Isolation of unusual pathogens often is a sign of an unexpected environmental exposure.[28,352] This statement is epitomized by the recent reports of SOTRs with uncommon zoonotic infections.[214] In the case of donor-derived rabies, lymphocytic choriomeningitis virus, and West Nile Virus infections, multiple cases were traced to a donor or donors with retrospectively assessed exposures or risk factors (or both).[125,172,191,393] West Nile virus in SOTRs also has been community acquired,[206,221] and cases of *Bordetella bronchiseptica* in transplant recipients have been traced to sick pet dogs.[34,77,295] These cases are humbling in many respects. Many of these infections have no established therapy and, as expected, are associated with increased morbidity and mortality in SOTRs.[98,125,206,221,295] Therefore, prevention is of utmost importance. These cases advise us to counsel our post-transplant recipients on avoidance of potentially infectious exposures, such as sick pets and arthropod vectors of diseases.[214,218,295] Undeniably, they remind us of the almost limitless pathogens that may befall SOTRs, including those not yet described. These cases have newly informed the policies for reporting suspected donortransmitted conditions and opened a new dialogue on how screening procedures of organ and blood donors are conducted.[105,125,180,204]

CHAPTER 83

Opportunistic Infections in Liver and Intestinal Transplantation

Michael D. Green ✪ Marian G. Michaels

For more than 20 years, liver transplantation has been established as an effective treatment of end-stage liver disease in children. Improved surgical techniques and the availability of new and more potent immunosuppressive regimens have led to enhanced short- and long-term survival rates that now approach or exceed 80 percent. In response to these excellent results, more children are being referred for liver transplantation, and increasing numbers of pediatric centers routinely perform this procedure. More recently, intestinal transplantation, performed as an isolated procedure or in combination with the liver or other organs, also is gaining expanded acceptance as treatment of refractory intestinal failure in children, particularly those who experience

progressive liver failure as a result of hyperalimentation-induced liver disease. Although this newer procedure has been performed routinely at only a limited number of centers, an increasing number of transplant programs are beginning to offer intestinal transplantation.

Infectious complications have been a significant cause of morbidity and mortality in children undergoing liver transplantation since this procedure gained initial acceptance in the 1980s. However, improvements in immune suppression management along with the increasing availability of new antimicrobial agents and diagnostic tools have resulted in improved treatment regimens that have reduced the impact of infectious complications on these children. The introduction of intestinal transplantation brought with it many of the same infectious complications seen after liver transplantations, as well as a number of infectious issues that appear to be unique to this procedure. The experience garnered from the treatment of patients undergoing liver and other organ transplant procedures has been translated effectively to the management of infections occurring after intestinal transplantation. Although development of increasingly effective treatment strategies is of great benefit to the children undergoing these procedures, emphasis also focuses on the development of strategies aimed at prevention of infectious complications in children undergoing abdominal transplantation. This chapter provides a general overview of the problem of infections that develop after liver transplantation and intestinal transplantation in children.

PREDISPOSING FACTORS

Liver transplantation and intestinal transplantation are associated with a set of technical and medical conditions that predispose one to a unique set of infectious complications. The abdomen is a common site of infection in patients undergoing both these procedures,[29,77] almost certainly as a result of local ischemic injury and bleeding as well as potential soilage with contaminated material.[59] Additional factors predisposing recipients to infection can be divided into those that exist before transplantation and those secondary to intraoperative and post-transplant activities.

PRETRANSPLANT FACTORS

The underlying illnesses leading to transplantation may be associated with intrinsic risk factors for the development of infection. Some disorders may have required palliative surgery that increases the technical difficulty of the transplant procedure and may be associated with an enhanced risk for the development of post-transplant infection.[25] For example, in children undergoing liver transplantation for biliary atresia, a Kasai procedure (choledochojejunostomy) may have been performed previously and predisposed them to recurrent episodes of bacterial cholangitis before transplantation, thereby increasing the likelihood of colonization with multiple antibiotic–resistant bacteria, which can cause infection after transplantation. Similarly, children undergoing liver transplantation for cystic fibrosis may have an increased risk for the development of invasive aspergillosis if they were colonized with this pathogen before receiving the transplant. Complications of end-stage liver disease (as part of a primary liver disease or as a consequence of hyperalimentation in patients with intestinal insufficiency) also may predispose the patient to the development of infection after undergoing transplantation. A history of one or more episodes of spontaneous bacterial peritonitis before transplantation in patients with ascites has been associated with an increased rate of bacterial infection developing after liver transplantation[120] and could be expected in patients with liver disease associated with intestinal insufficiency. Finally, children undergoing intestinal transplantation experience frequent episodes of gastrointestinal-associated bloodstream infections. Recurrent exposure to antimicrobials to treat these episodes of bacteremia increases the likelihood that colonization and disease with multiply resistant bacterial and fungal pathogens will occur after transplantation. Risks for the occurrence of bacterial translocation after intestinal transplantation, with resultant bloodstream infection, include the presence of a colon graft,[21] hospitalization before transplantation, and treatment with mycophenolate mofetil.[77]

Age, another important pretransplant factor, is a major determinant of susceptibility to certain agents, severity of expression of infection, and immune maturation. Young children undergoing abdominal transplantation may experience moderate to severe infection with certain viral (e.g., respiratory syncytial virus [RSV]) or bacterial (coagulase-negative staphylococci) pathogens, as opposed to the milder illness experienced by adult recipients infected with these pathogens. In contrast, infections caused by certain pathogens, such as *Cryptococcus neoformans*, are seldom manifested before young adulthood.[124] Age also is an important factor governing clinical expression of infection with cytomegalovirus (CMV) and Epstein-Barr virus (EBV). When transplants are performed in young patients, a high likelihood exists that they will be seronegative for CMV and EBV and, therefore, susceptible to primary infection, which is more severe than that caused by reactivation.[11,60,96]

Donor-related issues represent another set of pretransplant factors. Transplant recipients are at risk for acquiring infections that may be active or latent within the donor at the time of organ harvesting. The best described examples of donor-associated infections are CMV and EBV.[10,12,19,96] Infections caused by CMV and EBV have been more severe after intestinal transplantation than after transplantation of other organs. This difference may be due to the fact that the intestine is an organ rich in lymphoid tissue, which may result in transmission of a larger viral load from the donor than with other graft types. Similarly, adenovirus has been isolated more commonly from pediatric recipients of intestinal transplants than from other organs, which also may be related to donor transmission in the accompanying lymphoid tissue.[83,92] Although the frequencies of some donor-associated pathogens (e.g., human immunodeficiency virus [HIV],[30] hepatitis B, hepatitis C) have decreased substantially with better diagnostic screening tests,[5] recent evidence now demonstrates donor-associated transmission of West Nile virus and rabies.[67,112] Because organs from a single donor often go to disparate sites, it is important for the recipient center to report back to United Network for Organ Sharing (UNOS) any unusual infections that possibly could have come from the donor.

INTRAOPERATIVE FACTORS

Operative factors unique to liver transplantation may predispose the recipient to infectious complications. For example, liver transplant recipients undergoing Roux-en-Y choledochoduodenostomy experience more infectious episodes than do those who undergo choledochocholedochostomy with T-tube drainage.[70,102] However, usually only the former option is performed in children undergoing liver transplantation because of the small size of their bile ducts. For combined liver-intestinal transplantation, evolution to en bloc replacement of the liver and intestine avoids the need for performing an additional biliary anastomosis and minimizes the risk of development of infection related to biliary complications. Prolonged operative time (>12 hours) during the initial transplant procedure has been associated with an increased risk for developing infection after transplantation[36,70] and probably is a surrogate marker for the technical difficulty of the surgery. Intraoperative events, such as contamination of the operative field, also predispose the recipient to postoperative infections.

Finally, inability to close the abdomen after the transplant has been performed, as a result of size discrepancy or intraoperative complications, appears to increase the risk for development of postoperative infections.

POST-TRANSPLANT FACTORS

Technical problems, immunosuppression, the presence of indwelling cannulas, and nosocomial exposure are major postoperative risk factors for the development of infectious complications. Thrombosis of the hepatic artery is the most serious technical problem after liver transplantation and predisposes the recipient to the development of areas of necrotic liver, hepatic abscesses, and bacteremia.[99,102] Bile duct strictures, developing as a sequela of a thrombosed hepatic artery and ischemia or as a result of technical difficulties, may predispose the recipient to the development of cholangitis.[102] Retransplantation represents a high risk for the development of intra-abdominal infection after intestinal transplantation.[77]

Immunosuppression is the critical postoperative factor predisposing to the development of infection in all transplant recipients. Immunosuppressive regimens have evolved in an attempt to achieve more specific control of rejection with the least impairment of immunity. Thus, this evolution is aimed not only at improved control of rejection but also at a decreased rate of morbidity and mortality from infections. The use of cyclosporine-based regimens has resulted in a decreased incidence of infections in renal and cardiac transplant recipients.[29,61,89] The introduction of tacrolimus has allowed many patients to be managed without steroids.[49,118] Although reported rates of infection have been similar in liver transplant recipients treated with either tacrolimus or cyclosporine, an apparent decrease in morbidity and mortality rates, especially from viral pathogens, has been noted with tacrolimus.[2,49] In contrast to these results, some centers have reported an increased rate of EBV-associated post-transplant lymphoproliferative disease (PTLD) in patients receiving tacrolimus.[24] However, data from the University of Pittsburgh suggest that the short- and long-term incidence of EBV-associated PTLD appears to be similar in pediatric liver transplant recipients treated with either cyclosporine or tacrolimus.[15]

Children undergoing intestinal transplantation require a higher baseline level of immunosuppression than do patients undergoing most other solid organ transplant procedures.[96] With this increased level of immunosuppression has come an increased risk for the development of infection. In an effort to overcome this risk, numerous alternative immunosuppressive strategies have been explored. Looking at one such alternative strategy, Loinaz and colleagues[77] found an increased risk for the development of bacterial infection after intestinal transplantation with both mycophenolate mofetil and daclizumab.

Treatment of rejection with additional or higher doses of immunosuppressants increases the risk for development of invasive and potentially fatal infection. Of particular concern is the use of antilymphocyte preparations, especially OKT3, which often is indispensable in the management of rejection refractory to steroids.[10,36,70] Newer antilymphocyte antibodies (e.g., thymoglobulin) also are likely to be associated with an increased risk for the development of infection.

The prolonged use of indwelling cannulas at any site is an important cause of infection throughout the postoperative course. The presence of central venous catheters is a cause of bacteremia after transplantation. This is a particularly important consideration for children undergoing intestinal transplantation, for which maintenance of long-term central venous access has been required for prolonged periods after transplantation. Urinary tract infections and bacterial pneumonia are associated with the use of urethral catheters and prolonged nasotracheal or endotracheal intubation, respectively.[36,70]

Nosocomial exposure constitutes the final group of postoperative risk factors. Transplant recipients, especially children, may be exposed to many common viral pathogens (e.g., rotavirus, RSV, or influenza) while hospitalized. In addition, all transplant recipients are at risk for exposure to transfusion-associated pathogens (e.g., hepatitis B, hepatitis C, HIV). Finally, the presence in the hospital of heavy areas of contamination with pathogenic fungi, such as *Aspergillus*, may increase the risk for acquisition of invasive fungal disease in these patients. The rate of fungal colonization increases during times of hospital reconstruction. Implementation of infection control policies aimed at the local epidemiology of circulating infections is paramount.

TIMING OF INFECTIONS

The time of onset of infection with various pathogens after transplantation tends to be predictable. Most clinically important infections occur within the first 180 days after transplantation.[46,70] The timing of infections can be divided into three intervals: early (0-30 days after transplantation), intermediate (30-180 days after transplantation), and late (>180 days after transplantation). In addition, some infections may occur throughout the postoperative course. These divisions, though arbitrary, generally are useful in approaching a patient with fever after undergoing transplantation and can be used as a guide to the differential diagnosis. An overview of the infectious complications occurring during each of these time periods is provided in Tables 83–1 to 83–3 and is summarized in the following sections.

EARLY INFECTIONS (0 TO 30 DAYS)

Early infections tend to be associated with preexisting conditions and surgical manipulation (Table 83–1). In general, they are caused by either bacteria or yeast. Bacterial infections are particularly common developments after intestinal transplantation and have been reported in up to 90 percent of recipients.[62,77,116] As many as half of these early infectious complications may develop in the first 2 weeks after the patient has undergone abdominal transplantation.[9] Cholangitis or spontaneous bacterial peritonitis occurring at or near the time of liver transplantation may lead to the development of intra-abdominal infection after the procedure. Herpes simplex infection also can reactivate and cause early symptomatic disease,[70] although reactivation is an uncommon occurrence in children. Technical difficulties (e.g., thrombosis of the hepatic artery or portal vein, biliary strictures) predispose recipients to early development of bacterial infections. Likewise, the development of bile leaks and bowel perforations is associated with polymicrobial intra-abdominal infections, primarily consisting of enteric bacteria and *Candida* species, in the first month after transplantation.[38] Bacteremia may be seen in intestinal transplant recipients in association with the presence of central venous catheters, intestinal rejection, or PTLD involving the intestine.[41,107] Finally, re-exploration of the abdomen has been linked to increased rates of fungal infection.[70]

INTERMEDIATE PERIOD (31 TO 180 DAYS)

The intermediate period (Table 83–2) is the typical time of onset of infections associated with donor transmission (either organ or blood products), reactivated viruses, and opportunistic infections. CMV infection peaks in incidence during this time.[10,70] However,

if CMV prophylaxis is instituted, disease from this virus may occur after 180 days. The intermediate period also is when many patients begin to have EBV-associated PTLD[60] and *Pneumocystis jiroveci* (formerly *P. carinii*) pneumonia (PCP).[70]

LATE INFECTIONS (>180 DAYS)

Late infections developing after abdominal transplantation (Table 83–3) are less well characterized than those of other periods because patients usually have been discharged from the transplant center to their respective homes, which often are quite far away. This renders accumulating accurate data on these late infections difficult. Nonetheless, problems such as recurrent episodes of bacterial cholangitis in liver transplant recipients (typically associated with underlying problems of the biliary tree), bacteremia associated with intestinal graft rejection, and PTLD (in both groups of patients)[78] occur in this period. In addition, children who are at high risk for the development of CMV disease and have been maintained on prophylaxis may have the onset of CMV disease delayed to the late period.[17]

INFECTIONS OCCURRING THROUGHOUT THE POSTOPERATIVE COURSE

Iatrogenic factors are important causes of bacterial and fungal infection at all times but predominately in the early transplant period. Central venous lines are maintained for a variable time; the risk of infection developing persists for the entire period that

the catheter remains in place. This problem is particularly important for recipients of intestinal transplants, in whom central line access is maintained until the graft is fully functional. Similarly, the presence of urethral catheters and endotracheal tubes also increases the risk for the development of infections whenever they are in use.

Nosocomial acquisition of community viruses, such as RSV, rotavirus, and influenza A or B, can occur at any time after transplantation. These viruses spread easily in hospital environments from personnel or other hospitalized patients to transplant recipients. It is, therefore, important to modify diagnostic considerations according to local epidemiologic considerations.

BACTERIAL AND FUNGAL INFECTIONS

Bacterial and fungal pathogens are important causes of morbidity and occasionally mortality in children undergoing liver or intestinal transplantation (or both). With the exception of infections related to the use of indwelling catheters, sites of bacterial infection tend to occur at or near the transplanted organ. Accordingly, the intra-abdominal space is an important site of infection after any of the abdominal transplant procedures. Adding to the complexity of management of bacterial infections in children undergoing abdominal transplantation is the fact that recovery of multiply antibiotic-resistant bacteria is occurring increasingly frequently. Outbreaks of colonization and disease caused by vancomycin-resistant *Enterococcus faecium* and extended-spectrum β-lactamase (ESBL)-producing *Klebsiella pneumoniae* have been reported in pediatric liver and intestinal transplant recipients.[40,42] These multiply resistant bacteria have been transmitted from patient to patient, thus prompting the imposition of strict infection control procedures. Reports of multiply resistant strains of *Enterobacter cloacae* associated with de-repression of a chromosomally located, broad-spectrum, β-lactamase enzyme have identified this very resistant organism as an important pathogen after liver transplantation.[20] More recently, isolates of *E. cloacae* identified to also be carrying ESBL enzymes have been recovered from our intestinal transplant candidates and recipients and, as a result, have limited our antimicrobial alternatives even further. The increasing prevalence of these multiply antibiotic-resistant organisms limits the therapeutic options available for the treatment of bacterial infections that occur after abdominal transplantation; in some cases, effective antimicrobials may be unavailable to treat these complications. Knowledge of the results of previous cultures and local antimicrobial resistance patterns is critical in choosing initial empiric antibiotic therapy in these patients to maximize their outcomes.

LIVER TRANSPLANTATION

Bacterial and fungal infections are common early problems after liver transplantation.[22,23,57,62,122,130] Rates of bacterial infection of 40 to 70 percent have been reported from multiple series.[49,70,102] Bacteremia often occurs in association with intra-abdominal infection or with the use of central venous catheters, but it can develop without an obvious source. Enteric gram-negative organisms account for more than half of these episodes. Bacterial infections involving the abdomen or surgical wound are common developments in most series. Infectious complications of the transplanted liver also occur. The most important complication is hepatic abscess associated with hepatic artery or portal vein thrombosis, often accompanied by persistent bacteremia. However, the introduction of frequent surveillance Doppler studies early after transplantation to monitor for the development of thrombosis, coupled with the use of operative thrombectomy and thrombolysis, has essentially eliminated the development of hepatic abscesses in this population.

Ascending cholangitis is a common occurrence after liver transplantation and usually is associated with biliary abnormalities. This diagnosis typically is made on clinical grounds in a patient with fever and biochemical evidence of biliary inflammation. Enteric gram-negative bacteria and enterococcal species predominate. However, because this clinical picture can be identical to that of acute graft rejection, liver biopsy should be performed to differentiate these processes. A cholangiogram is performed to assess the status of the biliary tract in patients with proven cholangitis.

As many as 40 percent of children undergoing liver transplantation may contract a fungal infection during the first year after the procedure.[122] *Candida* spp. are the most common fungal pathogens, and infection usually is associated with an intra-abdominal focus or indwelling catheter. Infections caused by *Candida* spp. usually are recognized in the first month after transplantation, with *Candida* peritonitis most likely occurring in the first 2 weeks after liver transplantation in association with a bile leak or bowel perforation. Other risk factors associated with the development of *Candida* infection include a prolonged duration of intubation after transplantation, hepatic artery thrombosis, volume of blood transfused, and exposure to steroids within the 3 months before the transplant procedure. Recovery of *Candida* from a Jackson-Pratt drain in the early postoperative period may be the first indication of either of these two technical complications and may occur before the onset of clinical symptoms of intra-abdominal infection.[40] Accordingly, recovery of *Candida*, alone or in combination with enteric bacteria, should prompt initiation of antimicrobial therapy and aggressive evaluation for the presence of these complications. Early initiation of treatment is particularly important, given an attributable mortality rate of up to 33 percent for candidal infections in pediatric liver transplant recipients.[40] The availability of fluconazole and the newer echinocandin antifungal agents (e.g., caspofungin and micafungin) has increased the number of therapeutic options for the treatment of *Candida* infection. However, acquired or inherent resistance to the azoles is an increasing concern, as are drug-drug interactions between azoles and echinocandins with both cyclosporine and tacrolimus.

Episodes of invasive aspergillosis are uncommon occurrences but can be fatal.[50] Children undergoing liver transplantation for cystic fibrosis are at particular risk for infection with *Aspergillus*.[121] We have observed early disseminated disease in children with cystic fibrosis undergoing liver transplantation, which has prompted the use of perioperative antifungal prophylaxis in liver recipients with cystic fibrosis and a history of recovery of *Aspergillus* before transplantation. Because data defining the precise duration of prophylaxis necessary to protect against this complication are not available, prophylactic treatment has ranged from 1 month of intravenous amphotericin to prolonged use of an oral azole agent (e.g., itraconazole or voriconazole). The availability of newer antifungal agents, including the advanced-generation azoles (voriconazole and posaconazole), as well as the echinocandins, has increased the number and complexity of therapeutic options for the treatment of aspergillosis in children undergoing liver transplantation. A summary of a suggested approach to the diagnosis and management of fungal infections that occur after liver transplantation in children is provided in Table 83–4.

INTESTINAL TRANSPLANTATION

A relatively small number of children have undergone intestinal transplantation. Many have received combined liver and intestine or multivisceral transplants. Bacterial infection occurs frequently in these patients.[41,106] One recent series reported that as many as

**Common, greater than 5 percent; uncommon, 1 to 5 percent; rare, less than 1 percent.*
†*Amphotericin B is dosed at 0.75 to 1.0 mg/kg/day; lipid formulations are used if renal failure is present.*
‡*Topical amphotericin B for bladder wash for noninvasive candiduria. Ultrasound of the kidneys is recommended to determine that no invasive disease is present.*
§*Azole use must be accompanied by close follow-up of levels of cyclosporine or tacrolimus. In general, tacrolimus dosing should be cut in half when using a standard dose of fluconazole.*
¶*Radiographic staging includes computed tomography of head, chest, and abdomen.*
||*Fluconazole is the alternative first-line drug for invasive disease if the species is known to be sensitive to fluconazole and the patient is clinically stable. Fluconazole is dosed at 6 to 12 mg/kg/day based on the severity of infection.*
***The use of either of the approved echinocandins (caspofungin or micafungin) may be an appropriate alternative for the treatment of invasive candidiasis, candidemia, and aspergillosis. Dose adjustments may be necessary in the face of impaired liver function. Monitoring of tacrolimus levels is indicated because these agents may decrease tacrolimus levels.*
††*5-Flucytosine should not be used alone but is synergistic when used in conjunction with amphotericin B. Flucytosine is dosed at 100 to 150 mg/kg/day divided every 6 hours.*
‡‡*Itraconazole can be used long-term for patients who have been treated for invasive Aspergillus, but in general it is not recommended as first-line therapy.*
§§*Itraconazole absorption can be erratic. Accordingly, monitoring of itraconazole levels is recommended. Itraconazole is dosed at 3 to 5 mg/kg/day as a single dose. Dosing adjustment based on monitoring of levels is recommended. Adjustment of cyclosporine or tacrolimus dosing should be individualized.*
¶¶*Voriconazole levels should be checked in patients treated with oral therapy.*
CSF, cerebrospinal fluid.

92 percent of children undergoing intestinal transplantation experienced an average of 2.9 episodes of bacterial infection per patient.[77] In more than 80 percent of these patients, the first bacterial infection occurred during the first 2 months after receiving the transplant. Bacteremia, which can be explained in part by disruption of the mucosal barrier associated with harvest injury or intestinal allograft rejection, is a common finding.[41,106] Coagulase-negative staphylococci and enterococci and gram-negative enteric bacilli account for most episodes. As noted earlier, antibiotic resistance is seen commonly in recovered pathogens. In our experience, episodes of gut-associated bacteremia frequently are responsible for secondary infection of central venous catheters, and persistent positive cultures are produced even after resolution of clinical symptoms. Accordingly, treatment strategies aimed at preserving the catheter (e.g., antibiotic lock therapy) may need to be implemented in conjunction with systemic antibiotics to achieve a sustained clinical cure.

Intra-abdominal and wound infections also are seen commonly in this population; they occur in more than a third of patients and typically are detected during the first month after transplantation. Gram-negative enteric pathogens, which frequently demonstrate multiple-antibiotic resistance, as well as enterococci (often exhibiting vancomycin resistance), are the most common organisms associated with these complications. Recurrent laparotomy has been identified as a risk factor for intra-abdominal infection. One unique aspect of intestinal transplantation is the potential inability to achieve abdominal wall closure. Although failure to close the abdominal wall is an obvious risk for the development of intra-abdominal infection, the use of abdominal mesh as part of an effort to resolve difficult abdominal wall closure also has been associated with the development of superficial and deep wound infection.[28] Successful treatment of mesh-related infections may require removal of the mesh to obtain a sustained clinical cure.

Another important site of infection is the intestine itself. *Clostridium difficile* enteritis can be accompanied by a pattern of fever, abdominal pain, and diarrhea that easily can be mistaken for graft rejection or viral infection caused by CMV, EBV, and adenovirus. Accordingly, the diagnosis of *C. difficile* enteritis must be considered in any child in whom fever and changes in stool output are noted. In one small series, *C. difficile* enteritis was diagnosed in nearly 10 percent of children undergoing intestinal transplantation.[129] The frequent exposure to antibiotics and prolonged hospital stays that children undergoing intestinal transplantation experience are major risk factors for the development of this complication. Standard treatment with oral metronidazole is the recommended first-line therapy. However, prolonged therapy or oral vancomycin might be necessary for patients who

experience relapse or recurrent episodes after primary treatment.

Candidemia also may occur in any of the settings in which bloodstream infections are observed after intestinal transplantation. Although the majority of episodes of candidemia take place in the first 3 to 6 months after transplantation, episodes may occur later. Intra-abdominal infection with *Candida* also is observed, typically as part of a polymicrobial infection related to technical problems occurring during the initial transplant surgery or subsequent laparotomies.

Invasive mycoses caused by fungal pathogens other than *Candida* seldom are observed. Rare infections with *Aspergillus*, *Alternaria*, and *Scedosporium* spp. have occurred in children undergoing intestinal transplantation at our institution. In general, these children have been receiving high levels of immune suppression, and the outcome of these infections has been poor. Guidelines for the diagnosis and management of fungal infection in children undergoing intestinal transplantation are provided in Table 83–4.

VIRAL INFECTIONS

Viral pathogens, especially herpesviruses, are a major source of morbidity and mortality after solid organ transplantation. Patterns of disease associated with individual viral pathogens generally are similar among all transplant recipients. However, frequency, mode of manifestation, and relative severity can differ according to the type of organ transplanted and the serologic status of the recipient.

CYTOMEGALOVIRUS

CMV continues to be the most common and one of the most important viral pathogens seen after organ transplantation in children. CMV infection can be asymptomatic or symptomatic and may be due to primary infection (from either the donor graft or blood products), reactivation of latent infection, or superinfection with a different CMV strain in a previously seropositive child. Before the use of prophylaxis, the incidence of symptomatic CMV infection was reported to be as high as 22 percent in adult[53] and 40 percent in pediatric[10] liver transplant recipients. Use of ganciclovir prophylaxis has resulted in a decreased rate and severity of CMV disease.[44] Intestinal transplantation was introduced after ganciclovir became available and, therefore, has been able to take advantage of using ganciclovir both as prophylaxis and as treatment. Nonetheless, CMV disease can be very severe after intestinal transplantation and has a high rate of recurrence.[12,71] Primary CMV infection, typically acquired from the donor organ (or passenger donor leukocytes that accompany the organ), is associated with the greatest degree of morbidity and mortality.[39,44] Accordingly, CMV-seronegative recipients of organs from CMV-seropositive donors are considered at high risk for the development of CMV disease. Reactivation of or superinfection with CMV tends to result in milder illness after liver transplantation but still can be severe after intestinal transplantation.[11,13] CMV disease appears to be more likely to develop in CMV-seropositive recipients of CMV-seropositive donor organs than in seropositive recipients of seronegative donor organs.[39] Patients treated with unusually high doses of immunosuppressants, especially antilymphocyte antibody preparations, experience an increased rate of CMV disease regardless of previous immunity.[10,70]

Symptomatic CMV disease typically occurs between 1 and 3 months after transplantation. An important note is that the use of prophylactic regimens may delay the onset of CMV disease. A characteristic constellation of fever (which may be high-grade, prolonged, and hectic) and hematologic abnormalities (including leukopenia, atypical lymphocytosis, and thrombocytopenia) frequently is seen. This "CMV syndrome" occurs in 25 to 50 percent of patients with symptomatic CMV infection. Invasive CMV disease is characterized by visceral organ involvement; common sites include the gastrointestinal tract, liver, and lungs. CMV hepatitis appears to be the most common site in liver transplant recipients, whereas CMV enteritis is a frequent finding in intestinal transplant recipients. CMV chorioretinitis is a rare development in organ transplant recipients.

The diagnosis of CMV disease may be confirmed by positive buffy coat culture, pp65 antigenemia assay,[117] or the presence of CMV DNA in the blood of a patient with a compatible clinical syndrome.[71] However, clinicians must be aware that the results of viral culture of urine and even bronchoalveolar lavage specimens are difficult to interpret in previously infected patients because CMV frequently is shed asymptomatically in these secretions. Similarly, the presence of pp65 antigen and CMV DNA in blood can be misleading because these assays often are positive in asymptomatic patients. The specificity of this approach may be improved by quantitative determination of pp65 antigen or CMV DNA. Because of the lack of specificity of these assays, histologic examination of involved organs to confirm the presence of CMV is critical when the diagnosis of invasive CMV is being entertained.

Antiviral agents with activity against CMV (e.g., ganciclovir, foscarnet, and cidofovir) have improved the survival of transplant recipients with CMV disease. Fatal, disseminated CMV disease occurred in 19 percent of infected children[10] and 5 percent of infected adults undergoing liver transplantation in the preganciclovir era.[105] For clinical CMV disease, ganciclovir therapy is given in conjunction with reduction of immunosuppression unless evidence of rejection is present. Clinical response usually occurs 5 to 7 days after initiation of therapy. Baseline immunosuppression levels typically are restored at the time of initial clinical response or upon recognition of rejection. Recent evidence supports serial monitoring of CMV load in peripheral blood as a guide to the duration of treatment of CMV disease.[26,104] The role of CMV hyperimmune globulin in combination with ganciclovir for the treatment of CMV disease is controversial, although some evidence of improved outcome has been reported in the treatment of CMV pneumonia in adult liver transplant recipients.[37] Finally, because of the relatively high rates of nephrotoxicity associated with their use, foscarnet and cidofovir should be restricted to patients with apparent or proven resistance to ganciclovir.

In approximately 25 percent of patients treated with ganciclovir for an initial episode of symptomatic CMV disease, one or more episodes of recurrent CMV disease will develop.[104,114] Recurrences are observed approximately 1 month after the initial infectious episode occurs and may be associated with invasive disease. More commonly, however, these recurrent episodes tend to be milder than is the initial episode. Factors associated with an increased risk for the development of recurrent CMV disease include being a CMV-seronegative recipient of a CMV-seropositive organ, having disseminated CMV disease, and having a history of multiple treatment courses for rejection.[104] In addition, one center has demonstrated a correlation between the height of the CMV viral load in peripheral blood leukocytes before treatment and also at the end of treatment and the likelihood of recurrent CMV disease developing.[104] These results are the basis for the recommendation to use the results of CMV viral load measurement to guide the duration of therapy for CMV disease.[26] A summary of our suggested approach to the diagnosis and management of CMV infection is provided in Table 83–5.

†Foscarnet is used for CMV infection when ganciclovir resistance is suspected or proven. Experience from patients infected with human immunodeficiency virus suggests that a synergistic benefit will be obtained from the combined use of both of these agents when ganciclovir resistance is present.

CMV, cytomegalovirus; EBV, Epstein-Barr virus; IS, immune suppression; IVIG, intravenous immunoglobulin; NP, nasopharyngeal; PCR, polymerase chain reaction; RSV, respiratory syncytial virus.

EPSTEIN-BARR VIRUS

EBV infection, including EBV-associated PTLD, is an important cause of morbidity and mortality after liver transplantation and intestinal transplantation,[60,81,113,119,128] particularly in children undergoing intestinal transplantation, who experience the highest rates of EBV-related disease among transplant recipients.[91]

Symptomatic EBV infection in general and PTLD in particular most commonly occur in transplant recipients experiencing primary EBV infection, especially those who receive organs from seropositive donors. Accordingly, children undergoing transplantation are disproportionately affected by EBV when compared with their adult counterparts.[51] In as many as 80 percent of children who are EBV-seronegative before undergoing liver transplantation, primary EBV infection will develop after this procedure.[108,111] Although primary infection occurs in the vast majority of seronegative patients, clinical disease develops in less than a third of these children.[108,111] In one study, PTLD developed in 4 percent of children undergoing solid organ transplantation and 10 percent of children with primary EBV infection between 1 month and 5 years after transplantation[60]; 75 percent of cases occurred during the first postoperative year in patients receiving cyclosporine-based immune suppression. The cumulative incidence can be as high as 12 to 20 percent by 7 to 12 years after liver transplantation.[78,87]

Pediatric recipients of intestinal transplants appear to behave differently from children undergoing other types of organ transplantation in that the rate of EBV disease, including PTLD, appears to be similar in both patients who are EBV-seronegative and those who are EBV-seropositive before undergoing intestinal transplantation. Rates of EBV disease and PTLD after intestinal transplantation as high as 30 to 40 percent were reported during the initial experiences with intestinal transplantation. More recently, these rates have declined to approximately 10 percent as a result of improved immune suppression regimens and EBV-monitoring protocols. However, these rates still remain higher than those seen in other organ recipients.

A wide spectrum of EBV disease is recognized and includes nonspecific viral illness, mononucleosis, and PTLD, including lymphoma. Histologic evaluation is important in differentiating among these categories; manifestations can evolve in individual patients, and asymptomatic seroconversion also occurs. Variation in severity and extent of disease is related to the degree of immunosuppression and adequacy of the host immune response. Although EBV disease and PTLD may affect many different clinical sites, the tendency of EBV disease is to involve the transplanted organ. Thus, EBV hepatitis and PTLD of the liver are observed more commonly in liver transplant recipients.[18] Similarly, the intestine is the most frequently observed site of involvement of EBV disease in intestinal transplant recipients. Of interest, involvement of sites beyond the gastrointestinal tract is an uncommon occurrence in intestinal transplant recipients.

The onset of viral syndrome, mononucleosis, and PTLD takes place primarily within the first year, whereas lymphoma tends to occur later. Immunosuppressive regimens based on the use of tacrolimus appear to have induced a shift in the timing of PTLD; only rare cases develop more than 18 months after transplantation.[16,128] This pattern of timing of EBV disease and PTLD appears to apply to all pediatric organ recipients, including children undergoing liver or intestinal transplantation. However, the impact of newer immunosuppressive agents and regimens on EBV disease remains to be determined.

The diagnosis of EBV-associated PTLD is made on the basis of clinical, laboratory, and histopathologic examination and should be suspected in patients with protracted fever, exudative tonsillitis, lymphadenopathy, organomegaly, leukopenia, or atypical lymphocytosis.[46,91] Gastrointestinal involvement should be suspected in patients with persistent fever and diarrhea. Accordingly, EBV must be considered in the differential diagnosis of rejection in intestinal transplant recipients. Serologic diagnosis often is confounded by the presence of passive antibody acquired at the time of transplantation or during subsequent transfusions. Detection of increased EBV viral load in peripheral blood by polymerase chain reaction (PCR) has gained wide acceptance as

a means of predicting the risk for or presence of EBV or PTLD.[48,69,91,97,100] Though extremely sensitive, these assays are limited by their lack of specificity; they often are elevated in asymptomatic patients.[3] Accordingly, every effort should be made to confirm the diagnosis of EBV or PTLD histologically. Occult sites of PTLD are assessed by performance of computed tomography of the chest and abdomen. Palpable nodes or lesions (or both) identified by radiographic surveillance should undergo biopsy. Endoscopic evaluation should be considered in patients with diarrheal illnesses and elevated viral loads. Histologic evaluation for typical features may be augmented through use of the Epstein-Barr–encoded RNA (EBER) probe.[95] Use of the EBER probe may be particularly helpful in differentiating between the presence of rejection and EBV infection in intestinal transplant recipients.

Management of patients with PTLD is controversial.[14,16,46,91] Reduction of immunosuppression is recommended widely. Antiviral agents typically are used,[54.55,98] although their role has not been studied formally. Reduction of immunosuppression, alone or in combination with antiviral agents, results in an approximate 67 percent cure rate of EBV disease and PTLD. The potential impact of monoclonal antibodies,[33] interferon,[103] and chemotherapy[35] awaits formal clinical trials. Resection of tumor also may be of value for patients with lymphoma. Recent experience has focused on several novel approaches to the management of EBV disease and PTLD. These newer strategies generally have been used for patients who fail to respond to reduction of immune suppression (with or without the use of antiviral agents). Rituximab, an anti-CD20 antibody, has been used increasingly for the treatment of EBV disease. Experience to date suggests that as many as two thirds of patients who fail initial withdrawal of immunosuppression will respond to a 4-week course of this agent.[47] However, relapse of EBV disease has been observed in 20 to 25 percent of treated patients 6 to 8 months after completion of therapy, at the time that rituximab no longer is present in the body. An alternative, chemotherapy-based approach for patients who fail to respond to initial reduction or withdrawal of immunosuppression also has been proposed.[52] This strategy, which uses modified doses of cyclophosphamide and prednisone, likewise has achieved success in approximately two thirds of treated patients. Unfortunately, as with rituximab, relapse of PTLD has been seen in 22 percent of treated patients, and outright treatment failures have occurred in patients with fulminant disease. Definitive studies comparing these two second-line therapies are needed to determine the best option for children who fail to respond to initial therapeutic modification of immunosuppression. A summary of our suggested approach and management of EBV/PTLD is provided in Table 83–5.

OTHER HERPESVIRUSES

Other herpesviruses also can be hazardous after transplantation. Herpes simplex can reactivate early after surgery or after augmentation of immunosuppression. Prophylaxis with acyclovir has been beneficial in these situations. A summary of the suggested approach to the diagnosis and management of infection with herpes simplex virus is provided in Table 83–5. Varicella in nonimmune transplant recipients can lead to disseminated fatal disease[82] and should be treated early and aggressively with intravenous acyclovir.

More recently, interest has focused on determining what role, if any, the recently recognized human herpesvirus-6 (HHV-6) and HHV-7 may play in causing disease in organ transplant recipients in general and abdominal transplant recipients in particular. Several groups of investigators have identified a potential interaction between the development of HHV-6 and HHV-7 and CMV infection in organ transplant recipients.[65,84] Reactivation of HHV-6 infection after liver transplantation has been associated with the development of an increased CMV viral load in peripheral blood, as well as a greater likelihood of symptomatic CMV disease developing.[65] In addition, some investigators have suggested that some or all of the symptoms typically associated with CMV syndrome (e.g., fever, leukopenia) in patients with proven CMV infection may be attributable in part to HHV-6 or HHV-7. Studies in children have suggested that infection with HHV-6 alone is a relatively common cause of unexplained fever in pediatric liver transplant recipients.[126,127] Interest also has begun to focus on what role, if any, HHV-8 may have in causing infection and disease in organ transplant recipients, particularly recipients from countries with moderate to high rates of HHV-8 prevalence, such as Africa, the Middle East, and the Carribean.[86] The full spectrum of disease caused by these newer viruses and their potential therapies remain to be determined.

ADENOVIRUS

Adenovirus has been reported to be the third most important virus affecting pediatric liver transplant recipients; it was found in 10 percent of our series of 484 children undergoing liver transplantation under cyclosporine-based immunosuppression.[85] Symptomatic disease (ranging from self-limited fever, gastroenteritis, or cystitis to devastating illness with necrotizing hepatitis or pneumonia) occurred in more than 60 percent of infected patients. Infection developed within the first 3 months after transplantation. The frequency of invasive adenovirus infection after pediatric liver transplantation appears to have decreased markedly with the use of tacrolimus-based immunosuppression.[50] In a more recent report, McLaughlin and colleagues[83] found that only 4.2 percent of pediatric liver recipients receiving tacrolimus-based therapy had adenovirus disease. This rate is in contrast to a significantly higher incidence of adenovirus infection of 20.8 percent in pediatric intestinal transplant recipients at the same institution. The increased prevalence of adenovirus in intestinal transplant recipients is illustrated further by the report of Pinchoff and colleagues,[92] who found adenovirus in all 14 of their pediatric intestinal transplant recipients. However, this exceptionally high rate might be attributable to the fact that viral cultures were performed as part of routine screening of graft biopsy specimens and not all of the patients were symptomatic. In both these studies, high volume of stool output, alone or in the presence of fever, was the most common symptom found in the patients.

Presumptively diagnosing infection caused by adenovirus in pediatric abdominal transplant recipients is very difficult inasmuch as fever, hepatitis, and pneumonia may be due to a variety of other pathogens and high volume of stool output after intestinal transplantation is nonspecific and can occur with rejection as well. The presence of high-grade fever and symptoms suggestive of adenovirus infection should prompt obtaining serial cultures for viruses (including adenovirus) or PCR investigation and evaluation of graft biopsy tissue. Unexplained elevations in hepatocellular enzymes suggestive of hepatitis should warrant consideration of liver biopsy. Similarly, an increase in stool output, with or without fever, should prompt endoscopic evaluation of the intestinal allograft. Histologic examination for the presence of adenoviral inclusions, as well as immunohistochemical staining of biopsy specimens from either site, should be undertaken to help confirm this diagnosis.

Unfortunately, no definitive treatment is available for adenoviral infection at this time. The most important component of therapy is supportive care along with a decrease in immunosuppression. The role of antiviral agents is unproven. A small number of case reports describe the use of ribavirin[8,68,76,83,88] and ganciclovir[125] in the treatment of single patients with adenoviral infection

after undergoing solid organ or bone marrow transplantation. In vitro evidence supports the theoretical role of ribavirin but not that of ganciclovir in the treatment of these infections. In addition to these published reports, an adult lung transplant recipient with disseminated adenovirus type 7 improved after treatment with cidofovir and pooled, high-titer immunoglobulin against RSV (Respigam) along with decreased immunosuppression.[43] Several other case reports have described the successful use of cidofovir for the treatment of adenoviral disease in a bone marrow transplant recipient, as well as a patient with acquired immunodeficiency syndrome.[56,96] A single case report also raised the possibility of a role for intravenous immunoglobulin (IVIG) as treatment of adenovirus infection.[27] Unfortunately, no conclusive evidence of the efficacy of these antiviral agents or IVIG can be drawn from these reports. A summary of a suggested approach to the diagnosis and management of adenovirus infection is provided in Table 83–5.

COMMON COMMUNITY-ACQUIRED VIRUSES

Although the course of illness has been poorly documented, most children who undergo liver and intestinal transplantation experience the usual respiratory viruses and gastrointestinal illness without significant problems. However, infection by influenza, parainfluenza, or RSV leads to more severe disease in young children, especially if the infection occurs soon after transplantation and during periods of maximal immunosuppression.[6,31,66,93] Likewise, transplant recipients may have prolonged viral shedding even after resolution of symptoms. A summary of suggested strategies for the diagnosis and management of these community-acquired viruses can be found in Table 83–5.

OTHER VIRUSES

Other viruses, including both donor-associated viral infections (e.g., hepatitis B and C) and community-acquired viral pathogens (e.g., enterovirus, rotavirus) are relatively uncommon causes of infection or disease after abdominal transplantation. Suggested approaches to the diagnosis and management of each of these viral pathogens are provided in Table 83–5.

OPPORTUNISTIC INFECTIONS

P. jiroveci is a well-documented cause of pneumonia in immunocompromised patients, including liver and intestinal transplant recipients. Prophylactic trimethoprim-sulfamethoxazole (TMP-SMX) is safe, inexpensive, and effective.[64] Use of this strategy has eliminated PCP in these patients at our center. Alternative prophylactic regimens for sulfa-allergic patients include aerosolized pentamidine (for patients >5 years of age)[74] or dapsone.[63]

Tuberculosis (TB) is a particular concern in immunosuppressed hosts, including recipients of liver and intestinal transplants. The incidence of TB after liver transplantation in Europe and the United States has been reported to range from 0.9 to 2.3 percent, with most cases reported in adults.[106,121] In contrast, TB may develop in as many as 15 percent of organ transplant recipients in areas of high-level endemicity.[106] However, development of TB after pediatric liver transplantation is an extremely uncommon event, with only 11 cases reported thus far.[79,106,121] To date, no cases have been reported in recipients of intestinal transplants. The development of TB in solid organ transplant recipients is associated with mortality rates ranging from 25 to 40 percent, with additional morbidity and mortality associated with the development of rejection in patients receiving antituberculous therapy.[106,121] The diagnosis of TB in transplant recipients is complicated by the fact that extrapulmonary disease occurs frequently and purified protein derivative (PPD) testing is likely to be unreliable after transplantation. Management of TB in liver transplant recipients is difficult because of both the side effects of antituberculous agents and their potential interactions with immunosuppressive agents.[106,121] Limited published experience in pediatric liver transplant recipients suggests that most infections caused by *Mycobacterium tuberculosis* in all probability are due to a primary infection, often associated with family contacts who have positive skin tests.[79,121] In contrast, experience with adult transplant recipients suggests that the development of TB is more likely to be due to reactivation of latent TB.[58,106,121] Despite the limited published information describing TB in these patients, transplant recipients known to have a positive PPD test or who come from an area endemic for TB appear to be at increased risk for symptomatic reactivation after transplantation.[58,121] Similar data are not available for recipients of intestinal transplants. Additional factors predisposing to the development of TB after transplantation include severe hepatic failure at the time of transplantation, aggressive anti-rejection therapy, and HIV infection.[58,115] Experience with adult renal transplant recipients suggests that even though the risk appears to be greatest in patients who received inadequate or no previous TB therapy,[75,78] it also can occur in patients who received appropriate anti-TB therapy in the pretransplant period.[75,78,94] Although TB has been encountered only rarely in pediatric liver transplant recipients[121] and not in intestinal recipients, screening for TB by history and PPD testing, along with review of a chest radiograph for lesions consistent with healed TB, is highly recommended. Patients with a positive TB history or a positive PPD test, or both, should receive isoniazid for 6 to 12 months after undergoing transplantation, although some experts recommend continuing isoniazid indefinitely while patients remain on immunosuppression. Attempts at establishing a more definitive diagnosis are indicated for patients from endemic areas with a negative PPD test but a suspicious chest radiograph. Careful evaluation for evidence of side effects, particularly hepatotoxicity, is recommended, and isoniazid is discontinued if unacceptable toxicity is identified.

Additional potential opportunistic infections include cryptococcosis, coccidioidomycosis, and histoplasmosis, although these pathogens have not been reported frequently in pediatric liver or intestinal transplant recipients. Previous infection with these pathogens is common in geographic areas where they are endemic. Because patients often travel to transplant centers distant from their homes, it is imperative that transplant physicians be aware of the local environmental risks for each patient. Experience with coccidioidomycosis in transplant recipients suggests that a minimum of 4 months of antifungal therapy, such as fluconazole, should be given to transplant recipients with this history.[53] Similarities between coccidioidomycosis and other fungal pathogens suggests that similar strategies may be necessary for patients with a positive history of previous fungal infection with pathogens known to recur after resolution of the primary infection.

MANAGEMENT

PRETRANSPLANT EVALUATION

Pretransplant evaluation is helpful in the management of infectious complications in liver and intestinal transplant recipients. A complete history and physical examination should be performed with particular attention given to previous infections, immunizations, and drug allergies. Attention should be paid to a history of infection with multiply antibiotic-resistant bacteria, which may provide guidance for any future empiric treatment that may be required after transplantation. An intermediate-strength tuberculin skin test should be performed on all patients.

We recommend serologic evaluation of all candidates for CMV; EBV; varicella; herpes simplex virus; hepatitis A, B, and C; and HIV. Serologic tests on the donor should include HIV, hepatitis B and C viruses, CMV, and EBV. Donors positive for HIV or hepatitis B virus should be excluded. The use of organs from donors positive for hepatitis C probably would be contraindicated except in the circumstance in which the recipient also is positive for hepatitis C. Knowledge of donor and recipient status for these viruses allows one to anticipate infection, identify patients who might benefit from prophylactic regimens, and narrow the differential diagnosis in a patient with fever.

PROPHYLACTIC REGIMENS

Prophylactic regimens vary among transplant centers. These strategies have been divided into perioperative and long-term prophylaxis and often evolve to reflect the infectious complications seen at individual institutions.

Perioperative prophylaxis is used to prevent intraoperative sepsis and wound infection. It is based on individual patient characteristics and the expected normal flora. We consider piperacillin-tazobactam an appropriate agent for perioperative prophylaxis. If sepsis is suspected in the donor, antibiotics are chosen to cover organisms identified from the donor, and treatment usually is extended to a therapeutic course of 10 to 14 days. In the absence of proven or suspected infection in the donor, perioperative prophylaxis generally is limited to the first 48 hours after transplantation.

Considerations regarding long-term prophylaxis against infections occurring beyond the perioperative period include the risk and severity of infection, as well as the toxicity, cost, and efficacy of a given prophylactic strategy. Nystatin is recommended for all pediatric transplant recipients in an effort to prevent oropharyngeal candidiasis. TMP-SMX is used to prevent PCP. Although some centers recommend using TMP-SMX for only the first 6 months after liver transplantation, anecdotal experience of PCP occurring long after patients receive their transplants and the relative safety of this agent have led us to recommend its use indefinitely after liver and intestinal transplantation in children.

The frequency and severity of CMV infections in transplant recipients prompt consideration of prophylactic strategies, and optimization of the target population and timing of interventions require further study.[7,26,32,90,101,123] Potential roles exist for intravenous and oral ganciclovir[34,42,72] and oral valganciclovir.[109,110] Currently, we recommend the use of intravenous ganciclovir alone (for varying durations) for liver and low-risk intestinal transplant recipients (recipient CMV-positive before transplantation or donor and recipient seronegative) and ganciclovir plus IVIG with a high titer of antibody against CMV for high-risk (donor CMV-positive/recipient CMV-negative) intestinal transplant recipients if it is available. At the present time, oral valganciclovir is an alternative to prophylaxis with intravenous ganciclovir for adolescents. Pharmacokinetic studies of dosing of oral valganciclovir suspension in children after transplantation are ongoing. On completion of these studies, the use of valganciclovir suspension probably will be of merit as an alternative to intravenous treatment in younger children.

Serial monitoring of the blood CMV viral load with either the pp65 antigen assay or quantitative CMV PCR as an indicator for the use of preemptive antiviral therapy has been proposed as an alternative to these chemoprophylactic and immunoprophylactic strategies.[45] In this approach, only patients demonstrating increased risk because of increased viral load are treated with intravenous or oral ganciclovir. Although this strategy has gained acceptance at some centers, experience in pediatric transplant recipients in general and abdominal transplant recipients in particular remains limited. The use of viral load monitoring after completion of chemoprophylaxis is gaining increasing acceptance.

The growing recognition of the importance of EBV infection in pediatric organ transplant recipients has led to an interest in the prevention of EBV infection and PTLD. Numerous strategies (e.g., immunoprophylaxis, monitoring, and preemptive therapy) are being explored,[47,80] the efficacy of these approaches has not been established. The use of viral load monitoring to inform preemptive reductions in immunosuppression appears to be the most promising of these strategies.[73,80] Because reduction of immune suppression is not always possible for intestinal transplant recipients with a rising EBV load, preemptive intravenous ganciclovir and IVIG have been used in addition to reduction of immune suppression (when possible) for this cohort of patients. Although prospective comparative data are not available, the use of this strategy appears to have resulted in a decreased risk for disease and better outcome than in historical controls who were not managed with this strategy.[41]

SUMMARY

Infections remain an important problem after liver and intestinal transplantation. Knowledge of the type, timing, and predisposing risk factors for these infectious complications allows for timely and appropriate diagnosis and management.

CHAPTER 84

Opportunistic Infections in Kidney Transplantation

Gail J. Demmler-Harrison

Renal transplantation is the therapy of choice for end-stage renal disease (ESRD) in children and adolescents.[139] It is successful in 90 percent of recipients and allows most children the best opportunities for normal growth and development and an almost normal lifestyle.[74,142,221] Despite the overall success of renal transplantation, infection remains the major cause of morbidity, graft loss, and mortality in renal transplant recipients.[50,214] Newer and more effective immunosuppressive regimens have reduced the rates and hospitalizations for graft rejection after renal transplantation, but rates and hospitalizations for bacterial and viral infections seem to be unchanged or increasing.[53,143,185] Prednisone-free maintenance immunosuppressive combinations with tacrolimus, mycophenolate mofetil, and sirolimus help maintain graft function, but they also may increase the risk for development of post-transplantation lymphoproliferative disorders (PTLD) and invasive fungal diseases.[104]

These infections can be managed successfully if detected early and treated appropriately.[104] This chapter presents a general approach to renal transplant recipients from the perspective of the infectious disease specialist. Specific, detailed information regarding the diagnosis and management of each particular pathogen can be found in the respective chapters in the section of this textbook dedicated to infections with specific microorganisms.

PRE-TRANSPLANT EVALUATION

The role of the pediatric infectious disease specialist in the care of a renal transplant recipient ideally begins during the pre-transplantation period.[168,169] Before the patient undergoes transplantation, a thorough history and physical examination should be performed, with a focus on evaluation for evidence of an active infection that may require immediate therapy or, rarely, preclude transplantation (Table 84–1). The history should be comprehensive but focus on the details of any history of previous infections that may re-emerge during the post-transplant period, including urinary tract infections (UTIs); mucocutaneous diseases such as herpes simplex virus (HSV); systemic illnesses such as tuberculosis; chronic infections such as hepatitis B virus (HBV), hepatitis C virus (HCV), or human immunodeficiency virus (HIV); and diarrheal diseases. Infection with HIV previously was regarded as a reason to exclude a potential recipient from undergoing rental transplantation. More recent successes with highly active antiretroviral therapy have improved long-term survival in HIV-infected pediatric patients, however, and have led clinicians, research scientists, and family members themselves to investigate the role of renal transplantation as a treatment for ESRD.[60,167]

Renal transplant candidates undergo peritoneal dialysis or hemodialysis, so a history of previous dialysis catheter–associated infections should be documented, and any current infection should be treated and eliminated before transplantation is performed. Another focus of the history should include an exposure history for the patient's country of origin or foreign travel, especially to areas endemic for organisms such as *Strongyloides stercoralis*, *Coccidioides immitis*, *Blastomyces dermatitidis*, or *Histoplasma capsulatum* and for diseases such as malaria and tuberculosis.[87,185] Other important exposures include blood product transfusions; exposure to animals or plants; well water as a source of drinking water; and dietary habits, especially consumption of raw or undercooked eggs or meat or unpasteurized dairy products.[168,169]

TABLE 84–1 Guidelines for Pre-transplant Evaluation in Pediatric Kidney Transplant Candidates

History
Past infectious diseases
Routine childhood illnesses
Travel to, birth or residence in areas endemic for fungal or parasitic diseases
Tuberculosis exposure
Animal exposure
Diet preferences and water resources
Vaccinations
Reactions or allergies to antimicrobials
Current or past immunosuppression
Physical
Search for active or latent focus of infection
Nutritional status
Laboratory and Other Testing
PPD
Chest radiograph
Urinalysis and urine culture
Viral serology for HSV, CMV, EBV, VZV, human *Erythrovirus* (human parvovirus B19), HAV, HBV, HCV, HIV, BK virus, WNV, and others depending on the history
Baseline HSV, CMV and EBV DNA PCR or CMV antigenemia, parvovirus B19, HCV, BK virus if seropositive or post-transplant monitoring is anticipated
Fungal and parasitic testing if travel or exposure history positive; sputum or stool tests as indicated
Anticipatory Guidance
Update vaccines
Counsel regarding measures to reduce infection risk
Consider antimicrobial prophylaxis if at risk

CMV, cytomegalovirus; EBV, Epstein-Barr virus; HAV, hepatitis A virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HSV, herpes simplex virus; PCR, polymerase chain reaction; PPD, purified protein derivative; VZV, varicella-zoster virus; WNV, West Nile virus.

In children, a careful history of routine childhood illnesses, including varicella, measles, mumps, and rubella, should be documented.[107]

The immunization history of the patient should be documented carefully and, if needed or indicated, updated before the patient undergoes transplantation. Ideally, children with chronic renal disease should be fully immunized before progression to ESRD, for optimal immune response and protection during outbreaks of vaccine-preventable diseases.[41] Vaccinations against tetanus, pertussis, and diphtheria; polysaccharide vaccines, such as those against pneumococcus and *Haemophilus influenzae* type B; inactivated vaccines against polio and hepatitis A; and recombinant vaccines, such as those for hepatitis B, may be given or updated at any time before transplantation is performed.[28,208,220] Meningococcal vaccine is indicated routinely now for specific age groups and for special outbreak situations. The live varicella vaccine is recommended for renal transplant candidates who have not had varicella; it should be given at least 2 to 4 weeks before transplantation is performed.[238] Measles, mumps, rubella vaccine should be administered even earlier, preferably months before the patient undergoes transplantation. In addition, annual influenza vaccine and a tetanus booster every 10 years are recommended for patients who are renal transplant candidates or recipients.

If the child is unable to be fully immunized before undergoing transplantation, the routine immunization schedule for the inactivated vaccines may be reinstituted after immunosuppression is decreased, approximately 6 to 12 months after an uncomplicated transplant procedure.[28,208,220] Live virus vaccines should be avoided in the post-transplant period in most instances. Reports of safe and effective vaccination with varicella vaccine in selected post-transplant patients have been published, however.[26,34,71,161,162] Close contacts and family members of renal transplant candidates and recipients also should be fully immunized and should receive the annual influenza vaccine.[10] Other important points in the pre-transplant evaluation history include allergies or reactions to medications, especially antibiotics, and the use of immunosuppressive agents.

Pre-transplant laboratory and diagnostic imaging evaluations for most renal transplant candidates should include a tuberculin skin test, chest radiograph, urinalysis, and urine culture for bacteria. Baseline renal and liver function tests also should be performed.

Serologic screening of the transplant recipient's status regarding organisms that may reactivate in the recipient or infect the recipient via the donor organ should be performed; such screening should include tests for HSV; cytomegalovirus (CMV); varicella-zoster virus (VZV); Epstein-Barr virus (EBV); human *Erythrovirus* (human parvovirus B19); syphilis; toxoplasmosis; hepatitis A, B, and C viruses; and HIV. Transplant recipients who are seropositive for HSV or CMV usually receive antiviral prophylaxis during the peritransplant period, whereas recipients seropositive for EBV may undergo post-transplant monitoring. It may be helpful to save an aliquot of the recipient's (and donor's) serum in case unusual circumstances occur, such as infection with West Nile virus (WNV). In CMV-seropositive transplant candidates, baseline CMV antigenemia or quantitative DNA polymerase chain reaction (PCR) may be useful, and in EBV-seropositive candidates, detection of EBV DNA by quantitative PCR may be helpful to document pre-transplant viral load, especially if post-transplant virologic monitoring is to be performed. Other laboratory tests or imaging studies may be useful, depending on the patient's exposure history and physical examination.

The pre-transplant evaluation also is an opportunity for the infectious disease specialist to counsel the patient and family about measures that may reduce the transplant recipient's risk for development of infectious disease complications post-transplant. Patients who have an exposure, or even a suspected exposure, to varicella (chickenpox) or zoster (shingles) should contact their physicians immediately to see whether passive immunoprophylaxis with varicella-zoster immunoglobulin or post-exposure antiviral therapy with acyclovir or valacyclovir is indicated. Plans for foreign travel to remote areas also should be discussed with the physician. The transplant recipient should consume only thoroughly cooked meat and seafood and thoroughly washed fresh fruits and vegetables. In addition, drinking water should be pure. Transplant recipients should avoid, if possible, changing cat litter boxes, aquariums, and birdcages and should avoid close contact with people who have viral respiratory illnesses. Finally, medical attention should be sought if fever occurs, especially if it is significant or persistent.

