococci have been found consistently.[58] Infants with group B streptococcal osteomyelitis generally are older (2-4 weeks old), have no recognized preceding infection, and have only a single bone involved, often the right tibia or humerus.[7]

Osteomyelitis in the skull, an uncommon disease, can occur in neonates. Frequently, it is associated with a cephalhematoma, with or without loss of skin integrity,[123] but it can be caused by fetal monitoring without a cephalhematoma.[142] Numerous bacteria have been isolated from such lesions; as one might expect, most of these bacteria have been present as vaginal flora. Radiographic changes (i.e., bony erosion) are a late finding, but CT of the skull seems to assist in establishing the diagnosis. Infection of a cephalhematoma should be considered if it is enlarging, if it is inflamed, or if laboratory evidence of infection is present, such as an increased CRP concentration or leukocyte count. In most cases, the lesion is drained and treated with an antibiotic appropriate for the infecting organism.

In older descriptions of neonatal osteomyelitis, sequelae were common findings. In more recent series,[118,224] approximately three fourths of all cases have had good outcomes, even when the hip has been involved. When seen, sequelae include avascular necrosis of the femoral head, bony deformities, and shortening of the involved limb.[161]

OSTEOMYELITIS IN LONG-TERM HEMODIALYSIS PATIENTS

Patients undergoing long-term hemodialysis, with multiple invasions of the vascular compartment, seem to be at greater risk for development of hematogenous osteomyelitis.[125] Their indwelling intravenous cannulas can be colonized with coagulase-negative staphylococci or *S. aureus*, and osteomyelitis may develop. The thoracic spine and ribs are the bones most commonly involved; other tubular and cuboidal bones that have been traumatized also can become infected.

OSTEOMYELITIS IN CHILDREN WITH HEMOGLOBINOPATHIES

After pneumonia, osteomyelitis is the most common serious infection in children with sickle-cell disease.[11] Children at risk are children with hemoglobin SS, hemoglobin S-Thal, or hemoglobin SO-Arab and certain children with hemoglobin SC disease.[93,186] The clinical manifestations of osteomyelitis are similar to those of other children with osteomyelitis, but there is a propensity for simultaneous involvement of multiple sites, a tendency toward recurrence, and a greater frequency in children 18 to 48 months of age.

As noted earlier, the microbiology of osteomyelitis in children with sickle-cell disease is complex and dominated by *Salmonella* spp.[11,31] Seventy percent of all lesions or blood cultures in children with hemoglobinopathy and presumptive osteomyelitis yield *Salmonella* microorganisms; 10 percent contain *S. aureus*; and aerobic gram-negative rods, including *Shigella sonnei*,[173] *Escherichia coli*,[92] *Serratia* spp.,[70] and *Arizona hinshawii*,[103] are isolated in 7 percent. Although *Salmonella* osteomyelitis occurs in less than 1 percent of normal patients with *Salmonella* bacteremia,[222] the frequency of *Salmonella* osteomyelitis in sickle-cell disease is several hundred times that occurring in the general population, with an incidence estimated at 0.36 percent per annum.[11,53,163]

Many factors probably contribute to the greater incidence of osteomyelitis in patients with sickle-cell hemoglobinopathy. Injuries to the intestinal mucosa from local thrombosis during a thrombotic crisis may facilitate the entrance of *Salmonella* and other enteric organisms into the bloodstream.[31,222] When infection of the bloodstream occurs, the splenic dysfunction in these patients may allow a prolonged period or greater magnitude of bacteremia. Evidence of impaired production of opsonic antibodies also exists. Whether bacteria lodge in infarcted bone, or whether a different pathogenesis exists is unclear. Infarction occurs in the capital femoral epiphysis, hands, feet, and vertebrae, whereas osteomyelitis involves the metaphyseal-diaphyseal junction of long tubular bones.[60,163]

Infants with hand and foot syndrome are not distinguished easily from infants with osteomyelitis of the phalanges of the hands or tarsal bones of the feet.[16,41,219] The changes caused by osteomyelitis that are seen on plain radiographs are more severe than the changes expected in uncomplicated sickle-cell disease. The most common radiographic findings are a longitudinal intracortical diaphyseal fissure and overabundant periosteal new bone formation. The cortical fissures are thought to represent a layer of purulent exudate in and between the periosteal new bone and dead bone.[53]

Radionuclide scans also are used frequently to help differentiate osteomyelitis from bone infarction. In theory, bone infarction should have decreased uptake of Tc 99m in the early "blood pool" phase of the scan; increased uptake would be found only as the lesion healed.[115] In one series with 34 sites of infarction, increased Tc 99m uptake occurred in 10, normal uptake occurred in 9, and decreased uptake surrounded by zones of increased concentration occurred in the remaining 15 sites.[81] Ga 67 or bone marrow scans of lesions with Tc 99m sulfur colloid

also may be valuable in differentiating infarction from infection; increased uptake of the radionuclide is seen more frequently with infection than with infarction.[166] Acute infarction and osteomyelitis cannot always be differentiated by MRI, perhaps because of pre-existing abnormalities in bone marrow. MRI may be useful, however, for presurgical evaluation. Ultrasound imaging also has been used to distinguish osteomyelitis and sickle-cell crisis and, if confirmed, may prove to be a useful adjunct to other imaging modalities.[23]

Generally, patients with bony infarcts have had dactylitis as an infant and multiple episodes; their temperature usually is less than 39º C. Children with hemoglobinopathy and osteomyelitis may lack this history and have a modest leukocytosis of immature granulocytes.[105] If fever, leukocytosis, and local symptoms persist despite provision of hydration and other supportive measures, needle aspiration of the area must be considered. Identification of an infectious pathogen is particularly important because of the large number of possible organisms involved.

OSTEOMYELITIS IN PATIENTS WITH HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Although recurrent invasive bacterial infections often complicate human immunodeficiency virus (HIV) infection in children and adults, few reports of osteomyelitis in these patients exist.[104,143,190] Many of the existing reports involve patients with recent intravenous drug use, which probably acted as a predisposing factor. *S. aureus* was recovered most commonly, although *E. coli*, *Salmonella enteritidis*, *Cryptococcus neoformans*, *Mycobacterium kansasii*, *Histoplasma capsulatum*, and other organisms also were seen in individual cases. To date, no evidence supports the view that the initial signs and symptoms or treatment needed for recovery from osteomyelitis is affected by co-infection with HIV.

OSTEOMYELITIS IN PATIENTS AFTER CLOSED FRACTURES

Acute hematogenous osteomyelitis sometimes develop after closed fractures of tubular bones occur.[33,218] The diagnosis generally is not recognized until fluctuation is apparent at the fracture site. A clue to diagnosis is that after the initial post-fracture pain has subsided, the pain of osteomyelitis occurs. It begins 1 to 6 weeks after the injury occurs. The pain differs from that associated with the fracture by being progressive, and it is not relieved by immobilization. When the cast is removed, local erythema and warmth are apparent and are increased when these findings would seem to be resolving if they were secondary to the fracture. Patients are febrile and may be thought to have another focus of infection before osteomyelitis is discovered. Anaerobic superinfection of staphylococcal osteomyelitis at the fracture site has been recognized.[201] Adequate débridement, administration of appropriate antibiotics, and external fixation have been used in such cases. The outcome varies, however.

OSTEOMYELITIS IN PATIENTS WITH CHRONIC GRANULOMATOUS DISEASE

The phagocytes of patients with chronic granulomatous disease fail to kill intracellular organisms, and infections with catalase-positive bacteria or fungi are frequent complications. Although staphylococci are a common cause of cutaneous infection in chronic granulomatous disease, osteomyelitis is caused most often by *Serratia* and *Aspergillus* spp. Osteomyelitis is attributed less often to staphylococci, *Pseudomonas*, *Burkholderia*, *Nocardia*, and other bacterial and fungal species.[225]

NONHEMATOGENOUS OSTEOMYELITIS

Nonhematogenous infections of the bone arise either through inoculation or from a contiguous focus of infection.

PUNCTURE WOUND OSTEOMYELITIS

Inoculation osteomyelitis most often involves either the patella or the bones of the foot. Soft tissue infections occur after puncture wounds of the foot approximately 15 percent of the time, and osteomyelitis occurs in 1.5 percent of these injuries.[67] Osteomyelitis of the foot that develops after children sustain puncture wounds should be termed *osteochondritis* because it commonly includes infection of the articular cartilage in the metatarsals. Most patients are aged 9 to 18 years. After the initial pain of the puncture wound subsides (in 24-48 hours), the signs of osteochondritis appear after another 48 to 72 hours. Typically, joint tenderness and localized swelling, erythema, and pain over the entrance of the puncture wound are present. Fever is an infrequent finding, and the patient seldom has any other constitutional symptoms. No peripheral leukocytosis is noted, and ESR is increased minimally.

Although the offending organism most commonly is *P. aeruginosa* (90% of the time), staphylococci, streptococci, *Stenotrophomonas maltophilia*,[9] and *Serratia marcescens*[151] also have been isolated.[25,67,106,107,109] In some series,[107] 20 percent of the cases involved infection with *P. aeruginosa* and *S. aureus*. The predominance of *Pseudomonas* can be explained partially on the basis of the mechanism of injury. *Pseudomonas* is not found commonly in surveys of the microbial flora of the skin of the feet,[85,145,198] but often it is found by culture of the sponge liner from children's sneakers.[66] In addition, many patients in whom *P. aeruginosa* osteochondritis develops have received prophylactic treatment with oral antibiotics that have activity against gram-positive bacteria. A semisynthetic penicillinase-resistant penicillin and an aminoglycoside or ceftazidime often are used as initial therapy.[106,107]

Surgical débridement of necrotic cartilage is a key element of treatment because foreign material frequently is found embedded in the soft tissue; débridement also provides the opportunity to identify organisms resistant to the initial antibiotic agents. The local signs and symptoms of infection usually resolve 4 to 5 days after adequate débridement is performed, and the patient is able to bear weight on the foot. In contrast, antibiotic therapy alone after diagnostic aspiration may need to be continued 6 to 8 weeks before weight bearing is possible. Long-term follow-up of *P. aeruginosa* osteochondritis indicates that many patients have asymptomatic radiographic abnormalities.[13] Radiographic abnormalities are found more commonly in patients in whom an adjacent joint was involved initially.[13]

Osteomyelitis also has been described repeatedly after puncture wounds occur from stepping on wooden toothpicks. In these cases, *Eikenella corrodens*, a member of the human oral flora, has been found with other organisms. Surgical débridement to remove toothpick fragments and drain local abscesses is essential.[168]

Osteomyelitis of the patella is a disease of children aged 5 to 15 years old, the time in life during which the patella is vascularized. By adulthood, the vessels are almost completely atrophied. In almost all cases, the diagnosis shows the cause to be by inoculation, such as kneeling on a needle. The most common etiologic agent is *S. aureus*; signs of osteomyelitis appear 1 week after the puncture occurs. No constitutional symptoms occur, but extension of the leg produces pain over the anterior aspect of the patella. The diagnosis is made by isolating the organism from the patella. Radiographic confirmation of the diagnosis often requires 2 to 3 weeks. Because the bone lacks periosteum, no periosteal

elevation is present, but rarefaction and sclerosis may be seen on the profile view or on tomograms. Treatment of this disease is similar to that for other forms of osteomyelitis.

OSTEOMYELITIS CAUSED BY SPREAD OF INFECTION FROM A CONTIGUOUS FOCUS

In children, osteomyelitis related to an infected contiguous focus is a rare finding. Almost all cases of osteomyelitis from a contiguous source in childhood are nosocomial or are caused by an infected burn wound. The probability of postoperative osteomyelitis developing is a function of the surgeon's experience, the technique, the length of time that the wound was open, and whether prophylactic antibiotics were administered.[192] The interval between the precipitating event and pain and the appearance of persistent sinus drainage or ulceration is 2 to 4 weeks. The peripheral white blood cell count often is normal, as is ESR. More than half of cases are caused by multiple organisms. When small draining sinuses are present, correlation between sinus culture and bone biopsy findings is good. With large open areas, organisms obtained by culture of the wound may not be important etiologically, and obtaining a bone biopsy specimen is necessary for making a definitive bacteriologic diagnosis. Staphylococci and streptococci predominate; however, nosocomial gram-negative organisms often are seen.

ORTHOPEDIC FIXATOR DEVICES

Infection involving the wires or pins used for orthopedic stabilization represents a diagnostic and therapeutic challenge. Osteomyelitis is suspected when evidence of inflammation or infection is noted near these materials, but it seldom can be proved.[20] Plain radiographs are essential because they may reveal bone destruction at the site of entry of fixation pins. No controlled studies of treatment are available. Soft tissue débridement and removal of necrotic bone should be done as soon as possible, but fixation devices generally are left in place.[10,160] Prolonged therapy usually is given, guided by the susceptibility pattern of any organisms recovered from local cultures.[160]

UNUSUAL MICROBIAL CAUSES OF OSTEOMYELITIS

ACTINOMYCES

More than half of all actinomycotic infections involve the facial or cervical area. The most common site of actinomycotic bone infection is the jaw, with the mandible being involved more frequently than the maxilla. Local signs and symptoms of fever and discharge from a sinus indicate the presence of the disease. Radiographically, periosteal elevation is followed by lytic changes. Often, several "eggshell" areas of new bone are present.

Forty percent of all actinomycotic infections occur in the vertebral bodies. In this illness, the infection almost always is associated with a focus elsewhere; the condition comes to medical attention because of mild pain, tenderness, and some stiffness. It can be distinguished from tuberculosis radiographically by the diffuse honeycombing of the vertebral bodies and the periosteal reaction; large lytic lesions usually are absent. Although no controlled trials of therapy have been done, long-term (>3 months) penicillin G therapy is indicated at doses of 150,000 U/kg body weight per day (i.e., approximately 100 mg/kg/day). Extensive débridement may be needed and has been linked to successful short-term treatment of mandibular actinomycosis.[12]

BRUCELLA

Although an uncommon cause of osteomyelitis in developed countries, *Brucella* spp. are a well-known cause of skeletal infections, most often following the consumption of unpasteurized milk products. *Brucella* spp. can produce abscesses in the vertebral bodies or long bones, although they are not striking features of the disease. The disease often is subacute in presentation, and malaise, headaches, night sweats, and minimally tender cervical adenopathy with hepatosplenomegaly are common initial findings.

FUNGI

Osteomyelitis may be caused by numerous endemic and opportunistic fungal agents, including *C. immitis*, cryptococci, *Candida* spp., *Blastomyces* spp., and *Aspergillus* spp. Coccidioidomycosis may be characterized by cough, chest pain, night sweats, and anorexia, and it often is associated with erythema nodosum or erythema multiforme. This disease commonly is found in the southwestern United States. Extrapulmonary involvement is suggested by persistent high temperature and toxicity. *C. immitis* occurs primarily in cancellous bone (e.g., vertebral bodies, distal tubular bones, and the skull).[167] These lesions are not radiographically distinct from the lesions seen in osteomyelitis from other causes.[183] Débridement of bone lesions often is needed initially, and years of therapy are required. Oral triazole agents generally are recommended.[74]

Blastomycosis may mimic coccidioidomycosis, but the pulmonary involvement is much more varied, and fusion of the vertebral bodies rarely occurs. A propensity for the development of verrucous, reddened, weeping skin lesions has been noted, and prostate involvement may be seen. Bone involvement occurs frequently, with the skull and vertebral bodies being infected most often. Distinguishing it from other forms of osteomyelitis is impossible by radiographic examination.

Aspergillus osteomyelitis is being recognized with increasing frequency.[35] Most commonly, it is a disease of immunosuppressed patients, with *Aspergillus* pneumonia seen initially followed by disseminated disease. Bone disease occurring by hematogenous spread has developed, however, in normal individuals and after injectable drug use.[43,172] *Aspergillus* osteomyelitis developing after trauma also has been reported.

Other fungi are causes of osteomyelitis. The medical literature contains dozens of reports of osteomyelitis caused by *C. neoformans*, generally in immunocompromised patients and in the setting of disseminated or pulmonary infection. The few reports in pediatric patients generally have involved immunocompromised adolescents. In adolescents and adults, usually only one bone is involved. The lesions generally are slowly destructive, very discrete lesions occurring primarily in the long tubular bones without marginal sclerosis. This radiologic reaction is confused most commonly with tumor and, occasionally, with tuberculosis. Infection of the ribs and skull also has been reported. Although experience with this disease is limited, débridement of the lesions and medical therapy seem to be highly effective.[14,30,37,84,131,132] Cases of *Rhizopus* osteomyelitis have been reported intermittently and apparently are hematogenous in origin.[57]

CHRONIC OSTEOMYELITIS

Chronic osteomyelitis often is the result of bone infection that develops after a surgical procedure or major trauma.[209] Inadequate treatment of acute hematogenous osteomyelitis also can lead to the development of chronic osteomyelitis. The diagnosis

of chronic osteomyelitis usually is straightforward; patients generally have a painful, nonfunctional extremity and may have chronically draining sinuses. Cultures of the purulent exudate or necrotic bone usually reveal *S. aureus.* Gram-negative bacteria, including *H. influenzae*,[120] may be isolated from an intraosseous abscess. Plain radiographs, CT, and MRI all play roles in medical and surgical management by revealing details of the bony and soft tissue involvement, including the formation of abscesses[164] and sequestra (Fig. 61–7).

Treatment of chronic osteomyelitis involves the removal of devitalized bone, management of soft tissue disease, and long-term administration of appropriate antibiotics. Few controlled trials comparing different modes of therapy have been performed. Antimicrobial regimens for chronic staphylococcal osteomyelitis that have been studied include oral cloxacillin plus probenecid for 6 to 12 months; 9 of 19 patients apparently were treated successfully.[15] In another study, the outcome of a 6-week course of nafcillin was compared with that of nafcillin and oral rifampin. No statistically significant differences were observed with the addition of rifampin, but most (10 of 17) of the patients showed no evidence of disease activity 2 years after the cessation of treatment with antibiotics.[157]

The high failure rate in these and other studies has led to investigation of a variety of adjunctive measures to improve the outcome of chronic osteomyelitis. Local irrigation with antibiotic solutions, with[136] and without[3] added detergents, has been examined. The use of surgically implanted polymethyl methacrylate beads impregnated with an antibiotic (usually gentamicin) has been compared with conventional antibiotic therapy and with therapy with both.[19] No differences were seen among the three groups in a preliminary analysis. Hyperbaric oxygen also has been suggested as an aid to therapy, but no comparative studies have been done.[150]

Because perpetuation of chronic infection seems to be caused by the presence of avascular bone and tissue, advances such as laser Doppler flowmetry ultimately may improve the outcome of this disease.[195] Surgical approaches to close open wounds after débridement and improve blood flow with mobilized tissue flaps also seem to bring about prolonged remission in some patients.[4] Meticulous surgical technique is essential to avoid thermal injury and to retain the vascular supply to compromised areas.[202] Complications of chronic osteomyelitis include secondary amyloidosis and local sarcomatosis or carcinomatous changes at the site of infection. The high likelihood of a poor outcome in chronic osteomyelitis must be kept in mind during treatment of acute hematogenous osteomyelitis. Failure to comply with a regimen of oral therapy may result in chronic infection.[196]

CHRONIC RECURRENT MULTIFOCAL OSTEOMYELITIS

Giedion and coworkers[79] first described chronic recurrent multifocal osteomyelitis, an illness characterized by multiple chronic focal, inflammatory lesions in bone with periodic exacerbation and remission, moderate bone pain, and sterile lesions.[213] Initially, this disease is difficult to distinguish from pyogenic osteomyelitis; the only difference seems to be the apparent absence of an infecting agent. Repeated biopsy of lesions that prove to be sterile usually leads to the diagnosis. It occurs more commonly in girls younger than 10 years of age.

At initial evaluation, slightly more than 50 percent of patients have fever, and virtually all have an increased ESR (or increased CRP). The lesions occur primarily in the distal femoral, distal tibial, and proximal tibial regions. Virtually all tubular bones can be involved.[179] Patients may have 1 to 18 lesions at a time; biopsy specimens show a nonspecific chronic inflammatory process. Occasionally, a predominance of plasma cells is present, which erroneously leads to this disease being termed *plasma-cell osteomyelitis*. In the first reported cases, the lesions were symmetric. This feature has not been present consistently, however, as more cases have been described. Many of the cases are in children of northern European origin.[18,117]

Approximately 20 percent of patients have a pustular eruption of the palms and soles at the same time that they come to medical attention with bone lesions; this condition is termed *pustulosis palmaris et plantaris*. Some patients also may have Sweet syndrome, in which painful, indurated, cutaneous plaques are accompanied by fever and leukocytosis. Sweet syndrome and pustulosis palmaris et plantaris may be variations of the same illness. Sweet syndrome and congenital dyserythropoietic anemia also have been associated with chronic recurrent multifocal osteomyelitis.[59]

The long-term outlook in children with this disease generally is good, although numerous relapses may occur.[18] Glucocorti-

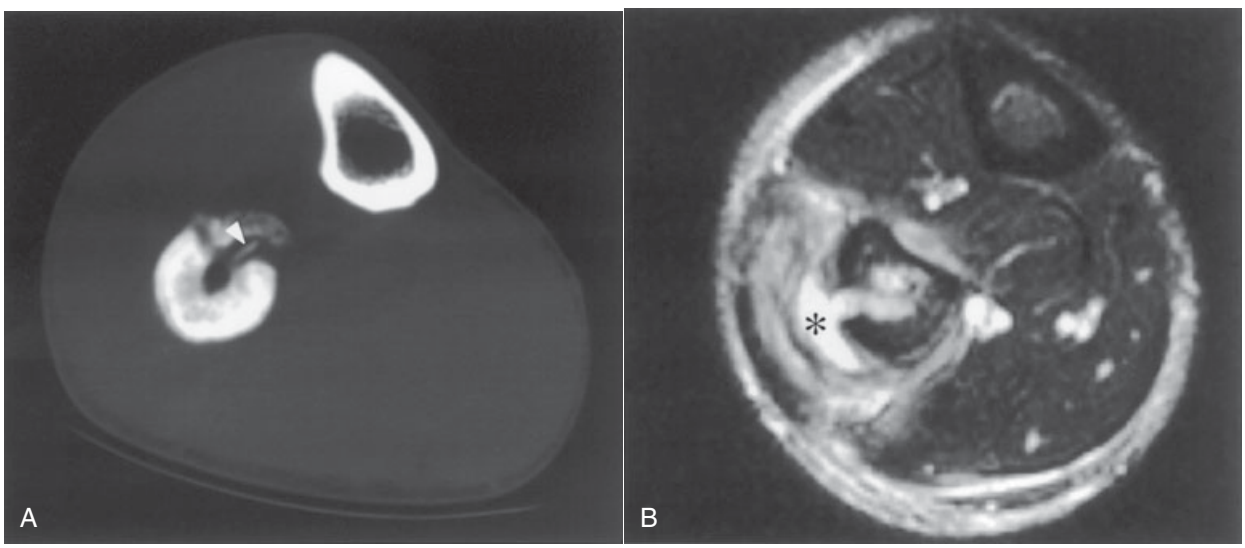

Figure 61–7 Chronic osteomyelitis. **A,** Computed tomography reveals thickening of the fibular cortex and a sinus tract that contains a sequestrum *(arrowhead)*. **B,** T2-weighted axial magnetic resonance imaging from a different level shows a lateral sinus tract through the cortex communicating with a soft tissue abscess *(asterisk)*. Edema is surrounding the entire fibula. *(Courtesy of Dr. Leanne Seeger.)*

coids and nonsteroidal anti-inflammatory drugs have been administered to children with this disease and afford transient relief. Patients usually have a recurrence of symptoms and lesions, however, when these agents are discontinued. Treatment with interferon-γ and tumor necrosis factor–α blocking agents also has been reported to be helpful.[51,75]

CHAPTER 62

Septic Arthritis

Paul Krogstad

This chapter addresses acute infection of the joints caused by bacteria, fungi, and viruses. Bacterial infections occur most frequently. The terms *septic arthritis*, *acute suppurative pyarthrosis*, and *infectious arthritis* are used interchangeably with regard to bacterial infections; they refer to the presence of organisms in the joint space.

EPIDEMIOLOGY

Septic arthritis occurs most frequently in childhood. The overall incidence of septic arthritis in children has been estimated as 5.5 to 12 cases per 100,000 individuals.[32] Describing the age distribution of septic arthritis is difficult because of the varying age intervals selected by authors of different studies. In a review from the pre-antibiotic era, half of the patients were younger than 20 years old.[45] In a later study, performed after antibiotics became available for systemic use, 31 of 66 patients (47%) were younger than 20 years old.[6] Males are affected more often than are females by ratios of 1.2 to 2.1, and most cases occur in children younger than 10 years old.[10,34,55,59,77,91]

PATHOPHYSIOLOGY

Synovial joints, also termed *diarthrodial joints*, are freely movable articulations containing synovia. Synovia is a transparent viscous fluid that lubricates the joint and nourishes the avascular articular cartilage. The synovium, a connective tissue layer interposed between the fibrous joint capsule and the fluid-filled synovial cavity, is responsible for formation of the joint fluid. The synovium contains a prominent capillary supply embedded in a connective tissue network containing at least two types of cells. One morphologic type (type A) seems to be related to mononuclear phagocytes; fibroblast-like type B cells seem to be responsible for the synthesis of hyaluronic acid. Joint fluid (synovia) is formed by filtration through the capillary network (i.e., the net balance of back-diffusion into the capillary bed and diffusion into the joint space). Diarthrodial joints normally contain small amounts of fluid (e.g., 0.5 to 3 mL in the knee),[81] with glucose and electrolyte concentrations equal to those in plasma. An oxygen partial pressure of 60 to 70 mm Hg, an albumin concentration of 10 to 20 g/L, and an IgG content of 500 mg/L are typical.[22,24,30,81]

Diffusion from the joint space is increased by any mechanism that increases pressure (distention with injected solution, active or passive motion, or external massage). Particulate material is removed from the joint space by synovial membrane macrophages and free monocytes (the latter usually are present in concentrations of $<60 \times 10^6$/L).[75] The viscosity of joint fluid is due to hyaluronic acid; enzymatic depolymerization produces a viscosity approximately equivalent to that of water. With the loss of hyaluronidase from the synovia, the articular cartilage, with continued use, becomes eroded and sclerotic.[9] The vasculature of the synovial membrane is innervated, which has two consequences: Joint pain is localized poorly because it results from stretching of the fibrous joint capsule, and inflammation within the joint cavity elicits an axon reflex leading to vasodilation and warmth over an infected joint. Lymphatic channels drain to the regional lymph nodes and are present in all the joint tissues except cartilage.

Microorganisms can enter the joint space by hematogenous spread, direct inoculation, or extension of a contiguous focus of infection. The synovial membrane has been shown to have highly effective blood flow, approximately equal to that of the brain (if one assumes that 1 g of synovial membrane is in an adult knee joint). Numerous bacteria in blood potentially are delivered to the synovial membrane during transient bacteremia. A history of trauma often is cited as a predisposing factor for development of bacterial arthritis, but the significance of such a history is unclear in view of the great frequency of minor trauma in childhood.

Upper respiratory tract infections frequently precede the development of septic arthritis caused by *Haemophilus influenzae* and *Kingella kingae* and oral ulcers with *Kingella* infections. Similar to traumatic injuries, they are presumed to increase the likelihood of bacteremia occurring.[10,90] Septic arthritis also may develop after joint surgery and joint injections. Gram-negative organisms are the most frequent pathogens when septic arthritis occurs after surgery or instrumentation of the urinary or intestinal tract. *Salmonella* septic arthritis may develop during the course of *Salmonella* bacteremia in a normal host, but it occurs with increased frequency in patients with sickle-cell disease and related hemoglobinopathies. Although septic arthritis occurs in children and adults infected with human immunodeficiency virus (HIV),[58] as yet no data have substantiated that HIV increases the incidence of musculoskeletal infections in children. Septic arthritis has been described during varicella, presumably caused by bacteremia resulting from infection of skin lesions. It must be differentiated

from the apparent ability of varicella-zoster virus to cause joint inflammation on its own.[61,74] Arthritis also occurs during acute infection with other viruses (e.g., variola, Epstein-Barr virus, *Erythrovirus* [parvovirus B19], mumps, measles, and enteroviruses).

Inoculation arthritis occurs after invasion of the joint by a contaminated object. In one series, 5 of 35 cases of septic arthritis were caused by such a mechanism. A predilection for the knee exists; four of five cases cited in this study were secondary to kneeling on sewing needles.[77]

Aside from joint involvement during osteomyelitis, contiguous extension of an infection into the joint space rarely occurs. In one series, 10 of 77 patients with septic arthritis had disease originating from a contiguous focus.[18] None involved the joints of the foot, and eight occurred before the availability of many antibiotics (1951). This high frequency of septic arthritis caused by spread of infection from a contiguous focus has not been seen in more recent studies.

ETIOLOGY

Staphylococcus aureus is the most common agent causing septic arthritis, and infection with community-acquired methicillin-resistant *S. aureus* (MRSA) is now commonly reported.[3,57] Streptococci (especially group A beta-hemolytic organisms and pneumococci) have been responsible for most other gram-positive infections (Table 62–1). *H. influenzae* type b historically has been an important cause of septic arthritis in children younger than 2 years, but now is seen only rarely in areas with widespread immunization.[13,41,55] Arthritis caused by *Streptococcus pneumoniae* also generally occurs in children younger than 2 years old and may diminish in frequency with broader use of protein conjugate vaccines. *K. kingae* has been recognized increasingly as a cause of septic arthritis,[25,39,55,91] perhaps because of improvements in laboratory methods.[92] In one series from Israel, *Kingella* was the most common bacterial isolate (48% of cases), and *S. aureus* was not found.[91] In a few cases, septic arthritis is seen with acute *Neisseria meningitidis* infection. In newborns and sexually active adolescents with suspected septic arthritis, *Neisseria gonorrhoeae* should be considered.[35,51,53]

Salmonella spp. cause approximately 1 percent of the total cases of septic arthritis. Beyond the newborn period, infections with other enteric gram-negative bacteria are rare occurrences in pediatric septic arthritis and often are associated with inoculation, instrumentation, or an immunocompromised state.[35] Infections with *Serratia*, *Aeromonas*, *Enterobacter*, *Bacteroides*, and *Campylobacter* generally occur in patients with malignancy who are immunosuppressed.[1,6,19,35,56,63,67] *Pseudomonas aeruginosa* infections are associated with arthritis in infants, with infection of puncture wounds, or with injectable drug use.[59,63,83] Other rare bacterial causes of septic arthritis include *Propionibacterium acnes*,[93] *Corynebacterium pyogenes*,[67] and *Pasteurella multocida*.[38] *Streptobacillus moniliformis* infection of joints may become evident 2 to 3 days after a rat bite occurs; a macular rash commonly is present at initial evaluation. Discussion of Lyme arthritis is beyond the scope of this chapter, but intermittent, inflammatory arthritis is seen in many patients after *Borrelia burgdorferi* is transmitted by a tick bite.[49,80] *Brucella*, mycobacteria (*Mycobacterium tuberculosis* and atypical species), and *Nocardia asteroides* may cause a chronic monarticular arthritis with a granulomatous reaction.

DIAGNOSIS

CLINICAL FINDINGS

Almost all patients have fever and constitutional symptoms within the first few days of acquiring infection with the most common bacterial pathogens.[31] Table 62–2 presents the frequency of specific joint involvement in hematogenous septic arthritis of childhood. Lower extremity (knee, hip, and ankle) infections consistently account for approximately 80 percent of all cases.[34,45,59,63,77] Focal findings in the joint involved almost always are present.

In infants, in whom the hip is one of the most frequent joints involved, swelling, tenderness, and heat may be absent. Most commonly, the infant lies with the involved leg abducted and externally rotated. Often, dislocation occurs.[65] When the capsule of the joint can be examined, swelling is noted; effusion was present in 22 of 24 cases in one series.[87] Because pain fibers are located in the capsule, any maneuver that increases intracapsular pressure also produces pain. In the hip, this pain can be elicited by compression of the head of the femur into the acetabulum. A portal of entry almost never is apparent, and bilateral hip joint infection occurs in a few cases.[69] Pyogenic sacroiliitis often is accompanied by tenderness detected by pressure applied over the sacrum during a digital rectal examination and by pain experienced during simultaneous flexion, abduction, and external rotation at the hip.[2]

Gonococcal arthritis in newborns has nonspecific prodromal symptoms, including poor feeding, irritability, and fever. The

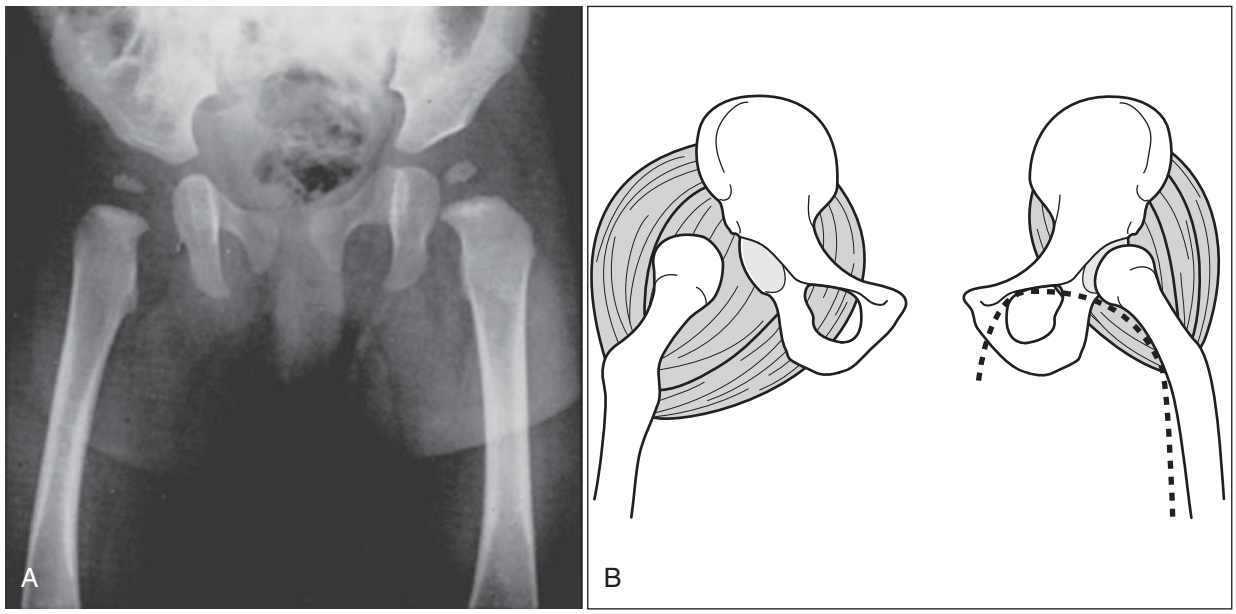

Figure 62–1 **A** and **B**, The obturator sign in the hip is one of the oldest signs of septic arthritis. Another consistent finding is obliteration or lateral displacement of the gluteal fat lines and loss of continuity of the Shenton line. These findings are illustrated radiographically **(A)** and schematically **(B)**.

portal of entry is unknown, and the joints below the hip usually are involved (knee, ankle, and metatarsal). During adolescence, gonococcal arthritis occurs as a manifestation of sepsis with fever, chills, rash, and multiple small joint involvement, often with tenosynovitis.[29] The illness frequently follows the onset of menses by a few days.

RADIOLOGIC FINDINGS

Findings on plain-film radiographs are due to capsular swelling. In the joints readily accessible to physical examination, radiographs add little to the diagnostic evaluation, but when septic arthritis of the hip is suspected in a child, they are a valuable adjunct and may identify other causes of hip pain, such as Legg-Calvé-Perthes disease, slipped capital femoral epiphysis, and fracture. Films of the hip should be made with the child in the frog-leg position and with the legs extended at the knee and slightly internally rotated. The early signs of septic arthritis are caused by swelling of the capsule, which displaces the fat lines. One of the oldest signs is the obturator sign: As the tendon of the obturator internus passes over the capsule of the hip joint, the margins of this muscle are displaced medially into the pelvis (Fig. 62–1).[46] With continued swelling of the hip joint capsule, the femoral head is displaced laterally and upward.[20]

One of the most consistent findings is obliteration or lateral displacement of the gluteal fat lines (see Fig. 62–1).[89] Coincident with filling of the capsule with exudate, the femoral portion of the Shenton line is raised, and its arc is widened.[89] If a technetium bone scan is performed, increased uptake on either side of the joint is seen during the "blood pool" phase of the scan.[86] Ultrasound evaluation has proved useful in evaluation of septic arthritis of the hip.[48,94] In a series of 96 patients, none of the 40 patients with normal ultrasound findings had septic arthritis.[94] Bacterial infections causing pyogenic sacroiliitis may be particularly difficult to diagnose. Bone scans and computed tomography may be negative initially. Magnetic resonance imaging seems to be the diagnostic radiologic method of choice.[2,27]

LABORATORY EVALUATION

Diagnostic evaluation for suspected septic arthritis generally includes determination of the erythrocyte sedimentation rate or C-reactive protein, and the peripheral blood leukocyte count and differential. These may be only mildly elevated in cases of proven infection, however.[26,94] Blood for culture always should be obtained because blood cultures sometimes may yield the pathogen when joint fluid cultures do not.[52]

Joint fluid should be collected in a heparinized syringe so that the large clot that usually forms in fluid obtained from patients with septic arthritis or juvenile rheumatoid arthritis does not preclude enumeration of leukocytes. A cell and differential count should be performed on aspirated joint fluid, and it must be Gram-stained and cultured. Identification of organisms in joint fluid is the primary criterion for diagnosis of septic arthritis. Careful examination of a Gram-stained smear of joint fluid aspirates must be emphasized because joint fluid exerts a bacteriostatic effect on microorganisms and organisms that can be seen but may not grow in culture. Approximately 35 percent of joint aspirates are sterile in patients with other clinical and laboratory findings of a septic joint, including positive blood cultures.[10,63] Joint fluid should be cultured aerobically and under anaerobic conditions. The use of cell lysis culture bottles may enhance the recovery of *K. kingae* and other organisms.[92] *N. gonorrhoeae* is a highly fastidious organism, and oropharyngeal, rectal, and urogenital cultures or detection of gonococcal DNA in urine may be needed to confirm the diagnosis of gonococcal arthritis. Polymerase chain reaction analysis of joint fluid is likely to become a useful adjunct to the diagnosis of culture-negative disease, although it remains investigational.[60,84]

The median synovial fluid leukocyte count in bacterial arthritis in one study was 60.5×10^9 cells/L.[79] In this and other surveys,[75] polymorphonuclear leukocytes accounted for 75 to 90 percent of the white blood cells. Cell density generally is lower in fluid obtained from patients with acute rheumatic fever, juvenile rheumatoid arthritis, and other inflammatory causes of arthritis (Table 62–3).[8,75,79] The glucose concentration often is decreased in septic arthritis, but it may be normal.[79,87] It also may be depressed in rheumatoid arthritis and other conditions. A joint fluid leukocyte density of 5 to 8×10^9 cells/L has been found in joint fluid from patients ultimately proved to have septic arthritis.[75] Minimally turbid fluid with a seemingly low number of cells still should be processed for bacterial culture and Gram stain. Examination of the fluid for uric acid and other types of crystals should be considered in certain children (e.g., children with hyperuricemia).

DIFFERENTIAL DIAGNOSIS

Although bacterial infections are the most common cause of septic arthritis, other microorganisms, including viruses (varicella-zoster, *Erythrovirus* [parvovirus B19], rubella, chikungunya and other togaviruses, variola, vaccinia, certain enteroviruses, others), mycobacteria, and fungi (*Coccidioides immitis*, *Sporothrix schenckii*, *Blastomyces dermatitidis*, *Candida* spp.), may be involved. The differential diagnosis includes obturator internus muscle abscess,[85] epiphyseal osteomyelitis, traumatic arthritis, bacterial endocarditis, villonodular synovitis, leukemia, deep cellulitis, serum sickness, ulcerative colitis, granulomatous colitis, Schönlein-Henoch purpura, traumatic arthritis, fracture, Legg-Calvé-Perthes disease, slipped femoral capital epiphysis, and metabolic diseases affecting joints (e.g., ochronosis in adults with alkaptonuria).

Toxic (or transient) synovitis (also referred to as *irritable hip* and *reactive synovitis*) frequently is seen in children and has milder presenting features than bacterial infections of the hip. The combination of fever, elevated white blood cell count, erythrocyte sedimentation rate (>40 mm/hr), C-reactive protein, and inability to bear weight permits septic arthritis to be distinguished from transient synovitis with high accuracy; greater than 90 percent sensitivity for the detection of septic arthritis has been reported when all of these factors are present.[15,26,52,94] Septic (suppurative) bursitis, although rare in childhood, can be difficult to distinguish from septic arthritis. Children with septic bursitis frequently have a history of recent trauma and fever along with limitation of joint movement.[44,71] Careful physical examination and aspiration of bursal fluid allow the entities to be differentiated.

TREATMENT

ANTIBIOTIC THERAPY

Antibiotic treatment of septic arthritis should target the most common pathogens. In children beyond the neonatal period, *S. aureus* and other gram-positive organisms currently predominate.[13,55,63] Although the risk of acquiring invasive *H. influenzae* infection is low in areas with effective immunization, rare cases continue to be reported. Children younger than 2 years who have not been immunized against *H. influenzae* type b should be treated initially with a regimen that contains an antistaphylococcal agent, such as nafcillin, vancomycin, or clindamycin, and an agent active against this agent (e.g., cefotaxime). Cefuroxime, which is active against *S. aureus* (and other gram-positive pathogens) and *H. influenzae*, is a useful alternative. As with osteomyelitis, vancomycin or clindamycin should be used as the empiric antistaphylococcal agent in areas where community-acquired MRSA is a concern.[3,57] Some authorities advocate that this be done when community-acquired MRSA represents more than 10 percent of *S. aureus* in a geographic area.[50] At present, no regimen is preferred for the treatment of penicillin-nonsusceptible *S. pneumoniae*, but ceftriaxone, cefotaxime, and clindamycin have been used successfully.[14] If β-lactam resistance continues to increase in *S. pneumoniae* and *S. aureus*, other regimens that target highly resistant gram-positive organisms may be needed. Ceftriaxone and cefotaxime are appropriate for the treatment of gonococcal infection.

All antibiotics that have been studied penetrate into joint fluid readily; soon after administration, at the time of peak serum levels, the joint fluid concentration averages 30 percent of the serum value.[5,7,62,73] The efflux of antibiotic from joint fluid back to serum is slow, however. Immediately before the next systemic dose is administered, joint fluid antibiotic concentrations frequently exceed the concentrations present in serum. Antibiotics, whether administered orally or parenterally, can achieve efficacious concentrations in joint fluid.

Injecting antibiotics into the joint space usually is unnecessary because of their excellent penetration. Many antibiotics (e.g., cephalothin) are capable of evoking an intense inflammatory reaction, much as they do if they are infiltrated beneath the skin. Tetzlaff and associates[82] have shown that septic arthritis can be treated for 1 week (or less) parenterally, with the balance of the

drug given orally. These investigators caution that the drug dosage should be adjusted for each patient to ensure a peak serum bactericidal titer of at least 1:8, and that the patient should remain hospitalized so that compliance can be ensured. These investigators considered the minimal duration of therapy to be 3 weeks.

The adequacy of antibiotic therapy can be assessed by serial joint fluid examinations, leukocyte density, and culture results.[87] The time required for resolution of joint symptoms and the time for the synovia to become sterile are proportional to the duration of symptoms before the initiation of appropriate antibiotic therapy.[47] In one study, some patients still had cultures yielding bacteria after undergoing 1 week of therapy. In these patients, cellular density ranged from 25 to 253×10^9 cells/L (mean 109×10^9 cells/L) at the beginning of therapy; 92 percent of the cells were polymorphonuclear leukocytes. By the end of 2 weeks of therapy, all cultures were sterile, and leukocyte density ranged from 4.9 to 23×10^9 cells/L (mean of 12.3×10^9 cells/L).[87] Similar studies of the rate of resolution of indicators of inflammation in joint fluid have suggested that after receiving 9 days of treatment, patients who ultimately recovered completely had a density of 5×10^9 cells/L; however, in patients with recrudescent infection or a poor outcome, the density was 6×10^{10} cells/L.[35]

When an effusion reaccumulates, one should remove it by arthrocentesis, not only to make the patient more comfortable, but also to permit serial assessment of therapy. Generally, disease caused by *S. aureus* and Enterobacteriaceae requires longer treatment than disease caused by *H. influenzae* or meningococci. Radiographs should be obtained during therapy to seek bone changes indicating that osteomyelitis may have been present. Osteomyelitis may require surgical intervention or more prolonged antibiotic therapy.

SURGICAL TREATMENT

In infants, septic arthritis in the hips or shoulders is a surgical emergency; these joints should be drained as soon as the diagnosis is apparent to prevent bony destruction.[69] In a study in adults, the outcome of septic arthritis was better in patients treated by repeated needle aspiration than in patients treated by surgical drainage.[36,37] Eighty percent of the patients treated by needle aspiration were thought to have a good outcome versus 47 percent treated by surgical drainage. All wrist joint infections in this series were treated only by needle aspiration; in treatment of septic arthritis of the knee, however, the outcome was almost equivalent. Similar findings have been reported by others.[11] The investigators suggested that surgical drainage should be performed in any joint whenever the presence of large amounts of fibrin, tissue debris, or loculation prevents adequate drainage by needle aspiration.

PROGNOSIS

Sequelae, including hip dislocation, are more likely to develop in infants and patients with symptoms of longer duration.[87,88] In one study, seven of eight patients in whom "permanent" hip dislocation developed had symptoms for 7 or more days before receiving treatment.[88] Similarly, all patients with spontaneous ankylosis had symptoms longer than 7 days.[88] Comparable data were obtained by Samilson and colleagues.[77] Eight of 10 patients with pathologic dislocation of the hip had symptoms for longer than 7 days.

A detailed analysis of factors affecting satisfactory outcomes in hematogenous septic arthritis of childhood showed no significant difference in the joint when arthrotomy, with or without irrigation, was compared with repeated aspiration.[59] Likewise, the specific antibiotic used had no effect on outcome as long as it was effective against the infecting organism. The literature does suggest that septic arthritis caused by Enterobacteriaceae is associated with more frequent sequelae than when caused by other pathogens.[37,64] *S. aureus* is more likely to cause sequelae than *H. influenzae*.[10] A single randomized, placebo-controlled study has examined the impact of a brief course of dexamethasone on the outcome of bacteriologically confirmed cases of septic arthritis of hematogenous origin in children. Children younger than 3 months were excluded from participation, and *H. influenzae* was responsible for 13 percent of cases among the 100 evaluable patients. After 1 year of follow-up, limping, joint pain, and restriction of movement were found in 26 percent of patients who received a placebo, but in only 1 of 50 patients treated with dexamethasone. If confirmed, this anti-inflammatory therapy may prove useful to limit the sequelae of septic arthritis.[70]

SPECIAL PROBLEMS

NEONATAL SEPTIC ARTHRITIS

Neonatal septic arthritis is a problem that warrants special attention because of its subtle signs and symptoms,[21] its potential for catastrophic consequences of untreated disease,[68] and the unusual organisms occasionally seen. Any newborn who has swelling in the region of the thigh and the buttock and holds that leg flexed with slight abduction and external rotation at the hip should be suspected to have femoral-acetabular septic arthritis. It can occur 1 to 28 days after femoral venipuncture (in most newborns, 5 to 9 days) and should not be confused with femoral vein thrombosis.[4,17]

In most newborns, no toxemia, fever, or leukocytosis is present. More than one joint may be involved when initially evaluated. The progression of disease in newborns can be so indolent that the hip spontaneously drains along the obturator internus, and the condition is manifested as a lower abdominal mass just above the inguinal canal.[28] Problems in recognizing the disease in newborns undoubtedly contribute to the poor outcome. In one series, the delay from onset to diagnosis was an average of 1 week; only two of the nine infants in this series had a normal hip examination at follow-up.[68]

In most series, the causative agents are staphylococci and streptococci,[4,12,17,21,68] but gram-negative organisms often are found. More importantly, arthritis caused by *Candida albicans* has been described,[23] and the gonococcus should not be forgotten. In gonococcal arthritis, the symptoms, which usually become apparent in infants 1 to 5 weeks of age, generally are polyarthritic (more than one joint involved).[33] As previously noted, other symptoms of neonatal gonococcal arthritis are no different from symptoms caused by other pathogens.

Initial antibiotic therapy for neonatal septic arthritis should be directed toward *S. aureus* and the nosocomial gram-negative bacteria that are prevalent in the nursery. Antibiotic therapy can be altered when the susceptibility of the causative bacterium is known. As noted earlier, the usual duration of therapy is 3 to 4 weeks, and radiography should be performed toward the end of treatment. Oral therapy has been used successfully to complete treatment of septic arthritis in newborns,[72] but absorption of antibiotics in this age range is unpredictable.[78] Consequently, either intravenous therapy or measurement of serum bactericidal activity should be used to verify absorption.[82]

FUNGAL ARTHRITIS

Fungal arthritis is rare in children, but may be seen with pathogens of endemic mycoses, such as *Histoplasma capsulatum*, *C. immitis*, and *B. dermatitidis*, and with opportunistic fungal pathogens (e.g., *Candida* spp., *Cryptococcus neoformans*).[55,63] These pathogens usually manifest after an indolent course. The recom-

mended medical treatment generally is that required for other systemic infections caused by these organisms.

JOINT INFECTIONS DURING RHEUMATOID ARTHRITIS

Joint infections that develop during a case of rheumatoid arthritis seem to occur more frequently in adults with rheumatoid arthritis than in children. In one series, only 2 of 17 patients were younger than 10 years.[6] The notable features are that the hips generally are not involved, and infection of multiple joints (17 of 44 patients had more than one joint involved) frequently occurs. Because of the preexisting joint disease, the diagnosis often is delayed, and the outcome usually is poor. Septic arthritis should be considered if an unusual worsening of one joint occurs during a flare-up of rheumatoid arthritis.

REACTIVE ARTHRITIS

After infections with *Shigella* spp.,[16,66] *Chlamydia trachomatis*, *Salmonella* spp.,[43] and *Yersinia* spp., a reactive arthritis can occur.[54] This postinfectious joint inflammation seems to develop with greater frequency in individuals who express the histocompatibility antigen HLA-B*27, perhaps as a result of molecular similarities between bacterial antigens and the human protein. In addition, during the initial infection, bacterial antigens apparently may be deposited in the synovium and may persist for a long time and lead to pathogenic inflammation.[40,54] Generally, the onset of joint symptoms occurs a few days to several weeks after a transient and often mild episode of diarrhea. The arthritis may mimic rheumatic fever and is characterized by daily low-grade fever and an increased erythrocyte sedimentation rate. Reactive arthritis generally can be distinguished from septic arthritis by analysis of synovial fluid; infectious arthritis usually is associated with high white blood cell fluid numbers.[8] Resolution of joint symptoms in reactive cases takes 7 to 10 days.

Reactive arthritis also may occur after acute infections with *N. meningitidis*[42] and *H. influenzae*.[76] Symptoms and signs of joint inflammation often appear 1 week or more after the acute septic episode and resolve without sequelae.

CHAPTER 63

Bacterial Myositis and Pyomyositis

Charles Grose

Myositis is not a common manifestation of bacterial infection, but when it occurs, the consequences to the patient may be severe or even fatal. *Staphylococcus aureus* and group A streptococci are the most likely causative organisms. Myositis also has been associated with several other infectious agents, including viruses, fungi, and parasites. These pathogens are listed in Table 63–1; they are discussed briefly herein and more thoroughly in the chapters on the specific microorganisms. This chapter focuses on two forms of pyogenic myositis, designated as *acute bacterial myositis* and *tropical pyomyositis*. The former is caused primarily by group A streptococci and the latter by *S. aureus*. Tropical (or staphylococcal) pyomyositis is the more common of the two bacterial diseases and should be considered a distinct nosologic entity.

Toxoplasmosis

PYOMYOSITIS

The pathologic entity termed *spontaneous acute myositis* was recognized by Virchow in the mid-19th century, but the first clinical description of suppurative myositis generally is attributed to the Japanese surgeon Scriba.[20] In 1904, another Japanese surgeon, Miyake,[17] extensively reviewed the subject of skeletal muscle abscesses and added 33 more cases. As the British and French expanded their colonial empires at the turn of the 20th century, the disease was recognized with increasing frequency in the native populations and in the soldiers who lived in the tropical areas of Asia and Africa.[26] It acquired the name by which it now is known widely—*tropical pyomyositis*.[9,10]

The suitability of this designation was confirmed by an epidemiologic study in East Africa, which discovered that the disease was found commonly only in regions with a truly tropical climate (i.e., a fairly constant high temperature and high relative humidity) at an altitude below 4000 ft.[15] Pyomyositis has been described, however, in children from geographic regions of the United States as diverse as New England,[9] northern California,[2] Iowa,[16] and Texas.[11,19,21] Numerous reported cases within the continental United States have occurred in and around San Antonio, Texas.[5] In a 10-year chart review, 1 or 2 cases of pyomyositis per 4000 pediatric admissions occurred annually. In contrast, a review of consultations of pediatric infectious diseases at the University of Iowa Hospital disclosed fewer cases of pyomyositis among children younger than 16 years old.[7] Pyomyositis seems to occur more commonly in children who live in the southernmost regions of the United States (e.g., Texas) than in children who live in the northern regions (e.g., Iowa).

PATHOPHYSIOLOGY

The etiologic agent of the skeletal muscle abscesses in more than 90 percent of cases is *S. aureus*. Phage typing of many isolates in different countries has not identified a particular staphylococcal strain that is more likely to cause pyomyositis.[11] The second most common bacteriologic isolate is *Streptococcus*, including group A and nonhemolytic strains. Whether more virulent streptococcal infections are occurring at the beginning of the 21st century is an issue that remains unresolved.

Miyake[17] studied extensively the experimental conditions under which staphylococci cause muscle abscesses. When healthy rabbits were given boluses of staphylococci intravenously, they occasionally developed small abscesses in the kidney, liver, or spleen but never in the skeletal muscles. When specific muscles were damaged by mechanical pinching or electric current 24 or 48 hours before the intravenous injection of bacteria was administered, small abscesses developed within 2 to 28 days at some of the injured sites in nearly half of the animals. Abscesses were not found in healthy muscle tissue.

The role of trauma was supported further by a study of pyomyositis in the British Army.[3] After physicians found this disease to be a common problem in Gurkha army recruits, they investigated 32 cases and made several observations: Two thirds of the men recalled having experienced trauma at the affected site, the incidence of abscesses increased as the severity of physical training increased, and the abscesses occurred three times more commonly on the dominant (right) side of the body. In an analysis of 78 cases in Uganda, abscesses also were found more commonly on the right side of the body.[15]

From experimental evidence and clinical observations, two conditions commonly are found when pyomyositis occurs: muscle injury and bacteremia, usually staphylococcal. A reported case is illustrative.[11] A 12-year-old girl caught her left foot in the wheel of a moving bicycle and tumbled to the ground. One week later, she developed a furuncle of the foot, and within the next 2 weeks, she developed painful lumps in muscles of the thigh, shoulder, and chest wall (which had been injured during the original accident). Cultures from the furuncle and blood and from the incised muscle abscesses grew *S. aureus*. All isolates were identified as phage type 94. The initial episode of trauma resulted in a staphylococcal skin lesion and, presumably, a bacteremia that seeded sites of previously bruised muscle.

Seven children with pyomyositis are described in Table 63–2. An analysis of all seven cases illustrates the association of pyomyositis with trauma. The sources of muscle trauma have ranged from bicycle accidents to strenuous aerobic exercises. These cases also may explain the predilection of the disease to occur in warmer climates; concomitant skin infections and muscle trauma are more likely to occur in a climate in which children can play or work outside wearing fewer clothes for most of the year.

In tropical countries, pyomyositis is said to occur in individuals who are malnourished and who have multiple parasitic infections. This association has not been confirmed, however, in children with pyomyositis seen in the United States or Australia.[5,7,13] The children have not been malnourished or vitamin-deficient, and they have not had parasitic infestation or marked eosinophilia. Extensive immunologic evaluations also have been normal; the tests included quantitative immunoglobulins, enumeration of T-lymphocyte subpopulations, total hemolytic complement levels, and leukocyte function as tested by reduction of nitroblue tetrazolium.

CLINICAL PRESENTATION

Pyomyositis often is considered a disease of adolescents and young adults, even though it occurs in individuals of all ages, including infants and young children.[2,6,13] Boys are affected more

TABLE 63–2 Pyomyositis and Trauma

Case*	Sex	Age (yr)	Source of Trauma	Circumstances of Trauma	Extent of Disease
1	F	12	Bicycle accident	Thrown from bicycle onto street after foot was caught in the wheel	Right deltoid/right chest wall/left thigh/right groin
2	M	3	Fall while running	Fell while running on street	Left calf/right scapula/right buttock
3	M	11	Hay bale accident	Struck in abdomen by bale of hay thrown from a hay baler	Abdominal wall musculature
4	M	6	Blunt trauma to abdomen	Struck in abdomen during mock fistfight with sibling	Abdominal wall musculature
5	F	17	Aerobic exercises	Injured while instructing others in aerobic exercises	Left thigh
6	M	7	Bicycle accident	Fell from fast-moving bicycle onto street	Left calf
7	F	13	Volleyball accident	Fell several times diving for volleyball during training exercises	Left iliopsoas

**Cases 1 and 2 from reference 11, cases 3 and 4 from reference 5, cases 5 and 6 from reference 7, and case 7 from reference 16.*

often than are girls. As more girls enter competitive sporting activities, however, pyomyositis is being reported in female athletes.[16] Most children with pyomyositis have a solitary lesion, but multiple lesions are common findings. The most common site of abscess formation is the thigh, followed by the calf, buttock, arm, scapula, and chest wall. The muscle lesions are firm or "woody" to palpation, with a well-defined border. The sign of fluctuation may be difficult to elicit. Erythema and warmth often are not apparent because of the deep location of the masses, although diffuse tenderness usually occurs. When a muscle in an extremity is involved, the entire limb may be swollen. Occasionally, pyomyositis also can occur in muscles of the pelvis, in which case pain may be transferred to the hip.[14,19]

In case reports with a clinical history, children with pyomyositis often had similar presenting complaints.[7,11] Many had incurred a recent accidental injury (often involving a leg) that usually was not considered serious. After a few days, the children developed low-grade fever (38.3° C to 39° C), muscle pain, and, occasionally, an impaired gait. These symptoms persisted a few days to a few weeks until a mass appeared. When first examined, many of the patients were considered to have only a contusion or a hematoma; occasionally, a child was diagnosed as having a rhabdomyosarcoma. Although the disease usually occurs in individuals who are otherwise healthy, pyomyositis has been reported in patients with malignancy. Pyomyositis also may develop in children with acquired immunodeficiency syndrome or other immunodeficiency.[13] The pathophysiology of pyogenic muscle abscess may not be the same, however, in immunodeficient individuals with increased susceptibility to bacterial infection. Most children with pyomyositis have no definable immunologic abnormalities.

An unusual clinical presentation is acute abdominal pain. Beck and Grose[5] described two children with pyomyositis whose initial complaints were confined to the abdominal wall. One patient, a 6-year-old child, had been struck in the abdomen in a mock fist-fight with an older sibling. One week later, he developed a low-grade fever and began to walk with a stoop; after another week, his mother detected a "knot" in his right mid-abdominal wall. The second case involved the 11-year-old son of a rancher; the boy was struck in the abdomen by a bale of hay tossed from a hay baler. When he subsequently developed symptoms of abdominal pain, the diagnosis of appendicitis was entertained. When a mass later became palpable in his abdominal wall, rhabdomyosarcoma was suspected. A correct diagnosis was made after the use of scintigraphy and sonography, as described later.[5] A review from Nigeria found muscle abscesses in the anterior abdominal wall to be common.[2]

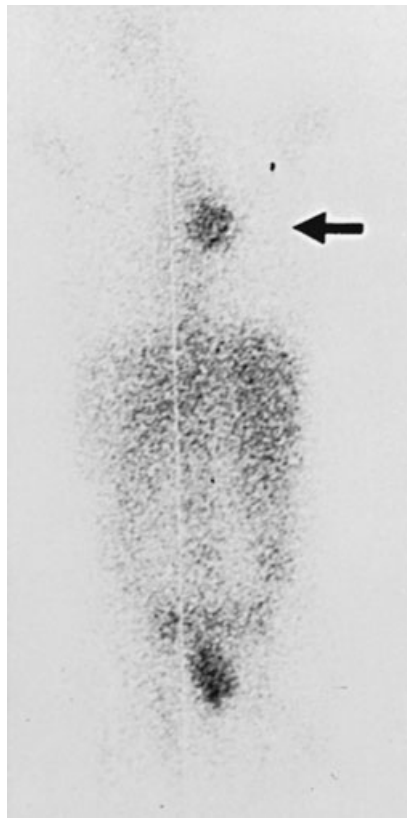

Figure 63–1 Scintigram of a patient with pyomyositis. Posterior gallium 67 citrate scan shows abnormally high uptake over the right scapula (*arrow*), where an abscess cavity was located within the muscle. Increased radioactivity also is observed in the bladder, which is a normal finding.

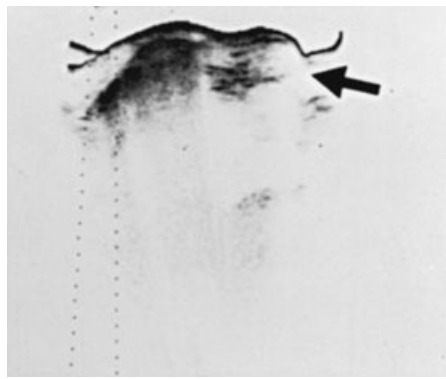

Figure 63–2 Sonogram of the abdominal wall of a patient with pyomyositis. The transverse view of the abdomen shows an abscess cavity in the right belly of the rectus abdominis muscle (*arrow*).

DIAGNOSIS

The diagnosis of pyomyositis should be considered in any child with fever and muscle pain, especially if a recent history of trauma exists. When a child has visible masses at commonly involved sites, such as the thigh, the diagnosis of pyomyositis can be made by needle aspiration of a mass. If a febrile child complains of myalgia in an extremity but has no palpable masses, the differential diagnosis must include more common inflammatory and infectious conditions of the bone or joint. A definitive diagnosis usually depends on one or more radiologic procedures. Plain films may show a soft tissue swelling or even a widened fascial plane suggestive of a mass lesion. A combination of plain radiography and radionuclide (technetium 99m phosphate) bone scintigraphy often can exclude osteomyelitis and pyoarthritis. If the diagnosis still is in question, scanning with gallium or indium can localize a muscle abscess precisely and can visualize other intramuscular abscesses too small to palpate (Fig. 63–1). Alternatively, ultrasonography can detect muscle abscesses and may be preferable as an initial procedure because it avoids the radiation exposure from computed tomography (CT) or scintigrams (Fig. 63–2).[27]

Magnetic resonance imaging (MRI) is very helpful in delineating the extent of a muscle abscess. In many cases, the abscess is much larger than suspected by physical symptoms and signs. The MRI scans of an illustrative case are presented in Figure 63–3. The patient was a 17-year-old girl with a swollen left lower thigh. She worked part-time as an attendant in an athletic club, where she participated in some of the vigorous exercise programs. Radiographs of the knee were normal, whereas a technetium

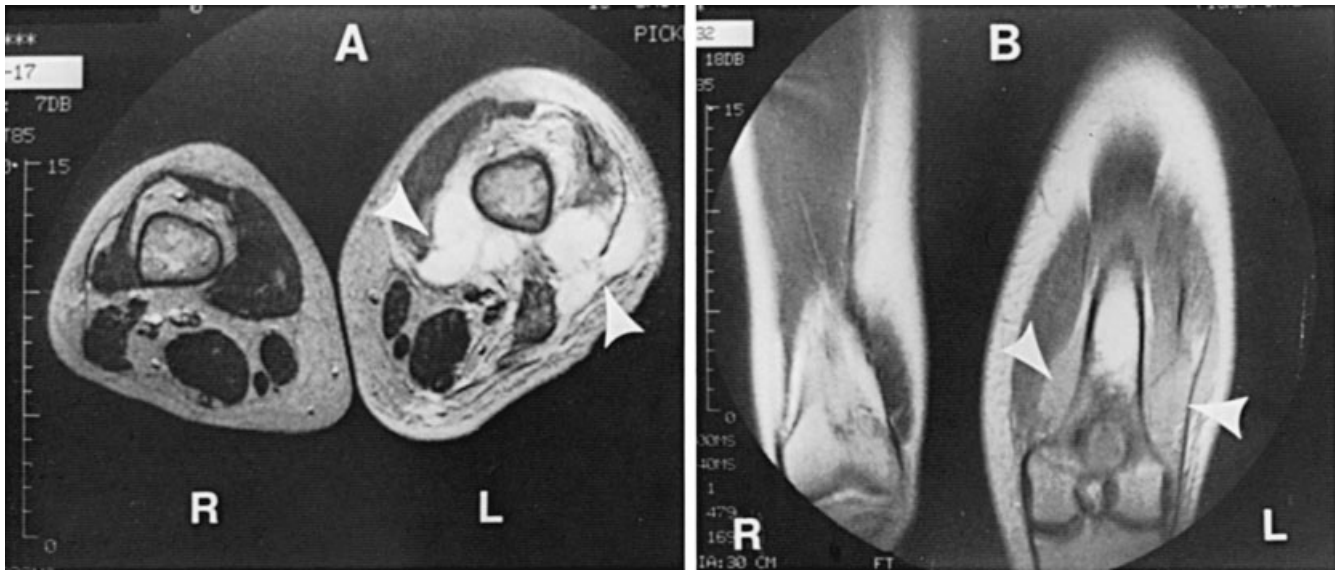

Figure 63–3 Magnetic resonance imaging of the thighs of a patient with pyomyositis. **A,** Axial images of the right (*R*) and left (*L*) thighs. **B,** Coronal images around the distal femoral shafts and femoral condyles. The scans show several well-defined areas of extremely high intensity in the muscle bundles and fascial planes from the middle to distal left femur (*arrows*). The high signal intensity suggests a fluid collection (e.g., an abscess), rather than a neoplastic process. Edema of the subcutaneous tissues also is evident in the lateral aspect of the swollen left thigh. There are no abnormal signals within the bone.

bone scan showed slightly increased radionuclide uptake in the soft tissues around the distal left femur. MRI of the left and right thighs showed a large fluid collection extending from the middle to distal left femur. Surgical exploration identified extensive abscess formation around the posterior aspect of the femur; the culture grew *S. aureus*. The affected muscle groups included the vastus medialis, vastus intermedius, vastus lateralis, and biceps femoris. The bone was not involved. For the reasons described, MRI has become the preferred procedure for establishing the diagnosis of pyomyositis.[14,22,27]

TREATMENT

Because pyomyositis is an abscess of skeletal muscle, the treatment is surgical incision and drainage.[2] Several physicians have seen that smaller lesions resolve spontaneously, even before the antibiotic era. An important role for systemic antibiotics is to prevent the formation of further muscle abscesses, especially in a patient with proven bacteremia. Because *S. aureus* is the most likely agent, a semisynthetic penicillinase-resistant penicillin is the preferred antibiotic in communities with little or no methicillin-resistant *S. aureus* (MRSA). Usually, nafcillin or oxacillin is administered intravenously every 6 hours at a total daily dosage of 150 to 200 mg/kg. When pyomyositis occurs in a patient with penicillin hypersensitivity, clindamycin, 40 mg/kg/day, divided every 8 hours, can be substituted because of its excellent coverage of gram-positive cocci. Parenteral therapy is continued until clinical improvement is evident, usually within a few days after surgical drainage. Thereafter, the antibiotics can be given orally at a reduced dosage for an additional 2 to 3 weeks. A penicillin derivative (dicloxacillin, 25 mg/kg/day, or cefadroxil, 30 mg/kg/day) or clindamycin, 20 to 30 mg/kg/day, is acceptable.

In many communities, MRSA is now a common agent. In a clinical analysis of 182 patients with pyomyositis from Texas Children's Hospital in Houston, Texas, more than 50 percent of the isolated *S. aureus* strains were MRSA.[19] In these communities, initial antibiotic management must include either intravenous clindamycin or vancomycin, 40 mg/kg/day, divided every 6 hours. Clindamycin can be continued as an oral antibiotic. For MRSA isolates resistant to clindamycin, treatment with intravenous vancomycin can be followed by administration of oral linezolid, 30 mg/kg/day, divided every 8 hours, for children younger than 12 years; for children 12 years and older, 20 mg/kg/day, divided every 12 hours, is given. Therapy of MRSA infection may require a longer duration, from 3 to 4 weeks. Before discontinuing antibiotics, the patient should have documented normal levels of C-reactive protein and erythrocyte sedimentation rate.

ACUTE BACTERIAL MYOSITIS

Far less common than tropical pyomyositis is acute bacterial myositis, usually caused by group A streptococci. In this condition, the bacterial infection often is not confined to distinct abscesses within the muscle, but instead it extends diffusely through one or more muscle groups. As with pyomyositis, the disease occurs more commonly in males than in females and usually is associated with prior physical exertion and perhaps minor trauma. In contrast to pyomyositis, most published cases of acute bacterial myositis have occurred in adults and not in children.[4] The disease has been divided by Svane[25] into the following four main types:

1. A malignant form with septicemia and a uniformly fatal outcome
2. An acute form with a more protracted clinical course and other foci of suppuration, such as the bones, joints, or viscera
3. A subacute form with a better clinical prognosis
4. A benign type associated with more distinct muscle abscesses

The benign type of acute bacterial myositis by the Svane classification is the same disease process as described in the preceding section on pyomyositis.

CLINICAL PRESENTATION

The main clinical difference between the acute myositis syndrome and the pyomyositis syndrome is the virulence of the

former disease, especially the malignant type. A case in a San Antonio, Texas, native is illustrative. The patient was a 23-year-old jackhammer operator who was admitted because of high fever, malaise, and pains in his arms. On examination, both upper extremities were tender to palpation, and faint erythema was visible over the same areas. He soon became incoherent, and his general condition quickly deteriorated. Death followed within 24 hours. Blood cultures drawn before death grew group A streptococci, and cultures of the biceps muscles obtained at autopsy grew the same organism. This case is similar to others described in the literature.[4,25] The patient worked as a jackhammer operator, who presumably would incur considerable minor trauma to the muscles of the upper arms and shoulders. Two reported cases of streptococcal myositis in children involved the left thigh and the left paravertebral muscles.[18] The first child developed septic shock and required intensive care for 27 days before a definitive diagnosis was made by CT.

A case of generalized myositis with staphylococcal septicemia has been described in a 15-year-old boy.[1] The patient presented with signs of fever and very diffuse muscle swelling and tenderness. All muscle groups of the extremities appeared to be inflamed and markedly tender; the creatine phosphokinase enzyme levels were markedly elevated. Culture of a muscle biopsy specimen grew *S. aureus*, as did previously drawn blood cultures. The patient experienced a stormy hospital course with severe hypotension and shock syndrome, requiring treatment with intravenous fluids, corticosteroids, dopamine, heparin, and assisted ventilation. He also received a total of 4 weeks of antistaphylococcal antibiotic therapy.

DIAGNOSIS

Blood cultures are positive most often in patients with the most significant clinical symptoms. Cultures of muscle biopsy specimens may yield a profuse growth of bacteria. Rarely, myositis has occurred as a delayed complication of chickenpox, often together with fasciitis.[12,17,23] In this situation, bacteremia may not be documented because the bacterial process usually is the result of contiguous spread from a secondarily infected pock lesion. These streptococcal complications of chickenpox often occur in an extremity, which may become swollen and painful. Under these circumstances, MRI can be an extremely valuable diagnostic tool to gauge the depth and extent of inflammation.[27]

TREATMENT AND THE EAGLE EFFECT

The treatment of acute streptococcal or staphylococcal myositis of the malignant type is a medical emergency. As soon as the diagnosis is suspected, bacteriologic cultures should be obtained, and intravenous therapy should be initiated with a high-dose semisynthetic penicillin (e.g., nafcillin, 50 mg/kg every 6 hours) and vancomycin. If the cultures yield group A streptococci rather than *Staphylococcus*, the antibiotic can be switched to penicillin G at an equivalent high dosage. Surgical consultation is required to evaluate the need for débridement and drainage. Obtaining MRI scans may be advisable to document the extent of the disease and the response to antibiotic therapy. In severe cases of bacterial myositis, the total duration of hospitalization can exceed 4 weeks.[1,18]

The apparent resurgence of serious streptococcal infection has led to an increased interest in what has been called the *Harry Eagle effect*, named after the scientist who first described the failure of penicillin to eradicate group A streptococcal infection in a mouse model.[8] Eagle inoculated mice intramuscularly with group A streptococci and observed a markedly retarded bactericidal action of penicillin on organisms in the older abscesses, even though the bacteria remained highly sensitive to the antibiotic. Even massive doses of penicillin 10,000 times greater than the minimum inhibitory concentration were not effective at eradicating the bacteria. Subsequent studies by other investigators confirmed the existence of the Eagle effect and disclosed that clindamycin showed superior efficacy to penicillin in treatment of streptococcal myositis in the mouse model.[24] In an editorial comment, Stevens[23] observed that penicillin most likely fails to kill stationary-phase streptococci in muscle infections, an explanation for the Eagle effect. He suggested that streptococcal myositis or fasciitis be treated with intravenous clindamycin, 40 mg/kg/day, if the condition fails to respond to penicillin therapy.

MISCELLANEOUS CAUSES OF MYOSITIS

Viral infection occasionally leads to myositis (see Table 63–1). The most common example undoubtedly is myositis associated with influenza virus infection in children. Typically, school-aged children are affected. Muscle groups of the legs often are involved, associated with a marked elevation of serum creatine phosphokinase. Clinical symptoms generally last 2 to 4 days. Another, far less common myositis is caused by coxsackievirus B infection. This disease is called *epidemic pleurodynia* because the myositis frequently involves the chest and upper abdomen. The enteroviral infection is known as *Bornholm disease*, named after the Danish island where it was first described.

Fungal infection (e.g., *Candida albicans*) can cause myositis. Candidal myositis is uncommon, however, and usually occurs in patients who are severely immunocompromised. Frequently, other sites also are involved by the disseminated fungal infection in addition to muscle.

Parasitic infection can cause myositis. The best known is trichinosis, caused by ingestion of the encysted larvae of *Trichinella spiralis*. The larvae typically are found in products containing pork and wild game, such as bear meat. The first signs of illness are fever and abdominal pain. Later, muscle pain is noted in the neck and chest. Eventually, calcifications form in the involved muscles. Treatment of the acute disease with mebendazole or albendazole may be beneficial. Another parasite more common in Central and South America is *Taenia solium*. Ingestion of eggs of this pork tapeworm leads to cysticercosis, with calcified densities in skeletal muscle. Finally, toxoplasmosis infection can lead to symptoms of myositis. During acute infection, *Toxoplasma gondii* can encyst in the skeletal muscle and lead to an inflammatory myopathy closely resembling dermatomyositis.

SECTION X

SKIN INFECTIONS

CHAPTER 64

CUTANEOUS MANIFESTATIONS OF SYSTEMIC INFECTIONS

James D. Cherry

Many illnesses caused by infectious agents have associated cutaneous manifestations. In some cases, the exanthem may be the hallmark of the disease; in others, it may be only a vague indicator of a more significant underlying process. When an exanthem occurs, it often offers important clues to the etiology of a patient's illness. Although most exanthematous illnesses in children are benign, their differential diagnosis is critical because the early manifestations of potentially fatal bacterial and rickettsial diseases frequently have cutaneous findings.

HISTORY

Exanthematous manifestations of infectious illnesses have been important since medical antiquity. Major epidemics of both measles and smallpox occurred in the Roman Empire and in China at the beginning of the Christian era.[25,130] Scarlet fever was recognized as a distinct entity in the 17th century, and chickenpox and rubella were identified in the 18th and 19th centuries, respectively.[49]

In the writings of the early 20th century, maculopapular exanthematous illnesses of children frequently were referred to by number. Scarlet fever and measles historically were the first two classic maculopapular exanthems of childhood. Which one had the honor of being the "first disease" is unknown today. The "third disease" was rubella, which was recognized by the beginning of the 20th century as a distinct entity.[68,70,87,157,178-180] In 1900, Dukes[68] described an exanthematous illness with the characteristics of both rubella and scarlet fever, which he suggested was a "fourth disease." The general opinion today is that his disease was not a distinct entity. Shaw[180] suggested that Dukes' cases had mild atypical scarlet fever, and Powell[157] raised the possibility that the illness resulted from epidermolytic toxin–producing staphylococci. Most probably, rubella and scarlet fever both were epidemic in the student population under Dr. Dukes' care; combined infections led to the confusion.

Erythema infectiosum (see Chapter 164) commonly is referred to as the *fifth disease*, and roseola infantum (see Chapter 65) qualifies as the *sixth disease*.[179]

During the last 55 years, interest in exanthematous diseases has been renewed because a large number of previously unknown viruses and other infectious agents that cause cutaneous manifestations have been discovered. In addition, the pattern of disease caused by classic exanthem-producing agents has changed; smallpox has been eradicated, the epidemiology of measles and rubella has been altered by immunization, and ecologic changes have resulted in differences in viral and bacterially induced rashes.

ETIOLOGIC AGENTS

Many different types of viruses, chlamydiae, rickettsiae, mycoplasmas, bacteria, fungi, and protozoan and metazoan agents cause illnesses with associated cutaneous manifestations. Although this chapter is devoted to systemic infectious diseases with cutaneous manifestations, the demarcation between exanthematous disease of systemic and local origin is not always readily apparent. For example, the recurrent cold sore caused by herpes simplex virus (HSV) infection frequently is considered a local problem, although its nature and pathogenesis involve central virus latency and host systemic immune functions. Similarly, superficial fungal diseases and other local infections, such as warts, may be quite dependent on more general immunologic functions of the host. The exanthems of enteroviral infections frequently are confused with those caused by insect bites and allergic problems.