POST-TRANSPLANT INFECTIOUS COMPLICATIONS

Infections occurring in the post-transplant period can be grouped into three main time frames: the first month post-transplant (early), 2 to 6 months post-transplant (middle), and 6 months post-transplant and onward (late).[187,204] Although almost any organism or pathogen can infect a transplant recipient at any time, these time periods provide the clinician with a guide to the organisms and disease processes most commonly encountered (Table 84–2).

INFECTIONS OCCURRING DURING THE EARLY POST-TRANSPLANT PERIOD

Infections occurring during the first month after renal transplantation has been performed usually are bacterial.[193] Common sites of early infections include the wound, urinary tract, lungs, and indwelling intravascular catheters.[174]

Wound Infections

As with any surgical procedure, wound infections may develop in a renal transplant recipient. They occur in approximately 2 percent of renal transplant recipients and range in severity from a superficial wound infection, easily treated with wound care and antimicrobial therapy, to deep perinephric abscesses that may be difficult to treat and result in transplant nephrectomy.[188,193] Wound infections are more likely to occur in patients with technical problems associated with the transplant surgery, including urinary leaks, vesicoureteral reflux, wound hematomas, or lymphoceles.[148,239] Malnutrition during the pre-transplant period may impair wound healing and predispose the patient to development of wound infection.

Open Penrose drains may increase the likelihood of introducing microorganisms into the wound, whereas closed suction drainage, such as with a Jackson-Pratt drain, may reduce this risk. In addition, prompt removal of all drains, usually within 5 days in most uncomplicated cases, and administration of prophylaxis with perioperative antibiotics may decrease the incidence of wound infections; such measures are performed routinely in most renal transplant centers. The regimen usually is aimed at uropathogens and staphylococci. One dose generally is given pre-transplant, and the regimen is continued for only 24 hours post-transplant.

The diagnosis of a wound infection should be suspected if erythema, warmth, or discharge is present at the wound site or if an unexplained fever develops. Fluid may drain from the wound persistently, or a fluid collection or abscess may be seen on imaging of the deeper operative sites. The patient will be receiving immunosuppressive agents, however, and the findings may be unusual, or the symptoms may be blunted. Any fluid or pus

TABLE 84–2 Timetable for the Occurrence of Common Infections and Usual Pathogens after Kidney Transplantation

Early Period
Wound infections
UTI
Bacteremia and sepsis syndrome
Pneumonia
HSV
HBV

HIV/AIDS

AIDS, acquired immunodeficiency syndrome; CMV, cytomegalovirus; EBV, Epstein-Barr virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HHV, human herpesvirus; HIV, human immunodeficiency virus; HSV, herpes simplex virus; UTI, urinary tract infection; VZV, varicella-zoster virus; WNV, West Nile virus.

obtained should be stained and cultured for bacterial, mycobacterial, and fungal organisms. Organisms most likely to be identified as causes of wound infection include staphylococci (*Staphylococcus aureus*, especially methicillin-resistant *S. aureus*, but also coagulase-negative staphylococci), streptococci, and gram-negative enteric organisms. Unusual, multidrug-resistant, or health care–associated bacterial pathogens and yeast, such as *Candida albicans*, also may cause wound infections post-transplant. In addition, case reports of wound and perinephric fluid collections infected with *Mycoplasma hominis* have been published.[206]

Appropriate antimicrobial therapy, initially broad-spectrum and then ultimately tailored to the isolated organism and its susceptibility pattern, should be administered. The duration of appropriate antimicrobial therapy usually is 10 to 14 days, or until the wound infection has resolved and the patient has been afebrile for 3 to 5 days. Deep abscesses or unusual organisms may require longer therapy.

Urinary Tract Infections

UTIs are common developments after renal transplantation and may affect 35 to 79 percent of renal transplant recipients.[116,239] Post-transplant UTIs are associated with acute and chronic graft dysfunction and may threaten renal graft survival.[2,11,30,48,106,151,213] They may occur during the early, middle, or late post-transplant period. A UTI that occurs during the early or early/middle post-transplant period often is a severe illness complicated by pyelonephritis, urosepsis, metastatic foci of infection, allograft dysfunction, rejection, and relapse.[152,189] UTIs occurring in the early post-transplant period are associated more often with graft loss than are UTIs that occur later.[48]

The risk for developing an invasive UTI after undergoing renal transplantation seems to be increased in patients with prolonged bladder catheterization (most catheters can be removed during the first few days post-transplant), dysfunctional bladder, ureterovesical disorders with reflux, malnutrition, underlying disorders, renal stones, obstructive uropathy, or a contaminated cadaveric kidney.[2,168] Surgical complications, such as hematoma, reflux, or obstruction at the urinary anastomosis, or inability of the bladder to empty completely are associated with UTIs. In addition, young infants, especially infants who have vesicoureteral reflux, seem to have a high incidence of complicated UTIs post-transplant.[152] Procedures that address the etiology and correct underlying physiologic and anatomic abnormalities of the bladder and ureters should be performed before transplantation to avoid or lessen development of complications associated with these problems.[2,11,30,213] Newer surgical techniques allow children with reconstructed bladders to undergo successful renal transplantation with minimal risk for post-transplant development of UTIs.[148,189]

The organisms most commonly isolated from patients with early-onset UTIs include not only the typical gram-negative enteric bacteria, but also enterococci, staphylococci, and *Pseudomonas aeruginosa*. Unusual organisms, such as *Streptococcus mitis*, *Serratia marcescens*, and *Corynebacterium urealyticum*, also can be found. Antimicrobial therapy should be tailored to the susceptibility pattern of the organism isolated from the urine. Because 30 percent of patients experiencing a UTI during the early post-transplant period may have recurrent UTIs, a prolonged 6-week course of antibiotics usually is recommended to reduce the risk of developing a relapsing kidney infection.[148,189] Antimicrobial prophylaxis may reduce the risk of developing a UTI. Trimethoprim-sulfamethoxazole administered for the first 4 months after renal transplantation is effective in preventing most UTIs and can provide cross-cover prophylaxis against *Pneumocystis carinii* pneumonia and other diseases.[69]

Pneumonia

Pneumonia can occur during the first month after renal transplantation and often is associated with prolonged endotracheal intubation. Gram-positive and gram-negative bacterial pathogens acquired from normal oropharyngeal flora and unusual or health care–associated multidrug-resistant organisms predominate during the early post-transplant period.[169] *Legionella pneumophila* and unusual *Legionella* spp., such as *Legionella micdadei*, *Legionella bozemanae*, and *Legionella dumoffii*, also have caused outbreaks of serious, life-threatening pneumonia in transplant recipients in some centers.[29,39,115,169] *P. carinii* can cause pneumonia in a transplant recipient during the early post-transplant period, but more often it is associated with disease after the first month post-transplant.[89] Rare or unusual pathogens, such as *Rhodococcus equi*, may cause pneumonia in these patients.[128]

Patients with pneumonia usually present with fever, chills, chest pain, malaise, change in tracheal secretions, cough, dyspnea, tachypnea, change in ventilatory status, rales or rhonchi on auscultation of the lungs, and pulmonary infiltrates on chest radiograph. Pneumonia may be complicated by pleural effusion, empyema, or pulmonary abscess, and death may occur if pneumonia is severe and not diagnosed and treated promptly.

Treatment with antibiotics effective against the bacterial pathogens isolated from culture of tracheal aspirates, bronchoalveolar lavage fluid, or lung tissue is appropriate.

Bacteremia, Fungemia, and Sepsis

Bacteremia, fungemia, and sepsis occurring during the early post-transplant period often are associated with indwelling catheters.[167] The urinary tract, surgical wound, or transplanted or native kidney also may be a source.[138] Usual bacterial organisms such as coagulase-negative staphylococci or *S. aureus*, unusual bacterial organisms, and yeasts such as *C. albicans* and other *Candida* spp. may be involved. *Listeria monocytogenes* also may cause primary bacteremia or sepsis at any time after a kidney transplantation has been performed, but the greatest risk occurs during the early period. Complications include meningitis, and 10 percent of these patients may die.[150,199] Renal transplant recipients also are at increased risk for development of bacteremia with *Salmonella* nontyphoidal species.[47,100,167]

Complications such as UTI, graft infection, peritonitis, abscesses, and meningitis can occur, and recurrences are common. Therapy for bacteremia, sepsis, or its complications is tailored to the susceptibility pattern of the organism isolated from the patient's blood. The duration of therapy for uncomplicated bacteremia usually is 10 to 14 days, but a longer course of treatment may be indicated if abscesses occur or an unusual organism is isolated. Removal of the indwelling catheter may be necessary to clear persistent bacteremia, and abscesses and other foci of infection should be drained.

Other Bacterial Diseases

Pediatric renal transplant recipients also seem to be at increased risk for development of antibiotic-associated colitis caused by *Clostridium difficile*.[232] Infection of a lymphocele with *Pasteurella multocida* has been reported, as has systemic infection with *Bartonella henselae*.[3,37,52,132,167] A high index of suspicion always must be maintained when evaluating a transplant recipient for infection because the immunosuppression required to maintain the transplanted kidney predisposes the recipient to development of infection with unusual organisms.

Viral Infections

HERPES SIMPLEX VIRUS

HSV is the most common virus encountered during the early post-transplant period, although antiviral prophylaxis significantly reduces the risk of this infection.[56,57] It occurs less frequently in pediatric (8%) than in adult renal transplant recipients (30%).[167,168] Most HSV infections encountered post-transplant are due to reactivation of the recipient's strain; however, primary or recurrent infection acquired from the renal allograft may occur, and primary infection from person-to-person transmission has been documented.[56,167,168,189]

Post-transplant HSV infection may be asymptomatic or associated with disease, most frequently oral ulcers in pediatric patients.[83] Genital and perianal ulcers may occur in adolescents and adults. Rarely, HSV may cause disseminated cutaneous lesions or zosteriform eruptions. HSV esophagitis may be manifested as dysphagia, refusal to eat, irritability, and substernal chest pain, and it may complicate oral HSV disease, especially if the oral mucosa has been traumatized by orogastric or nasogastric tubes. Acute, severe hepatitis with hepatic necrosis, often accompanied by hypotension and disseminated intravascular coagulation, also can occur. Tracheobronchitis and pneumonitis may occur as a result of HSV, primarily in patients with pneumonia caused by another pathogen and whose mucosa has been traumatized by endotracheal intubation. It is often severe and life-threatening, even with appropriate supportive care and antiviral therapy.[167] Encephalitis also has been reported in renal transplant recipients.[79]

The diagnosis is made by isolation of HSV in cell culture or detection of viral antigen by immunofluorescence or viral DNA by PCR in the end-organ involved. Detection or isolation of HSV in body secretions may represent asymptomatic shedding or disease and should be correlated clinically. Treatment with acyclovir is recommended for patients with disease, and HSV-seropositive transplant recipients should receive acyclovir or valacyclovir prophylaxis during the peritransplant period to prevent development of HSV infection. Most patients receiving ganciclovir, valganciclovir, foscarnet, or cidofovir for CMV prophylaxis also are protected against HSV.

OTHER VIRUSES

Seasonal viruses, especially winter respiratory viruses such as respiratory syncytial virus, influenza viruses, parainfluenza viruses, and adenoviruses; winter diarrhea viruses, such as rotavirus; and late summer/early fall viruses, such as the enteroviruses, can infect the transplant recipient during the early post-transplant period and cause disease. Such infections may be acquired from the family or the community, or they may occur from health care-associated exposures. The illness associated with these viruses typically is not as severe as the illness seen with the herpes family of viruses or adenoviruses.

Renal transplant recipients who are chronically infected with HBV or HCV may experience liver dysfunction during the early transplant period, but the late post-transplant period, beyond the first year, carries the greatest risk for progression of liver disease to cirrhosis. If a renal transplant recipient acquires HBV soon after undergoing transplantation, acute hepatitis can develop, often with death from liver failure.[46,167]

Non-infectious Causes of Fever

The most common non-infectious cause of fever in the first post-transplant month is allograft rejection.[188] Fever often is the first sign of rejection, especially in children, and rejection should be considered if an infectious source of the fever is not identified. Another common non-infectious cause of fever early after transplantation is antilymphocyte antibody therapy (OKT3). The first two or three doses of OKT3 produce a release of cytokines, which cause fever and chills. In most patients, these symptoms resolve after the third dose. Other non-infectious causes of fever during this period include drug reactions and pulmonary emboli.

INFECTIONS OCCURRING DURING THE MIDDLE POST-TRANSPLANT PERIOD

The cumulative effects of immunosuppression begin to be revealed during the period 2 to 6 months after transplantation. If a significant amount of antirejection therapy is required for multiple episodes of rejection, the effects may be more pronounced. Such immunosuppression allows classic opportunistic pathogens, such as CMV, *P. carinii*, *Toxoplasma gondii*, *L. monocytogenes*, *Aspergillus*, and *Nocardia*, to evade immune surveillance and cause disease.[89,167,231,233] Reactivation of organisms previously infecting the transplant recipient or the donor allograft, including *Mycobacterium tuberculosis*, HBV, HCV, HIV, *H. capsulatum*, and *C. immitis*, also may cause disease. In addition, an occult bacterial focus of infection that was not adequately identified and treated pre-transplant may become apparent at this time and cause significant disease.[188]

Herpesviruses

The herpes family of viruses (HSV types 1 and 2, CMV, EBV, VZV, and human herpesvirus [HHV] types 6, 7, and 8) share the biologic properties of latency, reactivation, cell association, and oncogenicity, which renders them the most important group of pathogens that affect renal transplant recipients.[167,194] HSV is more important during the early post-transplant period, whereas the other herpes family members are important causes of morbidity and mortality during the middle and late post-transplant periods.[90]

CYTOMEGALOVIRUS

CMV may cause primary infection in a CMV-seronegative transplant recipient through a renal allograft or blood product transfusion from a seropositive donor.[16,45,186] Person-to-person transmission within the family or close community also is possible. Recurrent CMV infection develops in seropositive transplant recipients if the recipient's CMV strain becomes reactivated. The renal allograft from a seropositive donor also can be a source of re-infection to the recipient and produce active CMV infection or disease.[36,84] CMV infection in renal transplant recipients may cause silent or asymptomatic infection; end-organ diseases such as hepatitis, esophagitis, colitis, encephalitis, vasculitis, and retinitis; and systematic disease with persistent fever and leukopenia. A case report also linked CMV infection with post-transplant occurrence of atypical hemolytic-uremic syndrome that resolved with plasma exchange and ganciclovir antiviral therapy.[160] It has been linked in some studies to allograft dysfunction and nephropathy.

CMV also causes depressed cell-mediated immunity and impaired alveolar macrophage function, rendering the host more vulnerable to other opportunistic infections, such as fungal disease and *P. carinii* pneumonia, and it serves as a cofactor for other viruses, such as EBV and HHV-6 and HHV-7.[111,163,175,216,217] In addition, CMV is associated with acute and chronic rejection and allograft nephropathy and decreased long-term patient survival.[1,58,121,167,186]

Disease caused by CMV can be documented by isolation of CMV from blood or tissue; detection of CMV antigen pp65 in circulating leukocytes; or detection of CMV DNA by PCR or similar assays in blood, bronchoalveolar fluid, or tissue.[21,22,171,176,186] Isolation of CMV in urine or saliva documents active infection but has little significance in predicting disease; serologic tests may document seroconversion in primary infections but generally should be reserved for pre-transplant screening only. Most transplant patients at risk for acquiring CMV disease (i.e., CMV-seropositive recipients [D^+/R^+] or CMV-seronegative recipients [D^+/R^-] who received a renal allograft from a seropositive donor) should be monitored by viral surveillance, usually by testing blood weekly for CMV antigen pp65 or for CMV DNA by PCR.[20,94]

Detection of significant levels of the virus by quantitative or semiquantitative assay, or an increase from baseline levels, usually predicts CMV disease.[217] Reduction of immunosuppression, along with preemptive antiviral therapy, generally is indicated and results in a decrease or resolution of CMV levels detected in blood.[7,22,40,43,77,81,129] Despite receiving adequate antiviral therapy, some patients have persistently positive CMV DNA by PCR, however, which should be interpreted within the clinical context.[21] In some patients who otherwise appear well, the DNA may be fragmented and nonreplicating, whereas in other patients with persistent symptoms, a strain of CMV resistant to one or more antiviral agents may be the cause.

The antiviral agents currently available for the treatment of CMV disease and preemptive therapy for positive CMV markers include ganciclovir, valganciclovir, foscarnet, and cidofovir.[230] For renal transplant patients with moderate to severe CMV-associated disease, 2 to 3 weeks of therapy with intravenous ganciclovir usually is adequate to treat disease; however, patients with CMV retinitis or repeat episodes of rejection may require maintenance therapy, usually with oral ganciclovir or valganciclovir.[101,134,153] Asymptomatic or mild CMV infections may respond to oral ganciclovir or valganciclovir administered for 1 to 3 months.[135,149] Preemptive therapy should be continued throughout the period of immunosuppression in patients who are severely immunosuppressed and at risk for development of CMV disease and recurrence (D^+/R^-).[81,94,135,149] Foscarnet and cidofovir have significant renal toxicity and should be used with extreme caution in renal transplant recipients. Prophylaxis for CMV disease is indicated in high-risk transplant recipients (D^+/R^-); options include intravenous CMV immune globulin, oral and intravenous acyclovir and ganciclovir, and oral valacyclovir and valganciclovir.[25,66,77,124,153,198,205,226]

EPSTEIN-BARR VIRUS

EBV infection in children who have received a renal transplant may be asymptomatic or may be associated with a variety of different syndromes, including a nonspecific viral syndrome, mononucleosis, smooth muscle tumors (leiomyoma), post-transplant PTLD, and lymphoma.[23,24,54,86,88,96] Infection and disease may occur after primary and recurrent EBV infection, but primary infection is more likely to occur and produce PTLD in younger children than in adults who have received solid organ transplants.[35,96] EBV disease may affect 10 percent of pediatric renal transplant recipients and may develop 1 month to 5 or more years post-transplant, with the risk accumulating every year of post-transplant survival.[50,200]

Knowledge about post-transplant EBV infection and disease is evolving; as graft survival has improved, with more intense immunosuppressive regimens that preserve graft function, and other opportunistic infections such as HSV, CMV, and *P. carinii* being successfully managed, EBV has emerged as a formidable obstacle to successful solid organ transplantation in children.[23,49,51,54,86,109,200] The estimated overall risk for development of serious life-threatening EBV-associated illness is at least 4 percent and increases to 10 percent in children who experience a primary infection with EBV after undergoing renal transplantation.[49,96] Other risk factors for PTLD in children who have received solid organ transplants include receipt of antilymphocyte therapy such as OKT3 for rejection; receipt of tacrolimus, sirolimus, or mycophenolate mofetil, rather than cyclosporine, for immunosuppression; and CMV or EBV donor/recipient (D^+/R^-) mismatch.[51,103,104]

Nonspecific viral syndromes and mononucleosis occur during the earlier post-transplant period, whereas lymphoma and leiomyoma are more likely to be a manifestation during the late post-transplant period.[25,54,70,86] Uncomplicated post-transplant mononucleosis is characterized by the self-limited illness of fever, pharyngitis, cervical adenopathy, and splenomegaly. The signs and symptoms of PTLD vary but often include persistent fever, weight loss, and generalized adenopathy.[96] The disease frequently is multisystemic and progressive, and involvement of the neck, chest, lungs, gastrointestinal tract, liver, spleen, eyes, and brain, as well as lesions, may be detected by computed tomography of the head, neck, chest, and abdomen.[4,5,168,195] The renal allograft also may be involved and show dysfunction. Lymphoma may be manifested as solid tumors in the renal allograft, lung, liver, spleen, brain, and soft tissues.[70,88] Smooth muscle tumors (leiomyoma) frequently are multicentric and multifocal; they often occur in lung, liver, and spleen but also may occur in unusual locations, including the brain and renal allograft.[23,86,95]

Laboratory diagnosis of post-transplant, EBV-associated disease is based on detection by PCR of EBV DNA in circulating lymphocytes.[5,43,62] Quantitative or semiquantitative PCR assays

may show increasing or persistently high copies of EBV DNA in the circulating lymphocytes of patients who are at risk for developing PTLD.[5,85,184] If end-organ disease is observed, the diagnosis can be confirmed histopathologically by detection by PCR of EBV DNA in tissue or by in situ hybridization with an EBV-encoded RNA probe.[4,217]

The diseases associated with EBV also may be classified in the laboratory as polyclonal or monoclonal. Polyclonal illnesses seem to be more benign than are monoclonal diseases, which often are associated with chromosomal abnormalities and malignant transformation.[168] The virus cannot be cultivated by routine means; when studied by special culture techniques, EBV has been found frequently in the oropharyngeal secretions of seropositive transplant recipients and is not predictive of EBV-associated disease.[168,184] Similarly, serologic approaches to establishing the diagnosis of EBV infection post-transplant also are nonspecific and difficult to interpret in most patients, unless the recipient clearly has seroconverted during the post-transplant period.

Aggressive or intense treatment of uncomplicated EBV-associated viral syndrome or mononucleosis usually is unnecessary because these illnesses seem to be self-limited in most patients. Immunosuppression may be reduced, and acyclovir may be administered; the patient should be monitored carefully. If symptoms in the patient or EBV DNA levels in the blood persist or increase, PTLD should be suspected, and the diagnosis should be confirmed.[211,218]

Treatment of established PTLD is challenging.[82] Mortality rates are high, and the best results seem to occur if the disease is diagnosed by quantitative PCR viral-load monitoring and serial imaging studies and treated aggressively.[217] Preemptive therapy instituted when viral surveillance monitoring detects an increase in EBV DNA in circulating lymphocytes before end-organ disease is evident also may be helpful in some patients.[43,134] Reduction in immunosuppression remains the most widely recommended strategy, but a variety of regimens have been studied as well.

Antiviral agents such as acyclovir and ganciclovir seem to reduce EBV replication early in the course of the disease process and may halt the progression of disease in some patients.[51,169,230] Antiviral agents are ineffective, however, against latent EBV or cells that have been transformed by the virus. Interferon-α, immunoglobulin, and anti–CD20 monoclonal antibody preparations such as rituximab have been used successfully in patients with established PTLD. Experimental protocols evaluating adoptive immunotherapy in transplant recipients are under way. In addition, some experts suggest that administration of intense anti-CMV therapy with ganciclovir and CMV hyperimmune globulin may improve chances of survival in certain patients with PTLD because CMV may serve as a cofactor in progression of disease caused by other members of the herpes family.[1,16,24,163,203,216] Treatment of patients with lymphoma or leiomyoma includes a reduction in immunosuppression, chemotherapy, radiation therapy, and surgical resection of tumors.

VARICELLA-ZOSTER VIRUS

VZV can cause primary (varicella, chickenpox) or reactivation (zoster, shingles) disease in a renal transplant recipient.[168,204] Infection with VZV can occur at any time but does so most often during the middle post-transplant period. Patients present with fever and painful or pruritic vesicular skin lesions.[153] Hepatitis, encephalitis, acute or chronic recurrent cerebral vasculitis and vasculopathy, and pneumonia also may occur, even in the absence of skin lesions, especially in an immunocompromised host.[97] Varicella occurs more frequently in children, and zoster occurs more frequently in adolescent and adult transplant recipients.[35]

In contrast to other herpes family viruses, VZV almost always is transmitted person-to-person or by aerosol in health care, family, and community settings; it rarely, if ever, has been linked to the transplanted allograft.[141,168] Before the advent of routine immunization and antiviral therapy, infection with VZV was a major cause of morbidity and mortality in children receiving solid organ transplants.[35,64,189] Untreated primary varicella may continue for several weeks and result in visceral dissemination, pneumonitis, hepatic necrosis, encephalitis, vasculitis with stroke, disseminated intravascular coagulation, hemorrhagic skin lesions, and death.[64,169,194] Zoster in solid organ transplant recipients may remain localized to a dermatome, but it often disseminates beyond the dermatomal distribution and produces widespread skin lesions and even visceral dissemination.

The diagnosis of VZV disease often is clinical, but it should be confirmed by isolation of VZV from fresh, vesicular skin lesions or detection of viral antigen by direct immunofluorescence assay on cells obtained by scraping the base of the skin lesion.[169] Tzanck smear may show multinucleated giant cells, suggesting a viral infection, but it cannot differentiate VZV from HSV. Other pathogens, especially HSV, may mimic VZV disease, so establishing an accurate viral diagnosis is important. VZV also may be detected by PCR-based DNA detection methods, which also may distinguish wild-type strains from OKA vaccine strain of VZV; VZV PCR tests may be performed by reference and research laboratories. Establishing a serologic diagnosis of active VZV infection is difficult. Routine serologic screening performed in the pre-transplant period identifies patients who are seronegative and at risk for developing primary infection with VZV.

Treatment of established VZV disease should be instituted as early as possible during the course of the illness because survival is improved if treatment begins before the fifth day of illness.[64] Acyclovir is recommended for most renal transplant recipients experiencing either primary infection with varicella or zoster with dissemination; it is administered intravenously in high doses (500 mg/m^2 per dose every 8 hours if renal function is normal or adjusted for renal function as needed) for 5 to 10 days, or until new lesions have ceased to occur for 24 to 48 hours, old lesions have crusted, the fever has resolved, and disease has abated.[26,161,168,230] Uncomplicated zoster or very mild primary varicella may be treated with oral acyclovir, famciclovir, or valacyclovir, provided that the patient is monitored carefully for clinical response. Ganciclovir, foscarnet, or cidofovir also provide cross-cover protection for most VZV strains, if these antiviral agents are being administered for difficult CMV infections.

Prevention of post-transplant VZV disease can be accomplished by several effective strategies, which should be discussed during the pre-transplant evaluation. Transplant recipients who were seronegative for VZV during the pre-transplant evaluation should receive varicella vaccine before undergoing transplantation, if possible.[71,112,238] Pre-transplant varicella vaccination is safe, beneficial, and cost-effective when administered to pediatric renal transplant candidates and in selected renal transplant recipients post-transplant.[26,34,71,72,161]

Seronegative, unimmunized transplant recipients who are exposed to varicella or zoster during the post-transplant period should receive passive immunoprophylaxis with varicella-zoster immunoglobulin. Preemptive therapy with oral acyclovir also is recommended by some experts in this situation because varicella-zoster immunoglobulin does not prevent, but only attenuates, the postexposure disease process. Finally, acyclovir, valacyclovir, ganciclovir, and valganciclovir administered prophylactically to transplant recipients who are seropositive for HSV or CMV also may provide protection against VZV disease.[124,168]

HUMAN HERPESVIRUSES 6, 7, AND 8

HHV-6, HHV-7, and HHV-8 also infect renal transplant recipients by primary infection and by reactivation.[32,33,37,61,92,187,188,203] Infection with these viruses becomes evident during the middle

post-transplant period, but their roles in specific disease processes are unclear.[169,197,212] HHV-6 and HHV-7 may act as cofactors in the progression of a disease, especially diseases caused by CMV and EBV.[61,111,153,163,216] HHV-8 is associated with Kaposi sarcoma post-transplant in severely immunosuppressed adult renal transplant recipients, but it has not been appreciated as a major opportunistic pathogen in pediatric renal transplant recipients to date.[32,35,63,168,181,193] HHV-8 may be transmitted through the renal allograft or by blood product transfusion, or it can become reactivated in the recipient post-transplant.[181]

Polyomaviruses and Papillomaviruses

POLYOMAVIRUSES

Human polyomaviruses (JC, BK, and SV40) frequently infect children and are present in urine and stool.[224,225] They can be detected in the urine of 33 to 58 percent of renal transplant recipients and detected serologically in 56 percent, and they are found histopathologically and by PCR in blood, body fluids, and tissue in 8 to 13 percent.* Knowledge about the roles that these viruses play in the outcome of renal transplant patients is evolving.

The JC and BK polyomaviruses seem to have a significant impact on adult and pediatric renal transplant recipients.[18,73,133,154-156,182,190] BK virus has been implicated in various syndromes, including ureteral stenosis, hemorrhagic or chronic cystitis, interstitial nephritis with graft failure, allograft nephropathy (BK-associated nephropathy [BKAN]), and rejection, in renal transplant recipients.[18,38,95,98,155,166,176,188,190] Disease associated with these viruses most often occurs during the middle and late post-transplant periods. BK virus may be asymptomatic or cause increasing serum creatinine levels, cystitis, tubular necrosis, graft dysfunction, or allograft rejection.[179] Risk factors for BKAN seem to include BK serostatus at the time of transplant, greater immunosuppression with use of mycophenolate mofetil, and concurrent CMV infection.[59,75,76,91,127]

BK virus often is detected in urine by the presence of "decoy cells," which are cells containing intranuclear viral inclusions, or more recently by quantitative PCR assays that detect and quantify BK viral DNA. BK viruria precedes BK viremia, which precedes BK nephropathy.[93] Patients with BK-associated nephropathy may have BK viral DNA detected in the urine, blood, or plasma, and renal biopsy specimens may show characteristic viral inclusions. Most recently, quantitative PCR viral surveillance in blood or plasma has been shown in renal transplant recipients to be useful in predicting the development of BK nephropathy and in guiding preemptive antiviral and immunosuppressive strategies.

Pediatric kidney transplant recipients who have increasing BK viremia levels should be managed preemptively with carefully monitored reduction of immunosuppression to prevent development of more serious complications of BKAN and graft rejection. This strategy usually results in reduction and then clearance of BK viremia and development of BK-specific cellular immunity coincident with BK virus clearance.[127] Treatment of established BKAN includes a reduction in immunosuppression. Cidofovir has activity against BK virus and has been used anecdotally to treat severe disease caused by BKAN.[93,230]

JC virus causes a rare syndrome called *progressive multifocal leukoencephalopathy*. It may be diagnosed by viral DNA detection using PCR-based assays available in reference and research laboratories or histopathologically by brain biopsy or autopsy examination. Successful treatment options for progressive multifocal leukoencephalopathy caused by JC virus are very limited, and most, if not all, patients die of progressive encephalopathy.

PAPILLOMAVIRUSES

Human papillomaviruses are common viruses that infect healthy children, adolescents, and adults. Adult renal transplant recipients are at increased risk for development of human papillomavirus–associated disease, such as cervical cancer and anogenital papillomas, whereas pediatric patients may develop numerous disfiguring warts post-transplant, especially if they require severe immunosuppression.[158,168,188] Malignant transformation of cutaneous warts caused by high-risk types has been documented.[188] Treatment options are limited but include physical removal of papillomas with laser and cryotherapy and careful reduction of immunosuppression. Information on the use of human papillomavirus vaccines in patients with ESRD or renal transplant recipients has not been published at this time.

Adenoviruses

Adenoviruses may infect pediatric renal transplant recipients at any time, but they are most likely to cause significant disease during the middle post-transplant period. They continue to emerge as a significant pathogen in pediatrics, including transplant recipients. They do not seem to play as important a role in renal transplant outcome, however, as do other viruses, such as the herpes family of viruses, and they currently are not as prominent in renal transplant recipients as they are in other transplant recipients, such as recipients of liver, lung, bone marrow, or stem cell transplants.[80,137,159,168,169] Nonetheless, infections with adenoviruses in pediatric renal transplant recipients, when they occur, can be serious and include hemorrhagic cystitis, diarrhea, allograft nephropathy, pneumonia, hepatitis, and disseminated disease with multisystemic involvement.[19,110,188,214,233,235]

The diagnosis is made by isolation of the virus in respiratory secretions, stool, urine, blood, or tissue. Rapid diagnosis may be accomplished within 30 to 60 minutes, using a rapid immunochromatographic assay that detects adenovirus antigens in eye secretions, respiratory samples, urine, and stool. Viral DNA also may be detected by PCR or quantitative PCR available in reference or research laboratories, and characteristic changes may be seen by histopathology in tissue. Adenovirus serotyping by neutralization assays and genotyping by PCR sequence-based assays are available in reference laboratories.[80] Treatment of serious adenoviral disease primarily is supportive. Immunosuppression also may be reduced, when possible. Antiviral agents, such as ribavirin, ganciclovir, and cidofovir, have activity against adenoviruses. Clinical reports of use of these agents in children with serious adenovirus disease post-transplant are published, but clinical trials documenting efficacy have not been performed.[31]

Human *Erythrovirus* (Human Parvovirus B19)

Human *Erythrovirus* (human parvovirus B19) has been reported to cause acute and chronic infection, manifesting as chronic anemia, red blood cell aplasia, and pancytopenia in renal transplant recipients.* It also has been implicated in collapsing glomerulopathy and thrombotic microangiopathy in renal transplant recipients.[228] Unusual manifestations, such as hepatic necrosis or central nervous system infection with vasculitis, also have been reported.[15,17,118,119] Transmission most likely is person-to-person; however, some reports indicate that the virus may be transmitted

*See references 6, 55, 59, 67, 68, 73, 75, 76, 91, 93, 95, 98, 127, 147, 154-156, 164, 166, 176, 177, 190, 219.

*See references 9, 14, 15, 17, 118, 126, 131, 144, 165, 209, 228, 234.

by blood product transfusion or in the renal allograft.[14,15,117] More recent reports suggest that the role that this virus plays in the outcome of renal transplant recipients may be more important than previously recognized, but systemic studies in pediatric patients have not been done.[14]

The diagnosis of acute infection with human parvovirus B19 is supported by parvovirus B19–specific IgG seroconversion; detection of parvovirus B19–specific IgM antibodies in serum; or detection of viral DNA in plasma, blood, body fluids, bone marrow, or tissue. The virus is not cultivatable in clinical virology laboratories that use routine cell cultures, but laboratories using special erythroid precursor cell lines may be able to cultivate parvovirus B19 for research purposes. No specific antiviral therapy is available, but anecdotal experience and case reports support a beneficial role for intravenous immunoglobulin and carefully monitored reduction in immunosuppression as management strategies to resolve parvovirus B19 viremia and associated end-organ disease.[149]

WEST NILE VIRUS

WNV is a single-stranded RNA flavivirus that has emerged as an important pathogen worldwide. It usually is transmitted by mosquitoes and causes a febrile illness, viral meningoencephalomyelitis, and acute flaccid paralysis in the normal host. Renal transplant recipients may become infected with WNV that is transmitted by the organ donor, by blood product transfusions, or naturally from mosquitoes.[44,102,112,180,227] Infection with WNV may manifest in the early post-transplant period if it is transmitted by the graft or blood products and, because of immunosuppression, produce severe febrile illnesses, seizures with status epilepticus, encephalitis, paralysis, and movement disorders. Death also may occur.[44] A high index of suspicion is required, and if WNV is suspected, serum and CSF should be sent for WNV-specific IgG and IgM antibody testing. The virus also may be isolated in special cell cultures and detected by reverse transcriptase PCR-based assays. Immunohistochemical staining may show WNV proteins in tissues from biopsy or autopsy examination. Outcome in renal transplant recipients with WNV disease improves with early establishment of the diagnosis and carefully managed reduction of immunosuppression.[180]

Mycoplasma

Mycoplasma spp. commonly infect school-aged children. Children and adolescents who undergo renal transplantation also may experience respiratory tract infections with *Mycoplasma pneumoniae* and *M. hominis*. The infection also may disseminate to extrapulmonary sites, causing hepatitis, septic arthritis, or perinephric fluid collections in pediatric renal transplant recipients.[108,136,206] *Mycoplasma* spp. may be detected using special biphasic culture media or PCR-based assays. Serologic diagnosis is difficult to accomplish, owing to cross-reactivity of antigens producing the possibility of false-positive reactions in some patients. Antimicrobial therapy with macrolide antibiotics, along with carefully managed reduction of immunosuppression, may be beneficial in selected patients.[108,136]

Bacterial and Mycobacterial Diseases

Bacteria that commonly produce disease in renal transplant recipients during the middle post-transplant period include *L. monocytogenes*, which often causes sepsis or meningitis.[168,199] Routine bacterial illnesses that were not identified and properly treated during the pre-transplant period also may emerge at this time and cause abscesses, sepsis syndrome, and death.

Mycobacterial disease caused by *M. tuberculosis* may occur at any time post-transplantation, but it occurs most frequently during the middle post-transplant period.[122,125,168,178] *M. tuberculosis* causes disease in approximately 1 percent of renal transplant recipients in the developed continents, such as North America and Europe, and in 15 percent of renal transplant recipients in developing countries with a high prevalence of tuberculosis, such as India or Pakistan.[105,168,178,185,191,192] Tuberculosis may develop in renal transplant recipients as a result of primary and reactivation infection in almost any site, and transmission from the renal allograft and reactivation in the native kidney have occurred.[114,145,146,185] *M. tuberculosis* may cause various diseases, including pulmonary infiltrates, cavitary lesions, adenopathy, cutaneous lesions, bone and joint disease, liver or spleen granulomata, and meningitis. Fever frequently occurs, and miliary or disseminated disease may occur, especially in young children.

Because the purified protein derivative (PPD) test is negative in most renal transplant recipients with active tuberculosis, the diagnosis is determined best by detection of acid-fast bacilli in smears from tissue or sputum and by isolation of *M. tuberculosis* in cultures of gastric aspirates, sputum, tracheal secretions, spinal fluid, or tissue.[125,168] The presence of granulomata in tissue also strongly suggests the diagnosis of tuberculosis.

Treatment of tuberculosis in a renal transplant recipient usually includes isoniazid, rifampin, and pyrazinamide for 1 year, although shorter courses may be acceptable in some patients.[122,168] Other antituberculous drugs may be added to or substituted for this standard regimen, depending on the disease process, the susceptibility pattern of the organism, and potential drug interactions. Because many antituberculosis drugs are excreted by the kidney, doses may need to be adjusted in a renal transplant recipient. Because rifampin may interact with cyclosporine, levels of cyclosporine should be monitored closely to avoid rejection of the allograft.[157] If a history of tuberculosis exposure is elicited during the pre-transplant evaluation, the transplant candidate should be evaluated for tuberculosis, including having a PPD and chest radiograph.[145,146,178] All close contacts also should be investigated for evidence of having tuberculosis. Treatment is recommended if disease is discovered, and prophylaxis with isoniazid is indicated for most patients who have a recently positive PPD on pre-transplant evaluation.[122,168,169,192,237] A transplant recipient who receives an allograft from a donor with a history of tuberculosis or a positive PPD also may be a candidate for prophylaxis with isoniazid post-transplant.[122,168,169]

Atypical mycobacteria are ubiquitous nontuberculous mycobacteria that can infect and produce disease in renal transplant recipients. They can cause disease during the middle post-transplant period and so are included here. Their effects usually do not become evident, however, until many years after the patient has undergone transplantation, during the late post-transplant period.[42,146,170] Atypical mycobacteria that have been documented to cause disease in solid organ transplant recipients include *Mycobacterium kansasii*, *Mycobacterium avium-intracellulare*, *Mycobacterium fortuitum*, *Mycobacterium xenopi*, *Mycobacterium haemophilum*, *Mycobacterium marinum*, *Mycobacterium chelonae*, *Mycobacterium abscessus*, *Mycobacterium gastri*, *Mycobacterium scrofulaceum*, and *Mycobacterium thermoresistibile*.[105,168,169]

A high index of suspicion is necessary to detect these elusive pathogens. They should be considered as the cause of disease in patients with persistent cutaneous ulcers, abscesses, adenopathy, pulmonary nodules, chronic wound infections, or bone and joint disease after negative routine bacterial cultures have been obtained, and the patient has failed to respond to standard antimicrobial therapy.[188] Disseminated, multisystem disease also can occur. Environmental sources of atypical mycobacteria include contaminated dialysis equipment, soil, and contaminated water in aquariums and pools. The diagnosis is established by isolation of nontuberculous mycobacteria in fluid or tissue. Granulomata are not observed consistently in tissue, and acid-fast stains may be negative.[188] Atypical nontuberculous mycobacteria are difficult

to treat, and treatment must be individualized to each patient. Strategies include reduction of immunosuppression and surgical débridement of localized disease. Antimicrobial therapy based on in vitro susceptibility testing of the isolate also should be administered, often for a prolonged period.

Nocardia

Nocardia asteroides is the most common *Nocardia* spp. causing illness in renal transplant recipients; however, other, more unusual *Nocardia* spp., including *Nocardia transvalensis*, *Nocardia brasiliensis*, *Nocardia nova*, *Nocardia otitidiscaviarum*, and *Nocardia farcinica*, also have been shown to cause disease in solid organ transplant recipients.[168,169,233] The most common manifestations of nocardial disease in transplant recipients are fever, cough, and pulmonary infiltrates.[233] Pleural effusion, pulmonary nodules, and cavitary lesions also may occur. Cutaneous infection, adenitis, arthritis, meningitis with brain abscesses, and infection of the renal allograft also may occur. *Nocardia* spp. can be seen on Gram and modified acid-fast stains of sputum, bronchoalveolar lavage fluid, abscess fluid, and tissue. They can be isolated on routine media but may take longer than conventional bacteria to grow. Prolonged treatment with sulfonamides, alone or in combination with trimethoprim, is recommended. Amikacin and other antimicrobials may be added in selected patients with severe disease, provided that renal function is monitored closely.[188] Trimethoprim-sulfamethoxazole prophylaxis for UTI and *P. carinii* also may be effective in preventing disease caused by *Nocardia*.

Fungal Diseases

Fungal infections occur infrequently in renal transplant recipients relative to other solid organ transplant recipients.[168,169,188] This lower rate of infection probably is related to technical procedures performed at the time of transplantation and the lower level of immunosuppression required to maintain most renal allografts.[188] When they do occur, however, fungal infections often are serious and life-threatening.[87,90,99] Fungal disease in a renal transplant recipient usually is manifested in one of two ways: (1) pulmonary or disseminated disease caused by one of the environmental mycoses, such as *H. capsulatum* or *C. immitis*, or (2) opportunistic infection with fungi that rarely cause disease in a normal host, such as *Candida* spp., *P. carinii*, *Aspergillus* spp., *Cryptococcus neoformans*, *Nocardia* spp., and others.[87,201]

Travel to endemic areas increases a transplant recipient's risk for development of histoplasmosis and coccidioidomycosis and may be identified during the pre-transplant evaluation. Factors that increase a transplant recipient's risk for acquisition of opportunistic fungal disease include underlying conditions such as diabetes mellitus, repeated episodes of rejection, long-term administration of steroids, prolonged use of antibiotics, and CMV infection. Similar to tuberculosis, invasive fungal disease can be a result of primary infection or reactivation infection with secondary dissemination.[188]

P. carinii, currently classified as a fungus, may cause pneumonia in 10 percent of solid organ transplant recipients, most often during the first 6 months post-transplant.[8,168,169] It seems to occur more commonly in children than in adults and usually causes fever, dyspnea, tachypnea, hypoxemia, and a nonproductive cough.[57,168] Interstitial pulmonary infiltrates are typical findings, but almost any radiographic picture can be observed, and pneumothorax is common in severe disease. The diagnosis can be suspected clinically but is documented best by organisms being shown in lung biopsy specimens; bronchoalveolar lavage may provide the diagnosis in some patients.

Treatment with high-dose oral or intravenous trimethoprim-sulfamethoxazole for 14 to 21 days is used most often. Intravenous pentamidine may be administered to selected patients, but renal function should be monitored carefully.[188] Corticosteroids may be helpful in treating severe disease if given early in the course. Low-dose oral trimethoprim-sulfamethoxazole provides effective prophylaxis against *P. carinii* pneumonia and UTIs and usually is administered to renal transplant recipients for at least 6 months post-transplant.[69] Transplant recipients experiencing repeated episodes of rejection, allograft dysfunction, or CMV disease may require a longer period of prophylaxis.[168,169] Aerosolized pentamidine is an alternative prophylaxis strategy for some patients.[188]

Candida spp., especially *C. albicans*, are the opportunistic fungi most frequently isolated in renal transplant recipients.[168,169] Other *Candida* spp. isolated include *Candida krusei*, *Candida glabrata*, and *Candida tropicalis*. Most fungal infections caused by *Candida* spp. occur during the first 2 months post-transplant, usually at the site of indwelling intravascular and urinary catheters.[188] Esophagitis, abscesses, and arthritis also can develop, and endocarditis with metastatic foci can occur if the fungemia persists. Other opportunistic fungi such as *Aspergillus* most often cause sinusitis and pulmonary disease, and, because of its angioinvasive nature, *Aspergillus* often disseminates and causes lesions in the liver, spleen, and brain.[168,169,201,202]

A thorough search for metastatic foci always should be undertaken when a primary focus of invasive fungal disease is documented. *C. neoformans* usually causes cutaneous lesions or abscesses and pneumonia with pleural effusion, but meningitis, arthritis, and pyelonephritis also can occur.[168,169,196] Exposure to soil or bird droppings provides an epidemiologic clue to the diagnosis. In addition, the Zygomycetes, including *Rhizopus*, *Mucor*, *Rhizomucor*, and *Absidia* spp., can cause disease in solid organ transplant recipients.[201,202] They most often cause cutaneous, rhinocerebral, or pulmonary disease or brain abscesses in renal transplant patients. Cutaneous and soft tissue infections, wound infections, and gastrointestinal disease with perforation also have been described. The Zygomycetes, similar to *Aspergillus*, are angioinvasive and disseminate via the bloodstream to cause disease, which often is severe. A variety of unusual fungi, such as *Paecilomyces*, *Fusarium*, and *Bipolaris*, have been shown to cause cutaneous infection, usually at the site of indwelling catheters, and *Hansenula anomala* reportedly has caused UTI in a renal transplant recipient.[78]

The endemic dimorphic fungi include *H. capsulatum*, *C. immitis*, *B. dermatitidis*, and *Paracoccidioides brasiliensis*. Infection with these organisms can occur anytime after the patient has undergone transplantation but usually occurs during the intermediate post-transplant period.[215] These organisms usually are noted in renal transplant recipients who reside in endemic areas. Histoplasmosis is endemic in the central part of the United States and many foreign countries, and nosocomial outbreaks have occurred during hospital construction projects. Fever, chills, and cough are the usual initial signs. Skin lesions, hepatosplenomegaly, and meningitis also can occur. Pancytopenia often is present as well, and the organism frequently is found in the bone marrow of patients with disseminated disease. Coccidioidomycosis is endemic in the southwestern portion of the United States and northern Mexico. It usually is manifested as fever, cough, and pulmonary infiltrates, but extrapulmonary dissemination frequently occurs. Blastomycosis is endemic in the southern United States, along the Mississippi and Ohio River valleys, and in the Great Lakes area. It is a rare development after renal transplantation, but most often causes lung and skin lesions. Paracoccidioidomycosis rarely has been reported in renal transplant recipients.[210]

The diagnosis of invasive fungal disease is established best by isolating the fungus from sputum or tracheal aspirate, bone marrow, tissue, or fluid. *C. neoformans* also may be isolated from urine. Fungal serology and tests for cryptococcal antigen may support the diagnosis.[210]

Fungal identification and susceptibility testing now can be performed in reference laboratories and should be used to guide therapy whenever possible. Amphotericin B usually is used to treat most invasive fungal disease in transplant recipients, and the deoxycholate, lipid complex, or liposomal forms can be used, provided that renal function is monitored closely.[123] Flucytosine may have additive or synergistic effects against many yeasts and fungi. The azole antifungal agents are not nephrotoxic and are used in renal transplant recipients whenever possible. Many *Candida* spp. are susceptible to fluconazole, although resistance is emerging in all *Candida* spp. and is present in a high percentage of *C. krusei* and *C. glabrata*. Itraconazole and voriconazole may be effective against other fungi, such as *Aspergillus.* Voriconazole has emerged as a treatment of choice for most *Aspergillus* infections. Itraconazole should be used with caution, however, because it has variable oral absorption and may interact with cyclosporine.[215] Caspofungin also has activity against most *Candida* spp. and a variety of opportunistic fungi, including *Aspergillus.* Currently, experience using the newest triazole, posaconazole, and the newest echinocandin, micafungin, in pediatric renal transplant recipients is limited.

Surgical resection or drainage of abscesses, avascular cavities, or effusions may be required to treat some forms of invasive fungal disease of the lungs, liver, or spleen. Carefully monitored reduction in immunosuppression also may help the host recover from invasive fungal disease.

Parasitic Infections

The parasites most commonly encountered in renal transplant recipients during the intermediate post-transplant period are *T. gondii*, *S. stercoralis*, and *Trypanosoma cruzi*.[65,168] These infections occur most often in adults. Children also may be infected with routine parasites such as *Enterobius vermicularis*, *Ascaris*, *Giardia*, and others pre-transplant. Other parasitic infections that may be found in renal transplant recipients include leishmaniasis, schistosomiasis, and malaria. Renal transplant recipients seem to be at much lower risk for acquisition of parasitic diseases than are other solid organ transplant recipients.

T. gondii usually occurs as a result of reactivation of latent disease in the donor allograft or recipient.[130] It is encountered most frequently in heart transplant recipients, but any solid organ recipient, including renal, may be affected. Clinical manifestations of infection with *T. gondii* include focal meningoencephalitis, brain abscesses, pneumonia, myocarditis, pericarditis, hepatitis, and retinochoroiditis.[140,207,215,222] The diagnosis may be made by demonstration of the organism in tissue by histopathology, detection of DNA by PCR in body fluids or tissue, or serologically by detection of high titers of IgG and specific IgM antibody to *T. gondii.* Treatment with pyrimethamine, sulfadiazine, and folinic acid usually is recommended; however, some patients also may respond to clindamycin. Routine prophylaxis with trimethoprim-sulfamethoxazole for UTI and *P. carinii* infection may help prevent disease with *T. gondii.*

S. stercoralis is an important pathogen in adult transplant recipients, but it is rarely, if ever, a significant problem in pediatric patients. Because *S. stercoralis* can be maintained in the human intestinal tract for decades, it can disseminate and cause serious disease in transplant recipients who were infected pre-transplant. A complete blood count for eosinophilia should be obtained, and stool and other specimens should be examined for rhabditiform larvae if the pre-transplant evaluation reveals travel to endemic areas. Thiabendazole should be given before transplantation is performed if *S. stercoralis* infection has been documented or is suspected. *T. cruzi*, the cause of Chagas disease, rarely has been transmitted by renal transplantation.[65,120]

INFECTIONS OCCURRING DURING THE LATE POST-TRANSPLANT PERIOD

Infections occurring 6 months or more after the patient has undergone renal transplantation usually are less severe than infections experienced in the earlier periods, especially if the level of immunosuppressive therapy is low and the allograft is functioning well.[187] Constant vigilance for health care–associated and community-acquired viral and bacterial diseases and unusual infections should continue, however.

Chronic rejection or repeated episodes of acute rejection complicated by allograft dysfunction predispose the patient to development of more serious opportunistic infections, similar to infections encountered during the first 6 months post-transplant. UTIs that develop during this period, in contrast to UTIs in the early post-transplant period, usually are benign and may be treated with conventional antimicrobial therapy in most instances, if they do not seem to threaten the function of the allograft or the patient's survival. Patients also may experience community-acquired infections with respiratory viruses, such as influenza virus and respiratory syncytial virus, and with bacteria, especially *Streptococcus pneumoniae* (pneumococcus) or *S. aureus*. These common community-acquired bacterial pathogens may be resistant to usual β-lactam antibiotics.[208,220] In addition, patients vaccinated with 7-valent or 23-valent pneumococcal vaccines still may acquire invasive pneumococcal disease with emerging, non-vaccine serotypes, such as 19A and 3A. These serotypes often are also multidrug-resistant. Opportunistic viral infections encountered during this period are zoster or, rarely, CMV retinitis.[149] The risk for developing PTLD also persists during this late post-transplant period.

Renal transplant recipients may be chronically infected with HBV or HCV pre-transplant. Increased risk of mortality from fulminant hepatitis with hepatic failure may occur during the early pre-transplant period, and chronic liver disease, cirrhosis, and liver failure may be seen 10 years or more after renal transplantation has been performed in hepatitis B surface antigen (HBsAg)–positive recipients.[236] All transplant recipients who are not immune to HBV should receive HBV vaccine before transplantation.[229] Most experts agree that renal allografts from HBsAg-positive donors should not be used, but the decision to perform renal transplantation in recipients who are HBsAg-positive is controversial and must be made on an individualized basis.

Renal transplant recipients who are infected with HCV pre-transplant usually do well during the early post-transplant period, but long-term survival is poorer than in recipients who are not infected with HCV. Not only can chronic liver disease develop, but also membranoproliferative glomerulonephritis has been reported in renal transplant recipients infected with HCV.[27] Despite these risks, however, most experts do not consider infection with HCV a contraindication for renal transplantation in patients with ESRD.[173] Hepatitis G virus also has been detected in the serum of renal transplant recipients, and at least one association with membranous glomerulonephritis has been reported.[12,13] The role of HGV in clinical disease in renal transplant recipients is not established, however.

HIV may be transmitted by kidney transplantation despite routine screening of donors of blood and organs.[117,183] A transplant recipient also may become infected with HIV after undergoing transplantation.[168] Shortly after a patient has undergone transplantation, HIV infection may cause fever and a mononucleosis-like syndrome. Complications of acquired immunodeficiency syndrome may develop during the late transplant period. HIV-infected patients with ESRD traditionally have been excluded from receiving renal transplantation. More recent advances in HIV therapy have caused some experts to reconsider this policy on an individual basis, however.[168]

CHAPTER 85

Infections Related to Prosthetic or Artificial Devices

Ram Yogev ❂ Tina Q. Tan

The development of biomaterials used in the manufacturing of temporary or permanent implantable prosthetic devices has been one of the greatest advances in modern medicine.[64,85,86] These devices have become an integral and important part of the current practice of medicine and have improved considerably the lives and health of countless patients. In the United States, the number and types of permanent prosthetic devices implanted to replace diseased or damaged body parts has increased substantially during the last several decades. An estimated 3 million or more people in the United States currently have some type of long-term bio-

TABLE 85–1 Temporary or Permanent Implantable Devices Currently in Use

Temporary Devices
Intravascular catheters
Urinary catheters
Endotracheal and tracheostomy tubes
Permanent Devices
Central nervous system shunts
Deep-brain stimulators
Peritoneal dialysis catheters
Orthopedic prostheses (artificial hip, knee, and other joints; screws, pins, plates, and rods)
Intracardiac and intravascular prostheses (heart valves, vascular grafts)
Ventricular assist devices
Pacemakers and defibrillators
Ocular prostheses (artificial globes, intraocular lenses, ocular explants)
Implantable pump devices (baclofen, insulin)
Cochlear implant devices
Tissue expander devices

medical implant.[80,322,377] Table 85–1 is a listing of the implantable prosthetic devices in use today.

One of the major medical complications associated with the use of implantable prosthetic devices is infection, which may result in serious tissue destruction and dysfunction of the prosthetic device or in local and systemic consequences that may be life-threatening. In most cases, these infections are very difficult to cure with antimicrobial agents alone, and removal of the device usually is required for resolution of the infection.

INTERACTION OF THE HOST WITH A PROSTHETIC DEVICE

The prosthetic devices currently in use are composed of a variety of biomaterials, including cobalt-chromium-molybdenum alloy, titanium alloy, and complex polymers such as polytetrafluoroethylene, silicone, and polyethylene, which in general are chosen for their inert, nonreactive, and nontoxic qualities. The interplay of both implant and host factors determines the risk of acquiring and the severity of infection. The human body has numerous well-developed defense mechanisms to protect it against possible invasion by various microorganisms. Such mechanisms include cellular and humoral immune systems, anatomic barriers, and an elaborate network of cells that phagocytize and destroy invading organisms. The presence of a foreign body may compromise one or more of these defenses and elicit a complex acute or chronic inflammatory response (or both) from the host. Many of these devices breach cutaneous and mucosal barriers, thereby creating a direct route by which bacteria and fungi may invade. In addition, implanted devices may alter the local immunity of the host directly or indirectly.[18,85,322,377,389]

Shortly after being implanted, hydrophobic polymeric materials such as polyethylene, Dacron, polydimethylsiloxane, and polyether urethanes become coated with a layer of host proteins such as plasma and interstitial fluid proteins (fibronectin, albumin, laminin, collagen, immunoglobulin G, fibrinogen) that bind to and are absorbed readily into the surface of the implant.[21,291,377] This protein layer (especially fibrinogen) has a major influence on the body's response to and the biocompatibility of the implant. The presence of fibrinogen attracts a large number of phagocytic cells (neutrophils, monocytes/macrophages) to the implant; these cells interact with the implant surface and initiate an acute inflammatory response.[85,377] Some of these host proteins also serve as a receptor for various colonizing microorganisms. Collagen, laminin, and fibrinogen have been reported to play a role in adherence of bacteria,[393] whereas fibronectin has been found to be the major receptor for gram-positive cocci, especially *Staphylococcus aureus*.[314,382]

Chronic inflammatory responses, also known as *foreign body reactions*, are seen around many types of biomaterial implants and arise from interactions among the protein-coated surfaces of the implant and host tissues and adhering phagocytic cells such as macrophages and foreign body giant cells. These interactions may result in degradation and damage to the implant from the continuous generation of toxic catabolites and release of inflammatory mediators such as hydrolases, activated complement components, tumor necrosis factor (TNF), interleukins, prostaglandins, coagulation factors, and plasminogen activator by the phagocytic cells.[375,377,389]

INTERACTION OF MICROORGANISMS WITH A PROSTHETIC DEVICE

Once a prosthetic device is implanted, the surface of the device provides a potential area for adherence and multiplication of bacteria. Adherence is a complex process that involves electrostatic attachment of the bacteria to the surface of the implant, bacterial mechanisms that function specifically in attachment, and host-derived substances that coat the prosthetic device and serve as receptors for various bacteria. Bacteria arrive at the surface of the implant by many different routes: they may be inoculated at the time of implantation, the patient may have episodes of transient bacteremia, the device may be exposed by local trauma or infection, or the device may be implanted within an area in which the organism is part of the normal flora.[80,85]

Adherence of bacteria to the surface of an implant is influenced by numerous different factors, including the material used to make the device, the source of the device material (adherence is greater with synthetic material than with biomaterial), the surface of the device (irregular more than regular, textured more than smooth, hydrophobic more than hydrophilic), and the shape of the device.[80] Cell surface molecules or structures known as adhesins also play a role in adherence by attaching or binding an organism to specific receptors on implant surfaces; different bacteria use different adhesins to attach to and colonize medical implants. For example, *Staphylococcus epidermidis* uses proteinaceous autolysin and capsular polysaccharide intercellular adhesin for initial adherence to the implant surface and for adherence of bacteria to each other. These bacteria also produce a biofilm that increases cell-to-cell association and allows accumulation of bacteria.[330] *Streptococcus pyogenes* uses lipoteichoic acid as its adhesin, whereas *S. aureus* uses both lipoteichoic acid and host-tissue ligands (e.g., fibronectin, fibrinogen, collagen) for adherence. Binding of *S. aureus* to host-tissue ligands is mediated by genetically defined microbial surface proteins known as *microbial surface components recognizing adhesive matrix molecules* (MSCRAMM).[81] *Escherichia coli* and other bacteria use fimbriae as an adhesin to mediate binding to receptors on the surfaces of target cells.

Bacteria also can protect themselves from host defenses by synthesizing and excreting numerous complex polysaccharides, known as glycocalyces, that function either as part of the bacterial capsule or as the slime layer. This slime layer is known to play a major role in keeping an organism attached to an implant surface by coalescing with the polysaccharides of other bacteria and with host products to produce a thick, adherent, and somewhat impenetrable biofilm.[390] The biofilm functions by trapping nutrients and protecting the organism from phagocytosis, antimicrobial agents, and competing microflora. It also plays a role in inhibiting the response to chemotactic stimuli, increases both *N*-formyl-methionyl-leucyl-phenylalanine (FMLP)-induced

superoxide generation and release of specific granules, and impairs natural killer cell function while also altering the composition of T-lymphocyte cell subpopulations.[136,184,390] Therefore, the biofilm aids bacteria in evading host cellular and humoral defense mechanisms and thereby allows the organism to colonize and infect an implanted device effectively.