Table 64–1 presents viruses that have cutaneous manifestations in humans. Erythema infectiosum is caused by human parvovirus B19.[7,205] This virus also is an important cause of the papular-purpuric gloves and socks syndrome that is an uncommon occurrence and mainly affects young adults.[3,6,50,85,91,184,185] Human parvovirus B19 also has been associated with a vesiculopustular exanthem, erythema multiforme, and other petechial and purpuric rashes. In one study, an erythematous maculopapular rash was noted in 9 percent of children with human bocavirus infections.[8] Adenovirus types 1, 2, 3, 4, 7, and 7a have been isolated from children and young adults with exanthem.[49,110,208,209] The overall clinical expression rate of exanthem in adenovirus infection rarely has been studied. Fukumi and associates[79] noted that rash occurred in 2 percent of adenoviral infections; Hope-Simpson and Higgins[98] indicated a rate of approximately 8 percent.

Eight species in the *Herpesvirus* genus have cutaneous manifestations associated with infection, but clinical expression rates vary greatly. Nearly all primary varicella infections are associated with exanthem, whereas exanthem with acquired cytomegalovirus infection is a rare manifestation.[19,22,49,166,190,208] The incidence of exanthem in Epstein-Barr virus infection varies from 3 percent to nearly 100 percent, depending on whether concomitant ampicillin is administered.[16,28,95,104,111,146,159,197,198] Although firm data are lacking, probably less than 10 percent of primary infections with HSV type 1 are associated with cutaneous manifestations. Erythema multiforme occasionally occurs with recurrent HSV infections.[36,76,107,144] Human herpesvirus–6 (HHV-6) is a major cause of roseola infantum.[11,205,217] HHV-7 also is a cause of roseola infantum[10]; in addition, some evidence suggests that this virus may play a role in pityriasis rosea.[66] HHV-8 infection is necessary

Text continued on p. 762

TABLE 64–1 Clinical Characteristics of Viral Infections with Cutaneous Manifestations

Virus	Disease or Syndrome	Incubation Period (days)	Main Season	Clinical Characteristics	Exanthem		Usual Duration (days)
					Lesions	Distribution	
Human parvovirus B19 (see Figs. 64–6 to 64–8)	Erythema infectiosum; gloves and socks syndrome	7-17	Winter and spring	Biphasic illness with mild prodromal period with headache and malaise for 2-3 days, then 7-day symptom-free period, followed by typical exanthema	Three-stage exanthema: initially, rash on cheeks (slapped-cheek appearance) and then erythematous maculopapular rash on trunk and limbs; finally, rash develops a reticular pattern	Starts on face More prominent on extensor surfaces of extremities	7-21
Human bocavirus			Fall, winter, and spring	Fever, cough, coryza, respiratory distress (bronchitis, bronchiolitis, pneumonia)	Erythematous maculopapular	Mainly face, chest, and trunk	
Human papillomaviruses	Warts		Nonseasonal	Local cutaneous disease	Papular or nodular isolated lesions	Most common on extremities	100+
Adenovirus types 1, 2, 3, 4, 7, and 7a		6-9	Winter and spring	Fever and signs and symptoms of respiratory illness Occasionally, rash occurs after defervescence (roseola-like)	Most commonly erythematous, maculopapular, and discrete (rubelliform), but occasionally confluent (morbilliform) Rarely, erythema multiforme and Stevens-Johnson syndrome	Usually starts on face and spreads downward to trunk and extremities	3-5
Herpes simplex types 1 and 2 (see Fig. 64–5)	Cold sores, genital herpes, neonatal herpes, or other	2-12	Nonseasonal	Primary disease associated with fever and systemic symptoms Recurrent disease caused by exogenous and endogenous infections	Singular or grouped vesicular lesions varying in size from 2 to 10 mm, frequently on a mildly erythematous base Occasionally, erythema multiforme, Stevens-Johnson syndrome, and erythema nodosum	Lesions in primary infection with type 1 virus are mainly in and around the mouth Recurrent type 1 lesions usually perioral Primary and recurrent type 2 lesions usually on genitals	7-14
Human herpesvirus–6 (HHV-6)	Roseola infantum		Nonseasonal	Fever 3-5 days in duration, rapid defervescence, and then the appearance of rash	Erythematous macular or maculopapular	Most prominent on neck and trunk Face and extremities may be affected	1-2
Human herpesvirus–7 (HHV-7)	Roseola infantum		Nonseasonal	Fever 3-5 days in duration, rapid defervescence, and then the appearance of rash	Erythematous macular or maculopapular	Most prominent on neck and trunk Face and extremities may be affected	1-2
Human herpesvirus–8 (HHV-8)	Kaposi sarcoma	Months to years	Nonseasonal	Asymptomatic infection Most commonly noted in AIDS patients but occurs in other immunodeficiency states	Purple to blue nodular, raised lesions	Any epidermal or mucosal surface	Months to years
Varicella-zoster (see Fig. 64–4)	Chickenpox (varicella)	12-20	Late fall, winter, and spring	Malaise and fever of 5-6 days duration	Basic lesion is vesicular, but lesions go through stages: macules, papules, vesicles, and crusts Lesions occur in crops	Lesions more profuse on trunk than on extremities Proximal end of extremities more involved than distal end	8-10
	Herpes zoster		Nonseasonal	Endogenous infection Pain and paresthesia with dermatome distribution	Basic lesion is vesicular, but lesions go through stages: macules, papules, vesicles, and crusts	Lesions localized to area of skin innervated by a single sensory ganglion	10-28

Epstein-Barr	Infectious mononucleosis	28-49	Nonseasonal	Fever, pharyngitis, and lymphadenopathy Exanthem occurs in 3-13% of cases If ampicillin is administered, then exanthema in 50% of cases	Most commonly erythematous, macular, maculopapular, and discrete (rubelliform) In association with ampicillin administration, the rash may be more vivid Erythema multiforme and urticaria may occur	Mainly on trunk and proximal end of extremities	2-7
Cytomegalovirus	Cytomegalovirus mononucleosis		Nonseasonal	Acquired: mild febrile illness with lymphadenopathy Congenital: disseminated disease	Erythematous, maculopapular, and discrete Vesicular or petechial in congenital infection	Located mainly on trunk and proximal end of extremities	2-7
Vaccinia	Roseola vaccinatum, eczema vaccinatum, vaccination "take," or disseminated vaccinia		Nonseasonal	Illness caused by direct exposure via vaccination or exposure to a vaccinee	Vaccination and eczema vaccinatum lesions go through stages: papule, vesicle, pustule, and scab Roseola vaccinatum: erythematous maculopapular lesions Occasionally erythema multiforme Disseminated vaccinia: papular or vesicular lesions	Lesions in roseola vaccinatum, eczema vaccinatum, and disseminated vaccinia are generalized	7-14
Variola	Smallpox	8-17	Seasonal by geographic area	Abrupt onset of high fever, headache, and muscle and joint pain Rash appears 2-4 days after onset	Basic lesion is vesicular, but lesions go through stages: macules, papules, vesicles, pustules, and crusts	Most prominent on exposed body surfaces Starts on extremities and face Spreads centripetally	12-20
Monkeypox				Similar to mild smallpox Exposure to monkeys No human-to-human spread	Similar to mild smallpox	Similar to mild smallpox	
Orf	Ecthyma contagiosum	4-7	Spring	Disease of sheep acquired by humans	Initially erythematous papule Becomes umbilicated, nodular, and then vesicular Occasionally erythema multiforme	Solitary lesion, usually on hands	30-40
Molluscum contagiosum	Molluscum contagiosum			Local cutaneous disease	Umbilicated nodular lesions: singular or clusters	Most common on face, inner aspect of thigh, breasts, and genitalia	100+
Paravaccinia	Milker's nodules	4-7		Human infection acquired from infected calves	Nodular lesion Occasionally erythema multiforme	Solitary lesion, usually on hands	30-40
Tanapox				A virus of monkeys Human infection associated with fever and regional lymphadenopathy	Umbilicated vesicular lesion	Upper part of body Solitary lesion	35-56
Coxsackieviruses A2, A4, A5, A7, A9, A10, and A16; coxsackieviruses B1-B5; echoviruses 1-7, 9, 11-14, 16-19, 22, 24, 25, 30, and 33; enterovirus 71 (see Figs. 64–9 to 64–16)		4-7	Summer and fall	Fever and mild to moderate pharyngitis Occasionally, herpangina, meningitis, and other manifestations of systemic viral infection Exanthem occurs in 5-50% of infections, depending on virus type Rash may occur during fever or after defervescence; hand, foot, and mouth syndrome	Most commonly erythematous, maculopapular, and discrete May have macular, petechial, vesicular, and urticarial components Rarely erythema multiforme	Usually starts on face and spreads downward to trunk and extremities May have peripheral distribution (hand, foot, and mouth syndrome)	3-7

TABLE 64–1 Clinical Characteristics of Viral Infections with Cutaneous Manifestations—cont'd

Virus	Disease or Syndrome	Incubation Period (days)	Main Season	Clinical Characteristics	Exanthem		Usual Duration (days)
					Lesions	Distribution	
Rhinoviruses (many types)		2-4	Fall, winter, and spring	Mild fever and signs and symptoms of respiratory illness Exanthem occurs in about 5% of cases	Erythematous or maculopapular and discrete	Starts on face and spreads downward to trunk and extremities	1-4
Foot and mouth		3-4		Direct animal contact Fever, sore mouth, and lymphadenopathy Vesicles and ulcers within the mouth	Vesicular lesions	Hands and feet	3-6
Colorado tick fever		3-5	Summer	Fever, chills, eye pain, myalgia, and headache Diphasic course Rash in only about 10% of cases	Occasionally maculopapular but usually petechial	Maculopapular rash is generalized Petechial rash most prominent on arms, legs, and trunk	2-7
Reovirus 2 and 3		4-7	Summer	Fever, mild pharyngitis, and cervical adenopathy	Erythematous or maculopapular Discrete or confluent Occasionally vesicular	Starts on face and spreads downward to trunk and extremities	3-9
Rotavirus	Gianotti-Crosti syndrome; infantile acute hemorrhagic edema	2-4	Fall, winter, and spring	Gastroenteritis	Petechial and morbilliform	Generalized	7-14
Chikungunya, o'nyong-nyong, Ross River, Sindbis			During periods of arthropod prevalence	Fever, headache, eye pain, and marked myalgia, arthralgia, and arthritis Geographically localized diseases	Rubelliform and morbilliform Frequently vesicular and petechial	Starts on face and spreads downward to trunk and extremities	
Rubella (see Fig. 64–3)	Rubella (German measles)	15-21	Winter and spring	Mild symptoms with onset 1-5 days before rash Fever usually <38.5° C (101.5° F) Headache, malaise, and suboccipital and postauricular lymphadenopathy	Erythematous, maculopapular, and discrete	Starts on face and spreads downward to trunk and extremities	4-7
West Nile				Sudden onset of fever, chills, and drowsiness Rash may appear during or after fever Geographically localized disease	Erythematous, macular, and maculopapular	Starts on trunk and spreads to extremities	3-6
Dengue and Kunjin		7	During periods of specific arthropod prevalence	Sudden onset of high fever, then severe headache, myalgia, arthralgia, abdominal pain, and marked diaphoresis Fever lasts 5-6 days and ends by crisis Rash appears within 48 hours of onset of fever Geographically localized diseases	Initially, macular, flushed appearance, then erythematous, maculopapular rash May be scarlatiniform Frequently becomes petechial and purpuric Small vesicles occur in Kunjin virus infection	Initial macular rash is more prominent centrally Maculopapular rash may start on hands and feel and spread to trunk	3-10
Influenza A and B		2-5	Fall, winter, and spring	Fever, cough, headache, and muscle aches and pains Usually in young children Rash an occasional occurrence	Erythematous, maculopapular, and discrete (rubelliform) Rarely erythema multiforme	Starts on face and trunk and spreads to extremities	1-3
Respiratory syncytial		2-5	Fall, winter, and spring	Fever, coryza, and respiratory distress (bronchitis, bronchiolitis, or pneumonia) Usually in children <2 years	Erythematous, maculopapular, and discrete (rubelliform)	Starts on face and trunk and spreads to extremities	1-3
Human metapneumovirus			Fall, winter, and spring	Fever, coryza, and respiratory distress (bronchitis, bronchiolitis, or pneumonia)	Erythematous, maculopapular		

Parainfluenza 1-3		2-5	Fall, winter, and spring	Fever, coryza, nasopharyngitis, croup, and bronchitis Usually in young children	Erythematous, maculopapular, and discrete (rubelliform)	Starts on face and trunk and spreads to extremities	1-3
Mumps	Mumps	14-21	Fall, winter, and spring	Fever, headache, and salivary gland swelling	Erythematous, maculopapular, and discrete; also, urticaria and vesicles; rarely, erythema multiforme	Most prominent on trunk	2-5
Measles (see Figs. 64–1 and 64–2)	Measles	8-12	Winter and spring	Onset with fever, cough, coryza, and conjunctivitis About 2 days after onset, appearance of enanthem (Koplik spots); and 2 days later, onset of exanthem	Erythematous, maculopapular, and confluent Develops a brownish appearance, and fine desquamation occurs	Starts behind ears and on forehead Spreads downward over body Confluence most prominent on face, trunk, and proximal end of extremities	5-7
Lassa	Lassa fever			Sudden onset of fever, chills, headache, and sore throat Progresses to pneumonia and renal failure Geographically localized outbreaks	Macular and sometimes petechial	Localized or general	
Hepatitis B	Papular acrodermatitis of childhood	50-180		Insidious onset with arthralgia, arthritis, and rash occurring before jaundice	Maculopapular, macular, or urticarial In young children, papular (Gianotti-Crosti syndrome or papular acrodermatitis of childhood) Rarely, erythema multiforme	Generalized	4-10
Hepatitis C	Mixed cryoglobulinemia (not reported in children)	7-14	Nonseasonal	Acute hepatitis followed by chronic infection Skin findings occur late in disease	Palpable purpura	Mostly buttocks, lower extremities	Variable
Marburg		5-7		Headache, conjunctivitis, photophobia, myalgia, vomiting, diarrhea, and fever (biphasic) Exposure to vervet monkeys	Initially erythematous macular, then discrete maculopapular, and finally confluent maculopapular Exfoliation occurs Occasionally purpura	Generalized	2-14
Ebola	Hemorrhagic fever	5-10	Occurs in outbreaks	Febrile illness that progresses to hemorrhage, shock, and coma	Maculopapular rash that appears toward end of first week of illness	Lateral sides of trunk, groin, and axillae Can become generalized but spares the face	14-60
Hantavirus	Hemorrhagic fever with renal syndrome (nephropathia epidemica)		Spring and summer outbreaks	Febrile illness with hemorrhagic and renal manifestations	Flushing and petechial rash	Face (flushing), skin folds (petechiae)	14-28
HIV		14-60	Nonseasonal	Fever, pharyngitis, myalgia, arthralgias, adenopathy, and rash	Macular	Mainly chest and abdomen	7
Human T-lymphotropic virus	Infective dermatitis		Nonseasonal	Acute onset of eczema	Severe exudative eczema with a crusting, generalized, fine papular rash	Scalp, eyelid margins, perinasal skin, retroauricular areas, axillae, and groin	Months to years

for the development of Kaposi sarcoma in patients with acquired immunodeficiency syndrome (AIDS) and other immunodeficiency states.[102,114,135]

At present, human illnesses with cutaneous manifestations caused by poxviruses rarely occur. Because smallpox as a disease has ceased to exist, the use of vaccinia virus for immunization has decreased dramatically. However, the terrorist events of 2001 raised concern about the possible use of smallpox virus as a terrorist weapon. Because of this potential danger, smallpox vaccines are being produced and used again. With the increased use of these vaccines, cutaneous complications of vaccinia virus infection can be expected. Monkeypox, orf, and paravaccinia (milker's nodules) continue to occur as isolated events in exposed individuals.[170,208,209] Human infection with tanapox virus is a geographically related illness occurring in limited areas of Kenya.

In the present era, enteroviruses are the leading cause of infection-related exanthematous diseases.[51,55,109,208,209] Thirty-seven types have been associated with rash illnesses. The clinical expression rate varies greatly among the different types; it is as high as 50 percent in children with coxsackievirus A16 and echovirus 9 infections. Only approximately 15 percent of individuals infected with echovirus 4 have exanthem, and rash is a rare occurrence in echovirus 6 infection. Hope-Simpson and Higgins[98] noted exanthem in approximately 5 percent of patients with rhinoviral respiratory illness.

A young adult research worker had an influenza-like illness and a hand, foot, and mouth syndrome–like rash caused by infection with a calicivirus (San Miguel sea lion virus serotype 5) of oceanic origin.[183]

Two percent of patients with Colorado tick fever encephalitis have exanthem.[51] Although infection with reoviruses occurs commonly, exanthem has been noted on only nine occasions.[51,121] A morbilliform rash has been observed in one adult with a rotavirus infection, and a 4-year-old boy was noted to have a petechial rash in association with a rotaviral illness.[60,167] Di Lernia and Ricci[63] described three cases of Gianotti-Crosti syndrome and one child with infantile acute hemorrhagic edema associated with rotavirus infections.

Of the *Togaviridae* family of viruses, rubella virus is the most important as a worldwide cause of exanthematous disease. Several alphaviruses also frequently cause exanthems.[108,141,208,209] Each of these viruses has a marked geographic distribution. Similarly, flaviviruses also have exanthem as part of their clinical expression, and they too have specific geographic boundaries.[208,209] In the New York City area outbreak of West Nile virus infection in 1999, 19 percent of patients had exanthem.[138] The rash was erythematous macular, papular, or morbilliform.

Exanthem generally is not considered to be a manifestation of influenza virus infection, but Hope-Simpson and Higgins[98] noted exanthem in approximately 8 percent of patients from whom influenza B virus was isolated and in 1 or 2 percent of those infected with influenza A virus. Measles virus is the most notable of the *Paramyxoviridae* family with an associated exanthem. However, exanthem occurs rather frequently in young children infected with parainfluenza virus types 1, 2, and 3 and also in those with respiratory syncytial virus (RSV) illnesses.[81,93,94,199,202] Hope-Simpson and Higgins[98] noted a 15 percent incidence of rash in RSV infection and an approximately 15 percent incidence in parainfluenza virus infection. Rash, which was not described further, was observed in four children with respiratory illnesses caused by human metapneumovirus infections.[158] Exanthem also has been noted on rare occasion with mumps virus infection.[49]

Lassa fever virus, Marburg virus, Ebola virus, and hepatitis B virus all have been associated with exanthem on occasion.[42,46,62,75,152,208] Hepatitis B virus is the main cause of papular acrodermatitis (Gianotti-Crosti syndrome) in children.[46,171,175] Chronic hepatitis C virus infection occasionally causes systemic vasculitis and cryoglobulinemia in adults, with purpuric lesions concentrated on the lower extremities.[2,97] Other cutaneous manifestations of chronic hepatitis C virus infection include urticaria, erythema nodosum, lichen planus, and nodular prurigo.[106,216]

Hantaviruses cause two major syndromes throughout the world: hemorrhagic fever with renal syndrome and hantavirus pulmonary syndrome.[4,39,150,174] Exanthem (facial flushing and petechial lesions in skin folds) occurs in approximately 30 percent of patients with hemorrhagic fever with renal syndrome, but rash is not reported in the hantavirus pulmonary syndrome. A macular rash has been noted in association with acute infection with human immunodeficiency virus type 1 (HIV-1).[137,139,140,189] Several reports have associated human T-lymphotropic virus type 1 (HTLV-1) with an atypical form of eczema called infective dermatitis. This exanthem has an acute onset and is somewhat recalcitrant to treatment.[116,117,126]

Chlamydiae, rickettsiae, and mycoplasmas associated with cutaneous manifestations are listed in Table 64–2. Of the chlamydiae, only *Chlamydia psittaci* has been associated with exanthem. In contrast, all rickettsiae that infect humans, with the exception of *Coxiella burnetii*, usually display some cutaneous manifestations as part of their systemic disease.[31,69,84,115,122,143,147,173] Approximately 4 to 7 percent of adults with Q fever have exanthem.[40,187] Of the mycoplasmas that infect humans, only *Mycoplasma pneumoniae* is associated with exanthem.[13,51,53] In epidemics, exanthem occurs in approximately 15 percent of persons with respiratory illness.

In Table 64–3, bacterial agents for which cutaneous manifestations are part of the clinical illness are presented (see Chapter 66). The clinical expression of exanthem varies tremendously among the different etiologic agents, as do the conditions associated with a specific infection. For example, infection with phage group 2 staphylococci usually results in cutaneous disease in young infants, whereas the same organisms rarely cause illness in adults. Symptomatic infection with *Streptococcus pneumoniae* is associated with cutaneous manifestations only occasionally; on the other hand, similar systemic disease with *Neisseria meningitidis* virtually always is associated with the characteristic petechial exanthem. Of the other bacterial agents listed in Table 64–3, exanthem is most important in the following: *Neisseria gonorrhoeae*, *Salmonella typhi*, *Streptobacillus moniliformis*, *Spirillum minus*, *Pseudomonas aeruginosa*, and *Treponema pallidum*.

Fungal, protozoan, and metazoan agents associated with cutaneous manifestations in humans are listed in Tables 64–4, 64–5, and 64–6, respectively. These agents and their diseases, discussed more completely in other chapters, are included here for completeness of the differential diagnosis.

EPIDEMIOLOGY

Tables 64–1 through 64–6 clearly show that exanthematous disease has many possible etiologic agents; hence, no unified epidemiology exists. Epidemiologic events related to specific agents are considered in the appropriate sections throughout this text. Each agent with exanthem as a clinical manifestation has a unique epidemiologic pattern that, if understood, distinguishes it from many of the other agents that cause otherwise identical clinical illnesses. In the evaluation of all patients with rash, exposure, season, and incubation period are important aspects of the diagnostic process.

PATHOPHYSIOLOGY AND PATHOLOGY OF EXANTHEMS

Even though the skin can respond in only a limited number of ways, what is obvious from the extensive number of etiologic agents is that multiple pathogenic mechanisms must occur. In many sections of this book, the pathology and pathophysiology of specific agents are presented in detail. An overview is presented here.

Small vessel vasculitis (leukocytoclastic vasculitis) is a leading event in most exanthematous illnesses caused by infectious agents.[186] The cutaneous manifestations of systemic diseases can be separated into three broad categories. The first category involves dissemination of infectious agents by blood (viremia, bacteremia, and so on), which results in secondary infection at the cutaneous site. The clinical cutaneous findings in this type of infection can be the direct result of infectious agents in the epidermis, dermis, or dermal capillary endothelium or can be the result of an immune response between the organism and antibody or cellular factors in the cutaneous location. The possible events in the skin with this type of infection are presented in Table 64–7. Chickenpox, many enteroviral infections, and meningococcemia are examples of diseases in which infectious agents have reached the skin through the blood and are causing the cutaneous findings without the additional contribution of host immune factors. In illnesses such as measles, rubella, and gonococcemia, the timing, histologic picture, and difficulty of direct recovery of the agent by culture suggest both a direct effect and an immune-mediated response.

The second category of pathogenesis relates to the dissemination of known specific toxins of infectious agents. The infection is in a localized area of the body, but the toxin liberated by the infectious agents reaches the skin by blood-borne dissemination. Three examples of toxin-mediated exanthematous disease are streptococcal scarlet fever, staphylococcal scalded skin syndrome, and toxic shock syndrome.

The third category of pathogenesis in systemic disease with exanthem is poorly understood but appears to have an immunologic basis. Most important in this category are the clinical pictures of erythema multiforme, erythema multiforme exudativum (Stevens-Johnson syndrome), and erythema nodosum. In erythema multiforme associated with *M. pneumoniae* and HSV infection, the respective organisms have been isolated or identified at the skin site. In most instances, however, neither antigen localization nor disseminated toxin has been identified.

Important clinical aspects of exanthematous diseases are the distribution and progression of the lesions, yet little is known of the cause of these aspects. Differences in skin thickness, vascularity, proliferation rate, temperature, and metabolic activity are important in animal diseases with cutaneous manifestations.[51,75,124,134,154] In humans, similar factors must be important but obviously affect the various etiologic agents differently (e.g., the more central exanthem of chickenpox versus that of the hand, foot, and mouth syndrome of coxsackievirus A16 infection).

Text continued on p. 770

TABLE 64–2 Clinical Characteristics of Chlamydial, Rickettsial, and Mycoplasmal Infections with Cutaneous Manifestations

Agent	Disease or Syndrome	Incubation Period (days)	Main Season	Clinical Characteristics	Exanthem		Usual Duration (days)
					Lesions	Distribution	
Chlamydia psittaci	Psittacosis	7-14	Nonseasonal	Fever, chills, headache, and cough Respiratory distress	Erythematous macules Occasionally erythema multiforme or erythema nodosum	Mainly on trunk	2-7
Rickettsia akari	Rickettsialpox	7-14	Nonseasonal	Fever, chills, headache, backache, and malaise 4-7 days after onset of primary lesion at site of mite bite Geographically localized disease	Initial lesion at site of mite bite is papular and then vesicular, and finally an eschar forms Two days after onset of fever, erythematous maculopapular discrete rash occurs Lesions progress to small vesicles and later to scabs	Most prominent on trunk and proximal end of extremities	7-10
Rickettsia typhi	Endemic, murine typhus	7-14	Nonseasonal	Fever and headache Rash appears on 4th-7th day Geographically localized disease	Initially discrete macules and then erythematous maculopapular May become purpuric	Initially upper part of trunk and axilla Progresses to entire body except face, palms, and soles	7-21
Rickettsia prowazekii	Epidemic typhus	10-14	Nonseasonal	Sudden onset of fever, chills, headache, and myalgias Rash appears on 4th-7th day Geographically localized disease	Initially discrete macules and then progresses to maculopapular and petechial lesions Sometimes purpuric	Appears first on trunk and spreads to extremities Spares palms and soles	7-14
Rickettsia tsutsugamushi	Scrub typhus	7-21	Nonseasonal	Sudden onset of chills, fever, and headache	Local lesion at site of chigger bite is present at onset of symptoms; characterized by vesicle, ulcer, and eschar Maculopapular rash occurs 5-8 days after onset of fever	Maculopapular rash first occurs on trunk and then becomes generalized	7-14
Rickettsia rickettsii	Rocky Mountain spotted fever	3-12	Summer	Abrupt onset of fever, chills, and headache Rash appears 2-4 days after onset	Early maculopapular, then petechial, and sometimes purpuric	Rash starts on distal end of extremities Rarely involves the trunk	7-14
Other tick-borne rickettsiae			Tick seasons	Similar to mild Rocky Mountain spotted fever	Similar to Rocky Mountain spotted fever; eschar at site of tick bite	Similar to Rocky Mountain spotted fever	7-14
R. sibirica	North Asian tick-borne rickettsiosis						
R. australis	Queensland tick typhus						
R. conorii	Boutonneuse fever						
R. africae	African tick fever						
Coxiella burnetii	Q fever	20-40	Nonseasonal	Acute febrile illness with chills, headache, and myalgia	Fine discrete macular rash occurring during febrile illness Transient urticarial rash also noted	Mainly on trunk	2-7
Ehrlichia species	Ehrlichiosis	14-28	Tick seasons	Similar to Rocky Mountain spotted fever, but rash usually not on palms and soles	Similar to endemic typhus	Similar to endemic typhus	7-14
Mycoplasma pneumoniae		21	All seasons	Gradual onset of fever, malaise, headache, and cough	Maculopapular rash occurs in 5-15% of cases Vesicular and bullous lesions common (Stevens-Johnson syndrome); more common in males Papular, petechial, and urticarial lesions also noted Erythema multiforme common	Rash most prominent on trunk and proximal end of extremities	7-14

Data from references 13, 14, 18, 31, 35, 40, 51, 53, 69, 84, 92, 115, 122, 129, 136, 143, 147, 160, 173, 187, 210, 215.

TABLE 64–3 Bacteria Associated with Cutaneous Manifestations

			Exanthem	
Agent	**Disease or Syndrome**	**Clinical Characteristics**	**Lesions**	**Distribution**
Gram-positive cocci				
Staphylococcus aureus, exfoliative toxin-producing, mainly phage group 2 (see Figs. 64–17 and 64–18)	Bullous impetigo	Usually occurs in neonates May be epidemic	Rapid progression from vesicles to bullous lesions	Most common in diaper area
	Scalded skin syndrome Toxic epidermal necrolysis (Ritter disease in infants <4 months; Lyell syndrome in older children)	Usually occurs in infants and children 1 month–5 years of age Mucopurulent nasal and eye discharge Fever	Scarlatiniform eruption with exfoliation Nikolsky sign present Crusty appearance around eyes and under nose	Generalized Most marked on trunk
	Staphylococcal scarlet fever or staphylococcal scarlatiniform eruption	Fever and staphylococcal infection in throat, but no evidence of pharyngitis	Scarlet fever–like rash with desquamation Pastia lines present	Generalized
Staphylococcus aureus, non–exfoliative toxin-producing	Septicemic disease	Severe septicemia with osteomyelitis, arthritis, endocarditis, or pneumonia	Diffuse, erythematous, confluent, and macular rash (flush) With endocarditis, may have petechiae and splinter hemorrhages, Osler nodes, Janeway spots	Trunk and proximal end of extremities
Staphylococcus aureus, toxin-1 (TSST-1)–producing	Toxic shock syndrome	Fever, intense myalgias, vomiting, and diarrhea Mental confusion and hypotension	Erythematous, deep red (sunburn-like) rash Desquamation occurs	Generalized
Staphylococcus aureus, non–exfoliative toxin-producing	Folliculitis, furuncles, or carbuncles	See primary skin infections, Chapter 66		
Streptococcus pyogenes	Scarlet fever	Fever, pharyngitis, and cervical lymphadenitis Rash onset within 2 days of first symptoms Incubation period 3-4 days	Diffuse erythematous and fine maculopapular (looks and feels like red sandpaper) Rash darker in skin folds (Pastia lines) Desquamation occurs	Circumoral pallor Generalized rash, with trunk and proximal end of extremities being most involved
	Erysipelas	Fever, headache, and vomiting Localized infection	Circumscribed area that is raised and erythematous Advancing edge is irregular	Anywhere
	Impetigo	Localized superficial pyoderma See primary skin infections, Chapter 66	Discrete and coalescent lesions of a vesicular nature Quickly becomes more pustular and then crusts over with a yellowish brown appearance	Forearms, legs, and face
	Septicemia	Fever and systemic foci of infection	Petechiae	Diffuse
	Miscellaneous skin manifestations of *S. pyogenes* infections		Erythema multiforme, erythema nodosum, and erythema marginatum	
Streptococcus pneumoniae	Septicemia	Fever	Petechiae	Diffuse
Enterococcal and viridans group streptococci	Endocarditis	Endocarditis	Petechiae, splinter hemorrhages, Osier nodes, and Janeway spots	
Gram-negative cocci				
Neisseria gonorrhoeae	Gonococcemia	Fever and polyarthralgias	Papular, petechial purpuric, pustular, or necrotic lesions	Most common on extremities Extensor surfaces over joints
Neisseria meningitidis	Meningococcemia	Fever and pharyngitis Sudden onset of rash	Characteristic rash is petechial or purpuric Early lesions may be erythematous maculopapular, or urticarial	Generalized
Moraxella catarrhalis	Bacteremia	Fever and pharyngitis	Maculopapular and petechial	Generalized

TABLE 64–3 Bacteria Associated with Cutaneous Manifestations—cont'd

Agent	Disease or Syndrome	Clinical Characteristics	Exanthem	
			Lesions	Distribution
Gram-positive bacilli				
Bacillus anthracis	Anthrax	Fever, headache, malaise, and joint pain	Initially, macular, pruritic lesion Later, a papule forms and then vesiculation Vesicles last 2-6 days, and then eschar forms	Usually, single lesion initially at point of exposure, secondary lesions in area develop later
Listeria monocytogenes	Listeriosis	Neonatal meningitis with hepatosplenomegaly	Maculopapular, discrete lesions Pustules	Trunk and legs
Erysipelothrix rhusiopathiae	Crab or fishnet dermatitis	Fever and local pain	Erysipeloid lesion (violet or red)	Hands
Corynebacterium diphtheriae	Cutaneous diphtheria	Secondary infection in cutaneous wounds	Impetigo or ecthyma-like Rarely, erythema multiforme	Exposed surfaces
Arcanobacterium hemolyticum	Scarlet fever–like illness	Fever and pharyngitis	Scarlet fever–like rash Occasionally, rubelliform	Generalized rash with peripheral predominance
Enteric gram-negative bacilli				
Salmonella typhi	Typhoid fever	Malaise, headache, and marked fever Rash onset 10 days after onset of fever	Rose spots, 2- to 4-mm macular lesions	Discrete lesions on abdomen
Other *Salmonella* species	Septicemic salmonellosis	Similar to mild typhoid fever	Similar to typhoid fever	Similar to typhoid fever
Shigella sonnei	Shigellosis	Diarrhea	Urticaria	Diffuse
Campylobacter species		Gastroenteritis	Skin pustules and erythema nodosum	Lower part of legs
Other gram-negative bacilli				
Francisella tularensis	Tularemia	Chills, fever, headache, and localized lymphadenopathy	Initial papule that later ulcerates	Site of inoculation
Haemophilus ducreyi	Chancroid	Local pain and tenderness	Pustular lesions that ulcerate	External genitalia
Haemophilus influenzae	Septicemia	Fever	Petechiae Reddish purple cellulitis	Diffuse Cellulitis mainly on cheeks and extremities
Streptobacillus moniliformis	Rat-bite fever	Fever, chills, malaise, headache, and polyarthritis	Erythematous, maculopapular rash that may become petechial	Most prominent on extremities, including palms and soles
Yersinia pestis	Septicemic plague	Sudden onset of fever	Initial generalized erythema followed by petechiae and purpura	Generalized
Yersinia pseudotuberculosis		Mesenteric lymphadenitis	Erythema nodosum and scarlatiniform eruption	Lower part of legs and generalized
Yersinia enterocolitica	Yersiniosis	Enterocolitis	Erythema nodosum and urticaria	Lower part of legs and generalized
Bartonella bacilliformis	Bartonellosis, Carrión disease, or Oroya fever	Initially intermittent fever, malaise, and myalgias 30-60 days after initial fever, exanthem appears	Erythematous maculopapular Later recurrent nodules	Face and extensor surface of extremities
Bartonella quintana	Trench fever	Usually mild fever, headache, chills, and tibial bone pain	Macular rash	Mainly on trunk
Calymmatobacterium granulomatis	Granuloma inguinale	See *Calymmatobacterium granulomatis*, Chapter 141	Nodular, ulcerovegetative, hypertrophic, or cicatricial lesions	Genitals
Pseudomonas aeruginosa	Ecthyma gangrenosa	Septicemia (usually in immunocompromised patients)	Initially vesicular and then hemorrhagic Become ulcerated with central black necrotic eschar	Anywhere
	Pseudomonas folliculitis (health spa dermatitis)	Headache, malaise, and fatigue	Papular and pustular	Generalized
Burkholderia mallei	Glanders, melioidosis	Fever, malaise, chills, arthralgia, and muscle pains	Nodule or ulcer at site of inoculation and then widespread papules, bullae, and pustules	Generalized
Brucella species	Brucellosis	Acute or subacute febrile illness Exanthem in 8% of cases	Erythematous and maculopapular Occasionally vesicles	Generalized
Legionella pneumophila	Legionnaires' disease	Severe pneumonia	Maculopapular	Anterior of trunk

TABLE 64–3 Bacteria Associated with Cutaneous Manifestations—cont'd

			Exanthem	
Agent	**Disease or Syndrome**	**Clinical Characteristics**	**Lesions**	**Distribution**
Bartonella henselae	Cat-scratch fever	Subacute regional lymphadenitis	Erythematous maculopapular, morbilliform, petechial, erythema nodosum, erythema multiforme, and erythema marginatum May be pruritic	Generalized
Acid-fast bacilli				
Mycobacterium tuberculosis	Lupus vulgaris	Usually associated with other manifestations of tuberculosis	Reddish brown nodular or scaling lesions	Mainly on face and neck
	Papulonecrotic tuberculids	Associated with disseminated tuberculosis	Initially vesicular Become pustules, umbilical, and ulcerated and then form scabs and leave scars	Single or multiple lesions anywhere
Atypical mycobacteria			Granulomatous and ulcerative lesions at site of superficial injury	Usually on hands
Mycobacterium leprae	Erythema nodosum leprosum	General findings of lepromatous leprosy	Erythematous nodular lesions	Disseminated Most prominent on face and extremities
Spirochetes				
Treponema pallidum	Primary syphilis	Chancre	Large ulcers with indurated edges	Genitals
	Secondary syphilis		Erythematous maculopapules that frequently are scaly (psoriasiform)	Generalized, including palms and soles
Treponema pertenue	Yaws		Papular lesions at sites of inoculations Lesions ulcerate, leaving a wart-like appearance	Anywhere
Borrelia burgdorferi	Lyme disease (erythema chronicum migrans)	Skin, cardiac, neurologic, and joint abnormalities	Expanding erythematous, annular lesions	Thighs, buttocks, or axillae
Treponema carateum	Pinta		Initially, erythematous, papular lesions; increase in size during 1-month period and become scaly	Exposed surfaces of body
Spirillum minus	Rat-bite fever	Fever and chills	Discrete, macular rash	Trunk and extremities, including palms and soles
Leptospira species	Leptospirosis	Fever, conjunctivitis, and anorexia Rash rarely noted	Erythematous maculopapular rash	Mainly on trunk
Borrelia species	Relapsing fever	Relapsing fever, headache, myalgia, and photophobia	Morbilliform and petechial Erythema multiforme	Generalized

TABLE 64–4 Fungi Associated with Cutaneous Manifestations

			Exanthem	
Agent	**Disease or Syndrome**	**Clinical Characteristics**	**Lesions**	**Distribution**
Dermatophytic fungi	Tinea capitis, tinea cruris, tinea pedis, or tinea circinata		Localized, brownish, maculopapular lesions that are scaly Erythema nodosum	
Candida albicans	Congenital cutaneous candidiasis	Congenital infection	Discrete vesicular lesions	Generalized
	Chronic mucocutaneous candidiasis	Immunodeficiency disease	Confluent, erythematous, and exudative lesions	Generalized, including scalp
	Acquired candidiasis		Confluent, fiery red lesions	Most common in diaper area
Candida spp.	Systemic candidiasis	Severe opportunistic infection	Erythematous nodular lesions	Generalized
Histoplasma capsulatum	Histoplasmosis	Primary respiratory infection	Erythema nodosum, erythema multiforme, and erythematous maculopapular	
Cryptococcus neoformans	Cryptococcosis	Primary respiratory infection	Erythema nodosum and acneiform eruptions	
Coccidioides immitis	Coccidioidomycosis	Primary respiratory infection	Initially, erythematous, maculopapular rash Later, erythema multiforme and erythema nodosum	Generalized maculopapular rash
Sporotrichum schenckii	Sporotrichosis	Cutaneous inoculation	Nodular lesions that ulcerate	Usually, hands, arms, and legs
Blastomyces dermatitidis	Blastomycosis	Primary respiratory infection	Nodular lesions that ulcerate Erythema nodosum	
Scedosporium spp.	No specific syndrome	Severe opportunistic infection	Nodular or necrotic skin lesions	Generalized
Fusarium spp.	No specific syndrome	Severe opportunistic infection	Nodular skin lesions, abscesses	Generalized
Aspergillus spp.	No specific syndrome	Severe opportunistic infection	Nodular and purpuric lesions	Generalized

TABLE 64–5 Cutaneous Manifestations of Protozoan and Helminthic Infections

Agent	**Disease or Syndrome**	**Cutaneous Manifestations**
Plasmodium spp.	Malaria	Occasionally generalized urticaria in chronic infection
Toxoplasma gondii	Acquired toxoplasmosis	Occasionally generalized erythematous, maculopapular rash
	Congenital toxoplasmosis	Generalized petechial rash
Giardia lamblia	Giardiasis	Rarely urticaria
Entamoeba histolytica	Amebiasis	Rarely urticaria
Leishmania tropica	Oriental sore	Red nodular lesion that ulcerates; lasts 2-3 months
Leishmania braziliensis and *mexicana*	American cutaneous leishmaniasis	Erythematous papular lesion that vesiculates and ulcerates
Trypanosoma gambiense	African trypanosomiasis	Red nodular lesion at site of bite, followed by generalized, pruritic, erythema multiforme–like rash
Trypanosoma cruzi	American trypanosomiasis or Chagas disease	Nodular lesion at site of bite; generalized recurrent erythematous, maculopapular rash
Trichomonas vaginalis	Vulvovaginalis	Rarely urticaria and erythema multiforme
Ascaris lumbricoides	Roundworm infestation	Erythema nodosum
Enterobius vermicularis	Pinworm infestation	Rarely urticaria
Necator americanus	Hookworm disease	Papules and papulovesicles on exposed surfaces (feet); generalized urticaria
Trichinella spiralis	Trichinosis	Urticaria common; also, generalized maculopapular rash may occur; petechiae frequently develop
Strongyloides stercoralis	Strongyloidiasis; also, creeping eruption (cutaneous larva migrans)	Erythematous, maculopapular lesions on feet; creeping eruption
Ancylostoma braziliense	Creeping eruption (cutaneous larva migrans)	Creeping eruption
Dermatobia hominis	Cutaneous myiasis	Creeping eruption, subacute draining lesions
Schistosoma haematobium, *mansoni*, and *japonicum*	Schistosomiasis	Pruritic papular eruption where exposed; generalized urticaria and granulomatous lesions
Trichobilharzia ocellata, *physellae*, and *stagnicolae*	Swimmer's itch or collector's itch	Initial erythema and urticaria followed by papules and vesiculation; pruritic
Wuchereria bancrofti	Filariasis	Localized erythema urticaria and erythema nodosum
Onchocerca volvulus	Onchocerciasis	Chronic, papular, scaly rash
Echinococcus granulosus and *multilocularis*	Echinococcosis	Frequent urticaria

Data from references 14, 20, 43, 56, 69, 72, 83, 89, 133.

TABLE 64–6 Cutaneous Manifestations of Arthropod Bites and Stings

Agent	Disease or Syndrome	Cutaneous Manifestations
Spiders		
Loxosceles rectus	Recluse spider bite or brown spider bite	Erythema followed by blister and necrosis
Ticks	Tick bite	Initial pruritus at site; becomes ulcerated and granulomatous
Mites		
Sarcoptes scabiei	Scabies	Pruritic burrows in body creases and generalized; become erythematous and then papular urticaria
Trombicula irritans	Chigger bite	Marked pruritus and then papular urticaria
Other mites: food, grain, murine, and fowl		Marked pruritus and then papular urticaria
Lice		
Pediculus humanus	Body lice or pediculosis	Erythematous, maculopapular, pruritic lesions; sometimes urticaria
Phthirus pubis	Crabs	Pruritus and erythema under pubic hair
Bedbugs and kissing bugs		
Cimex lectularius	Bedbug bite	Pruritic papular urticaria
Triatoma sanguisuga	Kissing bug bite	Papular urticaria; occasionally hemorrhagic nodular lesions
Gypsy moth caterpillar		
Lymantria dispar	Gypsy moth rash	Pruritic blotchy erythema and maculopapular
Moths		
Hylesia alinda	Moth-associated dermatitis	Erythema and pruritus; feeling of warmth in area of rash; may have vesicular lesions
Ants		
Solenopsis saevissima	Fire ant bite	Painful papular urticarial lesions that become pustular and then nodular
Fleas		
Pulex irritans (human flea) and fleas of many animals	Flea bite	Papular urticaria
Flies and mosquitoes	Fly and mosquito bite	Papular, nodular, and urticarial lesions in sensitive persons

Data from references 45, 47, 61, 69, 96, 148, 165, 176, 181.

TABLE 64–7 Aspects of Pathogenesis in Exanthems Associated with Blood-borne Dissemination of the Infectious Agent

Anatomic Location	Spread of Agent	Histology	Clinical Expressions	Pathophysiology
Blood	Free in plasma; Associated with leukocytes			
Dermal capillary endothelium	Infection	Damage to vessel, endothelial swelling, perivascular edema, cellular infiltration, hemorrhage	Macule, papule, petechia	Direct effect of agent or immune reaction with pathologic consequences
	To dermis through breaks in basement membrane (secondary to trauma); To dermis by diapedesis; Contiguous spread			
Dermis	Infection; Contiguous spread	Edema, cellular infiltration, hemorrhage, microscopic visualization of organism	Papule, urticaria, purpura, vesicle	Direct effect of agent or immune reaction with pathologic consequences; histamine release
Epidermis	Infection	Cytopathic effects (inclusions, ballooning, vacuolation, necrosis, nuclear disruption), microscopic visualization of organism	Papule, vesicle, ulcer	Direct effect of agent

Modified from Cherry, J. D.: Newer viral exanthems. Adv. Pediatr. 16:*233-286, 1969.*

CLINICAL MANIFESTATIONS

The clinical findings in exanthematous diseases resulting from systemic infections are varied and depend on the inciting pathogens. By examination of skin alone, differentiating an exanthematous disease resulting from systemic infection (e.g., coxsackievirus A9, rubella virus infection) from primary cutaneous diseases of infectious and noninfectious origin (insect bites, acne, and contact with poison ivy) frequently is difficult. In Tables 64–1 through 64–6, the clinical characteristics of viral, chlamydial, rickettsial, bacterial, fungal, parasitic, and arthropod-induced illnesses with primary or secondary cutaneous manifestations are presented. In Tables 64–8 through 64–17, etiologic agents and clinical manifestations are presented on the basis of the more pronounced cutaneous manifestations or syndrome associations. The clinician must keep in mind that other aspects of an illness (e.g., exposure, season, incubation period, geographic location, patient age, associated signs and symptoms) may be more important in determining the underlying etiologic agent. Clinical manifestations of specific exanthematous diseases are presented in greater detail in other chapters of this book.

ERYTHEMATOUS MACULAR EXANTHEMS

When all infectious diseases with exanthems are taken into consideration, the occurrence of illnesses in which the lesions are just macular is rare. However, many important, severe diseases have a transitory erythematous macular rash early in their course, and recognition of this fact can be lifesaving. Infectious agents associated with illnesses in which macular exanthems have been observed are presented in Table 64–8.

The most common rash in infectious mononucleosis is erythematous and maculopapular, but rarely (most often in association with the administration of ampicillin) the exanthem is generalized, confluent, fiery red, and macular. Blotchy or diffuse erythematous macular rashes have been caused specifically by 12 different enterovirus types. Most of these descriptions involve neonates, other very young infants, and adults; children in the peak ages for enteroviral exanthematous diseases do not seem to have solely macular lesions. In neonates, enteroviral disease with a blotchy macular rash in association with fever and lethargy usually is confused with bacterial sepsis.

Patients with dengue, Lassa, and Marburg viral infections frequently have a macular, flushed appearance before other cutaneous manifestations develop. Similarly, in both murine and epidemic typhus, the initial skin manifestations are macular but progress rapidly to more pronounced findings.

Bacterial septicemia with both common and exotic organisms is associated frequently with a generalized flush. In staphylococcal disease, the rash is particularly apparent in endocarditis and osteomyelitis. The most famous disease with a macular rash is typhoid fever. Rose spots occur most commonly on the abdomen, but they also are seen on the chest and back. They are erythematous, macular lesions 2 to 4 mm in size. Lesions likewise have been noted in leptospirosis and psittacosis. In addition, rose spots are seen occasionally in septicemic illnesses caused by other *Salmonella* spp.

The slapped-cheek appearance in erythema infectiosum (Fig. 64–6) is caused by an erythematous macular flush of the cheeks. The full-blown rash in streptococcal scarlet fever is maculopapular, but frequently in mild cases and in those altered by antibiotic therapy, the exanthem is only macular in character (scarlatina).

TABLE 64–8 Infectious Agents Associated with Illness in Which a Macular Exanthem Has Been Observed

Infectious Agent	Illness
Human herpesvirus–6, –7	Roseola infantum
Epstein-Barr virus	Infectious mononucleosis
Coxsackieviruses Bl, B2, B5	—
Echoviruses 2, 4, 5, 14, 17-19, 30	—
Enterovirus 71	—
Dengue virus	Dengue fever
Lassa virus	Lassa fever
Marburg virus	Marburg fever
Parvovirus	Erythema infectiosum
HIV-1	Manifestation of acute infection
Hantavirus	Hemorrhagic fever with renal syndrome
Chlamydia psittaci	Psittacosis
Rickettsia typhi	Murine typhus
Rickettsia prowazekii	Epidemic typhus
Rickettsia quintana	Trench fever
Coxiella burnetii	Q fever
Mycoplasma pneumoniae	—
Staphylococcus aureus	Septicemia and toxic shock syndrome
Streptococcus pyogenes	Scarlatina and septicemia
Bacillus anthracis	Anthrax
Salmonella typhi	Typhoid fever
Salmonella species	Septicemic salmonellosis
Spirillum minus	Rat-bite fever
Leptospira species	Leptospirosis
Yersinia pestis	Plague

ERYTHEMATOUS MACULOPAPULAR EXANTHEMS

An erythematous maculopapular rash is the most common cutaneous manifestation of systemic infection (Figs. 64–2, 64–8, 64–10, and 64–13). It also is an exceedingly common occurrence in allergic conditions. However, all too frequently, the rash of an infectious illness is ascribed to an allergic reaction to an administered drug rather than correctly to the disease process. The converse—an allergic rash illness that is attributed mistakenly to an infectious agent—rarely occurs. Infectious agents associated with illnesses in which maculopapular exanthems occur are presented in Table 64–9.

Both by the number of possible etiologic agents and by total infections, viruses account for the vast majority of illnesses with maculopapular eruptions. Although the distribution and progression of rashes are important aspects relating to the differential diagnosis, the single most important point is whether the lesions are discrete (rubelliform) or confluent (morbilliform). Adenoviruses are not uncommon causes of erythematous maculopapular eruptions. In most instances, signs and symptoms of upper respiratory infection are present. Most commonly, the lesions are discrete, but occasionally, a confluent morbilliform rash is present. A roseola infantum picture—occurrence of rash after the fever falls by crisis—frequently occurs. As a rule, the exanthem in adenoviral infections starts on the head and spreads to the trunk and extremities.

Enteroviruses account for the greatest number of erythematous maculopapular rash illnesses; 36 different serologic types have been implicated. The enteroviral types most commonly associated with maculopapular exanthems are coxsackieviruses A9 and B5 and echoviruses 4, 9, and 16. Echovirus 9 has been the most frequent cause of enteroviral exanthem for the last 35 years (Fig. 64–13). Although morbilliform rashes do occur, the more usual cutaneous manifestation is one suggestive of rubella. The exanthem usually starts on the head and upper part of the trunk and spreads to the extremities.

Although they are not common manifestations of respiratory viruses (rhinoviruses, influenza A and B viruses, RSV, and para-

influenza viruses types 1 through 4), exanthems probably occur more often than is generally realized. Because children infected with these agents frequently are given antibiotics, confusion often occurs between an allergic and an infectious etiology. With all the respiratory viruses, the signs and symptoms of respiratory illness (cough, coryza, croup, bronchiolitis, and so on) are prominent. The exanthems virtually are always discrete and rubelliform in character.

In dengue, the exanthem goes through several stages. Initially, it is macular, then erythematous maculopapular, and finally hemorrhagic. Similarly, the exanthems in the rickettsial diseases go through stages that vary in relation to the specific agent (see Table 64–2). In Rocky Mountain spotted fever, the rash starts on the distal ends of extremities. Although the hallmark of meningococcemia is a petechial or purpuric rash, in the initial stages, the exanthem may be erythematous and maculopapular. In addition, maculopapular eruptions are observed in chronic meningococcemia. The most notable cutaneous lesion in coccidioidomycosis is erythema nodosum, but a rubelliform rash early in infection is not an unusual manifestation.

VESICULAR EXANTHEMS

The three main categories of vesicular exanthems are single or localized lesions, generalized lesions in greatest concentration on

TABLE 64–10 Infectious Agents Associated with Illnesses in Which Vesicular Exanthems Occur

Infectious Agent	Illness
Human parvovirus B19	
Herpes simplex virus types 1 and 2	Cold sores, genital herpes, or neonatal herpes
Varicella-zoster virus	Chickenpox (varicella) or herpes zoster
Vaccinia virus	Disseminated vaccinia or eczema vaccinatum
Variola virus	Smallpox
Monkeypox virus	
Orf virus	Ecthyma contagiosum
Tanapox virus	
Coxsackieviruses A4, A5, A8, A10, A16	
Coxsackieviruses Bl-B3	
Echoviruses 6, 9,11, 17	
Enterovirus 71	
Reovirus 2	
Calicivirus of oceanic origin	
Alphaviruses: chikungunya, o'nyong-nyong fever, Ross River, Sindbis	
Kunjin virus	
Mumps virus	Mumps
Measles virus	Atypical measles
Rickettsia akari	Rickettsialpox
Rickettsia tsutsugamushi	
Mycoplasma pneumoniae	
Streptococcus pyogenes	Impetigo
Pseudomonas aeruginosa	
Brucella species	Brucellosis
Bacillus anthracis	Anthrax
Mycobacterium tuberculosis	Papulonecrotic tuberculids
Candida albicans	Congenital cutaneous candidiasis
Leishmania braziliensis	American cutaneous leishmaniasis
Necator americanus	Hookworm disease

TABLE 64–11 Infectious Agents Associated with Illness in Which Petechial and Purpuric Exanthems Occur

Infectious Agent	Illness
Human parvovirus B19	Glove and socks syndrome
Varicella-zoster virus	Hemorrhagic chickenpox
Cytomegalovirus	Congenital cytomegalovirus infection
Variola virus	Hemorrhagic smallpox
Coxsackieviruses A4, A9	
Coxsackieviruses B2-B4	
Echoviruses 4, 7, 9	
Colorado tick fever virus	Colorado tick fever
Rotavirus	
Alphaviruses: chikungunya, o'nyong-nyong fever, Ross River, Sindbis	
Rubella virus	Rubella (German measles) or congenital rubella
Respiratory syncytial virus	
Measles virus	Hemorrhagic (black measles) or atypical measles
Lassa virus	Lassa fever
Marburg virus	
Hepatitis C virus	Mixed cryoglobulinemia
Hantavirus	Hemorrhagic fever with renal syndrome
Rickettsia typhi	Murine typhus
Rickettsia prowazekii	Epidemic typhus
Rickettsia rickettsii and other tick-borne rickettsiae	Rocky Mountain spotted fever
Ehrlichia species	Ehrlichiosis
Mycoplasma pneumoniae	
Streptococcus pyogenes	Scarlet fever or septicemia
Streptococcus pneumoniae	Pneumococcal septicemia
Enterococcal and viridans group streptococci	Endocarditis
Neisseria gonorrhoeae	Gonococcemia
Neisseria meningitidis	Meningococcemia
Moraxella catarrhalis	
Haemophilus influenzae	*H. influenzae* septicemia
Pseudomonas aeruginosa	Ecthyma gangrenosa
Streptobacillus moniliformis	
Yersinia pestis	Septicemic plague (black death)
Bartonella henselae	Cat-scratch fever
Treponema pallidum	Congenital syphilis
Borrelia species	Relapsing fever
Toxoplasma gondii	Congenital toxoplasmosis
Trichinella spiralis	Trichinosis

the trunk and head, and generalized lesions with the greatest concentration on the extremities (Figs. 64–4, 64–5, and 64–9). Infectious agents associated with illnesses in which vesicular rashes develop are presented in Table 64–10. The exanthem in primary or recurrent HSV infection is localized, as it is in recurrent endogenous varicella-zoster infection (herpes zoster), ecthyma contagiosum, tanapox, scrub typhus, anthrax, and papulonecrotic tuberculids (Fig. 64–5).

The vesicular exanthematous disease that occurs most commonly in children today is chickenpox (Fig. 65–4). It should be a readily recognizable disease, but is all too frequently confused with enteroviral infections or insect bites and allergic conditions. Chickenpox has a long incubation period (16 days) and is associated with mild fever and an exanthem that starts on the head and upper part of the trunk and spreads to the extremities. The rash always is more prominent on the trunk than on the extremities. At any time during the first few days of the rash, lesions in all stages (macules, papules, and vesicles) can be seen. Individual lesions in chickenpox form scabs that persist for approximately 7 days.

In contrast to that of chickenpox, the exanthem in enteroviral infections frequently is peripheral in distribution, and the lesions generally heal without scabs. The incubation period (5 days) is much shorter than that of chickenpox. The hand, foot, and mouth syndrome is a common manifestation of enteroviral vesicular rash illnesses (Figs. 64–9 to 64–11). The most frequent etiologic agent in the hand, foot, and mouth syndrome is coxsackievirus A16, but the syndrome also has been attributed to coxsackieviruses A5, A9, A10, B1, and B3 and enterovirus 71.

Enteroviral infections with vesicular exanthems in which the hand, foot, and mouth distribution is not present quite frequently are diagnosed erroneously as insect bites or poison ivy.

PETECHIAL AND PURPURIC EXANTHEMS

A large number of infectious agents are associated with petechial and purpuric skin manifestations (Figs. 64–14 and 64–15). They are listed in Table 64–11. Infectious diseases with hemorrhagic rash can be fulminant fatal events or relatively benign illnesses. On a worldwide basis, meningococcemia is perhaps the most important and feared, although it is not the most prevalent of the petechial and purpuric exanthematous diseases. The relatively sudden onset of fever and a petechial rash must be considered and treated as meningococcemia unless another etiology can be established with absolute certainty. The most important of the

differential diagnostic problems is exanthem caused by enteroviral infection. Many different entero-virus illnesses have a sudden onset with accompanying fever and petechial rash. In addition, the situation frequently is complicated further by the occurrence of meningitis. The most important enterovirus in its ability to mimic meningococcemia is echovirus 9.

Purpuric and petechial lesions in infectious illnesses can result from a direct or indirect (immunologic) effect of the infectious agent at the cutaneous site or from the occurrence of thrombocytopenia. Thrombocytopenia is noted most commonly in acquired rubella virus infections.

URTICARIAL EXANTHEMS

The occurrence of urticaria all too frequently leads the physician to suspect an allergic or dermatologic condition (Figs. 64–12 and 64–16).[199,200] However, what has become quite evident in recent years is that when urticaria develops in association with an acute febrile illness, the cutaneous reaction is a direct effect of an infectious agent, and its mediation does not require an allergic response. Listed in Table 64–12 are infectious agents associated with urticarial exanthems.

Papular urticaria occurs very commonly in children in the summer and fall and most frequently is the result of insect bites (see Table 64–6). However, virtually identical lesions occur in infections with coxsackievirus A as well as with other enteroviruses (Fig. 64–12). The main point for differentiation is that fever regularly develops in the virus-induced exanthems but is not a characteristic associated with insect bites.

Early in the course of meningococcemia, the exanthem can be urticarial, so an illness of sudden onset with fever and this cutaneous manifestation never should be taken lightly.

TABLE 64–12 Infectious Agents Associated with Illness in Which Urticarial Exanthems Occur

Infectious Agent	Illness
Epstein-Barr virus	Infectious mononucleosis
Coxsackieviruses A9, A16, B4, B5	
Echovirus 11	
Mumps virus	Mumps
Hepatitis B virus	
Hepatitis C virus	
Mycoplasma pneumoniae	
Neisseria meningitidis	Meningococcemia
Shigella sonnei	Shigellosis
Yersinia enterocolitica	Yersiniosis
Borrelia burgdorferi	Lyme disease
Plasmodium species	Malaria
Coxiella burnetii	Q fever
Giardia lamblia	Giardiasis
Entamoeba histolytica	Amebiasis
Trichomonas vaginalis	Vulvovaginalis
Enterobius vermicularis	Pinworm infestation
Necator americanus	Hookworm disease
Trichinella spiralis	Trichinosis
Schistosoma species	Schistosomiasis
Trichobilharzia species	Swimmer's itch or collector's itch
Wuchereria bancrofti	Filariasis
Echinococcus species	Echinococcosis
Sarcoptes scabiei	Scabies
Trombicula irritans	Chigger bites
Other mites	Mite bites
Pediculus humanus	Pediculosis
Bedbugs, kissing bugs, ants, fleas, flies, and mosquitoes	Bites and stings

PAPULAR, NODULAR, AND ULCERATIVE LESIONS

In many instances, the lesions in this category occur as single events at the site of primary inoculation. Specific illnesses and etiologic agents are listed in Table 64–13.

DISTINCTIVE CLINICAL FEATURES OR SYNDROMES

(Figs. 64–19 to 64–24)

Erythema Multiforme

Erythema multiforme is a self-limited skin eruption that is erythematous and characterized by distinctive target or iris lesions or both. Small vesicles and urticarial areas also may develop. On occasion, the disease is severe and associated with mucosal involvement and genital lesions. In this latter illness—the Stevens-Johnson syndrome, bullous erythema multiforme, erythema multiforme exudativum major—severe ulcerative, oral, and genital lesions occur; generalized exanthems become bullous, and

Figure 64–19 An erythematous maculopapular discrete and confluent rash on the thigh and arm of a 16-year-old girl with pharyngitis and *Arcanobacterium haemolyticum* isolated from her throat. (See companion Expert Consult web site for color version.) *(From Mackenzie, A., Fuite, L. A., Chan, F. T. H., et al.: Incidence and pathogenicity of Arcanobacterium haemolyticum during a 2-year study in Ottawa. Clin. Infect. Dis. 21:177-181, 1995.)*

Figure 64–20 Numerous flat-topped and dome-shaped, slightly erythematous papules over the skin of the perineum of a young girl with bowenoid papulosis. (See companion Expert Consult web site for color version.)

conjunctivitis is present. The illness is associated with fever and general distress.

Although the pathogenesis of erythema multiforme is unknown, what is clear is that multiple factors, including infectious agents, are responsible for its occurrence. Infectious agents associated with erythema multiforme are listed in Table 64–14. The single most important infectious cause of erythema multiforme and Stevens-Johnson syndrome is *M. pneumoniae*. When *M. pneumoniae* is the instigating agent, the patient nearly always has concomitant pneumonia.

HSV frequently has been recovered from the throats of persons with erythema multiforme, but the cause-and-effect relationship in many cases must be questioned. However, in a recent study, HSV DNA was found in the skin lesions of 11 of 31 patients with erythema multiforme.[58]

Figure 64–21 Numerous isolated purple papules of dermal erythropoiesis overlying the icteric skin of a neonate with congenital cytomegalovirus infection. (See companion Expert Consult web site for color version.)

Figure 64–22 Tinea pedis. Peeling, macerations, and fissuring in the fourth interdigital space of the foot are characteristic of dermatophytic infections. (See companion Expert Consult web site for color version.)

Figure 64–23 Clinical photograph of an infant with *Candida* diaper dermatitis. Confluent and discrete erythematous papules and plaques involving the scrotum, penis, and suprapubic and inguinal area are evident. (See companion Expert Consult web site for color version.)

TABLE 64–14 Infectious Agents Associated with Erythema Multiforme

Agent	Illness
Human parvovirus B19	Erythema infectiosum
Adenovirus 7	Respiratory infection
Herpes simplex virus type 1	Perioral or respiratory infection
Epstein-Barr virus	Infectious mononucleosis
Varicella virus	Chickenpox
Coxsackieviruses A10, A16, B5	Enterovirus syndrome
Echovirus 6	Enterovirus syndrome
Poliomyelitis virus	Poliomyelitis
Vaccinia virus	Smallpox vaccination
Variola virus	Smallpox
Orf virus	Ecthyma contagiosum
Paravaccinia virus	Milker's nodules
Influenza A virus	Influenza
Mumps	Mumps
Hepatitis B virus	Serum hepatitis
Chlamydia psittaci	Psittacosis
Chlamydia trachomatis	Lymphogranuloma venereum
Mycoplasma pneumoniae	Respiratory symptoms
Staphylococcus aureus	Septicemia
Streptococcus pyogenes	Respiratory symptoms
Neisseria gonorrhoeae	Gonorrhea
Corynebacterium diphtheriae	Diphtheria
Pseudomonas aeruginosa	Septicemia
Salmonella species	Gastroenteritis
Francisella tularensis	Tularemia
Yersinia species	Gastrointestinal symptoms
Vibrio parahaemolyticus	Gastroenteritis
Treponema pallidum	Syphilis
Bartonella henselae	Cat-scratch fever
Mycobacterium tuberculosis	Tuberculosis
Mycobacterium leprae	Leprosy
Coccidioides immitis	Coccidioidomycosis
Histoplasma capsulatum	Histoplasmosis
Trichomonas vaginalis	Vulvovaginalis

Figure 64–24 An extensive crusted erosion on the left thigh of a child with a cryptococcal skin infection. (See companion Expert Consult web site for color version.)

Erythema Nodosum

Erythema nodosum most commonly occurs on the anterior aspect of the lower part of the legs but may be seen anywhere on the body. The lesions are raised, erythematous, and painful to touch. Their usual size is approximately 2 to 4 cm, with a duration of 2 to 6 weeks.

TABLE 64–15 Infectious Agents Associated with Erythema Nodosum

Agent	Illness
Herpes simplex virus	Perioral or respiratory infection
Epstein-Barr virus	Infectious mononucleosis
Chlamydia psittaci	Psittacosis
Chlamydia trachomatis	Lymphogranuloma venereum
Streptococcus pyogenes	Respiratory infection
Neisseria meningitidis	Meningococcemia
Corynebacterium diphtheriae	Diphtheria
Campylobacter species	Gastroenteritis
Haemophilus ducreyi	Chancroid
Salmonella species	Salmonellosis
Yersinia species	Gastrointestinal symptoms
Brucella species	Brucellosis
Treponema pallidum	Syphilis
Bartonella henselae	Cat-scratch fever
Mycobacterium tuberculosis	Tuberculosis
Mycobacterium leprae	Leprosy
Trichophyton species	Kerion of scalp
Histoplasma capsulatum	Histoplasmosis
Cryptococcus neoformans	Cryptococcosis
Coccidioides immitis	Coccidioidomycosis
Blastomyces dermatitidis	Blastomycosis
Ascaris lumbricoides	Roundworm infestation
Wuchereria bancrofti	Filariasis

Erythema nodosum occurs less commonly today than it did 4 decades ago, and the frequency of specific associated infectious agents also is different. In the past, streptococcal and mycobacterial infections were the agents most commonly related. Now, the exanthem most often is associated with respiratory infection with *Histoplasma capsulatum*, *Cryptococcus neoformans*, and *Coccidioides immitis*. Infectious agents associated with erythema nodosum are listed in Table 64–15.

Hand, Foot, and Mouth Syndrome

The hand, foot, and mouth syndrome is a clearly recognizable viral illness characterized by vesicular lesions in the anterior of the mouth and on the hands and feet in association with fever. Although several enteroviruses (coxsackieviruses A5, A9, A10, A16, B1, and B3 and enterovirus 71) have been implicated, as have HSV and foot and mouth disease virus, most of these cases are caused by coxsackievirus A16.

Roseola-like Illness

Roseola infantum is a classic pediatric illness characterized by fever of 3 to 5 days' duration, rapid defervescence, and then the appearance of an erythematous macular or maculopapular rash that persists for 1 to 2 days. Roseola is an age-related response to infection with many viruses. Recent studies suggest that a leading cause of roseola infantum is primary infection with HHV-6. The following other viruses have been noted in association with roseola: adenoviruses 1, 2, 3, and 14; coxsackieviruses A6, A9, B1, B2, B4, and B5; echoviruses 9, 11, 16, 25, 27, and 30; parainfluenza virus type 1; and measles vaccine virus.

Rocky Mountain Spotted Fever–like Illness

Rocky Mountain spotted fever is a clinical illness characterized by fever and a petechial rash located mainly on the distal ends of extremities. The illness is caused by *Rickettsia rickettsii* and is prevalent in many areas of North America; the infectious agent is transmitted to humans by ticks. In other areas of the world,

other tick-borne rickettsiae *(Rickettsia sibirica*, *Rickettsia australis*, *Rickettsia conorii)* produce similar human illness. Infection with *Ehrlichia canis* also can cause an illness similar to Rocky Mountain spotted fever.

The most important illness confused with Rocky Mountain spotted fever is atypical measles (see Chapter 192). This illness, which has both the constitutional symptoms of Rocky Mountain spotted fever and a rash most prominent on the extremities, occurs almost exclusively after exposure to measles virus in some persons previously immunized with inactivated (killed) measles vaccine.

Rat-bite fever caused by *S. moniliformis* also has been misdiagnosed as Rocky Mountain spotted fever.[156]

Exanthem and Meningitis

Aseptic and also bacterial meningitis frequently are characterized by both exanthem and symptoms and signs of neurologic involvement. Infectious agents associated with exanthem and meningitis are presented in Table 64–16. Of most importance in this category is the differential diagnosis of enteroviral syndromes and meningococcemia.

Exanthem and Pulmonary Involvement

Infectious agents associated with exanthem and pulmonary involvement are listed in Table 64–17. In patients older than 5 years old, the leading cause of exanthem and pneumonia is *M. pneumoniae* infection. In younger children, adenoviruses are the most important etiologic agents. With the exception of enteroviral infections, which are more likely to involve young children, most of the illnesses listed in Table 64–17 occur in older children and young adults.

TABLE 64–16 Infectious Agents Associated with Exanthem and Meningitis

Agent	Illness
Herpes simplex virus type 2	Recurrent genital herpes
Coxsackieviruses A2, A9, B1, B4, B5	Enterovirus syndrome
Echoviruses 4, 6, 9, 11, 14, 17, 25, 33	Enterovirus syndrome
Colorado tick fever virus	Colorado tick fever
Reovirus 2	Respiratory infection
West Nile virus	Meningoencephalitis
Neisseria meningitidis	Meningococcemia
Borrelia burgdorferi	Lyme disease
Listeria monocytogenes	Listeriosis
Toxoplasma gondii	Toxoplasmosis

TABLE 64–17 Infectious Agents Associated with Exanthem and Pulmonary Involvement

Agent	Illness
Adenoviruses 7,7a	Respiratory infection
Herpes simplex virus type 1	Respiratory infection
Varicella-zoster virus	Chickenpox pneumonia
Epstein-Barr virus	Infectious mononucleosis
Coxsackievirus A9	Enterovirus syndrome
Echovirus 11	Enterovirus syndrome
Reovirus 3	Respiratory infection
Measles virus	Measles pneumonia and atypical measles
Chlamydia psittaci	Psittacosis
Mycoplasma pneumoniae	*M. pneumoniae* pneumonia
Neisseria meningitidis	Meningococcal pneumonia
Mycobacterium tuberculosis	Tuberculosis
Histoplasma capsulatum	Histoplasmosis
Cryptococcus neoformans	Cryptococcosis
Coccidioides immitis	Coccidioidomycosis

Gianotti-Crosti Syndrome (Papular Acrodermatitis)

Gianotti-Crosti syndrome is a distinct clinical entity characterized by a papular (lichenoid) exanthem, generalized lymphadenopathy, hepatomegaly, and acute anicteric hepatitis.[46,170,173] In most instances, this illness has been associated with hepatitis B virus infection. The syndrome also has been noted in association with Epstein-Barr virus, cytomegalovirus, coxsackievirus B virus, and RSV infections.[65,111,171,193]

Cutaneous Manifestations Associated with Infections in Immunocompromised Patients

All infectious agents that cause exanthems in immunologically normal children can cause infections in immunocompromised children. However, the clinical manifestations may be different. For example, measles virus infection in a child who is T-cell-deficient may be associated with a severe, progressive pneumonia but not the typical rash. Other viral exanthems that are self-limited in normal children, such as varicella, may be progressive and develop into hemorrhagic skin lesions with disseminated organ involvement in children with T-cell-deficiency.

Of particular concern are bacterial and fungal infections, which are rarely a problem in normal children but are rapidly fatal in granulocytopenic children. These patients have characteristic skin lesions resulting from disseminated infections. Of importance are ecthyma gangrenosa resulting from *Pseudomonas aeruginosa* septicemia and the nodular and purpuric lesions of disseminated fungal infections caused by *Aspergillus*, *Candida*, and other less common agents.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

The diagnosis of infectious exanthems frequently is considered an impossible task by many physicians. Other physicians glibly call the first maculopapular exanthem of childhood "roseola" and the first vesicular rash "chickenpox" without consideration of more appropriate choices. The hallmark of diagnosis in exanthematous disease is careful elicitation of historic data. Differential diagnosis requires the consideration of noninfectious etiologies as well as different infectious agents. Listed in Table 64–18 are the major considerations in the diagnosis of diseases with cutaneous manifestations.

A history of exposure is most important in making a differential diagnosis. For example, was the patient exposed to poison ivy, insects, or a person ill with a specific disease? In infectious illnesses with high clinical expression rates (measles, chickenpox, rubella), proper questioning usually reveals a contact case or at least other cases in the community. On the other hand, in ill-

TABLE 64–18 Important Aspects in the Diagnosis of Exanthematous Illness

Exposure	Types of Rash
Season	Distribution of rash
Incubation period	Progression of rash
Age	Exanthem
Previous exanthems	Other associated symptoms
Relationship of rash to fever	Laboratory tests
Adenopathy	

From Cherry, J. D.: Newer viral exanthems. Adv. Pediatr. 16:233-286, 1969.

nesses with low rates of clinical expression of exanthem, such as adenoviral and some enteroviral infections, the source may not be apparent.

Consideration of the seasonal occurrence of different infectious agents, as well as insects, is particularly useful in making a differential diagnosis. In temperate climates, enteroviral and arthropod-mediated diseases occur in the summer and fall. Exanthems with measles, varicella-zoster, and rubella viruses occur most often in the winter and spring. The diagnosis of rubella is important because of fetal consequences. All too frequently, rubella is overdiagnosed and underdiagnosed, both of which can be avoided if its seasonal prevalence is understood.

The incubation period is important in separating the exanthem caused by rubella, varicella-zoster, or measles viruses from rash illnesses caused by enteroviruses or common respiratory viruses. The former have long incubation periods, whereas in the others, the period from exposure to the onset of illness is less than 1 week. Age can be useful. Today in the United States, measles and rubella often are illnesses of adolescents and young adults. Enteroviral exanthem frequency is related inversely to age.

Questioning to obtain a pertinent history of previous exanthems can give useful information if it is done with care. For example, if patients are asked whether they had rubella, the answer is quite unreliable. However, if the past illness is documented by year, season, and symptoms, accurate information often is obtained. The relationship of rash to fever is most significant in the diagnosis of roseola. The presence or absence of fever is important in separating exanthems of infectious and noninfectious etiology. Frequently, insect bites are diagnosed as chickenpox by parents and physicians as well. Chickenpox rarely occurs without fever.

The type and distribution of exanthem obviously are important. They virtually are diagnostic in hand, foot, and mouth syndrome, Rocky Mountain spotted fever, and atypical measles. Enanthem can lead to a specific diagnosis (Koplik spots in measles [Fig. 64–1]) or a category diagnosis (herpangina in enteroviral infections). Other characteristics, such as those listed in Tables 64–8 through 64–17, obviously are useful in delineating a specific illness.

SPECIFIC DIAGNOSIS

As with other infectious diseases, establishing specific diagnosis depends on the acquisition of proper cultures, serologic tests, and microscopic study of secretions or histologic or cytologic preparations. These techniques are discussed in other chapters of this book.

Vesicular lesions always should be scraped for cytologic study or direct antigen identification (varicella, herpes simplex), and, frequently, petechial lesions should be scraped and stained in a search for infectious agents (meningococci). The etiology of viral infections can be established by isolation of virus, direct antigen detection, or serologic methods. In most instances, a virus recovered from the throat indicates acute infection and is the probable cause of a particular illness. Serologic study without culture is useful in diagnosing rickettsial diseases, some viral infections, and a few illnesses of bacterial origin. Serologic study without virus isolation generally is not useful in diagnosing enteroviral illnesses.

TREATMENT, PROGNOSIS, AND PREVENTION

The treatment, prognosis, and prevention of exanthematous diseases are presented in appropriate chapters throughout this text.

CHAPTER 65

Roseola Infantum (Exanthem Subitum)

James D. Cherry

Roseola infantum (i.e., exanthem subitum, pseudorubella, exanthem criticum, sixth disease, or 3-day fever) is a common, acute illness of young children characterized by a fever of 3 to 5 days' duration, rapid defervescence, and then the appearance of an erythematous macular or maculopapular rash that persists for 1 to 2 days.

HISTORY

Zahorsky[80] generally is given credit for the original description of roseola infantum. In his writings, he pointed out, however, that the syndrome was described in earlier pediatric and dermatology texts.[81-83] Altschuler[1] observed that a British dermatologist, Willan, presented a description of the illness in his 1809 book *On Cutaneous Diseases*. The descriptions in the older literature did not separate the syndrome from the known exanthematous diseases (i.e., measles, rubella, and scarlet fever), an omission that Zahorsky corrected.

In 1921, Veeder and Hempelmann[75] described the syndrome further and noted that leukopenia and relative lymphocytosis occurred. These investigators objected to the name *roseola infantum*, which in the past had been used to describe a large group of diseases with indefinite causes. They suggested the term *exanthem subitum* because it was "descriptive of the most striking clinical symptom, namely, the sudden, unexpected appearance of the eruption on the fourth day." Currently, the term *roseola* is used most commonly to describe the syndrome.

From 1920 through 1940, many excellent clinical descriptions of the syndrome were published.* From 1940 through 1988, articles relating to roseola were concerned with unusual manifestations and complications[8,11-13,22,32,46,48,49,53,56,63] and attempts to recover an etiologic agent.[26,30,40,45,64] In 1988, Yamanishi and associates[78] identified human herpesvirus–6 (HHV-6) in the blood of infants with roseola, and since then, the association between this virus and the disease has been confirmed on many occasions.† HHV-7 also has been found to be the cause of many cases of roseola.[3,14,31,68,71,72,74]

*See references 6, 7, 10, 17, 18, 20, 24, 25, 36, 83, 84.