Substantial progress has been made in our understanding of the pathogenesis, prevention, and treatment of foreign body infections; this increased knowledge has resulted in a dramatic decrease in the morbidity associated with these infections, as well as subsequent improvement in the patient's quality of life. In the following sections we discuss specific device-related infections and the suggested treatment and management of these infections.

TISSUE EXPANDERS

The use of soft tissue expansion in reconstructive surgery was reported in the literature first in 1957, and since that time it has been used widely for the correction of multiple problems in plastic and reconstructive surgery in the adult and pediatric populations.[12,19] These expanders consist of an alloplastic prosthesis with a filling port that is implanted into a subcutaneous pocket. The expander is filled with saline through the filling port at various intervals to create adequate expansion of the skin. In children, tissue expansion is used most commonly to provide coverage for skin defects caused by burns, trauma, hemangiomas, and other congenital deformities.[237]

The most common complication of tissue expansion is infection of the subcutaneous expander pocket, usually with skin organisms introduced during insertion of the expander. Cellulitis of the overlying skin and hematogenous or lymphatic seeding of the expander pocket are seen as well but occur much less frequently.[12,123,171,235,237,272] In several pediatric case series, the infection rate ranged from 3.4 to 11 percent.[123,237] *S. aureus*, *S. epidermidis*, and group A streptococci are the microorganisms recovered most commonly from these infections.[123,171,236,237] Less commonly, nontypable *Haemophilus influenzae*,[237] *Pseudomonas aeruginosa*, *E. coli*, and *Actinomyces* spp.[252] have been isolated from infections of expander pockets.[236]

In cases of infection of subcutaneous pockets, treatment consists of removal of the tissue expander, débridement and drainage of the subcutaneous pocket, and administration of intravenous antibiotic therapy tailored to the organism isolated. For cellulitis of the overlying skin of an expander pocket, treatment with intravenous antibiotics but without removal of the tissue expander has been shown to be successful.[12]

The most common empiric antimicrobial therapeutic regimen consists of a first-generation cephalosporin or an extended-spectrum, penicillinase-resistant penicillin. For all of the infections of prosthetic devices discussed in the chapter, empiric antistaphylococcal coverage should include agents effective against community strains of methicillin-resistant *S. aureus* (MRSA) if warranted by their frequency in the area.

Therapy is tailored once the organism has been identified and its antibiotic susceptibility has been determined.

COCHLEAR IMPLANTS

During the last several decades, cochlear implantation has emerged as one of the best methods of providing auditory rehabilitation for the profoundly deaf (congenital or acquired). The goal of this surgery in young children is to provide hearing that is adequate to facilitate the development of receptive and expressive language. The surgical technique involves the creation of a C-shaped flap in the postauricular and parietal-occipital scalp skin areas, elevation of the flap, implantation of a multichannel prosthesis, and insertion of an electrode array into the cochlea through openings drilled into the temporal bone.[68,71,230]

The most common infectious complications associated with these implants are cellulitis of the overlying skin flap, meningitis, otitis media, and delayed cochlear implant infections leading to extrusion of the implant.* Rates of infection range from 0.3 to 0.5 percent for meningitis, 2 to 3 percent for cellulitis of the skin flap and delayed cochlear implant infections, to 36 percent for otitis media. The reported cases of meningitis have occurred either in association with leakage of cerebrospinal fluid (CSF) in persons with a malformed cochlea who undergo cochlear implantation or as a consequence of intracranial spread of a developing middle ear infection along the electrode pathway. In June 2002, the U.S. Food and Drug Administration received numerous reports of bacterial meningitis in children with cochlear implants who were younger than 6 years old when they received the implants. The most common causative organism identified was *Streptococcus pneumoniae*, followed by nontypable and type b *H. influenzae*. The incidence of pneumococcal meningitis in this group of patients was calculated to be 138.2 cases per 100,000 person-years—more than 30 times the incidence in the same-aged cohort in the general population. This increased incidence of meningitis was found to be associated strongly with the use of a cochlear implant with a positioner (a wedge-shaped insert that facilitates transmission of the electrical signal by pushing the electrode against the medial wall of the cochlea) in conjunction with the presence of radiographic evidence of a malformation of the inner ear and leakage of CSF. Cochlear implants with a positioner were voluntarily recalled in the United States in July 2002, although removal of existing implants containing a positioner was not recommended; use of appropriate vaccination against *S. pneumoniae* and type b *H. influenzae* was strongly recommended.[17,131,321] Children with cochlear implants may have a higher risk for the development of middle ear infections because of several factors, including the naturally high incidence of acute otitis media (AOM) in this population, the presence of a foreign body in the area of the infection, and the potential for spread of the infection into the cochlea along the electrode pathway. In a study of 50 children who received cochlear implants between 1991 and 1995, researchers found that children prone to the development of otitis media before undergoing implantation were at higher risk for developing postimplantation AOM but responded well to routine oral antimicrobial therapy. The overall prevalence and the severity of AOM were not found to be increased in children with cochlear implants.[227]

In cases of cellulitis of the skin flap, intravenous antimicrobial therapy commonly consists of a first-generation cephalosporin or an extended-spectrum, penicillinase-resistant penicillin to provide coverage for *S. aureus* and group A streptococci. Empiric antimicrobial therapy for meningitis usually consists of vancomycin and a third-generation cephalosporin that is tailored to the organism isolated. For delayed development of cochlear implant infections, therapy consists of removal of the implant and administration of intravenous antibiotics.

OCULAR PROSTHESES

This group of prosthetic devices includes artificial globes used primarily for cosmetic purposes, orbital implants, ocular explants, intraocular lenses (IOLs), and contact lenses.

ORBITAL IMPLANTS

Orbital implants are made of hydroxyapatite or porous polyethylene and frequently are used in orbital reconstruction after

*See references 32, 69-71, 82, 158, 159, 168, 175, 176, 227, 277, 289.

enucleation or evisceration surgery. Infection of these implants is a rare event, with only a handful of cases reported in the literature.* Patients most commonly complain of anophthalmic socket pain, discomfort, and irritation while wearing an artificial globe. Papillary conjunctivitis of the socket with exudate and sometimes dehiscence of the overlying conjunctiva also may be seen.[125,261] Infection may develop months to years after placement of the implant, and severity ranges from cellulitis to the development of an abscess around the implant itself.

Radiographic studies that can aid in the detection of these types of infection include technetium 99m–labeled leukocyte scintigraphy, which is most useful in detecting early low-grade graft infection,[186] and computed tomography (CT) and magnetic resonance imaging (MRI), which are useful later in the course of the infection to detect the presence of abscesses and structural tissue changes. Gram-positive cocci, primarily *S. aureus* and coagulase-negative staphylococci (CoNS), are the organisms associated most commonly with these infections; however, *H. influenzae*, *S. pneumoniae*, alpha-hemolytic streptococci, *Capnocytophaga*, *Pseudomonas*, and *Aspergillus fumigatus* have been cultured as well.[321,365,419,427] To cure the infection effectively, treatment involves both removal of the implant and institution of topical and parenteral antibiotic therapy directed against the organism isolated. Empiric therapy directed against gram-positive organisms may be started initially until the results of culture and sensitivity testing are available. The most common empiric regimens include a first-generation cephalosporin, a second-generation cephalosporin, or an extended-spectrum, penicillinase-resistant penicillin.

INTRAOCULAR LENSES

Insertion of polymethyl methacrylate (PMMA) IOLs at the time of removal of a cataract is the standard surgical therapy for this disorder. Even though the rate of postoperative infection of IOLs is low (ranging from 0.10% to 0.30%), the infection usually is serious and results in endophthalmitis and permanent loss of vision.[187,206] The predisposing factor for infection is bacterial adhesion to IOLs during their insertion. After adhesion is accomplished, the bacteria replicate, congregate, and form multiple layers of microcolonies that represent a biofilm in which the bacteria are embedded in a layer of slime. The major pathogens associated with this infection are *S. aureus* and *S. epidermidis*, which account for 90 percent of all isolates, although gram-negative bacilli, fungi, *Chlamydia trachomatis*, and rapidly growing mycobacteria are isolated on occasion.[6,93,206,239,348,428] IOL-associated endophthalmitis is a serious infection that is difficult to diagnose and treat.[412] In a few cases, use of topical and systemic antibiotics alone has been successful in eradicating the infection, but in most cases surgical débridement and systemic antibiotics are required for cure. Empiric therapy for these infections consists of an extended-spectrum, penicillinase-resistant penicillin, a second-generation cephalosporin, or, in some instances, clindamycin or vancomycin. In cases of fungal endophthalmitis, treatment with the later-generation azoles alone and in combination with an echinocandin has been shown to have clinical success[93]; in rapidly growing mycobacterial endophthalmitis combinations of topical and intravenous antibiotics to which the organism is susceptible have been used for treatment.[239]

CONTACT LENSES

Primarily three different types of contact lenses are available. Hard lenses are made of PMMA, a substance that is impermeable to water and gas. This type of lens is designed to be worn only during waking hours because it limits oxygen flow to the cornea to that present in tears. Gas-permeable hard lenses are composed of silicone, cellulose acetate butyrate, or PMMA-silicone copolymers; they allow gas but not fluid to pass through the lens. Hydrophilic or soft lenses are made of a cross-linked hydrogel polymer or copolymer and consist of between 38 and 85 percent water by weight; these lenses are permeable to both gas and water and allow the user to wear them continuously. However, for all these types of lenses, infection may result in damage to the corneal epithelium.

The two main infections that occur in association with contact lenses are conjunctivitis and keratitis.[55] The causative bacteria seen most commonly with these infections are *S. aureus*, streptococci, *Pseudomonas* spp. (found in improperly stored cleansing solutions), and fungi. Improper cleaning of soft or hydrophilic lenses may cause them to become a source of infection when bacteria penetrate the lens matrix. Treatment usually consists of removal of the lens and application of topical antibiotics. To prevent the development of infections associated with contact lenses, users should adhere strictly to the manufacturer's suggested guidelines for wearing and cleaning the lenses.

A rare and often devastating infection associated with the use of contact lenses is infection with the fresh-water protozoan *Acanthamoeba*.[67,157,261,367] This organism contaminates the lens when sterility of the cleansing solutions is not maintained; it usually is associated with users who prepare their own solutions. *Acanthamoeba* is very difficult to eradicate because it is not susceptible to standard antiparasitic agents, and it produces a chronic keratitis that can be complicated by corneal perforation and loss of the eye. Corneal transplantation may be necessary in many cases to restore vision.[157,367]

LEFT VENTRICULAR ASSIST DEVICES

The development plus use of mechanical circulatory assist devices has grown very rapidly in the last decade, especially with the shortage of available donor hearts. Such devices have improved considerably the hemodynamic status and quality of life of patients with heart failure who are awaiting cardiac transplantation. Figure 85–1 shows a left ventricular assist device (LVAD), a pneumatically driven pump located outside the heart that draws blood from an inflow cannula in the left ventricular apex and ejects the blood through an outlet into the ascending aorta. Within the pump are several sections of Dacron graft material and two trileaflet porcine valves in the inflow and outflow positions to ensure that blood flow is unidirectional. The pump is encased in titanium and implanted via an extended median sternotomy into the left rectus sheath. A percutaneous driveline connects to an exterior power pack for venting or for pneumatic actuation and exits the body, after passing through a subcutaneous tunnel, in the left lower quadrant. The interior surface of the pump is textured to prevent the formation of thrombi and encourage the deposition of a biologic pseudo-intimal lining. Once the device is implanted, in most cases it cannot be removed without performing concurrent cardiac transplantation.[154,193,243,245,288]

The approach taken by many centers for infection of an LVAD includes both preventive and interventional steps that are instituted before, during, and after implantation. Preventive strategies are focused on prevention of infections related primarily to the driveline and device pocket through the use of clean implantation techniques and limited traffic in the operating room in which the procedure is being performed. Antibiotic prophylaxis usually is given for 48 hours near the time of implantation of the LVAD and may include intravenous trimethoprim-sulfamethoxazole, rifampin, and fluconazole, along with the application of mupirocin ointment to the nares. Additional

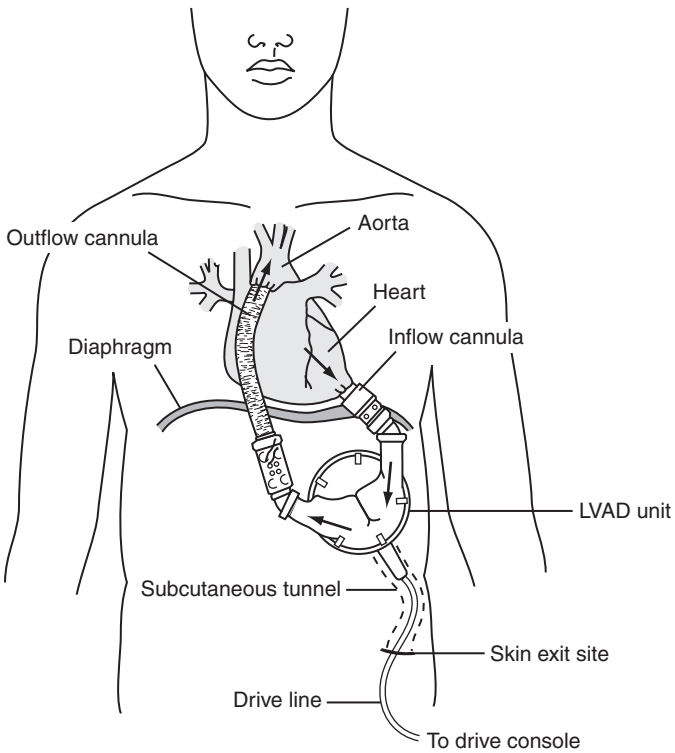

Figure 85–1 Left ventricular assist device (LVAD). *(Adapted from Fisher, S. A., Trenholme, G. M., Costanzo, M. R., and Piccione, W.: Infectious complications in left ventricular assist device recipients. Clin. Infect. Dis. 24:18-23, 1997.)*

preventive measures include soaking the surfaces of the LVAD in vancomycin and gentamicin for 30 minutes before placing it, irrigating the device pocket with povidone-iodine (Betadine), and meticulously placing the subcutaneous tunnel in the appropriate position. Postoperative care with sterile and semi-sterile dressing changes around the driveline is emphasized.[105,163,355]

Despite the preventive measures taken, infection, thromboembolism, and hemorrhage at the time of implantation remain the most common complications associated with the use of mechanical circulatory support devices. Of these complications, infection has the most significant impact on morbidity and mortality.[116] Predisposing factors for development of device-related infections in these patients include contact of blood with the prosthetic surfaces, device-related pockets and cavities, transcutaneous drivelines, and power cables; extent of surgery necessary for implantation; hemorrhage; reoperation; frequent occurrence of multiple organ dysfunction or failure; duration of mechanical circulatory support; poor health; and comorbid conditions. The incidence of infection in patients on LVAD support for longer than 60 days is reported to be two times higher than that in patients with an LVAD in place for less than 30 days; initial episodes of infection after 90 days are rare.[271,306,354] In addition, some evidence indicates that implantation of an LVAD itself may lead to defects in cellular immunity secondary to an aberrant state of T-cell activation that predisposes LVAD recipients to the development of candidal and other systemic infections.[11,128,174,306] The incidence of infection after implantation of an LVAD is reported to range between 13 and 80 percent, with most studies documenting an infection rate of 30 to 50 percent.* Most series report that the device pocket and drivelines are the device-related sites that account for most of the infections. Placement of the LVAD in the abdominal cavity instead of the preperitoneal area has been shown to decrease the chance for development of infection.[271]

Driveline infections are thought to result from a lack of integration of tissue around the driveline that allows the driveline to move and irritate surrounding tissues, which can result in an infection in the exit site and, in some cases, bacteremia. Such infections generally are defined by pain, erythema, warmth, drainage, or purulent discharge at the driveline exit site in the presence of a positive culture. Bacteremia developing after implantation of a pump and infections of the pump itself are additional reported complications.[14,244] In a study of 205 patients who underwent placement of LVADs at the Cleveland Clinic, positive blood cultures were noted in 52 percent, infections of the driveline site occurred in 22 percent, and infections of the pump pocket developed in 9.2 percent.[193] Sun and colleagues[373] reported their experience with 95 patients who underwent insertion of an LVAD. Twenty-six (27%) of these patients experienced device-related infections involving the driveline, device pocket, or blood-contacting surfaces; 15 of the 26 (57.7%) had infections of the driveline site. Persistent bacteremia and progression of infection of the device pocket and driveline site can lead to the serious infection of LVAD endocarditis, which mimics prosthetic valve endocarditis, is very difficult to treat, and is associated with a high mortality rate. LVAD endocarditis is defined as positive cultures of the LVAD surface in conjunction with clinical signs and symptoms of infection during LVAD support. Manifestations of this condition are varied and range from persistent fever and bacteremia or fungemia to cerebral thromboembolism, LVAD inlet obstruction with hemorrhage, or LVAD outflow graft rupture.[14] In a report by Weyland and associates[414] of 27 patients who underwent insertion of LVADs, infections of the driveline developed in 8 (30%) of the 27 recipients, and LVAD endocarditis, defined as positive cultures from the pump chamber, was found in 12 (44%) of the patients; 8 of the 12 (67%) died of endocarditis.

Despite a high potential for the development of serious morbidity after placement of an LVAD, studies have shown that the presence of an infection after insertion of an LVAD does not seem to have very much influence on eventual cardiac transplantation and post-transplant outcome. During a 5-year period, Argenziano and coworkers[14] compared the effect that infection after insertion of an LVAD had on mortality, the development of LVAD endocarditis, and eventual heart transplantation. The study found that infection subsequently developed in 29 of 60 (48%) patients who underwent insertion of an LVAD. The most frequent sites of infection were the blood (27%), LVAD driveline (13%), LVAD surface (13%), and central venous catheter (10%); these sites thus represented 63 percent of all infections.[11,14] The overall mortality rate, the rate of successful cardiac transplantation, and the rate of infection after transplantation were not influenced by the presence of infection during LVAD support.[14] In another study, Sinha and colleagues[355] reviewed their experience with 86 patients who received LVADs; device-related infections developed in 6 patients, 5 (83%) of whom had infections of the pocket. This study also found that that the presence of infection during LVAD support did not influence successful cardiac transplantation or patient survival after transplantation.

MICROBIOLOGY OF LEFT VENTRICULAR ASSIST DEVICE INFECTIONS

Numerous organisms have been isolated from LVAD infections. In most series, *S. aureus*, *S. epidermidis*, and *Enterococcus* spp. are the organisms most commonly isolated from these infections, usually within the first 4 weeks after implantation. Other organisms such as *Enterobacter*, *P. aeruginosa*, *Serratia marcescens*, other gram-negative organisms, and polymicrobial

*See references 14, 105, 114, 163, 244, 246, 298, 346, 373, 414.

organisms were seen more commonly later in the clinical course.[14,87,105,130,163,242,244,355,414] Fungal infections (e.g., *Candida albicans*) were reported as well and were responsible for only approximately 16 percent of the infections.[87,163,242] However, colonization with fungi occurs in 35 to 39 percent of patients with LVADs.[128] Investigators suggested that treatment with broad-spectrum antibiotics (common in these patients) rendered them more susceptible to the development of fungal infection. When a fungal LVAD infection is suspected, signs of thrush, esophagitis, retinal changes, peripheral embolization, and unexplained decrease in LVAD output should be investigated. The presence of yeast on Gram stain of the fluid surrounding the device and ultrasound showing increasing amounts of fluid around the device can be used to help in confirming the diagnosis.[128] Management of these infections, especially LVAD endocarditis, presents a major challenge, given that the device usually cannot be removed unless simultaneous heart transplantation is performed; moreover, if transplantation is accomplished, multiple issues regarding the immunosuppressed condition of the patient are raised. In most cases, management involves a prolonged course (usually 4 to 6 weeks) of aggressive antimicrobial or antifungal therapy (or both) appropriate for the organism or organisms isolated, with meticulous attention given to skin care around the driveline exit site; débridement, drainage, surgical revision, and irrigation with povidone-iodine of infected wound sites; or in certain instances, replacement of the LVAD unit or cardiac transplantation before completing antibiotic therapy if a donor heart becomes available and all blood cultures are negative.[105,163,244]

EXTRACORPOREAL MEMBRANE OXYGENATION CIRCUITS

Extracorporeal membrane oxygenation (ECMO) is the method used most commonly for treating severe cardiac and pulmonary failure in neonates and children. Almost 1 percent of all children treated by open heart surgery will undergo ECMO. In addition to these postcardiotomy patients, a growing number of children receive ECMO for acute decompensation of myocarditis or cardiomyopathy. ECMO also is used to support children after sudden cardiac arrest when conventional closed or open heart massage is unsuccessful. In children, perfusion through the neck venoarterial vessels is the preferred method, but the trans-sternal approach is used when direct decompression of the distended left ventricle is required. Although the overall survival rate of children managed by ECMO has improved in recent years, it still is only 50 to 70 percent,[23,408] in contrast to 88 percent in neonates treated for respiratory failure.[9,313] Multiple cardiac and noncardiac factors are associated with increased morbidity and mortality rates. Patients with a single ventricle or residual cardiac defect after surgery have a less favorable ECMO outcome.[34,79,202] Renal dysfunction, multiple organ system failure, initiation of ECMO in the operating room, blood product transfusion, mediastinal bleeding, ECMO circuit problems, and duration of ECMO for longer than 10 days also were predictors of increased risk of mortality.[202,260] The presence of infection (mostly nosocomial) while being supported by ECMO was associated with increased mortality rates.[207,260,315,431] Of interest, none of the patients who had a positive blood culture in the first 24 hours of ECMO survived.[262]

The same organisms that cause LVAD-associated infections also are associated with ECMO infections.[47,260] The distribution of these pathogens is similar to their distribution in other patients with infections treated in the intensive care unit, except for an increase in the incidence of *Enterobacter* and *Acinetobacter* infections.[47]

The signs and symptoms of infection often are subtle and nonspecific. Fever develops in only half of these patients. The value of tachycardia and elevated cardiac output also is limited because these patients frequently are tachycardic with increased cardiac output caused by a systemic inflammatory response (e.g., complement; cytokines such as TNF, interleukin-1 [IL-1], and IL-6), which is characteristic of cardiopulmonary bypass procedures.[257] For the same reason, leukocytosis (unless developing acutely) and an elevated erythrocyte sedimentation rate (ESR) should be interpreted with caution. Consequently, a high index of suspicion with random surveillance of blood and urine cultures and chest radiographs (to rule out pneumonia) is needed to identify these infections.

Most patients undergoing ECMO are treated with multiple broad-spectrum antibiotics. This practice probably is one of the reasons for the increased incidence of multidrug-resistant, gram-positive (e.g., *Enterococcus*) and gram-negative bacteria, as well as fungal (e.g., *Candida*), infections. In addition, many of these patients will be colonized with these same bacteria. Therefore, if a deep bronchial suction or urine culture (performed routinely) becomes positive but without supporting evidence of infection (e.g., increased white blood cell [WBC] count, fever), serious effort to distinguish between colonization and infection should be made before initiating an unnecessary change in antimicrobial therapy. If a decision to treat is made, appropriate coverage for both gram-positive and gram-negative organisms should be chosen. If blood, urine, and bronchial cultures remain negative and the patient's condition is not improving or the culture becomes positive for a fungus, antifungal therapy should be added.

PERMANENT CARDIAC PACEMAKER AND IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR INFECTIONS

PERMANENT CARDIAC PACEMAKER INFECTIONS

Cardiac pacemakers were developed in the late 1950s, and since that time the field of cardiac pacing has made great strides with regard to the development and design of multiple types of pacemakers and the implantation of millions of devices into both adults and children worldwide. In the United States alone, the number of patients who have permanent pacemakers is estimated to be greater than 1 million.[95,403] The two types of permanent pacemaker generators in use include those with transvenous electrodes and those with epicardial electrodes. Both types are implanted in either the chest or the abdominal wall; pacemakers with epicardial electrodes are the ones used most commonly in the pediatric population.[403]

Infection is the most common medical complication of implantation of permanent pacemakers, with reported rates ranging from 0.13 percent to as high as 20 percent and a mortality rate of 27 to 66 percent.[36,49,62,95,113] An estimated 25 percent of cardiac pacemaker–associated infections develop within 1 to 2 months of placement of the device, but delays of up to 12 months may occur before diagnosis is established. However, since the 1980s, the incidence of infection associated with permanent pacemakers has decreased significantly because of improved surgical techniques and better design of the devices themselves; most series since that time report infection rates no higher than 5.7 percent.[13,36,95,156]

Studies have shown that infections of permanent cardiac pacemakers seem to occur more commonly in patients with both local and systemic underlying medical problems, especially diabetes mellitus or an underlying malignancy, or in those who are undergoing treatment with corticosteroids, anticoagulants, or other types of immunosuppressive therapy.[60,313] Other well-characterized independent risk factors include surgery related

to any part of the pacemaker (especially replacement of a battery or upgrade of the pacemaker),[60,149,150,156,210] the presence of a hematoma after implantation,[50,60,153,201] temporary transvenous pacing,[156,268] and operative time.[268] Multiple (two or more) pacemaker insertions and physician inexperience with insertion also represent significant risks for development of infection.[149]

Infections of permanent cardiac pacemakers are subdivided into different groups depending on the specific site of involvement and whether they are early infections (<1 to 2 months after implantation) or late infections (>2 months after implantation). The different groups include (1) local inflammation, infection, and the formation of an abscess in the generator pocket or subcutaneous portion of the lead, or in both sites; (2) secondary infection involving either the generator or the electrodes (including pacemaker endocarditis)[13,50,95,201]; (3) fever plus associated bacteremia, with or without concomitant infective endocarditis, in a patient without any apparent focus of infection[13,95]; and (4) mediastinitis, pericarditis, bronchopleural cutaneous fistulas, and mixed infections.[95]

The generator pocket and the subcutaneous portions of the leads (transvenous and epicardial) are the most common sites of infection. In a case series of permanent pacemaker–associated infections, Choo and associates[60] reported that abscesses in the generator pocket were present in 72 percent of the patients and were the only manifestation of infection in almost 40 percent. Infections of the pocket often are difficult to diagnose and may develop at any time after implantation; however, most tend to develop early and frequently are the result of contamination by skin flora at the time of the procedure.[258] Late infection usually occurs as a consequence of erosion of the device through the subcutaneous tissue and skin. The infection may remain localized to the pocket or may spread to the adjacent electrodes and lead to the development of bacteremia.[26,36] Infection of transvenous pacemaker leads may occur in as many as 17 percent of patients who receive permanent pacemakers. These infections often are not apparent initially but have been associated with significant morbidity and mortality. Bluhm[36] and others[140] reported a 25.3 percent mortality rate in 1734 patients with permanent pacemakers who had retained infected transvenous leads. Infection generally develops along the subcutaneous portion of the leads and, if unrecognized, may progress centrally and result in sustained bacteremia, endocarditis, or both.[36,140] Infections of the leads tend to occur later than infections of the pocket, with the median time of occurrence being 7 to 8 months after implantation of the pacemaker.[36,37] Endocarditis as a complication of unrecognized infected transvenous leads usually develops an average of 37 months after placement of the pacemaker.[263] Infections of permanent epicardial leads generally occur as a complication of infections of the generator pocket, skin erosion, or direct contamination at the time of placement. However, in contrast to infections of the transvenous leads, infections of the epicardial leads usually result in only local symptoms; rarely, they may lead to more severe disseminated disease such as pericarditis, mediastinitis, bronchopleural cutaneous fistulas, bacteremia, or sepsis.[26]

Clinical Findings

Diagnosing a pacemaker-associated infection can be difficult because of its nonspecific symptomatology, and months may elapse after the onset of symptoms before the diagnosis is established. Symptoms may be confined to a local area or may be more widespread with the development of bacteremia or other systemic effects. Fever (84-100%) and chills (75-84%) are considered the most common systemic symptoms and are indicators of local infection, especially if they occur after the second postoperative day in association with other signs; however, they may be the only clinical manifestation in more than a third of patients.[50,201,259,263,269,416] Early infections are more likely to be accompanied by both local and systemic clinical findings and are manifested more commonly as infections of the generator pocket, bacteremia, or septicemia[50,217,229,432]; late infections, on the other hand, typically cause vague symptoms that evolve over the course of time and usually are lead-related infections and endocarditis.[60,194,210,397]

Infections of the generator pocket typically cause local swelling (21%), erythema (34%), pain (32%), drainage (through an incompletely healed incision or fistulous tract) over or adjacent to the generator pocket (25%), and warmth (11.5%).[62] Sterile breakdown of the pacemaker pocket develops in an estimated 5 percent of patients with permanent pacemakers, and skin or soft tissue erosion over the electrodes occurs in an additional 2 to 4 percent. Because these complications are associated with a high risk for the subsequent development of infections, the presence of any erosion is considered a potential indicator of device-related infection, especially if the erosion occurs more than 24 months after placement of the pacemaker, at which time the infection rate may be as high as 80 percent.[33,138,143] Pacemaker-related endocarditis is a relatively rare complication that occurs in 0.05 to 0.5 percent of cases after implantation of a pacemaker. Such endocarditis is associated with a mortality rate as high as 34 percent in some series.[50,115,170,201] It tends to be a late complication; only 27 to 36 percent of patients are seen within 6 to 12 weeks after the last procedure at the pacemaker implant site, with symptoms developing in most patients a mean of 25 months after the last procedure at the implant site. The diagnosis of pacemaker-related endocarditis is difficult to establish, and usually a delay in making the diagnosis, with a mean interval of 5 to 8 months after the onset of symptoms, occurs.[50,201] Pulmonary symptoms are found in 20 to 45 percent of patients with pacemaker-related infections and may consist of bronchitis, lung abscess, pneumonia, or pulmonary embolism; these symptoms are seen more commonly in late-onset infection and in patients with intravenous lead–related infection.[50,201]

A variety of laboratory and imaging studies may be performed to aid in establishing the diagnosis of a pacemaker-related infection. An elevated ESR is found in 82 to 97 percent of patients, and peripheral leukocytosis is seen in 50 to 66 percent. The presence of a collection of fluid around the device as seen on ultrasound is suggestive of device-related infection. Gallium scanning may be performed in an attempt to determine the nature of the fluid (inflammatory versus infectious). Transthoracic echocardiography has emerged as a major tool in diagnosis; studies have shown that this test was able to demonstrate vegetations and other lesions on the electrodes, ventricular endocardium, and tricuspid valve in 90 to 96 percent of patients with pacemaker-related infections.[50,201,397]

Microbiology

Staphylococci (*S. aureus* and CoNS) are the most common causes of pacemaker-related infections, and they account for more than 85 percent of such infections; however, a wide variety of organisms have been isolated.[13,36,50,51,60,201,217,397] A higher proportion of *S. aureus* is isolated from early infections, whereas CoNS are isolated more commonly from late infections.[36,78,217] An increasing number of these organisms are methicillin-resistant. Other gram-positive organisms such as viridans streptococci, other streptococci, enterococci, *Listeria*, and *Corynebacteria* have been isolated as well, but each causes less than 1 percent of cases. Gram-negative organisms such as *E. coli*, *Proteus*, *Enterobacter cloacae*, *P. aeruginosa*, *Klebsiella*, and *S. marcescens* are isolated from 5 to 20 percent of device-related infections. In addition, *Candida*, *Aspergillus*, and other fungi have been isolated rarely; however, infections with these organisms generally are associated with poor clinical outcomes.[13,50,69,72,201,205,262,397,416,417]

Management and Treatment of Infection

Appropriate therapy for pacemaker-related infections is tailored to the specific clinical situation and depends on several different factors: (1) whether the infection is limited to the generator pocket or subcutaneous electrodes without bacteremia, (2) whether bacteremic pacemaker-related endocarditis is present with or without involvement of the subcutaneous electrodes, and (3) what organism is involved.

If the infection is limited to the generator pocket or subcutaneous electrodes, optimal treatment consists of both medical and surgical intervention in which all the parts of the infected device are removed. Studies have shown that failure to remove completely all portions of the infected device results not only in failure to cure the infection but also in higher mortality rates.[51,60,324,400] The patient is given parenteral antimicrobial therapy, and an exchange of the pacing system with total removal of the infected device and simultaneous insertion of a new pacemaker at a different site is performed surgically. The infected subcutaneous pocket is drained, débrided, and packed open, and local wound care is instituted. Initial antibiotic therapy should provide coverage for both staphylococci and gram-negative bacteria; therapy is tailored once the organism is identified and its antibiotic susceptibility is known. Typical regimens include vancomycin plus an aminoglycoside for a duration of 2 to 4 weeks, or oxacillin or nafcillin plus an aminoglycoside may be used. In certain instances, a new pacemaker cannot be placed at the time of removal of the infected device; in such situations, a period of temporary transvenous pacing is instituted until a new pacemaker can be implanted.[217]

The consensus approach to the management of pacemaker-related endocarditis and bacteremia involves removal of both the generator unit and the electrodes in conjunction with prolonged administration of parenteral antibiotic therapy designed to treat endocarditis (usual duration, 4-6 weeks). Mortality rates may be as high as 50 percent for patients in whom total removal of the pacemaker unit is not performed.[13,50,51,201] If the electrodes have been in place for longer than 18 months or large vegetations (>10 mm) are associated with them, extraction of the electrodes by traction may be difficult and risky to perform, so surgical extraction by cardiotomy may be necessary. In patients who require a pacemaker, temporary transvenous pacing may be implemented until a new permanent pacemaker can be placed. Antimicrobial therapy targeted at the causative organism should be administered for a minimum of 2 weeks, and sterility of blood cultures should be ensured before a new pacemaker generator and electrode are placed. Typical empiric therapy consists of vancomycin plus gentamicin and rifampin; therapy may be tailored once the organism has been identified and its antibiotic susceptibility is known.

INFECTION OF IMPLANTABLE CARDIOVERTER-DEFIBRILLATORS

The first implantable cardioverter-defibrillator (ICD) was placed in 1980, and during the last several decades it has become a successful therapeutic modality for the treatment of patients (both adults and children) with life-threatening ventricular arrhythmias. Older devices required surgical placement of a pulse generator, extrapericardial or epicardial defibrillation patches, and a transvenous rate-sensing electrode. The systems placed today use a rate-sensing lead that is implanted transvenously, a superior vena cava coil electrode, and additional subcutaneous or epicardial electrodes all connected to a pulse generator that is placed subcutaneously or submuscularly and usually is located in a pocket created in the abdominal region.[195,362,420]

Infection is the most serious complication of placement of an ICD.[50,211] Infection rates associated with placement of ICDs ranged from 1 to 7 percent.[13,363,383] However, infection rates have decreased substantially with the advent of transvenous non–thoracotomy-placed systems, with rates ranging from 0.8 to 1.5 percent.[127,286,357] Several risk factors that have been identified as increasing the likelihood for development of infection include steroid use, diabetes, malignancy, and renal failure.[35] Most ICD-related infections are clinically apparent within 3 to 6 months after placement, with infections of the generator pocket, subcutaneous patch wound site, or epicardial patches or bacteremia and endocarditis being the most common manifestations. An increased WBC count and ESR, anemia, and microscopic hematuria are the most common laboratory findings. Echocardiography may be helpful in half of the cases. Infection of the generator pocket or subcutaneous patch wound site usually causes local findings of pain, erythema, and collection and drainage of fluid from the site. Occasionally, these patients also may be bacteremic or hypotensive. In contrast, infection of the epicardial patches generally results in more systemic symptoms, bacteremia, or pericarditis.[286] The diagnosis of ICD-related infection typically is made on clinical grounds and confirmed by culture of the fluid or drainage around the device.

Microbiology

S. aureus and CoNS are the major pathogens seen with ICD-related infections, and they account for 60 to 80 percent of cases.[211,286,336,363] However, a broad spectrum of other gram-positive, gram-negative, and fungal organisms, including *P. aeruginosa*, corynebacteria, streptococci, *E. coli*, *Klebsiella*, *Bacteroides fragilis*, *Propionibacterium acnes*, atypical mycobacteria, and *Candida* spp., have been isolated from ICD-related infections. Polymicrobial infections may occur in the generator pocket.[211,336,357]

Management

To eliminate ICD-related infections effectively, optimal management involves a combination of medical and surgical interventions, especially if the patient is bacteremic or has systemic findings or if the causative organism is *S. aureus*. Several studies have suggested that conservative management (i.e., antibiotic therapy without removal of the hardware) may be sufficient. However, such an approach should be tried in cases in which only the generator pocket is infected (management may consist of the administration of parenteral antibiotics, wound care, and removal of only the generator portion of the device, with implantation of another generator at a different site) or in patients whose condition prevents removal of the entire device. In these situations, treatment of the ICD-related infection should include a prolonged course of parenteral antibiotics, followed by continuous suppressive oral antibiotic therapy.[286,386] The optimal management of ICD-related infections is parenteral antibiotics and removal of the entire ICD system.[13,62,211,336] The duration of antibiotic therapy varies from 2 to several weeks.

PROSTHETIC JOINT AND ORTHOPEDIC IMPLANT INFECTIONS

The implantation of prosthetic joints along with the use of other implantable orthopedic devices (e.g., pins, screws, plates, rods, external fixators, Ilizarov apparatus) has improved the quality of life greatly and restored function to patients suffering from debilitating bone and joint disease, tumor, or injury. Based on conservative estimates, millions of people worldwide have some form of prosthetic joint or other implantable orthopedic device. Of the possible complications associated with implantation, infection is the second most common cause of prosthetic

joint failure.[10] It occurs in 1 to 13 percent of cases[213] and results in postoperative prosthesis failure, chronic pain, immobility, and, in some cases, loss of the affected limb or, in the worst-case scenario, loss of life.[2,31,90,119,366] The health care cost in the United States for treating a single infection of a prosthetic joint is estimated to be more than $50,000, with an extrapolated expenditure of greater than $100 million per year nationwide.[28,152,344,366]

Prosthetic joints and implantable orthopedic devices may become infected by two major mechanisms: (1) the prosthetic device may be contaminated by microorganisms at the time of implantation, either as a result of airborne contamination in the operating room or by direct inoculation at the time of surgery, or (2) the prosthetic device may become infected as a result of hematogenous seeding from bacteremia or by direct contiguous spread from an infection adjacent to the prosthesis. Twenty to 40 percent of infections of prosthetic joints arise by hematogenous seeding, with the remainder occurring as a result of airborne or direct inoculation.[1,41,220,221,233] Infections may remain asymptomatic for years before symptoms become apparent, and usually a long delay occurs between onset of the infection and the appearance of symptoms and confirmation of the diagnosis. The overall rate of infection of prosthetic joints has been shown to be highest in the first 6 months postoperatively, with a steady decline occuring after this time. The incidence rate for infection of total-hip and total-knee arthroplasties during the first 2 years postoperatively is reported to be 5.9 infections per 1000 joint-years; in contrast, during postoperative years 2 to 10, it is 2.3 infections per 1000 joint-years.[366] The risk of acquiring infection and the incidence of infection depend on the anatomic location of the implanted orthopedic device or prosthetic joint, with the hips having the highest risk followed in descending order by the knees, elbows, shoulders, wrists, and ankles.[65,143,317,371] For implantable orthopedic devices, rates of infection range from 2 to 30 percent.[234,396,422]

RISK FACTORS

Numerous factors have been identified as increasing a patient's risk for developing infection of a prosthetic joint or orthopedic implant. These factors include rheumatoid arthritis, diabetes mellitus, obesity, poor nutritional status, the use of steroids, immunocompromised status, psoriasis, hemophilia, sickle-cell hemoglobinopathy, solid-organ transplant, dialysis-dependent renal failure, joint dislocation, and extremes of age.* In addition, previous surgery at the site of the prosthesis or implant also increases the risk of acquiring an infection. For example, several studies showed that the risk of deep infection developing in patients undergoing revision of a hip or knee arthroplasty was twofold to eightfold higher than that in patients with primary arthroplasty.[312,316,425] The relative risk for the development of prosthesis-related infections in patients with poor healing and wound complications increases from 13- to 20-fold after total-knee replacement and from 22- to 52-fold after total-hip replacement.[425]

The implanted metal prosthetic device and the PMMA cement that binds the prosthetic device to adjacent bone also predispose the joint space and bone to infectious processes, given that both are foreign bodies. In vitro studies have shown that the unpolymerized form of PMMA cement predisposes to infection by inhibiting phagocytic, lymphocytic, and complement function; the risk of acquiring infection seems to be enhanced further once the cement has polymerized in the body.[300,301] Cementless prostheses have been designed in an attempt to overcome the problem of infection associated with the PMMA cement. For certain orthopedic implants, the integrity of the skin is compromised chronically, thus providing ready access to organisms from the external environment.

MICROBIOLOGY

More than 65 percent of infections associated with prosthetic joints and implanted orthopedic devices are caused by *S. aureus*, CoNS, beta-hemolytic streptococci, viridans streptococci, and enterococci. Antibiotic resistance in these organisms is increasing, and multiple different strains of staphylococci may be present in a single prosthetic joint infection.[173,180,234,337,396,421] Less commonly, aerobic gram-negative bacilli, including *E. coli*, *Proteus mirabilis*, *Klebsiella* spp., *Salmonella* spp., *S. marcescens*, other Enterobacteriaceae, and *P. aeruginosa*, may cause infection. In addition, 4 to 10 percent of infections are caused by anaerobic organisms such as peptostreptococci and *Bacteroides* spp.; polymicrobial infections occur in approximately 12 percent of cases.[173] Infections with fungi, particularly *Candida*, *Aspergillus*, and *Penicillium* spp., or with mycobacteria (i.e., *Mycobacterium tuberculosis*, *Mycobacterium avium* complex [MAC], and other rapidly growing mycobacteria) also have been described.[20,30,41,236,385] Rarely, a wide spectrum of other organisms, including *Corynebacterium*, *Propionibacterium*, *Bacillus* spp., and *Mycoplasma hominis*, have been reported to cause infection.[41] Zoonotic bacteria such as *Brucella* spp., *Yersinia* spp., and *Pasteurella* spp. rarely can cause infection and should be considered in the correct epidemiologic setting.[236]

Certain clinic situations may predispose a patient to particular organisms as the cause of infection. Pyogenic skin infections commonly result in staphylococcal and streptococcal infections of prosthetic joints, whereas infections of the teeth and gums are frequent causes of viridans streptococcal and anaerobic infections in prostheses. Genitourinary and gastrointestinal tract procedures or infections frequently are associated with enterococcal and gram-negative bacillary infections of prostheses.[41]

CLINICAL MANIFESTATIONS

The clinical findings and the severity of symptoms seen with infections of prosthetic joints are highly variable and determined primarily by three factors: (1) the route of infection—the hematogenous route versus direct inoculation; (2) the virulence of the infecting pathogen—*S. aureus* and, to a lesser extent, beta-hemolytic streptococci and gram-negative bacilli seem to be particularly virulent pathogens capable of producing a fulminant clinical picture, whereas infection with organisms such as CoNS is associated with a more chronic, indolent course; and (3) the nature of the tissue in which the microorganism proliferates—hematomas, seromas, ischemic wounds, and the tissues of diabetic patients and those receiving steroids all enhance the ability of the bacteria to proliferate and spread, thereby promoting the development of a more deep-seated fulminant infection.

The most common initial symptom is joint pain, which occurs in 95 percent of cases. Such pain can range from an acute fulminant illness with erythema, severe joint pain, swelling (38%), high fever (43%), and systemic symptoms to, more frequently, a chronic, slowly increasing pain in the joint that may be associated with the formation of a cutaneous draining sinus (32%) but no systemic symptoms.[173] The presence of constant joint pain is more indicative of infection than is the presence of pain occurring only with movement or weight bearing, which is indicative of mechanical loosening and inflammation.[139]

For implantable orthopedic devices, the most common initial symptom of infection is erythema, swelling, pain, or drainage from the area around and adjacent to the implant. Local symptoms also may be associated with fever, especially if the device is extensive or deep-seated.

DIAGNOSTIC STUDIES

Laboratory screening tests commonly used to diagnose infection of a prosthetic joint or implanted orthopedic device are the peripheral WBC count, C-reactive protein (CRP), and the ESR. Elevation of one or more of these factors may help support the diagnosis of an infection.[22,360]

The principal radiologic studies used for detection of an infected prosthetic joint include plain radiographs, arthrograms or sinograms, and radioisotope scans (indium and technetium diphosphate). Abnormalities that may be suggestive of infection and can be seen on plain radiographs include radiolucency at the bone-cement interface, motion and changes in position of the prosthetic components, evidence of osteomyelitis, cement fractures, and periosteal reaction. Intra-articular injection of dye (arthrogram or sinogram—in the presence of a sinus tract) may demonstrate abnormal communication between the joint space and the bone-cement interface. These radiographic abnormalities are present in approximately 50 percent of infected prostheses.[77,139,231] Nuclear scans with indium or technetium diphosphate may be used to detect periprosthetic inflammation. Both these scanning techniques are very sensitive but lack specificity. Technetium diphosphate (^{99m}Tc) shows increased uptake in areas of bone with an enhanced blood supply or increased metabolic activity. Increased uptake normally is seen around uninfected prostheses within the first 6 months after implantation; positive findings after this time are abnormal and reflect inflammation (which could be due to a variety of causes) but not specifically infection.[94,160,191,287] Indium 111–labeled leukocyte scanning has been shown to have a specificity of only 50 to 80 percent for knee and hip prosthetic infections.[278] In contrast, ^{99m}Tc-labled ciprofloxacin (which probably binds to live bacteria at the infection site) was shown to be 94 percent sensitive and 83 percent specific for the diagnosis of chronic infection.[359] Use of this technique allowed 11 of 12 infections of prosthetic joints to be identified, whereas ^{99m}Tc-WBC scintigraphy was positive in only seven patients.[359] CT and MRI are not used routinely in the evaluation of a patient with a suspected infection of a prosthetic implant because of the large amount of imaging artifact created by prosthetic devices.[40,256]

Aspiration of joint fluid for culture and culture of tissue obtained intraoperatively are the optimal ways of establishing a specific diagnosis of infection of a prosthetic joint. Although joint fluid findings indicative of an infectious process are a high leukocyte count (consisting mainly of polymorphonuclear leukocytes [PMNs]), a high protein content, and a low glucose concentration, these changes are not specific for bacterial infection and are present in only some patients. Nonetheless, infection should be suspected if there are five or more neutrophils per high-power field in a periprosthetic specimen.[360] The fluid obtained should be cultured for a variety of organisms; Gram stain is positive in a third of the cases, and a causative pathogen can be identified in only two thirds of patients.[297,361] Intraoperative cultures should include, if possible, any purulent discharge, devitalized bone, and tissue from the bone-cement interface. Vortexing or bath sonication (or both) of the explanted prosthesis may increase the yield.[294] Histopathologic examination of this tissue usually reveals an infiltration of PMNs consistent with an acute inflammatory reaction but not specific for infection.[141] More rapid, specific, and sensitive tests (e.g., in situ hybridization, immunofluorescence, polymerase chain reaction) are needed to differentiate between noninfectious inflammation and bacterial infection.

TREATMENT

Successful treatment of an infected prosthetic joint involves extensive surgical débridement of all devitalized bone and tissue, removal of the prosthesis and all associated cement, and prolonged parenteral antibiotic therapy.[22] For optimal results, the débridement should be performed within 1 to 2 weeks.[213] Microbiologic cure has been found to correlate well with the extent of débridement and the completeness of removal of all residual methylmethacrylate cement.[52] Historically, attempts at simple surgical débridement without removal of the prosthetic device in conjunction with parenteral antibiotic therapy have been successful in only 20 percent of cases, with relapse rates being as high as 88 percent by 2 to 4 years after therapy.[107,338,418] However, recent studies have shown that in patients with a short duration of prosthetic joint infection caused by penicillin-susceptible streptococci, débridement and antibiotic therapy alone appear to be sufficient, with a low risk of relapse.[251]

Two protocols have been used for the treatment of these infections. A two-stage surgical procedure with prolonged parenteral antibiotic therapy has been shown to be one of the most successful treatment regimens with the best functional results. The first stage involves complete removal of the prosthesis and cement followed by a 6-week regimen of antibiotic therapy empirically chosen to cover the most likely organism and then tailored once the organism has been identified and its antibiotic susceptibility known. The second stage involves reimplantation of a new prosthetic device at the end of the antibiotic course. Success rates with this procedure range from 53 to 100 percent.[104,119,124,222,270] An alternative method of therapy involves a one-stage exchange operation in which the infected prosthetic device and cement are removed, all devitalized tissue and bone are débrided, and a new prosthesis is reimplanted immediately, followed by 6 weeks of parenteral antibiotic therapy. Antibiotic-impregnated (either tobramycin or gentamicin) methylmethacrylate cement is used in these situations, and success rates range from 33 to 80 percent.[46,53,97,148,253,319,388] This procedure is appropriate only for patients with infections caused by less virulent microorganisms because of the high failure rates seen when a more virulent organism such as *S. aureus* or a gram-negative bacillus is the cause of the infection.[106]

The Ilizarov method allows simultaneous treatment of infection, bone and joint deformities, bone loss, and shortening of the limb. This device includes proximal and distal circular external rings with wires passing through the bone and soft tissue from one side of the limb to the other. The wires are placed in several planes and orientations to stabilize the bone. The rings are connected with threaded rods and nuts to allow for lengthening or shortening of the limb. Although this method is used more often for the treatment of bone nonunion or bone loss with or without infection,[265,290,296,350] David and colleagues[83] used this technique successfully to treat 12 patients who failed total-knee arthroplasty because of infection. Wound infection and chronic osteomyelitis caused by infection of the wire tract occur infrequently and should be treated by débridement of the infected soft tissue and curettage of the infected bone.

Currently, a two-stage prosthetic removal-reimplantation procedure coupled with the incorporation of antibiotic-impregnated cement during reinsertion of the implant, in combination with a 6-week antibiotic regimen, is the mainstay of therapy for infections of prosthetic joints.[120,270] Selection of antibiotics should take into account the recent increase in methicillin resistance among staphylococci for the following reasons: MRSA infections of the prosthetic joint result in a higher incidence of treatment failure than do infections with methicillin-susceptible *S. aureus*, and the former result in longer durations of hospitalization and a low survival rate free of treatment failure.[332] Thus, vancomycin (with and without rifampin) should be the initial drug of choice for gram-positive bacteria until the susceptibility of the infecting organism is known. Recent reports of treatment failures (even with vancomycin susceptibility within the treatment range [i.e., 2 to 4 μg/mL])[169,379] suggest that other

antibiotics (e.g., trimethoprim-sulfamethoxazole, linezolid) should be considered. Several reports have shown that linezolid is a reasonable alternative that results in control of the infection.[394]

For infected implanted orthopedic devices, the success of therapy is based on total removal of the device together with parenteral antibiotic therapy. In cases in which the foreign body cannot be removed, extended parenteral antibiotic therapy should be instituted and continued until the device can be removed. The duration of therapy varies with the severity of the infection and ranges from several weeks to several years.

CENTRAL NERVOUS SYSTEM SHUNTS

Infection is a major cause of morbidity in children who undergo CSF shunting procedures. Such procedures are performed to divert CSF in symptomatic hydrocephalic patients and are used commonly in patients with anatomic abnormalities (e.g., meningomyelocele and Chiari malformations), in premature newborns with intraventricular hemorrhage or intracranial infections (e.g., congenital cytomegalovirus, congenital toxoplasmosis, bacterial meningitis), and in patients with central nervous system (CNS) tumors or head trauma. Usually, the proximal end of the shunt is placed in the frontal or fourth ventricle and the distal end is inserted into the peritoneal cavity (i.e., ventriculoperitoneal [VP] shunt). Other compartments such as the right atrium (i.e., ventriculoatrial [VA] shunt), the pleural cavity, or the gallbladder can be used to place the distal end. CSF shunts are prone to complications, with a 10-year failure rate greater than 50 percent.[88,305] The most common complication is mechanical (such as obstruction or overdrainage from siphoning), followed by shunt-related infection. The incidence of shunt-related infection varies considerably, from 0.3 to 12 percent.[45,61,74,99,147,197,208,395] These infections increase morbidity rates and, in some cases, significantly affect patients' outcomes.[25] Recent understanding of some of the factors that contribute to the development of these infections has helped reduce their incidence.[61,102,198,409]

EPIDEMIOLOGY

Almost two thirds of shunt-related infections occur within 1 month after placement of the shunt, and 90 percent of infections are manifested within 6 months.[146,204,248] The incidence of shunt-related infections is significantly higher in infants in the first 6 months of life than in older children.[98,310,398] The infection rate is even higher in newborns with intraventricular hemorrhage who undergo shunting in the first week of life[7] and in premature infants.[208,249] Reasons for the increased incidence of shunt-related infection in very young patients are multifactorial. Several mechanisms that have been suggested include delayed wound healing, higher skin density of bacteria that are more resistant to antibiotics and more adherent to the shunt than in older children, longer duration of hospitalization, surgical technique, and increased exposure to antibiotics just before the shunt is placed.

No significant difference in infection rate is seen in patients with VP or VA shunts,[284,352] but a lower infection rate was noted in those with lumboperitoneal or cholecystic shunts. An increased risk of development of infection was reported for shunts placed immediately after removal of a previously infected shunt, probably because of incomplete eradication of bacteria.[99,199,346] Several other factors, including the underlying cause of the hydrocephalus,[98] the surgeon's experience,[66,196] previous shunt infection,[249] the duration of surgery, the number of people in the operating room, operative technique (e.g., prophylactic antibiotics, skin preparation, shaveless operation),[166] operative time, open surgery to insert the abdominal catheter versus direct puncture of the abdominal wall with a trocar, and postoperative CSF leakage,[208] have been reported to be associated with an increased incidence of shunt-related infection. Although a trend toward more shunt-related infections has been reported with these factors, it has not been demonstrated consistently. A few studies suggest that tapping the shunt may result in an infection, with an incidence ranging from negligible to greater than 30 percent in premature infants with shunts tapped multiple times.[45]

ETIOLOGY

Staphylococcal species are the most common cause of shunt-related infection, with CoNS (e.g., *S. epidermidis*, *Staphylococcus capitis*, *Staphylococcus hominis*, *Staphylococcus lugdunensis*)[96] being isolated in 25 to 70 percent of cases (Table 85–2).[96,204,264,352] *S. aureus*, the second most common gram-positive bacterium, is responsible for 10 to 40 percent of cases. Streptococci (e.g., viridans, group B or C, *S. pyogenes*, *S. pneumoniae*, enterococci) are identified less commonly (3% to 7%). Other gram-positive bacteria such as *Propionibacterium*[381] and *Corynebacterium* (diphtheroids)[15,137] are isolated as well. The seemingly increased incidence of shunt-related infections caused by these two groups of bacteria probably is the result of poor culture technique (e.g., failure to use anaerobic culture media, less than 5 to 7 days' incubation period) or misinterpretation of culture results (e.g., culture contamination) leading to under-reporting (or both).

Gram-negative bacteria (e.g., *E. coli*, *Klebsiella* spp., *Proteus* spp.) together are the cause of 5 to 25 percent of shunt-related infections.[364] *Pseudomonas* spp. and *Acinetobacter* spp. are reported as well, but less frequently. Shunt-related infections caused by gram-negative bacteria occur more commonly in patients with myelomeningocele and those in whom the distal part of the VP shunt is inserted into the peritoneal cavity via a percutaneous trocar (i.e., with an inadvertently perforated intestinal tract). Many other etiologic agents, including fungi (e.g., *Candida*,[76,122,133] *Histoplasma*,[342] *Cryptococcus*,[172] *Torulopsis*[405]), *Pasteurella multocida*,[214] *Neisseria* spp.,[167,372] *S. marcescens*,[44] nontuberculous myco-

TABLE 85–2 Pathogens Causing Cerebrospinal Fluid Shunt Infection

Pathogens	Incidence (%)
Gram-Positive Bacteria	
Staphylococcus, coagulase-negative (e.g., *Staphylococcus epidermidis*, *Staphylococcus capitis*, *Staphylococcus hominis*, *Staphylococcus warneri*, *Staphylococcus lugdunensis*, *Staphylococcus haemolyticus*)	25-70
Staphylococcus aureus	10-40
Streptococci (e.g., *Streptococcus pyogenes*, group B or C streptococci, Enterococcus, *Streptococcus pneumoniae*)	3-7
Propionibacterium species	Rare
Corynebacterium species	1-2
Gram-Negative Bacteria	
Escherichia coli	5-25
Klebsiella species	5-10
Proteus species	2-6
Pseudomonas species	2-4
Acinetobacter species	1-3
Other gram-negative bacteria (e.g., *Neisseria* species, *Haemophilus influenzae*, *Pasteurella*)	<1
Fungi	<1
Candida species	
Histoplasma	
Cryptococcus	
Torulopsis	

bacteria,[56] and others, have been reported less commonly as causing shunt-related infections. With the increase in the number of patients who are immunocompromised for various reasons (e.g., neutropenia, chronic intravenous catheters, prolonged administration of broad-spectrum antibiotics, hyperalimentation), the incidence of these rare infections will increase. Bacteria that traditionally cause meningitis, such as *H. influenzae*,[323,369] *S. pneumoniae*,[283] and *Neisseria meningitidis*,[215] were reported as causing shunt-related infections. Whether these cases were isolated shunt-related infections or extension of meningitis into the ventricular system (i.e., ventriculitis) is not clear. Therefore, if such bacteria are isolated from a suspected shunt and the patient has a communicating hydrocephalus, lumbar puncture should be performed to rule out meningitis.

PATHOGENESIS

Several observations suggest that most CNS shunt–related infections are caused by inoculation of the organism during surgery or contamination of the device by ward personnel during manipulation.[91,310,406] These observations include the facts that common skin flora (e.g., CoNS, *S. aureus*) are the pathogens most frequently encountered, most of the infections occur within the first few weeks after surgery, and irrigation of the system is a risk factor for the development of infection. Another common mechanism (occurring with gram-negative bacterial infections) is retrograde progression of bacteria from the gastrointestinal tract (i.e., bowel perforation)[164,328] or from the urinary tract (in the case of a ventriculo-ureteral shunt).[118] Other mechanisms by which shunts become infected include (1) hematogenous infection in which a distant site of infection produces bacteremia leading to a shunt infection (this type of infection occurs quite rarely and in most cases represents meningitis with secondary infection of the shunt, such as *S. pneumoniae* or *N. meningitidis* CNS infection in patients with a shunt) and (2) wound or skin infection (e.g., cellulitis, decubitus ulcer), with direct extension from the infection site to the shunt.