EPIDEMIOLOGY

In his original article, Zahorsky[80] reported that roseola occurred most commonly in the fall. In his second article, he observed a year-round incidence[81]; in 1925, he pointed out that most cases occurred in the spring, summer, and fall.[82] Breese[10] noted that the greatest number of cases occurred in the summer and early fall. In contrast, 55 percent of Clemens' cases occurred in February, March, and April; 16 percent were seen in October.[17] In a review of 243 cases during a 10-year period, Juretic[38] observed that the peak month was May. Juretic also reviewed the seasonal incidence in 10 other studies and found only minor variations by month. Prevalence was greatest in March, April, and October and least in December. One epidemic of roseola in a maternity hospital occurred in the summer,[36] another epidemic in an infants' home occurred in the fall,[6] and a hospital outbreak occurred in the winter.[18]

Roseola predominantly is an illness of young children. It occurs rarely in infants younger than 3 months old or children older than 4 years. In a review of 1462 cases, the peak age range prevalence was 7 to 13 months of age; 55 percent of the cases occurred within the first year of life, and 90 percent occurred within the first 2 years of life.[38] Occasionally, cases have been seen in older children, adolescents, and young adults and in neonates and other infants younger than 6 months.[25,36]

Although Faber and Dickey[20] found twice as many girls as boys with the syndrome, the sex ratio in most large studies has been equal.[7,10,17,25,45] Although three epidemics have been reported, and cases frequently occur in groups by season, most cases occur sporadically without known exposure. The syndrome, when seen sporadically, generally is considered to be noncontagious, but secondary cases have been reported occasionally.[6,10,18,36] The incubation period range in epidemics is 5 to 15 days.[6,10,18]

The attack rate of roseola has not been well studied. Berenberg and associates[7] stated that roseola is the exanthem most commonly encountered in children younger than 2 years old. Breese[10] found that 16 percent of a group of infants he followed for the first 12 months of life had definite roseola. He estimated that 30 percent of children would have clinical roseola. Juretic[38] looked at the frequency of roseola in 6735 children; the yearly attack rate during a 10-year period ranged from 1 to 10 percent, with a mean of 3.3 percent.

ETIOLOGY

In 1941, Breese[10] reported vigorous attempts to isolate a filterable virus from three children with pre-eruptive roseola. These studies included extensive animal inoculations, but no viral agents were uncovered. In 1950, Kempe and associates[40] reported the passage of the illness to a 6-month-old susceptible infant by the intravenous injection of serum from an 18-month-old child with pre-eruptive roseola. Febrile illnesses without exanthem also were produced in monkeys with serum and throat washings from a child with the syndrome. In similar experiments, Hellström and Vahlquist[30] produced the syndrome in three children aged 6 to 9 days after the intramuscular administration of blood from typical roseola cases.

In electron microscopic studies, Reagan and associates[61] observed uniform virus-like particles (100-110 nm) in the blood of an 18-month-old child with the syndrome. Febrile illness was produced in two monkeys after concentrated virus-containing material was inoculated.

Since the advent of modern diagnostic virology in the early 1950s, numerous viral agents have been recovered from children with roseola. In 1951, Neva and associates[52] studied an epidemic exanthematous illness (i.e., Boston exanthem) caused by echovirus 16, in which many of the illnesses were characteristic of roseola. In 1954, Neva[50] observed additional cases of roseola-like illness associated with echovirus 16 infection. In 1974, Hall and colleagues[27] reported four additional echovirus 16 infections with clinical manifestations of roseola. The reporting of roseola in Rochester, New York, nearly doubled during the time of echovirus 16 activity in the area. Roseola-like illnesses that also have been associated with these enteroviruses are caused by coxsackievirus A6, A9, B1, B2, B4, and B5 and echovirus 9, 11, 25, 27, and 30.[15,16,27,66,77] Outbreaks of roseola that occur in the summer and fall probably are caused by enteroviral infections.

In addition to enteroviruses, adenovirus types 1, 2, 3, and 14 and parainfluenza type 1 virus have been recovered from children with roseola.[23,37,51,77] Saitoh and associates[64] detected rotavirus capsomeres in fecal specimens of nine children with roseola. In contrast to these findings, Gurwith and colleagues[26] studied fecal specimens from five children with roseola, and in none were viral particles identified. One of 13 children in this study did develop antibody to rotavirus around the time of illness, however. In addition to the occurrence of roseola associated with numerous natural viral infections, its pattern (i.e., fever and then rash with defervescence) was observed frequently in recipients of Edmonton B measles vaccine.[15]

In 1988, Yamanishi and associates[78] isolated HHV-6 from four infants with roseola, and all four had significant titer increases for this virus. Shortly after this finding was reported, several other investigators noted similar findings.[2,4,19,33,42,69,73] The implication from these studies, as suggested by the various investigators, is that HHV-6 is the cause of roseola. This viewpoint overlooks or ignores the past experience in which other viral agents have been associated with the clinical syndrome. Subsequent studies indicate that HHV-6 is a major cause of roseola and the cause of acute febrile illness without exanthem in infants.* Since 1993, HHV-7 has been accepted as an additional causative agent in roseola.[3,14,31,68,71,76]

In a study of 1653 infants and young children with acute febrile illnesses, Hall and colleagues[27] found that 160 (9.7%) had primary HHV-6 infections; 27 (17%) of the children who were infected with HHV-6 had roseola. Zerr and associates[85] identified 80 children with primary HHV-6 infections, and of these, 30 percent had roseola. In the same population-based study, 3 of 80 (4%) children without primary HHV-6 infection also had roseola. In a study of clinical roseola, Okada and associates[54] found that 81 percent had serologic evidence of HHV-6 infection, and that 8 percent had an echovirus-18 infection. In a study of roseola in Italy, Braito and Uberti[9] found serologic evidence of HHV-6 infection in only 30 percent of the cases. In 33 percent of the remaining cases, they attributed the illnesses to another infectious agent. In 1994, Hidaka and associates[31] estimated that 73.5 percent, 10.2 percent, and 16.3 percent of their roseola cases were caused by HHV-6, HHV-7, and other viruses. HHV-6 seems to be the major cause of roseola.

PATHOPHYSIOLOGY

The pathophysiology of roseola is unknown. Watson[77] suggested that roseola is not an infection caused by one particular pathogen, but is the result of an immunizing reaction against many different viruses. He also suggested that the rash is caused by the neutralization of virus in the skin at the end of the period of viremia.

Because viremia is common in HHV-6, HHV-7, enteroviral, and adenoviral infections, a reasonable conclusion is that the rash in roseola is related to an immunologic event resulting from the virus that is localized in the skin. Why the pattern of fever and then rash with defervescence is so clearly age-dependent is

*See references 5, 9, 27, 34, 41, 44, 54, 58, 60, 67, 76, 85.

unknown. Most of the viruses that in the past have been associated with roseola cause other exanthematous manifestations in older patients.[15]

CLINICAL PRESENTATION

The basic clinical pattern of roseola is a febrile period of 3 to 5 days, defervescence, and the appearance of a rash that persists for 1 to 2 days. Because the syndrome is caused by many different viruses, the illness apparently may be associated with numerous other symptoms and signs. The major manifestations have been reviewed elsewhere.[7,10,17,25,38,81]

Illness usually occurs with the apparent abrupt onset of fever. Slight irritability and malaise occur frequently, but more commonly, the child's temperature is taken because a parent notices that the child feels warm. The temperature usually is in the range of 38.9°C to 40.6°C (102°F to 105°F). Despite the high fever, the child usually is active, alert, and generally unphased. The fever is constant or intermittent, with its greatest degree occurring in the early evening. Restlessness and irritability occur with higher temperatures. The usual duration of fever is 3 to 5 days, but it has persisted for 9 days. The temperature most often returns to normal by crisis, but in some cases, temperature "lysis" occurs over the course of 24 to 36 hours.

Mild cough and coryza are seen frequently in cases occurring in the winter and spring. Headache and abdominal pain are reported in older children, mainly in the summer and fall. Vomiting and diarrhea occur infrequently.

On initial physical examination during the febrile period, most children appear to be happy, alert, and playful. With high temperatures, some children are irritable; occasionally, a child appears to be sick, which suggests more serious illness, such as meningitis or septicemia. Examination within the oral cavity frequently reveals one or more abnormalities. Mild inflammation of the pharynx and tonsils occurs most commonly. Occasionally, small exudative follicular lesions are noted on the tonsils. In other cases, small ulcerative lesions on the soft palate, uvula, and tonsillar pillars are observed. Usually, the lesions on the soft palate consist of only erythematous macules and maculopapules, presumably because of lymphoid hyperplasia.

Mild injection of the tympanic membranes occurs commonly. Enlargement of the suboccipital, posterior cervical, and postauricular lymph nodes is a common finding, but the degree is not remarkable.

Berliner[8] noticed that children with roseola had palpebral edema. He suggested that the "heavy eyelids" or "droopy" or "sleepy" appearance resulting from this edema was diagnostic of the syndrome before the appearance of the rash. Bulging of the anterior fontanelle also has been observed in roseola.[56]

Appearance of the rash in roseola usually coincides with the subsidence of fever, but it may occur after an afebrile interlude of several hours to 2 days. When defervescence occurs by lysis, onset of the exanthem can occur before the temperature has returned entirely to normal. By definition, it is incorrect, however, to call an illness roseola if the fever and rash are truly concomitant.

Zahorsky[80,81] originally described the rash as morbilliform, but his use of morbilliform was not the same as ours is today (i.e., measles-like, erythematous, maculopapular with confluence). The rash is erythematous and macular or maculopapular, and the lesions are discrete. The lesions are 2 to 5 mm in diameter, and they blanch on pressure. Frequently, individual lesions are surrounded by a whitish ring. The rash is most prominent on the neck and trunk, but the proximal extremities and the face also may be affected. Although they have been reported,[17,24] pruritus and desquamation usually do not occur. The rash usually persists for 24 to 48 hours. In occasional cases, well-documented rashes have been observed to appear and resolve within 2 to 4 hours. Yoshida and associates[79] described a 7-month-old boy with HHV-6 infection and typical roseola initially. On the ninth day of illness, vesicular lesions appeared on the face and limbs, however. These lesions persisted for 12 days.

Except for the white blood cell count, routine laboratory studies are of little use in roseola. The total white blood cell count usually is low. Early in the febrile period, high counts occasionally are found, however. The total count reaches its nadir by the third to sixth day of illness, and then gradually returns to normal over the ensuing 7 to 10 days. During the same time frame, the percentage of lymphocytes increases from a normal value of about 50 percent to 60 to 80 percent on days 3 to 10, and then returns to normal over the next 7 days. Frequently, extreme counts in the range of 3000 cells/mm^3 with 90 percent lymphocytes are found, which raises the consideration of a granulocytic defect.

CLINICAL COMPLICATIONS

The most important complications of roseola are convulsions and other neurologic symptoms.* The incidence of convulsions has varied widely among reports. Juretic[38] did not find one instance of convulsions in the 243 cases in his study. Breese[10] did not report convulsions in any of 100 roseola attacks that he studied. In contrast, Greenthal[25] noted convulsions in 6 percent of his cases, and Faber and Dickey[20] found seizures in 8 of 26 cases of roseola. Möller[48] observed that 8 percent of children admitted to the hospital because of febrile convulsions eventually were diagnosed with roseola infantum.

Möller[48] also reported cerebrospinal fluid evaluations in 29 cases of roseola and febrile convulsions. In six instances, the pressure was elevated; in two, there were 5 white blood cells/mm^3; and in another instance, there were 9 white blood cells/mm^3. In most other cerebrospinal fluid examinations, the findings have been normal, but mild pleocytosis with mononuclear cells has been identified occasionally.[7,32] A surprising number of cases of encephalitis associated with roseola have been reported,[13,22,32,35] and residua have been common. Hemiplegia has occurred after illness,[13,22,59,62] and permanent paresis and mental retardation have occurred in some affected patients. The syndrome of inappropriate secretion of antidiuretic hormone has been reported in roseola associated with HHV-6 infection.[55,65] Facial nerve palsy and Guillain-Barré syndrome also have been noted after HHV-6 induced roseola.[47,57]

Thrombocytopenic purpura was noted in one report in five children with roseola; all of these patients recovered.[53] In a more recent study, Hashimoto and colleagues[29] noted five children with thrombocytopenia during the acute phase of roseola caused by HHV-6 infection. Their data suggested that the thrombocytopenia was due to bone marrow suppression, rather than immune-mediated peripheral consumption. A 14-month-old girl developed a generalized eruptive histiocytoma with rapid progression and then resolution after roseola.[70]

DIAGNOSIS

Although detecting leukopenia with relative lymphocytosis is fortuitous, the only necessity in establishing the diagnosis of roseola is to document the fever, defervescence, and exanthem pattern. Frequently, the first exanthematous illness that a child has is called roseola, regardless of whether the exanthem and the fever are concomitant, or the child has no febrile period at all.

*See references 2, 7, 11-13, 20, 22, 25, 32, 35, 43, 48, 59, 62, 63.

The only problem in the differential diagnosis occurs when a febrile child is receiving antibiotics and a rash follows defervescence. This event occurs frequently, and the child usually is labeled allergic to the antibiotic, rather than suspected of having roseola. In most instances of drug allergy, the exanthem lasts longer than roseola does, and in allergic cases, pruritus and fever may accompany the rash.

TREATMENT AND PROGNOSIS

No specific treatment for roseola exists. When fever is a problem, it may be treated with acetaminophen. Acetaminophen can alter the temperature curve, possibly obscuring the correct diagnosis. Febrile seizures and other neurologic complications should be treated vigorously.

In most cases, the outlook is excellent. When encephalitis occurs, the prognosis must be guarded. Because roseola is the result of infection with multiple different viruses, no practical way to prevent it exists.

CHAPTER 66

Bacterial Skin Infections

Mary Anne Jackson

NORMAL SKIN

ANATOMY

The epidermal skin layer provides the primary barrier to invasion by microorganisms and an interface between the body and the environment. Hair follicles, sebaceous glands, nails, and sweat glands are considered epidermal appendages and as such may be involved in skin infection. A dermal layer composed of collagen and elastic fibers gives skin its elasticity; however, other cell elements that are present, including mast cells, blood and lymph vessels, and cutaneous nerves, may be involved in the inflammatory process in response to infection. The subcutaneous fat layer is just beneath the dermis and contributes primarily to thermal stability, but it also may be involved when infection extends beyond the epidermal-dermal layer.

FLORA

Colonization is defined as the presence of a microorganism on the skin without either clinical signs or symptoms of infection at the time of isolation. Normal bacterial skin colonization is divided into resident and transient flora. Resident flora predominates and includes typical nonpathogens, such as *Staphylococcus epidermidis* and *Propionibacterium acnes*, in addition to other anaerobic diphtheroids and micrococci. Transient flora include pathogenic organisms, such as *Staphylococcus aureus*, streptococci, gram-negative enterics, and *Candida albicans*; these pathogens usually are present in smaller numbers than the resident flora and may be removed by skin cleansing. Acutely or chronically damaged skin, contact with animate and inanimate environmental sources, and exposure to antimicrobial agents or indwelling devices can modify the skin flora and predispose to infection by resident or acquired transient flora.[80,90]

CUTANEOUS INFECTION AND DERMATOLOGIC MANIFESTATIONS OF SYSTEMIC DISEASE

Dermatologic manifestations of infection can occur when the skin is infected primarily or as a secondary phenomenon. Prompt diagnosis and treatment of certain systemic or disseminated diseases may be accomplished when the secondary dermatologic manifestations are recognized. Empiric treatment of systemic diseases such as endocarditis (septic emboli) or septicemia caused by bacterial pathogens, such as *Neisseria meningitidis* or *Pseudomonas aeruginosa*, is possible when the dermatologic manifestations (purpura fulminans, ecthyma gangrenosum) are noted. Generalized viral infections may be heralded by pathognomonic skin findings, such as occur in varicella or measles. Alternatively, skin manifestations may be mediated by toxin (staphylococcal scalded skin syndrome or toxic shock syndrome [TSS]) or by immunologic mechanisms (gonococcemia).

The list of bacterial infectious agents associated with skin infections is extensive (Table 66–1). This chapter focuses on the bacterial skin infections most frequently encountered by practicing clinicians.

IMPETIGO

NONBULLOUS OR SIMPLE SUPERFICIAL IMPETIGO

The bacterial skin infection most commonly encountered in children is nonbullous impetigo, which accounts for more than 70 percent of impetigo cases in children. This superficial infection is seen predominantly in summer, with insect bites, cutaneous injuries, and primary dermatitis serving as the portal of entry.[46,61]

TABLE 66–1 Bacterial Infectious Agents Associated with Cutaneous Manifestations

Anthrax	*Bacillus anthracis*
Blistering dactylitis	*Streptococcus pyogenes*
	Streptococcus agalactiae
	Staphylococcus aureus
Cellulitis	*S. pyogenes*
	Staphylococcus aureus
	Haemophilus influenzae type b
	Streptococcus pneumoniae
Chancroid	*Haemophilus ducreyi*
Diphtheria	*Corynebacterium diphtheriae*
Ecthyma gangrenosum	*Pseudomonas aeruginosa*
Erysipelas	*S. pyogenes*
	S. agalactiae; group C, G streptococci
	S. pneumoniae
Erysipeloid	*Erysipelothrix rhusiopathiae*
Folliculitis	*S. aureus*
	Coagulase-negative staphylococci
	Klebsiella spp.
	Enterobacter spp.
	Escherichia coli
	P. aeruginosa
	Proteus spp.
Erythrasma	*Corynebacterium minutissimum*
Furunculosis	*S. aureus*
Hidradenitis suppurativa	*S. aureus*
	Streptococcus milleri
	E. coli
	Anaerobic streptococci
Granuloma inguinale	*Calymmatobacterium granulomatis*
Impetigo	
Simple superficial	*S. aureus*
	S. pyogenes
Bullous	*S. aureus*
Lymphogranuloma venereum	*Chlamydia trachomatis*
Melioidosis	*Burkholderia pseudomallei*
Necrotizing fasciitis	*S. pyogenes*
	Polymicrobial
Nocardiosis	*Nocardia brasiliensis*
	Nocardia asteroides
Paronychia	Polymicrobial
Perianal dermatitis	*S. pyogenes*
Pitted keratolysis	Coryneform bacteria
Syphilis	*Treponema pallidum*

Entries in bold are discussed in the text.

Nonbullous impetigo, sometimes called *thick crusted impetigo*, is characterized by the appearance of erythematous maculopapules that rapidly evolve from a vesicular to a pustular stage. Centrally crusted plaques range in size from a few millimeters to 1 cm and are surrounded by a distinct margin of erythema. The honey-colored crust is a classic feature, and removal of the crust results in the reaccumulation of fresh exudate. Regional lymphadenopathy can occur and often is the reason that the patient seeks medical attention. Spread to exposed areas, usually the face, neck, and limbs, occurs frequently. This form of pyoderma often is associated with a 2- to 3-week delay in establishing the diagnosis because the lesions are slow to progress, only mildly tender at the site of the lesion, and generally not associated with systemic signs or symptoms.

Nonbullous impetigo classically has been associated with infection caused by group A beta-hemolytic streptococci (GABHS). More recent data underscore the importance of *S. aureus*, however, which now accounts for most cases of nonbullous impetigo in the United States.[6,50]

Primarily a disease of children, nonbullous impetigo is spread within families and by close physical contact. It is prevalent during warm, humid seasons and is seen year-round in tropical regions. Endemic disease occurs in the southeastern United States and Hawaii.

Epidemics of streptococcal impetigo have been associated with postinfectious glomerulonephritis, and streptococcal strains, including types 2, 31, 49, 53, 55, 56, 57, and 60, have been implicated in such outbreaks.[12,67] Studies published in the 1950s and 1960s from the Red Lake Indian Reservation in Minnesota first confirmed the association of impetigo in school-aged children with a postinfectious nephritis that occurred 18 to 21 days after the onset of impetigo and implicated the so-called Red Lake strain, M-type 49.[5] Further studies in this population performed in the early 1970s found that GABHS was isolated from normal skin in 23 of 31 high-risk children a mean of 10 days before the development of impetigo.[34] Local trauma and other environmental factors seemed to explain the predilection of exposed skin to streptococcal infection, especially the skin of the legs, where 62 percent of the total lesions were noted. Secondary acquisition of streptococcal isolates in other family members occurred a mean of 5 days after the primary case, a time frame that was noted to be significantly shorter than that of secondary respiratory acquisition.[52] Rheumatic fever does not occur as a postinfectious sequela of streptococcal skin infection.

Cutaneous botryomycosis, an indolent infection reminiscent of crusted impetigo, usually is caused by *S. aureus*. Characterized by plaquelike lesions with superficial pustules and crusts, this entity has a predilection for patients with altered immune function.[23] Histologic examination may suggest the diagnosis of actinomycosis if a granulomatous lesion with granules resembling those seen with *Actinomyces* is noted. Successful treatment can be accomplished after the bacterial pathogen has been identified.

BULLOUS IMPETIGO

Bullous impetigo is diagnosed when the primary lesion begins as small vesicles and later appears as flaccid, painless bullae, generally measuring greater than 1 cm (see Fig. 64–17). Initially filled with clear fluid, the lesions eventually may exhibit a purulent fluid level. Rupture of the thin bullae usually reveals a moist, erythematous base that dries to a shiny lacquer-like appearance, sometimes described as a varnished finish (Fig. 66–1). Systemic toxicity is not seen except in neonates, in whom disseminated disease may occur.

In contrast to thick, crusted impetigo, in virtually all cases of bullous impetigo, staphylococci are isolated in pure culture from aspirated bulla fluid. Other bullous dermatitides of childhood, such as pemphigus or Stevens-Johnson syndrome, may be excluded by isolation of the organism. Occasionally, biopsy is done in cases in which extensive bullae or an atypical clinical appearance is noted. Confirmation of a cleavage plane high in the epidermis with gram-positive organisms and polymorphonuclear leukocytes present is a definitive diagnosis of bullous staphylococcal disease.

Infection generally is caused by phage group II strains, particularly phage type 71, but also 3A, 3C, and 55, which are noted to elaborate epidermolytic toxins A and B. Pathologically, these toxins act by disrupting the intercellular attachment of epidermal cells of the stratum granulosum. The toxin is thought to function as a protease in separating the upper layers of the epidermis of adult and infant human skin. Production of antibody to epidermolytic toxin occurs with age; however, it does not protect against the development of new bullous lesions during the localized impetiginous stage of this staphylococcal disease.

Epidemiologically, large outbreaks of bullous impetigo have been traced most notably to hospital nurseries, where identification of infected infants always occurs within the first month of life but after the infant has been sent home. A more severe, generalized form of the epidermolytic toxin-mediated disease (Ritter disease) may be seen in a few infants during one of these out-

Figure 66–1 Flaccid bullae and shiny lacquer base of staphylococcal impetigo.

Figure 66–2 Typical appearance of a neonate with Ritter disease.

breaks, underscoring the importance of infection control surveillance practices in recognizing such an outbreak (Fig. 66–2).

TREATMENT OF IMPETIGO

Topical mupirocin may be used in cases of nonbullous impetigo in which adequate coverage of the affected sites can be ensured.[18,33,99] In other cases, systemic treatment with an oral antistaphylococcal antimicrobial agent, such as cephalexin, should be employed.[38,39,45,109] As in other staphylococcal diseases, an increase in community-acquired, methicillin-resistant *S. aureus* (MRSA) cases has been noted in the last decade.[62,63,72,124] In cases for which traditional antistaphylococcal agents are unsuccessful or in patients with recurrent disease, culture should be done to identify the bacterial strain and susceptibility pattern. Currently,

most community-acquired MRSA isolates are susceptible to clindamycin.[17,24]

PERIANAL STREPTOCOCCAL DERMATITIS

Formerly called *perianal cellulitis*, perianal streptococcal dermatitis, a commonly recognized superficial skin infection, is characterized by the presence of marked, well-demarcated, perirectal erythema with associated swelling, pruritus, and tenderness but an absence of systemic symptoms or progressive disease. Approximately half of patients complain of significant rectal pain on defecation, and a third note blood in their stools.[4,29,70,98]

Heavy growth of GABHS is seen on perianal culture, and in one study, isolation of a specific T-type streptococcus (T 28) raised the question of whether certain streptococcal strains have tropism for the perineal region.[104] Asymptomatic patients were evaluated in two studies, and only sparse growth of GABHS was noted in 6 percent of cases.

Perianal streptococcal dermatitis is treated with oral penicillin agents. Topical mupirocin also has been used successfully. Recurrences are noted commonly, however. In one large series of patients, one third had recurrent disease.[87] Intrafamilial spread of disease frequently occurs and may provide a vector for recurrence. For patients with recurrent or persistent disease, clindamycin or a β-lactam agent plus rifampin may be used, and identification and treatment of other affected family members may be necessary.

BLISTERING DISTAL DACTYLITIS

Most commonly identified in school-aged children, blistering distal dactylitis is a distinctive superficial skin infection classically associated with GABHS.[13] Bullae 2 cm in diameter develop over the anterior fat pad of the distal phalanges, sometimes extending to involve the nail folds. Involvement of the proximal phalanges or the palms occasionally is noted. Frankly pustular lesions may occur, but the lesions themselves usually are asymptomatic or only mildly tender. A thin purulent exudate generally is apparent on incision and drainage.[71]

The diagnosis is confirmed by recovery of the etiologic agent on culture, most commonly GABHS, although group B streptococci and *S. aureus* also have been noted.[58] Concurrent recovery of GABHS in the pharynx has been reported in a few cases. Treatment includes a 10-day course of an oral β-lactam agent, usually penicillin or amoxicillin, in addition to incision and drainage of any tense bullae.

ERYSIPELAS

The superficial cellulitis erysipelas, referred to as *St. Anthony's fire* in the Middle Ages, is characterized by the appearance of a bright erythematous plaque with a distinct, elevated border that sharply demarcates affected from unaffected skin. The lesion most often involves the face or lower extremity, although extensive involvement of the trunk has been noted. The involved skin is warm and tender and may have a peau d'orange appearance. Large tension bullae may be seen in the erythematous zone.[65] The patient generally appears toxic and is highly febrile, and rapid extension of the affected skin may occur over the course of hours.[31,66,136]

Histopathologic findings include intense edema with vascular dilation of the dermis and uppermost subcutaneous tissue. Involvement of lymphatic channels and tissue spaces with polymorphonuclear leukocytes is a typical finding.

Surgical wounds, the umbilicus of the neonate, or any break in the skin may serve as the portal of entry; however, the initial lesion may be inapparent. Localized edema, such as occurs from a renal or lymphatic source, is a predisposing factor, and antecedent respiratory infection often is reported. An increased risk for development of erysipelas has been noted in patients with hypogammaglobulinemia, certain malignancies such as lymphoma, or lymphedema complicating radiation therapy.

The diagnosis generally is recognized on clinical grounds, and GABHS traditionally has been isolated by aspiration of the advancing margin of the lesion. A few case reports have identified other streptococci (including group B, C, and G), *Moraxella* spp., *Haemophilus influenzae*, and *Streptococcus pneumoniae* as etiologic agents.[15,30,42,88,102,123,137] A combination of intravenous penicillin and clindamycin should be used until the results of culture are available. Erysipelas has a classic clinical appearance, and appropriate diagnosis and therapy result in a prompt clinical response in most cases. Penicillin prophylaxis may be considered for patients with recurrent erysipelas, particularly patients with underlying risk factors.[16,40]

ECTHYMA

Ecthyma gangrenosa is a deep-seated infectious process that manifests as a necrotic ulcer covered by a black eschar. Usually, the initial lesion, a vesicopustule, sits on an erythematous base; it eventually erodes through the epidermis to the dermis, where it forms a crusted ulcer with heaped-up borders and then becomes frankly necrotic.[64]

This process rarely occurs in an otherwise healthy child, and if it does, an immunodeficiency work-up should ensue. *Chromobacterium violaceum* has been reported to cause ecthyma and similarly should result in an immunologic evaluation focusing on neutrophil defects, including disorders such as chronic granulomatous disease.[22]

Ecthyma can occur as a primary cutaneous infection in an immunocompetent host, and other etiologic agents that have been confirmed include *S. aureus*, *Aeromonas hydrophila*, and GA BHS.[48,57,73,84,96,105,134] A similar-appearing lesion is seen with cutaneous anthrax; however, extensive nonpitting edema of the surrounding soft tissues is an important clue to this diagnosis. Ecthymatous-like lesions have been seen in patients with herpes simplex infection.[85] Additionally, human orf infections result in ulcerative skin lesions that appear similar to lesions of ecthyma; the clue to establishing the diagnosis is contact with an infected animal, usually sheep or goats, or a contaminated fomite.[26]

When an ecthymatous lesion is noted in a febrile neutropenic host, it generally signals disseminated infection. *P. aeruginosa* is the etiologic pathogen identified most commonly in such cases, but other gram-negative pathogens and fungi, including *Enterobacter*, *Escherichia coli*, *Morganella*, *Pseudomonas cepacia*, *Serratia marcescens*, *Stenotrophomonas maltophilia*, *Aspergillus*, *Mucor*, *Fusarium*, and *C. albicans*, have been implicated in ecthyma gangrenosum in compromised hosts.[36,51,53,97,107,112,117,122] Ecthyma has been seen as the heralding manifestation of acute lymphoblastic leukemia in children.[111] Empiric antimicrobial therapy for ecthyma gangrenosum in a neutropenic host should include intravenous therapy with an anti-*Pseudomonas* agent plus an aminoglycoside. Biopsy of the lesion may provide more specific etiologic information and allow for confirmation of antimicrobial susceptibility.

FOLLICULITIS, FURUNCULOSIS, AND CARBUNCLES

Folliculitis, furunculosis, and carbuncles represent a group of infections characterized by their origin in the hair follicles and

the formation of abscesses. Virtually always caused by *S. aureus*, these infections were seen commonly in the 1950s in disease that often involved multiple family members. Outbreaks among athletes likewise have been reported.[130]

By definition, these infections involve sites where body hair is present, including the axilla, breast area, perineum, neck, and extremities. Lesions of folliculitis represent abscesses of a single hair follicle with limited surrounding tissue involvement. When deeper inflammatory nodules are associated with tissue edema, furunculosis is diagnosed. When several interconnecting furuncles are present, the lesion is referred to as a carbuncle. Generally, older children and adolescents are predisposed to the development of follicular infections, and individuals with diabetes mellitus, abnormal neutrophil chemotaxis, and impaired circulation may have recurrent disease.

Although *S. aureus* nearly always is the cause of folliculitis as in the past, outbreaks of so-called hot tub folliculitis have been described and almost always are caused by *P. aeruginosa*; rarely, other gram-negative organisms have been reported.[27,28] Folliculitis in an immunocompromised host often is caused by unusual fungal pathogens.[3,115,127] Although typically associated with hot tubs and whirlpools, a large outbreak of *Pseudomonas* folliculitis reported in 1984 involved 117 individuals after swimming in an indoor pool. An incubation period of 24 to 30 hours could be ascertained, and a typical follicular, pustular eruption was noted. The mean duration of the folliculitis, 15 days, is consistent with other reports, but some patients continued to complain of rash for weeks, and recurrent pustules appearing months later have been reported in other studies.[56]

A more recent report has identified four cases of *Mycobacterium fortuitum* complex furunculosis that developed after pedicures, suggesting this pathogen may be added to the differential diagnosis in such cases when a patient presents with nonhealing furuncles on the lower legs, especially when bacterial cultures have been negative, or the disease is unresponsive to antistaphylococcal therapy (including MRSA).[114] Early recognition and institution of appropriate therapy are essential, and the history of pedicures may be a clue to establishing the diagnosis. Cutaneous myiasis has been reported to manifest as a chronic boil or furuncle, but the diagnosis should be considered only in such cases in which an appropriate travel history is elicited.[32]

Recognition of the typical skin lesion usually is sufficient to establish the diagnosis. Unless the patient has a history of exposure to a hot tub or whirlpool, or recently has had a pedicure, a regimen of antistaphylococcal therapy should be sufficient. In the era of MRSA infection, local susceptibility profiles should be used to confirm appropriate therapy. Isolated boils resolve with drainage alone. Systemic therapy may be considered in cases in which lesions are large or multiple. Trimethoprim-sulfamethoxasole is a good choice for a nontoxic patient older than 2 months. Clindamycin is a good choice for most locales, although resistance may be increasing.[82,91] Because MRSA now accounts for 75 percent of cases in which children present with skin and soft tissue infection, treatment should be individualized, based on type of presentation, patient age, and underlying disease.[81] Systemic agents should be used for 7 to 10 days in patients who are toxic, who have extensive disease, or who have associated cellulitis. Large lesions, specifically larger than 5 cm, should be incised and drained, and culture should be done in all cases to confirm susceptibility testing. In some patients, hematogenous metastatic spread may occur, and a search for foci in the heart, bones, joints, deep tissues, or brain should be done in patients with significant systemic toxicity.

For patients in whom recurrent disease develops, chronic dermatoses, such as eczema, should be identified, and in obese adolescents, the diagnosis of diabetes mellitus should be considered.[7] The patient should be cautioned to refrain from sharing washcloths or towels, and skin trauma and use of irritants such as deodorants should be avoided.

The utility of decolonizing regimens with topical agents, such as mupirocin (nares and perianal area) and chlorhexidine or bleach baths (skin), may be considered in certain cases. *S. aureus* colonization of the nares, rectum, or skin can be detected by culture of these areas, but confirmation of carriage is likely necessary only in specific cases for which decolonization is desirable. The indications for and benefit of decolonization vary depending on host factors, underlying disease, and circumstances related to the health care setting.[126] Outbreaks of MRSA colonization/infection require a multifaceted approach, including attention given to handwashing, cohorting, barrier measures, and decolonization strategies. Examples of special circumstances include the following: (1) patients who are immunosuppressed and colonized, and at risk for development of systemic infections; (2) patients who are more likely to spread the organisms, owing to behavior (e.g., mentally retarded patients); or (3) patients who have repeated infections caused by the MRSA strain that they carry.

Most children with recurrent furunculosis are otherwise healthy, and no specific immunologic evaluation is necessary; however, cases of recurrent furunculosis in patients with hyper-IgE syndrome and common variable immunodeficiency have been reported, and an association with mannose-binding lectin deficiency was confirmed in a family.[78,83,125] Rarely, children with white blood cell defects may have recurrent staphylococcal skin abscesses, and tests of white blood cell function may be considered in specific patients. Data suggest that vitamin C may be beneficial in cases of recurrent folliculitis.[93,94]

HIDRADENITIS SUPPURATIVA

Hidradenitis suppurativa, a chronic, debilitating condition, is a disorder of the apocrine glands that involves primarily skin in the axilla and anogenital region, although scalp, umbilical, and breast involvement has been reported. Seen mainly in adolescents, this androgen-dependent condition is manifested by the development of multiple painful nodules and the formation of deep abscesses in the skin in areas where apocrine glands are present. The formation of fistulas, ulcers, and contracted scars may complicate the course, and recurrent relapses may be noted. Infection usually is polymicrobial, and pathogens to consider include *S. aureus*, gram-negative enterics, and anaerobes. Drainage of abscesses and institution of systemic antimicrobial therapy may be necessary. When fistulas associated with anogenital disease develop, adjacent structures, including the urethra, bladder, and rectum, may be involved. Surgery usually is required for cure. Carbon dioxide laser treatment in some cases may be beneficial.[89]

CELLULITIS

The diagnosis of cellulitis is made when the subcutaneous tissues and dermis are involved in a clinical process manifested as localized edema, erythema, warmth, and tenderness of the tissues. The leading edge of the involved site may be notable, but it is not raised and well demarcated as in erysipelas.

Infection usually is caused by coagulase-positive staphylococci and GABHS; however, infection also is caused by group B streptococci (neonates) and *S. pneumoniae*, and, in the past, *H. influenzae* type b (Hib) cellulitis was described.[131] Streptococcal and staphylococcal cellulitis can involve patients of any age and any site, although the extremity is noted most often. Frequently, the patient has a history of antecedent trauma at the site of involvement, but the injury may not have appeared significant. Some researchers advocate culture of the cellulitic site, but in practice, it rarely is performed. Blood cultures are valuable in individuals

Figure 66–3 Buccal involvement in an infant with invasive *Haemophilus influenzae* type b disease.

with disease caused by group B streptococci, *S. pneumoniae*, and Hib.[75]

Group B streptococcal cellulitis occurs in neonates and generally is seen as part of invasive, late-onset disease. Unilateral involvement of the face or submandibular sites occurs most commonly, but inguinal, scrotal, and prepatellar involvement has been described.[10,69] When cellulitis occurs in an infant younger than 3 months old, group B streptococcal bacteremia should be suspected, even in the absence of other signs of systemic infection.

Pneumococcal soft tissue infections are common findings.[110] Patients with connective tissue disorders, such as systemic lupus erythematosus, seem especially prone, although these infections can occur in healthy infants and children. Sites of involvement include the head, neck, leg, and torso.

Hib cellulitis often involves the face of infants (Fig. 66–3). A violaceous hue of the cellulitic area, which some researchers thought to be pathognomonic, might be observed. This process nearly always was the result of hematogenous seeding by Hib, and meningitis occurred in 15 to 20 percent of such patients.[68,129,140] As has been the case with other forms of Hib disease, almost complete eradication has been achieved in the last decade with the use of conjugate vaccine.

Treatment of simple cellulitis in patients with a clear-cut area of preceding trauma should include an agent that is active against *S. aureus* and GABHS, and in most locales, clindamycin remains a good choice for therapy, although resistance for *S. aureus* (10-15%) and GABHS (2-3%) is noted. The aforementioned caveats for treating staphylococcal skin infections should be followed. In infants with buccal or periorbital involvement or in infants with soft tissue involvement but without a clear-cut focus of infection, a third-generation cephalosporin, such as cefotaxime or ceftriaxone, should be included with clindamycin. Vancomycin always should be included in cases of a patient who is toxic and when metastatic suppurative disease is suspected.

NECROTIZING FASCIITIS

Necrotizing fasciitis is a rapidly progressive bacterial infection of the soft tissues associated with a fulminant course and a high mortality rate. This infection spreads rapidly in the plane between the subcutaneous tissue and superficial muscle fascia and causes widespread necrosis. Prompt and aggressive medical and surgical management is necessary to ensure a good outcome.

Figure 66–4 Necrotizing fasciitis in a toddler with varicella.

In children, necrotizing fasciitis usually is caused by GABHS; traumatic lesions involving the skin, including varicella, burns, or eczema, may predispose to this aggressive process.[19,47,55,59,76,108,119,120,142] An association has been noted among varicella, ibuprofen use, and invasive GABHS infection, although no data convincingly link this triad to necrotizing infection.[54,92,143] Patients with congenital or acquired immunodeficiencies are at greater risk for the development of necrotizing fasciitis, and in neonates, omphalitis and circumcision are predisposing conditions.

CLINICAL MANIFESTATIONS

The child generally has a high fever and is fussy. In infants, the irritability may be profound and may not appear to be localized to an involved site, unless the clinician is meticulous in conducting the examination. An extremity most commonly is involved, and older infants and children often refuse to bear weight or move the affected extremity. Swelling of soft tissue usually is noted, but the erythema may be subtle. The hallmark tip-off on examination is the finding of intense pain on manipulation of the involved site that is out of proportion to the cutaneous signs. Skin changes that occur during the subsequent 24 to 48 hours include blistering with bleb formation, and a dusky appearance of the involved site is noted as vessels are thrombosed, and cutaneous ischemia develops. Skin necrosis is a late sign and indicates a poor prognosis (Fig. 66–4).[79,135]

Recognition of the manifestations of TSS is crucial because mortality rates of 60 percent have been reported in patients with associated fasciitis. Multisystem complaints, including vomiting, diarrhea, and severe myalgia, are present when GABHS fasciitis is associated with streptococcal TSS. Tachycardia out of propor-

tion to fever and altered mental status may be early signs of TSS. Renal and hepatic dysfunctions occur typically, and symptoms and signs of adult respiratory distress syndrome often are identified.