The predominant role of CoNS and *S. aureus* in CNS shunt–related infection is the result of their being the major constituents of normal cutaneous flora, especially in young children,[218,347] and their having the ability to adhere directly to the shunt (e.g., *S. epidermidis*) or to host proteins covering the shunt (e.g., *S. aureus*). In addition, CoNS (and some *S. aureus* strains) produce large amounts of extracellular slime (i.e., biofilm) that completely covers the organism.[42] More than 60 percent of staphylococci isolated from infected shunts produce biofilm.[84,101,142] The biofilm of *S. epidermidis* is a mixture of teichoic acid and protein.[170] Production of biofilm also was reported in corynebacterial infection, which may explain the increasing importance of this bacterium in CNS shunt–related infections.[24] The biofilm facilitates attachment of these organisms to the surface of the shunt and protects the bacteria from the host's immune defenses (i.e., reduces phagocytosis). Once the organisms are attached to the shunt material, they are extremely difficult to remove except by completely replacing the shunt. In addition, penetration of antibiotic into the biofilm is variable, and the biofilm antagonizes the antimicrobial activity of some antibiotics (e.g., vancomycin).[89,103] The importance of production of biofilm for the establishment of shunt-related infection caused by CoNS was shown by Younger and colleagues,[429] who found that 88 percent of the CoNS strains isolated from true shunt-related infections produced slime. Moreover, infections caused by nonadherent organisms were significantly more likely to be cured by antibiotics alone (without removal of the colonized shunt) than were infections caused by adherent organisms. Similarly, Diaz-Mitoma[84] and coworkers found that both obstruction of VP shunts and failure to cure the infection with antibiotics alone occurred more frequently when infectious episodes were caused by biofilm-producing CoNS. Therefore, complete removal of the shunt should be considered in patients with CoNS or *S. aureus* infection because biofilm-producing organisms may not be treated effectively when the shunt is in situ.

S. aureus infection is established primarily by the production of adhesin proteins. The most important proteins are fibronectin-binding (finb A and finb B) and fibrinogen-binding (Clf A and Clf B) proteins.[110] The ability to bind to fibronectin is very common in isolated strains of *S. aureus*, and its efficiency depends on the amount of finb A and finb B expressed on the cell surface of the individual isolate. The two fibrinogen-binding proteins attach to different parts of the host ligand, which suggests that they are acting synergistically or allow the bacteria to adhere to the ligand even during unfavorable conditions (e.g., antibodies against one of them).

The immature humoral immune system of young infants is not likely to explain the increased incidence of shunt-related infections in patients younger than 6 months old because these infants mount antistaphylococcal antibody responses that are comparable to those of older children.[310] Although levels of immunoglobulins and complement proteins are lower in this young group, levels of these proteins normally are very low in the CSF of older individuals (CSF levels of IgG and IgA are between 0.25% and 0.5% of those in serum). In addition, the types of bacteria causing CNS shunt–related infections are not associated commonly with humoral immunodeficiency states, thus suggesting that humoral protection is less important in CNS shunt–related infections. Little is known about the possible role of reduced tissue immunity in these infections.

The foreign body nature of the shunt apparatus plays an important role in the local host defense defect.[39] Electron-microscopic findings demonstrate irregularities in catheters that allow microorganisms to be buried in the catheter. In addition, the function of neutrophils is suboptimal because phagocytic and bactericidal activities are reduced as a result of the loss of lysosomal contents. Therefore, even when pathogens are phagocytized, they may not be killed and are protected from antibiotics that do not penetrate the cell membrane.

Other mechanisms that may contribute to shunt-related infections include (1) abnormal CSF flow (not being absorbed by the venous sinuses, thought to be important for prevention of infection in the CNS) and (2) interruption of the blood-brain barrier by the shunt catheter, with the creation of a direct tract between the subcutaneous tissues and the ventricles resulting in significant compromise in host defenses.[406]

CLINICAL MANIFESTATIONS

The initial signs and symptoms of most patients with shunt-related infections are nonspecific and include mild to moderate fever, malaise, irritability, nausea, vomiting, vague abdominal pain, and headache. With such nonspecific findings, the physician must be careful to differentiate between the possibility of a shunt-related infection and an intercurrent viral or bacterial infection of the upper respiratory, urinary, or gastrointestinal tract. Examination of the CSF (from a shunt tap) may be of help (see "Diagnosis"). Only a minority of patients have the classic signs and symptoms of CNS inflammation, such as a stiff neck, bulging fontanelle, change in mental status, cranial nerve palsy, or papilledema. In some patients the shunt tract may be infected, with evidence of cellulitis or dehiscence (or both) of the surgical wounds. Tenderness, edema, or erythema along the tract itself may be the only sign.

The type of shunt affects the nature of the infection. For example, VP shunt–related infections may cause symptoms and signs confined to the abdominal cavity, such as abdominal

pain, tenderness (with or without guarding), intestinal obstruction,[325] or spontaneous bacterial peritonitis.[121] Rarely, a distal shunt-related infection will be manifested as frank ascites as a result of CSF malabsorption.[209] A relatively common complication of VP shunts is an inflammatory peritoneal exudate that may lead to CSF loculation and the subsequent formation of a peritoneal pseudocyst.[8,326] These pseudocysts often are palpable and can be visualized by ultrasonography or CT. Bacteria are isolated in a third of cases, suggesting that infection may play a role in the pathogenesis of pseudocysts. In most cases, however, a high index of suspicion is required because the initial symptoms frequently are abdominal only, with no signs of shunt malfunction.

A unique complication of patients with VA shunts is the development of immune complex disease such as "shunt nephritis" (a form of acute glomerulonephritis), arthritis, or rash. In most of these cases, the infecting organism has been *S. epidermidis*, but other bacteria such as *Corynebacterium* can cause this complication.[38] In the case of shunt nephritis, the patient has fever, edema, malaise, hepatosplenomegaly, hypocomplementemia, anemia, azotemia, hematuria, and proteinuria.[78] Pathologic findings consist of mesangial hypercellularity and granular deposits of immunoglobulins and complement along the glomerular membrane. Rarely, arthritis may be the initial symptom because it may develop by the same immunologic mechanisms that cause nephritis.[216]

DIAGNOSIS

Although shunt-related infections are not common occurrences, the nonspecific signs and symptoms and the insidious onset in many cases render establishing a diagnosis very difficult. Therefore, any patient with a CNS shunt and fever without an obvious source should be suspected of having a shunt-related infection, especially if the symptoms continue for longer than a week. A higher index of suspicion for shunt-related infection is needed in young patients, in whom fever develops within 3 to 6 months after placement of the shunt. The only definitive diagnostic test is direct observation and culture of CSF. Tapping the shunt or sampling fluid in direct contact with the shunt should be performed if no signs or symptoms of increased intracranial pressure (ICP) are noted. CT of the head is recommended before the tap is done if such symptoms exist. The shunt tap should be performed with utmost attention given to sterile technique. The tap should be done by a neurosurgeon or physician who is familiar with the technique and the underlying hardware.

When percutaneous needle aspiration is performed, the area around the shunt reservoir should be scrubbed with antiseptic soap and the surrounding hair shaved (2 inches in each direction). The scalp area should be prepared by repeated application (at least three times) of povidone-iodine solution followed by alcohol. A 21- or 23-gauge butterfly needle is placed into the reservoir (or valve if no reservoir is present). Measurement of opening pressure can help in diagnosing a distal malfunction (i.e., increased pressure) or proximal shunt obstruction (i.e., less than expected pressure). CSF sample aliquots then should be allowed to drip into sterile vials. Gentle aspiration of CSF sometimes is performed if no fluid returns spontaneously. If only a few drops of CSF can be obtained, the more important tests, Gram stain and culture, should be performed first. Culturing the shunt wound, blood, or CSF obtained by lumbar puncture (which usually is not communicating with the ventricular fluid) often is unrevealing, misleading, or both. Although bacteremia frequently is present in patients with VA shunts and may help in diagnosing the etiologic agent, blood cultures generally are negative in patients with all other shunts (e.g., VP or pleural shunts). In addition, CoNS are the most common contaminants of blood cultures, and, therefore, interpreting a positive blood culture in these patients would be difficult.

CSF should be tested for glucose concentration, differential cell count, Gram stain, and culture. Protein concentration is requested often, but it is of very limited help in evaluating the presence or absence of an infection because high protein levels are found in many patients with shunt malfunction and no infection. In contrast, normal protein levels have been reported in many patients with shunt-related infections. A low glucose level suggests an infection, but one should confirm that the CSF sample was not diluted before the test was performed. Some physicians use saline to get a better flow of CSF (because of an occluded tube), which may affect the biochemical results. Of importance is to note that in many cases of shunt-related infection, the glucose level is within the normal range. Usually, pleocytosis with a predominance of PMNs is indicative of a shunt-related infection. Although in some cases the finding of a positive CSF culture is interpreted as a shunt-related infection despite a normal WBC count (<10 WBCs/mm^3), the absence of clinical symptoms (e.g., fever) in many of these patients suggests that the positive culture probably represents colonization or contamination. Other cells such as mononuclear cells[204,364] or eosinophils[247,384,399] may predominate during an infection. If eosinophilia is the predominant cellular response, an allergy to the shunt (e.g., silicone[183]) or the materials used for sterilization (e.g., ethylene oxide[307]) or intraventricular administration of antibiotics (e.g., gentamicin,[255] vancomycin[135]) should be considered.

Interpretation of the WBC count should be done cautiously if the red blood cell count is high because the increased number of WBCs can be the result of blood spilling into CSF without any infection or be part of the inflammatory response to the presence of blood (i.e., chemical ventriculitis). A positive Gram stain with an increased CSF WBC count or reduced glucose level (or both) is helpful in making the diagnosis of a shunt-related infection. A negative Gram stain does not exclude an infection, and one should wait for the results of culture. Ventricular fluid always should be cultured anaerobically as well as aerobically. Although most bacteria causing shunt-related infections grow within 48 to 78 hours, cultures should be held for 7 days (if still negative) for fastidious organisms such as *Propionibacterium*. The possibility of contamination or colonization of the shunt without infection should be considered when the culture is positive but other CSF parameters are normal. If such a scenario occurs and bacteria are growing only from one sample (e.g., a shunt tap) and not from follow-up cultures (i.e., from extraventricular drainage), a shorter course of therapy (see later) may be sufficient.

Blood cultures, a peripheral complete blood count (CBC), and ultrasound of the abdomen (for VP shunts) are of limited value. For example, although 90 percent of patients with VA shunt–related infection will have a positive blood culture, less than 10 percent of patients with other shunt-related infections will have a positive culture. In addition, in more than a third of patients with shunt-related infections, no elevation in the peripheral WBC count was found. Some investigators suggest that blood but not CSF CRP levels may be helpful in establishing the diagnosis of shunt-related infection when other concurrent infections (e.g., sinusitis, pneumonia) were excluded.[212,340] One suggestion is that if the CRP level is less than 7 mg/L, the shunt should not be removed because no infection is present. More data are needed to verify this observation. In patients with a VA shunt–related infection, measurement of serum anti-staphylococcal antibodies or the C3 and C4 components of the complement cascade may aid in establishing the diagnosis.[25,334] The triad of fever, abnormal CSF WBC count, and greater than 5 percent eosinophilia is highly predictive of a shunt-related infection.

TREATMENT

A variety of medical and surgical approaches to treatment of an infected shunt have been suggested.[415] Regimens include (1) the use of antibiotics alone (systemically, with or without intraventricular administration) without replacement of the shunt; (2) removal of the infected shunt followed by immediate insertion of a new shunt and the administration of systemic or intraventricular antibiotics, or both; (3) removal of the infected shunt and insertion of an extraventricular device (EVD) to monitor the patient's response to the accompanying antibiotic therapy, with a new shunt inserted only when the ventricular system is sterilized; (4) removal of the infected shunt followed by a stereotactic third ventriculostomy and administration of antibiotics; and (5) externalization of only the distal (e.g., peritoneal) catheter along with the administration of systemic or intraventricular antibiotics, or both.

The use of antibiotics alone without surgery was justified by the need to maintain CSF drainage and avoid costly operations and lengthy duration of hospital stay. The low success rate of this approach (33%) and the higher mortality rate associated with it suggest that it should not be used (Table 85–3). Of interest, the failure rate was much higher with infections caused by slime-producing organisms than with infections caused by non–slime-producing bacteria.[84] Only in shunted patients with purulent meningitis caused by *S. pneumoniae*, *N. meningitidis*, or *H. influenzae* did the administration of systemic antibiotics alone without removal of the shunt seem to be an acceptable option.[215,288,323,369]

Combining immediate replacement of the infected shunt with a new shunt and antibiotic therapy has a higher rate of success (70%, see Table 85–3) than does the use of antibiotics alone. Nonetheless, it is less effective than removal of the infected shunt accompanied by insertion of an EVD and administration of antibiotic therapy (88% success rate, see Table 85–3). A decision analysis of 17 studies reached the same conclusion and suggested that "this treatment option has the highest cure rate and the lowest failure and mortality rates."[339] In addition, lack of the ability to monitor when the ventricular fluid is sterilized results in a longer period of systemic antibiotic therapy (e.g., 4 to 8 weeks), which may lead to an increase in iatrogenic infections and cost. Some surgeons suggest removing the shunt and delaying replacement (i.e., a few days after removal to allow sterilization of the shunt's tract), but this approach is associated with increased morbidity.[108,407]

For infection that involves only the distal part of the shunt (e.g., pseudocyst, appendicitis,[295] erythema or swelling along the shunt tract, surgical wound infection), externalization of only the distal end of the shunt along with the administration of antibiotic therapy is recommended by some neurosurgeons. Potential advantages of this technique include (1) diversion of CSF from an infected area to avoid ascending infection, (2) maintenance of CSF flow to prevent increased ICP, (3) the ability to perform frequent CSF sampling, and (4) the capability of monitoring therapy. The disadvantage is that early infection or colonization of the proximal portion of the shunt may be obscured by the antibiotic treatment and become active after discontinuation of therapy and reinsertion of the distal part.

Internal shunting by a third ventriculostomy (with avoidance of a prosthetic device) was shown to be effective in managing patients with refractory shunt-related infections who have a noncommunicating hydrocephalus, patent subarachnoid space, and adequate CSF absorption.[108,185,264,275,352] Shunt independence for extended periods was documented in many patients without myelomeningocele. The success rate is lower in those with myelomeningocele or hemorrhage or after meningitis. Disadvantages of this technique include increased morbidity (e.g., hypothalamic injury, subarachnoid hemorrhage), technical difficulty in younger children, and, if the stereotactic technique is used, cost and availability of the necessary equipment.

The most effective treatment of shunt-related infections is to remove the entire infected shunt and insert an EVD to control ICP and monitor the infection (i.e., provide CSF access). After

antibiotic therapy has been successful, a new shunt is placed. With this approach, treatment success is very high (see Table 85–3), with more rapid clearance of the infection and a shorter duration of therapy. The choice of intravenous antibiotic depends on local patterns of antimicrobial susceptibility and the ability of the antibiotic to penetrate the blood-brain barrier. With the increasing rate of methicillin-resistant staphylococci, vancomycin should be used as initial therapy while awaiting bacteriologic identification and the results of antibiotic sensitivity testing. Effort should be made to discontinue vancomycin as soon as the infecting bacteria are found to be sensitive to the semisynthetic penicillins so that the chance of the bacteria becoming resistant to vancomycin is reduced. In addition, even if in vitro data suggest that the bacteria are highly sensitive to the first-generation cephalosporins (e.g., cephalothin, cefazolin, cephapirin), they should not be used because they penetrate the blood-brain barrier poorly. Linezolid has been used successfully in a few cases of shunt infection.[54] This drug has a good CSF penetration, with concentrations above the minimal inhibitory concentration (MIC) of most gram-positive bacteria, including MRSA. It is also effective against bacteria living in biofilms. The limited data available suggest that linezolid should be considered cautiously when vancomycin fails or cannot be given.

To achieve more consistent and efficient eradication of bacteria, the CSF drug level should be at least 10 times higher than the MIC of the pathogen. Therefore, the dosage of antibiotic or antibiotics and the dosing interval should be maximized (i.e., "meningeal schedule"). If the selected antibiotic does not clear the infection within 2 to 3 days and no improvement occurs in CSF biochemical and WBC parameters (i.e., seemingly no control of the infection), measurement of the bactericidal titer of ventricular fluid should be considered. To determine bactericidal titer, 1 mL of CSF (if CSF production is >5 mL/hr) at the expected peak antibiotic level (i.e., 2 to 3 hours after the antibiotic is given parenterally) is diluted serially with culture media to produce dilutions of 1:2, 1:4, 1:8, and 1:16. To these dilutions, an equal amount of medium with 10^5 colonies per milliliter of the offending bacteria is added (the final CSF dilution is 1:4, 1:8, 1:16, and 1:32). After 24 hours of incubation, the tubes are observed for turbidity, which reflects the growth of bacteria. If no turbidity is seen in the 1:8 and 1:16 or higher dilution tubes, the CSF level of the antibiotic probably is sufficient, and continued growth of bacteria from CSF may be caused by colonization of the EVD or contamination. On the other hand, if turbidity is noted in the tube with less than a 1:8 dilution (i.e., a 1:4 dilution), the CSF level of antibiotic may not be sufficient to combat the infection, and the addition of another antibiotic or change to a different antibiotic is warranted.

In vitro synergy studies can help determine the best drug combination. Rifampin should be considered as one of the drugs in the combination for gram-positive bacteria for three reasons. First, most staphylococci are still sensitive to this antibiotic and their MIC usually is 10-fold lower (i.e., 0.05 μg/mL) than that of other anti-staphylococcal drugs (e.g., vancomycin, 0.5 μg/mL). Unfortunately, the use of rifampin alone may be followed rapidly by rifampin-resistant variants because they already are present in small numbers in any staphylococcal population. Second, rifampin penetrates CSF well and easily achieves a greater than 10-fold level over the MIC of most staphylococci. Third, rifampin has demonstrated good bactericidal activity even when staphylococci were embedded in slime. In contrast, staphylococcal slime inhibits the antimicrobial activity of vancomycin.[103]

Selection of the initial antibiotic before culture results are known can be based on the patient's clinical and CSF findings. An algorithm for initial antibiotic therapy before CSF culture results are available is presented in Figure 85–2. This algorithm should not be used for neonates or immunocompromised patients with suspected shunt-related infections because they often have less severe clinical symptoms and CSF response. The decision-making process starts with assessment of the patient's clinical condition. Usually, patients with infection in the CNS are only mildly symptomatic, whereas patients with *S. aureus* or gram-negative bacterial infection often are more seriously ill.

The next step is evaluation of the Gram stain. If the Gram stain is positive for gram-positive bacteria (e.g., *Staphylococcus*, *Streptococcus*), the drug of choice is vancomycin. If the Gram stain shows gram-negative bacteria, the drug of choice is cefotaxime or ceftriaxone. Treatment with an aminoglycoside is acceptable, but the outcome seems to be less favorable because of poorer penetration into CSF.[364] If the Gram stain is negative, other CSF parameters (e.g., WBC count and glucose) should be examined. If either is abnormal and the patient is not severely sick, vancomycin alone should be started because the chance of having a gram-negative infection is low.[364]

In contrast, if the patient is more seriously ill, coverage for gram-negative bacteria should be added (e.g., cefotaxime or ceftriaxone). In nontoxic patients with normal CSF parameters and no distal symptoms (e.g., peritonitis, wound or tract infection), antibiotic therapy can be withheld until the results of culture are known. On the other hand, if distal signs or symptoms exist, therapy is tailored according to the site. In patients with skin involvement, vancomycin is the drug of choice, whereas in febrile patients with abdominal symptoms, the combination of cefotaxime (or ceftriaxone) and clindamycin (to cover both gram-positive and anaerobic bacteria) is preferred.

Direct instillation of antibiotics into the ventricular system to increase their levels is recommended by some experts. Unfortunately, the suggested doses for intraventricular treatment have been determined empirically on only a small number of patients, and their pharmacokinetics and pharmacodynamics have not been studied well. This therapy is not without hazard, especially when the recommended doses often are much higher than those found to cause neurotoxicity.[200,356,411,413] Pleocytosis and eosinophilia also have occurred in patients receiving intraventricular vancomycin[224] or gentamicin.[255] In addition, preservative-containing preparations should be checked for appropriateness for intraventricular instillation. Limited pharmacokinetic data suggest that clearance of the instilled intraventricular antibiotic is sufficiently slow to allow once-daily administration. If possible, the EVD should be closed for 30 to 60 minutes after the drug is administered. If the EVD cannot be closed and the amount of CSF drainage exceeds 7 to 10 mL/hr, the frequency of intraventricular antibiotic instillation should be increased to twice daily.

Antibiotics commonly recommended for intravenous and intraventricular use according to the etiologic agent are shown in Table 85–4. A recent small study in adults showed that administration of 10 mg of vancomycin intraventricularly once daily was safe and achieved levels above 5 μg/mL (the recommended CSF trough level needed to achieve cure) for up to 21 hours.[303] Because of the potential toxicity of the empirically recommended intraventricular antibiotic doses and the unpredictability of CSF levels, irrigation of the ventricular system with a known concentration of an antibiotic solution is preferred when systemic antibiotics fail to eradicate the bacteria. To achieve irrigation, two EVDs must be inserted to produce a continuous flow of solution. The concentration of antibiotic in the solution should be equal to the highest safe plasma level when the drug is given intravenously. For example, for treating gram-negative bacteria sensitive to amikacin, amikacin at a dose of 30 to 40 mg/L of saline solution (producing a concentration of 30 to 40 μg/mL) is recommended. Gentamicin at a dose of 10 to 12 mg/L (using a special intrathecal preparation) is an acceptable alternative when the gentamicin MIC for the bacteria is less than 1 μg/mL. The antibiotic solution is administered through one EVD at a rate of 10 mL/hr, and the second EVD is left open to drain the fluid and to remove debris and pus from the ventricles.

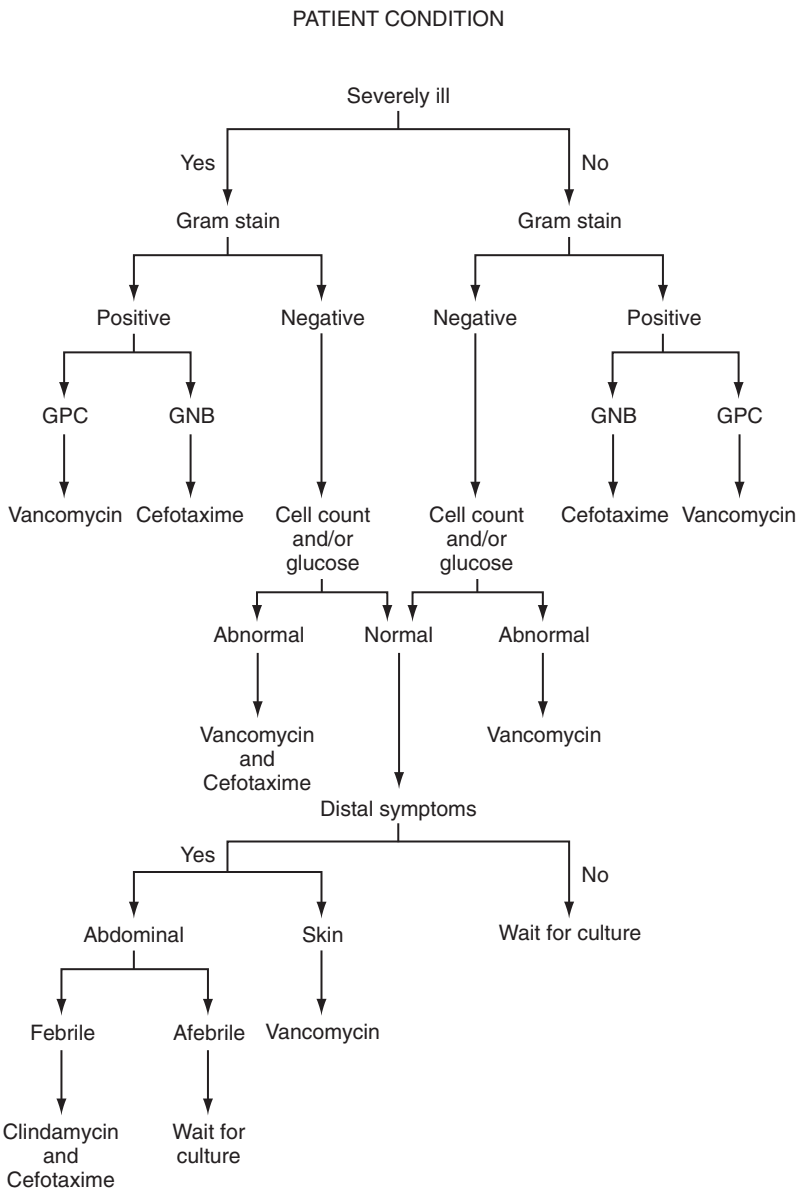

Figure 85–2 Algorithm for selection of antibiotic therapy before culture results are known. GNB, gram-negative bacillus; GPC, gram-positive coccus.

When antibiotic therapy is completed, abnormal CSF findings such as low glucose or mildly elevated protein or cell counts should not delay reshunting. The duration of treatment is empiric and depends on the etiologic agent, the CSF parameters at initial evaluation, and the time to sterilization. In our institution, we found the following schedule to be successful. If CSF parameters are *normal* but culture yields CoNS only from the operating room (i.e., the initial sample), therapy should be given for only 3 to 4 days. If subsequent cultures also are positive, therapy should continue until negative cultures have been obtained for 7 days. If CSF parameters are *abnormal* in the operating room and culture is positive *only* from that specimen, therapy should continue for 7 days. If subsequent samples show abnormal CSF findings and positive cultures, therapy should be extended until negative cultures have been obtained for 10 days.

A longer duration of antibiotic therapy is recommended with other bacteria (e.g., *S. aureus*, gram-negative bacteria). If culture is positive *only* on samples from the *operating room* and CSF findings are normal, treatment should be given until negative cultures have been obtained for 7 days. In all other situations, therapy should continue until negative cultures have been achieved for 10 days. Reshunting should take place immediately at the end of treatment. No benefit is found in observing the patient for a time without antibiotics for relapse of the infection.[409]

COMPLICATIONS

Shunt-related infections are associated with increased morbidity and mortality rates. Patients with shunt-related infection have an increase in shunt-related operations, which contributes to the increased morbidity and cost. In addition, these patients have been shown to have an increase in mortality rates in comparison to patients without shunt-related infection.[356] Even when the original infection is treated successfully, secondary infection (or contamination) of the EVD occurs in 5 to 10 percent of cases. To minimize the risk of development of a secondary infection, a sterile closed-drainage system should be maintained carefully. Only trained personnel should be allowed to drain CSF samples from the system, and injections into the system should be avoided. Continuous external drainage of CSF also causes loss of electrolytes and fluid. Therefore, routine assessment of serum

electrolytes once or twice weekly is recommended, and the total daily amount of drained CSF should be replaced. Recurrent shunt-related infection after completion of treatment is common, with two thirds of such infections being caused by the same organism.[197] Unusual complications of ventricular shunt infections include brain abscess and subdural empyema.[100,402]

PROGNOSIS

Long-term morbidity occurring after a shunt-related infection includes seizures, psychomotor retardation, and cognitive deficiency. The intelligence quotient (IQ) scores of children with myelomeningocele who had a shunt-related infection were found to be significantly lower (mean IQ, 72) than the scores of children with shunts but no infection (mean IQ, 95).[250] A trend was observed in which younger children with shunt-related infections had a lower IQ than older children with shunt-related infections did, especially if the infection was caused by gram-negative bacteria. In addition, shunt-related infection adversely affected school performance.[398] With appropriate combined medical and surgical therapy, the mortality rate from shunt-related infection is low, but any episode of shunt-related infection appears to increase the probability of another episode developing.

PREVENTION

Preventive measures to reduce the incidence of shunt-related infection include attention to preoperative and intraoperative technique and the prophylactic use of antibiotics. Bactericidal shampoos (e.g., chlorhexidine) should be used to reduce the bacterial density of the scalp before surgery is performed. Shaving the scalp seems to be a risk factor, so shaveless surgery should be considered.[166] During the operation, only essential personnel should be present, and the skin should be cleaned with a fat solvent, followed by solutions that reduce the number of bacteria (elemental tincture of iodine, 20 ppm, is preferred over 10% povidone-iodine, which contains <1 ppm free iodine)[58] or their ability to adhere to the shunt (bacitracin A).[134] Careful attention should be paid to surgical technique, with contact between the shunt and the skin being avoided. A detailed preoperative protocol developed by Choux and associates[61] has reduced the infection rate from greater than 7 percent to less than 1 percent. This

protocol emphasizes a shorter operating time, less operating room staff and traffic, and fewer manipulations of the shunt. Even though several investigators were able to reduce the infection rate by using measures similar to those suggested by Choux and coworkers,[59,198] other studies have failed to show that all the factors emphasized by Choux and associates have a positive effect on the infection rate.[305,310] Although a few recent studies suggested that use of an antibiotic-impregnated shunt significantly reduces the incidence of shunt infections in comparison to the use of a standard shunt,[132,343] no significant reduction in the overall shunt-related infection rate was observed in other studies.[151,189] Large prospective, randomized studies are needed to evaluate the real contribution of an antibiotic-impregnated shunt to the reduction in infection rate.

Multiple studies have examined the effect of prophylactic antibiotics for the shunt insertion procedure on reducing the infection rate. Major variations in study design and the number of patients in each study preclude arriving at definitive conclusions. Previous meta-analyses of well-designed studies suggest that the use of prophylactic antibiotics is associated with a significant reduction in the incidence of infections *if* the baseline rate of shunt-related infections is greater than 5 percent.[145] If the infection rate is lower than 5 percent, prophylactic antibiotics are *not* recommended. A recent meta-analysis of 2134 patients (in 17 trials) found a statistically significant benefit for either systemic antibiotic prophylaxis (15 studies) or antibiotic-impregnated catheters (2 studies) in reducing the incidence of shunt-related infections.[318] The choice of antibiotics should be based on the local antibiotic sensitivity pattern of the pathogens commonly causing shunt-related infections in that area. Preferably, prophylaxis should be started 8 to 12 hours before surgery to allow higher levels of drug to accumulate in skin tissue than would do so if treatment were given just before the operation. The duration of prophylaxis should not exceed 24 to 36 hours. Further studies are needed to identify factors important in the development of shunt-related infections so that better techniques can be developed to further reduce or even eliminate this devastating complication of CNS shunting.

INTRACRANIAL PRESSURE MONITORS

Monitoring of ICP has become an important part of the evaluation, treatment, and management of children with a variety of intracranial pathologic processes,[225] including congenital anomalies (e.g., cranial or craniofacial dysostosis), metabolic diseases (e.g., Reye syndrome), trauma, intraventricular or subarachnoid hemorrhage, intracranial infections (e.g., encephalitis), and other ischemic or hypoxic insults. Several studies have demonstrated the therapeutic and prognostic benefit of monitoring ICP in children with high ICP[111,181,219,380]; nonetheless, this procedure is not without complications such as hematoma, bleeding, leakage of CSF, and infection. Infections for which monitoring of ICP is used include ventriculitis, meningitis, brain abscess, subdural empyema, skin infection, and cranial bone infections.[201,224,241,273,423]

Several methods are available for monitoring ICP. Intraventricular placement of a catheter with the distal end connected to a pressure transducer is the method used most frequently because of its accuracy and ease of calibration. This procedure also allows drainage of CSF for biochemical or dynamic testing. Disadvantages of ventriculostomy are penetration of the meninges and brain, technical difficulties if the ventricles are small, and greater risk for the development of infection. Other methods used to monitor ICP include a subdural bolt or catheter (only the meninges are penetrated, but the brain remains intact), an epidural transducer (the dura remains intact), and a continuous intraparenchymal monitor (i.e., a fiberoptic cable is inserted through the dura into the brain parenchyma, not intraventricularly). Although both the epidural transducer and the intraparenchymal monitor have fewer complications (e.g., infection) than the intraventricular devices do, they are prone to inaccuracy, which limits their use. Selection of the appropriate ICP-monitoring method depends on the patient's condition and the risk associated with the procedure.[232]

EPIDEMIOLOGY

Assessing the true infection rate of ICP monitoring devices is very difficult, mainly because the methods used to define infection (i.e., inclusion and exclusion criteria) and antibiotic use vary widely among reported studies. The incidence of infection ranged from less than 1 percent to 40 percent, with an average incidence of 8.8 percent.[63,73,223,233,346,368,401] A much higher rate of infection was reported in patients who had devices that penetrated the meninges[18,162,273] than in those who had parenchymal monitors.[311]

Multiple factors were suggested as increasing the risk for development of ICP device–related infection (Table 85–5). Patients with intracerebral hemorrhage usually do not have a higher risk for acquiring infection than do those without such hemorrhage. In contrast, if the bleeding is intraventricular, the incidence of infection increases dramatically.[241] The rate of infection also is higher in patients with open head trauma than in those with closed head trauma or intracranial malignancy.[168] Neurosurgical operations contributed significantly to the risk of acquiring infection,[241,374] and the same was noted if ICP was greater than 20 mm Hg.[241]

Interruption of the monitoring system's integrity (e.g., in-line stopcocks, number of times that the system was open, blockage of drainage, and irrigation) was identified by several investigators as increasing patients' risk of acquiring infection.[18,241,254,280] The effect of the duration of monitoring on the risk for infection is controversial, especially in patients with ventriculostomy catheters. Although several studies found a correlation between the length of time that the monitoring device was in place and the infection rate,[18,162,190,273] some investigators found no relationship with the duration of monitoring.[282,358,374,422] The different conclusions probably were the result of differences in the populations studied, the types of devices used to measure ICP, the definitions of infection, and analyses of the data. One critical review of the

TABLE 85–5 Risk Factors for Infection of Devices for Monitoring Intracranial Pressure

Factors Associated with Increased Risk for Infection

Drainage of cerebrospinal fluid
Previous ICP monitoring device in the intensive care unit
ICP device dressing changes
ICP device component changes

literature found a correlation between the duration of ICP monitoring and the rate of infections.[223]

The need to replace the device at a certain time has been challenged. Analysis of the outcome in 584 patients (receiving 712 ventriculostomy catheters) who had 61 infections showed a steady increase in the daily incidence of infection, with a peak occurring at day 10. The average time until the onset of infection was 6.8 days.[162] In addition, replacing the ventriculostomy catheter before day 5 did not affect the daily rate of infection. The authors concluded that the lowest rate of infection occurred in the first 4 days of monitoring but that replacement of the catheter by day 5 did not reduce the infection rate, which continued to rise until day 10. The authors recommended that "ICP monitoring [devices] should be removed as quickly as possible," but if "prolonged monitoring is required, there appears to be no benefit from or need for catheter exchange."[162]

Several potential risk factors for ICP monitor–related infections that do not increase the infection rate are shown in Table 85–5.

ETIOLOGY

In general, the microorganisms that cause infections related to ICP monitoring devices are the same as those causing CNS shunt–related infections (see Table 85–2). The major difference is that gram-negative bacteria are isolated more often in ICP monitor-related infection than in CNS shunt–related infections. The more common bacteria include *Enterobacter* spp., *Klebsiella* spp., *S. marcescens*, and *Acinetobacter* spp. These bacteria are found in water and cause widespread colonization of hospitalized patients. Colonization of the respiratory tract is an especially common occurrence in patients in the intensive care unit and in those with serious underlying disease. Thus, these organisms are occurring increasingly frequently in ICP monitor–related infections. Few infections are caused by *Corynebacterium*, *Propionibacterium*, and fungi.[144]

CLINICAL MANIFESTATIONS

ICP monitor–related infections often occur in patients with an altered sensorium; therefore, the signs and symptoms of meningeal irritation usually are not present. The clinical diagnosis is complicated further by the fact that these patients frequently are critically ill and their signs and symptoms are caused by the underlying condition and are not a result of the ICP monitor–related infection. In addition, they may be receiving multiple antibiotics for other sources of infection (e.g., pneumonia, bacteremia, urinary tract infection), both nosocomial and nonnosocomial. Although fever is the most frequent indication of infection, the presence of infections or inflammatory processes at other body sites causes the predictive value of fever to be low. Therefore, providing close follow-up, having a high index of suspicion, and obtaining frequent cultures of CSF when available (e.g., ventriculostomy device) are recommended.

DIAGNOSIS

The predictive value of the peripheral WBC count and differential count is very low, and the only definitive diagnostic tests are the CSF WBC count and culture.[304] CSF biochemistry (i.e., protein and glucose) has a very low predictive value. Although a low glucose level may be of help in establishing the diagnosis, a normal level does not exclude the possibility of an infection. Calculation of the ratio of leukocytes to erythrocytes in CSF versus their ratio in peripheral blood was suggested as a potential diagnostic tool for early infection.[302] Most patients with ICP monitor–related infection will have an increased CSF WBC count with a predominance of PMNs. In some cases, with low growth of bacteria, no elevation in CSF WBC counts ($<10/mm^3$) was reported. Most of these cases were caused by CoNS. In such cases, if no other indicators of infection (e.g., clinical symptoms, low glucose) are present, the possibility that the positive cultures represent colonization or contamination should be considered before treatment is initiated.

TREATMENT AND PROPHYLAXIS

The same principles used for the management of CNS shunt–related infections can be applied to infections associated with ICP monitoring devices. The use of antibiotics alone without removal of the device may be adequate for the treatment of infections associated with devices placed in the subdural or epidural space, unless an abscess or empyema has formed. In the case of ventriculostomy, the infected device should be removed and appropriate antibiotic therapy instituted. Because gram-negative bacteria are almost as common as are gram-positive bacteria in causing ICP device-related infections, initial antibiotic therapy should include both vancomycin and cefotaxime or ceftazidime if the Gram stain is negative. When the etiologic agent is identified, the specific antibiotic or antibiotics can be chosen from those listed in Table 85–4. The duration of therapy depends on the etiologic agent and the CSF parameters. In patients with positive CSF culture but minimal CSF pleocytosis, if the CSF culture becomes negative immediately after removal of the catheter, therapy should be given for only 3 or 4 days because the cultures before removal of the catheter reflect colonization and not infection. If subsequent cultures are positive, therapy should continue for 10 days of negative cultures.

Removal of the ICP monitor (if longer than 5 days) and reinsertion at an alternate site was recommended as a prophylactic approach to reduce the infection rate. This recommendation is controversial, and several studies showed that routine changes of the ICP monitor did not reduce the risk for development of infection.[223,424]

Many physicians use prophylactic antibiotics for the duration of ICP monitoring in the hope of preventing infection. Unfortunately, the few studies that have evaluated the utility of antimicrobial agents in preventing such infections did not find any efficacy.[24,320] The optimal duration of antibiotic prophylaxis is controversial. Jacobs and Westerband[177] showed that patients who received prophylaxis had statistically significantly higher rates of septic morbidity and pneumonia. Yet a decreased rate of ICP monitor infection was reported in patients who received prophylaxis for the duration of the ICP monitoring.[309] Most studies found that the use of prophylaxis has no effect on infection rates. In addition, broad-spectrum antibiotic prophylaxis was associated with shifting to resistant gram-negative pathogens.[240]

INTRATHECAL PUMP INFUSION DEVICES

The intrathecal pump infusion system currently is used to infuse morphine to treat refractory pain,[285] to deliver baclofen (a γ-aminobutyric acid agonist), or to treat spasticity of spinal or cerebral origin.[4,16,297] In addition, patients with generalized dystonia also benefited from intrathecal baclofen.[5] More than 50,000 patients are being treated with implanted intrathecal pumps for pain or spasticity. Several pump systems are used. The simpler systems consist of an externalized catheter system similar to the Hickman catheter[89] or a subcutaneous reservoir system similar to an intravascular implanted port.[43] The more sophisticated systems include a programmable pump that usually is implanted in an

abdominal subcutaneous pocket and connected via a subcutaneous catheter to the subarachnoid space.[27,43] An optional sideport in some of these implanted pumps allows aspiration of CSF from the subarachnoid space.

Complications of the intrathecal pump system are relatively rare events[129,391] and include mechanical problems with the catheter, such as breaking, kinking, dislodging, or leaking.[378] Skin necrosis also has been reported.[117,378] Complications (especially wound complications such as CSF fistula, dehiscence, granuloma formation, and infection) occur more frequently in children than in adults, probably because of their decreased muscle and subcutaneous tissue.[391] The pump itself is very durable and only very rarely causes a mechanical problem. Overdose that may result in coma, respiratory depression, apnea, cardiac conduction abnormalities, hypotension or hypertension, and abnormalities of the pupils was reported as well.[299] Intrathecal baclofen can induce both recurrent and new-onset seizures.[16,203] In addition, acute withdrawal syndrome was reported when treatment was stopped.[353] Infectious complications included suppuration at the exit site,[48,92,161,308] along the subcutaneous catheter (tunnel infection),[27,48,92,161] or around the pump.[27,48,57] Furthermore, more severe infections such as epidural abscess and meningitis also were reported.[29,48,75,92,274,335,430]

EPIDEMIOLOGY

The infection rate of intrathecal pump infusion devices ranges from 0 to 27 percent (median, 4%). Of note, in general the infection rate was lower in studies that included a larger number of patients. A more accurate description of the incidence would be the infection rate per 1000 catheter-days, which ranged from 0 to 2.5. The infection rate was higher in patients with an externalized catheter (0.65 per 1000 catheter-days) than in those who had an implanted system (0.48 per 1000 catheter-days). Most of the infections occurred at the exit site, along the catheter, or in the subcutaneous pocket of the pump, but the infection in as many as 16 percent of cases involved the epidural space, the meninges, or both. The incidence of infections can be reduced by using the subfascial pump implementation technique and perioperative antibiotic prophylaxis.[267]

Infections occur more often within 2 to 4 weeks after insertion of the catheter, which suggests that the initial surgery to place the intrathecal pump system may be a risk factor. Byers and coworkers[48] found that the only risk factor associated with infection during this surgery was a prolonged duration of the procedure (i.e., >100 minutes). Multiple other factors, such as the patient's age, underlying diseases, immune deficiency, other concurrent infections (e.g., pneumonia), previous intrathecal catheter, number of pump refills, intraspinal anesthetics, surgeon's or anesthesiologist's experience with the procedure, and operative complications (e.g., operative loss of blood), were not associated significantly with an increased risk for the acquisition of infection.[48] Very thin or malnourished patients may be prone to wound dehiscence, which may increase their vulnerability to infection. In addition, patients with narrowed intervertebral spaces tended to have operations of longer duration, which puts them at risk for the development of infection.

ETIOLOGY

The most common bacteria causing intrathecal device–related infection are from the skin flora. CoNS and *S. aureus* lead the list, but *Streptococcus mitis*,[48,279] *Streptococcus* group G,[48] *Corynebacterium striatum*,[48] and *Enterococcus faecalis*[115] infections are observed as well. In addition, several studies have reported gram-negative bacteria as the cause of the pump-related infection. Such bacteria include *P. aeruginosa*,[48,115] *Pseudomonas paucimobilis*,[297] *E. coli*,[92] and *Klebsiella pneumoniae*.[297] One case each of *C. albicans*,[92] *Mycobacterium* spp.,[92] and *Acinetobacter baumanii*[387] also has been reported. A rare case of baclofen vial contamination with the fungus *Wangiella* that caused infection was reported as well.[249,297]

CLINICAL MANIFESTATIONS

Clinical findings depend on the site of the infection. Patients with more severe infections (i.e., epidural abscess, meningitis) may have symptoms of these infections (e.g., fever, irritability, headache, nerve root pain, meningeal signs). In some patients, pain experienced during the injection may be the clue, but in many patients, a high level of awareness for possible infection is important because they will have nonspecific signs and symptoms.

Exit-site and superficial catheter-related infections usually cause local inflammation (e.g., swelling, redness), tenderness, and drainage. The more serious deep-tract (tunnel) infections are more difficult to assess. Visible inflammation along the tract or a soft fluctuant fluid collection around it may be the only clue. Fever is not always present.

DIAGNOSIS

Performing a complete physical and neurologic examination may be helpful in some cases. A routine CBC is relatively unhelpful because leukocytosis is not always present. MRI may be useful for diagnosing an epidural abscess and evaluating its extent. The only definitive diagnostic tests are Gram stain and culture of exudate/drainage from the exit site (if available) or an aspirate of the fluid collection along the catheter tract if tunnel infection is suspected or CSF for suspected meningitis. Irrigation of the epidural space with 1 or 2 mL of saline after removal of the pump filter (which should be sent for culture) may help in diagnosing an epidural abscess or empyema.

TREATMENT AND PROPHYLAXIS

If infection has occurred only at the exit site and the superficial catheter tract, local drainage with aggressive cleansing (i.e., topical antibiotics and antiseptics) but without removal of the catheter was suggested.[92] Unfortunately, more severe infections developed (e.g., deep-tunnel and epidural abscess) in some of these patients. In addition, failure of "catheter-sparing" treatment also was reported.[161,308] Therefore, removal of the catheter should be considered even for mild infections if they do not respond promptly to therapy. In patients with pocket, epidural, and meningeal infections, the intrathecal pump system should be removed as soon as possible and systemic antibiotic therapy initiated (for selection of drugs and doses, see Table 85–4). With the increasing rate of multidrug-resistant staphylococci and the low CSF levels of vancomycin (only 20% to 30% of serum levels), linezolid should be considered as an alternative. Linezolid has very good CSF penetration (60-70% of the serum level) and was effective in treating severe CNS infections,[331] including intrathecal infusion pump infection.[188] Although a few studies have reported clinical improvement (and sometimes cure) of tunnel infection or meningitis with the administration of intravenous antibiotics and retention of the catheter, in many cases, the infection recurred when the treatment was stopped.[48,92] A few reports suggest successful treatment of severe pump infections (including meningitis) without removal of the pump system.[29,43,115,308,335,391,430] In some of these cases, the pathogen was considered to be of low virulence (e.g., CoNS) or colonization. In most of these cases, however, instillation of antibiotics into the

reservoir with cautious flushing of the catheter was combined with systemic antibiotics. In one protocol, "intrapump therapy is started by filling the pump to the total reservoir volume with a 5-mg vancomycin/185-µg baclofen/ml solution and programming the pump to deliver an initial volume of 1 mL per day and oral baclofen therapy is initiated to prevent withdrawal. Intravenous vancomycin therapy is used concomitantly and serum trough levels are drawn to optimize the dose and to avoid toxicity."[391] The main reason for the intrathecal administration of antibiotics is to increase the level of drug in CSF. Before antibiotics are added to the baclofen infusion, their compatibility with baclofen should be verified or tested (vancomycin is compatible and can be used safely according to Zed and associates[430]).

No guidelines exist on how to treat severe infections of intrathecal pump systems, but in most cases, removal of the pump system while systemic antibiotics are given and then reimplantation appear to be the treatment of choice. In rare cases in which removal of the pump will be detrimental to the patient, a trial of intrathecal administration of antibiotics may be justified, with close observation to ensure that the patient is not getting worse.

Although many physicians use perioperative (or longer) antibiotics for prophylaxis, their efficacy in preventing infection has not been proved. Therefore, prophylactic antibiotics should not be used or, if given, should not be administered for longer than 24 to 36 hours after the operation.

CHAPTER 86

Infections Related to Craniofacial Surgical Procedures

Marc A. Mazade

Advances in plastic and reconstructive surgery have created the opportunity for surgeons to offer patients with complications of facial neoplasia, craniosynostosis, fibrous dysplasia, Crouzon syndrome, Apert syndrome, Treacher Collins syndrome, craniofacial clefts, and other anomalies relief from associated mechanical complications and restoration of a more normal cosmetic appearance. Operative procedures to address these problems involve cranial vault remodeling or reconstruction (or both) or advancement of the midface and maxillary block and, occasionally, correction of malocclusion by repositioning of the mandible. The overall incidence of infection associated with these procedures was 14.7 percent in one study,[10] but it varies greatly and may range from 3 to 45 percent, depending on the number of procedures attempted during a single anesthetic regimen, the duration of surgery, and the structures involved. A review published in 2005 demonstrated a rate of 3.2 infections per 100 craniofacial surgical procedures and found that surgical duration longer than 426 minutes, closure of skin under tension, use of bovine pericardium, and the presence of more than four surgeons in the operating suite were common risks for development of infection.[24] Many patients suffering infection were categorized as having complicated diagnoses.

PROCEDURES AND OSTEOTOMIES

Some familiarity with a few of the more common procedures in craniofacial surgery, beyond basic craniotomy and cranial vault remodeling, is necessary to understand the pathogenesis of associated infectious complications. Although every patient has a unique set of problems, several corrective procedures are used frequently and then are modified as specifically needed for each circumstance.

In young children with midfacial retrusion, frontofacial monoblock advancement may be performed.[17] This procedure involves detachment and advancement of the entire facial bony mask, excluding the mandible. Exposure for this procedure commonly requires a large frontal craniotomy, the bone from which may be shaped to complete the repair or used as needed to form a suitable foundation to which the advanced block can be secured. Retraction of the frontal lobes is necessary to provide access to the roof of the orbits, and much of the procedure is performed intracranially. The boundaries of the advancement block are formed by osteotomies performed horizontally along the lower portion of the frontal bone and posteriorly along the roof of the orbits, vertically along the lateral and medial inferior walls and horizontally along the inferior walls of the orbits, and vertically through the zygomatic arches, with subsequent dissection and pterygomaxillary disjunction. Finally, a frontoethmoidal osteotomy divides the posterior portion of the nasal septum to free the monoblock so that it can be advanced and secured in place, perhaps by wiring it anteriorly to a slightly fore-tilted strip of frontal bone and stabilizing it laterally with wired-in strips of calvarial bone grafts to bridge gaps in the zygomatic arches. Bone blocks in the pterygomaxillary area help to hold the maxillary portion forward. The temporary dead space created in the anterior cranial fossa after this procedure eventually is obliterated in a growing, developing child, although its persistence is problematic in some patients.[23] This intracranial procedure is associated with an inherent risk of developing meningitis, which is associated less frequently with the extracranial procedures described later, although meningitis still may occur.[21]

A subcranial Le Fort III osteotomy sometimes is used for the treatment of midface retrusion in children.[11,17] Exposure is provided through a coronal incision, but craniotomy is not necessary. Neither the orbital roof nor any portion of the frontal bone is advanced with this procedure. Osteotomies are required to free part of the medial, lateral, and inferior walls of the orbit and the nasal bridge, and the remainder of the block is freed by pterygopalatine disjunction and osteotomies of the zygomatic arch and posterior nasal septum. The entire inferior orbital and nasomaxillary unit is brought forward, and interposition grafts, hydroxyapatite, microplates, and wires secure the block in the advanced position. An intraoral stab incision may be required for pterygopalatine disjunction. As in the frontofacial advancement, split calvarial bone grafts bridge the space in the zygomatic arches.

If further advancement of the maxilla is desired, a subsequent Le Fort I osteotomy, which is an isolated maxillary advancement procedure that changes the position of the upper teeth, is performed.[11,14,17] This entirely intraoral procedure involves making various buccal sulcus and upper vestibular incisions. The palate and maxillary arch are freed for advancement by transverse osteotomies at the level of the nasal floor, through the nasal septum, and then posteriorly.

Another procedure that may be performed in some cases of Treacher Collins syndrome is the integrale (simultaneous midfacial and mandibular osteotomies).[17] In this complicated procedure requiring a tracheostomy, the midface osteotomies exclude the temporal, lateral walls of the orbits from the advanced block. In addition, C-shaped or inverted V-shaped osteotomies through the mandibular rami with placement of the interposition bone grafts and wiring provide advancement of the mandible. Split calvarial bone grafts subsequently reestablish the zygomatic arches. Incidentally, the bone grafts are harvested either by performing a true craniotomy or by removing the outer cortical bone table from the donor site.

More thorough descriptions of these and other operations, such as facial bipartition, are provided in the referenced texts,[11,17] to which the reader is referred for a better grasp of the inherent risks of bacterial contamination from intraoral, sinus, and skin sources that are specific to each craniofacial procedure. Nonetheless, suffice it that the infections encountered usually are caused by bacteria that are resident or pathogenic in the clean-contaminated sites through which incisions and osteotomies are performed and that each additional site that is surgically violated increases the risk of developing an infection.

Many reconstructive materials are used for various procedural applications. Some materials include bone autograft and solvent-treated allograft, titanium plates, and alloplasts such as polymethylmethacrylate (PMMA) and hydroxyapatite cements, some of which readily accept bone ingrowth. In an effort to limit postoperative infection, antibiotics such as tobramycin sometimes are mixed into hydroxyapatite cements, which are released into the surrounding field within the first 24 hours of placement.[15] Efficacy data regarding prevention of infection using this practice are not widely available.

EPIDEMIOLOGY

Infections that may be encountered include cellulitis and dehiscence of the wound, infection of subgaleal fluid, osteomyelitis, focal soft tissue abscesses, epidural abscesses,[23,24] and septicemia. In many instances, infection permeates the entire operative field and encompasses any number of these specific entities.[10] Donor bone graft sites may be involved in some instances. Bacteria may infect the wound or soft tissue area, may spread by contiguous extension through cortical bone during long periods of contact, or may extend through osteotomies that have disrupted the integrity of the periosteum and cortical bone barriers. Additionally, surgical alteration of the local blood supply to the cranial bones through disruption of medullary channels and removal of the adherent periosteum, as well as the presence of hardware required to secure the bony structures in their new locations, can render infection difficult to treat. Repeated or prolonged hospitalizations for previous surgical procedures, often for co-morbid conditions such as syndactyly, gastroesophageal reflux, or dysphagia, result in colonization of the skin and sinopulmonary tracts and subsequent postoperative infection with multidrug-resistant bacteria. Attempts to reduce the incidence of infection have made the use of parenteral prophylactic perioperative antibiotic regimens for 2 to 5 days commonplace.

The development of meningitis always is a concern when craniofacial procedures are performed. The presence of a cerebrospinal fluid leak is a predisposing factor, and meningitis may be manifested years after the procedure in the case of a leak.[21] However, the dura provides a significant barrier to infection when painstaking neurosurgical technique is applied during repair. In fact, no cases of meningitis were identified from a combined report of complications after 567 procedures spanning 6.5 years at Medical City Dallas Hospital and at the Division of Plastic Surgery at the University of Pennsylvania in Philadelphia, primarily for cranial vault remodeling.[9] Similarly, meningitis was not identified from an earlier report of 170 transcranial operations spanning 10 years at the South Australian Cranio-Facial Unit in which 53 accidental dural tears occurred and 32 planned dural openings were performed.[8] Nonetheless, meningitis has been documented to occur in association with a frontal abscess with osteomyelitis, subgaleal fluid infection, and contamination of cerebrospinal fluid drains.[10]

The Australian group just mentioned documented an average operative time of 10.5 hours for patients in whom a postoperative infection developed, 2.5 hours longer than operations on patients in whom an infection did not develop.[8] However, these observations were confounded by variables such as type of procedure and whether the procedure was a primary or subsequent operation. Longer and more complicated monoblock advancement procedures have been associated with infection rates as high as 45 percent,[10] whereas anterior cranial vault remodeling may be associated with infection rates as low as 2.5 percent.[9] In staged or subsequent procedures, the dura encountered during primary craniofacial procedures is manipulated more easily and has better vascularization than does the scarred dura encountered in more complicated and laborious secondary procedures, which are associated with higher rates of infection.[9] Additionally, craniofacial postoperative infections develop in infants far less frequently than in adults.[8,9] Whether this age difference is a reflection of the types of surgeries performed in infants or other microbial or host factors is not clear. Of the common procedures, infection remains a relatively rare complication of the less complicated Le Fort I maxillary osteotomy. In a large review of outcomes of 1000 such procedures, only 1.1 percent developed abscess or related infection.[12]

As experience in craniofacial surgery has grown, the reduction in the frequency of infection has been attributed to shortened operative time, attempts to avoid entrance into the contaminated sinus cavities (an easier task in young children, in whom the sinuses often are still poorly developed), and mucosal repair at the end of surgery.[22] The mean time to diagnosis of infection is approximately 10 days.[10]

MICROBIOLOGY

Organisms causing infection include flora of the skin such as *Candida albicans*, *Staphylococcus aureus*, *Staphylococcus epidermidis*, beta-hemolytic streptococci, and *Propionibacterium acnes.* Resident flora of the oropharynx such as *Bacteroides* spp., *Corynebacterium* spp., various alpha-hemolytic streptococci, *Streptococcus pneumoniae*, *Morganella morganii*, *Eikenella corrodens*, *Haemophilus influenzae*, and *Haemophilus parainfluenzae* can be causative, as can nosocomial gram-negative bacilli such as *Pseudomonas aeruginosa*, *Escherichia coli*, *Klebsiella* spp., and *Acinetobacter calcoaceticus.*[6,9,24] Procedures that disrupt the oropharynx and sinus cavities are more apt to be complicated by polymicrobial infections. Procedures that do not violate these spaces are more inclined to be complicated solely by infection with skin flora. The frequency of infection with *Candida* spp. may rival the frequency of infection with more common bacteria.[9,23,24]

PREOPERATIVE PREPARATION, INTRAOPERATIVE IRRIGATION, AND PERIOPERATIVE ANTIBIOTIC THERAPY

Because wounds created during craniofacial surgery fall between the clean-contaminated category and the contaminated category,[6,7] giving attention to the treatment of dental caries, periodontal disease, and acute sinusitis is prudent before embarking on procedures involving intraoral incisions and trans-sinus osteotomies.[21] Protocols for the administration of perioperative antibiotics and for preoperative preparation of the oral cavity have been developed. Many of these protocols involve irrigation of the oral cavity with povidone-iodine (Betadine) solutions. Nonetheless, the sinus cavities do not lend themselves to preoperative antiseptic washing. Some surgeons make use of intraoperative antibiotic-containing irrigants to help reduce the incidence of infection. These irrigants may be flushed over the intact cranium after subperiosteal exposure and again before skin closure. Other surgeons prefer to use a solution of one part povidone-iodine to four parts saline for intraoperative irrigation.[21] No strong evidence supports any one approach over others for reducing infection.[10]

The choice and duration of perioperative antibiotics vary among surgical centers and their surgical teams. Antibiotic regimens may consist of the following: penicillin; ampicillin-sulbactam; a first-, second-, or third-generation cephalosporin; clindamycin; or any two of these drugs in combination.[6,7,9,10,12] Erythromycin is used in penicillin-allergic patients in some centers.[1]

Continuation of antibiotics may be necessary for 0 to 5 days postoperatively. The optimal duration of treatment is not clear. Higher infection rates occurred in some centers that tried restricting antibiotics to intraoperative use only.[1] Reports from one orthognathic surgical center showed a 10-fold reduction in infection rates with a 5-day antibiotic regimen in comparison with a single-day regimen.[2] Furthermore, isolation of a few infecting organisms that were susceptible in vitro to an antibiotic given 6 hours preoperatively until 48 hours postoperatively suggested that longer durations of treatment with postoperative antibiotics are needed for patients with more heavily contaminated wounds.[6] Some advocates of a shorter duration of treatment with perioperative antibiotics suggested that longer administration of peri-

operative antibiotics contributes to infection with gram-negative organisms or may result in infection with more resistant gram-negative bacilli such as *P. aeruginosa* or other pathogens such as *C. albicans*.[7-10]

Nonetheless, although the use of antibiotics indeed selects for these organisms, many single-organism infections occurring after initiation of antibiotics would have been polymicrobial were it not for intraoperative and immediate postoperative treatment. From an infectious disease perspective, continuation of antibiotics beyond the intraoperative period is similar to treatment of an open fracture and not very much like antibiotic prophylaxis in the traditional sense. Perhaps better stated is that the use of intraoperative antibiotics and immediate postoperative treatment may kill bacteria that have contaminated operative sites, including surgically fractured bone.

POSTOPERATIVE FEVER

Pyrexia is thought to be a normal physiologic response to craniofacial surgery. In a study of 136 transcranial surgical procedures performed for nonsyndromic craniosynostosis, postoperative temperatures of 38° C or higher were encountered in 76 percent of subjects, and hyperpyrexia exceeding 39° C was encountered in 11 percent. Temperature elevations usually are encountered in the first 48 hours but occasionally occur up to 5 days postoperatively.[18] Close clinical evaluation is warranted in all cases of pyrexia.

EVALUATION

Signs of postoperative craniofacial surgical infection include the following: fever (although not in all cases)[18]; the rapid development of unilateral local soft tissue warmth, tenderness, and erythema; and rapid recurrence of swelling.[5] Reasons for the delay in establishing the diagnosis and for providing definitive treatment of some infections are multifactorial. Postoperative swelling may persist for some time, often improving and worsening in dependent areas according to the patient's sleeping or resting position. Periorbital tissues are particularly prone to fluctuations in swelling. Violaceous discoloration and bruising of the overlying skin may complicate assessment further. In addition, the overall facial appearance of the child may be so altered by the surgical intervention that parents may not recognize subtle signs of infection immediately. In some instances, large distances may separate the child from the craniofacial surgery referral center after discharge from the hospital, and the surgeon must rely on verbal descriptions of the child's postoperative appearance from concerned caregivers. Therefore, patients who live far from the referral center should be educated that prompt local medical evaluation along with a phone call to the craniofacial surgeon at the referral center can assist in early diagnosis, determination of bacteriology by needle aspiration, and initiation of preliminary treatment during travel back to the referral center. Prescription of oral antibiotics in the hope of preserving the tenuous bone grafts without aspiration may render the interpretation of subsequent surgical culture results difficult.

Evaluation of extraocular movement may be limited by the age of the child, by postoperative swelling, and, frequently, by the limited capacity of the patient to comply interactively with the examination. Few operations, however, limit the ability to assess the presence of meningismus. Some patients may exhibit lassitude, lethargy, or increased irritability, subtle signs in children who have limited capacities to communicate.

The wound, often a coronal incision, should be examined closely. Purulent or seropurulent wound drainage or persistent serous wound drainage usually is indicative of underlying soft tissue and possibly bone infection, although infection may not be limited to the structures located directly beneath an area of wound dehiscence.[5] Drainage at one location along a wound may be the result of inflammatory fluids that originate elsewhere and are following a hydrodynamic gravity flow pattern or an established route to a low-pressure efflux portal at a nonhealing area of the wound, especially when the infection has become well established. Similarly, fluid collections in suborbital areas of the face such as the malar or submalar areas may suggest a local abscess when, in fact, the primary site of infection is cranial and the collection is only a dependent pool.

Laboratory abnormalities may be subtle. Leukocytosis may be present. The erythrocyte sedimentation rate has been shown to peak approximately 5 days after major orthopedic surgery and to decline slowly and irregularly for a period of 3 to 9 weeks, but it provides little diagnostic value initially.[3,13,19] C-reactive protein (CRP) levels peak within 2 to 3 days but usually normalize within 21 postoperative days.[3,13,16,19] Because an abrupt increase in CRP may be indicative of infection, some orthopedic centers monitor CRP levels to assist in early detection of infection after elective procedures such as total-joint replacement and spinal surgery.[13,19] Similarly, monitoring serial CRP levels is helpful when trying to discriminate between infection and shifting postoperative dependent swelling and in assessing the response to therapy in a craniofacial surgical patient.

Needle aspiration of underlying fluid collections is the best primary means of diagnosing infection, especially if significant residual postoperative swelling has rendered clinical assessment of a particular area difficult. In most instances, needle aspiration cultures are superior to surface cultures of wound drainage, which often yield coagulase-negative staphylococci of uncertain significance. However, cultures of wound drainage sometimes grow obvious pathogens and may be helpful.

Diagnostic imaging such as computed tomography with contrast or magnetic resonance imaging may identify occult fluid collections, but diagnosing bone infection, especially in the flat bones of the cranium, is difficult with these modalities. Not infrequently, focal enhancement of the meninges in regions where the cranium has been manipulated is noted on postoperative imaging. Corresponding postoperative cerebral gliosis also can be difficult to differentiate from cerebritis developing near an area of infection above the dura. Serial weekly or biweekly imaging can provide a means of performing ongoing evaluation of these abnormalities inasmuch as neurologic manifestations of cerebritis in the frontal lobes may not be elucidated easily. Surgical exploration of suspected areas of infection remains the most helpful source of diagnostic information regarding infection.

TREATMENT

Management of infections complicating craniofacial procedures is primarily surgical. Open débridement, inspection and scraping of contiguous bone, and copious pressurized saline irrigation are essential. The value of adding antibiotics to the irrigant is questionable. Some physicians argue that irrigation with povidone-iodine may devitalize tissues that participate in the healing process and should not be used, whereas other physicians avoid using povidone-iodine irrigation because of concern about systemic iodine absorption.[9] Removal of all hardware provides the best chance for eradicating the infection, but occasionally, as in the case of procedures that involve maxillary distraction devices, removing all the hardware initially is impractical. Furthermore, distraction pins may dislodge as the integrity of the bone is compromised by infection.[20]

Placement of several drains ensures an opportunity for drainage of what otherwise would remain sequestered focal soft tissue fluid collections. Continuous subgaleal flow-through irrigation

with saline at a rate of 15 to 30 mL/hr (with or without antibiotic additives) is an adjunctive measure instituted by some surgeons; other surgeons question the advisability of this approach.[9] Removal of devitalized bone and of any bone grafts in the infected surgical bed is an unpopular but necessary part of treatment. Failure to do so may result in multifocal osteomyelitis, possible meningitis or cerebritis, and persistence of chronic infection with potentially multidrug-resistant organisms.

Reluctance by the surgical team to excise infected bone aggressively and widely and to remove devitalized bone is understandable because the initial surgical procedure itself involves extensive planning, operative time, and anesthetic risk. In addition, interposition grafts may provide architectural platforms for the advanced structures, and successful treatment of these infections was reported in some surgical centers in which the initial bony débridement was limited to areas of visibly apparent osteitis.[9]

With regard to post-craniotomy wound infections, traditional dogma suggested operative débridement and complete removal of devitalized bone flaps followed by delayed cranioplasty.[4] However, some patient groups may fare better with attempted preservation of bone flap with minor surgical débridement and systemic antibiotic therapy. Within a small group of five patients who had undergone craniotomy without a history of previous craniotomy, radiation therapy, or skull-base surgery, operative débridement accompanied by culture and susceptibility data-driven systemic antibiotic therapy successfully treated infection with a mean of 35 ± 20 months of follow-up. Several other patients required second-look operations with more débridement, but they did not require removal of the bone flap and were cured. In the same study, the two other subjects had undergone more extensive craniofacial surgery and had recurrent infection requiring removal of the bone flap at 2 months after presentation in one patient and at 29 months in the other one, respectively; this finding bears out the concern that contamination of the bone flap can result in persistent, long-standing infection.[4]

As an advisor, the infectious disease consultant should point out evidence of persistent infection, suggest the possibility of deeper or more serious infection when concern arises, alert the surgical team when a point of failure of medical therapy has been reached, and emphasize that antimicrobial therapy is only an adjuvant to bony débridement and copious intraoperative irrigation, which may improve the outcome and limit the spread of infection. Recurrent wound dehiscence and continued wound drainage should prompt thorough exploration of the soft tissues and bone for evidence of osteomyelitis or retained hardware, including wires. Advanced infection in devitalized bone cannot be treated effectively in situ, and often entire bone plates must be removed, with cranioplasty performed months later.

For infections that complicate procedures not involving the oropharynx or sinus cavities, an antistaphylococcal antibiotic such as vancomycin, cefazolin, or nafcillin may be an appropriate empiric antibiotic choice pending the results of intraoperative drainage and débridement cultures. A third-generation cephalosporin with or without an aminoglycoside may be considered if the risk of developing an infection with a nosocomial pathogen is high because of prolonged hospitalization or persistent tracheal colonization with gram-negative bacilli such as *Pseudomonas*[8] or if infection of the central nervous system threatens. Infections complicating procedures involving the oropharynx or sinuses often are caused by organisms resistant to the perioperative prophylactic antibiotic chosen.[6] Thus, it may be reasonable to consider antibiotic therapy with clindamycin or metronidazole when a cephalosporin has been used or treatment with a second- or third-generation cephalosporin or ampicillin-sulbactam when clindamycin has been used prophylactically. The duration of antibiotic therapy must be individualized to each case. A period of 6 weeks of antibiotic therapy has been suggested for patients with suspected osteomyelitis.[21]

CHAPTER 87

Infections in Burn Patients

Janak A. Patel ✪ Natalie Williams-Bouyer

According to the American Burn Association, approximately 500,000 persons are treated for burns every year in the United States; of these, approximately 40,000 are hospitalized and approximately 4000 die from the burn injury.[4] Improvement in the rate of burn-associated mortality is a direct result of advancement in burn care, comprising developments in fluid resuscitation, wound care, early excision and grafting, nutritional support, infection control, and antimicrobial therapy. The mortality rates and lengths of stay of burned children have been reduced greatly in the past several decades. In the 1960s, the likelihood of survival was only 50 percent for pediatric patients with burns covering 35 to 44 percent of the total body surface area (TBSA), and few children with burns covering more than 45 percent of TBSA survived. The average length of stay was 103 days. In 2008, the LA_{50} (lethal burn size for 50% of patients) for children exceeded 95 percent of TBSA, and the average length of hospital stay for most serious burn injuries can be expected to be only 0.5 days per percent TBSA that is burned. Since 1998, the mortality rate at the Shriners Burns Hospital for Children (Galveston, Texas) has ranged from 1 to 3 percent.

BURN WOUND

1. **Burn wound depth:** Burn wounds are categorized by their depth (Fig. 87–1).[42]

a. *First-degree burns* consist of epidermal damage only. These wounds are painful and erythematous resulting from local vasodilation. They heal spontaneously, usually without forming scars, within 7 days.

b. *Second-degree burns* are injuries with partial thickness and are further categorized as *superficial* or *deep*. The epidermis and superficial portions of the dermis are injured in superficial second-degree burns. These wounds are painful and often result in formation of blisters. Healing occurs via epithelial migration from the wound edges, hair follicles, and sebaceous glands. Relatively little scarring occurs, and reepithelization occurs within 2 weeks. Deep second-degree burns are much more serious. The majority of the dermis is destroyed, leaving the bases of the epidermal appendages spared. The nerve endings also are destroyed, rendering the wound insensate. Blisters usually are not present owing to the thicker formation of eschar. These wounds are treated as full-thickness injuries. Reepithelialization is tenuous and slow. The protracted inflammatory phase often results in excessive deposition of collagen and extensive scarring.

c. *Third-degree burns* are full-thickness injuries to the skin. Healing occurs by contraction and reepithelialization from the edges of the wound. As with deep second-degree burns, these wounds are insensate and without blistering. Infants and young children have a much thinner dermal layer to their skin, resulting in increased propensity for deeper burn injury. Treatment for third-degree burns is with excision and skin grafting.

d. *Fourth-degree burns* extend into the deep tissue, which includes muscle, bone, and viscera. Treatment is débridement and possible amputation. Closure of these wounds may vary from primary closure post amputation to skin grafting and possibly flap reconstruction.

2. **Cytologic findings:** The effects of extreme heat on the skin lead to cellular and subcellular impairment. The determining factors of how severe a burn will be are the temperature, the length of exposure, and the actual burning agent. Moritz and Henrique[83] showed that the skin is able to withstand temperatures up to 40°C (104°F) for relatively long periods of time before an injury becomes apparent.[83] Increase in temperature leads to cell membrane dysfunction as ion channels are disrupted, resulting in sodium and water intake. As temperatures exceed 45°C, protein denaturation supersedes the cell's reparative capabilities and oxygen radicals are liberated. Plasma membrane necrosis has been observed in cells exposed to 45°C for 1 hour. Other cytologic findings in thermal injury include the redistribution of solid and fluid components of the cell nuclei. Imbibition of fluid results in nuclear swelling, rupture of membranes, and pyknosis. As denaturation proceeds, vital cellular metabolic processes are injured. If enzyme activity is decreased to less than 50 percent of its normal level, cell death occurs. In lesser degrees of enzyme impairment, cell recovery may be possible.

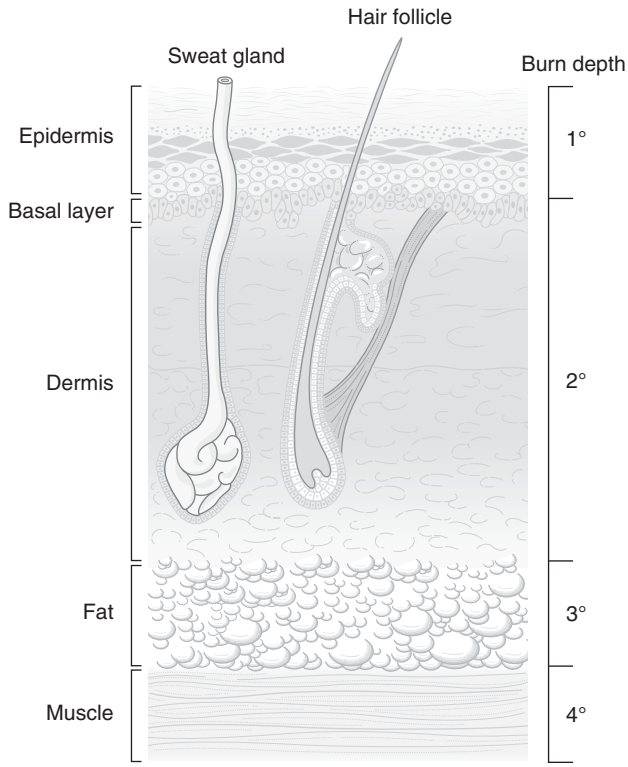

Figure 87–1 The burn wound depth. (See companion Expert Consult web site for color version.) *(With permission from Greenhalgh, D.: Wound healing.* In *Herndon, D. N. [ed.]: Total Burn Care. Philadelphia, WB Saunders, 2007, p. 579 [Fig. 46.1]).*

3. **Local tissue changes:** Local burn injury is classically described by Jackson[54] in three concentric zones. As temperature increases, protein denaturation results in coagulation. The protein architecture is destroyed and new aberrant macromolecules are formed. The central area of a burn wound is that which is in direct contact with the source of heat. Cell necrosis is com-

plete and is called the *zone of coagulation*. Cellular recovery is impossible, and the severity of injury decreases from the surface to the deeper levels. This zone is called the *burn eschar*. At the peripheral margins of the zone of coagulation, a less injured zone is present. The cells in this *zone of stasis* show direct injury from the heat, but the damage is not lethal. However, blood flow becomes progressively impaired to this area. Ischemia to the already compromised cells may lead to necrosis and conversion to dead eschar. Circulatory impairment occurs via adherence of neutrophils to the vessel wall, deposition of fibrin, formation of platelet microthrombus, vasoconstriction, and endothelial swelling. Heat-compromised erythrocytes lose their ability to deform, and their passage through microvessels is impeded. The circulatory embarrassment may be delayed for up to 24 hours, and the ischemia may progress for up to 48 hours after the burn has occurred. If stasis conditions are minimal, the injury may be halted and cell recovery may occur within 1 week. However, this tissue is fragile, and further insults such as infection, hypovolemia, pressure, and over-resuscitation can lead to further necrosis. Finally, the *zone of hyperemia* lies peripheral to the zone of stasis. This zone sustains minimal injury and often recovers within 7 to 10 days. Notable vasodilation is caused by potent vasoactive mediators secondary to the inflammatory response. Complete recovery is expected in this zone barring further trauma or infection.

4. **Burn inflammation:** Many of the above processes are either part of or result from the inflammatory process. Cellular infiltration, initiated by local inflammatory mediators such as prostanoids and leukotrienes, as well as proinflammatory cytokines from the burn wound, begins with the arrival of neutrophils at 4 to 5 days postburn, followed by macrophages.[106] The neutrophils further mediate damage by releasing oxygen free radicals.[36] Reestablishment of blood flow in the zone of stasis is yet another setting wherein oxygen free radicals are produced, leading to further injury. This phenomenon of ischemia-reperfusion injury occurs as oxygen is restored to the tissues.[59] Inflammation becomes prominent at 7 to 10 days. Consequently, blood flow is maximal at this stage, creating a troublesome and hazardous setting for surgical excision of the eschar. Along with local inflammatory responses, several systemic responses occur with burns of more than 15 percent of the TBSA.

5. **Inhalation injury:** Burn victims, especially those trapped in enclosed areas, injure the respiratory tract upon inhalation of toxic gases from surrounding burning materials. An actual thermal airway injury is quite rare. The upper airway is rather effective in cooling and warming inspired air. Also, air has a very low heat capacity. In order to have direct injury to the airway, the flames must come into direct contact with them. Injury to the oropharynx after inhalation of toxic gases resembles thermal injury elsewhere in the body.[1] Protein denaturation, release of inflammatory mediators, and increased cellular and microvascular permeability all occur, leading to airway edema and consequent obstruction of the airway.

The chemical injury from inhalation of toxic gases can damage the tracheobronchial tree. First, separation of ciliated epithelial cells from the basement membrane occurs.[11] Next, the circulation of blood to the lung, as well as to the bronchial tree, is increased due to vasodilation. Shortly thereafter, edema is evident. The inflammatory phase is followed by an exudative phase.[52] Furthermore, the protein component of this fluid is composed of lung lymph and induces bronchoconstriction. As postburn time increases, fibrin casts are formed from the exudates, resulting in obstruction of the airway. As the epithelium sloughs and formation of fibrin casts increases, susceptibility to infection also increases. Pneumonia leading to sepsis and death are well-known sequelae at this stage. Finally, formation of pseudomembranes proceeds and then squamous metaplasia follows.[92] Healing may take weeks to initiate, and permanent damage to the airway (e.g., stenosis and formation of tracheal granulomas) may occur.

INFLAMMATORY AND IMMUNE RESPONSES IN BURNS

Intact human skin is vital for preservation of the host's protection against infection. A combination of impaired local and systemic host defenses and loss of the skin barrier are major factors responsible for the increased susceptibility to infections in patients with burns. The major elements initially contributing to the inflammatory response that occurs after burns are incurred include the plasma proteins, mast cells, tissue macrophages, and systemically recruited neutrophils and monocytes.

Alterations in the host defenses include induction of local and systemic cytokine synthesis, decreased immunoglobulin levels, changes in the concentration and activity of both the classical and alternative complement pathways, reduced levels of circulating plasma fibronectin, depressed serum opsonic activity, and impairment of the macrophages, lymphocytes, neutrophils, and the reticuloendothelial system. However, many mechanisms of immune alterations remain unknown; for example, an association of the volume of blood transfusions with increased mortality rates and infectious episodes in patients with major burns was observed in two reports.[56,92] The immunologic status of the burned patient has a measurable impact on survival, death, and major morbidity.

1. The cytokine response: After burn injury occurs, numerous cytokines are induced rapidly. Many cytokines correlate with the severity of the burn injury and the prognosis. Recent studies at our center have shown a specific pattern of systemic cytokine responses in children with thermal injury. Compared with unburned healthy children, children with burns covering more than 40 percent of TBSA had significant increases in serum levels of 15 cytokines and immunoregulatory molecules during the first week after incurring the thermal injury: interleukin (IL)-1β, IL-2, IL-4, IL-5, IL-6, IL-7, IL-8, IL-10, IL-12 p70, IL-13, IL-17, interferon gamma, monocyte chemoattractant protein-1 (MCP-1), macrophage inflammatory protein (MIP)-1β, and granulocyte colony-stimulating factor (G-CSF).[31] Granulocyte-macrophage colony-stimulating factor (GM-CSF) was significantly increased during the second week after burn occurred. Within 5 weeks, the serum concentrations of most cytokines decreased, approaching normal levels. In another study of children, serum IL-8, tumor necrosis factor (TNF), IL-6, IL-12p70, MCP-1, and GM-CSF were significantly increased in those with large burns.[56] In general, the notion was that the smaller the burn size, the lower the cytokine concentration.

In children with inhalation injury, the serum cytokine studies at enrollment showed significant reduction in level of IL-7 and elevation of IL-12p70, as compared with children without inhalation injury.[30] However, 5 to 7 days later, the levels were comparable. Host genetic factors also may affect the cytokine response in patients with burns. For example, single nucleotide polymorphisms for TNF-α (308G), Toll-like receptor 4 (+896G), IL-6 (174C), and CD14 (159C) were significantly associated with an increased risk for severe sepsis following burns.[7]

2. Neutrophils: Thermal injury induces neutropenia and myeloid maturation arrest despite elevated G-CSF levels.[108] The degree of neutropenia correlates with the reduction in bone marrow G-CSF receptor expression. The neutrophils of patients with burns also are functionally altered[84]: The expression of the Fc receptor is decreased, and intracellular killing capacity is depressed (this is a differential suppression, more for some organisms than others) and is accompanied by a brief increase in neutrophil respiratory burst response. Failure of initial alkalization

of the phagolysosome and alteration of subsequent kinetics of acidification also occur.[14] This depression of oxygen-independent bactericidal mechanism may impair the capacity of the neutrophil for intracellular killing after a thermal injury occurs. Expression of CD16 (Fc receptor [FcR], Fc immunoglobulin G [IgG] receptor) and CD11 (adhesion molecule) on neutrophils is impaired after a major injury occurs; this reduction appears to be related directly to the appearance of bacteremia or pneumonia.[5] These changes in expression of adhesion molecules, which is closely related to chemotaxis, may play a part in the failure of delivery of neutrophils in adequate numbers to the local site of a burn. Furthermore, a defect is present in actin polymerization in the neutrophils of patients with burns; as a basic mechanism of chemotaxis, it also may contribute to a failure of motility.

Generation of leukotrienes from the neutrophils of severely burned patients also is impaired and appears to be based on the availability, or lack of availability, of the metabolizable substrate-free arachidonic acid.[62] Because leukotriene B also is a potent neutrophil chemotactic agent, this impairment may further contribute to the failure of neutrophil function.

3. Complements: The fluid of the burn blister shows much lower opsonic activity for bacteria such as *Pseudomonas aeruginosa* than the patient's own serum.[90] A mild impairment of production of C3 and release by macrophages of burn patients in vitro also occurs. Systemically, both the classical and the alternative pathways are depleted, but the alternative pathway is more profoundly perturbed. After the development of bacteremia, additional complement activation and depletion occur.[115]

4. Macrophages: Suppression of the ability of the reticuloendothelial system to take up particulate material was among the original observations of burn immunology made in the 1960s. More recent reports, however, have described the demonstration of a differentially increased uptake of colloid in alveolar macrophages compared with other organs, perhaps indicating alveolar macrophage activation. Macrophages and monocytes appear to be activated in a fashion similar to that of lymphocytes after thermal injury occurs. Activation of macrophages, as measured by the serum neopterin level, is increased after thermal injury occurs.[6] This activation is confirmed by increased expression of the monocyte cell surface antigens C3b and iC3b.[82] At the same time, expression of human leukocyte antigen (HLA)-DR, HLA-DQ, and HLA-DP by monocytes is reduced, and these class II antigens are obligatory for many cell-mediated immunologic processes, thereby implying that a possible loss of function of monocytes occurs after thermal injury.[39] Production of C3 by macrophages is suppressed in patients with burns, but the synthetic ability for key cytokines such as IL-6 is increased.[126]

Peripheral blood monocytes are superstimulated to produce large amounts of IL-1, leading to exhaustion of the function on monocytes.[73] Reduced production of IL-1 by monocytes was found in patients with complicated organ injury, multiorgan failure, and systemic infection. Blood monocytes of patients with burns produce significantly more IL-10 at 7 to 10 days after burn injury, which correlates significantly with subsequent septic events.[61]

5. T lymphocytes and cell-mediated immunity: Early studies of T cells in patients with burns showed a variety of changes: impairment in mitogenic and antigenic responsiveness of lymphocytes, suppression of graft-versus-host reactivity related to the size of the burn, suppression of delayed cutaneous sensitivity tests, and diminution in both numbers of peripheral lymphocytes and concentration of thoracic duct lymphocytes. Whether the failure of T cell functions is due to an intracellular defect related to thermal injury, the result of "overuse," or indirectly the result of down-regulation by the cytokine cascade or other products of the inflammatory reaction remains controversial.

Analysis of peripheral blood T cells supports the theory that, rather than an absolute reduction in CD4 and an increase in CD8 cells, a redistribution of lymphocyte traffic may occur.[91] Suppression in the numbers of the total population of lymphocytes is the only consistent overall change. Further, not only does lymphocyte traffic between stores of central lymphocytes and the peripheral blood occur after a thermal injury, but the responsiveness of these populations of lymphocytes also vary according to the site; for example, splenic lymphocytes of experimentally burned animals remain most profoundly depressed in response to antigenic stimulation, compared with the peripheral blood and other organs.[25] In addition, in peripheral blood, the appearance of "activation" antigens on CD4 and CD8 cells (HLA-DR, IL-2 receptor [IL-2R], and transferrin receptor) is depressed significantly as early as 1 day after burn injury occurs.[75]

Addition of recombinant IL-2 does not appear to reverse the suppression of the appearance of surface markers such as IL-2R in burned patients, although it does not improve the response of natural killer (NK) cells to stimulation.[34] In experimental preparations, at least some of the observed T-cell suppression can be alleviated by early removal of the burn wound, thereby creating one further argument for promptly closing the burn wound.[45]

6. B lymphocytes and humoral immunity: The function of B cells after the occurrence of a thermal injury is less well documented than is that of macrophages or T cells. The expression of this major histocompatibility complex is impaired and, therefore, some diminution of B-cell function can be expected as a result of diminished recognition of antigenic presentation.[87] Under the influence of stress-induced corticosteroids, the number of circulating B cells is relatively increased compared with T cells in peripheral blood.[58] Spontaneous cytokine (IL-4 and IL-2)-induced expression of the activation antigen CD23 is reduced significantly during the second to fifth week after burn injury occurs.[103]

If the products of B-cell activation, namely the immunoglobulins, are measured in vivo, the results are somewhat difficult to interpret because of the increased catabolism of protein and the leakage through the burn wound. Briefly, marked diminution of serum IgG concentration, total and all subclasses, is present; these levels return to normal between 10 and 14 days after the burn injury has occurred. Extremely low levels of IgG on admission (300-400 mg/dL) are predictors of a poor prognosis. Levels of IgM and IgA appear to be relatively unaffected. Overall, the defective production of immunoglobulin after a thermal injury occurs appears to be a factor of macrophage/lymphocyte interaction rather than a failure of intrinsic activity by B cells.[29]

BURN WOUND MICROBIOLOGY

A working knowledge of the common flora of burn wounds is essential to appropriately tailor therapy. Pathogens peculiar to thermal injuries are basically no different from the normal flora of the environment. Table 87–1 shows the types of microorganisms found in various body tissues and secretions as either normal flora or as pathogens. However, the organisms that predominate as causative agents of infections of burn wounds in any burn-treatment facility change over the course of time. Gram-positive organisms prevail in the early postburn period and then are replaced by gram-negative bacteria and fungi.[27]

1. **Gram-positive bacteria:** The gram-positive predominance is consistent with the normal inhabitants of the skin prior to the thermal injury. *Staphylococcus* spp., *Micrococcus* spp., *Streptococcus* spp., *Pediococcus* spp., and *Enterococcus* spp. are gram-positive cocci commonly encountered in burn wounds. Erol and associates[27] recently demonstrated that coagulase-negative staphylococci and *Staphylococcus aureus* were the most prevalent isolates in admission cultures, followed by diphtheroids. These organisms can be life-threatening as invasive infections or simply be locally

TABLE 87–1 Tissue Association of Microorganisms Most Commonly Found in Burn Wound Infection*

Organism	Soft Tissue Skin	Upper Respiratory	Lower Respiratory	Endocardial	Gastrointestinal	Urogenital	Bone and Joint
Staphylococcus aureus	NF, P	P, NF	P	P	P	NF, P	P

TABLE 87–2 Bacteria Isolated from 304 Acute Care Pediatric Burn Patients Admitted to Shriners Burns Hospitals for Children—Galveston, Texas (January 2006 to December 2006)

Gram-Positive Organisms	No. (%) of Isolates
Methicillin-resistant *Staphylococcus epidermidis*	196 (23.7)
Methicillin-resistant *Staphylococcus aureus*	152 (18.4)
Enterococcus faecium	119 (14.4)
Methicillin-sensitive *S. epidermidis*	84 (10.2)
Methicillin-sensitive *S. aureus*	82 (9.9)
Enterococcus faecalis	80 (9.7)
Other gram-positives*	113 (13.7)
Total no. of gram-positive isolates	826
Gram-Negative Organisms	
Carbohydrate Fermenters (Enterics)	
Escherichia coli	103 (17.4)
Enterobacter cloacae	67 (11.3)
Klebsiella pneumoniae	66 (11.1)
Other fermentors†	132 (22.3)
Noncarbohydrate Fermenters	
Pseudomonas aeruginosa	122 (20.6)
Acinetobacter spp.	48 (8.2)
Stenotrophomonas maltophia	16 (2.7)
Other nonfermentors‡	38 (6.4)
Total no. of gram-negative isolates	592
Total no. of bacterial isolates	1418
Gram-positive organisms (%)	(58.3)
Gram-negative organisms (%)	(41.7)

**Includes other Staphylococcus, Enterococcus spp.; Micrococcus, Pediococcocus and Streptococcus spp.*
†Includes other Enterobacter, Klebsiella, Serratia, Proteus, and Citrobacter spp.
‡Includes other Aeromonas and Achromobacter spp.

colonized. Table 87–2 shows the distribution of gram-positive bacteria at Shriners Burns Hospital for Children in Galveston, Texas, which receives pediatric burn patients from all over the world. For the year 2006, the gram-positive cocci accounted for 58.3 percent of bacterial isolates. Within this group, the staphylococci are more prevalent (62.2%) than are the enterococci, which account for 24.1 percent. Among staphylococci, a predominance of methicillin-resistant (42.1%) versus methicillin-sensitive (20.1%) isolates was noted. The rate of staphylococcal methicillin resistance has increased in this patient population since 2000. This increase is reflective of a worldwide emergence of such antimicrobial resistance in both hospitalized-acquired and community-acquired infections.

Because of such resistance patterns, Cook[21] stresses the importance of microbial surveillance and epidemiologic studies. This approach is thought to reduce the prevalence of methicillin-resistant *S. aureus* (MRSA), yet it may be inadequate for eradicating or preventing outbreaks. Minimizing transmission and infection is emphasized. However, Reardon and colleagues[95] suggest that this process is time-consuming and requires extensive resources for little gain. Colonization with methicillin-sensitive *S. aureus* and MRSA in 86 patients was studied and found to have no significant changes on length of stay, number of operations, or mortality between these two organisms. However, the presence of either type of *S. aureus* significantly increased the number of surgical procedures performed and the lengths of stay. Many burn units report frequent colonization of burn patients with toxic shock toxin (TSS-1)–producing strains of staphylococci; however, their presence does not correlate well with increased morbidity or mortality rates.[20]

In the past, group A β-hemolytic *Streptococcus* frequently was the cause of epidemics in burn units, but it seldom is encountered today because of the frequent emperic use of antibiotics for manipulations of burn wounds. Other β-hemolytic streptococci belonging to groups B, C, E, F, and G can be encountered as well.[71] Significant infection-control vigilance still is necessary, as occasional clusters of outbreaks of group A streptococcal infection continue to be reported.[43,98] Fortunately, group A *Streptococcus* remains uniformly sensitive to penicillins; hence, prophylaxis and treatment are easily accomplished.

Although enterococcal infections (*Enterococcus faecalis* and *Enterococcus faecium*) account for only 24.1 percent of burn-wound infections caused by gram-positive bacteria (see Table 87–2), a significant cause for concern is the emergence of vancomycin-resistant *Enterococcus* (VRE) in burn units.[67,69] Although additional morbidity associated with VRE itself is not clear, when it occurs as a polymicrobial bacteremia, a mortality rate as high as 20 percent has been noted.[69]

Other gram-positive bacilli include the aerobic *Corynbacterium* spp. and *Listeria* spp., as well as the spore-forming *Bacillus* spp. (aerobe) and *Clostridium* spp. (anaerobe). *Bacillus* and *Clostridium* spp. are associated with burn wounds that have come in contact with contaminated soil. In avascular muscle injuries (e.g., electrical injuries or crush injuries combined with burns), the risk for

developing tetanus *(Clostridium tetani)* is high[68] and has led to the practice of using tetanus immunoprophylaxis and booster vaccines.[105]

2. **Gram-negative bacteria:** The presence of the gram-negative bacteria in burn wounds is due in part to translocation of the bacteria from the gastrointestinal tract of the patients.[8] In a study of children with burns at our center, patients with large wounds (>50% TBSA) were found to have significantly higher colonization with their fecal gram-negative bacteria than were those with smaller wounds.[32] At our center, although the gram-negative bacteria account for only 41.7 percent of the total bacterial isolates of the wound, they represent a formidable adversary (see Table 87–2). The majority of this group are extended β-lactam–resistant (EBLR) bacteria. Although the carbohydrate fermenting enterics seem to account for 62.1 percent of the gram-negative isolates as a whole, *P. aeruginosa*, a nonfermentor, is the most common gram-negative pathogen in burned patients. Other important gram-negative bacteria include the Enterobacteriaceae such *as Escherichia coli*, *Enterobacter cloacae*, *Klebsiella pneumonia*, and *Serratia marcescens.* The Enterobacteriaceae also are encountered as a cause of nosocomial pneumonia in patients with inhalation injury who are on ventilators, and they are a cause of urinary tract infection in patients with indwelling urinary catheters. *Acinetobacter*, an increasingly more common cause of gram-negative infections, has been found more frequently in burned patients with glucose intolerance or preexisting diabetes mellitus.[33] *Acinetobacter* infections also are found more often in patients with more severe burns and comorbidities.[3]

Even without invasive infections, gram-negative bacteria have been implicated in systemic inflammatory diseases, including shock and disseminated intravascular coagulation, secondary to the circulation of bacterial endotoxin from the gut and the burn wound.[64,74] Often gut decontamination is instituted to reduce the incidence of endotoxin-mediated disease.

3. Fungi: Until the advent of topical antimicrobials and systemic antibiotics, fungal infections were not common developments in patients with burns. The burn wound is the site most commonly infected, although fungemia and dissemination to the respiratory tract in patients on ventilators and to the urinary tract in patients with indwelling catheters are encountered frequently. *Candida* spp. are the most common fungal colonizers of the wound (Table 87–3); however, less than 20 percent of patients develop widespread candidiasis. Overall, the rate of candidemia in the burn population is 3 to 5 percent, and burn-wound invasion has a comparable rate. A study of burned children at our center showed that those developing candidemia did so during the first week postburn and 7 days after excision of burn eschar.[24] One hypothesis is that massive burns with immunosuppression are further suppressed by repeated surgical intervention, anesthesia, and perioperative use of broad-spectrum antibiotics, further predisposing these patients to early development of *Candida* septicemia. With early recognition of invasion of burn wounds by routine biopsies, wound swabs, and early amphotericin therapy, the mortality rate has been reduced to less than 10 percent, as compared with 60 to 90 percent reported in earlier series.[104]

TABLE 87–3 Medically Important Fungi Isolated from 304 Acute Care Pediatric Burn Patients Admitted to Shriners Burns Hospitals for Children—Galveston, Texas (January 2006 to December 2006)

Organism	No. (%) of Isolates
Candida species	86 (83.5)
Fusarium species	6 (5.8)
Trichosporon beigelii	5 (4.9)
Rhizomucor species	2 (1.9)
Aspergillus species	2 (1.9)
Geotrichum species	1 (1.0)
Curvularia species	1 (1.0)
Total no. of fungal isolates	**103**

Unlike *Candida*, true fungal infections caused by *Aspergillus*, *Penicillium*, *Rhizopus*, *Mucor*, *Rhizomucor*, *Fusarium*, and *Curvularia* occur early in the hospital course, specifically in those exposed to the spores on the ground or in water at the time the injury occurred. Once colonized, broad nonbranching hyphae extend into subcutaneous tissue and stimulate an inflammatory response. Vascular invasion occurs frequently and often is accompanied by thrombosis and avascular necrosis, which is clinically observed as rapidly advancing dark discolorations of the wound margin. Systemic dissemination occurs with invasion of the vasculature.

4. Viruses: Linnemann and MacMillan[72] performed a retrospective survey of serum for viral antibodies in pediatric burn patients, 22 percent had fourfold increases in antibodies to cytomegalovirus (CMV), 8 percent had increases to herpes simplex virus (HSV) and to Epstein-Barr virus, and 5 percent had increases in antibodies to varicella-zoster virus (VZV). None of the patients had evidence of adenovirus or hepatitis B virus infection. On the basis of these observations, a prospective study of viral infections, using both serologic and viral culture techniques, was performed. This study showed that CMV infection developed in 33 percent of the children; herpes simplex infection in 25 percent, and adenovirus infection in 17 percent. CMV infections developed in all of the most severely burned children, and both primary and reactivation infections were observed. Most primary CMV infections that develop during treatment for burns are likely to occur from transfusion of blood products. CMV infection typically occurs approximately 1 month after the burn occurs and clinically presents as fever of unknown origin with lymphocytosis; however, it rarely alters the patient's clinical course.[23] Kealey and colleagues[60] have shown that 56 percent of burned patients who initially were seropositive for CMV had a fourfold or greater rise in CMV antibodies as evidence of CMV reactivation. These patients tended to be younger, to have a larger burn area, and to have a longer hospital stay. No patient who experienced CMV infection, whether primary or reactivated, had serious complications attributable to CMV. On the basis of these observations, despite the availability of anti-CMV agents such as ganciclovir and valganciclovir, treatment for CMV infection remains controversial.[96]

Since the screening of blood began, hepatitis C virus (HCV) has been an important risk. Coursaget and colleagues[22] screened 45 burn patients for anti-HCV antibodies, at the time of burn injury and more than 6 months postburn. HCV infection was detected in 18 percent of these patients, as a consequence of the numerous transfusions of blood or blood derivatives used during the postburn treatment. Five patients displayed evidence of anti-C100, anti-C33c, and anti-core antibodies together; two patients had only anti-C100 and anti-C33c antibodies, and the last one showed only anti-core antibodies. Chronic hepatitis was observed in 83 percent of HCV infections. Kinetics of appearance of anti-HCV antibodies varied among patients. Anti-core generally is the first to be detected at high levels; however, in at least one case, it was detected only 2.5 months after C100 and C33c antibodies were detected. The incidence of HCV using polymerase chain reaction (PCR) technique to detect the viral genome has not been evaluated in burn patients. Nonetheless, the current blood banking procedures have decreased the transmission of HCV by blood products.

Another transfusion-related agent is human immunodeficiency virus (HIV), which has become extremely rare as a result of the screening of donors that began in 1987 in the United States. However, significant risk existed prior to that period. A retrospective review of burned children at our center who had received blood/blood products between 1978 and 1985 identified

52 patients at risk for developing HIV infection.[100] More than 50 percent of the identified population had received three or more units of blood/blood products during their acute hospital stay. A total of 214 patients (36.8%) were tested for HIV seroconversions: five tested HIV-positive by enzyme-linked immunosorbent assay (ELISA) and four were confirmed by Western blot, yielding a 1.9 percent incidence. The four confirmed patients received two to nine total body blood volume turnovers during their postburn period in the hospital. HIV may affect the outcome of burn wound injury. A study of Malawian children showed that with burns affecting 11 to 30 percent of the body surface area, HIV-positive children had a mortality rate approximately twice that of the of HIV-negative children.[55]

HSV is of significant concern in burn units because it is a dermatopathologic virus. A review of the literature suggests that patients younger than 10 years of age were at greater risk of acquiring an HSV infection when the size of the burn wound was greater than 15 percent of TBSA.[46] However, the role of HSV in the healing of wounds is unclear. Bourdarias and colleagues[15] showed that in 11 patients with burns, local areas of active epidermal regeneration were affected most often. Acyclovir therapy was not used, and the duration of hospitalization was normal when compared with other children. Nonetheless, HSV in lungs may worsen morbidity. Byers and associates[17] showed that the relative risk for developing HSV infection was higher for cases with adult respiratory distress syndrome but not with pneumonia. Disseminated HSV infection also can be fatal.[17]

Another dermatopathologic virus is VZV. Mini-epidemics of VZV have occurred within pediatric burn units.[122] With the routine VZV vaccination of young children (1 to 2 years of age) in the United States, the outbreaks of varicella in burn units are now uncommon. The characteristic fluid-filled lesions appear in partial-thickness burns that are healed or healing, as well as in uninjured epithelium and mucous membranes. The vesicles are much more destructive in the injured than uninjured skin and may present as hemorrhagic, oozing pockmarks that are prone to development of secondary infection and subsequent scarring. Neovascularized skin grafts may be lost; therefore, further grafting procedures should be delayed until the lesions are quiescent.

The morbidity due to respiratory virus infections, particularly in those with inhalation injury, has not been studied well. More than 100 pediatric burn patients at our center were tested for respiratory syncytial virus (RSV) during the winter seasons of 1995 and 1996 (unpublished observations). Only six patients were found to be positive for RSV, with one death (1% mortality rate).

5. **Parasites:** Parasitic infestation also is seen especially in children from the developing world. Because many patients in our center originate from Mexico, where such infestation is endemic, parasitemia has been found to complicate burn injuries. Parasites that are asymptomatic in sites such as the intestinal tract and the respiratory tract can become symptomatic as a result of the stress of a burn injury. At the Shriners Burns Hospital for Children in Galveston, Texas, we have described three cases of ascaris pneumonitis that exacerbated the smoke-induced lung injury.[47] In 2006 the parasites isolated most frequently were *Giardia lamblia* and *Blastocystis homini*.

CLINICAL MANIFESTATIONS OF INFECTION

LOCAL SIGNS

An open burn wound is a favorable target for bacterial colonization. The progression from simple eschar colonization to the invasive process is favored by a series of factors related to the patient, such as extension and depth of the burn, age, presence of previous disease, and local conditions of the wound; to the microorganism such as density, motility, toxins and antimicrobial resistance; to iatrogenic causes such as prosthetic devices; and to the nosocomial spread of bacteria. It is essential to recognize the early signs of infection of a local burn wound by examining the wound at least once a day.

The local signs of burn wound infection include black or dark brown focal areas of discoloration, conversion of partial-thickness injury to full-thickness necrosis, hemorrhagic discoloration of subcutaneous tissue, enhanced sloughing of burned tissue or eschar, and purplish discoloration or edema of skin around the margins of the wound. Presence of *Pseudomonas* infection can lead to ecthyma gangrenosa and green pigmentation of subcutaneous fat. In fungal infection, centrifugal advance of subcutaneous edema with central ischemic necrosis and hemorrhagic saponification of subcutaneous fat in fungal infection can be seen. In viral infection, vesicular lesions in healing or healed partial-thickness burns and crusted serrated margins of partial-thickness burns may be observed.

SYSTEMIC SIGNS

Progression from local to systemic invasion can occur rapidly, which correlates with the size of the burn wound, the extent of environmental contamination, and the surgical procedures. Early recognition of systemic invasion is critical to avoid the high rates of mortality. Many of the signs of sepsis resemble complications of the burn itself; for example, fevers, tachycardia, shock, and elevated or depressed neutrophil count can occur in burned patients with or without infection. However, certain patterns of clinical signs and symptoms may help recognize the systemic bacterial invasion (Table 87–4).[35] A rise in levels of C-reactive protein serum has been found useful in predicting systemic infection, although increases in the first 2 days after the burn or the day after surgery may occur without infection.[86] When sepsis did occur, it always was preceded by increased levels of C-reactive protein approximately 2 days before the patient was deemed septic clinically. Elevated levels of certain cytokines may be useful markers, but they largely remain research tools.

TABLE 87–4 Signs and Symptoms of Progression from Local Invasion to Systemic Illness*

Gram-Negative Sepsis	Gram-Positive Sepsis
Burn wound biopsy $>10^5$ organisms/g tissue and/or histologic tissue invasion	Same
Rapid onset, well to ill in 8-12 hr	Gradual
Temp. 37-39°C, can be normal, followed by hypothermia (34°-35°C), plus decrease in WBC	Temp. >40°C
WBC may be elevated	WBC 20-50 $\times 10^3$, hematocrit decrease
Ileus	Same
Decreased blood pressure and urinary output	Same
Wounds develop focal gangrene, satellite lesions away from burn wound	Macerated wounds, Ropy and tenacious exudate
Mental obtundation	Anorexic and irrational

Five or more signs or symptoms are definitive diagnostic parameters.
**Modified from reference 35.*
WBC, white blood cell count.

INFECTION COMPLICATIONS

Other than the primary infection of the burned skin, several types of infectious complications in the burned patients have been recognized. Bacteremia is a frequent complication. Surgical burn wound manipulations are responsible for development of bacteremias in approximately 50 percent of cases, but routine instrumentation and intravascular catheter devices also can cause bacteremia.[13,44] The risk of developing bacteremia also correlates with the TBSA affected by burns; Sasaki and colleagues[101] showed that those patients with a positive blood culture had an average total body surface area injury of 47 percent, whereas those with a 26 percent injury had negative blood cultures. TSS caused by TSS toxin–producing strains of *S. aureus* has been identified in acutely burned children. Childs and colleagues[20] found that 13 percent of children developed a toxic shock–like illness; however, its effect on overall burn mortality was not clear.

Subacute bacterial endocarditis is a risk associated with persistent bacteremia caused by any cause, including repeated instrumentation, surgical intervention, and placement of central venous catheters.[12,18] *S. aureus* and gram-negative bacilli are the most frequent cause. In most cases, the antemortem diagnosis rarely is suspected in burned children.[2,12] In addition to causing local valvular damage, infected vegetations may dislodge septic emboli. Suppurative thrombophlebitis occurs at the site of the insertion of the catheter. It may occur in as many as 5 percent of patients with burns covering 20 percent of the TBSA.[109]

Suppurative chondritis occurs in patients with full-thickness burn of the ear. Because of the auricle's relatively low level of blood supply, chondritis frequently follows the progression of tissue ischemia, usually 3 to 5 weeks after burn injury occurs.[80] *P. aeruginosa* and *S. aureus* are the most common pathogens. However, with use of mafenide acetate as a topical agent, the incidence of suppurative chondritis has decreased significantly.

Suppurative sinusitis is seen in patients with long-term nasotracheal intubation. In one study, 8 percent of patients with burns who had nasotracheal intubation for more than 7 days developed sinusitis.[16] Pneumonia may occur with or without inhalation injury, although those with inhalation injury have a substantially higher risk.[107] Bronchopneumonia is the most common type of pulmonary infection, usually occurring in the second week of burn injury. Predisposing factors are size of the burn wound (hematogenous spread), aspiration, presence of tracheostomy or nasotracheal tube (nosocomial spread from burn wound), existence of inhalation injury, and disturbances of fluid and electrolyte balances. Currently, most infection-related deaths in burned patients are caused by pneumonia rather than wound infection.[107]

Urinary tract infection occurs in association with prolonged and often unnecessary catherization.[102] Osteomyelitis can occur when bones are exposed by the burn or by open fracture accompanying the burn; from extension of infection from a septic joint, introduction of organisms along traction pins, and internal fracture fixation devices; or by bacteremia. However, clinically significant osteomyelitis in burned patients is rare.[28] Septic arthritis occurs when a joint is exposed by a burn or by removal of burn eschar.[28] The joints most frequently exposed are the knee, the elbow, the proximal interphalangeal joints of the hand, and the metacarpophalangeal joints on the dorsal surfaces of the hand. The incidence of septic arthritis is obscured by its frequent association with signs and symptoms of severe burns that rarely are separable. Rarely in burns, a joint may become infected from adjacent metaphysical osteomyelitis. In children, most joints can be salvaged. Adult joints are less resilient.

Central nervous system infections in burned patients include meningitis, microabscesses, and septic infarcts. In one review, *Candida* spp., *S. aureus*, and *P. aeruginosa* caused almost 80 percent of infections, occurring most frequently in patients with extensive burns with wound infection or endocarditis.[123]

MICROBIOLOGIC INVESTIGATIONS

The three major approaches to determine burn wound infection are (1) quantitative burn wound cultures (BWCs), (2) histologic assessment of bacterial invasion, and (3) bronchioalveolar lavage (BAL).

1. **Quantitative BWC by biopsy:** Teplitz[112] demonstrated that quantitative bacterial counts of BWCs correlated with histologic specimens showing invasion or colonization. Burn wound infection (often referred to as "burn wound sepsis" in surgical literature) is suspected when proliferating microorganisms exceed 10^5/g tissue and when there is invasion of subjacent unburned tissue has occurred (Fig. 87–2). The presence of microorganisms within the necrotic eschar cannot be considered evidence of burn wound infection. Furthermore, although a bacterial count of 10^5/g tissue is likely to indicate bacterial invasion, this is not invariably true. Only the histologic sections can indicate the level of infection. Therefore, BWCs always should be accompanied by histologic sections from the same area.[93,94]

At the time that surgery is performed, the potentially infected tissues should be excised with a punch biopsy (Fig. 87–3) and divided into equal aliquots.[50] One aliquot should be placed into saline and delivered to the microbiology section for quantitative assessment. These biopsies are weighed aseptically, homogenized in a sterile tube in 3 mL of sterile saline. Known dilutions of the homogenate then are plated using precalibrated loops (10 μL) onto blood agar, colistin-neomycin agar, MacConkey agar, and Sabourands agar for identification in the initial dilutions of 0.1 mL with a 1-mL sterile pipette. After 24 hours, the number of colonies are counted and the quantitative wound culture (QWC) is calculated according to the following formula.

Colony forming unit (CFU) × g of tissue = *number of colonies* × *volume* × *dilution* weight of biopsy in grams

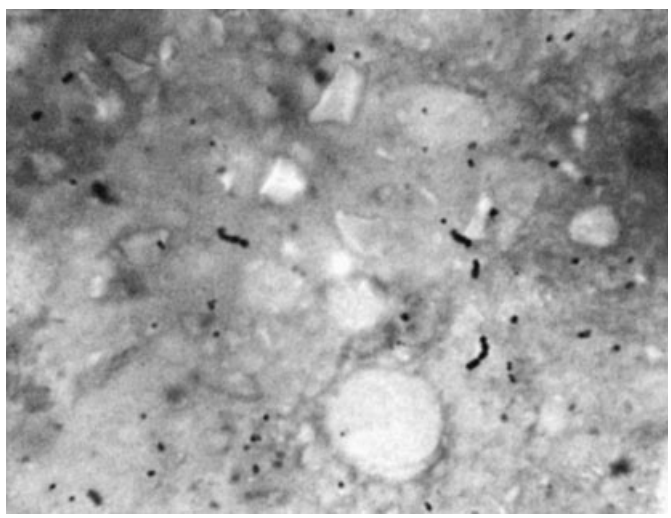

Figure 87–2 Photomicrograph of a homogenized biopsy stained with Gram stain. Gram-positive cocci are seen (cultures grew group A *Streptococcus* at $>10^5$ colony-forming units/gram tissue). *(With permission from Hunsicker, L., Heggers, J. P., Patel, J. A.: Infections in burn patients. In Patrick, C. C. [ed.]: Clinical Management of Infections in Immunocompromised Infants and Children. 2nd ed. Philadelphia, Lippincott Williams & Wilkins, 2001, p. 338 [Fig. 16.2]).*

A.: Infections in burn patients.* In *Patrick, C. C.: Clinical Management of Infections in Immunocompromised Infants and Children. 2nd ed. Philadelphia, Lippincott Williams & Wilkins, 2001, p. 339 [Fig. 16.3]).*

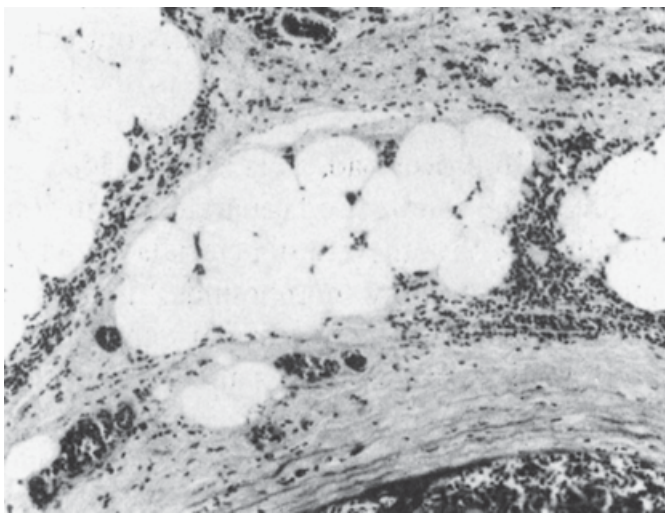

Figure 87–4 Photomicrograph of a cross-section of tissue stained with hematoxylin and eosin showing invasion of *Pseudomonas aeruginosa*. *(With permission from Hunsicker, L., Heggers, J. P., Patel, J. A.: Infections in burn patients.* In *Patrick, C. C. [ed.]: Clinical Management of Infections in Immunocompromised Infants and Children. 2nd ed., Lippincott Williams & Wilkins, 2001, p. 338 [Fig. 16.4]).*

Despite the dependence on quantitative tissue cultures, reliability of this procedure has been questioned because of the high degree of variability in quantitative counts. In a study published in 1981, Woolfrey and colleagues[124] found that when biopsy samples were divided and cultured separately, only 38 percent of paired quantitative results agreed within the same $\log_{10}$ unit, whereas 44 percent differed by +2 $\log_{10}$ units or more.

2. **Histologic procedures:** Standard histologic procedures, as well as cyrostat examination, are necessary.[94] The tissues should be examined for morphologic changes and for the presence of pathogens. Many bacterial and fungal pathogens can be identified by staining with Gram stain and Gomori–methamine silver stains (Fig. 87–4). More specialized stains may be necessary to identify other fastidious bacteria and fungi. Tzanck stain can be used to identify inclusion bodies suggestive of invasion of HSV or VZV. Viral-specific antibodies also can be used to detect these viruses by immunohistochemistry. The microbial status of the burn wound (i.e., colonization or invasion), as assessed by histologic examination of a biopsy specimen, can be graded on the basis of the density and depth of penetration of microorganisms (Table 87–5).[94]

TABLE 87–5 Staging of Microbial Status of the Burn Wound by Biopsy Histology*

Stage I: colonization
A. Superficial: microorganisms present only on burn wound surface
B. Penetrating: variable depth of microbial penetration of eschar
C. Proliferating: variable level of microbial proliferation at nonviable-viable tissue interphase (subeschar space)
Stage II: invasion
A. Microinvasion: microorganisms present in viable tissue immediately subjacent to subeschar space
B. Deep invasion: penetration of microorganisms to variable depth and expanse within viable subcutaneous tissue
C. Microvascular involvement: microorganisms within small blood vessels and lymphatics (thrombosis of vessels common)

**Modified from reference 94.*

3. **BAL:** BAL fluid needs to be collected by personnel experienced in the evaluation of patients with inhalation injury who are at risk for developing airway edema and obstruction. Ventilator-associated pneumonia can be diagnosed if 10^4 or more organisms/mL are cultured. In a study reported by Wahl and colleagues,[118] BAL eliminated the unnecessary antibiotic treatment of 21 percent of patients. In winter months, BAL fluids also can be processed for prevalent respiratory viruses such as RSV and influenza by rapid antigenic detection by immunoassays that are within the capability of most laboratories, or by culture that requires specialized virology laboratory.

PREVENTION AND TREATMENT OF INFECTION

Care of the wound is the mainstay of burn therapy. The goal is to minimize infection and facilitate healing of the burn wound. Wound care addresses both partial- and full-thickness burn injuries until all wounds are closed.

1. Wound dressing: The superficial epidermal layer provides a barrier to microorganisms while the deeper lipid epidermal layer provides protection against loss of water vapor. In full-thickness burns, the eschar may extend beyond the skin into the subcutaneous fat and muscle. Closure of the wound cannot occur until the eschar is removed. Bacterial proteases lead to eschar pseudo-separation and are slowed with antiseptic therapies. Then, the eschar is allowed to fragment and slough, with resultant decreased size. This process is called *wound contraction.* This can also be excised and skin grafted. Full-thickness skin grafts have the least contraction rates. Deep dermal wounds allowed to heal spontaneously lead to hypertrophic scarring. Compression garments are used for prevention and treatment.

When approaching burn wound care, a plan must first be decided. Outer burn dressings provide comfort, metabolic enhancement, and protection. First, superficial burns are exquisitely sensitive to air currents, as are deeper burns after some healing. Also, dressings provide splinting and drainage containment. Next, occlusive dressings help eliminate shivering, cold stress, and evaporative heat loss. In open, granulating wounds, loss of water vapor is maximal. Finally, the protective component

deals with the control of topical organisms. Supplies consist of large 9 × 9-inch burn gauze, Kerlex wraps, Ace wraps, and topical antimicrobials. Gentle cleansing of the wound and daily débridement also are important. Buttock burn wounds should be examined carefully and frequently for the presence of deep stool staining, an ominous predictor of burn wound sepsis and death.[97] Such wounds should be emergently excised.

2. Topical antimicrobials: Topical antimicrobial agents are used extensively in burned patients. Most patients with stage I and stage II A and B wounds (Table 87–5) can be treated with topical or subeschar antimicrobials alone.

Silver sulfadiazine (Silvadene, SSD, Thermazine, Flamazine, Burnazine): Silver sulfadiazine is a 1 percent water-soluble cream combining sulfadiazine with silver (Ag^+). The Ag^+ ion binds with the DNA of an organism and consequently releases the sulfonamide that interferes with the intermediary metabolic pathway of the microbe. It is most effective against *P. aeruginsosa*, the gram-negative enteric bacteria, and *C. albicans*. *S. aureus*, and some strains of *Klebsiella* spp. have been less effectively controlled.[35] Antimicrobial effectiveness has been observed to last for up to 24 hours. More frequent changes are required if a creamy exudate forms on the wound. The benefits of this topical agent are its ease of use and its ability to reduce pain. It has some tissue-penetrating ability, but it is limited to the epidermis.

Silver sulfadiazine can be used separately or in combination with other antibacterials or enzymatic escharotomy compounds. It can be combined with nystatin, which enhances the antifungal activity of this agent. By itself, silver sulfadiazine has been shown to retard wound healing; however, in conjunction with nystatin or *Aloe vera*, the wound-retardant effect is reversed.

Cerium nitrate–silver sulfadiazine (Flammacerium): The lanthanide salt cerium nitrate has been added to silver sulfadiazine since the 1970s and has been shown to have increased bacteriostastic effect in large burn wounds. The antimicrobial spectrum is similar to that of silver nitrate. Methemoglobinemia has been seen only rarely, and no associated electrolyte disturbances occur. Only minimal cerium absorption has been noted in patients with large burns treated for weeks. No complications were noted. Its use is somewhat limited because it is not commercially available in the United States. It is, however, available in several western European countries. Koller and Orsag[63] studied the effects of cerium sulfadiazine in 20 burn patients and found it to be safe and effective in the treatment of deep, extensive burn wounds. Caution is advised for use of sulfadiazine products as cases of *P. aeruginosa* resistance to sulfadiazine have been reported.[49]

Silver nitrate: Silver nitrate is available as a 0.5 percent solution that does not injure the regenerating epithelium in the wound and provides bacteriostatic effect against *S. aureus*, *E. coli*, and *P. aeruginosa*.[35] Silver nitrate is most effective when the wound is cleansed carefully of all emollients and other debris. Multilayered coarse mesh dressings should be placed over the wound and saturated with the silver nitrate solution. Like silver sulfadiazine, silver nitrate has limited penetration because the Ag^+ ion is bound rapidly to the body's natural anions such as Cl^-. Because it is hypotonic in nature, it can cause osmolar dilution, resulting in hyponatremia and hypochloremia. Serum electrolytes should be monitored very carefully.