DIAGNOSIS

The diagnosis cannot be based on the appearance of the involved site because none of the early findings of necrotizing fasciitis are pathognomonic. Plain radiographs usually are normal and of no value in establishing the diagnosis. Magnetic resonance imaging (MRI) is the preferred technique to detect soft tissue involvement. MRI permits visualization of the soft tissue edema infiltrating the fascial planes.[21,113,144] Although MRI may be helpful, it should not delay performing surgical intervention. Waiting for a radiographic procedure to be performed to confirm the diagnosis may serve only to delay implementing definitive surgical therapy and to increase the risk for development of systemic complications, contributing further to the increased morbidity and mortality rates. In the typical clinical scenario in which the index of suspicion for necrotizing fasciitis is high, surgical exploration is appropriate, even in the presence of "normal" MRI findings.

Laboratory manifestations of streptococcal TSS should be sought in any pediatric patient with fasciitis. Typically, the white blood cell count is normal; however, most patients have a significant increase in band forms (>50%) noted on the peripheral blood smear. Thrombocytopenia and evidence of coagulopathy are found commonly, and marked hypoalbuminemia with hypocalcemia is a typical finding. Laboratory findings associated with renal failure, myocardial dysfunction, and adult respiratory distress syndrome may develop during the first 48 to 72 hours.

A microbiologic diagnosis can be made by isolating bacteria from blood, tissue, or wound culture. In some cases, a polymicrobial etiology has been noted, particularly in patients with so-called Fournier gangrene or necrotizing fasciitis of the perineum.[49,74] In these cases, *S. aureus*, GABHS, and one or more anaerobes, including *Peptostreptococcus*, *Prevotella*, *Bacteroides fragilis*, and *Porphyromonas*, have been implicated in infection.[20] Fasciitis caused by *P. aeruginosa* or *Clostridium septicum* has been seen in neutropenic patients. In the last decade, GABHS has been reported widely as a single pathogen and is the etiologic agent in most cases of pediatric fasciitis. As in other cases of invasive disease caused by GABHS, virulence is related to certain structural characteristics of the organism and to its ability to produce biologically active substances, some of which facilitate invasion and spread of the pathogen.

TREATMENT

Surgical débridement of necrotic tissue is the key to managing necrotizing fasciitis, and increased mortality rates have been observed when débridement is delayed more than 24 hours.[106] Mandatory return to the operating room for examination and repeat débridement should occur during the following 24 to 48 hours. Careful management of fluids, attention to pain control, anticipation and management of multisystem organ failure, and administration of appropriate parenteral antimicrobial therapy should be initiated promptly. The use of intravenous immunoglobulin may be considered in cases of TSS-associated fasciitis.[25]

Appropriate therapy includes intravenous penicillin, 150,000 U/kg/day divided into four to six doses; clindamycin, 40 mg/kg/day divided into four doses; and vancomycin, 40 mg/kg/day divided into three to four doses. The use of additional coverage with agents active against *P. aeruginosa* and gram-negative enterics should be considered in neutropenic patients.

Response to therapy is assessed by careful serial examination. Control of pain is crucial in such patients, while keeping in mind that persistent, severe pain suggests ongoing tissue necrosis and may signal the need for further surgical intervention. Careful attention to nutritional support should be maintained throughout the child's hospital stay. Physical therapy is necessary for most patients, especially patients who require amputation, skin grafting, or extensive reconstructive surgery, and providing for the psychosocial needs of the child and the family is imperative.

CONTAMINATED WOUNDS

Although staphylococci and streptococci are the most likely causes of infection after traumatic skin lesions, the list of causes may be extensive, depending on the nature of the injury. Specific pathogens should be considered when infections develop after human or animal bites, soil or water contamination, or various types of injury. Management of such infections depends on recognizing infection patterns and obtaining cultures for careful identification of the specific organism or organisms involved (Table 66–2).

HUMAN BITES

Two types of human bites are described: occlusional and clenched fist (see also Chapter 259). Occlusional bites are related most commonly to child abuse, although in a pediatric patient, a biting toddler may be the culprit. Accidental bites may occur during sporting activities and generally involve the face of a teammate. Clenched-fist injuries are associated with the most prevalent and severe infections that occur after human bites. Rapidly progressive infection may follow despite the patient's receiving early medical attention.[11] When clenched-fist injuries are associated with bite wounds, laceration and puncture wounds commonly occur along the dorsal aspect of the third metacarpophalangeal joint, and bone, joint capsule, or tendon structures may be involved.

Polymicrobial infection is the usual finding, and in such cases, broad-spectrum empiric antimicrobial coverage should be initiated promptly, after adequate drainage has been performed.[118] In a multicenter study of infected human bites, the median number of isolates per wound was four, and aerobes and anaerobes were

TABLE 66–2 Infections Associated with Animal Bites

Nature of Injury	Pathogens Involved
Human bites	Staphylococci Anaerobic and aerobic streptococci *Eikenella corrodens*
Animal bites	
Dog/cat	*Pasteurella* species *Staphylococcus aureus* Streptococci Anaerobes *Capnocytophaga canimorsus*, *Capnocytophaga cynodegmi* *Moraxella* species *Corynebacterium* species *Neisseria* species
Reptile	Enteric gram-negatives Anaerobes
Horse and sheep	*Actinobacillus* species, *Pasteurella* species
Pig	*Flavobacterium* species, *Actinobacillus* species, *Pasteurella aerogenes*
Rat	*Streptobacillus moniliformis*, *S. aureus*

identified. The common pathogens were *Streptococcus anginosus*, *S. aureus*, *Eikenella corrodens*, *Fusobacterium nucleatum*, and *Prevotella melaninogenica*. *Candida* spp. were noted less commonly.[132] Many strains of *Prevotella* and *S. aureus* are β-lactamase producers, and *E. corrodens* is intrinsically resistant to clindamycin and cephalosporins. Ampicillin with clavulanate given orally (simple infections) or ampicillin-sulbactam given intravenously for more complicated infections may be used as a single agent. Unusual pathogens rarely occur. A report of a human bite infection caused by *Mycobacterium ulcerans* is noted; this pathogen is emerging rapidly in West African countries.[35] Antimicrobial prophylaxis should be considered for patients with human bites to the hands, feet, and skin overlying joints and for patients with bites that penetrate deeper than the epidermal layer.[116]

ANIMAL BITES

Animal bite wounds occur commonly, with more than 4 million reported annually in the United States (see also Chapter 260). Children account for more than half of patients who go to emergency departments for care of bite wounds.[2] Although one survey has revealed that rodents and lagomorphs are the biting animals most commonly reported, wounds related to these bites seldom are associated with infection. By contrast, cats and dogs together account for approximately 40 percent of bites, and their bites are associated more frequently with morbidity. The etiology of animal bite infections often is related to the species of animal involved (see Table 66–2).[41,44,77,95]

Approximately 1000 emergency department visits related to dog bites occur each day, at a cost of more than $100 million/yr.[128] The incidence of infection related to dog bites has been estimated at 3 to 17 percent.[9,37] Cat bites are most likely to become infected, probably because of the puncture-like nature of the injury. One study suggests that half of cat bites result in infection, prompting recommendations for prophylaxis of such bites, especially if they involve the face or hands. In the presence of infection, exploration plus débridement of devitalized tissue is necessary, and purulent collections should be drained.

Although *Pasteurella multocida* is implicated most frequently, numerous other pathogens, including *S. aureus*, *Capnocytophaga canimorsus*, and other aerobic and anaerobic bacteria, are associated with dog and cat bites. Depending on the depth of the wound's penetration, underlying structures such as bones, joints, and tendons may be involved in such infections.[60] The wound itself may not appear significant, particularly in the case of puncture wounds, but several clinical features should influence treatment decisions. The presence of tissue edema and point tenderness on palpation over the site should signal that deeper structures may be involved. Soft tissue imaging may be necessary, and appropriate drainage or débridement of involved sites should be pursued.

As with human bites, oral amoxicillin-clavulanate may be used for prophylaxis or treatment of simple infections. Indications for prophylaxis of bite wounds include bites associated with a crush or puncture injury and bites involving the face, hands, feet, and genitalia. Wounds in immunocompromised, especially asplenic, individuals should be considered for prophylaxis. Intravenous ampicillin-sulbactam or ticarcillin-clavulanate can be used for more serious infections. For individuals who have a history of anaphylaxis with penicillin or cephalosporins, a combination of clindamycin plus trimethoprim-sulfamethoxazole or ciprofloxacin can be used.[113,115] Antimicrobial therapy may be modified further depending on the biting animal and suspected pathogen (see Table 66–2).[14]

Appropriate prophylaxis against tetanus should be considered for all bites. Hepatitis B can be transmitted by human bites, and appropriate management should be ensured for susceptible patients. Rabies vaccine should be administered after bat, skunk, or raccoon bites; public health information should be accessed to decide whether rabies vaccine is indicated for other animal bites.

SOIL-CONTAMINATED AND WATER-CONTAMINATED WOUNDS

Four factors that must be considered in the acute care of contaminated wounds include the (1) mechanism of injury, (2) the length of time that transpires from injury to treatment, (3) the type of pathogens that occur in the environment, and (4) the presence of underlying disease in the host.[43] When a traumatic wound becomes infected, a polymicrobial etiology is typical, and common pathogens such as *S. aureus*, gram-negative enterics, and anaerobes characteristically are involved.[1] Unusual and rare organisms, such as nontuberculous mycobacteria, *Nocardia*, *Actinomyces*, fungi including *Aspergillus* spp., and unusual gram-negative organisms, occasionally may be encountered (Table 66–3).[86,100,101,103,138] *A. hydrophila* has been implicated in infections associated with injuries contaminated by fresh water and may produce rapidly progressive wound infection with fascia, tendon, muscle, bone, or joint involvement.[121]

Managing wounds contaminated by soil or water is difficult, especially if the mechanism of injury is a catastrophic event with complex bone and soft tissue injuries. In the acute setting of such an event, complete exploration and thorough débridement with copious irrigation are performed primarily, and signs of infection generally are not present. Days later, the clinician often is faced with the dilemma of a patient who is receiving antimicrobial prophylaxis with broad-spectrum agents and in whom new signs or symptoms develop acutely. Separating infectious from noninfectious complications often is difficult; however, the onset of fever in such a patient, especially in the setting of an open fracture or dural tear, should prompt further evaluation. Careful serial examination of the site of injury is necessary, and more extensive evaluation generally is indicated. Such assessment may include radiographic imaging and specific evaluation of body fluids with appropriate cultures. Because open fractures are associated with an increased risk for development of infection, the utility of antibiotic-impregnated implants, which are biodegradable and osteoconductive, may prove beneficial in such cases.[133,139]

Infections associated with foreign bodies such as wood generally cannot be cured until the foreign body is identified and removed.[141] Puncture wounds should be explored carefully, and

TABLE 66–3 Infections Associated with Soil-Contaminated or Water-Contaminated Wounds

Soil-Contaminated Wounds
Staphylococcus aureus
Group A beta-hemolytic streptococci
Many gram-negative enterics
Enterobacter cancerogenus
Anaerobes
Nocardia asteroides, *Nocardia otitidis-caviarum*
Mycobacterium fortuitum, *Mycobacterium abscessus*
Actinomyces
Aspergillus species
Enterococcus species
Water-Contaminated Wounds
Aeromonas hydrophila
Pseudomonas species
Many gram-negative enterics
Edwardsiella tarda (catfish injury)
Mycobacterium marinum

further débridement of necrotic tissue or drainage of involved sites such as joints may be necessary.[8]

Treatment of simple wound infections associated with soil or water contamination should include an agent such as ciprofloxacin, although deeper tissue infection may develop after a seemingly innocuous injury, and tissue débridement may be necessary. Determining the appropriate therapy for a patient with infection involving extensive soft tissue injury and open fractures is problematic. Administration of an empiric regimen with an agent such as piperacillin-tazobactam, imipenem, or a fluoroquinolone plus vancomycin may be reasonable after evaluation and appropriate culturing have been done.

CHAPTER 67

Viral and Fungal Skin Infections

Meena R. Julapalli ✪ **Moise L. Levy**

VIRAL INFECTIONS

Cutaneous manifestations of viral infections are common. Exanthems often accompany acute viral infections. The Dukes numbering system of six exanthems is well known to clinicians but is now primarily of historic interest only (Table 67–1). With rare exceptions, skin manifestations that mimic the "typical" features of the six exanthems are seen with multiple infectious agents. Other infections result in lesions such as warts or molluscum contagiosum. This chapter focuses on the common viral illnesses that manifest with cutaneous manifestations. More detailed information on each of these illnesses can be found in the chapters devoted to specific viral agents.

Viruses can invade the skin indirectly as a result of viremia or directly, as with warts or molluscum. Other mechanisms of producing exanthems include interactions between the infecting agent and humoral or cell-mediated factors or a systemic immune response in the absence of viral antigen in the skin.[78]

The type of exanthem encountered depends on the virus, the pathophysiologic mechanisms involved, the location of the eruption, and local and systemic immune factors. A single virus may manifest with a variety of cutaneous reactions within the same host. Clinicians caring for a patient with an exanthem usually are faced with a challenge to determine its cause. Most viral exanthems are benign and self-limited, but understanding the exact cause can be important when evaluating immunocompromised patients or in the setting of a fetus. Similarly, distinguishing a viral exanthem from skin eruptions caused by other infectious agents or drugs is important.

Generally, children presenting with fever and a rash cannot be diagnosed accurately by the presentation of the eruption.[53] The distribution and character of exanthems, such as the often characteristic reticulated erythema after "slapped cheek" exanthem typical of parvovirus B19 infections, are helpful; however, the virus can manifest with several other cutaneous findings.[20,81,86] Typical hand, foot, and mouth syndrome is caused by coxsackievirus, although it has been related more recently to enterovirus 71.[25] The concurrent administration of antibiotics in the setting of Epstein-Barr virus infection is important to know, as is the possible relationship between human herpesvirus infection and certain drugs resulting in drug rash with eosinophilia and systemic symptoms.[35]

Laboratory studies, in addition to specific viral cultures, polymerase chain reaction, and serologies, may be helpful in distinguishing between viral and bacterial diseases or drug eruptions. Coagulation studies may help clarify whether a purpuric eruption is caused by a primary coagulopathy or a viral process. Other laboratory tests, such as streptococcal screens or throat cultures or both, serum antibody titers, viral cultures, and antigen detection methods, are required for evaluating exanthems, depending on the state of the patient being evaluated.

TABLE 67–1 Dukes Classification of Exanthems

First disease*	Measles
Second disease	Scarlet fever
Third disease	Rubella
Fourth disease†	Dukes disease
Fifth disease	Erythema infectiosum
Sixth disease	Roseola infantum

**It is not known definitively if measles or scarlet fever was the first disease.*
†This disorder had characteristics of many infections and today is not believed to represent a distinct entity.
Data from Cherry, J. D.: Cutaneous manifestations of systemic disease. In *Feigin, R. D., and Cherry, J. D. (eds.): Textbook of Pediatric Infectious Diseases. 3rd ed. Philadelphia, W. B. Saunders, 1992, pp. 755-782; Frieden, I. J., and Penneys, N. S.: Viral infections.* In *Schachner, L. A., and Hansen, R. C. (eds.): Pediatric Dermatology. New York, Churchill Livingstone, 1988, pp. 1371-1413; Hurwitz, S.: Clinical Pediatric Dermatology. 2nd ed. Philadelphia, W. B. Saunders, 1993, pp. 318-371.*

WARTS

Although most warts are easily recognized by practitioners and manifest with nothing more than local discomfort or embarrassment for school-aged children, some carry more ominous associations. Human papillomaviruses (HPV), which are DNA viruses, cause this infection. Approximately 120 different serotypes exist, and subclinical infections have been documented.[75] The common wart, or verruca vulgaris, is caused by infection with HPV type 2 or 4. Infection is transmitted by direct contact, and some site specificity exists for each HPV type. Some HPV types, such as 11 and 16, have documented associations with malignancy.[75,124] A vaccine directed against HPV types 6, 11, 16, and 18 has been released in an attempt to address this problem.[24,47] Immunocompromised patients, such as renal transplant recipients, can have persistence of a variety of HPV types, although not always the types having a malignant risk.[9] In healthy hosts, warts can resolve spontaneously within 2 years in most patients.[6] Persistence of infection can be a source of great concern, however, leading to consultation regarding treatment options.

No specific treatments are available for warts. Most treatments are physically destructive in nature, although some incite local immune responses. When discussing treatment options with patients or families, being frank about the lack of predictably useful therapies is important. One of the only therapies subjected to appropriately controlled trials is salicylic acid, which has shown efficacy in approximately 65 percent of the patients so managed. Office therapies using liquid nitrogen, acids such as trichloroacetic acid, or cantharidin have been used with variable success. Over-the-counter cryotherapy units typically do not freeze the lesions as quickly or as thoroughly as does liquid nitrogen. Laser such as carbon dioxide or erbium:YAG lasers are classic destructive lasers. Pulsed-dye lasers also have been useful for some patients through selective destruction of the vasculature. Multiple other modalities, such as duct tape, first suggested in 1978 and more recently by several authors, and antivirals such as cidofovir have been used. The goal of management of this infection must be tailored to the patient and the nature of the lesions.

The finding of condyloma in a young child always raises concern for sexual abuse. When a condyloma is seen in children younger than 2 to 3 years of age, vertical transmission is well recognized to be a means of transmission.[75,124] Caretakers known to have warts also are obvious transmitters of viruses causing such lesions. In these children or in the case of older children, obtaining a careful history regarding the child's behavior and caretakers and examining the child thoroughly for any signs of physical abuse always are important.

MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum represents a common viral infection of the skin (and sometimes mucous membranes) of children and adolescents. It is caused by a poxvirus and has not been grown in culture. The virus replicates within the cytoplasm[38] and is represented by four viral types based on DNA analysis: MCV-1 to MCV-4.[73] MCV-1 accounts for more than 90 percent of infections in the United States.[38,73] The subtypes do not show site specificity. MCV-2 was reported to be seen most commonly in patients infected with human immunodeficiency virus (HIV).[40,73]

EPIDEMIOLOGY

The disease is seen with increasing frequency in sexually active and immunodeficient individuals. Infection occurs at any age, with the highest frequency seen in patients younger than 5 to 10 years old.[17,38] The infection is two to three times more common in school-aged and sexually active males than in females. Transmission is via close contact. Spread is reported to occur via fomites. The incidence of disease is highest in warm climates and in areas of overcrowding.

CLINICAL MANIFESTATIONS

The incubation period for molluscum contagiosum is 2 to 7 weeks, but it has been reported to occur at 1 week of age. Typical lesions are 1 to 5 mm in size, dome-shaped, skin-colored or pink papules with a distinctive central umbilication (Fig. 67–1). Giant lesions 1 to 2 cm can be seen. According to an epidemiologic survey conducted at three pediatric dermatology centers, fewer than 15 lesions usually are seen.[38] In children, molluscum contagiosum is seen most frequently on the face, neck, trunk, and extremities but may be seen on any part of the body, including the mucous membranes.[17,38,72] Periocular lesions may lead to secondary keratoconjunctivitis or trachoma. In some cases, molluscum contagiosum is a sexually transmitted disease, raising the issue of sexual abuse when infection is seen in the genital area. The most common etiology of genital molluscum contagiosum is autoinoculation; however, if the lesions occur solely in the genital area, or a question exists about the patient's social situation, the possibility of abuse should be explored.

Atypical lesions of molluscum contagiosum are seen more commonly, particularly with the improved survival rates of patients with acquired immunodeficiency syndrome (AIDS) and other immunocompromised states. The incidence of molluscum contagiosum in HIV infection is 5 to 18 percent. With improved antiretroviral therapies, molluscum contagiosum has decreased in this population.[21,38]

Molluscum contagiosum lesions in immunocompromised patients often are large, are situated more deeply in the epider-

Figure 67–1 Grouped dome-shaped papules of molluscum contagiosum on the skin of the abdomen. (See companion Expert Consult web site for color version.)

mis, and may number in the hundreds. HIV-positive adults usually have molluscum contagiosum on the face, neck, and trunk. In a study of immunocompromised children, molluscum contagiosum was not considered to be common or severe, however. This study included only six patients, and two were disease-free and thought to be immunocompetent at the time of onset of the infection. This and other studies suggest that the presence and degree of cellular immunodeficiency are important in the presentation of molluscum contagiosum.

Patients with atopic dermatitis may be predisposed to develop more severe molluscum contagiosum infection. Available information is insufficient to know if this development is related to the dermatitis itself with its well-described barrier dysfunction or to the use of corticosteroids or other topical agents. The term *molluscum dermatitis* is used to describe an eczematous eruption, more commonly seen in patients with atopic dermatitis, which may occur around molluscum contagiosum lesions and is thought to represent a delayed-type hypersensitivity reaction to viral antigens in the dermis.

Molluscum contagiosum infections in healthy individuals usually resolve spontaneously over the course of several months to 3 to 5 years. For this reason, limited infections can be observed expectantly. More diffuse infections or infections that show continued extension can be considered for treatment. No definitive treatments are available for molluscum contagiosum. Most treatments, similar to those used for warts, are destructive in nature. Immune enhancement for these infections has been tried, but its utility has not been proven. Multiple treatments have been used, although utility is uncertain in all but curettage.

PARVOVIRUS B19 INFECTIONS

The most well-known infection caused by parvovirus B19 is erythema infectiosum or fifth disease.[86] The infection also is termed *slapped cheek disease* because of its initial skin manifestation of bilateral facial erythema (Fig. 67–2). Other manifestations include a papular purpuric glove-and-socks eruption and an eruption with pustules in a bathing-trunk distribution.

The virus is a single-stranded DNA virus that infects erythroid cells. The infection is spread via the respiratory route, with an incubation period of approximately 2 weeks. Most patients are asymptomatic. Serologic assays for IgG and IgM antibodies are used for confirmation of infection. The exanthem of fifth disease coincides with the presence of IgM antibodies. Viral DNA has been found in infected tissues.

Children with fifth disease or erythema infectiosum generally are not ill-appearing. Mild complaints of myalgias or low-grade fevers may be reported. As in adults, arthritis may be seen in older children and adolescents. Outbreaks often spread through schools or families. Most patients present to their physicians with a typical-appearing reticulated blanching erythema. The slapped cheek appearance characteristic of the disorder may be missed or elicited only on questioning.

The papular, purpuric glove-and-socks syndrome is another condition caused by infection with parvovirus B19.[62] When patients present with the eruption, they are infectious based on the finding of viral DNA. The eruption shows a curious distribution of the hands and feet with clear "cutoff" at the wrists and ankles. Changes in oral skin and mucous membrane may be seen, in addition to mild systemic complaints.

Diagnosis of erythema infectiosum or papular purpuric glove-and-socks syndrome is confirmed by serologic testing for antibodies or polymerase chain reaction. A report of loop-mediated isothermal amplification has shown its utility for rapid diagnosis of such infections and has compared favorably with polymerase chain reaction.[134]

GIANOTTI-CROSTI SYNDROME (PAPULAR ACRODERMATITIS OF CHILDHOOD)

Gianotti-Crosti syndrome (papular acrodermatitis of childhood) is a viral exanthem first reported in 1955 by Gianotti,[50] who described a group of children who presented with predominately acrally located, skin-colored or slightly erythematous, lichenoid papules (Fig. 67–3).[120] The flexures usually were spared. Involvement of the buttocks or trunk was seen in some cases. No involvement of mucous membranes occurred. Patients generally were healthy. The initial reports showed prior infection with hepatitis B. The eruption lasted 2 weeks to 2 months.

Since the initial report, similar cases have been associated with other infections, such as Epstein-Barr virus, coxsackievirus, echovirus, other viruses, and streptococcal disease.[85] Most cases are thought to be viral in origin and often caused by Epstein-Barr virus. Topical therapies do not hasten resolution of the exanthem.

Figure 67–2 Reticulated erythema on the face of a child with erythema infectiosum. (See companion Expert Consult web site for color version.)

Figure 67–3 Diffusely distributed, isolated, monomorphous skin-colored papules on the thigh of a child typical of Gianotti-Crosti syndrome.

ASYMMETRIC PERIFLEXURAL VIRAL EXANTHEM

Some children have been described with discrete or grouped lichenoid papules or urticarial papules beginning around flexures or the torso (Fig. 67–4).[49] The eruption generalizes over several days and can appear as a more diffuse case of the papular acrodermatitis of childhood. The condition also has been described as the unilateral laterothoracic viral exanthem and seems to be associated with the same infectious agents as described in papular acrodermatitis of childhood.[15] The evolution of this condition is similar to that in the papular acrodermatitis of childhood.

HAND, FOOT, AND MOUTH SYNDROME

Patients presenting with a distinctive eruption of sausage-shaped vesicles on the palms and soles with oral mucosal erosions after a mild viral gastroenteritis represent the classic case of hand, foot, and mouth syndrome. Patients may have erythematous papules found on the skin of the buttocks as well. Cases tend to cluster within homes, daycare centers, or schools. Most cases resolve spontaneously without sequelae over the course of 2 to 3 weeks. Hand, foot, and mouth syndrome traditionally is attributed to infection with coxsackievirus A16; however, more recent data suggest enterovirus 71 as a predominant cause as well.

A more recent publication followed a large outbreak of hand, foot, and mouth syndrome (and herpangina) in Taiwan.[25] As with known epidemiologic data, most cases occurred in younger children (93%, <4 years old; 75%, <1 year old). Enterovirus 71 and coxsackievirus A16 were the viruses predominantly recovered. Enterovirus 71 was seen in 66 percent of these patients. The authors emphasized the potential for mortality from this virus, particularly as a result of pulmonary edema or hemorrhage, although encephalitis also was seen. Enterovirus 71 was seen primarily in inpatients, whereas coxsackievirus A16 was recovered from outpatients.

HERPES SIMPLEX VIRUS

Herpes simplex virus (HSV) types 1 and 2 are members of the herpesvirus family, which includes varicella-zoster virus, Epstein-Barr virus, cytomegalovirus, and human herpesvirus. HSV-1 and HSV-2 infections may be asymptomatic or associated with classic and unusual clinical manifestations. Although a predilection exists for involvement of the oral mucosa for HSV-1 and the genitalia for HSV-2, either can infect any site. These infections occur worldwide and are transmitted by direct contact. Asymptomatic carrier states exist and are known to be the source of infection in patients. Immunity to HSV-1 generally is acquired during childhood, whereas HSV-2 immunity usually is seen after adolescence.

The virus replicates within the epidermis and travels to regional nerve ganglia. The incubation period ranges from 2 to 20 days. Recurrences, which occur in the same site as the original infection, usually are less severe than is the primary infection. In immunocompetent patients, the infection usually remains localized.

CLINICAL MANIFESTATIONS

Children most often present with oral or perioral disease, such as gingivostomatitis or herpes labialis.[124] Painful vesicles and discrete "punched-out" erosions can be seen on the lips, anterior surface of the tongue, or hard palate. Herpes pharyngitis can be seen in older children and can be caused by HSV-2 infection. Feeding problems and foul-smelling breath can occur in these settings. Grouped vesicles on an erythematous base are a common cutaneous finding (Fig. 67–5).

Disease manifestations can last 10 to 14 days. Herpes gladiatorum is caused by transmission of HSV by direct contact. The name derives from exposure and infection between wrestlers, although the infection also can occur in the setting of close contact between participants of other sports. Eczema herpeticum occurs when cutaneous HSV infection spreads over the skin of individuals with an abnormal skin barrier, such as in atopic dermatitis. Infections can be localized or very diffuse and can be associated with systemic involvement. Herpetic whitlow manifests as painful deep-seated vesicles or pustules on the tips of fingers (Fig. 67–6). This infection results from direct contact with active lesions of HSV. A common presentation is in an infant or

young child who has manipulated a lesion of herpes labialis on a parent. Lastly, HSV infection is perhaps the most common cause of recurrent erythema multiforme.[129] Clinicians should keep this association in mind.

Localized disease and disease without systemic symptoms can be treated symptomatically. Local wound care is appropriate, as indicated. Acyclovir or valacyclovir is useful for cases when antiviral therapy is chosen. Prophylactic antivirals should be considered for cases of recurrent erythema multiforme.

VARICELLA-ZOSTER VIRUS

Chickenpox is the most common presentation of varicella-zoster virus infection in childhood. After a 2-week incubation period, vesicles on erythematous bases ("dewdrops on rose petals") are seen on the head and neck and spread rapidly to the trunk. Involvement of mucous membranes occurs frequently. Lesions are seen in all stages. Constitutional symptoms also may be seen. Unless bacterial infection occurs, scarring seldom occurs. An uncommon and perhaps under-recognized presentation of varicella is photolocalized disease. Several cases of varicella presenting in a photodistributed fashion (i.e., over sun-exposed skin) have been reported.[126]

Shingles or herpes zoster occurs after primary infection with varicella-zoster virus or receipt of vaccination (Fig. 67–7).[112,125] Healthy children who have had a case of chickenpox before reaching 6 to 12 months of age are at risk for developing shingles.[74] Immunocompromised children are at risk for acquiring this infection as well. Ramsay Hunt syndrome is caused by infection of the geniculate ganglion in this setting.[124]

Most cases of chickenpox do not require antiviral therapy. Management of systemic symptoms and local skin care are needed. Antivirals are needed when treating neonates or immunocompromised patients or normal patients with severe skin disease. There is considerable anecdotal experience using corticosteroids and antivirals for the management of Ramsay Hunt syndrome.

FUNGAL INFECTIONS

Superficial fungal infections, which include dermatophytes, yeast, or dematiaceous fungi, are encountered frequently in general pediatric practice. Particularly in an immunocompromised patient, fungal infections also may involve deeper cutaneous structures and other organ systems. This section focuses on the skin manifestations, diagnosis, and treatment of pediatric fungal infections.

SUPERFICIAL FUNGAL INFECTIONS

DERMATOPHYTE INFECTIONS

Dermatophytes invade and grow in hair, nails, and the outer layer of the skin known as the *stratum corneum*. These lesions vary in appearance based on the site of infection and are named accordingly.

Tinea Capitis

Also known as *scalp ringworm*, tinea capitis is seen frequently in prepubertal children. The causative organisms vary according to country; in North America, tinea capitis is caused largely by *Trichophyton tonsurans* and less often by *Microsporum canis*.[101,121,128] *M. canis*, a zoophilic dermatophyte common to suburban and rural areas, can be transmitted to children who handle infected animals such as cats, dogs, and certain rodents; however, it does not spread between humans.[121] Thick, white patches of broken hair that fluoresce under Wood lamp examination characterize these lesions.

Human-to-human transmission of *T. tonsurans* occurs through the shedding of spores from infected skin scales and hair on items such as clothing, bed linen, combs, and hairbrushes. Lesions caused by *T. tonsurans* do not fluoresce under a Wood lamp and vary in appearance from diffuse scaling of the scalp to circumscribed areas of scaling and erythema with or without hair loss, and, in dark-haired individuals, to scaly patches of hair loss that may leave small dark hairs in the follicles (black-dot ringworm) (Fig. 67–8). Tinea capitis lesions may be associated with suboccipital or posterior cervical lymphadenopathy and may produce more inflammatory lesions, including scaly, pustular areas of hair loss and formation of a kerion—a boggy, erythematous mass with follicular pustules that may lead to permanent hair loss and scarring if left untreated (Fig. 67–9).[28,101,128] Another hypersensitivity response to the dermatophyte infection is a dermatophytid or id reaction, which involves papulovesicular inflammatory eruptions adjacent to or distant from the site of the primary infection (Fig. 67–10).[12]

Tinea capitis must be distinguished from alopecia areata, which consists of patches of total hair loss without scalp changes, and trichotillomania, which may be associated with excoriations,

Figure 67–8 Nonscarring alopecia associated with tinea capitis. (See companion Expert Consult web site for color version.)

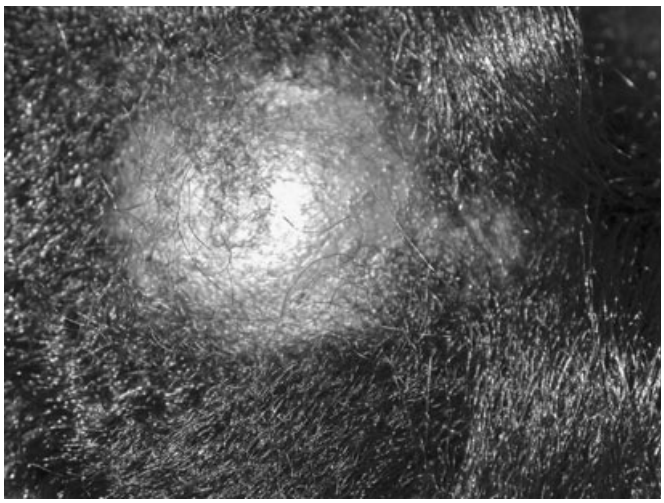

Figure 67–9 Indurated tumor on the scalp typical of kerion. (See companion Expert Consult web site for color version.)

Figure 67–10 Multiple skin-colored papules and pustules on the forehead typical of an id reaction to tinea capitis.

varying lengths of broken hairs, and ill-defined patterns of hair loss. Differential diagnosis also includes traction alopecia, seborrheic dermatitis, psoriasis, and pityriasis amiantacea. In addition, inflammatory lesions of tinea capitis may be confused with bacterial pyodermas of the scalp.[28,121,128]

Tinea Corporis

Tinea corporis refers to dermatophyte infection of the trunk or extremities. Lesions appear as erythematous patches or plaques with well-demarcated, annular borders that may be scaly, pustular, or vesicular.[28,121,128] The application of potent topical corticosteroids may obscure these characteristic borders, resulting in a manifestation termed *tinea incognito*.[121] The differential diagnosis includes seborrheic, atopic, and contact dermatitides; psoriasis; and granuloma annulare.[28,128]

Tinea Faciei

Dermatophyte infections of the face in children are characterized by erythematous, scaly plaques that may be unilateral or occur in a "butterfly" distribution, mimicking cutaneous findings of systemic lupus erythematosus and other collagen vascular diseases (Fig. 67–11). As with tinea corporis, differential diagnosis includes seborrheic, atopic, and contact dermatitides.[28,128]

Tinea Pedis

Tinea pedis, which occurs more commonly in adolescents than in prepubertal children, characterizes dermatophyte infection involving the feet. Findings vary and may be vesicles or erosions over the instep of the feet, fissuring between the toes with surrounding erythema and scaling, or diffuse scaling of the soles in a "moccasin-like" distribution. Differential diagnosis includes juvenile plantar dermatosis, dyshidrotic eczema, atopic dermatitis, contact dermatitis, granuloma annulare, scabies, psoriasis, and erythrasma.[28,121,128]

Figure 67–11 Diffuse scaling plaques on the face caused by tinea faciei. (See companion Expert Consult web site for color version.)

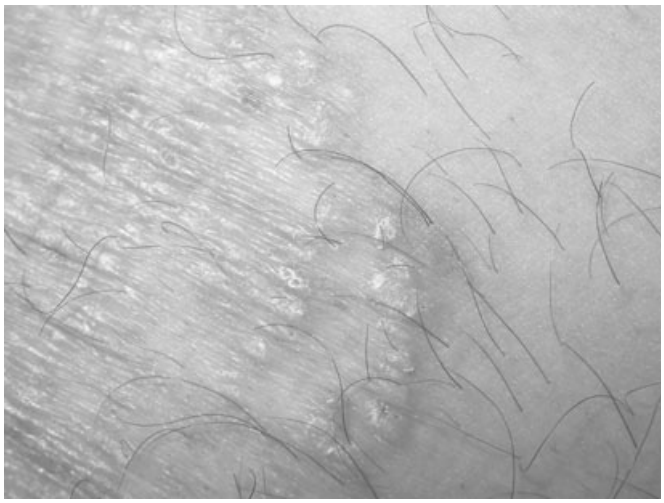

Figure 67–12 Annular scaling plaque on the upper inner thigh caused by tinea cruris. (See companion Expert Consult web site for color version.)

Tinea Cruris

Also predominately seen in adolescents, particularly boys, tinea cruris often occurs in association with tinea pedis and is transmitted through indirect or direct contact with infected skin scales or hair. Risk factors include obesity, friction, moisture, and tight clothing. The characteristic lesions are usually symmetric, well-demarcated, erythematous, scaly eruptions in the inguinal and inner thigh area with potential spread to the buttocks and perianal region. These lesions also may have a raised papular or pustular edge and often are very pruritic, leading to lichenification in chronic disease (Fig. 67–12). The differential diagnosis includes seborrheic dermatitis, *Candida* intertrigo, flexural psoriasis, irritant dermatitis, contact dermatitis, and erythrasma.[28,121,128]

Tinea Unguium

The term *onychomycosis* refers to fungal invasion of the nail plate, which is termed *tinea unguium* when the infection is caused by dermatophytes. The lower incidence of tinea unguium in children compared with adults may be due to faster nail growth, decreased likelihood of nail trauma, and less exposure to tinea pedis, which often is seen concurrently with onychomycosis.[63,106] Clinical findings of infection include superficial white patches on the surface of the nail plate, white spots under the nail, and yellowing and thickening of the nail plate that usually extends from the distal to the proximal end (Figs. 67–13 and 67–14). The differential diagnosis includes psoriasis, lichen planus, hereditary onychodystrophy, and acquired trachyonychia, all of which may be distinguished from tinea unguium by their diffuse nail involvement as opposed to the more limited disease of a dermatophyte infection. Tinea unguium also may mimic *Candida* infection of the nails, but the latter disease differs in that it tends to spread distally from the proximal nail plate.[28,57,63,101,106,128]

DIAGNOSIS

Light microscopy examination with potassium hydroxide should show spores in infected scalp hairs of tinea capitis and branching hyphae in affected nail samples or skin scrapings from advancing margins of lesions on the body (see Fig. 67–14). Fungal culture on Sabouraud dextrose agar treated with chloramphenicol and cycloheximide provides a growth medium selective for dermatophytes and may aid in differentiating various species. Rarely, biopsy may be required for definitive diagnosis.[28,101,121,128]

Figure 67–14 White superficial plaques typical of superficial white onychomycosis. (See companion Expert Consult web site for color version.)

TREATMENT

Localized lesions of tinea corporis, faciei, pedis, and cruris generally respond to a 2- to 4-week course of topical antifungals, such as clotrimazole, tolnaftate, ciclopirox olamine, amorolfine, or terbinafine.[101] Severe or refractory disease may require oral antifungal medications. Recurrence of tinea pedis can be prevented by avoiding occlusive footwear and keeping the feet clean and dry.[121]

Griseofulvin is the only oral antifungal medication that is approved by the U.S. Food and Drug Administration (FDA) for use in children. Many agents, including terbinafine, itraconazole, and fluconazole, have been used successfully as off-label alternatives, however, despite limited data regarding their safety and efficacy in children.

Griseofulvin remains the gold standard for the treatment of tinea capitis in the United States. The approved dose of microsized griseofulvin is 11 mg/kg/day for 6 to 8 weeks; however, 20 to 25 mg/kg/day often is required to achieve an adequate response.[114] A 2- to 4-week course of terbinafine also has been shown to be as effective as is griseofulvin, particularly in the treatment of tinea capitis caused by *Trichophyton* spp.[42,45,54,115] For *Microsporum* infections, higher doses or longer duration of therapy with terbinafine may be required.[42,45,54,76,115] Studies have shown that a fluconazole regimen of 6 mg/kg/day for 3 to 6 weeks has a cure rate comparable to that of griseofulvin.[43,54,114] Continuous or pulse itraconazole therapy of 5 mg/kg/day has been noted to result in significant improvement and even cure in *Trichophyton* and *Microsporum* tinea capitis by 6 weeks; however, infection with *Microsporum* may require a longer duration of treatment with itraconazole compared with effective courses for *Trichophyton* infection.[51,54,55] In addition, concomitant topical therapy with selenium sulfide 1 to 2.5 percent shampoo in affected individuals and household contacts reduces the number of viable spores and prevents the spread of infection.[52,105,121]

At present, no antifungal agent is approved by the FDA for treatment of onychomycosis in children, and data are limited regarding efficacy of topical and oral antifungal agents. Topical agents have poor penetration into the nail plate, usually leading to an inadequate response rate. Treating concurrent tinea pedis infections with topical therapy may help prevent recurrences of tinea unguium, however. Although griseofulvin is the drug of choice for treating other dermatophyte infections, it is not recommended for the treatment of onychomycosis because of the lengthy course (≤18 months), inadequate response, and high recurrence rate.

Terbinafine (3 to 6 mg/kg/day for 6 to 12 weeks), continuous or pulse itraconazole therapy (5 mg/kg/day for 3 months), and fluconazole (3 to 6 mg/kg once a week for 12 to 26 weeks) have been reported as safe, effective, and well-tolerated alternatives.[57,59,93,115] Because of their keratinophilic and lipophilic natures, these agents accumulate in the stratum corneum and persist at high concentrations in the nails for months, allowing for shorter courses of therapy.[55,57,59,63,115] Terbinafine may be crushed and taken with or without food. Optimal bioavailability with itraconazole capsules occurs when taken with fatty foods, whereas itraconazole solution should be taken on an empty stomach and may be associated with a higher incidence of gastrointestinal side effects than capsules. Studies regarding use of fluconazole for treatment of onychomycosis in children are limited, but successful therapy has been reported at a pulsed dose of 3 to 6 mg/kg once a week for 3 months.[57,59,115]

CANDIDA

The most common cause of fungal infection in healthy and immunocompromised children is *Candida*, and *Candida albicans* accounts for most cases. These yeast forms have a predilection for moist, warm areas of the body such as mucosal surfaces and intertriginous regions and often colonize these areas, becoming part of the normal flora. Disease is caused by overgrowth and infiltration into the epidermis. Superficial infections may be seen in healthy individuals and individuals with predisposing risk factors, such as prematurity; low birth weight; diabetes mellitus; antibiotic, corticosteroid, or oral contraceptive therapy; and other immunocompromised states. These individuals also are more likely to develop systemic candidiasis.[46,101,128]

Thrush is characterized by superficial, sometimes tender, white plaques on oral mucosa that reveal denuded, erythematous bases when scraped off (Fig. 67–15). These manifestations must be distinguished from other oral cavity lesions, such as aphthous stomatitis, epidermolysis bullosa, herpes simplex, hairy leukoplakia, lichen planus, geographic tongue, erythema multiforme, and burns.[128] Use of pacifiers in infants may increase the risk of development of thrush and colonization of the organism.[11] Oropharyngeal candidiasis may spread to the esophagus in immunocompromised individuals and lead to difficulty with feeding.

Figure 67–15 White patches on buccal mucosa caused by *Candida albicans*. (See companion Expert Consult web site for color version.)

Figure 67–16 Clinical photograph of an infant with *Candida* diaper dermatitis. Confluent and discrete erythematous papules and plaque involving the scrotum, penis, and superpubic and inguinal area.

Diaper candidiasis appears as beefy, erythematous plaques that involve the inguinal creases and perianal region and often are associated with satellite (or surrounding) erythematous papules, plaques, or pustules (Fig. 67–16). These lesions may cause discomfort when the infant urinates onto affected skin. Superinfection with *Candida* should be suspected when irritant diaper dermatitis fails to improve within several days. Other lesions that may be confused with diaper candidiasis include psoriasis, Langerhans cell histiocytosis, and seborrheic dermatitis.[128]

Thumb-sucking or other trauma near nail beds may lead to nontender, erythematous swelling at the base of the nails termed *paronychia* (Fig. 67–17). Some cases are complicated by *Candida* infection. Differential diagnosis of these lesions includes psoriasis, bacterial infection, lichen planus, and pachyonychia congenita. *Candida* also may produce onychomycosis, but its distribution usually involves the proximal nail plate, in contrast to dermatophytosis of the nails, which more commonly affects the distal nail plate.[128]

Adolescent girls may present with vulvovaginal candidiasis, which is characterized by thick, white discharge and white plaques on irritated, erythematous vaginal mucosa. These lesions may cause vaginal itching and dysuria.[128]

Figure 67–17 Onychodystrophy involving the thumb and index finger, with erythema and edema of the paronychium. These features are typical of *Candida* paronychia.

Figure 67–18 Dense crusting overlying the flank and buttocks of a neonate with *Candida* dermatitis. *(From Rowen, J. L., Atkins, J. T., Levy, M. L., et al.: Invasive fungal dermatitis in the 1000-gram neonate. Pediatrics 95:682-687, 1995.)*

Diagnosis of localized *Candida* infection usually is made clinically. Microscopic examination of potassium hydroxide–prepared scrapings of skin and mucosal lesions reveals pseudohyphae and elongated budding yeast forms. Positive cultures of infected material on Sabouraud dextrose agar or cornmeal agar may signify infection or benign colonization. Biopsy rarely is required for establishing a definitive diagnosis.

Treatment of localized *Candida* infection depends on good hygiene practices and maintenance of a dry environment in the susceptible area. Localized infections usually respond well to topical antifungal therapy. Nystatin solution is the first-line agent used for thrush, but oral fluconazole or itraconazole and intravenous amphotericin B may be required to treat recurrent, refractory, or extensive disease, especially in immunocompromised children.[65] Nystatin or imidazole creams in conjunction with frequent diaper changes, barrier creams, and sometimes low-strength topical steroids are the recommended treatment for diaper candidiasis. Paronychia also is susceptible to nystatin and imidazole creams but may require oral therapy. Vulvovaginal candidiasis often can be treated successfully with topical azole medications, but oral azoles are recommended for refractory or recurrent cases. Adolescents can be treated with a single, 150-mg dose of oral fluconazole.[22,65]

Congenital candidiasis, a rare form of infection acquired in utero as a result of *Candida* chorioamnionitis, can manifest in full-term and premature neonates within the first few days of life as a diffuse, erythematous, papular eruption that progresses to formation of vesicles and pustules, and subsequently crusting and desquamation. Palms and soles also may be affected. Term infants with congenital candidiasis rarely develop systemic manifestations, and the infection usually resolves spontaneously or with topical antifungal agents, such as nystatin, imidazoles, or allylamines. Premature, very-low-birth-weight neonates are at risk for developing ecchymosis and necrosis of the skin with dissemination of the *Candida* infection, requiring treatment with systemic antifungal medication. Congenital candidiasis in these premature infants may manifest as sepsis or pneumonia without cutaneous findings as well.[2,101,119]

Differential diagnosis of congenital candidiasis includes epidermolysis bullosa and infection with *Listeria monocytogenes*, *Staphylococcus*, herpesvirus, and syphilis.[36] Early diagnosis is established by histologic examination of the placenta and umbilical cord, which shows the characteristic pseudohyphae and spores and white microabscesses.[2,36] Microscopic examination and culture of the skin lesions can confirm the diagnosis.

Systemic candidiasis, in which *Candida* spp. can be isolated from the blood, urine, or cerebrospinal fluid, is seen more commonly in immunocompromised individuals, who often present with skin manifestations that include desquamation, abscesses at indwelling catheter sites, and progressive diaper candidiasis. Systemic candidiasis may be associated with signs of sepsis, such as hemodynamic and temperature instability, and respiratory changes.[65,128]

Invasive fungal dermatitis is a rare manifestation of *Candida* infection in premature, very-low-birth-weight infants. *Aspergillus*, *Trichosporon*, and *Curvularia* spp. also have been implicated in this type of infection, but *Candida* is the most common etiologic agent. Besides low birth weight and prematurity, additional risk factors for acquisition of invasive fungal dermatitis include hyperglycemia, steroid use, and vaginal birth. In contrast to congenital candidiasis, invasive fungal dermatitis usually does not manifest until after several days of life. Skin findings include erythematous, macerated plaques and crusted erosions that can spread rapidly over the body and may lead to development of systemic fungemia, with a high mortality rate (Fig. 67–18). Biopsy of these lesions shows invasion through the stratum corneum into the epidermis with occasional extension into the dermis.[107] Survival depends on prompt initiation of systemic antifungal medications.[94,119]

Treatment of disseminated *Candida* infection requires removal of infected indwelling catheters in addition to administration of systemic antifungal therapy. Intravenous amphotericin B is the drug of choice for treating disseminated disease and sometimes is administered in combination with 5-fluorocytosine for synergism. Other options include systemic itraconazole and fluconazole; however, some *Candida* spp. have shown resistance to fluconazole.[2,101,119] Azoles also have been used as prophylaxis for systemic fungal infections in neutropenic patients with hematologic malignancies and bone marrow transplant recipients,[30,66,90] but this practice, especially in preterm neonates, is controversial because of the potential for resistance.[19,23] Newer antifungal agents, such as voriconazole, posaconazole, and caspofungin, have been reported to be effective treatments, particularly in resistant candidemia.[5,85,88,91,114,118] Avoidance of prolonged antibiotic and steroid administration may aid in clearance of *Candida* infection.[65,128]

MALASSEZIA

Malassezia spp., most notably *Malassezia furfur*, are lipophilic yeast forms that are found more readily in humid, tropical environments and are part of the normal skin flora in humans. Colonization begins in the neonatal period and increases with age.[10] *Malassezia* is the organism thought to be responsible for neonatal cephalic pustulosis and tinea (or pityriasis) versicolor in older children, adolescents, and young adults. Invasion of the organism through indwelling catheters, particularly catheters being used for intralipid infusion, in premature, very-low-birth-weight infants also may lead to sepsis and death.[7,103,119] *Malassezia* also has been implicated in the pathogenesis of seborrheic dermatitis, atopic dermatitis, and psoriasis, although this implication is controversial.[7,28,56,84,92,110,123]

Neonatal cephalic pustulosis is a self-limited disease characterized by scattered, erythematous papules and pustules in a head-and-neck distribution (Fig. 67–19). Follicular accentuation and comedones are not observed. Diagnosis usually is made clinically, but may be confirmed by microscopic findings.[10,101,119]

Tinea versicolor is characterized by macules with fine scales that are distributed on the upper body and neck. The macules may appear hypopigmented in dark-skinned individuals or tan or dark brown in lighter skinned individuals (Fig. 67–20). Differential diagnosis includes vitiligo, pityriasis alba, pityriasis rosea, postinflammatory hypopigmentation, melasma, seborrheic dermatitis, contact dermatitis, and tinea corporis. Lesions of tinea versicolor are fluorescent yellow to orange under Wood lamp. Microscopic examination of potassium hydroxide–prepared scrapings of the lesions shows a "spaghetti and meatball" appearance owing to the presence of short, curved hyphae and round spores. Biopsy of the lesions, which usually is unnecessary, reveals the characteristic hyphae and spores invading the stratum corneum.

The recommended treatment is application of 2.5 percent selenium sulfide or ketaconazole shampoo. Other topical agents, such as ciclopirox, terbinafine solutions, sodium hypochlorite, and other azoles, also may be effective. Short 1- to 5-day courses of oral itraconazole, fluconazole, and ketoconazole in single daily doses have been suggested as effective treatments; however, these agents are not approved by the FDA for treating tinea versicolor in children because of their limited safety and efficacy profiles.[12,41,100] It is important to advise patients that skin discolorations may take months to resolve and that recurrences are very common and may require retreatment.[28,100,101,119,128] *Malassezia* sepsis responds well to removal of indwelling catheters and rarely requires systemic antifungal therapy.[119]

CHROMOBLASTOMYCOSIS

Fonsecaea pedrosoi, and less commonly *Cladophialophora carrionii* and *Phialophora verrucosa*, are found in tropical climates and are organisms responsible for causing chromoblastomycosis, a chronic granulomatous disease affecting skin and subcutaneous tissue. Infection is acquired through traumatic inoculation into the skin. Cutaneous manifestations are described as pink papules that progressively enlarge to become tender, pruritic, hyperkeratotic nodules or verrucous plaques (Fig. 67–21). Scratching may lead to secondary infection or result in autoinoculation of the organism to other areas of the body. Infection may lead to scarring of lymphatic vessels causing obstruction and lymphedema.[16,97,102,107]

Differential diagnosis includes tuberculosis, sporotrichosis, blastomycosis, leishmaniasis, and squamous cell carcinomas. Potassium hydroxide smears of skin scrapings reveal characteristic dark brown, round, sclerotic bodies with horizontal or vertical septa and thick, pigmented hyphae. Sclerotic bodies also are identified easily on hematoxylin and eosin stain. In addition, biopsy of the chromoblastomycosis lesions shows granulomatous inflammation with macrophages and neutrophils and a hyperkeratotic, hyperplastic epidermis with microabscesses.[16,102,107]

Treatment of localized lesions involves surgical excision, cryotherapy, or heat therapy. Chemotherapy with 5-fluorocytosine

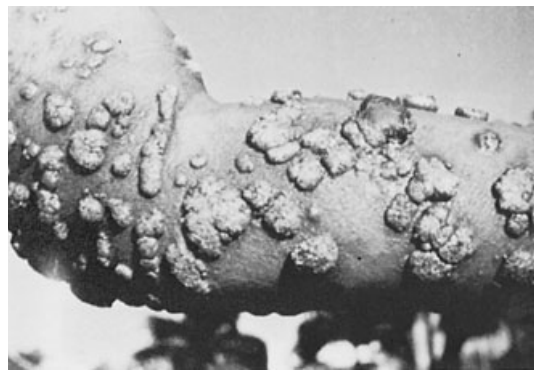

Figure 67–21 Chromoblastomycosis. The warty-like growth of epidermis and dermis is a result of traumatic implantation of the etiologic agent and subsequent autoinoculation from scratching. The agent was *Fonsecaea pedrosoi*.

and antifungal agents such as azoles, amphotericin B, and terbinafine has been used with some success in more widespread disease.[16,107,116]

TINEA NIGRA

Tinea nigra, caused by the organism *Phaeoannellomyces werneckii*, is a superficial fungal infection seen primarily in children and adolescents.[28,80,95] The organism is found in soil, wood, sewage, salted dried fish, and vegetation, mainly in beach environments of Central and South America, Africa, Asia, and, less frequently, in the United States and Europe. Transmission occurs by direct contact.[80,95,96]

Tinea nigra usually is characterized by an asymptomatic, well-demarcated, single brown to black macule or patch primarily on the palm, but may involve other areas of the body as well (Fig. 67–22). Lesions grow slowly and usually are nonscaly.[28,95] Tinea nigra lesions may mimic melanoma, lentigines, junctional nevi, and the hyperpigmented patches of Addison disease.[28,95,96] Under microscopic examination, potassium hydroxide–prepared scrapings of the lesion show yellow to light brown, branched, septate hyphae (Fig. 67–23).[28,96] Diagnosis is confirmed further by culture, which grows oval to spindle-shaped, moist, shiny, black colonies on Sabouraud agar.[95]

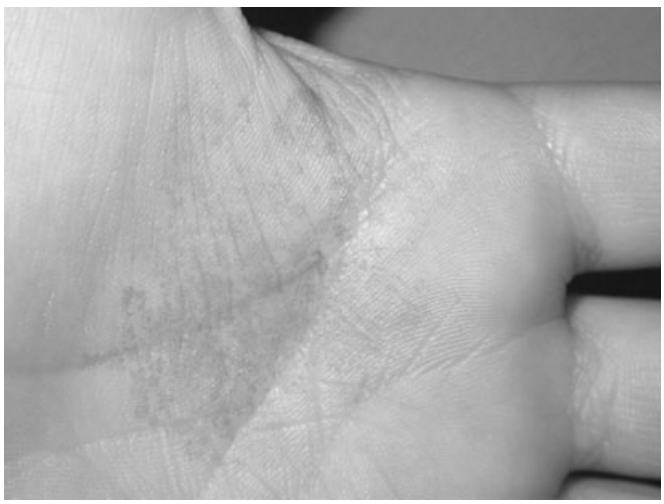

Figure 67–22 Brown patch on the palm of the hand caused by tinea nigra palmaris. (See companion Expert Consult web site for color version.)

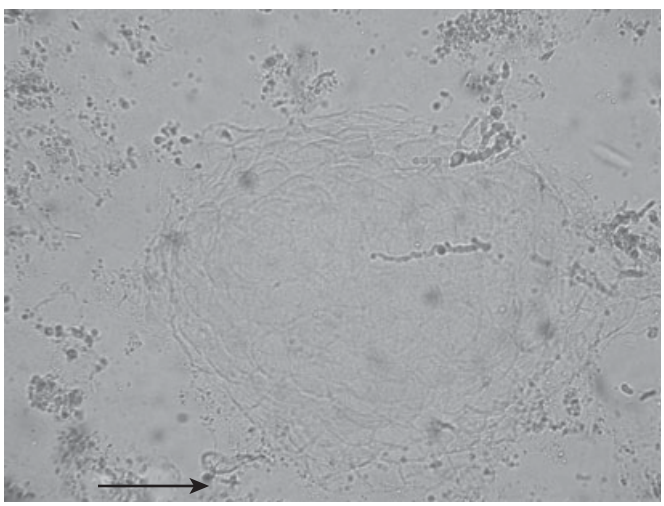

Figure 67–23 Septate hyphae seen by potassium hydroxide examination of scale from the patient in Figure 67–22. (See companion Expert Consult web site for color version.)

Tinea nigra has been treated successfully with keratolytic ointments or solutions, which include salicylic acid and benzoic acid and azole and allylamine creams.[28,95,96] Scraping the lesion with a scalpel also can remove the discoloration.[96]

TRICHOSPORONOSIS

Trichosporon spp., which are found in soil, vegetation, animal feces, and stagnant or fresh water, have a worldwide distribution with a predilection for tropical climates. They also may colonize human skin and digestive, respiratory, and urinary tracts. In immunocompetent individuals, *Trichosporon* organisms produce superficial fungal infections of the hair shaft termed *white piedra* and, less commonly, are one of the causes of onychomycosis. Systemic disease, termed *trichosporonosis*, may develop in immunocompromised patients, particularly neutropenic patients with hematologic malignancies, and in premature, very-low-birth-weight infants with colonization of indwelling catheters.[68,101]

White piedra is described as soft white, tan, or reddish-green nodules encircling the hair shaft that may be associated with scalp hyperkeratosis, brittle hair, and alopecia. These concretions do not fluoresce under Wood lamp examination. Differential diagnosis includes tinea capitis, pediculosis, black piedra, monilethrix, trichomycosis axillaris or pubis, and trichorrhexis nodosa.[70,135] Skin manifestations of disseminated infection include desquamation and serous drainage, purpuric papules or nodules with central ulceration or necrosis, and white plaques.[101,109]

Fungal blood culture reveals germ tube–negative and urease-positive yeast. Potassium hydroxide mounts of affected hair show hyaline septate hyphae, pseudohyphae, rectangular arthroconidia, and spherical blastoconidia that circumscribe the hair shaft.[70,107,109] Culture on Sabouraud dextrose agar shows cream-colored colonies that become wrinkled in a few weeks.[69] Biopsy specimen of skin lesions shows perivascular inflammation with budding yeast cells.[99]

White piedra is a difficult disease to treat because of the high recurrence rate. Although the American Academy of Dermatology Guidelines Committee recommends shaving affected hair to eradicate white piedra,[39] cosmetic and social considerations render this approach an unfavorable option for most patients. Topical antifungal agents that have been tried with varying degrees of success include ciclopirox olamine, imidazoles, chlorhexidine solution, 2.5 percent sulfide shampoo, zinc pyrithione, Castellani paint, mercury bichloride solution, 5 percent sulfur ointment, 5 percent ammoniated mercury ointment, and amphotericin B lotion. Although topical treatments may clear hair shaft concretions, they are not as effective at preventing recurrence. Because of their ability to bind keratin and their excretion in sebum, oral antifungal agents such as itraconazole may achieve higher concentrations in hair follicles and lead to greater success in eliminating colonized *Trichosporon* organisms and preventing relapse.[69,70]

Disseminated trichosporonosis is associated with high morbidity and mortality rates. It has been treated with varying degrees of success using amphotericin B with or without 5-fluorocytosine and the newer azole drugs, such as voriconazole.[4,68]

DEEP FUNGAL INFECTIONS

ASPERGILLOSIS

Aspergillosis, an opportunistic fungal infection caused by *Aspergillus* spp., affects primarily immunocompromised hosts, such as premature infants and children undergoing chemotherapy for

Figure 67–24 Eschar overlying eroded skin on a child with invasive aspergillosis. (See companion Expert Consult web site for color version.)

leukemia. It is acquired most commonly by inhalation of spores into the respiratory tract, with subsequent hematogenous spread to other organ systems including the skin. Cutaneous manifestations of aspergillosis may represent disseminated disease or, less commonly, infection limited to the skin. Premature infants have been reported to develop primary cutaneous aspergillosis at sites of skin trauma caused by adhesive tape, monitor leads, or placement of an intravenous catheter. Lesions appear as erythematous papules, pustules, nodules, or plaques that progressively enlarge and develop necrosis with formation of eschar (Fig. 67–24).[3,14,99,101,119] Differential diagnosis includes ecthyma gangrenosum, cutaneous candidiasis, mucormycosis, vasculitis, and pyoderma gangrenosum.[99,101]

Culture and histopathologic examination, revealing granulomatous inflammation with branched septate hyphae, of the skin biopsy specimen confirms the diagnosis.[14,99,101,119] Treatment of cutaneous aspergillosis includes surgical débridement or excision and administration of systemic antifungals.[101,119] Although amphotericin B remains the drug of choice, itraconazole and newer azoles such as voriconazole and other antifungal agents, including lipid-associated amphotericin B preparations and echinocandins such as caspofungin, also seem to be effective in individuals who cannot tolerate or are refractory to amphotericin B.[44,77,98,111,114] Data regarding safety and efficacy of these alternative therapies in children are limited.

BLASTOMYCOSIS

Blastomyces dermatitidis, a dimorphic fungus that causes North American blastomycosis, is found in the soil in the midwestern United States near the Ohio and Mississippi River valleys and the Great Lakes region, Canada, Central and South America, and tropical areas of Asia and Africa. Human disease is acquired through inhalation of spores, causing lung disease, and, rarely, through direct inoculation into the skin, which may cause primary cutaneous blastomycosis. Infection of the skin usually is due to hematogenous spread from a primary pulmonary focus, however.[13,48,99,113,125,136]

Cutaneous lesions are seen more frequently on sun-exposed areas and may begin as papules or pustules that progressively enlarge; become verrucous or ulcerative; and develop elevated, crusted borders. The central regions may heal, leaving an atrophic, hypopigmented scar, whereas the advancing borders remain active. Subcutaneous nodules with surface pustules and abscess formation may be seen as well. Erythema nodosum has been described as a reactive skin manifestation of pulmonary blastomycosis.[13,48,99,113,136]

Biopsy specimens show noncaseating granulomas with giant cells and microabscesses, and potassium hydroxide smears of purulent material obtained from lesions or biopsy specimens may reveal broad-based budding yeast forms with thick cell walls. Culture on Sabouraud dextrose agar confirms the diagnosis.[13,48,99,113,136]

Amphotericin B is the recommended treatment for blastomycosis with central nervous system involvement and disease in immunocompromised individuals or individuals with severe, disseminated disease. For mild to moderate blastomycosis, itraconazole, sometimes after a course of amphotericin B, is preferred.[13,48,99,113,136] Research on the development of a vaccine against *B. dermatitidis* for immunocompromised individuals in endemic areas or individuals with high exposure is in progress.[34,133]

COCCIDIOIDOMYCOSIS

Coccidioides immitis is a dimorphic fungus endemic to the southwestern United States, Mexico, and Central and South America. Transmission occurs through inhalation of spores from the soil, and the primary site of infection usually is in the lung.[29,99,117] Shortly after the onset of symptoms, primary pulmonary disease may be associated with reactive skin lesions, which do not contain viable organisms. These findings include a generalized, erythematous exanthem, erythema multiforme, Sweet syndrome, or interstitial granulomatous dermatitis.[29,37,99]

Erythema nodosum may be seen 1 to 3 weeks after the onset of infection. The exanthem, which may last several weeks, varies from macular, papular, morbilliform, to urticarial. The exanthem and erythema multiforme lesions may be associated with involvement of the oral cavity, pruritus, target-like lesions, and desquamation of the palms. Sweet syndrome, or acute febrile neutrophilic dermatosis, is characterized by abrupt onset of fever; leukocytosis; and tender, erythematous, well-demarcated papules or plaques. These lesions result from dense, neutrophilic infiltration of the dermis and respond well to topical corticosteroids. Interstitial granulomatous dermatitis, which may persist for 2 months, is a reactive eruption of indurated papules, nodules, and plaques that are caused by interstitial dermal infiltration with macrophages, neutrophils, eosinophils, and leukocytoclastic debris. Erythema nodosum manifests as painful, erythematous, subcutaneous nodules usually found on the lower extremities.[37]

Coccidioidomycosis may spread hematogenously to the skin, a common site of disseminated disease, and produce abscesses, sinus tracts, and granulomatous verrucous nodules or plaques. In contrast to the reactive skin manifestations, these lesions show the characteristic organism under microscopic examination. In extremely rare cases, traumatic inoculation into the skin may result in primary cutaneous coccidioidomycosis characterized by painless, ulcerated, and indurated nodules or plaques associated with regional lymphadenitis. Affected lymph nodes also may ulcerate.[37,99]

Histopathologic examination of infected cerebrospinal fluid and pleural fluid, bronchoalveolar lavage, and biopsy specimens of skin lesions may reveal large spherules containing endospores. Spherules may be seen on culture as well, but specimens should be handled using appropriate safety precautions because the organism may convert to active form during growth on culture plates. Serum antibody titers may be helpful for confirming the disease.[29,37,99,117]

Because uncomplicated primary coccidioidomycosis is self-limited in most patients, administration of antifungal treatment is unnecessary. Individuals with severe or disseminated disease or individuals with risk factors such as immunosuppression should

receive treatment. Amphotericin B is the recommended treatment for severe or progressive disease; otherwise, oral azole antifungals, such as itraconazole and fluconazole, are used most often for initial therapy of nonmeningeal coccidioidomycosis.[29,37,82,99,117] Oral fluconazole with or without administration of intrathecal amphotericin B is recommended for central nervous system involvement.[29,82,117] Additionally, surgical excision of localized infection with or without administration of antifungal therapy may be considered. Immunocompromised patients and patients with meningeal disease may require lifelong suppressive antifungal therapy with an azole to prevent recurrence.[29,37,117] The development of a vaccine against coccidioidomycosis is in progress.[31]

CRYPTOCOCCOSIS

Cryptococcus neoformans, the causative species of cryptococcosis, is an encapsulated yeast found worldwide in soil, fruits, and avian stool. Cryptococcosis affects primarily immunocompromised adults, particularly patients with AIDS, but it also may be seen in children. Infection usually is acquired through inhalation but rarely may spread through direct inoculation. Cutaneous findings, which often mimic other skin diseases, such as molluscum contagiosum and Kaposi sarcoma, vary as papules, nodules, vesicles, purpuric plaques, cellulitis, ulcers, abscesses, and sinus tracts.[27,32,64,99]

Diagnosis of these polymorphic lesions as a manifestation of cryptococcosis is established by visualizing the characteristic encapsulated yeast cells in culture on Sabouraud dextrose agar and on histopathologic examination of a skin sample stained with methenamine silver, periodic acid–Schiff, or mucicarmine. Another diagnostic method includes identification of the organism on smears of infected material prepared with potassium hydroxide and India ink.[27,32,64,99] Although a few cases of isolated cutaneous cryptococcosis have been reported, involvement of the skin usually reflects disseminated disease. Patients whose skin lesions show *C. neoformans* should undergo further evaluation for systemic disease and for cell-mediated immunodeficiencies.[27,32]

Although studies in children are limited, current treatment recommendations for cryptococcosis include a 6- to 12-week course of oral fluconazole or itraconazole for mild to moderate disease in immunocompetent individuals and intravenous amphotericin B in combination with oral fluconazole or flucytosine for more severe disease.[32,64,82,99] Immunocompromised patients continue on lifelong maintenance antifungal therapy because of the high rate of recurrence.[32,82]

FUSARIOSIS

Fusarium spp. are ubiquitous saprophytic fungi that affect primarily immunocompromised hosts, particularly neutropenic patients with hematologic malignancies. Fusariosis may produce localized infection of the nails, cornea, or skin and disseminated disease through hematogenous spread. Rarely, skin disease may result from traumatic inoculation. Lesions are seen most often on the extremities and manifest as tender, erythematous macules or plaques that develop central necrosis, form an eschar, and may become hemorrhagic.[79,87,99,107]

Because the mortality rate of disseminated *Fusarium* infection in neutropenic patients is 80 percent,[79,107] promptly establishing the diagnosis through biopsy and culture is important. Culture of tissue specimens reveals sickle-shaped macroconidia. On microscopic examination, *Fusarium* spp. appear as branched, septate hyphae with a perivascular distribution. Fungal blood cultures also may aid in establishing the diagnosis.[79,87,99,107]

Prognosis of *Fusarium* infection is poor, and treatment options are limited. Combination antifungal therapy with amphotericin B lipid complex and voriconazole and recovery of neutrophil counts have been reported to have some success in resolving the disease.[72,79,87,107,114]

HISTOPLASMOSIS

Histoplasmosis is caused by the organism *Histoplasma capsulatum*, a dimorphic fungus endemic to the Americas, particularly the Ohio, Mississippi, Missouri, and St. Lawrence River valleys. Cases also have been reported in Africa and Asia. The disease is acquired through inhalation of spores in soil contaminated by bird and bat droppings, producing a primary lung infection.[1] Most cases in immunocompetent patients are localized pulmonary infections, producing an influenza-like illness with symptoms that resolve within a few weeks. Disease also may be produced by reactivation of a latent infection.[82] Patients at extremes of age and patients who are immunocompromised, especially patients with AIDS and low CD4 lymphocyte counts, are at risk for developing progressive, disseminated disease.[1,58,60,82,122]

Involvement of the skin, causing chancriform lesions associated with regional lymphadenopathy, rarely has been described as a consequence of direct inoculation. These lesions typically resolve spontaneously in several months. Acute or chronic pulmonary histoplasmosis may produce reactive skin changes, such as erythema nodosum, erythema multiforme, and exfoliative dermatitis. Cutaneous manifestations through hematogenous spread in disseminated histoplasmosis include papules, nodules, ulcerative, or granulomatous lesions often involving oral mucosa. These lesions may progress to thick, verrucous vegetations that cause obstruction of the affected regions.[71,99]

Differential diagnosis includes tuberculosis, *Pneumocystis carinii* pneumonia, and other fungal infections caused by dimorphic fungi.[99] Biopsy specimens of skin lesions show granulomatous inflammation with macrophages, histiocytes, and giant cells and round, narrow-necked, budding yeast cells within phagocytes. Culture of involved tissue, bone marrow, blood, or sputum specimens provides the definitive diagnosis, but *H. capsulatum* may take several weeks to months for growth on culture media to occur. *Histoplasma* antigen may be detected in urine samples of individuals with disseminated histoplasmosis; however, this test is inconsistent in patients with localized infections.[1,99,104,108]

Self-limited disease in immunocompetent individuals does not require treatment. Amphotericin B remains the drug of choice for severe, disseminated histoplasmosis, whereas azole drugs can be effective for treating less advanced disease.[1,130] Itraconazole also is used for lifelong suppressive therapy in immunocompromised patients.[60,82]

MUCORMYCOSIS

Mucormycosis is an opportunistic fungal infection that affects primarily immunosuppressed hosts. Common risk factors include prematurity, diabetes mellitus, malignancies, neutropenia, burns, or malnutrition. Transmission may result from inhalation of spores or, in the case of primary skin disease, from direct inoculation through contaminated occlusive dressings or at sites of invasive procedures, trauma, or burns. Cutaneous manifestations may occur alone or in conjunction with disseminated disease. Mucormycosis has a tendency to invade vascular tissues, leading to inflammation, thrombosis, necrosis, and septic emboli. Infection may spread hematogenously to the skin, causing cellulitis with erythematous papules and pustules that progressively enlarge and develop necrosis with formation of eschar (Fig. 67–25).[89,99,101,132]

Differential diagnosis includes pyoderma gangrenosum, bacterial cellulitis, and necrotizing fasciitis. Tissue biopsy examina-

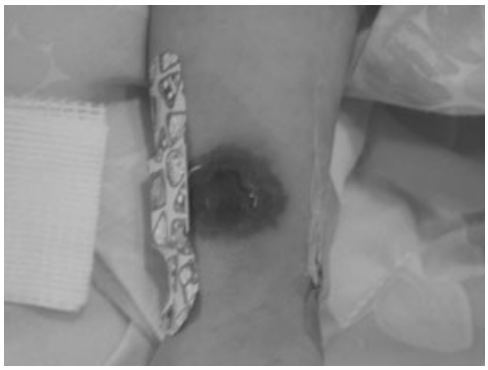

Figure 67–25 Purpura and ulceration in a patient with mucormycosis. (See companion Expert Consult web site for color version.)

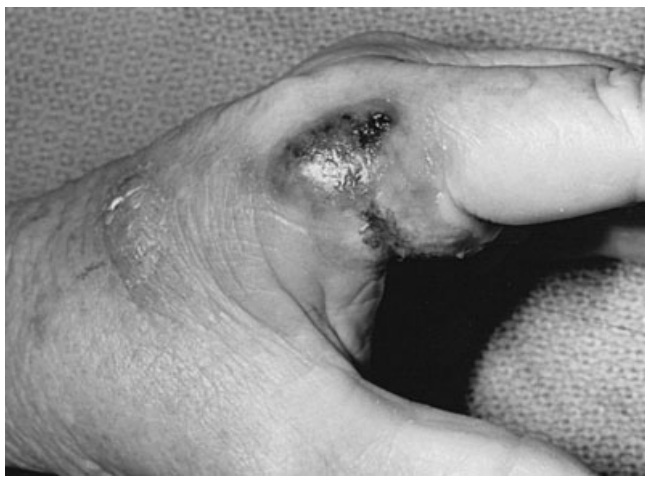

Figure 67–26 Two erythematous nodules on the dorsum of the left hand of a patient with sporotrichosis.

tion of mucormycosis lesions shows characteristic nonseptate hyphae with right angle branches, vascular invasion, necrosis, and inflammatory infiltrate. Administration of intravenous amphotericin B in addition to surgical débridement and wide excision of the skin disease is the recommended treatment.[89,99,101,132]

SPOROTRICHOSIS

Sporothrix schenckii, the organism responsible for sporotrichosis, is found in soil and plants worldwide with a predilection for tropical climates. Sporotrichosis usually is transmitted through inoculation at sites of trauma; however, pulmonary disease may be acquired through inhalation of spores. Infection with *S. schenckii* may produce four forms of disease, with lymphocutaneous being the most common and fixed cutaneous, disseminated skin, and extracutaneous disease being less common.[33,61,83,99,131] Children and individuals with prior exposure to the fungus may present more often with localized skin manifestations.[18] Characteristic lesions include erythematous papules, nodules, and scaly, verrucous plaques that progressively enlarge and ulcerate (Fig. 67–26). Regional lymphadenopathy and spread along the lymphatic drainage may soon follow. Scarring is a common occurrence. Although bone and joints are the most frequent sites of extracutaneous infection, hematogenous spread to almost every other organ system has been described. Disseminated disease should raise the suspicion of immunodeficiency in the affected individual.[33,61,83,99,131]

Definitive diagnosis is made by culture of wound material on Sabouraud agar. Itraconazole is the drug of choice for treating skin disease, whereas intravenous amphotericin B is the recommended treatment for severe, disseminated disease. Saturated solution of potassium iodide at 1 to 2 drops per the child's year of age administered three times daily also has been used as an effective treatment for uncomplicated cutaneous sporotrichosis in pediatric patients.[18,67]

SECTION XI

Ocular Infections

CHAPTER 68

Ocular Infectious Diseases

Kimberly G. Yen ✪ Madhuri C. Chilakapati ✪ David K. Coats ✪
Aaron M. Miller ✪ Evelyn A. Paysse ✪ Paul G. Steinkuller

The eye may be affected by a wide spectrum of infections and infestations manifested as primary disease or as part of a larger systemic process. Many infections are vision-threatening, whereas others have important implications affecting the generalized disease process. Findings in the eye, for example, can aid in narrowing the differential diagnosis in some cases of systemic disease, such as congenital viral infections. A helpful approach to delineating the ophthalmic manifestations of infectious diseases is to use an anatomic scheme that considers the primary site of involvement. This chapter proceeds systematically from infections involving the eyelids and ocular surface to those involving intraocular structures and concludes with a discussion of infections involving deeper tissues in the orbit. Some overlap and duplication are unavoidable because disease involvement that truly is isolated to a single anatomic component of the eye or orbit is an unusual occurrence. Most infectious processes involving the eye can be diagnosed accurately with a careful history and detailed ophthalmic examination. Simple tools such as a penlight and a direct ophthalmoscope facilitate establishing a diagnosis in many instances. In some cases, however, special ophthalmologic testing such as slit-lamp examination, indirect ophthalmoscopy, ocular ultrasound, and even biopsy or culture (or both) is required.

INFECTIONS OF THE EYELIDS

Despite being only 2 mm thick, the anatomy of the eyelids is complex and elegant. The eyelids are composed of dense connective tissue, hair follicles, sweat and sebaceous glands, smooth and striated muscles, sensory and motor nerves, and vascular elements. The skin covering the eyelids is the thinnest of the entire body. The internal surface of the eyelid, the part adjacent to the eye, is covered by the palpebral conjunctiva. Bulbar conjunctiva covers the surface of the globe itself. Sebaceous glands, known as the glands of Zeis, are associated with hair follicles. Meibomian glands, located within the tarsal plates of the eyelids, also are sebaceous and drain at the posterior aspect of the lid margin.

Infection of the eyelids may be generalized or focal. Involvement of the skin by an infectious agent is referred to as *dermatoblepharitis*. *Staphylococcus aureus* and *Staphylococcus epidermidis* infections predominate. The exception is angular blepharitis, characterized by inflammation in the lateral canthal region, which frequently is caused by *Moraxella* spp. Impetigo or erysipelas of the eyelids may be caused by *Streptococcus pyogenes*. A variety of infestations, including *Demodex folliculorum*, *Sarcoptes scabiei* (scabies), *Pediculus capitis*, and the pubic louse *Phthirus pubis*, may involve the eyelids.