Notable detriments to the use of silver nitrate include its high expense and light sensitivity. Furthermore, it also requires special handling because if it is allowed to dry or if it is covered with an impervious dressing, hyperpyrexia could occur. *Klebsiella*, *Providencia*, and other *Enterobacteriaceae* spp. are not as susceptible to it as are other bacteria. *E. cloacae* and other nitrate-positive bacteria can cause methemoglobinemia by converting nitrite to nitrate.

Mafenide acetate (Sulfamylon): Mafenide acetate is available both in a 10 percent water-soluble cream or a 5 percent solution and has more substantial bacteriologic data to support its efficacy than do any of the other topical antimicrobials.[66,78] It has been shown to be effective against a broad range of microorganisms, especially against all strains of *P. aeruginosa* and *Clostridium* spp.[101] After a wound has been cleansed of debris, mafenide acetate is applied to the wound like "butter." The treated burn surface is left exposed for maximal antimicrobial potency. The cream is applied a minimum of twice a day and can be reapplied as needed. The 5 percent solution is applied every 8 hours.

Additionally, mafenide acetate has the ability to permeate burn eschar and thereby reduce the risk of bacterial colonization of a deep burn wound, and it is especially effective after the dead tissue is removed from the granulating bed. Unfortunately, several detrimental aspects are associated with the use of mafenide acetate. Protracted use with the low environmental pH favors the growth of *C. albicans*. Mafenide acetate is converted to *p*-sulfamyl vanzoic acid by monamine oxidase, which is a carbonic anhydrase inhibitor; it subsequently causes metabolic acidosis in the patient. Another detrimental problem is that it is painful when applied to superficial, partial-thickness burns with intact free nerve endings. Also, its requirement to remain uncovered for antimicrobial activity may be considered a disadvantage when a dressing is required.

Membrane dressings: Acticoat and Aquacel are silver-coated dressings that have a broad antibacterial activity. Compared with silver nitrate or silver sulfadiazine use, Acticoat and Aquacel have been found easier to apply, were associated with less pain on removal, and have faster rates of reepithelialization.[19,114] Mepitel is another gridlike, silicone-coated, nylon dressing used in partial-thickness burn wounds. Gotschall and colleagues[40] found this product to decrease the pain experienced during dressing change, the time needed for the wound to heal, and the overall duration of the hospital stay as compared with silver sulfadiazine. This study did not find any difference in the incidence of infections between Mepitel and silver sulfadiazine treatments.

Topical antibiotics: Several topical antibiotics have been tried in the management of burn infections. These agents are highly discouraged in the setting of a burn unit because of rapid emergence of resistance:

a. Gentamicin sulfate: It is available as a 0.1 percent water-soluble cream and is chemically similar to the other aminoglycosides, such as kanamycin and neomycin. It has a broad spectrum of antimicrobial activity. It is used for its activity against *P. aeruginosa;* however, its topical use is highly limited because of the high level of gentamicin resistance in burn units.

b. Bacitracin/polymyxin: This antibiotic combination has little or no effect on localized infections of burn wounds.

c. Nitrofurantoin: It is used topically as adjunctive therapy in patients with second- and third-degree burns. With good eschar penetration, it can be used in the treatment of invasive burn wound infections with sensitive agents. The drug presents some advantages for the ambulatory patient. Tissue granulation begins sooner and crusts separate more rapidly.

d. Mupirocin (Bactroban): Studies at our center have shown mupirocin to be superior to silver sulfadiazine in treating methicillin-susceptible *S. aureus (*MSSA) or MRSA infection.[110] Although mupirocin is weaker against gram-negative bacteria, it is also comparable to silver sulfadiazine and mafenide acetate against *P. aeruginosa*, *E. coli*, and *K. pneumonia*.

Nystatin (Mycostatin, Nilstat): Studies at our center have noted that combining nystatin and silver sulfadiazine or nitrofurantoin results in effective prevention of local and systemic *Candida* infections, as well as burn wound sepsis.[48] However, in combination therapy of silver sulfadiazine and nystatin, mafenide acetate actually loses its antimicrobial activity. Therefore, use of nystatin with mafenide acetate is discouraged. Our investigators also have studied concentrated nystatin powder on the effect of angioinvasive fungi *(Fusarium*, *Aspergillus)* refractory to systemic amphotericin B and serial excisions, including amputations.[10] A

concentrated form of nystatin (6,000,000 units/g) was used as dry aerosol every 6 hours and wet to dry dressings laid overtop. Within 14 days, all four of the children studied recovered, with the eradication of their invasive fungal infections. Also, all areas previously autografted underneath the nystatin powder healed nicely.

Sodium Hypochlorite (0.025% Heggers Solution): Currently, the most effective topical antibacterial agent for cleansing a wound is sodium hypochlorite (NaOCl). It transcends the topical antimicrobial effects and tissue toxicity of such products as povidone-iodine, acetic acid, and hydrogen peroxide. The efficacy of NaOCl has been determined to be at a concentration of 0.025 percent, which is bactericidal, nontoxic to fibroblasts, and does not inhibit wound healing, provided buffers are used.[51] It is a broad-spectrum antiseptic and is bactericidal for *P. aeruginosa*, *S. aureus* (MRSA and MSSA), enterococci, and other gram-negative and gram-positive organisms.[101]

Povidone-iodine (Betadine): The active antimicrobial component in this compound is the iodine. It has a broad spectrum of antibacterial and antifungal activities. However, there are disadvantages that limit its use in a burn center. It is painful when applied and is inactivated by wound exudates. Renal dysfunction and acidosis have been noted in association with systemic absorption when applied to open wounds.[65]

Chlorhexidine: Chlorhexidine when combined with 0.5 percent silver nitrate has efficacy similar to that of silver sulfadiazine.[70] Some variants of this product have broader antimicrobial activities, but pain experienced by patients on application has limited its use. Unlike the sulfonamides, plasma-mediated resistance has not occurred.

Subeschar antibiotics: Moncrief[81] has described the technique of subeschar antibiotic infusion. It is used upon microbial invasion into unburned tissue, when topical therapies have not been effective, or in cases in which treatment has been delayed. The most common drugs used are tobramycin, gentamicin, and kanamycin. However, development of antimicrobial resistance is likely substantial, so subeschar infusion of antibiotics should be used infrequently. The antibiotic solution is administered via multiple needle infusions by subcutaneous lysis. The results of this technique are more rapid separation of eschar. The fluid infusion limit is 2000 mL (adult dose) and should be accounted for in patient's fluid requirements. The infusion fluid should consist of 0.25 to 0.45 N saline to avoid salt overload. Lactated Ringer solution should be avoided because some of the drugs are incompatible with calcium. Erythromycin has been studied but is too painful to use. Colistin, novobiocin, and cephaloridine have been used but found to be ineffective.

3. **Systemic anti-infective agents:** Drug pharmacokinetics are significantly altered in the burned patient and show significant inter- and intrapatient variation.[121] In 1976, altered aminoglycoside pharmacokinetics and the need for increased dosage in burned patients were reported, but despite this early study, a review of the currently available literature shows that for many drugs there is a paucity of information to support current dosage recommendations, specifically in children of various age groups. In addition, many reports are based on small numbers of patients, and even in larger studies, no standardization of the study population exists with regard to the important variables known to affect drug handling. For the subpopulation of burned patients who eliminate drugs extremely rapidly, a concern exists over the adequacy of antibiotic dosing. Researchers have suggested that antibiotic serum concentrations be measured for all drugs in every patient to ascertain whether a significant problem exists with dosing.

Whereas stage I and stage II A and B wounds (see Table 87–6) can be treated with topical or subeschar antimicrobials alone, stage II C wounds require the immediate institution of systemic anti-infective agents. Systemic agents also are indicated for the treatment of various systemic infectious complications as discussed earlier. Detailed information on selection of the appropriate systemic antimicrobials for specific bacterial, fungal, and viral pathogens is available in other chapters of this book. Nonetheless, the following general principles can help guide the use of antimicrobial therapy:

a. Each antimicrobial agent must be selected for its specificity for the microbe present.

b. Such decisions should be made on appropriately collected culture and susceptibility data.

c. Colonizing flora should be distinguished from those responsible for inflammation and invasion.

d. The time, dosage, route of administration, and duration of treatment should be in accordance with what is required to make the organism nonpathogenic.

e. The need for broad-spectrum antibiotics should be balanced with the risk of promoting fungal infections.

Treatment of multidrug-resistant, gram-negative bacteria: This issue deserves specific mention because it most severely affects the burn units. In many centers, pan-resistant *P. aeruginosa* strains and *Acinetobacter* spp. are identified frequently. In these cases, colistin and polymyxin B often remain the only susceptible antimicrobial agents. In a recent study, Goverman and colleagues[41] summarized their experience in 14 children treated with intravenous colistin: favorable response was obtained in 79 percent and the overall mortality rate was 14 percent. Both colistin and polymyxin B are associated with significant elevation in serum creatinine or renal failure in 15 to 25 percent of recipients. Neurotoxiciy in children is an infrequent occurrence. Intravenous and/or aerosol polymyxin B, doxycycline, and ampicillin/sulbactam (the active component is thought to be sulbactam) have been tried in multidrug-resistant *Acinetobacter* infections as well.[88] Other studies have demonstrated in vitro susceptibility of multidrug-resistant *Acinetobacter* to various synergistic combinations of antimicrobials, including carbapenems, colistin, rifampin, tigecycline, and ampicillin-sulbactam.[38,53,125] The clinical utility of these combinations against pan-resistant *Acinetobacter* remains to be determined.

4. Antibiotic prophylaxis: Prophylactic use of antibiotics remains a highly controversial topic in the literature. Penicillin prophylaxis is used commonly in many burn centers during outbreaks of group A streptococcal infections.[43,98] Prophylactic antibiotics also are used before surgical manipulation or instrumentation because the risk of developing bacteremia is as high as 50 percent. The choice of perioperative antibiotics is dependent on the knowledge of existing microorganisms, which are present not only on injured skin but also in the wound that is ready for surgery. Nonetheless, carefully controlled studies are necessary to identify the value of prophylactic antibiotics. In a placebo-controlled study of cefazolin use in burned children, researchers found that in children with less than 35 percent burn, cefazolin was not necessary, and in those with 35 percent burn or more, it was not effective.[99] In a retrospective review study, antibiotic prophylaxis was not associated with any reduction in the rate of wound infection; instead, the duration of hospitalization was found to be longer.[26]

5. Wound excision and grafting: Studies at our center have shown that early excision of wounds leads to significantly decreased rates of bacterial colonization and wound infection.[9] A meta-analysis of six trials found that early excision of burns is beneficial in reducing mortality (in patients without inhalational injury) and length of hospital stay. The only drawback is the greater volume of blood loss.[89]

6. Gut support and decontamination: The gut microflora have been implicated in the development of multiorgan failure when the gut barrier fails. Hence, one theory is that early enteral feeding of the gut, which promotes function of the gut barrier, is important for preventing multiorgan failure. A decontaminated gut with nonabsorbable, broad-spectrum antibiotics might dimin-

ish the impact of failure of the gastrointestinal barrier. Although the suggestion has been made that the rate of pneumonia may be decreased by such maneuvers, no apparent impact on mortality rates have been noted.[75] Overall, convincing human data on the beneficial effect of enteral feeding and decontamination of the gut on sepsis and multiorgan failure are lacking.

7. **Immunomodulators:** In view of the intricate relationship between altered immune defenses in burned patients and increased susceptibility to infections, various types of immunotherapies have been tried in burned patients. In an Italian study, treatment with intravenous pooled immunoglobulins (IVIG) was found to have a beneficial effect on septic phenomena and recovery.[79] However, in two U.S. studies, no change in rates of infection or mortality was shown. Overall, the beneficial role of IVIG as prophylaxis or treatment remains unproven.[85,119] In a German study, prophylaxis with intravenous *Pseudomonas* immunoglobulin did not appear to be beneficial to burned patients in general; however, it was shown to be effective in burned patients with inhalation injury.[111] In a South African study, prophylaxis with high-titer anti-lipopolysaccharide immunoglobulin G (IgG) reduced the incidence of burn wound infection but did not affect mortality.[57] Benefits of plasmapheresis or fresh frozen plasma infusion have not been proven.

INFECTION CONTROL

Hospital-acquired infections in burn patients are common occurrences. In burned children, wound infections, ventilator-related pulmonary infections, central-line bacteremias, and catheter-associated urinary tract infections are the most common nosocomial infections.[102,120] The rates of infections may be lower than those seen in adults, but urinary tract infections occur more frequently in children.[102] In a German study of children with burns, the overall infection rate was 59.7 nosocomial infections per 1000 inpatient days, and the device-associated infections per 1000 device days were 55.2 for pneumonia, 8.9 for primary bloodstream infections, and 41.7 for urinary tract infections.[37] The incident density of burn wound infections was 18.5 per 1000 inpatient days, which was associated with the percentage of TBSA of the burn wound. On the other hand, the rate of device-associated infections was not associated with the percentage of TBSA.

Surveillance of infection in a burned patient is performed to implement prompt treatment on the basis of surveillance cultures and antimicrobial sensitivities at the earliest sign of invasion. Such surveillance requires cultures of sputum, urine, and wounds about three times weekly; however, the need for such cultures and the frequency of monitoring remain controversial. Additional infection control measures involve surveillance of spread of pathogens among burned patients of a unit. In dealing with the burn wound, strict infectious disease precautions must be maintained to prevent contamination and worsening infection in these already immunocompromised patients.

In the past, poor handwashing and shared hydrotherapy tubs were the source of many infections, some of which were life-threatening. Strict enforcement of handwashing and use of gowns, gloves, and masks have led to decreased rates of patient contamination. Also, disposable hydrotherapy tub liners are used without the risk of patient-to-patient transmission of infections.[113] Besides this, isolation of burned patients in a single room compared with an open ward scenario has dramatically affected infection rates. McManus and colleagues[77] studied this measure in 2519 patients and found significantly lower incidence and mortality rates associated with gram-negative bacteremia in the isolated patients. Also, the open ward bacterial isolates showed significantly more antimicrobial resistance compared with those of the patients in isolation.

Additional infection control measures include the use of germicidal solutions to clean daily all of the hardware, such as intravenous poles and pumps, monitoring equipment, bedside tables, and beds in patients' rooms. Upon discharge of the patient, the whole room, including floors, walls, ceilings, and mattresses, needs to be cleaned with germicidal solutions. Air filters should be monitored repeatedly for fungal and bacterial growth.

Lai and colleagues[67] studied the effects of strict isolation of patients with VRE, the use of vancomycin, and the cost-to-benefit analysis of barrier precautions. Their findings showed that pharyngeal swabs were poor for surveillance but that rectal swabs were more useful. Also, vancomycin-use guidelines were adhered by 85 percent of the staff. The overall cost for these implementations, including the barrier supplies and cleaning protocols, was $11,000. Nonetheless, VRE was not eradicated. On the other hand, van Rijn and colleagues[116] have shown that isolation in a quarantine unit was highly effective in preventing outbreaks of multidrug-resistant bacteria.

SECTION XV

Unclassified Infectious Diseases

CHAPTER 88

Kawasaki Disease

Stanford T. Shulman

Kawasaki disease is a multisystem acute febrile vasculitic syndrome of unknown (presumably infectious) origin that affects predominantly infants and young children. The diagnosis is based on characteristic clinical features (Table 88–1). Serious complications include coronary arteritis, coronary artery aneurysms and stenoses, coronary thrombosis leading to myocardial infarction, and, very rarely, rupture of a coronary aneurysm. Kawasaki disease has become the leading cause of acquired heart disease in children in most developed countries including the United States and Japan.[364,365] It has been reported in children of all racial groups and from all continents. Although the origin of Kawasaki disease remains unknown and a specific diagnostic test is lacking, establishing a timely diagnosis is very important because administration of intravenous immunoglobulin (IVIG) and aspirin before the 10th day of illness generally has a dramatic effect on the clinical manifestations and markedly reduces the likelihood of development of coronary abnormalities (see the later sections on treatment).[99,238,247,250-252,322,367]

Synonyms for Kawasaki disease include *Kawasaki syndrome* and *mucocutaneous lymph node syndrome* (MCLS, MLNS, or MCLNS). It also has been referred to as *lymphomucocutaneous syndrome* and similar terms. An earlier term used in autopsy reports was *infantile periarteritis nodosa* (IPAN), which is pathologically indistinguishable from fatal Kawasaki disease. The International Classification of Diseases (ICD-9) designates the condition as both Kawasaki disease and mucocutaneous lymph node syndrome (acute) (febrile) (infantile) under rubric 446.1. Before 1983, the National Library of Medicine listed Kawasaki disease publications under various subject headings, particularly "Lymphatic Diseases." Since 1984, publications have been listed under "Mucocutaneous Lymph Node Syndrome," a term very rarely used today.

HISTORY

The illness now bearing his name was first recognized as a clinical entity in 1961 by Dr. Tomisaku Kawasaki, who subsequently became Chairman of the Department of Pediatrics at Tokyo's Japan Red Cross Medical Center. Between 1961 and 1967, Kawasaki identified 50 infants and young children who manifested a distinctive constellation of signs that included prolonged high fever, unilateral cervical lymphadenopathy, bilateral conjunctival injection, a polymorphous erythematous rash, changes of the mucosa of the upper respiratory tract, and edema and erythema of the extremities, with subsequent desquamation of the finger and toes. Although the syndrome was impressive, its signs were nonspecific. Laboratory tests ruled out other disorders. A series of the first seven cases was presented by Kawasaki at the 61st Chiba General Meeting of the Japan Pediatric Society in 1962.[158] Convinced that he was observing a distinct clinical syndrome, Kawasaki published a report of his experience with 50 cases of "febrile oculo-oro-cutaneo-acrodesquamatous syndrome with or without acute nonsuppurative cervical lymphadenitis" in 1967.[159,160,162] Other Japanese physicians quickly recognized the syndrome after Kawasaki's report, although considerable discussion ensued about whether it was a distinct entity or an illness such as Stevens-Johnson syndrome.[161]

Cardiac involvement in this illness was suspected first in 1968, when Yamamoto and Kimura reported an infant with Kawasaki disease who had transient tachycardia with a gallop rhythm, cardiomegaly, and minor abnormalities on the electrocardiogram (ECG).[394] In 1970, Kawasaki succeeded in obtaining funding to establish the Research Committee of Mucocutaneous Lymph Node Syndrome, sponsored by the Japanese Ministry of Health and Welfare, which was organized with Dr. Fumio Kosaki as chair.[162] In the first national survey of this committee, four autopsied and six non-autopsied cases of children who had died of coronary artery complications after having apparent Kawasaki disease were identified.[175] These children were predominantly younger than 2 years of age and had died suddenly within 30 days of onset of disease, with evidence of coronary aneurysms and acute thrombosis. The first biennial national epidemiologic survey was conducted by this committee in 1970 under the leadership of Dr. I. Shigematsu and was published in 1972.[317] By this time, it had become well established that some patients who recovered apparently uneventfully from this acute illness were at risk for sudden cardiac death, with findings of acute myocardial infarction secondary to thrombosis within coronary arteries damaged by a severe vasculitic process.[175]

In 1971, physicians at the University of Hawaii who were unaware of the Japanese experience began to recognize patients with an unusual Reiter syndrome–like illness. When information about Kawasaki disease was published in the English-language literature,[162] the illness in Hawaii was recognized clearly as Kawasaki disease. Information exchanged between Japanese and U.S. investigators led to the 1974 publication of English-language articles by both groups[162,221,222] and triggered worldwide recognition of cases. In the early 1970s, death from myocardial infarction was reported to occur in approximately 2 percent of cases of Kawasaki disease; more recent data reflect much lower mortality rates of less than 0.1 percent.[120,241,400] With the availability of echocardiography in the late 1970s, researchers determined that 20 to 25 percent of patients will develop evidence of coronary artery abnormalities.[147]

In the decades before Kawasaki recognized the clinical features of the illness, many individual reports of fatal coronary arteritis in children (usually labeled IPAN) were published in the non-Japanese pediatric and pathology literature.[54,77,234,271,283,290] Clinical details of these cases generally are highly suggestive of Kawasaki disease, and the pathologic features of IPAN are indistinguishable from those of Kawasaki disease, as demonstrated

TABLE 88–1 Diagnostic Criteria for Kawasaki Disease

Fever for at least 5 days*
PLUS
Presence of four of the following features:
Bilateral conjunctival injection
Polymorphous exanthem
Changes in the lips and oral cavity (erythema, cracking of lips; oropharyngeal erythema; strawberry tongue)
Peripheral extremity changes (erythema and swelling of hands and feet; later periungual desquamation, Beau lines)
Cervical lymphadenopathy (≥1.5 cm in diameter)
Exclusion of other diseases with similar features

Note: The finding of fever plus three criteria in the presence of coronary abnormalities qualifies.

**In the presence of classic features, experienced clinicians may be able to establish the diagnosis before the fifth day of illness.*

conclusively by Landing and Larson in 1977.[184] Almost 100 years before Kawasaki's description was published, Samuel Gee of St. Bartholomew's Hospital in London in 1871 reported the case of a 7-year-old boy who at death ("following scarlatinal dropsy") had three coronary aneurysms, each filled with a fresh clot; histologic examination of that patient's cardiac tissue is compatible with inactive Kawasaki disease with extensive coronary myointimal proliferation and fibrosis.[103,327] Shibuya and colleagues identified cases of illnesses compatible with Kawasaki disease that occurred in Japan up to 2 decades before Kawasaki's description was published.[316] Likely, patients with Kawasaki disease in previous decades were misdiagnosed as having measles, scarlet fever, rubella, or other once common conditions, and reductions in the numbers of cases of those illnesses helped to facilitate recognition of Kawasaki disease.[161]

Kawasaki's clinical description of the syndrome has remained the foundation of diagnosis and the basis of the clinical and epidemiologic case definitions in use today (see Table 88–1). The American Heart Association Committee on Rheumatic Fever, Bacterial Endocarditis, and Kawasaki disease published guidelines for the management of patients with incomplete (or atypical) Kawasaki disease (see later).[252]

EPIDEMIOLOGY

SOURCES OF EPIDEMIOLOGIC DATA

As with most notifiable diseases, passive reporting of Kawasaki disease cases is incomplete. Passive surveillance data may help to monitor secular trends and to identify epidemics, but these data are of little value in estimating the incidence of disease. Outbreak investigations are more sensitive in determining local disease incidence, and they enable investigators to study potential risk factors.

In the absence of a confirmatory diagnostic test, the epidemiologic case definitions of Kawasaki disease are strict and exclude from surveillance data other exanthematous conditions that could dilute "true" cases and thus could obscure secular trends. However, the original epidemiologic case definitions were not intended for clinical application, a very important point since effective treatment became available. Thus, less strict application of clinical case criteria is appropriate for management of patients. Clinicians must be aware that children often present with clinical illnesses that do not completely fulfill the diagnostic criteria for Kawasaki disease but who are nonetheless at risk for having coronary artery sequelae and therefore warrant therapy. These patients generally are considered to have *incomplete* or *atypical* Kawasaki disease.[28,91,252,299] Incomplete presentations of Kawasaki disease are particularly common occurrences in young infants in whom clinical signs often are subtle or fleeting but who are at the highest risk for development of coronary artery abnormalities.[40,293] In the United States, the Centers for Disease Control and Prevention (CDC) case definition usually is used for epidemiologic purposes, and the American Heart Association published an algorithm to aid in the diagnosis of incomplete (atypical) Kawasaki disease.[252] The current Japanese diagnostic guidelines were revised for the fifth time and also reflect the importance of incomplete cases.[16]

INCIDENCE RATES

The incidence of Kawasaki disease varies throughout the world and reflects primarily the racial composition of various countries. Rates in Japan have climbed steadily, with an annual rate of 151 per 100,000 children younger than 5 years of age in 2002 (17th National Survey)[400] and as high as 175 per 100,000 children younger than 5 years.[34] In countries with predominantly white populations, the rate is approximately 15 per 100,000 children younger than 5 years of age.[128]

GENDER

In virtually all population-based studies in many countries, the ratio of male to female patients with Kawasaki disease approximates 1.5 : 1.[400,402] In addition, serious and fatal complications also are significantly more common findings among male patients with Kawasaki disease compared with female patients.[241,401] Examination of fatal Japanese cases indicated almost three times as many Kawasaki-related fatalities among male patients compared with female patients, with a higher ratio in infancy.[241] The basis for the preponderance of Kawasaki disease in male patients and for the even greater predominance of serious coronary artery disease in male patients with Kawasaki disease remains unclear. Of interest is that a male predominance is observed in many infectious diseases.

RACE OR ETHNIC BACKGROUND

The first cases of Kawasaki disease were recognized in Japanese children and in Hawaiian children of predominantly Japanese ethnicity, and subsequent data consistently supported higher rates in those of Asian background. Annual incidence rates in Japan have climbed steadily to more than 150 cases per 100,000 children younger than 5 years of age,[400] from 102.6 in 1995 and 108 in 1996, reaching 184.6 in 2005-2006,[243a] and are among the highest in the world, exceeded only by rates for Japanese-American children in Hawaii (≈197/100,000 <5 years).[129] In epidemic years in Japan, the annual age-specific incidence rates have reached or exceeded 200 per 100,000 children younger than 5 years of age.[396] Incidence rates in white children in many communities are much lower, most often approximating 10 to 15 per 100,000 children younger than 5 years.[60,128,329] Surveys in countries with almost exclusively white populations often yield rates of 5 to 10 cases per 100,000 children younger than 5 years of age.[29,32,45,121,276,333] In Washington state, ethnic group–specific incidence rates per 100,000 children younger than 5 years of age were estimated to be 33.3 for Asian Americans, 23.4 for blacks, and 12.7 for whites.[60] In Hawaii, with its complex racial-ethnic make-up, data showed the overall annual incidence to be 45 per 100,000 children younger than 5 years of age.[129] The yearly incidence for Japanese children in Hawaii approaches 200 cases per 100,000 children, and for whites it is 35 per 100,000, with intermediate rates for those of native Hawaiian and Chinese, Filipino, and other Asian ancestry.[129] In New Zealand, differences in incidence between white and Polynesian children were not

apparent,[104] but in Singapore, a higher rate of Kawasaki disease in Chinese children compared with Malay children was suggested.[253] Extrapolation of data from surveys of U.S. hospitals with large children's services led to estimates of approximately 2500 cases per year in the United States from 1984 to 1993,[364,365] with other estimates as high as 5000 cases annually.[34] A study of Kawasaki disease in the United States identified approximately 4200 hospitalizations in the year 2000, with highest rates among Asian and Pacific Islanders, lowest in whites, and intermediate in blacks and Hispanics.[128] Recent data from Japan indicated that a steady increase to more than 10,000 patients with Kawasaki disease diagnosed yearly has occurred,[243a] with occasional local clusters rather than the nationwide outbreaks as seen in 1979, 1982, and 1985 to 1986.[400]

The higher rates of Kawasaki disease in those of Japanese and some other Asian backgrounds suggest a genetic rather than an environmental basis, as supported by increased rates among third- and fourth-generation immigrants from Japan to Hawaii.[129] The increased incidence of Kawasaki disease among siblings and parents of patients (see later) also supports a genetic predisposition.[383,399] The genetic basis is complex in that no single human leukocyte antigen (HLA) is common to most patients with Kawasaki disease. Early reports that Kawasaki disease was associated with HLA-Bw 22 (or subtype Bw 54)[157,177,217] were not confirmed by subsequent studies in Japan, Hong Kong, or Boston, where HLA-Bw 51 and HLA-B 44 were found to be more common.[46,178] HLA-Bw 51 also was increased in a series of Israeli patients.[164] A small Maryland study suggested that the A2 B44 Cw5 haplotype was a risk factor for epidemic Kawasaki disease.[146] Studies of HLA major histocompatibility complex (MHC) class II genes have detected no clear association.[19,81] Immunoglobulin allotypic markers were studied as possible genetic markers for Kawasaki disease.[330] The kappa chain allotype Km1, which is very common in Asian populations, and the combination of Km1 with Gm heterozygosity were present in significantly greater proportions of white patients with Kawasaki disease than in the control white population. In addition, the haplotype G1m(a), G3m(t) was found significantly more often in Japanese and Japanese-American patients with Kawasaki compared with race-matched control populations. This study supports a complex genetic basis for susceptibility to Kawasaki disease.[330] Susceptibility has been linked to other allelic variations in small studies, but larger and more definitive studies are in progress.[35] Transmission disequilibrium studies involving children with Kawasaki disease and their parents may provide better insights into the genetic basis of susceptibility, with functional polymorphisms in the inositol triphosphate kinase-3 gene[268a] and in a network of gene single nucleotide polymorphisms.[32a]

AGE

Kawasaki disease occurs almost exclusively in children. In the United States and Japan, adult cases are quite rare, although some reports of adults diagnosed by accepted diagnostic criteria have been published.* Many of these adult patients have been infected with human immunodeficiency virus (HIV).[141] Many of the early reported adult cases, however, appear to have been associated with toxic shock syndrome or drug hypersensitivity reactions. Perhaps the best-documented adult case was that of a 31-year-old Japanese man (confirmed by Dr. Kawasaki) who later developed bilateral coronary artery aneurysms.[343] Because the signs and symptoms are nonspecific, adults suspected to have Kawasaki disease should be evaluated carefully for infectious, toxic, and other possible causes of illness.

The distribution of Kawasaki disease by age in childhood is characteristic. The disease occurs most frequently in young children: 50 percent are younger than 2 years of age, 80 percent are younger than 5 years of age, and cases seldom occur in those older than 12 years of age.[128,336,400] Infants in the first 3 to 6 months of life have a low incidence of Kawasaki disease, but the incidence rises rapidly from that point. In the United States, the peak age is approximately 15-18 months, whereas more recent data from Japan identified 26 percent as younger than 1 year old, 89 percent as younger than 5 years, and the peak age incidence as 9 to 11 months of age.[400] In Hawaii, 29 percent of cases are in children younger than 1 year old, and 85 percent of patients are younger than 5 years.[129] The lower peak age in Japan and perhaps in Hawaii may reflect better recognition of Kawasaki disease in infants, in whom Kawasaki disease may be more difficult to diagnose, or it may indicate a biologic difference. The age-incidence curve may be helpful in elucidating risk factors for developing Kawasaki disease. Such a pattern is compatible with highly transmissible infectious agents, particularly respiratory agents, and suggests possible transplacental immunity. The features of 28 patients with Kawasaki disease who were aged 8 years and older at the time of diagnosis at our Chicago institution were reported.[336] Delays in establishing the diagnosis and in providing treatment were common occurrences and were at least partially related to the prominence of arthritic and gastrointestinal symptoms in this population. We recently cared for a 19-year-old woman with classic Kawasaki disease.

Japanese mortality data suggest that fatality rates are approximately three times higher in children younger than 1 year old at the time of onset of disease, compared with older children, and that fatalities occur predominantly in the first several months after onset of Kawasaki disease.[399] The overall mortality rate in Japan has dropped from the initial report of approximately 2 percent to more recent Japanese estimates of approximately 0.08 percent.[399] Male patients account for a disproportionate number of deaths in infants and older children.[120,243,399] Long-term mortality rates in a large Japanese Kawasaki disease cohort study were increased over background rates, particularly during and shortly after the acute stage of illness.[241,243]

RECURRENT KAWASAKI DISEASE

A recurrence of Kawasaki disease is defined generally as a new episode of illness meeting clinical criteria for Kawasaki disease that begins at least 3 months after the initial episode and after inflammatory markers such as the erythrocyte sedimentation rate or serum C-reactive protein level have normalized. The frequency of recurrences after first cases of Kawasaki disease in Japan was estimated to be approximately 1.9 percent during a 3-year follow-up period, with approximately 0.07 percent of patients experiencing a third episode.[240] This corresponds to a rate of 5.21 per 1000 person-years for one or more recurrences.[240] With longer follow-up, recurrence rates in Japan may approach 3 percent.[401] Data from the United States suggest a recurrence rate of approximately 2 percent.[23] Recurrences occur most frequently within the first 2 years after the initial episode, especially in male patients and in children who have their initial episode before reaching their second birthday.[240] The frequency of recurrences in Chicago appears to be approximately 1 percent, although recurrences were documented in about 2 percent of Hawaiian cases from 1996 to 2000,[129] a finding possibly reflecting a racial difference. The true recurrence rate will be determined only when a specific diagnostic test becomes available for Kawasaki disease and thus minimizes recognition bias.

FAMILY CASES

Simultaneous or sequential cases of Kawasaki disease in siblings, twins, or other family contacts also have been reported,

*See references 12, 42, 44, 76, 109, 141, 191, 226, 278, 282, 313.

particularly during outbreaks in Japan.[86,132,215,402] Japanese epidemiologists have documented secondary sibling cases in approximately 1 percent of cases, a rate that is approximately 10 times greater than that in the general child population.[86] However, such figures are difficult to interpret because they may be influenced by recognition and reporting biases. Sibling cases are reported to occur more frequently in twins than in non-twins. Only three sibling pairs were recognized in approximately 1300 Chicago patients, and none were reported in 400 children in Los Angeles.[213] A report from two U.S. medical centers noted 18 families with multiple affected Kawasaki disease patients, including 9 families with 2 affected siblings and 9 with Kawasaki disease in 2 generations or in multiple affected members.[64]

EPIDEMICS AND OUTBREAKS

Japanese investigators noted large nationwide outbreaks of Kawasaki disease in 1979, 1982, and 1985 to 1986, with wavelike spread occurring from one prefecture (state) to the next, suggesting an infectious origin.[242,395,397] The 1982 Japanese epidemic started simultaneously in four areas and spread outward from each region, similar to the way that epidemic influenza spreads in Europe and America.[242,395] In the 1985 to 1986 Japanese epidemic, investigators identified epidemic "waves" that spread outward from an initial focus in the Tokyo metropolitan area and extended simultaneously northward and southward to involve most of the country within approximately 4 months.[242,395,397] A similar but less distinctive pattern of interprefectural progression in waves was noted in the 1982 Japanese epidemic. Within the northern Tohoku District, for example, Kawasaki disease spread from prefecture to prefecture over a period of approximately 7 months.[395] Korean epidemics were detected 7 and 15 months after the Japanese epidemics of 1979 and 1985 to 1986, respectively.[190,395] More localized outbreaks also have been observed. In the United States and elsewhere, community-wide outbreaks have been documented beginning in 1977.[24] Investigation of outbreaks provides opportunities to study potential risk and etiologic factors. Clustering of cases within families, schools, or neighborhoods is quite unusual, even during large-scale epidemics. Japanese investigators have associated epidemics with a significantly increased likelihood of second cases occurring in families, fatalities, and recurrent cases, but the implications of these findings are uncertain. It is striking that since 1986 no further nationwide Japanese outbreaks have been identified, a finding suggesting that the epidemiology of Kawasaki disease may have changed.[399,404]

GEOGRAPHY

Kawasaki disease has been diagnosed throughout the United States and Japan and in virtually all developed and many developing countries on all continents, including temperate and tropical zones.[32,45,78,210,279,305,307,374] No striking rural-urban differences have been noted. Elevation, longitude, and latitude have not been implicated. Travel histories of patients are unremarkable, although an anecdotal report of a 7-month-old infant in Australia documented Kawasaki disease onset 17 days after leaving Japan during that country's 1982 epidemic.[333]

SEASONALITY

In Japan, Kawasaki disease occurs year round but is most prevalent in the winter and spring, with peaks usually occurring in December or January, with a lower peak in June, and the lowest number of cases in October.[36,398,401] In the United States and other temperate areas, the number of cases peaks in the winter and early spring and is least in late summer; nonetheless, cases occur throughout the year.[25,128,213,284] Winter predominance has been observed in at least some Southern Hemisphere countries. That sporadic cases are recognized year round is somewhat different from the pattern usually observed with highly transmissible respiratory viral diseases, incidences of which peak sharply in the winter and spring (e.g., measles, rubella, influenza).

COMMUNICABILITY

Although little direct evidence exists that Kawasaki disease is transmissible from person to person, considerable circumstantial evidence supports an infectious origin. Secondary or co-primary cases in families occur but are not common. Several outbreak investigations found a higher rate of antecedent respiratory tract illness in patients with Kawasaki disease compared with matched controls.[24,375] This finding is of particular interest in view of the finding that immunoglobulin A (IgA) plasma cells infiltrate the proximal respiratory tract in fatal cases of Kawasaki disease, and it supports a respiratory mode of spread of an inciting agent (see later).[300] A history of previous exposure of children with Kawasaki disease to food or objects from Japan or elsewhere in Asia is a common factor, but the ubiquity of such exposures renders interpreting the data difficult. Japanese family data suggest that sibling cases cluster either on the same day as the index case or 7 days later.[86] Because these results are based on questionnaire data, however, the possibility of ascertainment bias is great; thus, determining the degree to which Japanese familial cases represent co-primary or secondary cases is difficult.

OTHER RISK FACTORS

In addition to demographic risk factors for Kawasaki disease, specific exposures that could be related to an etiologic agent have been linked to the disorder by some epidemiologic investigations. As noted earlier, a history of more frequent recent antecedent respiratory illnesses in cases compared with controls was documented in the early 1980s.[24] Because many viral agents are prevalent in the winter and spring, when Kawasaki disease is most prevalent, "background" isolation of various viruses from patients and from matched controls is expected.

Other past Kawasaki disease associations include exposure to recent carpet cleaning or shampooing, exposure to house dust mites, and residence near bodies of water. The association of Kawasaki disease with exposure to recently cleaned or shampooed carpets was observed in some reports,[27,79,110,131,264,275,284,286] but not in others.[59,209,230,284,291,292,366] In three carpet shampoo-associated clusters investigated by the CDC, the exposures clustered significantly in the 2- to 4-week interval before onset of disease, with few exposures in the 2-week interval immediately preceding the onset. The significance of a possible association with shampoo is unclear, because it is absent entirely in many well-studied outbreaks, and carpets are relatively uncommon in Japan.[59,230] Conceivably, rug shampooing could lead to aerosolization of a microbial or sensitizing agent present in the carpet, such as mites or microbial agents. A possible link between Kawasaki disease and house dust mites (chiefly *Dermatophagoides farinae* and *D. pteronyssinus*), initially proposed as an allergic hypothesis,[100] gained support when the presence of mites and mite antigens in carpets was realized. A Japanese group reported *Rickettsia*-like bodies in the digestive systems of mites in house dust of patients with Kawasaki disease.[115] Other investigators suggested that Kawasaki disease could result from an infectious agent in dust mites.[85] However, counts of dust mites were not significantly different in the houses of case and control patients,[110,135] and no

evidence of increased anti-mite IgE, IgG, or antibodies to *D. pteronyssinus* was found in patients with Kawasaki disease.[110,142]

In a small number of outbreaks, CDC investigators found that patients with Kawasaki disease lived closer to "bodies of water" compared with control patients.[286,287] However, other studies, including one in Washington State, did not find living in proximity to water to be a risk factor.[60]

ETIOLOGY

The origin of Kawasaki disease remains unknown. However, clinical and epidemiologic features strongly suggest that the disease has an infectious cause. A self-limited, generally nonrecurring illness manifested by fever, rash, enanthem, conjunctival injection, and cervical adenitis fits well with an infectious cause. The epidemiologic features noted earlier, including the age distribution (Fig. 88–1), the winterspring seasonality, the occurrence of community outbreaks with wavelike geographic spread, and apparent epidemic cycles, resemble those of a transmissible disease of childhood. The laboratory features, including leukocytosis with a "left shift," elevated acute-phase reactants, and pyuria, also suggest infection. Vasculitis with inflammatory cell infiltration (including IgA plasma cells)[300] may be infectious or may represent an immune reaction to infection. A very attractive hypothesis is that Kawasaki disease is caused by a ubiquitous infectious agent that produces clinically apparent disease only in selected, genetically predisposed individuals, particularly Asians. Its rarity in the first few months of life and in older children and adults suggests an agent to which virtually all adults are immune and from which very young infants are protected by passive maternal antibody. Consistent with this hypothesis is the paucity of evidence of person-to-person spread of Kawasaki disease, because most infections would be asymptomatic, and only a very few of those infected would develop clinical features of Kawasaki disease. This would be analogous to acute poliomyelitis, the relatively uncommon complication of poliovirus infection that occurs in only approximately 1 in 200 of those infected. However, efforts to identify an infectious agent of Kawasaki disease using conventional bacterial and viral culture and serologic methods, as well as inoculation of primates, mice, and guinea pigs, have failed to yield an infectious cause.[326]

Two major theories to explain the etiology of Kawasaki disease have gained prominence in the past decade: the specific respiratory pathogen theory[295] and the superantigen theory.[201] A very long list of microorganisms, including bacteria, leptospires, spirochetes, fungi, chlamydia, rickettsiae, and viruses, have been suggested at one time or another to cause Kawasaki disease, without confirmation.[303] Chlamydial studies eliminated this possibility.[116,314,337] The hypothesis that Kawasaki disease may be

Figure 88–1 Evaluation of suspected incomplete Kawasaki disease (KD). *1*, In the absence of a gold standard for diagnosis, this algorithm cannot be evidence based but rather represents the informed opinion of the expert committee. Consultation with an expert should be sought anytime assistance is needed. *2*, Infants up to 6 months old on day 7 or later of fever without any other explanation should undergo laboratory testing and, if evidence of systemic inflammation is found, an echocardiogram, even if the infants have no clinical criteria. *3*, Patient characteristics suggesting Kawasaki disease are listed in Table 88–1. Characteristics suggesting disease other than Kawasaki disease include exudative conjunctivitis, exudative pharyngitis, discrete intraoral lesions, bullous or vesicular rash, or generalized adenopathy. Consider alternative diagnoses (see Table 88–2). *4*, Supplemental laboratory criteria include albumin less than or equal to 3.0 g/dL, anemia for age, elevation of alanine aminotransferase, platelets after 7 day 450,000/mm^{3}or greater, white blood cell count 15,000/mm^3 or higher, and urine with 10 or more white blood cells/high-power field. *5*, The patient can be treated before an echocardiogram is performed. *6*, Echocardiogram is considered positive for purposes of this algorithm if any of three conditions are met: Z score of left anterior descending (LAD) or right coronary artery (RCA) 2.5 or greater, coronary arteries meet Japanese Ministry of Health criteria for aneurysms, or ≥3 other suggestive features exist, including perivascular brightness, lack of tapering, decreased left ventricular function, mitral regurgitation, pericardial effusion, or Z scores in LAD or RCA of 2 to 2.5. 7. If the echocardiogram is positive, treatment should be given to children within 10 days of fever onset and to those beyond day 10 with clinical and laboratory signs (C-reactive protein [CRP], erythrocyte sedimentation rate [ESR]) of ongoing inflammation. *8*, Typical peeling begins under nail bed of fingers and then toes. See the text for further details. f/u, follow-up. *(Newburger, J. W., Takahashi, M., Gerber, M. A., et al.: Diagnosis, treatment, and long-term management of Kawasaki disease. (American Heart Association Scientific Statement). Circulation* 110*:2747-2771, 2004.)*

caused by *Rickettsia*-like agents also seems very unlikely.[143] *Yersinia*, particularly *Yersinia pseudotuberculosis*, causes a systemic illness resembling Kawasaki disease in selected areas of Japan,[50,188,310] but convincing evidence of an etiologic link between *Yersinia* and Kawasaki disease is lacking, despite the use of newer molecular tools.[357]

That Kawasaki disease may be caused by a novel retrovirus was suggested when two groups reported reverse transcriptase activity in cultured peripheral blood mononuclear cells from patients with acute Kawasaki disease.[37,325] Other studies failed to confirm this finding.[223,268] Serologic studies for the retroviruses HIV-1, human T-cell lymphotropic virus types I and II, simian immunodeficiency virus, and feline T-cell lymphotrophic virus have been negative,[254,268,285,301] although features resembling Kawasaki disease have been described in adults with HIV infection.[141]

The hypothesis that Kawasaki disease may be the result of a bacterial superantigenic toxin was suggested because of possible selective expansion of $V\beta_2$ and $V\beta_8$ T-cell receptor families among circulating mononuclear cells.[1] Superantigens such as bacterial toxins bind to MHC class II molecules on monocytes and B cells and to the T-cell receptor, with resultant activation of large numbers of immunoreactive cells with release of inflammatory cytokines. Superantigens potentially cause expansion of autoreactive T cells.[123,176] Features of immune cell activation characterize the acute phase of Kawasaki disease. Toxic shock syndrome and Kawasaki disease share the features of fever, rash, conjunctival infection, and convalescent desquamation to some degree, but differences are present, such as the rarity of hypotension in Kawasaki disease and the absence of maculopapular or erythema multiforme–like rashes in toxic shock syndrome.[117,277] Although one group of investigators reported selective expansion of the $V\beta_2$ and $V\beta_8$ T-cell receptor families in acute Kawasaki disease,[1,2,56] this finding was not confirmed by others.[3,256,280,376] Although 11 of 16 studied patients with Kawasaki disease and only 1 of 15 controls were colonized with toxic shock syndrome toxin I (TSST-I)–producing staphylococci,[201] *Staphylococcus aureus* colonization rates, including by TSST-I–producing staphylococci, were not significantly different among patients with Kawasaki disease and controls in other studies.[202,211,370] That most studies failed to show *any* disturbance of Vβ T-cell receptor expression in Kawasaki disease substantially challenges the superantigen hypothesis.[61]

More recent work indicated that the immune response in Kawasaki disease is oligoclonal (antigen driven, i.e., a response to a conventional antigen) rather than polyclonal (as typically found in superantigen-driven responses), with both B-cell and T-cell oligoclonality demonstrated.[51,302] In a series of studies, Rowley and colleagues[298,300] demonstrated that IgA plasma cells infiltrate peribronchial, coronary arterial, and other tissues in patients who have died of Kawasaki disease in the acute stage and that the IgA plasma cells are oligoclonal,[302] findings strongly suggesting an immune response driven by a conventional agent. Using the techniques of modern molecular biology, Rowley and colleagues[295] synthesized oligoclonal antibodies from the IgA genes from a fatal acute-stage case of Kawasaki disease and identified an antigen in acute Kawasaki disease (but not control) bronchial epithelial cells and in a subset of macrophages in inflamed acute Kawasaki disease tissues, including coronary arteries. This antigen was localized to distinctive perinuclear, primarily apical, intracytoplasmic "spheroidal bodies" in acute Kawasaki disease ciliated bronchial epithelium. Light microscopic and transmission electron microscopic studies showed that the bodies are homogeneous electron-dense perinuclear inclusion bodies up to 1.4 μg in diameter that contain both protein and RNA and are consistent with aggregates of viral proteins and RNA, possibly related to the etiologic agent of Kawasaki disease.[296] The specific agent is still under very active investigation.

Reports of an association between a novel human coronavirus (dubbed HCoV-NH but later shown to be HCoV-NL63) appeared in 2005,[75] thus raising the possibility that this virus could be the agent observed by Rowley and colleagues noted earlier. However, several additional studies from four countries were unable to confirm any relationship between Kawasaki disease and this agent,[22,47,67,72,318] and Rowley's synthetic antibodies do not bind to HCoV-NL63.

Researchers have suggested that Kawasaki disease may be an immunologic response triggered by any of several different microbial agents. Consistent with this hypothesis is documented infection by different microorganisms in different individual cases, failure to detect a single microbiologic or environmental agent after 4 decades of study, and analogies to other multifactorial syndromes (e.g., aseptic meningitis). However, this hypothesis is difficult to reconcile with the distinctive clinical and laboratory pictures of Kawasaki disease, with its epidemiologic features such as epidemics and wavelike geographic spread, and with the studies of Rowley and colleagues.[295,296]

Efforts to associate Kawasaki disease with exposure to drugs[130] or to such environmental pollutants as toxins, pesticides, chemicals, and heavy metals have failed. However, clinical similarities between Kawasaki disease and acrodynia (mercury poisoning) are notable.[15,269]

Clearly, conventional culture and serologic methodologies have failed to yield the causative agent of Kawasaki disease. In addition, establishing the diagnosis can be difficult, particularly in young infants and in those with incomplete or atypical presentations.[28,40,299] A useful diagnostic test probably cannot be developed unless it is based on the etiologic agent, and more specific therapy and preventive efforts also await discovery of the cause of this disease. The hope is that the use of modern molecular biology techniques[295,296,298,302,324] will finally clarify the origin of Kawasaki disease, as well as provide insights into the mechanisms of disease pathogenesis.

PATHOLOGY AND PATHOGENESIS

RELATIONSHIP WITH INFANTILE PERIARTERITIS NODOSA

When the first Japanese survey in 1970 yielded reports of 10 deaths, the pathologic diagnosis was IPAN.[139,163,175] Japanese and Western investigators quickly recognized the pathologic similarities between fatal Kawasaki disease and IPAN, long known to have an unusual predilection for the coronary arteries.[4,20,21,359-362] In the most definitive study, Landing and Larson[184,189] showed clearly that IPAN and fatal Kawasaki disease were indistinguishable pathologically. Published case reports of autopsies of children with IPAN frequently contain clinical histories that include many or all features of acute Kawasaki disease and the development of severe vasculitis affecting primarily the coronary arteries.[290] The failure of some reported patients with IPAN to meet Kawasaki disease case criteria applied retrospectively is likely related to documentation bias and to the young age of many of the patients. Young infants with Kawasaki disease are less likely to have a classic presentation than are older children (see later). When pathologic and clinical criteria are combined, the two diseases appear indistinguishable. Adult-type PAN was described first in 1866 by Kussmaul and Maier,[183] and it differs from IPAN primarily by the presence of hypertension and involvement of small and medium muscular arteries, especially in the lung, kidney, and intestines.[88,184,361,362] An early recorded case of possible IPAN dates from 1899.[180] In 1959, Munro-Faure[234] very clearly delineated a syndrome of infantile necrotizing arteritis with coronary artery involvement, fever, rash, conjunctival and pharyngeal infection, and cervical adenitis, distinct from classic PAN. Roberts and Fetterman[290] and others expanded on these

observations to define a distinct clinical-pathologic syndrome of IPAN shortly before Kawasaki recognized the clinical syndrome.[159,160]

Coronary artery aneurysms were described as early as the early 19th century, with a male-to-female ratio of roughly 3:1, including a male preponderance in childhood cases. Childhood death from multiple coronary artery aneurysms was known to occur at least as early as 1871, as reported by Samuel Gee.[103] The cardiac specimen from this case, formalin fixed for more than 120 years in the pathology museum at St. Bartholomew's Hospital, London, recently was sectioned and examined histologically. We found that the coronary arteries showed the characteristic histologic findings of inactive Kawasaki disease and IPAN.[327] Whether these early cases with childhood coronary artery aneurysms truly represented early examples of Kawasaki disease is not certain; details of the clinical histories usually were scant.[103,283] What is clear, however, is that most of these cases greatly resemble (and very likely do, in fact, represent) Kawasaki disease.[54,77,234,283] From the features of many such early case reports, a reasonably accurate picture of Kawasaki disease as recognized today emerges. It is highly likely that in the decades before the introduction of the measles vaccine in the 1960s, cases of Kawasaki disease were misdiagnosed as measles, scarlet fever, drug hypersensitivity, or other common conditions.

PATHOLOGIC FEATURES OF KAWASAKI DISEASE

Cardiac death in Kawasaki disease generally occurs in the subacute or convalescent stages of illness.[241,243] Autopsy findings usually reveal evidence of active or inactive vasculitis, which is most severe in the medium-sized arteries, with a marked predilection for the coronary arteries.[8,9,87,184,353,361,362] Small arterioles, larger arteries, capillaries, and veins also are affected to a lesser extent.[9,88] In more than 80 percent of fatal cases in the acute stage, the immediate cause of death is acute thrombosis of inflamed coronary arteries, with resultant myocardial infarction. In a few early deaths, pancarditis with inflammation of the atrioventricular conduction system apparently caused a fatal arrhythmia or intractable congestive heart failure, whereas small numbers of other deaths may have been associated with acute coronary rupture, usually within a few weeks of the onset of illness. Deaths that occur months to years after the acute episode of Kawasaki disease often are secondary to coronary stenosis, with or without thrombosis with myocardial ischemia, or, very rarely, to rupture of a coronary aneurysm. In some patients with coronary artery abnormalities (usually patients with quite severe coronary disease), aneurysms of other major medium-sized arteries, including the brachial, renal, and iliac arteries, also may be present. Although phlebitis may be found, vascular inflammation more typically and more severely affects medium-sized musculoelastic arteries in their extraparenchymal portions. In the acute stage of Kawasaki disease, systemic inflammatory changes also are evident in many other organs, including myocardium, pericardium, cardiac valves, cerebrospinal fluid, lung, lymph nodes, pancreas, spleen, joints, and liver.[10,88]

In the early stages of the vasculitis of Kawasaki disease, edema of endothelial cells with nuclear degeneration and mild adventitial inflammation are seen.[8,87,359] Mononuclear cells predominate even in the acute stage of Kawasaki disease, and neutrophils also are prominent in the first 10 days after onset.[354] In more severely involved vessels such as the coronary arteries, panvasculitis is present, with inflammation of the endothelium, the media with edema and necrosis of smooth muscle cells, and the adventitia. Fragmentation and destruction of elastin and collagen fibers and the internal and external elastic laminae are seen in severely affected vessels.[8] These changes eventually obscure the various layers of the wall. Structural integrity may be lost, resulting in an aneurysm. In larger arteries with vasa vasorum, inflammation is seen in and around these vessels.[8]

Within 1 to 2 months after the onset of Kawasaki disease, inflammatory cells disappear, and fibrous connective tissue, collagen and elastic fibers begin to form within the vessel wall. The intima proliferates and thickens. In time, the vessel wall may become stenotic, and occlusion by stenosis or by superimposed thrombus can result. Calcification may occur, and intraluminal thrombus may become organized, remodeled, and recanalized.[8,245,309,349,350] Several groups investigated the mechanisms of vascular remodeling in Kawasaki disease. Suzuki and colleagues[351] showed by immunohistochemistry that active remodeling continues for at least several years after the onset of Kawasaki disease, with luxuriant intimal proliferation and neoangiogenesis. Extensive expression of vascular growth factors, including vascular endothelial growth factor (VEGF) within smooth muscle cells, was evident particularly in newly formed microvessels in the intima.[351] Gavin and colleagues[102] showed the prominence of matrix metalloproteinases in this process, particularly within the intima and media. Suzuki and associates[352] found evidence of inflammatory changes in the intact coronary artery of a child who died 13 months after having Kawasaki disease and who had no evidence of coronary artery involvement during the acute stage.

Fujiwara and associates[89,90] identified significant atrioventricular conduction system lesions in 5 of 10 autopsy specimens, with a strong correlation found between findings on the ECG, especially PQ prolongation, and acute inflammation of the atrioventricular conduction system. Severe acute changes were most pronounced at 21 to 31 days after onset. In a unique study of 201 right ventricular endomyocardial biopsies in uncomplicated acute Kawasaki disease, Yutani and associates[406,407] noted some degree of myocarditis and cellular infiltration, ranging from very mild (subclinical) to quite severe myocardial inflammation, in all 201 patients studied.

A histologic/immunochemical study examined the intercostal arteries to compare the nature and developmental processes of lesions with those of the coronary arteries.[214] Although similar lesions were seen, the lesions appeared somewhat later in the intercostal arteries.

The precise nature of the inflammatory infiltrate in the vessel wall or myocardium has been studied. Terai and colleagues[368] demonstrated helper (CD4) T cells and monocytes/macrophages in the arterial wall of one patient with fatal acute Kawasaki disease, as well as expression of class II MHC antigen (an activation marker) in coronary vascular endothelium, findings supporting the importance of immune responses in this form of vasculitis. Terai[371] also reported evidence of eosinophils in epicardial microvessel lesions in acute Kawasaki disease leading to death.

Rowley and colleagues[298] demonstrated the presence of many plasma cells of the IgA isotype in the vascular walls of patients who died in the acute stage. These investigators also showed that the IgA plasma cells are oligoclonal (i.e., they appear to be responding in an antigen-driven process)[302] and that they can be observed also in peribronchial, pancreatic, and renal tissues.[300] A predominance of CD8 cytotoxic/suppressor T cells over CD4 helper T cells in seven of eight acute-stage deaths also was observed in our laboratory by immunohistochemistry.[31] Takahashi[354] reported $CD68^+$ monocytes and macrophages to be most prominent in acute Kawasaki disease, but $CD3^+$ cells (T cells), $CD20^+$ cells (B cells), and neutrophils also were present in autopsy specimens of children who died in the first month of the illness.

Other less commonly reported pathologic findings include renal infarcts and glomerular histologic changes, possible evidence of immune complex deposition,[304] including mesangial deposition of IgM and C3, and multifocal periglomerular infiltration of lymphocytes and IgA plasma cells.[300] Changes have been

noted in other arteries, the thymus, and lymph nodes. Tanaka[359] described thymic atrophy and nondiagnostic lymph node changes at autopsy (although most patients likely had been treated with steroids). Naoe and colleagues[246] reported lymph node biopsies to show thrombotic arteriolitis, severe lymphadenitis with necrosis, and postcapillary venules with endothelial cell and reticular cell hyperplasia. Other reports described early lymph node biopsies showing multiple foci of necrosis and fibrin thrombi within the microvasculature, as well as T-zone hyperplasia, B-zone macrophage infiltration, and immunoblast proliferation.[108] Rowley and colleagues[300] identified IgA plasma cells not only in vascular and renal tissues but also in pancreatic and peribronchial locations. Miura and associates[228] found prominent macrophage infiltration of pancreatic acini and islets in 3 of 10 fatal cases.

CLINICAL MANIFESTATIONS

CLINICAL PHASES OF ILLNESS

The clinical course of Kawasaki disease can be divided into acute, subacute, and late or convalescent phases. The *acute* febrile phase begins with fever, rash, conjunctival injection, "strawberry" tongue, red swollen lips, edema and erythema of the hands and feet, lymphadenitis, and sometimes aseptic meningitis and mild hepatic dysfunction. Young children often are quite irritable. Evidence of myocarditis, rarely including congestive heart failure or arrhythmias, may develop during this time. Pericardial effusion, mitral regurgitation, or depressed myocardial function may be detected by echocardiogram. Without aspirin and IVIG treatment, the acute phase generally lasts for 8 to 30 days (mean, 11 days). After defervescence, the physical findings rapidly disappear, but during this *subacute* phase, the child may remain irritable and anorectic, with decreased activity. Some conjunctival injection may persist. Arthritis or arthralgia, mainly of larger joints, may develop in the subacute phase. Desquamation of fingers and toes, typically beginning in the periungual region, and thrombocytosis are very common manifestations during this period. The subacute phase persists until the child has returned to his or her normal state of health at approximately 3 to 6 weeks after the onset of fever, with normalization of inflammatory markers. The time of greatest risk of sudden death occurring from acute coronary artery thrombosis in patients with coronary lesions is during the subacute phase and the early convalescent phase. The *convalescent* phase begins when all clinical signs and symptoms have disappeared and inflammatory markers are normal, usually at about 6 to 8 weeks after onset.

When manifested completely, Kawasaki disease is a distinctive clinical entity with a fairly predictable course.[57,252] However, children who do not fulfill the criteria for diagnosis of Kawasaki disease, in fact, may have the illness and are at risk of developing complications, particularly coronary artery disease (see "Incomplete or Atypical Kawasaki Disease" later).[252,299] The principal clinical diagnostic criteria are presented in Table 88–1. Kawasaki disease should be considered in the differential diagnosis of infants and children with fever for at least 5 days associated with two or more of the five classic features: generalized polymorphous erythematous rash, conjunctival injection, characteristic changes of the lips and mouth, bilateral redness and swelling of the hands and feet, or unilateral nonfluctuant cervical lymph node enlargement greater than 1.5 cm.[252] All features are not necessarily present at the same time. A diagnosis of typical Kawasaki disease, according to accepted clinical criteria (see Table 88–1), is made in patients with fever and at least four of the five clinical criteria and with exclusion of other illnesses that mimic Kawasaki disease. Each of the five clinical features is present in 80 to 90 percent of patients with typical cases, except cervical lymphadenopathy, which is present in approximately 50 percent of patients. The most commonly encountered diseases to be excluded are as follows: (1) febrile exanthems, presumably viral, including measles; (2) acute streptococcal and staphylococcal infections; and (3) drug hypersensitivity reactions. Japanese diagnostic guidelines for Kawasaki disease are similar to the U.S. guidelines with rare exception; they consider fever and the other five major features to be six equal criteria and require at least five of those six criteria for diagnosis. Thus, a child could have no fever but all five other criteria and be considered a typical case by the Japanese criteria. The Japanese criteria also accept a course of fever lasting less than 5 days if it is shortened by early IVIG treatment.[16]

Certain scoring systems using clinical and laboratory features have been developed, primarily in Japan.[13,119,172,244] The goal of these systems generally has been to identify those patients with Kawasaki disease at highest risk for development of coronary abnormalities and who, therefore, would benefit most from receiving IVIG therapy, as well as those at low risk for coronary changes who could be spared IVIG treatment. This practice is decreasing in Japan because no such scoring system appears sufficiently sensitive and specific to enable selective therapy (i.e., to allow non-treatment of patients predicted to be at low risk for development of coronary abnormalities). Patients who are at greatest risk are as follows: those younger than 1 year old; male patients; those with prolonged or recurrent fever; and those with anemia, hypoalbuminemia, hyponatremia, and thrombocytopenia. Nonetheless, we recommend that all patients diagnosed with Kawasaki disease within the first 10 days after onset of disease and those diagnosed later who are still manifesting significant inflammation be treated with IVIG and aspirin.[252] Newer scoring systems have been developed to help predict those patients who are likely to be unresponsive to IVIG therapy, but confirmation is necessary.[172]

In Kawasaki disease, fever typically is high-spiking and remittent, with peak temperatures generally exceeding 39° C (102° F) and in many cases exceeding 40° C (104° F). Unless treated with aspirin or IVIG, fever persists for a mean of 11 days,[125] but it may continue for 3 to 4 weeks, rarely longer. In patients treated with 80 to 100 mg/kg/day of aspirin and a single 2 g/kg dose of IVIG, fever generally resolves within 1 to 2 days.[249]

Bilateral painless vascular infection of the bulbar conjunctivae, clearly more severe than infection of the palpebral conjunctivae and sparing the limbic region around the cornea, generally is seen in the first week of illness, usually beginning shortly after onset of fever. It generally is not associated with exudate, conjunctival edema, or corneal ulceration, thus distinguishing the eye findings of Kawasaki disease from purulent conjunctivitis and from Stevens-Johnson syndrome. Mild acute iridocyclitis or anterior uveitis, which may be noted by slit-lamp examination, resolves rapidly and only rarely is associated with photophobia or eye pain.[33,105,187,265,332] Less common ocular findings include superficial punctate keratitis, vitreous opacities, vitreous and chorioretinal inflammation, lateral rectus palsy, periorbital vasculitis, and papilledema and other optic disk changes.[11,80,137,391]

Changes of the mouth and lips consist of the following: (1) erythema, dryness, fissuring, peeling, cracking, and bleeding of the lips; (2) a strawberry tongue indistinguishable from that associated with streptococcal scarlet fever, with erythema and prominent papillae; and (3) diffuse erythema of the oropharyngeal mucosae. Oral ulcerations, pharyngeal exudates, and Koplik spots are rarely, if ever, found in Kawasaki disease and when present help to exclude the diagnosis.

Changes in the extremities are among the most distinctive features of Kawasaki disease. The hands and feet become indurated and swollen with stretched, shiny skin, sometimes with painful induration. The palms and soles become erythematous, often with an abrupt change to normal skin at the wrist and ankle. Infants and young children frequently refuse to hold objects or

to bear weight. In the subacute phase, a distinctive pattern of periungual desquamation of fingers and toes may occur from 2 weeks to 2 months after onset of Kawasaki disease in 50 to 70 percent of affected patients. Beau lines, which are transverse grooves across the nails, may appear at the nail base 1 to 2 months after a case of acute Kawasaki disease and may grow out over several months.

The erythematous rash associated with Kawasaki disease may take many forms. Most common is a nonspecific, diffuse, macular-papular, primarily truncal erythematous rash. Occasionally, diffuse scarlatiniform erythroderma, urticaria, or an erythema multiforme–like rash with target lesions develops. Vesicles and bullae are not seen, although very fine pustules occur rarely. Perineal erythema and then desquamation are quite common manifestations in diapered as well as toilet-trained children in the acute stage of illness. Rashes in Kawasaki disease tend to be most prominent on the trunk, with perineal accentuation, but they frequently also involve the face and extremities.

Cervical lymphadenopathy is the least common of the principal diagnostic criteria, but it sometimes is the dominant clinical feature along with fever.[335] It usually is unilateral and confined to the anterior cervical triangle. To fulfill diagnostic criteria, the enlarged node or mass of nodes exceeds 1.5 cm, is not fluctuant, usually is not associated with erythema of the overlying skin, and is not tender or only moderately tender. Lymphadenopathy generally is benign and transient. Clinicians should be aware that children with suspected acute cervical adenitis that is unresponsive to antibiotic therapy may have Kawasaki disease. Because other features of Kawasaki disease often are present but overlooked, Kawasaki disease should be considered in febrile children with suspected acute bacterial cervical adenitis that is unresponsive to antibiotics and without an alternate diagnosis.[335] The ultrasound appearance of lymph nodes in Kawasaki disease has been described as similar to that of acute Epstein-Barr virus (EBV) infection and distinct from bacterial adenitis.[363] The absence of changes on imaging (e.g., ultrasound or computed tomography [CT]) suggesting suppuration of such lesions should strengthen the suspicion of possible Kawasaki disease in this setting. Impressive cervical adenopathy in patients with Kawasaki disease generally resolves remarkably promptly after administration of appropriate therapy.

The associated features of Kawasaki disease reflect its multisystemic nature (Table 88–2). Sterile pyuria as a manifestation of urethritis, occasionally with meatitis, is found in approximately half of patients. Arthritis appearing during the first week of illness can be polyarticular or oligoarticular, including the small interphalangeal joints as well as large weight-bearing joints, with a prevalence of approximately 7.5 percent.[111] Arthrocentesis manifesting during this early phase yields purulent-appearing fluid, with a mean white blood cell count of 125,000 to 300,000/mm^3, normal glucose levels, and negative Gram stain and bacterial cultures. Arthritis developing after the 10th day of illness has a predilection for large weight-bearing joints, especially the knees and ankles, with a somewhat lower synovial fluid white blood cell count.[125] Gastrointestinal complaints occur in approximately one third of patients with acute cases; these complaints may be severe, leading to laparotomy, and they include nausea, abdominal pain, and some diarrhea. These findings may be related to hydropic gallbladder, pancreatitis, or appendicular vasculitis.[14,408] Obstructive jaundice and acute hydrops of the gallbladder are not uncommon findings, whereas mild to moderate elevations of serum transaminases occur in almost half of patients. Central nervous system involvement including aseptic meningitis occurs in almost half of patients.[62] Transient unilateral lower motor neuron facial nerve palsy occurs rarely,[281] as does sensorineural hearing loss.[345] Characteristic extreme irritability is very common, especially in young infants. Reactivation of inflammation at the site of a previous bacillus Calmette-Guérin (BCG) vaccination coincident with acute Kawasaki disease is a common finding in Japan, where BCG is used widely,[331] and we observed a child in whom a BCG site and purified protein derivative (PPD) test site reactivated with acute Kawasaki disease.[371a] Some patients experience a flare of atopic dermatitis or psoriasis during or after experiencing acute Kawasaki disease.[30,71] Various pulmonary manifestations of Kawasaki disease, including isolated pulmonary nodules,[84] pleural effusions, acute respiratory distress syndrome,[273] and pulmonary infiltrates,[384] all of which are interesting in view of the increased numbers of IgA plasma cells found in respiratory tract tissue, have been observed.[298,300]

TABLE 88–2 Associated Noncardiac Features of Kawasaki Disease

Musculoskeletal System
Arthritis or arthralgia
Central Nervous System
Aseptic meningitis
Facial nerve palsy
Marked irritability
Sensorineural hearing loss
Gastrointestinal System
Hydrops of gallbladder
Abdominal pain, diarrhea
Hepatic dysfunction, obstructive jaundice
Pancreatitis
Genitourinary System
Urethritis, meatitis
Respiratory System
Pulmonary infiltrates, nodules
Preceding respiratory illness
Other
Erythema and induration of bacille Calmette-Guérin vaccine site
Anterior uveitis (mild)
Peripheral gangrene (young infants)
Desquamating groin rash
Flare of atopic dermatitis or psoriasis

By far, the most important associated feature of Kawasaki disease is cardiac involvement. Cardiac manifestations can be prominent in acute Kawasaki disease, and they certainly are the major cause of long-term morbidity and mortality. In addition to the coronary artery abnormalities that develop in 20 to 25 percent of untreated children, pericardial effusion and myocarditis with congestive heart failure, tachycardia, gallop rhythm, nonspecific changes on the ECG, or arrhythmia may occur.[147,150,152,252] An imperfect correlation exists between clinically apparent cardiac involvement and echocardiographic evidence of coronary abnormalities, although in the pre-IVIG era, echocardiographic evidence of mitral regurgitation or pericardial effusion in the acute stage was shown to be predictive of subsequent coronary abnormalities.[106] Acute Kawasaki disease may involve pericardium, myocardium, endocardium, coronary arteries, and cardiac valves. Clinical and auscultatory features may include a hyperdynamic precordium, tachycardia out of proportion for the child's age and temperature, a gallop rhythm, and a flow murmur. Some infants may manifest very low cardiac output, and ECG changes (ST-segment and T-wave changes, prolonged PR interval, and arrhythmias) may be present.

INCOMPLETE OR ATYPICAL KAWASAKI DISEASE

A substantial subset of children presents with illnesses that do not completely fulfill diagnostic criteria for Kawasaki disease but that

include at least 5 days of fever and some features of the disease. Incomplete or atypical Kawasaki disease (incomplete is the preferred usage) is associated with a substantial risk for development of coronary artery aneurysms,[28,91,205,252,299] but it can be very difficult to diagnose. Incomplete Kawasaki disease occurs most frequently in young infants, who unfortunately are at greatest risk of developing coronary disease with Kawasaki disease,[40,293,299] and fatalities have occurred. The laboratory profile of incomplete cases is similar to that of classic cases, and laboratory results can increase or decrease the likelihood of the presence of Kawasaki disease in a particular patient. Echocardiographic findings in the acute stage, including perivascular brightness, coronary ectasia, decreased myocardial contractility, pericardial effusion, and mild mitral regurgitation, can support the diagnosis of Kawasaki disease. Individual manifestations of Kawasaki disease in young infants tend to be more subtle than those in older children and can be fleeting.[252,293] Kawasaki disease should be considered in the differential diagnosis of prolonged fever in infants because patients are described in whom such fevers are virtually the sole manifestation of Kawasaki disease.

A committee of the American Heart Association developed an algorithm to assist in the evaluation of patients with suspected incomplete Kawasaki disease (see Fig. 88–1), with emphasis placed on clinical assessment and measurement of acute-phase reactants (C-reactive protein [CRP], erythrocyte sedimentation rate [ESR]) in patients with 5 or more days of fever and two or three features of Kawasaki disease, or in infants 6 months old or younger with 7 days or more of fever without other explanation.[252] In addition to elevated ESR (≥40 mm/hour) and CRP (≥3.0 mg/dL), a set of six supplementary laboratory criteria that can be useful in this regard is as follows: albumin, 3.0 g/dL or less; anemia for age; increased alanine transaminase (ALT); platelets after day 7 of more than 450,000/mm^3; white blood cell counts of 15,000/mm^3 or more; and 10 or more white blood cells/high-power field in the urine.

Retrospective diagnosis of Kawasaki disease often is based on finding coronary abnormalities by echocardiogram, although the real goal is to identify patients with incomplete Kawasaki disease before detection of coronary changes. The existence of these patients again emphasizes the need to identify the etiologic agent of Kawasaki disease so that a diagnostic test can be developed. When possible, patients with illnesses suggesting incomplete Kawasaki disease should be referred to physicians with considerable experience in making the diagnosis.

LABORATORY FINDINGS

A specific diagnostic test for Kawasaki disease is not available and awaits discovery of the etiologic agent of the illness (Table 88–3). The laboratory features of Kawasaki disease, albeit quite nonspecific, are nonetheless characteristic of the illness. Leukocytosis, especially with neutrophilia, is typical in the acute stage, with a predominance of immature and mature granulocytes. White blood cell counts in excess of 30,000/mm^3 occur in approximately 5 percent of patients and in excess of 15,000/mm^3 in approximately 50 percent. Leukopenia is quite rare. Toxic granulations and Döhle bodies occasionally are seen on peripheral blood smear.[26] Anemia may develop, usually with normocytic red blood cell indices, particularly in patients with more prolonged duration of active inflammation. Severe hemolytic anemia requiring transfusions occurs but is unusual and usually can be related to IVIG therapy.[53,323] Curiously, Kawasaki's first patient in 1961 (and only rare subsequent patients) manifested Coombs-positive hemolytic anemia.[159,327]

TABLE 88–3 Laboratory Features of Kawasaki Disease

Leukocytosis with neutrophilia
Elevated erythrocyte sedimentation rate
Elevated C-reactive protein (and other acute-phase reactants)
Anemia
Thrombocytosis after week 1
Sterile pyuria
Hypoalbuminemia
Hyponatremia
Elevated serum transaminases, gamma-glutamyltransferas
Plasma lipid abnormalities
Cerebrospinal fluid pleocytosis
Synovial fluid pleocytosis

Elevation of acute-phase reactants such as ESR, CRP, and alpha$_1$-antitrypsin is nearly universal in Kawasaki disease, with the ESR usually returning to normal by 6 to 10 weeks after illness onset. CRP values rise and fall much more quickly than do ESR values. Additionally, IVIG therapy per se leads to elevation of the ESR (but not CRP) for several weeks, and, thus, it is of limited value in assessing the degree of inflammatory activity in IVIG-treated patients; CRP or other acute-phase reactants clearly are superior for this purpose.

A very characteristic feature of the later phases of illness is thrombocytosis, with platelet counts ranging from 500,000 to more than 1,000,000/mm^3. Thrombocytosis rarely is present in the first week of illness, usually appears in the second week, and peaks in the third week, with a gradual return to normal by 4 to 8 weeks after onset in uncomplicated cases. The mean peak platelet count is approximately 700,000/mm^3. In one study, infants younger than 1 year old with fever without a source who had platelet counts greater than 800,000/mm^3 were 17 times more likely to be diagnosed with Kawasaki disease ultimately than were infants with platelet counts lower than 800,000/mm^3.[255] No differences exist in chromium-65–labeled autologous platelet survival between cases and controls, and little correlation exists between thrombocytosis and increased platelet aggregation. The latter situation has been detected in patients with Kawasaki disease from a few days until a year after onset.[155,392] The rare patients with thrombocytopenia in the acute stage of Kawasaki disease, most often young patients, appear to be at increased risk for development of coronary artery disease and myocardial infarction.[257,259] The mechanism of thrombocytopenia appears to be consumptive coagulopathy.[259]

Plasma lipids are markedly perturbed in acute Kawasaki disease, with depression of plasma cholesterol, high-density lipoprotein (HDL) cholesterol, and apolipoprotein A-I (apo A-I).[43,248,308] Similar changes are observed in other conditions associated with an acute-phase response.[43] Marked appearance of serum amyloid A (SAA) protein in plasma, associated with HDL3-like lipoprotein particles, is seen acutely.[43] Cabana and colleagues [43] also showed that total cholesterol, HDL cholesterol, apoA-I, and triglyceride levels normalize over the course of several weeks, and that SAA disappears from plasma. The core composition of HDL normalizes more slowly than do plasma HDL cholesterol and apoA-I levels, a finding suggesting that Kawasaki disease has a profound effect on the lipoprotein profile acutely and a more subtle sustained effect on HDL composition.

Mild to moderate elevations in serum transaminase levels are present in as many as 40 percent of patients, and mild hyperbilirubinemia occurs in approximately 10 percent.[38] Plasma gamma-glutamyl transpeptidase levels are elevated in most patients.[372] Hypoalbuminemia and hyponatremia[386] are associated with more prolonged and more severe disease. Hypoalbuminemia appears to indicate more severe and more prolonged acute disease.[119] Urinalysis reveals intermittent mild to moderate sterile pyuria in approximately one third of patients, although suprapubic urine generally does not show pyuria, a finding suggesting urethritis.[63,221] In those children who undergo lumbar puncture,

evidence of aseptic meningitis, with a predominance of mononuclear cells, normal glucose, and normal to mildly elevated protein levels, is a common finding.[62]

Laboratory tests, even though nonspecific, can provide diagnostic support in patients with clinical features that are suggestive, but not diagnostic, of Kawasaki disease[252] and may aid in prediction of nonresponder patients.[172] A moderately to markedly elevated CRP (>3.0 mg/dL) or ESR (>40 mm/hour), almost universal in Kawasaki disease, is an uncommon finding in viral exanthems and hypersensitivity reactions. Platelet counts higher than 450,000 mm^3 usually are present in patients with Kawasaki disease after the seventh day of illness. In cases of incomplete Kawasaki disease associated with coronary abnormalities, thrombocytosis and elevated ESR are very common events in the acute stage. Clinical experience suggests that Kawasaki disease is very unlikely if platelet counts and a full panel of acute-phase inflammatory reactants (e.g., ESR, CRP) are essentially normal after the seventh day of illness.

IMMUNOLOGIC FINDINGS

Studies of children with acute Kawasaki disease reveal widespread immune perturbations[328] and have focused on immune activation, endothelial activation, and vascular infiltration with a variety of immune cells. Evidence of marked immune activation is present and is reflected by increased levels of a wide variety of pro-inflammatory cytokines, including tumor necrosis factor-α (TNF-α), interferon-γ, interleukin-1 (IL-1), IL-2, IL-4, IL-6, IL-8, IL-10, and soluble IL-2 receptor.* Increased chemokine and selectin activity also have been reported in acute Kawasaki disease.[358,389] The most intense immune activation and cytokine production occur during the acute and early subacute phases, the period of most intense vascular inflammation and of aneurysm formation. The immune perturbations subside as the illness resolves either spontaneously[197] or more promptly in response to anti-inflammatory therapy, and the benefit of therapy appears to result from immune modulating effects, although precise details are lacking.[194,321]

In acute Kawasaki disease, serum IgG levels are lower than normal for age,[251] whereas in the subacute stage, polyclonal elevation of all immunoglobulin classes generally is found.[204] Serum IgE and IgM levels particularly are frequently elevated.[179,181] The increase in serum immunoglobulins is associated with a very high proportion of circulating activated B cells,[168] which is reversed by aspirin/IVIG treatment.[196] Shingadia and colleagues[320] found decreased numbers of circulating B lymphocytes and plasma cells with surface or cytoplasmic IgA in the acute and subacute stages of Kawasaki disease, thus complementing the finding of IgA plasma cell infiltration in tissues.[298,300]

Circulating immune complexes can be detected in the subacute and convalescent (but not the acute) stages; these complexes appear to be unrelated to the development of coronary abnormalities by virtue of their time course of detection[124,204,206,212,266,270,306,387] and to be unaffected by IVGG infusions.[212] Some investigators have detected IgA in these immune complexes.[266] Most circulating IgG immune complexes in Kawasaki disease contain IgG1 and IgG3 antibodies,[206] with Fc portions that bind to monocytes and platelets. Immune complexes in Kawasaki disease may promote aggregation of platelets, with release of vasoactive factors.[206]

Several autoantibodies have been found in Kawasaki disease sera, but antinuclear antibody and rheumatoid factor are very uncommon findings. Antibodies to type III collagen have been detected,[171] but without clear relation to coronary complications. Some acute-phase sera contain IgM anti-myosin antibodies directed against epitopes that differ from those reactive with acute rheumatic fever sera, a finding suggesting a possible relationship with myocarditis in Kawasaki disease.[55] Both IgM and IgG anti-neutrophil cytoplasmic antibodies (ANCAs)[288,312,334] and anti-myeloperoxidase antibodies[288] have been reported in Kawasaki disease. Several reports have noted IgM or IgG anti-endothelial cell antibodies in Kawasaki disease, which may injure endothelial cells directly or participate in complement-mediated injury or in antibody-mediated cytotoxic reactions.[145,195,198-200] Among the endothelial cell antigens of interest are adhesion molecules such as intercellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1), E-selectin, P-selectin, and endothelin, all of which may be up-regulated in Kawasaki disease.[35,93,166,232,261] The precise role of immunologic reactions to endothelial cells in the pathogenesis of Kawasaki disease is unclear; Miura and colleagues[229] found focal but not widespread expression of VCAM-1 or E-selectin on endothelial cells of acute Kawasaki disease coronary arteries, especially in areas of neovascularization. However, the temporal correlation of immune activation and endothelial cell activation with secretion of monocyte chemoattractant protein-1 (MCP-1)[35,200,368] and the development of coronary abnormalities and their suppression by IVIG are consistent with an immune stimulant that triggers an immune response leading to vascular damage in part through cytokine-induced exposure of endothelial epitopes, inflammatory cell infiltration, myointimal proliferation, matrix metalloproteinase release, and other mechanisms resulting in vascular wall damage.[102,315] A less than optimal animal model of Kawasaki disease induced by injected cell wall fragments of *Lactobacillus casei* has been reported.[193]

Investigation of the distribution of circulating T cells in acute and subacute Kawasaki disease has yielded conflicting results that range from no significant change in distribution of CD3, CD4, CD8, and CD19 cells at any stage of illness[51] to significant decreases in circulating CD8[203,369] or CD4[369] numbers acutely. An immunohistochemistry study of eight autopsied acute-stage Kawasaki hearts found activated T cells, a predominance of CD8 cells and macrophages, but no B cells,[31] whereas Terai and colleagues'[368] study of one autopsied child showed predominance of activated CD4 cells and macrophages as well as activated coronary endothelial cells. The presence of activated T cells in peripheral blood in acute Kawasaki disease is controversial.

As discussed earlier under etiology, expansion of Vβ2 and Vβ8 T-cell receptor families in acute Kawasaki disease has been reported,[1,2,56] but this finding has not been reproduced by other investigators.[3,211,224,256,280,370,376] Such expansion would suggest the possible role of a superantigen or could reflect clonal expansion of certain Vβ families in response to a conventional antigen. However, clonal expansion of CD8 T cells in acute Kawasaki disease supports the hypothesis that a conventional antigen rather than a superantigen is involved in the pathogenesis,[51,326] and compelling evidence of an oligoclonal IgA response in the vascular wall also strongly supports this hypothesis.[302]

Evidence for activation of neutrophils in Kawasaki disease is of interest because these cells, along with monocytes and macrophages, are postulated to mediate endothelial cell damage by production of oxygen radicals.[258,354,382] Kawasaki disease also is associated with widespread activation of monocytes and macrophages,[95-97] T lymphocytes,[98,311] and B lymphocytes.[168] Jejunal mucosal changes similar to delayed-type hypersensitivity in the epithelium and lamina propria, including decreases in $CD8^+$ cells and increases in $CD4^+$ and $HLA\text{-}DR^+$ cells, have been detected.[239] Delayed hypersensitivity skin test responsiveness to *Candida*, streptokinase/streptodornase, phytohemagglutinin, and PPD (tuberculin) is suppressed during the acute stage of Kawasaki disease but normalizes within 1 to 2 months.[403] Acute Kawasaki disease is associated with inflammatory reactivation of previous

*See references 17, 70, 94, 127, 165, 167, 185, 186, 197, 207, 208, 216, 218, 219, 301.

BCG vaccination sites, apparently reflecting both cellular and humoral responses.[405] We cared for a patient with acute Kawasaki disease and reactivation of a BCG site and the site of a recent tuberculin skin test.[371a] Plasma fibronectin levels are reported to be decreased early in illness but to rebound to high levels by the fourth week of illness.[319]

Circulating complement components C3 and C4 commonly are elevated, probably as acute reactants in the first several weeks of illness, and then normalize.[289] Nonetheless, complement appears to be activated through the classical pathway,[173] with high plasma C4D levels.[237]

Production of the chemoattractant leukotriene B_4 by polymorphonuclear cells is increased from 13 to 29 days after onset of Kawasaki disease,[114] and it may attract more inflammatory cells to the site. Leukotriene E_4 and prostaglandin E_2 also are elevated in Kawasaki disease,[92,192,220] as are increased platelet synthesis of thromboxane A_2 and plasma levels of thromboxane B_2.[126]

The strongest evidence of the importance of immunologic factors in the pathogenesis of vasculitis in Kawasaki disease is provided by the remarkably beneficial effect of IVIG on the acute febrile illness and the prevention of the development of coronary aneurysms.[238,247,251,262,321] It correlates with the effect of IVIG to reduce B-cell activation, more rapidly normalize T-cell activity, down-regulate cytokine secretion, and induce disappearance of endothelial cell activation antigens.[194,200] Potential mechanisms of the beneficial action of IVIG in Kawasaki disease include modulation of cytokine production, suppression of endothelial cell activation, inhibition of immunoglobulin production by a negative feedback mechanism, specific neutralization of an unknown etiologic agent or toxin, nonspecific blockade of a receptor for immune complexes, and augmentation of T-cell suppressor activity.[321]

TREATMENT IN THE ACUTE STAGE

INITIAL THERAPY

Patients diagnosed with Kawasaki disease should be admitted to hospital, undergo a baseline echocardiogram, and receive IVIG 2 g/kg over the course of 10 to 12 hours, with high-dose aspirin at 80 to 100 mg/kg/day in four divided doses (Table 88–4).[57,252] When administered by the 10th illness day, this regimen is highly effective in reducing the risk of development of coronary abnormalities.[249] Because few data exist regarding therapy of patients treated later than the 10th illness day, the goal is to treat by day 10 whenever possible. Patients who are diagnosed after the 10th illness day and who are still febrile may benefit from therapy, but the ability to prevent coronary changes is less certain. IVIG and aspirin have been shown to prevent the development of giant coronary aneurysms[52,297] and to have direct benefits on cardiac function.[249] The mechanism of action of IVIG in Kawasaki disease is unknown. The single high-dose schedule is superior to the earlier regimen of 400 mg/kg/day IVIG for 4 days with high-dose aspirin with respect to rapidity of defervescence and normalization of acute-phase reactants.[247,251,252,262] The large single-dose infusion generally is well tolerated, even in patients with decreased myocardial function.[249] Patients should remain hospitalized until they have been afebrile for at least 24 hours, to ensure that they are available for re-treatment if necessary.

TABLE 88–4 Treatment for Kawasaki Disease

Acute and Subacute Stages
IVIG, 2 g/kg infusion over 10-12 hr
PLUS
Aspirin, 80-100 mg/kg/day in four divided doses (until 14th illness day and patient afebrile at least 3-4 days), then 3-5 mg/kg once daily for 6-8 wk
IVIG may be repeated if fever persists or recurs together with at least one classic sign of Kawasaki disease (see text for other alternative "rescue therapies")
Convalescent Stage
No coronary abnormalities: no therapy
Transient coronary abnormalities: aspirin, 3-5 mg/kg once daily at least until resolution of abnormalities
Persistent small to medium coronary aneurysms: aspirin, 3-5 mg/kg once daily
Giant or multiple small coronary aneurysms: aspirin, 3-5 mg/kg once daily, with or without clopidogrel, with warfarin or low-molecular-weight heparin for most patients
Coronary obstruction: thrombolytic therapy, surgical or interventional procedures

IVIG, intravenous immunoglobulin.

Whether treatment with IVIG and aspirin earlier than the fifth illness day leads to poorer outcomes remains unclear. Tse and colleagues[378] compared 89 children treated on or before the fifth day of illness with controls treated on illness day 6 to 9. These investigators found significantly fewer patients with coronary ectasia at 1 year after Kawasaki disease and shorter total fever duration in the former group, without differences in frequency of recrudescence, need for additional therapy, need of steroids, length of hospitalization, or development of coronary aneurysms within 3 months. Zhang and associates[409] also concluded that patients treated before the sixth illness day had a significantly lower risk of developing cardiac sequelae compared with patients treated later than the sixth day. In contrast, Muta and colleagues[235] evaluated 4731 patients treated on days 1 to 4 and 4020 treated on days 5 to 9 and found that patients treated earlier were somewhat more likely to require additional therapy (odds ratio, 1.12, 1.10 to 1.16); no significant differences in cardiac sequelae were found between groups. Another study also found that treatment before illness day 5 was associated with increased need for re-treatment but no difference in coronary outcome.[82]

Single infusions of IVIG at doses less than 2 g/kg have not been demonstrated to be as effective as 2 g/kg.[18,74] A comprehensive meta-analysis of all Japanese and North American IVIG treatment trials showed that the coronary artery outcome is correlated directly with the *total* dose per kilogram of IVIG administered, with 2 g/kg superior to 1.6 g/kg, which is superior to 1.2 and 1.0 g/kg; the initial dose of aspirin used did not appear to influence coronary outcome.[367] Another study confirmed this finding.[69]

Patients diagnosed after the 10th illness day who are still febrile or who manifest other signs of active disease may benefit from IVIG and aspirin therapy because this treatment may result in prompt clinical improvement, with subsidence of fever and other signs of inflammation. No evidence supports that this approach results in lower rates of development of coronary abnormalities, however. Patients beyond the 10th to 12th illness day who have become afebrile and have resolved features of Kawasaki disease without therapy are unlikely to benefit from IVIG. Such children should be treated instead with aspirin, 3 to 5 mg/kg once daily, and should be evaluated carefully by serial echocardiograms. In patients who have already developed coronary aneurysms and whose acute manifestations of illness have resolved, no evidence suggests a beneficial effect of IVIG.

Various brands of IVIG differ in manufacturing processes and, therefore, in composition (e.g., proportion of IgG monomers, presence of proteins other than IgG). Although adverse reaction rates differ among products, clinical efficacy does not seem to differ.[294] An exception is a report that showed IVIG prepared with β-propiolactone, which can affect the biologic activity of the Fc portion of IgG, to be less effective in Kawasaki disease.[377] Measles and varicella immunizations (but not others)

should be deferred for 9 to 11 months after administration of high-dose IVIG because of impaired immune responses to these live virus vaccines.

The aspirin dosage for acute Kawasaki disease that is most thoroughly studied in the United States is 80 to 100 mg/kg/day in four doses. This therapy should be maintained until approximately the 14th day of illness (longer if necessary to ensure that the patient has been afebrile for ≥3 to 4 days) and then reduced to a daily dose of 3 to 5 mg/kg and continued until 2 to 3 months after onset of illness in those who have not developed coronary abnormalities.[252] Patients who develop coronary abnormalities should continue to take low-dose aspirin. High-dose aspirin is used for its anti-inflammatory activity, whereas the much lower doses inhibit platelet aggregation. Japanese clinicians generally use an intermediate anti-inflammatory dose of 30 to 50 mg/kg/day[182] because of perceived higher rates of untoward effects in Japan. Difficulty in achieving what are usually considered therapeutic anti-inflammatory serum salicylate levels during the acute phase of illness (20 to 25 mg/dL) may complicate aspirin treatment,[138] and selected refractory patients may require salicylate doses in excess of 100 mg/kg/day to achieve anti-inflammatory benefit. This situation probably reflects impaired absorption and bioavailability and enhanced salicylate clearance in acute Kawasaki disease.[174] An important note is that, with clinical improvement, patients with Kawasaki disease who are receiving very high doses can suddenly increase their salicylate absorption and may become salicylate toxic. Serum salicylate levels should be monitored if symptoms of vomiting, hyperpnea, tinnitus, lethargy, or striking liver function abnormalities develop in children receiving aspirin.

One study that randomized patients to receive salicylates at 80 to 100 mg/kg/day or 3 to 5 mg/kg/day for initial therapy (each regimen with 2 g/kg of IVIG) concluded that no difference in coronary outcome occurred, but a more prompt anti-inflammatory benefit was noted in the high-dose aspirin group.[225] In the absence of IVIG, aspirin therapy does not decrease the frequency of coronary abnormalities.[69] Reye syndrome has been reported rarely in children taking high-dose aspirin for Kawasaki disease, but whether low-dose aspirin poses this risk is unclear.[356]

The potential value of adding corticosteroid therapy to IVIG or aspirin for primary therapy was addressed in several trials.[250] For example, Jibiki and colleagues[140] compared 3 days of intravenous dexamethasone (0.3 mg/kg/day) plus heparin and IVIG, with subsequent low-dose aspirin, to IVIG plus higher-dose aspirin. These investigators found more prompt decreases in fever and inflammatory markers such as CRP in the dexamethasone-treated group, but no difference in rates of coronary abnormalities. Okada and associates[267] showed that the addition of intravenous prednisolone followed by a long taper of oral prednisolone to IVIG and aspirin was associated with shorter duration of fever and more prompt fall in CRP and circulating IL-2, IL-6, IL-8, and IL-10 levels. Inoue and colleagues[134] compared 88 patients treated with IVIG and aspirin with 90 patients who received in addition intravenous prednisolone (2 mg/kg/day in 3 divided doses) until afebrile and then orally until the CRP normalized, with a subsequent taper over 15 days, for a median of 23 days of steroids. The results indicated fewer coronary abnormalities, shorter durations of fever, more rapid decline in CRP level, and fewer initial treatment failures in the steroid recipients. Caution must be exercised in the interpretation of the findings of these Japanese trials because the IVIG regimens and aspirin doses differ from those used in the United States, and echocardiograms were not interpreted by investigators blinded to the treatment group.

The most definitive trial in this regard showed little if any direct benefit of the addition of a single dose of intravenous methylprednisolone (30 mg/kg) to the current IVIG and aspirin regimen, with the possible exception of patients who failed to respond to standard therapy and who required retreatment.[250] This observation will require additional study.

RESCUE THERAPY FOR TREATMENT FAILURES

Most patients with acute Kawasaki disease respond promptly to treatment with IVIG and aspirin, with defervescence and subsidence of inflammatory manifestations occurring within 48 hours.[57,247,322] A subgroup of approximately 5 to 15 percent, however, fails to show significant clinical response; these patients remain febrile 24 to 48 hours after receiving IVIG, or they manifest only transient improvement, with recurrent fever and clinical evidence of inflammatory signs. These patients need additional anti-inflammatory therapy, and specific guidelines or controlled treatment trials do not exist. Of course, when treating apparently treatment-refractory patients, it is also prudent to reconfirm the diagnosis.

In these patients, administration of a second dose of 2 g/kg of IVIG generally is effective in suppressing disease activity.[83,252,344] In a retrospective study of 179 patients with Kawasaki disease, 89 percent responded to the first dose of IVIG, and 67 percent of the nonresponders responded to a second IVIG dose; thus, only 3 to 4 percent of these patients failed to respond after a second dose of IVIG.[118] Carefully increasing the dose of aspirin to 120 mg/kg/day or higher, with monitoring of serum levels, may be helpful. Some physicians recommend a course (usually 3 days) of intravenous pulse methylprednisolone at 30 mg/kg/day instead of a second dose of IVIG.[390] We generally reserve pulse steroid therapy for the quite rare patient with highly refractory acute disease, who has failed to respond to at least two doses of IVIG, because early Japanese data suggested that steroids may predispose to development of coronary disease.[155] In addition, a more recent study noted coronary dilatation shortly after pulse steroids were administered in three of nine treatment-refractory patients.[122] No direct comparison between repeat IVIG dosing and corticosteroids has been performed. In a few particularly treatment-refractory patients, we employed a slow oral steroid taper over the course of several months once inflammatory activity appeared to have been controlled.

Infliximab (Remicade), a monoclonal anti–TNF-α antibody, has been reported in an open-label experience to be effective in most patients with acute Kawasaki disease who are refractory to standard therapy[39]; this agent is being studied in a randomized trial of patients with refractory Kawasaki disease. Even less published experience exists regarding other therapies for IVIG-refractory Kawasaki disease. Cyclophosphamide with or without methotrexate has been used in a very small number of patients.[385]

PREDICTION OF TREATMENT FAILURES

Several attempts have been made to develop scoring systems to predict, at the time of initial presentation, those patients who are at increased risk for failure to respond to standard therapy[73,172] or to develop coronary lesions after therapy.[231] In a retrospective analysis of 193 patients, Mori and colleagues[231] found that elevations in white blood cell counts, neutrophil counts, and CRP levels after IVIG treatment predicted increased risk for subsequent development of coronary lesions. Egami and colleagues[73] compared 279 patients who responded to initial standard treatment with 41 patients who were treatment resistant. These investigators developed a scoring system giving 1 point each for age less than 6 months, treatment before 4 days of illness, platelet count less than or equal to 300,000/mm^3, and CRP 8 mg/dL or higher, and 2 points for ALT 80 IU/L or higher; a score

of 3 points or higher identified the IVIG-resistant group with 78 percent sensitivity and 76 percent specificity.[73] A similar predictive scoring system for IVIG unresponsiveness was developed by Kobayashi and colleagues,[172] who gave two points each for day of illness at initial treatment 1 to 4 days, serum sodium less than 133 mmol/L, aspartate aminotransferase (AST) 100 IU/L or higher, and neutrophils 80 percent or greater, and two points each for CRP 10 mg/dL or higher, platelet count up to 300,000/mm^3, and age ≤12 months; this provided 86 percent sensitivity and 67 to 68 percent specificity for patients with 4 or more points.

SEQUELAE OF KAWASAKI DISEASE

The major (and virtually the only) sequelae of Kawasaki disease are cardiovascular, particularly involving the coronary arteries. Therefore, appropriate cardiac imaging is critical for the evaluation of patients suspected to have acute Kawasaki disease and for their subsequent follow-up. Echocardiography is considered the ideal imaging modality because it is noninvasive and has high sensitivity and specificity for detection of abnormalities of the proximal left main, left anterior descending, circumflex, and right coronary arteries.[252] This procedure should be performed under the supervision of an echocardiographer experienced with children, and internal arterial diameters should be measured and compared with normal standards for body surface area.[252] The American Heart Association classifies coronary aneurysms as small (<5 mm), medium (5 to 8 mm), or giant (>8 mm), and de Zorzi and colleagues[65] showed that adjusting coronary dimensions for body surface area may identify more accurately those patients with enlarged coronaries. Giant coronary aneurysms, defined as having 8 mm or larger internal diameter, are associated with worse prognosis, and these patients require particularly close follow-up.[52] The sensitivity and specificity of echocardiography to identify coronary thrombi and coronary stenosis are unclear, and visualization of coronary vessels is more difficult as body size increases. Therefore, angiography, magnetic resonance angiography (MRA), and ultrafast CT may be useful for selected patients with Kawasaki disease.[252]

MANAGEMENT BEYOND THE ACUTE STAGE

Patients with Kawasaki disease should be re-evaluated within 2 weeks after hospital discharge and again approximately 6 to 8 weeks after onset of illness because echocardiography at these time points is most likely to detect coronary artery aneurysms should they develop. If a baseline study and these two follow-up echocardiograms fail to detect evidence of coronary abnormality, performing further echocardiograms probably is unnecessary,[381] although a 6- to 12-month follow-up echocardiogram is performed at many centers.[58,252] Low-dose aspirin therapy (3 to 5 mg/kg/day) can be discontinued after the 6- to 8-week follow-up echocardiogram unless evidence of coronary abnormalities is present. To reduce the theoretical (and extremely low) risk of Reye syndrome in patients receiving low-dose aspirin, clopidogrel can be substituted for aspirin for a brief time in patients who develop varicella or influenza. Clopidogrel also can be used in the rare patient who is allergic to, or intolerant of, aspirin.

CARDIAC COMPLICATIONS

MYOCARDIAL INFARCTION

Myocardial infarction is the most common cause of death in Kawasaki disease (Table 88–5). In a cooperative Japanese study of 195 cases, the first myocardial infarction usually occurred in the first year after onset of disease and was fatal in 22 percent and asymptomatic in 37 percent of these patients. Major symptoms were shock, vomiting, and abdominal pain, with chest pain complaints only from children older than 4 years of age. Of those patients who survived a first infarct, 16 percent had a second myocardial infarct.[149,151] Patients with giant (>8 mm) coronary aneurysms are at greatest risk for having infarcts. Most fatal infarctions were the result of obstruction of the left main coronary artery or both the right coronary and left anterior descending coronary arteries; survivors were most likely to have isolated right coronary involvement. Approximately half the survivors of acute myocardial infarction had one or more complications, including ventricular dysfunction, mitral regurgitation, and arrhythmias. Parents of all children with Kawasaki disease with coronary abnormalities should be instructed to seek emergency medical care if chest pain, dyspnea, lethargy, or syncope develops. Prompt fibrinolytic therapy should be attempted at a tertiary care center if acute coronary thrombosis is diagnosed.[148] The degree of reversibility of coronary thrombosis in children with Kawasaki disease may be somewhat less than that in adults with atherosclerotic disease. Late cardiac sequelae of Kawasaki disease may not manifest until adulthood.[154]

TABLE 88–5 Cardiac Abnormalities in Kawasaki Disease

Acute Stage
Pericardial effusion
Decreased myocardial function
Mitral regurgitation
Brightness of coronary artery wall
Enlargement (ectasia) of coronary arteries
Arrhythmia (rare)
Subacute Stage
Coronary aneurysms, irregularity, ectasia
Mitral or aortic regurgitation, or both (rare)
Coronary aneurysm rupture (very rare)
Myocardial infarction (rare)
Convalescent Stage
Persistent coronary aneurysms
Regressed coronary aneurysms (residual fibrosis)
Coronary artery stenosis
Coronary aneurysm rupture (very rare)
Myocardial infarction (rare)

OTHER CARDIOVASCULAR COMPLICATIONS

Other cardiac complications include myocardial fibrosis, valvulitis, and coronary rupture. Some researchers have suggested that valvular disease occurs in as many as 1 percent of patients with Kawasaki disease; most of these cases result in mitral regurgitation.[5,170] Patients with well-documented aortic regurgitation also have been observed. At least one patient with Kawasaki disease developed severe aortic and mitral regurgitation that necessitated two valve replacements.[107] In an autopsy study, coronary rupture was a quite rare finding but was noted more commonly among older children who died of Kawasaki disease, whereas myocardial infarction was seen more commonly in younger fatal cases.[300]

Peripheral artery aneurysms develop in fewer than 1 percent of patients with Kawasaki disease, virtually always in those who have significant coronary abnormalities.[156,348] These abnormalities generally involve medium-sized muscular arteries, such as subclavian, brachial, axillary, iliac, or femoral arteries, and occasionally the hepatic or renal arteries or the abdominal aorta. In patients with Kawasaki disease who are undergoing their first coronary arteriography, abdominal aortography and subclavian arteriography are, therefore, recommended.[252]

PERIPHERAL GANGRENE

A rare but very serious complication in the acute febrile stage of Kawasaki disease is severe peripheral ischemia and dry gangrene of distal extremities.[373] Virtually all these patients have been young infants up to approximately 7 months of age with giant coronary aneurysms, and some have developed peripheral (especially axillary or iliac) arterial aneurysms as well. This complication is virtually unknown in Japan[161] and has been reported primarily in non-Asian children in North America.[68,373] Possible pathogenic mechanisms of peripheral gangrene include the following: severe arteritis of digital or other small peripheral arteries; arteriospasm of peripheral arteries, perhaps in association with severe vasculitis; thrombosis of inflamed or spastic arteries as a result of stasis and damaged endothelium; thrombosis of a more proximal aneurysm (especially axillary) with embolism distally; rarely, cardiogenic shock; and, most likely, a combination of these factors.[373,388] This process has led to amputations in a small number of infants. Therapy has been empiric, primarily because the precise mechanisms of disease are unclear, and has included aggressive use of anti-inflammatory agents, prostaglandin infusion, and anti-platelet, anti-coagulant, and vasodilation therapies.[68,373]

NONVASCULAR COMPLICATIONS

As many as 10 percent of patients with Kawasaki disease develop painful arthritis or arthralgia in the acute stage of disease, often in the ankles or elsewhere in the lower extremities, and they may require treatment with a nonsteroidal anti-inflammatory agent. Earlier-onset arthritis (≤10 days of illness) tends to be polyarticular, whereas later-onset arthritis involves primarily larger weight-bearing joints. We have used naproxen, usually 10 to 15 mg/kg/day divided into two or three doses, for several weeks with considerable success.

Abdominal pain and diarrhea in the early acute stage usually respond to intravenous hydration and supportive care. Acalculous distention (hydrops) of the gallbladder manifests clinically as right upper quadrant tenderness or a mass with or without obstructive jaundice and can be confirmed by ultrasonography.[338] Performing a cholecystectomy is not necessary. Hepatic involvement appears to be entirely self-limited and has not been associated with chronic liver disease.

Rare patients with Kawasaki disease develop hemophagocytic syndrome (HPS), also known as *macrophage activation syndrome* (MAS), as a complication. This syndrome manifests as persistent fever associated with cytopenias, hepatosplenomegaly, hepatic dysfunction, often hyperferritinemia, elevated serum lactate dehydrogenase, hypofibrinogenemia, and hypertriglyceridemia.[233,263,274] Therapy with high-dose prednisone or other immune modifiers are indicated for this rare but serious complication.

Rare events that occur in association with Kawasaki disease include sensorineural hearing loss,[345] transient unilateral facial nerve palsy,[101,281] and pneumonitis or pulmonary nodules.[84] We have cared for two older children who had sufficient abdominal findings to warrant performing appendectomies before establishing the diagnosis of Kawasaki disease. Consultation with a center that treats large numbers of patients with Kawasaki disease should be sought by the physician faced with rare or serious complications.

LONG-TERM FOLLOW-UP AND PROGNOSIS

Kawasaki disease normally is an acute and self-limited illness. However, cardiac abnormalities that develop when the disease is active may be progressive, and the prognosis clearly is related to the coronary artery status. Approximately 20 to 25 percent of patients not treated with IVIG develop coronary abnormalities that are detectable by two-dimensional echocardiography or angiography. The risk of development of coronary aneurysms is reduced to approximately 2 to 3 percent overall when IVIG is given in the first 10 days of illness.[247,251] However, the rates for coronary abnormalities for young infants are somewhat higher, even with timely IVIG therapy. Patients who develop moderate to severe coronary abnormalities are at risk of myocardial ischemia, myocardial infarction, and sudden death for at least 5 years after onset of illness.[151]

Children without apparent cardiac sequelae during the first month after onset of Kawasaki disease appear to return to their previous states of health, without cardiac signs or symptoms. However, some reports suggest the possibility of generalized endothelial dysfunction in patients with Kawasaki disease who never had coronary abnormalities. These dysfunctions include altered lipid metabolism,[43] increased brachial-radial artery mean pulse wave velocity,[49] lower myocardial flow reserve,[236] and abnormal endothelium-dependent brachial artery reactivity,[66,227,393] but the data conflict somewhat, and additional studies are needed.

Regression of small and medium aneurysms is a common occurrence. Overall, approximately half of all children with coronary aneurysms at 4 to 8 weeks after onset demonstrate regression by 1 to 2 years, with apparently normal vessels on angiography or echocardiography.[149] The likelihood that an aneurysm will regress is higher with smaller aneurysms, age younger than 1 year at the onset of Kawasaki disease, fusiform rather than saccular morphology, and involvement of a more distal coronary segment.[7,355] Regression of the internal diameter of the vessel to normal may occur by myointimal proliferation or by thrombus organization and recanalization.[87,309] If regression occurs, it generally does so within 2 years of the onset of disease.[152] Intravascular ultrasound studies show that thickened intima and media sometimes with calcifications are present in areas of regressed coronary aneurysms.[113,341] Regressed aneurysmal segments are histologically abnormal (intimal fibrosis) and have abnormal functional responses, with decreased vascular reactivity in response to exercise or pharmacologic agents such as isosorbide dinitrate or acetylcholine.[66,309,340] Only a small number of regressed aneurysms progress to stenosis.[153,340,347,350]

Functional abnormalities of coronary vessel endothelium relaxation have been reported years after the onset of Kawasaki disease[66,227] and warrant further investigation. Newer imaging methods have demonstrated vascular wall changes sometimes even in patients with no history of abnormalities in the acute phase. The meaning of these findings in patients thought to have escaped coronary abnormalities with acute Kawasaki disease and their long-term significance are uncertain.

Patients with giant coronary aneurysms are at the greatest risk for the development of significant stenosis with resultant myocardial ischemia.[133,156] The risk of significant stenosis, usually developing at the inlet or outlet of a moderate to large coronary aneurysm, shows a steady rise over 15 to 20 years of observation.[144,156,339,347] These markedly abnormal vessels are subject to calcification and thrombosis, which may lead to myocardial ischemia or infarction.

In 10- to 20-year follow-up studies of patients with Kawasaki disease, researchers found that the arteries most likely to develop stenosis are the right main and left anterior descending coronary arteries.[144,156,339,347,349] A limited number of studies of young adults with ischemic heart disease and history of diagnosed Kawasaki disease or a compatible clinical illness has been performed.[154] A survey of Japanese adult cardiologists identified 130 adult patients with coronary aneurysms detected by angiography to evaluate myocardial infarction or ischemia.[154] Twenty-one of these patients

(mean age, 34 years; range, 20 to 63 years) had a history compatible with Kawasaki disease in childhood. These patients had severe coronary disease with myocardial infarction, angina pectoris, mitral regurgitation, arrhythmias, congestive heart failure, and need for coronary bypass grafting. This study indicates that the coronary artery sequelae of Kawasaki disease likely are important causes of ischemic heart disease in young adults. Fatty deposits and advanced changes resembling atherosclerotic disease sometimes have been found at autopsy of children with a history of Kawasaki disease who died of other causes.[353] This finding raises the important but unanswered question of whether patients with Kawasaki disease are at increased risk for developing premature atherosclerosis or of having a more severe form of this disease.

LONG-TERM MANAGEMENT

The risk of coronary artery thrombosis or stenosis that may result in myocardial ischemia and infarction remains the most important long-term clinical problem in the subset of patients with Kawasaki disease who develop significant coronary abnormalities (see Table 88–5). Patients with medium (6 to 8 mm) and giant (>8 mm) aneurysms are at substantial risk for development of stenosis years after having the acute illness, compared with patients with small aneurysms or no aneurysmal changes,[7,144,149,152,156,348,380] and patients with giant aneurysms are at the highest risk for thrombosis.[252] Echocardiography and electrocardiography are not sufficiently sensitive to detect stenotic lesions. Various stress tests for detection of reversible myocardial ischemia, including nuclear perfusion scans with exercise, exercise echocardiography, and stress echocardiography with agents such as dobutamine, dipyridamole, or adenosine, have been used in children to detect stenosis.[252,260,272] Newer techniques, including stress magnetic resonance imaging (stress MRI), are being developed. Coronary arteriography remains the most definitive method to determine the degree of stenosis and the adequacy of collateral circulation. Intravascular ultrasound is an effective method to evaluate vascular wall morphology in selected patients during angiography.[342,346] All patients with evidence of myocardial ischemia or infarction should be studied by angiography to determine the need for intervention.[252] Most experts agree that patients with moderate to severe coronary artery aneurysms, a single large aneurysm, or multiple aneurysms should have their coronary anatomy defined by angiography at least once after the acute stage of illness (after the inflammatory process has subsided) to define fully the extent of involvement and to identify potential sites of thrombotic or stenotic complications.[252] Because aneurysms can occur in non-coronary arteries, especially the subclavian, brachial, axillary, iliac, and femoral arteries, and occasionally in the abdominal aorta and renal arteries,[348] in patients with coronary abnormalities, abdominal aortography and subclavian arteriography are recommended for patients with Kawasaki disease who are undergoing coronary angiography the first time.[252]

PATIENTS WITH NO EVIDENCE OF CORONARY ARTERY ABNORMALITIES AT ANY TIME (RISK LEVEL I)

Patients who have never manifested coronary artery abnormalities have no need for aspirin or other anti-platelet medication beyond 2 to 3 months after onset of illness or for restriction of physical activities in the convalescent stage. Only routine pediatric follow-up beyond 1 year, with routine cardiovascular risk assessment, is indicated.

PATIENTS WITH TRANSIENT CORONARY ECTASIA OR DILATATION (RISK LEVEL II)

Patients with transient coronary artery abnormalities that resolve by 6 to 8 weeks should be treated with aspirin, 3 to 5 mg/kg/day, until resolution of abnormalities. No restrictions are indicated after 6 to 8 weeks, angiography is not indicated, and risk assessment and counseling are recommended at 3- to 5-year intervals.

PATIENTS WITH ISOLATED (SOLITARY) SMALL TO MEDIUM (3- TO 6-MM) CORONARY ANEURYSM IN ONE OR MORE CORONARY ARTERIES (RISK LEVEL III)

Patients with solitary small to medium coronary artery aneurysms should be maintained on daily low-dose aspirin (3 to 5 mg/kg) at least until regression is documented with annual echocardiographic follow-up. For patients younger than 11 years old, no restriction on physical activity is indicated, but for those 11 years old and older, physical activity should be guided by a biennial stress test or myocardial perfusion test. Angiography should be performed if stenosis or ischemia is suggested.

PATIENTS WITH ONE OR MORE LARGE (>6-MM) OR GIANT (>8-MM) CORONARY ANEURYSM, OR MULTIPLE (SEGMENTED) SMALLER OR COMPLEX ANEURYSMS WITHOUT OBSTRUCTION (RISK LEVEL IV)

Long-term anti-platelet therapy with aspirin (3 to 5 mg/kg once daily) or clopidogrel (1 mg/kg/day up to adult dose of 75 mg) is indicated for these children and should be continued indefinitely. Anti-coagulant therapy with warfarin, with the international normalized ratio (INR) maintained at approximately 2.0 to 2.5, should be added for patients with giant aneurysms because these patients are at substantial risk for having coronary thrombosis. Daily subcutaneous low-molecular-weight heparin is an alternative to warfarin. All such patients should be under the care of a pediatric cardiologist with experience in managing patients with Kawasaki disease. Cardiac evaluation with echocardiogram and ECG should be performed every 6 months, with stress testing performed approximately annually. Angiography should be performed 6 to 12 months after the patient has recovered from the acute stage of disease to define the coronary anatomy, and it should be repeated whenever symptoms or stress tests suggest the presence of myocardial ischemia. Physical activity should be regulated on the basis of annual stress test results and level of anti-coagulation, and strenuous athletics should be discouraged.

PATIENTS WITH CORONARY ARTERY OBSTRUCTION (RISK LEVEL V)

Patients with obstructive lesions or signs of ischemia should be evaluated urgently for possible intervention. Balloon angioplasty, rotablator angioplasty, coronary artery bypass grafting, stent placement, and even cardiac transplantation all have been employed for patients with Kawasaki disease and particularly serious coronary artery disease.[6,48,112,136,379] Researchers have shown that arterial bypass grafts are superior to venous grafts in these patients.[169] Balloon angioplasty procedures have been associated with high rates of recurrent stenosis in patients with Kawasaki disease and coronary stenosis.[6]

CHAPTER 89

Chronic Fatigue Syndrome

Leonard R. Krilov

"*All cases are unique and very similar to others.*" T.S. Eliot, *The Cocktail Party*, 1949.

Chronic fatigue syndrome (CFS) is an illness complex characterized by a prolonged (>6 months) period of constant or intermittent debilitating fatigue in association with multiple, often nonspecific, symptoms that may include new-onset headaches, decreased ability to concentrate, recurrent complaints of sore throat and tender cervical or axillary lymphadenitis, reports of low-grade fever, diffuse muscle or joint pain, postexertional increase in fatigue, and unrefreshing sleep. To date, no specific cause for this syndrome has been identified, and, despite similar arrays of signs and symptoms, patients with CFS likely represent a heterogeneous population. Still, evaluation of groups of patients with this symptom complex has provided information about pathophysiologic changes occurring in patients with CFS, and potentially beneficial, although not curative, approaches to therapy for affected individuals have been developed.

In an attempt to provide a degree of uniformity as a basis for research into the evaluation of such patients, the U.S. Centers for Disease Control and Prevention (CDC) developed a definition of CFS in 1988.[38] These criteria were revised in 1994, with physical signs removed from the definition because they appeared to be unreliably documented in studies, and the required number of symptoms for the diagnosis of CFS decreased from 8 of a list of 11 to 4 of 8 components (Table 89–1).[33] These changes, being less restrictive, may serve to increase the sensitivity of the diagnosis, but they also decrease the specificity. However, these criteria are purely speculative in the absence of any gold standard or definitive diagnostic test for CFS. These 1994 criteria also suggest subdivisions of patients with CFS for research purposes and provide guidelines for non-research clinicians as well. Other international groups have generated similar definitions of CFS for evaluating this condition.[12,54,80]

TABLE 89–1 Centers for Disease Control and Prevention 1994 Workshop Case Definition of Chronic Fatigue Syndrome

1. Fatigue (persistent or relapsing) that has new or definite onset, is of >6 months' duration, and leads to a substantial (>50%) reduction in level of activity
   PLUS
2. At least four of the following:
   Impaired memory or concentration
   Sore throat
   Tender lymph nodes: cervical or axillary
   Myalgias
   Arthralgias (multiple joints, without swelling or erythema)
   New onset (or in severity) of headaches
   Unrefreshing sleep (hypersomnia or insomnia)
   Postexertional fatigue lasting >24 hours
   AND
3. The absence of another diagnosis for the individual's signs and symptoms

Modified from Fukuda, K., Straus, S. E., Hickie, I., et al.: The chronic fatigue syndrome: A comprehensive approach to its definition and study. Ann. Intern. Med. 121:953-959, 1994.

The primary manifestations of CFS are severe fatigue of more than 6 months' duration that limits activity to less than 50 percent of premorbid function and the association of multiple other symptoms, as outlined in the case definitions of CFS.[33,38,54,80] These symptoms include new or more intense headaches, decreased ability to focus or concentrate, recurrent sore throats, a sensation of tender cervical or axillary lymph nodes, low-grade temperature elevations, myalgias and arthralgias, postexertional fatigue lasting longer than 24 hours, and sleep disturbances (hypersomnia or insomnia). The severity and persistence of these findings vary among individual patients with CSF. In addition, although not included in the case definitions, many patients report dizziness, especially with changes in position, feeling hot when others are cold or vice versa, chronic costochondritis, and a Raynaud-like phenomenon.