Though more commonly found in adults, infection of the lid margin does occur in children. Infections of the anterior lid margin most frequently encountered include bacterial blepharitis, molluscum contagiosum, and parasitic diseases. Infections of the posterior lid margin include those associated with chronic meibomian gland dysfunction. Herpes simplex virus (HSV) and herpes zoster virus may involve the lid and lid margin and are discussed elsewhere in this chapter.

ANTERIOR EYELID INFECTION

Staphylococcal Blepharitis

Staphylococcal eyelid infection may be an acute or chronic condition. Typically, the chronic form of the disease is manifested as crusting of the lid margins, especially on awakening. Thickening of the lid margin, seen most easily on slit-lamp examination, is a frequent manifestation. Mild, chronic conjunctival infection often occurs as a spillover phenomenon caused by local reaction to materials secreted by the infecting organism. A child with staphylococcal blepharitis may be completely asymptomatic or may complain of ocular discomfort, burning, a foreign body sensation, or any combination of these symptoms. Lid hygiene usually is all that is required to treat the condition and can be accomplished through eyelid scrubs, with attention given to the lid margin. Tap water can be used, or in refractory cases, the eyelids and lid margins can be cleansed once or twice daily with a 50:50 mixture of baby shampoo and warm water. This mixture is applied gently with a clean washcloth. Lid hygiene is effective in decreasing the concentration of local bacterial flora and reducing or eliminating symptoms from chronic staphylococcal infection. A 2- to 4-week course of erythromycin or bacitracin ophthalmic ointment applied twice daily may hasten resolution and reduce exacerbation and recurrence. Because ophthalmologic ointments can produce temporary blurred vision, they often are used only at night before sleeping.

Molluscum Contagiosum Infection

Molluscum contagiosum is caused by a member of the family *Poxviridae*. Infection of the eyelid may be unilateral or bilateral. Infection may be transmitted by skin-to-skin contact, through fomites, or by auto-inoculation. Widespread development of lesions can occur as a result of auto-inoculation. Epidemics in people who live in closed communities have been reported.[160] Eyelid manifestations typically include an isolated nodule or nodules with mild surrounding inflammation (Fig. 68–1). The nodules vary in size but generally are 1 to 3 mm in diameter. Older lesions frequently become umbilicated and develop a white or waxy-appearing core. Mild conjunctival injection frequently accompanies lesions on or near the margin of the eyelid. The associated conjunctivitis occasionally can be severe and chronic. In chronic cases, corneal epithelial disease may develop.

Molluscum infection is considered to be self-limited, with most lesions resolving spontaneously within a few months.

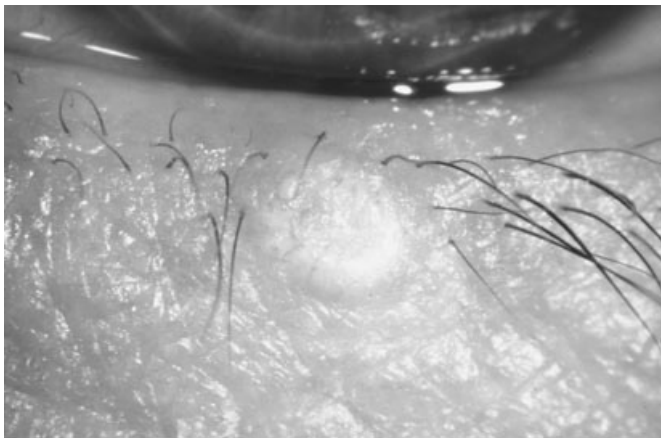

Figure 68–1 *Molluscum contagiosum* typically is manifested as an isolated nodule or nodules approximately 1 to 3 mm in diameter. Older lesions often become umbilicated and develop a white or waxy-appearing core. (See companion Expert Consult web site for color version.)

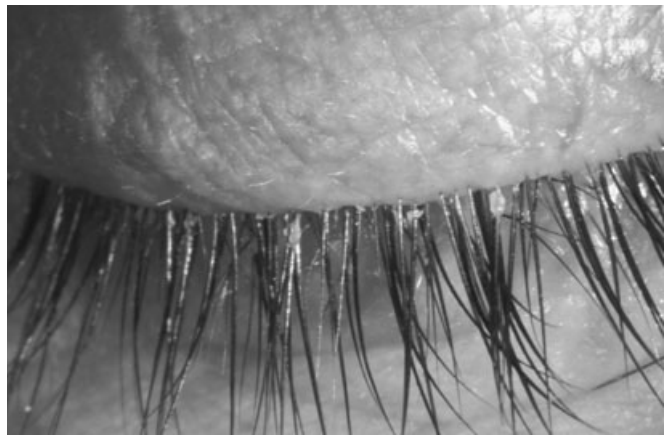

Figure 68–2 Slit-lamp photo of *Phthirus pubis* infestation demonstrating adult lice firmly adherent to the eyelashes and egg cases (i.e., nits) attached to the proximal ends of the hair shafts. (See companion Expert Consult web site for color version.)

However, the infection can be recalcitrant and problematic, especially in immunocompromised patients.[226,234] The presence of recalcitrant or atypical molluscum contagiosum lesions involving the eye have been reported in patients infected with human immunodeficiency virus (HIV).[144,188] Despite the self-limited nature of the disease in immunocompetent individuals, treatment often is advocated to prevent auto-inoculation, which may prolong the course of the disease. Treatment also may be offered to provide symptomatic relief. Mechanical treatments such as cryotherapy, expression or curettage of the central core, excision, and cautery have been effective.[46] Medical treatments that have been effective against molluscum infection remote from the eye include 1 percent imiquimod cream[202] and podophyllotoxin.[203] These agents are not recommended for the treatment of periocular lesions, however, because of the possibility of injury to the eye.

PARASITIC EYELID DISEASE

Phthirus pubis Infestation

The crab louse *Phthirus pubis* is a tiny insect well adapted to living in coarse, widely spaced hair. Infestation most commonly involves pubic, axillary, and body hair. The organism is transmitted by direct person-to-person contact and possibly by fomites.[192] Infestation of the eyelid often is a marker for sexually transmitted diseases, especially in adult patients.[192] Affected patients typically have unilateral, chronic blepharoconjunctivitis, but some patients may be asymptomatic. Although unmagnified ocular examination may reveal signs of the disease, diagnosis is facilitated by slit-lamp examination, which offers a magnified view of the eyelid margins and eyelashes (Fig. 68–2). Slit-lamp examination reveals adult lice firmly adherent to the eyelashes and egg cases (i.e., nits) attached to the proximal ends of the hair shafts. Reddish brown flecks of louse excreta frequently are found at the base of the lashes.[44]

Treatment can be facilitated by simple mechanical removal of the lice and associated nits under magnification offered by the slit lamp or other devices. Medical treatment often is preferred for young children because of their inability to tolerate mechanical removal. The organisms can be smothered by the application of a bland ointment such as petrolatum jelly applied four times each day to the eyelids. Physostigmine ointment administered twice a day frequently is used by ophthalmologists to treat eye lesions.[44] The agent inhibits nerve transmission in the insect and thus is directly toxic to the insect. It should be used with caution in infants and small children. If physostigmine comes into contact with the eye, it has several significant side effects, the most bothersome of which is stimulation of accommodation, which can produce blurred vision that may last for several hours. Medical treatment should be continued for as long as 2 weeks to ensure eradication of lice that emerge from nits during the normal life cycle of the organism.[44]

Patients also should undergo a general physical examination to assess for involvement of other body regions. Lindane shampoo scrubs of the scalp, pubic hair, and body are recommended if infestation is found in these areas. Clothing and bed linen should be laundered, and family members should be examined and treated as necessary. Follow-up at 4 to 6 weeks after treatment is recommended to detect re-infestation.

Demodex Infection

Demodex folliculorum and *Demodex brevis* are mites that frequently infest hair follicles in humans, including the hair follicles of the eyelids.[70] The organisms historically have been considered nonpathogenic parasites,[118] although they have been postulated to cause increased hordeola formation as a result of obstruction of sebaceous glands in the eyelids. *Demodex* is found commonly in patients with rosacea, although a causal relationship is difficult to establish.[172] Rosacea-like eruptions also have been attributed to *Demodex*, and one pathologic report demonstrated a granulomatous dermal inflammation associated with *Demodex* infection.[164] *Demodex* is found more commonly on eyelashes with cylindrical dandruff (Fig. 68–3).[80] Treatment with topical pilocarpine gel was shown in one study to alleviate the ocular itching associated with *Demodex* infection.[79] Because of the frequency of infestation and the paucity of definitive disease caused by the organism, treatment often is considered unnecessary.

POSTERIOR EYELID INFECTION

Hordeolum

A hordeolum (i.e., stye) is an infection of the sebaceous glands in the eyelids. When the glands of Zeis are involved, the term *external hordeolum* is used. The lesion typically points to the skin surface. When the meibomian glands are involved, the term *internal hordeolum* is used. An internal hordeolum may point toward the skin or toward the palpebral conjunctiva. *S. aureus*

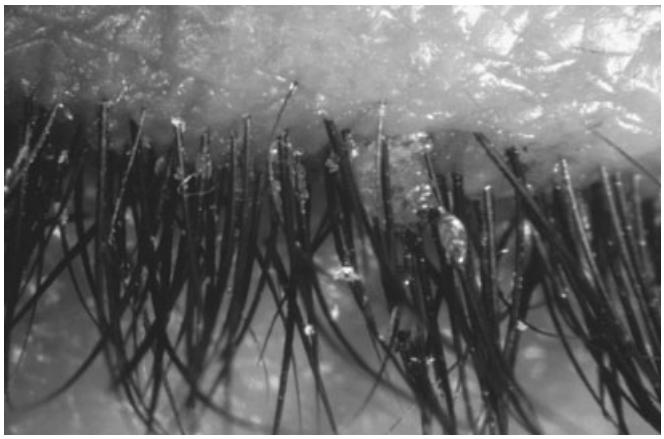

Figure 68–3 *Demodex folliculorum* and *Demodex brevis* are mites that can infect the hair follicles of the eyelids and are found more commonly on eyelashes with cylindrical dandruff. (See companion Expert Consult web site for color version.)

is the most common causal agent of internal and external hordeola.

Patients with disease of the lid margin, such as those with chronic blepharitis, seborrhea, or rosacea, are prone to recurrent hordeola, especially during the first decade of life. Hordeola are manifested as erythematous, elevated, tender nodules. Nodules typically are 5 to 10 mm in diameter and usually solitary, although they may be multiple or bilateral. Patients with a history of recurrent hordeola may have them in various stages of evolution or resolution.

The lesions usually are self-limited and typically resolve within 5 to 7 days with spontaneous drainage of the abscess. Warm compresses may hasten resolution and improve comfort. Parents should be advised to place a clean washcloth soaked in warm tap water on the involved eyelid for 10 to 15 minutes several times each day. Parents should be advised to ensure that the water is not hot enough to result in a burn. For significant coexisting blepharitis, a topical antibiotic such as erythromycin ointment may prove useful by reducing the normal bacterial skin flora of the eyelid and decreasing the risk of recurrence. Systemic antibiotics rarely are indicated for acute hordeola. Children with frequent recurrences, however, may benefit from a short course of systemic antibiotics such as erythromycin (younger than 12 years) or tetracycline (older than 12 years). These agents further decrease the bacterial flora on the eyelid and may reduce the risk of recurrence even more. Lid hygiene efforts, as described for the treatment of staphylococcal blepharitis, should be instituted and maintained for children with recurrent hordeola. Surgical drainage of a hordeolum usually is unnecessary.

Chalazion

Cytologically, a chalazion may represent either a mixed-cell granulomatous inflammation or a suppurating granuloma.[57] The lesion occurs in a meibomian gland as a result of a foreign body reaction to secretions produced by the gland that have been extruded into surrounding tissue. A chalazion may develop after resolution of an internal hordeolum, in which case it is preceded by an acute stage, or it may develop primarily, without a preceding acute inflammatory phase. A typical chalazion appears as a round, nontender nodule within the substance of the eyelid. Multiple and bilateral chalazia may occur in susceptible patients. Recurrent lesions are not uncommon findings. They are typically 2 to 10 mm in diameter.

Spontaneous resolution of smaller chalazia can be anticipated after a period of observation without treatment, sometimes as long as several months. Larger lesions, particularly those greater than 10 mm in diameter, frequently do not resolve without specific treatment. In patients with an acute or chronic inflammatory component, application of warm compresses may be beneficial. Surgical intervention may be warranted to treat medium to large chalazia that are cosmetically objectionable, produce astigmatism by pressing on the cornea, result in mechanical ptosis, or cause other symptoms. The most common surgical treatment offered is incision and curettage through an internal incision on the palpebral conjunctival surface. Surgery is highly effective. It can be performed in the office, but general anesthesia is required for most young children. Because of the need for general anesthesia, we typically recommend deferring surgical treatment until several months has elapsed without spontaneous resolution. Earlier intervention may be recommended if the chalazion is particularly large, if pigmentary changes have developed in the overlying skin, or if astigmatism or ptosis is present in a young child at risk for the development of amblyopia.

Chalazia can be treated by intralesional steroid injection, surgical incision,[58] or both.[72] Dhaliwal and Bhatia[58] reported that incision plus curettage was the procedure of choice for lesions that have been present for 8.5 months or longer and for lesions 11.4 mm or larger in size, based on the results of a prospective study. The major potential drawback of intralesional steroid injection is the risk of complications developing with an otherwise relatively benign condition. Rarely, steroid injection can result in sterile abscess formation or eyelid necrosis. Intralesional injections are done best with a chalazion clamp in place to protect the underlying globe from accidental needle trauma during injection. This device places a metal plate between the chalazion and the eye.

DACRYOADENITIS

Dacryoadenitis is an uncommon ophthalmic condition. Even in a busy ophthalmology practice, dacryoadenitis was diagnosed in approximately 1 in every 10,000 patient visits.[176] The clinical manifestation is variable. Localized tenderness and swelling of the temporal aspect of the upper eyelid usually occur and often produce an S-shaped deformity of the lid margin. Pain is frequently a predominant feature. Associated signs and symptoms include fever, follicular conjunctivitis, mucopurulent discharge, limited extraocular movement, and proptosis.[176] Keratoconjunctivitis sicca has been reported as a consequence of Epstein-Barr virus (EBV)-associated dacryoadenitis in a child.[139]

Before the era of widespread immunization, mumps was a leading cause of dacryoadenitis. Bacteria such as staphylococci, streptococci, and gonococci also have been implicated. Exceedingly rare organisms such as *Brucella* are involved occasionally in bacterial cases.[13] EBV has been implicated as the etiologic agent in a large proportion of nonsuppurative cases. Marked regional lymphadenopathy may be a distinguishing feature of EBV dacryoadenitis.[176]

Appropriate laboratory evaluation includes Gram stain and culture of mucopurulent discharge from the eye. Neuroimaging is indicated when the patient has severe inflammation, proptosis, limitation of extraocular movement, or other orbital signs to rule out a more generalized orbital process. The condition easily can be confused clinically with orbital cellulitis when signs and symptoms are severe. Biopsy of the lacrimal gland may be required to confirm the diagnosis in patients not responding to standard medical treatment or when atypical features are identified on clinical examination or radiographic studies. Blood cultures are indicated for patients with signs of systemic toxicity.

Intravenous nafcillin or vancomycin is a reasonable initial antibiotic choice for severe dacryoadenitis caused by gram-positive organisms. Oral anti-staphylococcal agents may be used

for less severe cases. For gram-negative cases, ceftazidime or other similar agents should be considered. For suppurative cases without Gram-stain guidance, intravenous nafcillin or vancomycin should be considered as initial therapy for severe cases and oral anti-staphylococcal agents for less acute cases.

Therapy in the form of warm compresses and oral analgesics is indicated for nonsuppurative dacryoadenitis. Serum testing for evidence of EBV infection should be considered in patients with regional lymphadenopathy.[176] Noninfectious causes of dacryoadenitis include sarcoidosis, Sjögren syndrome, leukemia, lymphoma, eosinophilic granuloma, and orbital pseudotumor. Noninfectious cases of dacryoadenitis sometimes can be difficult to distinguish from infectious cases. Lacrimal gland biopsy and neuroimaging usually are necessary to establish a diagnosis in noninfectious cases.[129] Intralesional steroid injection has been shown to be effective in the management of acute idiopathic dacryoadenitis; it results in marked improvement of symptoms within 7 days of treatment in most cases.[145]

DACRYOCYSTITIS

Dacryocystitis may result from congenital or acquired lacrimal outflow obstruction. Simple membranous nasolacrimal duct obstruction occurs in as many as 6 percent of the newborn population, and intermittent, mild, self-limited bacterial infection is a commonly associated feature. More severe infection of the lacrimal sac results in dacryocystitis. This condition is manifested as acute erythema, pain, and swelling in the medial canthal region. The swelling typically is located below the medial canthal tendon. Marked epiphora generally is present, and a mucopurulent discharge frequently can be expressed through the lacrimal punctum if the proximal aspect of the lacrimal drainage system is not obstructed. If the infection has resulted in or from obstruction proximal and distal to the lacrimal sac, the overlying skin may become tense as the nasolacrimal sac distends in response to the infectious process. Formation of a fistula to the overlying skin may occur as a result of dacryocystitis, and surgical excision of the fistula tract often is needed after the acute process has resolved. Dacryocystitis is a particularly common finding in neonates with a dacryocele, with dacryocystitis developing in as many as 60 percent of affected neonates.[163]

Aerobic and anaerobic bacteria and fungi may produce dacryocystitis.[29,30] In one study, *S. epidermidis* and *Pseudomonas* spp. were the aerobic organisms identified most frequently, and *Peptostreptococcus* spp. and *Propionibacterium* spp. were the anaerobes isolated most frequently. Less common agents include *Escherichia coli*, *Pseudomonas* spp., *Haemophilus influenzae*, *Pasteurella multocida*, and various anaerobes. Laboratory investigation should include aerobic and anaerobic culture of mucopurulent discharge from the lacrimal sac. Mild massage of the lacrimal sac may be used to facilitate expression of material for Gram stain and culture. A sepsis work-up should be considered for children who are acutely ill and for young infants.

Intravenous nafcillin, vancomycin, or both are good initial therapeutic choices for serious gram-positive infections. Mild cases in older children can be treated with oral antibiotics. Intravenous ceftazidime is a reasonable initial antibiotic choice for gram-negative dacryocystitis. Oral ciprofloxacin is useful for less severe cases in adult patients, although the drug is not approved for use in children. Intravenous nafcillin or vancomycin typically provides good initial empiric therapy in patients when Gram stain guidance is not available.

Ophthalmologic consultation should be requested in all cases of acute dacryocystitis. Decompression of the lacrimal sac by aspiration, incision and drainage, or probing the proximal lacrimal drainage system may be needed to hasten resolution. Probing of the distal lacrimal system often is deferred until the acute infection has subsided, although probing during the acute infection has been reported to be a safe and effective adjunct to treatment.[167] Mucopurulent material obtained during surgical decompression should be sent for appropriate culture.

PRESEPTAL (PERIORBITAL) CELLULITIS

The term *preseptal cellulitis* refers to an infectious process in the eyelids that is isolated to regions anterior to the orbital septum. The orbital septum is a thin layer of fascia that extends vertically from the periosteum of the orbital rim to the tarsal plate within the eyelids. Though penetrated by nerves and vascular structures, the septum provides a barrier that slows the spread of infectious agents into deeper orbital and retro-orbital structures.[198] Typical signs and symptoms of preseptal cellulitis include erythema and edema of the eyelids. Distinctively absent are signs of deeper orbital involvement such as restricted ocular motility, pain with eye movement, and proptosis. Preseptal cellulitis may occur after trauma or be caused by spread of infection from adjacent structures, such as skin and the upper respiratory system.[224]

Post-traumatic Preseptal Cellulitis

Post-traumatic preseptal cellulitis occurs after puncture wounds on the lids, face, or scalp. It also may occur after blunt trauma with no obvious entry wound. The etiologic agents most commonly identified are *S. aureus* and *S. pyogenes*, and polymicrobial infections can occur. Other bacterial causes include non–spore-forming anaerobes such as *Peptococcus*, *Peptostreptococcus*, and *Bacteroides*. Infection by aerobic gram-negative bacilli is an uncommon finding.[10] *P. multocida* is a common organism that produces post-traumatic preseptal cellulitis after dog and cat bites.[124,127] Cellulitis secondary to methicillin-resistant *S. aureus* (MRSA) is a common cause of community-acquired cellulitis in some locations.

Clinical signs and symptoms are determined in large part by the severity of the injury, the interval since injury, and the infecting organisms. The involved lids are edematous, erythematous, and typically quite tender. Fluctuation of subcutaneous tissue may be seen if an abscess has developed. Swelling of the uninvolved contralateral eyelids may occur as a result of lymphedema. As with any form of isolated preseptal cellulitis, vision is unaffected, and proptosis and eye movement disturbances are absent. On rare occasion, eyelid edema may be sufficiently severe to preclude adequate evaluation of the eye. Neuroimaging is required in such cases to assess the globe and rule out involvement of structures posterior to the orbital septum. Ophthalmologic consultation is critical in cases of severe post-traumatic preseptal cellulitis because of the potential for concurrent globe injury.

Laboratory analysis includes Gram stain and aerobic and anaerobic culture of mucopurulent material to aid in therapeutic decisions. Amoxicillin-clavulanate or a related agent is the drug of choice for treating post-traumatic cellulitis caused by a dog bite because of the high prevalence of *P. multocida*. Tetanus prophylaxis should be guided by standard recommendations. Surgical drainage of large abscesses may be required if a rapid response to antimicrobial therapy does not occur.

Nontraumatic Preseptal Cellulitis

The clinical features of nonsuppurative, nontraumatic preseptal cellulitis depend to a large degree on the causative agent. Erythema and swelling of the involved eyelids are typical and often are accompanied by pain. Signs of orbital infection, such as altered vision, proptosis, and eye movement abnormalities, are absent.

Before the advent of *H. influenzae* type b (Hib) vaccine, this organismly frequently was a cause of nonsuppurative preseptal cellulitis in children. Hib is seen infrequently as a cause of preseptal cellulitis today.[62] It was a particularly dangerous agent because of a high risk of spread to the central nervous system (CNS), which occurred in as many as 2 to 3 percent of patients. Though rare today, Hib infections still may be encountered. Like many infecting organisms, Hib gains access to subcutaneous tissue through infected nasal passages.

Streptococcus pneumoniae is now the most common bacterial cause of preseptal cellulitis in the pediatric age group.[62] It occurs in association with upper respiratory tract infection, although constitutional symptoms usually are less pronounced than those associated with Hib infection. A variety of other bacterial agents may cause preseptal cellulitis, but they are seen less commonly. Preseptal cellulitis occasionally has been reported to be due to a variety of other organisms, including *Trichophyton* (ringworm),[218] tuberculosis,[170] and anthrax.[35]

Adenovirus is another particularly common cause of preseptal cellulitis in children. Adenovirus is an important consideration in the differential diagnosis of childhood preseptal cellulitis because, despite being self-limited, the condition can occasionally mimic bacterial infection and prompt unnecessary treatment with antibiotics. Adenovirus can be recognized by its characteristic copious discharge, which may be serous. Swelling of the lid may be prominent, but erythema usually is minimal. Preauricular lymphadenopathy often occurs in older children, and marked conjunctival hyperemia with or without chemosis and subconjunctival hemorrhage may be present. Photophobia also may be noticed in cases of concurrent punctate keratopathy. A history of recent contact with other infected individuals frequently is noted and should be sought. Care should be taken to avoid spreading infection to family members, medical personnel, and others.

Hospital admission should be considered for children younger than 1 year of age with bacterial preseptal cellulitis. Hospitalization also is important for children with signs of systemic toxicity and those with inadequate *H. influenzae* immunization. A sepsis work-up is indicated for children with signs of systemic toxicity and for extremely young children. Ophthalmologic consultation is recommended if orbital involvement is suspected or if clinical examination is inconclusive. Computed tomography (CT) usually is unnecessary for isolated preseptal cellulitis. Cultures of blood obtained from patients with preseptal cellulitis generally are negative but are more likely to be positive in children younger than 2 years. Culture of conjunctival discharge is done often but rarely has significant diagnostic benefit.

A severity index for scoring preseptal cellulitis in children has been reported to help guide treatment decisions.[221] Antibacterial treatment should include intravenous agents for infants and those with signs of serious systemic infection. Intravenous cefuroxime or a combination of nafcillin plus cefotaxime or ceftriaxone frequently is recommended for empiric therapy. Outpatient treatment with intramuscular or oral antibiotics is reasonable for older, less acutely ill children. Intracranial infection has been associated with preseptal cellulitis in pediatric patients. Intracranial involvement should be suspected in any patient 7 years or older with preseptal or orbital cellulitis associated with an orbital subperiosteal abscess, Pott puffy tumor, concurrent sinusitis, complaints of headache, and persistent fever despite intravenous antibiotics.[175]

Systemic antibiotics should be continued for 7 to 10 days. Patients in whom intravenous antibiotics are started initially can switch to an oral antibiotic after they have been afebrile for at least 24 hours and otherwise have improved clinically, unless the possibility of development of sepsis or meningitis remains a concern.

ORBITAL CELLULITIS

Bacterial infection of orbital structures posterior to the orbital septum is the most frequent cause of acute orbital inflammation. Orbital cellulitis occurs more commonly in children and more frequently during cold weather, when sinusitis is more prevalent.

Initial signs and symptoms can vary from mild inflammation to severe and fulminant orbital disease. Cardinal signs and symptoms of infectious orbital cellulitis include proptosis, limited eye movement (including total ophthalmoplegia), pain with eye movement, and an abnormal pupillary response. Decreased vision or even blindness can occur as the most serious ophthalmic complication.[183] Death can result from intracranial extension of the infection if appropriate treatment is not initiated. Elevated intraocular pressure and chemosis of the conjunctiva are common ancillary signs. Preseptal cellulitis often coexists with orbital cellulitis but is not a prerequisite.

Most cases of orbital cellulitis are caused by spread of infection from an adjacent infected sinus.[40,151] Ethmoid sinusitis is the most common predisposing factor. Rare cases are due to penetrating orbital trauma or skin infection involving the face, with spread of organisms into the orbit. Orbital cellulitis may occur infrequently after orbital, ocular, or periocular surgery.[161,230] Orbital cellulitis and cavernous sinus thrombosis have been reported to occur after dental infections and dental surgery.[32]

Comprehensive evaluation of a patient with confirmed or suspected orbital cellulitis includes ophthalmologic and systemic examination. Assessment of visual acuity in both eyes is important for excluding vision loss and establishing a baseline to aid in monitoring progression of the disease or the effects of therapy. Evaluation of optic nerve dysfunction by examining the pupils for an afferent pupillary defect (APD) is important before pupillary dilation is performed to assess the retina. Careful evaluation of extraocular movement should be performed in all extreme positions of gaze to identify restriction of ocular duction and elicit pain on eye movement. The presence or absence of proptosis can be assessed clinically by viewing the eyes from above (bird's-eye view) or below (worm's-eye view) and by comparing their relative positions within the orbits. In severe cases of orbital cellulitis, funduscopic examination may reveal dilation of the retinal venules and signs of compressive optic neuropathy such as optic disk edema. Central retinal artery occlusion has been reported occasionally.[112] Systemic evaluation includes determination of temperature, which usually is in the range of 39° C to 40° C (102° F to 104° F). Sinus examination, a screening neurologic examination, and evaluation for signs and symptoms of sepsis and meningitis should be performed.

In any case of clinically definite or suspected orbital cellulitis, CT of the orbit and brain is indicated. CT can establish or confirm the diagnosis of orbital cellulitis and provides critical information needed to manage the patient. Imaging of the brain is important because orbital cellulitis can evolve into a brain abscess, meningitis, or cavernous sinus thrombosis. However, when a clinical response to treatment is noted, improvement in CT findings frequently is delayed. Therefore, recurrent CT scanning of a child with clinically improving findings is not indicated absolutely unless new signs or symptoms of concern develop.

Microbiologic studies often are acutely unhelpful for the routine patient with orbital cellulitis. Nonetheless, baseline studies remain important because critical information sometimes is acquired. Blood cultures should be obtained at a minimum, and a lumbar puncture with culture of cerebrospinal fluid (CSF) should be considered in infants and those with signs of CNS infection. Culture of the ocular, nasal, and nasopharyngeal mucous membranes is of limited value and can be omitted. However, if surgical drainage is performed, cultures of any material removed should be obtained.

Optimal management of a child with orbital cellulitis requires a multidisciplinary approach. In addition to evaluation and management by an experienced pediatrician, ophthalmologic and otolaryngologic consultation should be obtained. Neurosurgical consultation is required when involvement of the CNS is diagnosed or suspected. In atypical cases and those not responding to treatment, consultation with an infectious disease specialist is warranted.

The most common offending etiologic bacteria are *S. aureus*, *Streptococcus* spp., and *Haemophilus* spp. (other than *H. influenzae*). *S. pneumoniae* also is implicated frequently, and a variety of less common organisms have been reported. *H. influenzae* orbital cellulitis rarely has occurred since widespread use of the Hib vaccine was implemented.[3,62] Fungal infection of the orbit occasionally is encountered, typically in immunocompromised individuals.[137]

The differential diagnosis of orbital inflammation in children includes a broad range of noninfectious conditions, including cavernous sinus thrombosis, idiopathic inflammatory orbital pseudotumor, Wegener granulomatosis, sarcoidosis, leukemic infiltration, lymphoma, rhabdomyosarcoma, necrotic retinoblastoma, metastatic carcinoma, and histiocytosis X. Thyroid ophthalmopathy also can be manifested as an acute orbital inflammatory process, although usually its onset is slow and insidious.

Treatment of all patients with orbital cellulitis requires hospitalization and initiation of intravenous antibiotics as soon as possible after material has been obtained for culture. Infection with penicillin-resistant organisms is an increasingly common occurrence and must be considered during treatment.[37,181] Appropriate initial antibiotic therapy may include nafcillin, metronidazole, and cefotaxime as combination therapy. Given the increasing incidence of MRSA, initial treatment with vancomycin or clindamycin should be considered.[148,181] Other antimicrobial agents may be useful, and local susceptibility patterns should guide the choice of initial antimicrobial therapy. Antibiotic coverage should be modified according to the clinical course and culture results. If the patient fails to respond to antibiotic treatment within 24 to 48 hours, consultation with an infectious disease specialist and a repeat CT scan to look for the development of an orbital abscess should be considered (Fig. 68–4). The mean hospital stay for uncomplicated cases of orbital cellulitis is 10 to 14 days, and oral antibiotics should be prescribed for 7 to 10 days after discharge. A nasal decongestant commonly is prescribed at the time that the diagnosis is established to aid in opening the sinus ostia, promoting drainage of the infected sinus, and speeding resolution. Nasal decongestants should be continued for 7 to 10 days after initiation.

Although treatment of orbital cellulitis with steroids remains controversial, their use in the treatment of acute and chronic sinusitis has become increasingly common. Studies have shown that steroids can reduce levels of inflammatory cytokines in the sinonasal mucosa of individuals with sinusitis.[34,223] In a recent study on the use of steroids in children with orbital cellulitis, Yen and Yen[232] reported no adverse effects of this adjunct treatment with systemic antibiotics. Prospective studies on the use of steroids in orbital cellulitis have been proposed to determine whether they have any clinical benefit.

Children with orbital cellulitis require diligent follow-up while in the hospital. Vision should be assessed at the bedside daily; results may be more accurate if a single examiner routinely assesses vision for a given patient. Pupillary examination for an APD should be performed at each examination. Development of an APD indicates compromise of the optic nerve, warrants escalation of treatment, and usually requires urgent surgical intervention. Reduction of vision, development of an APD, onset of CNS signs, or worsening of systemic status should prompt emergency repeat neuroimaging of the brain and orbit, with further intervention as dictated by results of the scan. The close anatomic relationship of the orbit to the brain, with the orbital venous system freely anastomosing with the facial venous plexus and cranial venous sinus system through a series of valveless veins, seriously increases the potential for spread of infection to contiguous structures, including the brain.

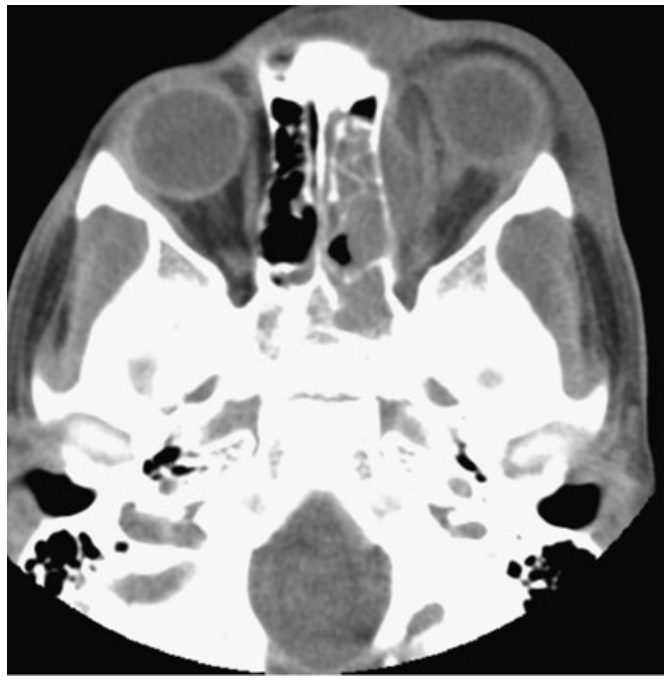

Figure 68–4 Failure of response of orbital cellulitis to antibiotic treatment may be a sign of development of a subperiosteal orbital abscess (seen here in the right medial orbit).

Acute surgical intervention to decompress the orbit or drain an orbital or subperiosteal abscess is indicated if vision loss or an APD is identified at any point during treatment. Immediate neurosurgical consideration is indicated if CNS involvement is documented. Most patients without evidence of vision loss, optic nerve dysfunction, or CNS involvement can be managed successfully medically. The surgical adage that all abscesses should be subjected to incision and drainage does not apply to abscesses associated with orbital cellulitis. Most subperiosteal abscesses located in the medial orbit can be managed successfully with medical therapy alone.[89,180] Formation of an abscess within the substance of the orbit (as opposed to a subperiosteal abscess) seldom occurs. Guidelines for surgical drainage are similar to those for subperiosteal abscess,[180] although such abscesses are more likely to require surgical intervention because of treatment failure or spread of infection to contiguous structures.[89] Provided that clinical improvement continues, no worrisome signs or symptoms of CNS involvement develop, and the patient's overall clinical status does not worsen, repeat neuroimaging of patients with an orbital abscess is unnecessary. Short-term resolution of an orbital abscess often is not obvious on CT. The radiographic appearance of the abscess typically remains unchanged on early follow-up scans, although it may no longer contain viable organisms.

Sinus drainage by an otolaryngologist frequently is required to hasten resolution. Formation of an abscess is not a prerequisite for surgical intervention, and orbital cellulitis without abscess formation may progress to the point of requiring surgery. Despite prompt and appropriate treatment, serious complications such as permanent vision loss and brain abscess can occur.[97,175,183] Most

patients, however, can be treated effectively with no permanent sequelae.

Orbital cellulitis caused by fungal infection has a course and prognosis markedly different from those of bacterial orbital cellulitis, particularly cellulitis caused by mucormycosis and aspergillosis. Fungal orbital cellulitis typically occurs in patients who are immunocompromised or patients with metabolic acidosis, such as those with poorly controlled diabetes. Orbital cellulitis may be manifested as a subacute or chronic process. Orbital apex syndrome is considered to be the most severe form, with loss of function of all cranial nerves traversing the orbital apex into the orbit (i.e., cranial nerves II, III, IV, V, and VI). A black eschar-like lesion may form in the oropharynx or nasopharynx.

Aspergillus orbital infections (most commonly caused by *A. flavus*, *A. fumigatus*, or *A. oryzae*) are rare findings in children and may take a slow, chronic course over a period of months or years. No clear predisposing factors exist, but it has a predilection for humid climates and most cases occur in otherwise healthy individuals. Signs and symptoms of orbital infection caused by *Aspergillus* spp. include loss of vision, constant dull pain, decreased or absent ocular motility, and proptosis with firm resistance to retropulsion. Palate and nasopharyngeal lesions occur but are rare. Biopsy is required for establishing the diagnosis.[88]

Effective treatment of orbital fungal infection requires correction of systemic and metabolic disturbances and administration of intravenous antifungal agents such as amphotericin B. Though still considered experimental, posaconazole has been shown to be effective as an alternative treatment in those who fail to respond to or cannot tolerate treatment with amphotericin B.[182] Surgical débridement of the orbit or adjacent infected sinuses frequently is required. Treatment often is unsuccessful, and fatalities are not uncommon, particularly with mucormycosis.

The larva of *Echinococcus granulosus* can produce a hydatid cyst in the orbit. The dog is the definitive host animal, although the organism also may live in the intestines of sheep, goats, cattle, pigs, and other animals. The disease is endemic in the Middle East, Africa, and Asia. Humans become infected by eating contaminated food, typically meat, and infection may occur in any age group. Affected patients have noninflammatory proptosis, decreased ocular motility, and dull orbital pain. Surgical excision is required for treatment. The cyst may be injected with hypertonic saline to kill the parasite, followed by excision.[86]

CONJUNCTIVAL INFECTIONS

The conjunctiva is the mucous membrane covering the inner surfaces of the eyelids and the anterior surface of the sclera. The mucous membrane lining the inner surface of the eyelids is called the *palpebral conjunctiva*, and that covering the globe is called the *bulbar conjunctiva*. The conjunctiva contains numerous small glands that produce most of the aqueous and mucous components of tears that are responsible for producing a smooth, uniform tear film over the cornea. The conjunctiva may be infected by a wide variety of bacterial and viral agents, as well as by noninfectious allergic and toxic agents.

Patients with conjunctivitis may complain of burning, itching, or a foreign body sensation. Significant itching usually signifies an allergic or viral cause. The conjunctival injection (erythema) in eyes with infectious conjunctivitis is located away from the cornea. Conjunctival injection concentrated adjacent to the cornea (i.e., limbal or ciliary flush) suggests keratitis (i.e., inflammation of the cornea), iritis (inflammation of the iris), or iridocyclitis (i.e., inflammation of the iris and ciliary body). When the eye is severely infected, however, such a differentiating pattern may not be discernible. Conjunctivitis usually is accompanied by a discharge that has some important diagnostic properties. Purulence suggests a bacterial cause, a mucoid discharge is seen most often with viral infections, and a serous discharge usually is seen with viral or allergic causes. Patients with isolated conjunctivitis do not have any significant alteration in vision. Conjunctivitis with poor vision warrants search for another diagnosis.[83,135]

BACTERIAL CONJUNCTIVITIS

Bacterial conjunctivitis is a common form of infectious conjunctivitis in children. It is characterized by a purulent discharge and can be unilateral or bilateral. It is useful clinically to divide bacterial conjunctivitis into mild and severe forms because treatment approaches are different.

Mild Bacterial Conjunctivitis

The agents most commonly causing mild bacterial conjunctivitis in children aged 5 years or older are *S. pneumoniae* and *Moraxella* spp.[83] *H. influenzae* was a prominent causative agent before the availability of Hib vaccine. *S. aureus* conjunctivitis is seen most frequently after trauma or surgical manipulation. Conjunctival stains and cultures usually are not necessary because the disease is self-limited or responds rapidly to topical antibiotics.