HISTORICAL OVERVIEW

In all likelihood, CFS is not a new illness. Numerous conditions with features comparable to those of CFS have appeared in the medical literature during the past several centuries.[91] Many of these descriptions attempted to associate an illness characterized by prolonged debilitating fatigue and numerous other symptoms with an infectious agent. They have included chronic brucellosis,[84] chronic enteroviral syndrome,[17,21,36] chronic candidiasis,[74] myalgic encephalomyelitis,[2] chronic mononucleosis (Epstein-Barr virus [EBV] infection),[3,40,96,97] human herpesvirus type 6 infection,[7,102] human herpesvirus type 7 infection,[26] chronic Lyme disease,[85] parvovirus B19 infection,[45] and a new retroviral infection.[23] Noninfectious conditions described with similarities to CFS include total allergy syndrome, hypoglycemia, neurasthenia, Iceland disease, Royal Free disease, and fibromyalgia rheumatica.[48] In addition to clinical similarity to CFS, all these conditions, at least at the time they were described, lacked a diagnostic test to confirm a definitive causative agent and, in their acute form, manifested with fatigue in association with multiple other complaints.

A review of the experience in the mid-1980s associated groups of patients with CFS-like illness with patients with chronic EBV infection.[3,40,96] These reports described elevated and aberrant

patterns of EBV antibody responses in individuals with prolonged fatigue and multiple symptoms consistent with CFS. Acute infectious mononucleosis also often manifests with fatigue, fever, malaise, sore throat, lymphadenitis, and multiple systemic complaints, although typically in a more pronounced manner. Subsequent studies, however, revealed that the elevation or pattern of EBV antibody responses in such patients were not consistently different from findings in others who resolved symptoms of acute EBV infection.[60] Additionally, shedding of EBV in secretions was not increased in these individuals, and no association was found between viral shedding and severity of symptoms.[98] Furthermore, no response to the antiviral drug acyclovir occurred in a group of such patients in a placebo-controlled, double-blind, crossover study, in terms of improvement of clinical symptoms.[93] After these observations were made, the name *chronic fatigue syndrome* was chosen to define this illness,[38] at least until a specific cause or marker for this illness is identified.

Cameron and colleagues recently reported on a cohort of patients with prolonged fatigue after having infectious mononucleosis. These investigators demonstrated no difference in EBV load in eight patients with 6 months or more of disabling symptoms after the diagnosis of infectious mononucleosis was established, and again they demonstrated a lack of correlation between persistent symptoms and viremia or altered host responses to EBV.[10]

TABLE 89–2 Symptoms Reported by 58 Children and Adolescents Evaluated for Chronic Fatigue Syndrome (1989 to 1994)

EPIDEMIOLOGY

The definitions of CFS allow for attempts to characterize the prevalence and demographic features of this condition. Still, given the vagaries of the symptom complex, possible variations in application of the diagnosis by different health care providers, and the potential differences within groups of people to seek medical attention for this condition, data reported on these issues may not be a complete representation of the epidemiology of this condition. CFS has been reported in all age groups, including children as young as 5 years of age, and in all ethnic, racial, and socioeconomic groups, but most CFS cases have been reported to occur in middle- to upper-class white women with a median age of 35 to 40 years.[47] Based on a study of physician-diagnosed patients from four cities using the 1988 case definition of CFS,[1] the CDC estimates a minimum prevalence rate of CFS of 2 to 10 cases per 100,000, or higher, in adults aged 18 years and older in the United States.[8,57,71] A population-based descriptive epidemiologic study conducted by the CDC in Kansas estimated the prevalence of CFS to be 235 per 100,000 persons and a 1-year incidence to be 180 per 100,000 persons.[75] Studies from outside the United States have reported similar or higher prevalence rates of CFS in adults.[27,54]

Although the CDC definition does not include age criteria for the diagnosis of CFS, the prevalence of CFS in the pediatric age range has not been studied well. Some researchers have suggested that the diagnosis of CFS should not be used in children, to avoid potential delay in making an alternative medical or psychological diagnosis.[70] However, many referral centers have reported groups of pediatric patients, primarily adolescents, with features and a clinical course similar to those reported in adults.[5,13,28,50,58,83] Furthermore, in these studies, missed or alternative diagnoses were not found, despite years of follow-up. Rimes and colleagues reported prevalence rates of CFS in an adolescent population similar to those reported in adults.[76]

In these pediatric studies, a predominance of female patients with a median age of 14 years at the time of diagnosis was noted. Additionally, these patients were from predominately middle- to upper-class families, and, as discussed later, their signs and symptoms at presentation (Table 89–2) and their course of illness were similar to those reported in adults with CFS. CDC studies suggest that the prevalence of CFS in adolescents approaches that reported in adults, but cases in children younger than 12 years of age occur much less commonly.[33] One suggestion is that a shorter duration of symptoms (3 to 4 months versus 6 months) may be appropriate for establishing the diagnosis of CFS in pediatric patients.[33,41] Multiple family members with CFS may be seen as well, but to date, evidence that CFS is contagious does not exist.

ETIOLOGY AND PATHOGENESIS

INFECTION

As noted previously, an infectious origin of CFS has not been demonstrated to date, and a single microorganism as the cause of CFS is unlikely. However, an acute infection appears possibly to play a role in precipitating CFS because most (as many as two thirds) patients with CFS relate a sudden onset of their symptoms to an acute infection, most often infectious mononucleosis. Lyme disease[56,85] and an influenza-like illness[39] also have been reported in association with the onset of CFS.

IMMUNOLOGIC DYSFUNCTION

A role for immunologic dysfunction in CFS has been suggested, based on numerous studies demonstrating abnormalities in lymphocyte function or cytokine production.[9,46,53,61,92,95,99] However, these findings have not been reproducible in different groups of patients with CSF. Some evidence suggests that nonspecific elevation of antibody titers and an increase in allergic symptoms occur in patients with CSF.[94] However, these findings are mild, and similar immunologic changes may be seen in other conditions, including depression. Individuals with CFS may report an increased frequency and duration of infections compared with their pre-CFS state, but they tend to be mostly routine viral illnesses. Neither unusual or opportunistic infection nor increased risk for developing malignant disease has been observed in these individuals. Intravenous immunoglobulin infusions have not

demonstrated long-term clinical benefit when they are administered to patients with CFS and may cause significant adverse reactions.[55,69,90]

Some studies have focused on potential genetic markers of CFS using DNA microarray technology.[86] An analysis of cytokine gene polymorphisms in 80 Italian patients with a diagnosis of CFS assessed using the 1994 CDC definition reported significant difference in tumor necrosis factor and interferon-γ phenotypes compared with controls. The authors hypothesized a potential altered immunologic or inflammatory response based on these differences as potentially contributing to the pathogenesis of CFS.[11] An analysis of prolonged post-infectious fatigue in patients who had had mononucleosis identified certain genes involved in immune responses, and hormonal and neurologic pathways that were altered in a subset of patients with mononucleosis were associated with the development of prolonged fatigue.[10] The CDC has developed a molecular epidemiology program to standardize assays that can be applied to understanding the potential of alterations in gene expression in CFS (available at http://www.cdc.ncidod/diseases/cfs/publications/molecular_epi.htm; accessed 7/12/2007).

NEUROLOGIC FEATURES

Many patients with CFS report cognitive impairment manifest as a decreased ability to concentrate and focus, difficulty in processing information, and trouble with word recall. Complaints of headache (new onset or altered pattern) and other neurologic symptoms, such as paresthesias and dysequilibrium, also are reported commonly by patients with CFS.

Despite these complaints, physical examination does not reveal abnormal neurologic signs. Formal neuropyschometric testing also may not reveal objective abnormalities to the extent reported by the patient. Whether this discrepancy reflects a problem with testing methods or altered perception on the part of the individual is uncertain at this time.[7,66]

Magnetic resonance imaging (MRI) studies have been reported to show an increase in cerebral white matter abnormalities in patients with CFS.[7,65,78] Similarly, in many studies, single photon emission computed tomography (SPECT) scanning has demonstrated changes in perfusion in certain areas of the brain in patients with CFS.[19,30,79] In other studies, however, abnormalities specific to CFS have not been observed consistently, and methodologic concerns have been raised regarding the interpretation of abnormal findings cited previously.[18,37] An abnormality at the base of the fourth ventricle detected on focal computed tomography (CT) scan of the base of the brain and responding to neurosurgical intervention was reported in a group of patients with CFS,[35] but this defect is not seen on routine CT or magnetic resonance imaging (MRI) views, and this observation requires confirmation by other researchers before determining its significance for these patients. At present, imaging of the central nervous system is not indicated routinely in the evaluation of a patient with CFS.

ENDOCRINOLOGIC FACTORS

Subtle defects in the hypothalamic-pituitary-adrenal axis have been described in cohorts of patients with CFS. These abnormalities include decreased free urinary cortisol levels and exaggerated adrenal responsiveness to corticotropin infusion.[25] These changes are quantitatively minor, and mean values are still within normal for age and sex, thus rendering these values unreliable as a diagnostic test for CFS. Similar changes have been described in patients with fibromyalgia and post-traumatic stress disorder.

CARDIOVASCULAR FACTORS

In 1995, investigators at Johns Hopkins Hospital in Baltimore described a cohort of seven adolescents with chronic fatigue and autonomic dysfunction as assessed by tilt-table testing.[77] Furthermore, these patients reported improvement or resolution of symptoms, including fatigue, with treatment of their orthostatic intolerance. Further studies from this group demonstrated some component of orthostatic hypotension in 92 percent of patients with CFS.[6] Studies in groups of adults, in contrast, showed tilt-table test abnormalities in only 25 to 40 percent of patients.[31,82] Whether this finding reflects true age-related differences in this phenomenon in patients with CFS is uncertain, given potential methodologic differences in the performance of the tests.

The pattern of orthostatic intolerance among adolescents with CFS was characterized further by Stewart and colleagues and is consistent with the postural orthostatic tachycardia syndrome (POTS).[87-89] Symptoms of POTS may develop after an acute infectious illness or with severe deconditioning and include fatigue, light-headedness, impaired cognition, inappropriate sweating, headache, palpitations, nausea, vomiting, and tremulousness. These authors suggest that CFS may be an extreme expression of POTS in at least some cases.

The importance of these cardiovascular findings in CFS remains unsettled. Subjective components may contribute to defining a tilt-table test as abnormal because subjects are not blinded during these studies. Some healthy individuals also may experience hypotension during these tests. Further studies defining the effect of treatment of POTS on the course of CFS should help to answer this question. In this context, evaluation and therapy of orthostatic changes, especially if dizziness is a significant component of the patient's complaints, may be indicated.[109]

SLEEP PHYSIOLOGY

Sleep disturbances have been described in selected groups of patients with CFS, and some of these patients may be amenable to therapy.[52,73] However, no single pattern of sleep abnormality has been reported for these patients, and in our experience, the pattern of hypersomnia or insomnia tends to improve as the patient recovers.

PSYCHOLOGICAL COMPONENTS

Psychological factors have been considered in the origin and perpetuation of CFS. Adults with CFS have demonstrated a higher frequency of depression and other psychiatric disorders before the onset of their CFS compared with age-matched controls.[1,51] Certainly, many of the symptoms reported in CFS also are reported commonly in depression. They may include sleep disturbances, loss of energy, difficulty in concentrating, changes in appetite, and musculoskeletal complaints. Studies in children and adolescents with CFS also have shown significant psychological features, especially depression and somatization, compared with both healthy controls and those with other chronic illnesses (e.g., juvenile rheumatoid arthritis, cancer, cystic fibrosis).[13,14,41,67,104] Still, certain features of CFS argue against its being solely a variant of depression. Individuals with CFS do not have the mood-related symptoms reported in patients with clinical depression. These mood-related symptoms include negative affect, anhedonia, low self-esteem, and suicidal ideation. Furthermore, patients with CFS and their families have a firm belief that an infectious, immunologic, or other medical cause for their symptoms exists, and the patients desire a return to normal activities.

In considering the possible link between depression or psychological stress and CFS, several possible relationships may exist. Preexisting depression or stress may create a psychological vulnerability that allows for the development of CFS in combination with any of numerous other factors discussed previously. Studies have demonstrated a role for psychological factors predicting the response to mononucleosis and influenza.[39,43] Similar factors may be involved in the development of CFS. Alternatively, depression may be a physiologic consequence of the central nervous system changes that occur in those who develop CFS, just as decreased concentration and memory occur as part of the syndrome.[41,104] Furthermore, reactive depression may occur in these patients in response to the inability to participate in their usual activities and to absence from school and separation from friends. Finally, CFS may be, at least in some cases, a manifestation of separation anxiety or school phobia in which secondary gain, as a conversion reaction, is playing a major role. Certainly, at least a subset of adolescents and children with CFS in our experience does not appear eager to return to school or activities, and secondary gain may play a role in the perpetuation of their illness.[48]

In summary, each of these potential links between depression or stress and CFS likely plays a role, with the relative contribution of each feature varying for different people. This suggestion is consistent with the overall hypothesis that many different factors appear to contribute to the development and perpetuation of CFS. The relative contribution of these different features may vary from individual to individual and even for the same patient over the course of the illness. The assessment and management of the patient with CFS should attempt to consider these issues and their relative importance for that individual.

DIAGNOSIS, DIFFERENTIAL DIAGNOSIS, AND EVALUATION

The diagnosis of CFS is one of exclusion and requires a comprehensive history. In the pediatric population, this information is obtained best from the patient and parents. Additionally, we request that families bring prior medical records, test results, and pertinent school records, to facilitate a complete evaluation. This process may be lengthy because the details are complicated, long standing, and often a source of debate between the patient and parents. The history should focus on the onset of illness, the duration and severity of symptoms, prior evaluations (often multiple) as well as medical history before the illness, family history, academic performance, and social history. The physical examination of the individual with suspected CFS almost always is essentially normal despite the multitude of symptoms. Findings of mild pharyngeal erythema and cervical adenopathy commonly are reported. However, finding fever, weight loss, significant adenopathy, or organomegaly should alert the clinician to the possibility of an alternative diagnosis.

DeMeirleir and colleagues reported increased detection of a 37-kd, 2-5A-synthetase binding protein in peripheral blood mononuclear cells from patients with CFS compared with healthy controls.[24] These binding proteins are related to the ribonuclease L antiviral pathway of these cells. This finding requires further confirmation before it can be considered a potential diagnostic test for CFS. At present, no specific tests for diagnosing CFS exist, and laboratory testing is aimed primarily at eliminating other possible diagnoses. Most patients have undergone multiple laboratory tests before a diagnosis of CFS has been considered, but these tests may be repeated or completed as part of the initial CFS evaluation. Additionally, interpreting previously performed tests may be part of the initial patient assessment. Screening studies may include complete blood count with differential and platelets, erythrocyte sedimentation rate, hepatic and renal function studies, urinalysis, and thyroid function tests. Additional tests that may be indicated based on history and physical examination may include toxicology screening, human immunodeficiency virus serology, antinuclear antibody, rheumatoid factor, tuberculin skin test, and cortisol level. Serologic evaluations for EBV, Lyme disease, and group A streptococcal infection may be requested based on history and physical infection. In most instances, these tests are not indicated; however, they often are obtained before CFS is suspected, and they need to be appropriately reviewed or repeated as part of the initial evaluation for CFS. Screening radiographic studies may include a chest radiograph or imaging of the paranasal sinuses based on the patient's symptoms.

Elimination of every possible disorder that may cause a patient to experience prolonged fatigue is impossible, but when guided by history, physical examination, and laboratory screening tests as outlined previously, the clinician can make a reliable diagnosis of CFS. Follow-up for periods of 4 to 13 years for pediatric patients diagnosed with CFS have not identified cases of missed or alternative diagnoses for their complaints.[4,50] In general, the longer the duration and the greater the number of symptoms, the less the need for extensive laboratory evaluations to suggest the diagnosis of CFS. Conversely, alternative diagnoses should be considered if a single symptom dominates the clinical presentation or if physical examination or laboratory tests reveal significant abnormalities.

Psychosocial assessment is indicated for all children and adolescents presenting for CFS evaluation. The extent of such evaluation may be limited to assessment by primary care personnel or may include collaboration with a social worker, psychologist, or psychiatrist, based on the individual's needs and the comfort level of the examiner. Cardiopulmonary and neurologic evaluations may be used in some cases, both to consider possible alternative diagnoses and to assist in assessing factors that may be contributing to the symptoms of CFS.

MANAGEMENT

"One of the essential qualities of the clinician is interest in humanity, for the secret of care of the patient is in caring for the patient."

Dr. Francis Peabody, 1926 (wall plaque, lobby of the Massachusetts General Hospital, Boston)

Management of patients with CFS is aimed at providing a combination of supportive treatment and emotional support.[32] Such an approach is outlined in Table 89–3.

This process can be initiated during the initial evaluation, with a discussion of the diagnostic criteria for CFS and a review of previously obtained laboratory tests. The relationship between physical and psychological symptoms can be explained, and the patient and family can be reassured that symptoms are real, even if the symptoms have psychiatric components. Additionally, the patient and family can be advised that most children and adolescents with CFS do well over time[4,28,49,50] and have a better long-term outlook than that described for adults with CFS.[42,108] Furthermore, emphasizing the frequent ups and downs in symptoms that generally characterize the course of CFS is important in assisting the patient and family to develop coping skills. This assistance may include guidance on how to modify lifestyle most appropriately and how to set realistic schedules and goals. Studies from the United Kingdom suggest that formal cognitive-behavioral therapy[22,72,81,107] or graded exercise programs, or both, may be beneficial for patients with CFS.[15,34,105]

Many other therapies have been advocated by different groups for patients with CFS. These treatments may include supplements, such as essential fatty acids,[103] magnesium,[20] liver extract

TABLE 89–3 Approach to Management of Chronic Fatigue Syndrome in Children and Adolescents

Evaluation and explanation of the diagnosis, including overview of multifactorial components
Reassurance that symptoms are real
Anticipatory guidance regarding secondary problems, up-and-down course of syndrome, secondary gain
Coping skills: lifestyle modification, decreased stress, and realistic expectations and schedule
Cognitive behavioral approaches: gradual increases in activity, an exercise program, attention to sleep patterns, attention to nutrition
Psychological support for individual and family
Educational issues: return to classes, home tutors, neuropsychiatric testing as indicated
Relationship issues: friends and family
Follow-up plan: monitoring of physical symptoms and psychological issues, ongoing guidance and reassurance (follow-up visits every 4 to 6 weeks)
Minimize: shopping for a doctor; unnecessary testing; family strain; unconventional, unproven, or experimental therapies

Modified from Krilov, L. R., and Fisher, M.: Chronic fatigue syndrome in children and adolescents. Contemp. Pediatr. 19*:61-68, 2002.*

injections,[44] and vitamin and nutritional supplements,[59] as well as pharmacologic treatments, such as steroids,[16,62,68] reduced nicotinamide adenine dinucleotide,[100] antidepressants,[64,101] and growth hormone.[63] Homeopathic therapies, osteopathy, and massage therapy[29] also have been reported to be beneficial in the management of CFS. Most of these approaches have not been studied adequately to allow definitive comment on their potential benefit for a given patient. Still, the clinician should be aware of them, to help guide patients who are likely to hear about them from other patients or outside sources, including the Internet.[35,106,107]

PROGNOSIS AND FUTURE DIRECTIONS

CFS likely affects heterogeneous groups of patients, and a single cause or definitive treatment modality most likely will not be uncovered. Nonetheless, studying groups of such patients yields helpful information on the pathophysiology of this condition, and useful steps to address and alleviate symptoms for patients have been reported. In recognition of the significance of this entity, the CDC launched an awareness campaign, including the development of an Internet site for health care professionals and the public (http://www.cdc.gov.cfs; accessed 7/12/2007). In addition, long-term follow-up data demonstrating improvement over the course of time, especially in children and adolescents, without emergence of significant other conditions, are encouraging for patients, families, and clinicians caring for such individuals.

SECTION XVI

BACTERIAL INFECTIONS

CHAPTER 90

NOMENCLATURE FOR AEROBIC AND ANAEROBIC BACTERIA

David A. Bruckner

Table 90–1 represents an update of the current nomenclature, taxonomy, and classification of various microbial agents. Taxonomic methods have evolved from the use of biochemical testing to molecular characterization using 16S or 23S rRNA. Molecular methods have helped to define groupings of organisms and have led to considerable changes in bacterial nomenclature. The classification process is not complete until molecular and phenotypic descriptions of the studied taxa are provided. The primary purpose of nomenclature is to permit us to know as exactly as possible what another clinician, microbiologist, epidemiologist, or investigator is referring to when describing an organism responsible for infecting individuals or for causing an outbreak. The *International Code of Nomenclature of Bacteria*[20] includes rules on how to name bacteria and use the name. The most comprehensive taxonomic information available for bacteriologic classification can be found in *Bergey's Manual of Determinative Bacteriology*, ninth edition,[9] and in *Bergey's Manual of Systematic Bacteriology*,[7,8] volumes 1 through 4. Leading journals that contain up-to-date information on nomenclature and new species include *Anaerobe*, *International Journal of Systematic and Evolutionary Microbiology*, *Annales de Microbiologie* (Institut Pasteur), *Current Microbiology*, *Journal of Clinical Microbiology*, and *Systematic and Applied Microbiology*. An overview of validly published names can be obtained at http://www.bacterio.cict.fr or http://www.dsmz.de/microorganisms/bacterial_nomenclature.php.

Taxonomic ranks for naming bacterial organisms include kingdom, division, class, order, family, genus, species, and subspecies. All these ranks have official standing in nomenclature. Ranks below subspecies have no official standing but are used to indicate groups of strains or isolates that can be distinguished by some special characteristics (Table 90–2). Each taxonomic name should be represented by a nomenclature type. The species is represented by a type strain that is deposited in a recognized culture collection.

Nomenclature priorities for bacteriologic names date back to May, 1753. Because of difficulties in searching literature and limited available information on described species, approved lists of bacterial names were published in the *International Journal of Systematic Bacteriology* in 1980. Names not included on those lists have lost all standing in nomenclature status.

Historically, bacterial classification has been based on phenotypic characteristics. Multivariate analysis has played a large role in classification since the 1950s. This analysis used biochemical, cultural, and morphologic characteristics and susceptibilities to antibiotics and inorganic compounds to define the degrees of similarities among organisms. More recently, molecular techniques (e.g., DNA hybridization, rRNA-DNA hybridization, gene sequence analysis) have played a major role in determining phylogenetic relationships.

The DNA molecular weight for most bacteria is 1×10^9 to 8×10^9 daltons, enough to specify 1500 to 6000 genes. Using nucleic acid analysis, researchers have developed numerous parameters to determine taxonomic relationships. These parameters include genome size, mole percent guanine plus cytosine content, DNA relatedness under optimal and supraoptimal conditions for DNA reassociation, and rRNA oligonucleotide sequences. By correlating phenotypic results with DNA homology and rRNA sequence analysis, researchers have been able to select phenotypic tests that can be used more accurately to identify organisms belonging to specific groups.

The bacterial classification shown in Table 90–1 is based on the organism's morphologic and stain characteristics. Organisms included are those that often are associated with pathologic processes or that are medically significant. The current names are those either officially recognized or proposed for recognition and currently used in the literature.[1-21] The type species for *Salmonella* is *Salmonella enterica* rather than *Salmonella choleraesuis*, although in the United States, Public Health uses the genus *Salmonella* and the serovar for reporting purposes.[4]

TABLE 90–1 Current Bacterial Nomenclature, Taxonomy, and Classification

I. Aerobic Gram-Positive Cocci

Characteristics: aerotolerant anaerobes that can occur singly or in pairs, tetrads, chains, or clusters; they can be catalase-positive or catalase-negative. Organisms positive for coagulase or clumping factor include *Staphylococcus aureus*, *Staphylococcus intermedius*, *Staphylococcus lugdunensis*, and *Staphylococcus schleiferi* subspecies *coagulans*.

Current Name	Synonym
Catalase-Positive Organisms	
Alloiococcus otitidis	*Alloiococcus otitis*
Kocuria kristinae	*Micrococcus kristinae*
Kocuria rosea	*Micrococcus roseus*
Kocuria varians	*Micrococcus varians*
Kytococcus schroeteri	
Kytococcus sedentarius	*Micrococcus sedentarius*
Micrococcus luteus	
Micrococcus lylae	
Nesterenkonia halobia	*Micrococcus halobius*
Staphylococcus arlettae	
Staphylococcus aureus subspecies *anaerobius*	
Staphylococcus aureus subspecies *aureus*	
Staphylococcus auricularis	
Staphylococcus capitis subspecies *capitis*	
Staphylococcus capitis subspecies *ureolyticus*	
Staphylococcus caprae	
Staphylococcus carnosus subspecies *carnosus*	
Staphylococcus carnosus subspecies *utilis*	
Staphylococcus casei	*Staphylococcus succinus* subspecies *casei*
Staphylococcus chromogenes	*Staphylococcus hyicus* subspecies *chromogenes*
Staphylococcus cohnii subspecies *cohnii*	
Staphylococcus cohnii subspecies *urealyticus*	
Staphylococcus condimenti	
Staphylococcus delphini	
Staphylococcus epidermidis	*Staphylococcus albus*
Staphylococcus equorum	
Staphylococcus felis	
Staphylococcus fleurettii	
Staphylococcus gallinarum	
Staphylococcus haemolyticus	
Staphylococcus hominis subspecies *hominis*	
Staphylococcus hominis subspecies *novobiosepticus*	
Staphylococcus hyicus	
Staphylococcus intermedius	
Staphylococcus kloosii	
Staphylococcus lentus	*Staphylococcus sciuri* subspecies *lentus*
Staphylococcus lugdunensis	
Staphylococcus lutrae	
Staphylococcus muscae	
Staphylococcus nepalensis	
Staphylococcus pasteuri	
Staphylococcus piscifermentans	
Staphylococcus pseudintermedius	
Staphylococcus saccharolyticus	*Peptococcus saccharolyticus*
Staphylococcus saprophyticus subspecies *saprophyticus*	*Micrococcus* subgroup 3
Staphylococcus schleiferi subspecies *coagulans*	
Staphylococcus schleiferi subspecies *schleiferi*	
Staphylococcus sciuri subspecies *rodentium*	
Staphylococcus sciuri subspecies *sciuri*	
Staphylococcus simulans	
Staphylococcus succinus subspecies *succinus*	
Staphylococcus vitulinus	
Staphylococcus warneri	
Staphylococcus xylosus	
Catalase-Negative Organisms	
Abiotrophia defectiva	*Streptococcus defectivus* Nutritionally variant streptococci
Aerococcus christensenii	
Aerococcus sanguicola	*Aerococcus sanguinicola*
Aerococcus urinae	
Aerococcus viridans	
Dolosicoccus paucivorans	
Dolosigranulum pigrum	
Enterococcus avium	*Streptococcus avium* Group D *Enterococcus*
Enterococcus caccae	
Enterococcus casseliflavus	*Enterococcus flavescens* *Streptococcus casseliflavus*
Enterococcus cecorum	*Streptococcus cecorum*
Enterococcus dispar	
Enterococcus durans	*Streptococcus durans* Group D *Enterococcus*
Enterococcus faecalis	*Streptococcus faecalis* Group D *Enterococcus*
Enterococcus faecium	*Streptococcus faecium* Group D *Enterococcus*
Enterococcus gallinarum	*Streptococcus gallinarum*
Enterococcus gilvus	
Enterococcus hirae	
Enterococcus italicus	*Enterococcus saccharominimus*
Enterococcus malodoratus	
Enterococcus mundtii	
Enterococcus pallens	
Enterococcus pseudoavium	
Enterococcus raffinosus	
Facklamia hominis	
Facklamia ignava	
Facklamia languida	
Facklamia sourekii	
Gemella bergeriae	
Gemella haemolysans	*Neisseria haemolysans*
Gemella morbillorum	*Streptococcus morbillorum* *Peptostreptococcus morbillorum*
Gemella sanguinis	
Globicatella sanguinis	Salt-tolerant viridans streptococci
Granulicatella adiacens	*Abiotrophia adiacens* *Streptococcus adiacens* Nutritionally variant streptococci
Granulicatella elegans	*Abiotrophia elegans* Nutritionally variant streptococci
Granulicatella para-adiacens	
Helcococcus kunzii	
Helcococcus pyogenica	
Helcococcus sueciensis	
Ignavigranum ruoffiae	
Lactococcus garviae	*Streptococcus garvieae* Lancefield group N
Lactococcus lactis	
Leuconostoc citreum	
Leuconostoc cremoris	
Leuconostoc dextranicum	
Leuconostoc lactis	
Leuconostoc mesenteroides	
Leuconostoc pseudomesenteroides	
Oenococcus oeni	*Leuconostoc oenos*
Pediococcus acidilactici	
Pediococcus damnosus	
Pediococcus dextrinicus	
Pediococcus equinus	*Streptococcus equinus*
Pediococcus parvulus	
Pediococcus pentosaceus	
Streptococcus acidominimus

Streptococcus gordonii	
Streptococcus massiliensis	
Streptococcus parasanguis	
Streptococcus sanguis	
Streptococcus suis	
Tetragenococcus halophilus	*Enterococcus solitarius*
Vagococcus fluvialis	
Weissella paramesenteroides	*Leuconostoc paramesenteroides*

II. Anaerobic Gram-Positive Cocci
Characteristics: occur singly or in pairs, chains, or clumps

Anaerococcus octavius	*Peptostreptococcus octavius* *Peptostreptococcus prevotii* *Peptostreptococcus tetradius*
Anaerococcus hydrogenalis	*Peptostreptococcus hydrogenalis* *Peptostreptococcus lactolyticus*
Gemella morbillorum	*Streptococcus morbillorum*
Micromonas micros	*Peptostreptococcus micros*
Peptococcus niger	*Micrococcus niger*
Peptoniphilus asaccharolyticus	*Peptostreptococcus asaccharolyticus*
Peptoniphilus harei	*Peptostreptococcus harei*
Peptoniphilus ivorii	*Peptostreptococcus ivorii*
Peptoniphilus lacrimalis	*Peptostreptococcus lacrimalis*
Peptostreptococcus anaerobius	
Peptostreptococcus indolicus	*Peptococcus indolicus*
Peptostreptococcus magnus	*Peptococcus magnus* *Peptococcus variabilis*
Peptostreptococcus massiliae	
Peptostreptococcus stomatis	
Peptostreptococcus trisimilis	
Ruminococcus hansenii	*Streptococcus hansenii*
Ruminococcus productus	*Peptostreptococcus productus*

III. Aerobic Gram-Negative Cocci
Characteristics: occur singly or in pairs or clumps; catalase and oxidase positive

Lautropia mirabilis	*Sarcina mirabilis*
Neisseria canis	
Neisseria bacilliformis	
Neisseria cinerea	*Micrococcus cinereus* *Neisseria pharyngis*
Neisseria elongata subspecies *elongata*	*Neisseria elongata*
Neisseria elongata subspecies *glycolytica*	*Neisseria elongata*
Neisseria elongata subspecies *nitroreducens*	*Neisseria elongata* CDC group M-6
Neisseria flavescens	
Neisseria gonorrhoeae	
Neisseria kochii	
Neisseria lactamica	*Neisseria lactamicus*
Neisseria meningitidis	
Neisseria mucosa	
Neisseria parelongata	
Neisseria polysaccharea	
Neisseria sicca	
Neisseria subflava biovar *flava*	*Neisseria subflava*
Neisseria subflava biovar *perflava*	*Neisseria subflava*
Neisseria subflava biovar *subflava*	*Neisseria subflava*
Neisseria weaveri	*Moraxella* sp. M-5 CDC group M-5

IV. Anaerobic Gram-Negative Cocci
Characteristics: occur in pairs or clumps

Acidaminococcus fermentans	
Anaeroglobus geminatus	
Megasphaera elsdenii	*Peptostreptococcus elsdenii*
Megasphaera micronuciformis	
Subdoligranulum variabile	
Veillonella atypica	
Veillonella dispar	
Veillonella montpellierensis	
Veillonella parvula	

V. Aerobic Gram-Positive Bacilli
Characteristics: rodlike; catalase-negative or -positive; some are acid-fast stain-positive, and some have branching. Only *Bacillus*, *Brevibacillus*, and *Brevibacterium* spp. produce spores.

Actinomadura latina	
Actinomadura madurae	
Actinomadura pelletieri	
Amycolata autotrophica	
Amycolatopsis orientalis	*Nocardia orientalis* *Streptomyces orientalis*
Arcanobacterium bernardiae	*Actinomyces bernardiae* CDC coryneform group 2
Arcanobacterium haemolyticum	*Corynebacterium haemolyticum*
Arcanobacterium pyogenes	*Actinomyces pyogenes* *Corynebacterium pyogenes*
Arthrobacter albus

Clostridium coccoides	
Clostridium cochlearium	*Clostridium lentoputrescens*
Clostridium cocleatum	
Clostridium difficile	*Clostridium difficilis*
Clostridium fallax	*Clostridium pseudofallax*
Clostridium ghonii	*Clostridium ghoni*
Clostridium glycolicum	
Clostridium haemolyticum	*Clostridium novyi* type
Clostridium hastiforme	
Clostridium hathewayi	
Clostridium hiranonis	
Clostridium histolyticum	
Clostridium indolis	
Clostridium innocuum	
Clostridium irregulare	*Clostridium irregularis*
Clostridium leptum	
Clostridium limosum	CDC group P-1
Clostridium malenominatum	
Clostridium neonatale	
Clostridium novyi	
Clostridium oroticum	*Zymobacterium oroticum*
Clostridium paraputrificum	
Clostridium perfringens	*Clostridium welchii* *Welchia perfringens*
Clostridium piliforme	*Bacillus piliformis*
Clostridium putrefaciens	
Clostridium ramosum	*Eubacterium filamentosum* *Ramibacterium ramosum* *Actinomyces ramosus* *Eubacterium ramosum*
Clostridium scindens	
Clostridium septicum	
Clostridium sordellii	
Clostridium sphenoides	
Clostridium sporogenes	Nontoxigenic *Clostridium botulinum*
Clostridium subterminale	
Clostridium symbiosum	*Fusobacterium symbiosum* *Fusobacterium biacutus* *Bacteroides symbiosus*
Clostridium tertium	
Clostridium tetani	
Filifactor alocis	*Fusobacterium alocis*
Filifactor villosus	*Clostridium villosum*

VIII. Aerobic Gram-Negative Bacilli: Enterobacteriaceae

Characteristics: ferment sugars; are oxidase-negative; most reduce nitrate to nitrite. Diagnostic laboratories may report *Salmonella* serovars by name (e.g., *Salmonella typhi* or *Salmonella* serovar *typhi*).

Current Name	Synonym
Budvicia aquatica	
Buttiauxella noackiae	CDC enteric group 59
Cedecea davisae	CDC enteric group 15
Cedecea lapagei	
Cedecea neteri	*Cedecea* subspecies 4
Cedecea subspecies 3	
Cedecea subspecies 5	
Citrobacter amalonaticus	*Levinea amalonatica*
Citrobacter braakii	*Citrobacter freundii*
Citrobacter farmeri	*Citrobacter amalonaticus* biogroup 1
Citrobacter freundii	*Colobactrum freundii*
Citrobacter gillenii	*Citrobacter* genomospecies 10 *Citrobacter freundii*

Vibrio parahaemolyticus	
Vibrio vulnificus	CDC group EF-3 *Beneckea vulnifica*

X. Aerobic Gram-Negative Bacilli: Nonenterobacteriaceae; Nonfermentative
Characteristics: may or may not oxidize sugars; are catalase positive; are oxidase variable

Achromobacter piechaudii	*Alcaligenes piechaudii*
Achromobacter xylosoxidans subspecies *denitrificans*	*Alcaligenes denitrificans* *Alcaligenes xylosoxidans* subspecies *denitrificans* CDC group Vc
Achromobacter xylosoxidans subspecies *xylosoxidans*	*Alcaligenes xylosoxidans* *Alcaligenes xylosoxidans* subspecies *xylosoxidans* *Alcaligenes denitrificans* subspecies *xylosoxidans* *Achromobacter xylosoxidans* CDC groups IIIa and IIIb
Acidovorax delafieldii	*Pseudomonas delafieldii*
Acidovorax facilis	*Pseudomonas facilis*
Acidovorax temperans	*Pseudomonas temperans*
Acinetobacter baumannii	*Acinetobacter anitratus*
Acinetobacter baylyi	
Acinetobacter bouvetii	
Acinetobacter calcoaceticus	*Acinetobacter anitratus* *Acinetobacter calcoaceticus* subspecies *calcoaceticus*
Acinetobacter gerneri	
Acinetobacter grimontii	
Acinetobacter haemolyticus	*Acinetobacter anitratus*
Acinetobacter johnsonii	
Acinetobacter junii	*Acinetobacter anitratus*
Acinetobacter lwoffii	*Acinetobacter calcoaceticus* subspecies *lwoffi*

TABLE 90–1 Current Bacterial Nomenclature, Taxonomy, and Classification—cont'd

Current Name	Synonym
Acinetobacter parvus	
Acinetobacter radioresistens	
Acinetobacter schindleri	
Acinetobacter tandoii	
Acinetobacter tjernbergiae	
Acinetobacter towneri	
Acinetobacter ursingii	
Agrobacterium radiobacter	*Agrobacterium tumefaciens*
	CDC group Vd-3
Alcaligenes faecalis subspecies *faecalis*	*Alcaligenes odorans*
	Pseudomonas odorans
	CDC group VI
Asaia bogorensis	
Azospirillum brasilense	*Roseomonas fauriae*
	CDC "pink coccoid" group
Balneatrix alpica	
Bergeyella zoohelcum	*Weeksella zoohelcum*
	CDC group IIj
Brevundimonas diminuta	*Pseudomonas diminuta*
	CDC group Ia
Brevundimonas vesicularis	*Pseudomonas vesicularis*
	Corynebacterium vesiculare
Burkholderia ambifaria	
Burkholderia anthina	
Burkholderia cenocepacia	
Burkholderia cepacia	*Pseudomonas cepacia*
	Pseudomonas multivorans
	Pseudomonas kingae
	CDC group EO-1
Burkholderia dolosa	
Burkholderia gladioli	*Pseudomonas gladioli*
	Pseudomonas marginata
Burkholderia mallei	*Pseudomonas mallei*
	Actinobacillus mallei
Burkholderia multivorans	*Burkholderia cepacia* genomovar II
Burkholderia oklahomensis	
Burkholderia pseudomallei	*Pseudomonas pseudomallei*
Burkholderia pyrrocinia	
Burkholderia stabilis	*Burkholderia cepacia* genomovar IV
Burkholderia thailandensis	
Burkholderia vietnamiensis	*Burkholderia cepacia* genomovar V
Chryseobacterium gleum	*Flavobacterium gleum*
	CDC group IIb
Chryseobacterium indologenes	*Flavobacterium indologenes*
	CDC group IIb
Chryseobacterium massiliae	
Chryseobacterium timonae	
Comamonas terrigena	CDC group EF-19
Comamonas testosteroni	*Pseudomonas testosteroni*
Delftia acidovorans	*Comamonas acidovorans*
	Pseudomonas acidovorans
Elizabethkingia meningoseptica	*Chryseobacterium meningosepticum*
	Flavobacterium meningosepticum
	CDC group IIa
Elizabethkingia miricola	*Chryseobacterium miricola*
Empedobacter brevis	*Flavobacterium breve*
Flavobacterium group IIe	CDC group IIe
Flavobacterium group IIh	CDC group IIh
Flavobacterium group IIi	CDC group IIi
Granulibacter bethesdensis	
Inquilinus limosus	
Laribacter hongkongensis	
Massilia timonae	
Methylobacterium spp.	
Methylobacterium aminovarans	
Methylobacterium extorquens	
Methylobacterium fujisawaense	
Methylobacterium mesophilicum	
Methylobacterium organophilum	
Methylobacterium podarium	
Methylobacterium radiotolerans	
Methylobacterium rhodesianum	
Methylobacterium rhodinum	
Methylobacterium zatmanii	
Moraxella atlantae	CDC group M-3
Moraxella canis	
Moraxella catarrhalis	*Branhamella catarrhalis*
	Neisseria catarrhalis
Moraxella lacunata	*Moraxella liquefaciens*
Moraxella lincolnii	
Moraxella nonliquefaciens	
Moraxella osloensis	
Myroides odoratimimus	
Myroides odoratum	*Chryseobacterium odoratum*
	Flavobacterium odoratum
	CDC group M-4f
Ochrobactrum anthropi	*Achromobacter* spp. biotypes 1 and 2
	CDC groups Vd-1, Vd-2
Ochrobactrum intermedium	
Oligella ureolytica	CDC group IVe
Oligella urethralis	*Moraxella urethralis*
	CDC group M-4
Pandoraea apista	
Paracoccus yeei	*Paracoccus yeeii*
	CDC group EO-2
Photorhabdus asymbiotica	*Xenorhabdus luminescens*
Pseudomonas aeruginosa	*Pseudomonas pyocyanea*
	Bacterium aeruginosum
Pseudomonas alcaligenes	
Pseudomonas chlororaphis	*Pseudomonas aureofaciens*
Pseudomonas fluorescens	
Pseudomonas luteola	*Chryseomonas luteola*
	CDC group Ve-1
Pseudomonas mendocina	CDC group Vb-2
Pseudomonas oryzihabitans	*Flavimonas oryzihabitans*
	CDC group Ve-2
Pseudomonas otitidis	
Pseudomonas pertucinogena	*Bordetella pertussis* rough phase IV
Pseudomonas pseudoalcaligenes	*Pseudomonas alcaligenes* biotype B
Pseudomonas putida	
Pseudomonas stutzeri	CDC group Vb-1
Pseudomonas stutzeri–like	CDC group Vb-3
Psychrobacter immobilis	*Micrococcus cryophilus*
Psychrobacter phenylpyruvicus	*Moraxella phenylpyruvicus*
	CDC group M-2
Ralstonia spp.	CDC group IVc-2
Ralstonia pickettii	*Burkholderia pickettii*
	Pseudomonas pickettii
	CDC groups Va-1, Va-2, Va-3
	Pseudomonas thomasii
Roseomonas cervicalis	CDC "pink coccoid" group
Roseomonas genomospecies 4	CDC "pink coccoid" group
Roseomonas genomospecies 5	CDC "pink coccoid" group
Roseomonas genomospecies 6	CDC "pink coccoid" group
Roseomonas gilardii subspecies *gilardii*	
Roseomonas gilardii subspecies *rosea*	
Roseomonas mucosa	
Shewanella algae	
Shewanella putrefaciens	*Alteromonas putrefaciens*
	Pseudomonas putrefaciens
	CDC groups Ib-1, Ib-2

TABLE 90–1 Current Bacterial Nomenclature, Taxonomy, and Classification—cont'd

Current Name	Synonym
Sphingobacterium mizutae	*Flavobacterium mizutaii*
Sphingobacterium multivorum	*Flavobacterium multivorum*
	CDC group IIk-2
Sphingobacterium spiritivorum	*Flavobacterium spiritivorum*
	Sphingobacterium versatilis
	CDC group IIk-3
Sphingobacterium thalpophilum	*Flavobacterium thalpophilum*
Sphingobacterium yabuuchiae	
Sphingomonas parapaucimobilis	
Sphingomonas paucimobilis	*Pseudomonas paucimobilis*
	CDC group IIk-1
Sphingomonas sanguis	
Sphingomonas yanoikuyae	
Stenotrophomonas africana	
Stenotrophomonas maltophilia	*Xanthomonas maltophilia*
	Pseudomonas maltophilia
Wautersiella falsenii	
Weeksella virosa	*Flavobacterium genitale*
	CDC group IIf

XI. Anaerobic Gram-Negative Bacilli

Characteristics: may appear as rods with rounded ends, curved rods, coccobacilli, or slender, spindle-shaped rods with tapered ends. *Dialister* and *Johnsonella* belong to the *Clostridium* subphylum.

Alistipes finegoldii	
Alistipes onderdonkii	
Alistipes shahii	
Anaerobiospirillum succiniciproducens	
Anaerobiospirillum thomasii	
Anaerorhabdus furcosus	*Bacteroides furcosus*
Anaerostipes caccae	
Atopobium parvulus	
Bacteroides caccae	
Bacteroides capillosus	
Bacteroides coagulans	
Bacteroides dorei	
Bacteroides eggerthii	
Bacteroides finegoldii	
Bacteroides forsythus	
Bacteroides fragilis	
Bacteroides fragilis group	True *Bacteroides*
Bacteroides intestinalis	*Bacteroides putredinis*
	Alistipes putredinis
	Bacteroides furcosus
Bacteroides massiliae	
Bacteroides nordii	
Bacteroides ovatus	
Bacteroides putredinis	
Bacteroides pyogenes	*Bacteroides tectus*
Bacteroides salyersae	
Bacteroides splanchnicus	
Bacteroides stercoris	*Bacteroides fragilis* subspecies a
Bacteroides tectus	*Bacteroides tectum*
Bacteroides thetaiotaomicron	
Bacteroides uniformis	*Bacteroides corrodens*
Bacteroides ureolyticus	
Bacteroides vulgatus	
Bilophila wadsworthia	
Butyrivibrio fibrisolvens	
Catonella morbi	
Centipeda periodontii	
Cetobacterium somerae	
Desulfobulbus spp.	
Desulfomonas pigra	
Desulfovibrio fairfieldensis	
Desulfovibrio desulfuricans	
Desulfovibrio vulgaris	
Dialister invisus	
Dialister pneumosintes	*Bacteroides pneumosintes*
Dichelobacter nodosus	*Bacteroides nodosus*
Fusobacterium gonidiaformans	
Fusobacterium mortiferum	
Fusobacterium naviforme	
Fusobacterium necrogenes	
Fusobacterium necrophorum subspecies *funduliforme*	
Fusobacterium necrophorum subspecies *necrophorum*	
Fusobacterium nucleatum subspecies *fusiforme*	
Fusobacterium nucleatum subspecies *nucleatum*	
Fusobacterium nucleatum subspecies *polymorphum*	
Fusobacterium nucleatum subspecies *vincentii*	
Fusobacterium periodonticum	
Fusobacterium russii	
Fusobacterium sulci	
Fusobacterium ulcerans	
Fusobacterium varium	*Fusobacterium pseudonecrophorum*
Johnsonella ignava	
Leptotrichia amnionii	
Leptotrichia buccalis	
Leptotrichia goodfellowii	
Leptotrichia hofstadii	
Leptotrichia shahii	
Leptotrichia trevisanii	
Leptotrichia wadei	
Mitsuokella multacida	*Mitsuokella multiacida*
	Bacteroides multiacidus
Olsenella profuse	
Olsenella uli	
Parabacteroides distasonis	*Bacteroides distasonis*
Parabacteroides goldsteinii	*Bacteroides goldsteinii*
Parabacteroides merdae	*Bacteroides merdae*
	Bacteroides fragilis T4-1
Porphyromonas asaccharolytica	*Bacteroides asaccharolyticus*
	Bacteroides melaninogenicus subspecies *asaccharolyticus*
Porphyromonas cangingivalis	
Porphyromonas canoris	
Porphyromonas cansulci	
Porphyromonas catoniae	*Oribaculum catoniae*
Porphyromonas circumdentaria	
Porphyromonas crevioricanis	
Porphyromonas endodontalis	*Bacteroides endodontalis*
Porphyromonas gingivalis	*Bacteroides gingivalis*
Porphyromonas gingivicanis	
Porphyromonas ulae	
Porphyromonas levii	*Bacteroides levii*
	Bacteroides melaninogenicus subspecies *levii*
Porphyromonas macacae	*Bacteroides macacae*
	Porphyromonas salivosa
Porphyromonas salivosa	
Porphyromonas somerae	
Prevotella bergensis	
Prevotella bivia	*Bacteroides bivius*
Prevotella buccae	*Bacteroides buccae*
	Bacteroides ruminicola subspecies *brevis*
	Bacteroides capillus
	Bacteroides pentosaceus
Prevotella buccalis	*Bacteroides buccalis*
Prevotella corporis	*Bacteroides corporis*

TABLE 90–1 Current Bacterial Nomenclature, Taxonomy, and Classification—cont'd

Current Name	Synonym
Prevotella dentalis	*Mitsuokella dentalis*
	Hallella seregens
Prevotella denticola	*Bacteroides denticola*
Prevotella disiens	*Bacteroides disiens*
Prevotella enoeca	
Prevotella heparinolytica	*Bacteroides heparinolyticus*
Prevotella intermedia	*Bacteroides intermedius*
	Bacteroides melaninogenicus subspecies *intermedius*
Prevotella loescheii	*Bacteroides loescheii*
Prevotella massiliensis	
Prevotella melaninogenica	*Bacteroides melaninogenicus*
	Bacteroides melaninogenicus subspecies *melaninogenicus*
Prevotella nigrescens	*Prevotella intermedia*
Prevotella oralis	*Bacteroides oralis*
Prevotella oris	*Bacteroides oris*
	Bacteroides ruminicola subspecies *brevis*
Prevotella oulorum	*Bacteroides oulorum*
	Prevotella oulora
Prevotella pallens	
Prevotella salivae	
Prevotella shahii	
Prevotella tannerae	
Prevotella veroralis	*Bacteroides veroralis*
Prevotella zoogleoformans	*Bacteroides zoogleoformans*
Selenomonas artemidis	
Selenomonas dianae	
Selenomonas flueggei	
Selenomonas infelix	
Selenomonas noxia	
Selenomonas sputigena	
Sneathia sanguinegens	*Leptotrichia sanguinegens*
Sutterella wadsworthensis	
Synergistes cluster I	
Synergistes cluster II	
Tannerella forsythus	*Bacteroides forsythus*
	Tannerella forsythensis
Tissierella praeacuta	*Bacteroides praeacutus*

XII. Aerobic Gram-Negative Fastidious Coccobacilli

Characteristics: small, curved or straight gram-negative bacilli or coccobacilli. They may require carbon dioxide and enriched media or special conditions for adequate growth.

Actinobacillus arthritidis	*Actinobacillus lignieresii*	
Actinobacillus equuii		
Actinobacillus hominis		
Actinobacillus ureae	*Pasteurella ureae*	
Afipia broomeae		
Afipia clevelandensis		
Afipia felis		
Aggregatibacter actinomycetemcomitans	*Actinobacillus actinomycetemcomitans*	CDC groups HB-3, HB-4
Aggregatibacter aphrophilus	*Haemophilus aphrophilus*	CDC group HB-2
Aggregatibacter paraphrophilus	*Haemophilus paraphrophilus*	
Aggregatibacter segnis	*Haemophilus segnis*	
Arcobacter butzleri	*Campylobacter butzleri*	
Arcobacter cryaerophilus	*Campylobacter cryaerophila*	
Bartonella alsatica		
Bartonella bacilliformis		
Bartonella clarridgieae		
Bartonella elizabethae	*Rochalimaea elizabethae*	
Bartonella grahamii		
Bartonella henselae	*Rochalimaea henselae*	
Bartonella koehleras		
Bartonella quintana	*Rochalimaea quintana*	
Bartonella vinsonii subspecies *arupensis*	*Rochalimaea vinsonii*	
Bartonella vinsonii subspecies *berkhoffii*		
Bartonella washoensis		
Bordetella bronchiseptica	CDC group IVa	
Bordetella hinzii		
Bordetella holmesii	CDC group NO-2	
Bordetella parapertussis		
Bordetella pertussis		
Bordetella trematum		
Brucella abortus		
Brucella canis		
Brucella melitensis		
Brucella suis		
Campylobacter coli		
Campylobacter concisus	CDC group EF-22	
Campylobacter curvus	*Wolinella curva*	
Campylobacter fetus subspecies *fetus*	*Vibrio fetus*	
Campylobacter fetus subspecies *venerealis*		
Campylobacter gracilis	*Bacteroides gracilis*	
Campylobacter hominis		
Campylobacter hyointestinalis subspecies *hyointestinalis*		
Campylobacter jejuni subspecies *doylei*		
Campylobacter jejuni subspecies *jejuni*		
Campylobacter lari	*Campylobacter laridis*	
Campylobacter mucosalis		
Campylobacter rectus	*Wolinella recta*	
Campylobacter showae		
Campylobacter sputorum subspecies *paraureolyticus*		
Campylobacter sputorum subspecies *sputorum*		
Campylobacter upsaliensis		
Campylobacter ureolyticus	*Bacteroides ureolyticus*	
Capnocytophaga canimorsus	CDC group DF-2	
Capnocytophaga cynodegmi	CDC group DF-2	
Capnocytophaga gingivalis	CDC group DF-1	
Capnocytophaga granulosa		
Capnocytophaga haemolytica		
Capnocytophaga ochracea	CDC group DF-1	
Capnocytophaga sputigena	CDC group DF-1	
Cardiobacterium hominis	CDC group IId	
Cardiobacterium valvarum		
Chlamydophila avium		
Chlamydophila pneumoniae	*Chlamydia pneumoniae*	TWAR
Chlamydophila psittaci	*Chlamydia psittaci*	
Chlamydophila trachomatis	*Chlamydia trachomatis*	
Chromobacterium violaceum		
Coxiella burnetii		
Dysgonomonas capnocytophagoides	CDC group DF-3	
Dysgonomonas gadei		
Ehrlichia spp.	Human granulocytic ehrlichiosis	
Ehrlichia canis		
Ehrlichia chaffeensis	Human monocytic ehrlichiosis	
Ehrlichia ewingii		
Ehrlichia sennetsu		
Eikenella corrodens	CDC group HB-1	
Francisella philomiragia	*Yersinia philomiragia*	
Francisella tularensis biovar *mediaasiatica*		

TABLE 90–1 Current Bacterial Nomenclature, Taxonomy, and Classification—cont'd

Current Name	Synonym
Francisella tularensis biovar *novicida*	*Francisella novicida* *Pasteurella tularensis* *Bacterium tularense*
Francisella tularensis biovar *palearctica*	*Francisella tularensis* type B *Bacterium tularense*
Francisella tularensis biovar *tularensis*	*Francisella tularensis* type A *Pasteurella tularensis* *Bacterium tularense*
Haemophilus ducreyi	
Haemophilus haemolyticus	
Haemophilus influenzae	*Haemophilus aegyptius*
Haemophilus parahaemolyticus	
Haemophilus parainfluenzae	
Helicobacter bilis	
Helicobacter cinaedi	*Campylobacter cinaedi*
Helicobacter bizzozeronii	
Helicobacter canadensis	
Helicobacter canis	
Helicobacter fennelliae	*Campylobacter fennelliae*
Helicobacter heilmannii	*Gastrospirillum hominis*
Helicobacter pullorum	
Helicobacter pylori	*Campylobacter pylori*
Helicobacter rappini	*Flexispira rappini*
Helicobacter westmeadii	
Helicobacter winghamensis	
Kingella denitrificans	CDC group TM-1
Kingella kingae	*Moraxella kingae* *Moraxella kingii*
Kingella oralis	
Kingella potus	
Legionella anisa	
Legionella birminghamensis	
Legionella bozemanii	*Fluoribacter bozemanae*
Legionella cincinnatiensis	
Legionella dumoffii	*Fluoribacter dumoffii*
Legionella feeleii	
Legionella gormanii	
Legionella hackeliae	
Legionella israelensis	
Legionella jordanis	
Legionella lansingensis	
Legionella longbeachae	
Legionella maceachernii	
Legionella micdadei	*Tatlockia micdadei*
Legionella oakridgensis	
Legionella pneumophila	
Legionella sainthelensi	
Legionella tucsonensis	
Legionella wadsworthii	
Orientia tsutsugamushi	*Rickettsia tsutsugamushi*
Rickettsia aeschlimannii	
Rickettsia africae	
Rickettsia akari	
Rickettsia amblyommii	
Rickettsia australis	
Rickettsia canadensis	
Rickettsia conorii subspecies *caspia*	
Rickettsia conorii subspecies *conorii*	
Rickettsia conorii subspecies *indica*	
Rickettsia conorii subspecies *israelensis*	
Rickettsia felis	
Rickettsia helvetica subspecies *heilongjiangensis*	
Rickettsia helvetica subspecies *mongolotimonae*	
Rickettsia helvetica subspecies *sibirica*	
Rickettsia honei	
Rickettsia japonica	
Rickettsia marmionii	
Rickettsia massiliae	
Rickettsia parkeri	
Rickettsia prowazekii	
Rickettsia rickettsii	
Rickettsia sibirica	
Rickettsia slovaca	
Rickettsia texiana	
Rickettsia typhi	
Streptobacillus moniliformis	*Haverhillia multiformis*
Suttonella indologenes	*Kingella indologenes*
XIII. Mycoplasma (Pleuropneumonia-like Organisms [PPLO]) **Characteristics: small, highly pleomorphic organisms that are difficult to observe with routine stains; require complex medium for growth**	
Acholeplasma laidlawii	
Mycoplasma amphoriforme	
Mycoplasma buccale	
Mycoplasma faucium	
Mycoplasma fermentans	*Mycoplasma incognitus*
Mycoplasma gallisepticum	
Mycoplasma genitalium	
Mycoplasma hominis	
Mycoplasma lipophilum	
Mycoplasma orale	
Mycoplasma penetrans	
Mycoplasma pirum	
Mycoplasma pneumoniae	
Mycoplasma primatum	
Mycoplasma salivarium	
Mycoplasma spermatophilum	
Mycoplasma synoviae	
Ureaplasma parvum	
Ureaplasma urealyticum	T-mycoplasma
XIV. Treponemataceae (Spiral Organisms) **Characteristics: filamentous, spiral organisms that may or may not stain with usual laboratory stains; require complex media or animal host for growth**	
Borrelia afzelii	
Borrelia andersonii	
Borrelia anserina

SUBSECTION 1

Gram-Positive Cocci

CHAPTER 91

STAPHYLOCOCCUS AUREUS INFECTIONS (COAGULASE-POSITIVE STAPHYLOCOCCI)

Sheldon L. Kaplan ❂ Kristina G. Hulten ❂ Edward O. Mason

Staphylococcus aureus is a gram-positive coccus that occurs in pairs, chains, and grapelike clusters (Fig. 91–1). *S. aureus* is ubiquitous in nature and can be pathogenic for humans and animals. Staphylococci are nonmotile, aerobic, or facultative anaerobic and are readily cultivated on routine laboratory media.

These organisms are part of the normal human flora. *S. aureus* is responsible for an impressive variety of diseases ranging from minor skin and soft tissue infections to major life-threatening and fatal infections such as bacteremia, endocarditis, pericarditis, pneumonia, empyema, osteomyelitis, myositis, and septic arthritis.

On blood agar, *S. aureus* forms round, convex, shiny opaque colonies 1 to 4 mm in diameter, often with a zone of clear beta-hemolysis (Fig. 91–2) surrounding the colony. Production of pigment is variable, with strains exhibiting a yellow or golden pigment on primary isolation; yellow pigment actually is an *S. aureus* virulence factor.[132] *S. aureus* secretes free coagulase, the basis for the most definitive and most accepted method for identifying pathogenic staphylococci associated with human and animal infection. Free coagulase reacts with coagulase activator in plasma and converts fibrinogen to fibrin, with the formation of a fibrin clot. Coagulase also can be evaluated by testing for bound coagulase or clumping factor in a rapid slide test (Fig. 91–3). Clumping factor bound to the organism acts directly on fibrinogen and converts it to fibrin; it is detected by visible clumping or agglutination when a suspension is incubated with plasma. The bound coagulase test is used frequently in clinical laboratories and is faster than the tube coagulase test. However, the slide test for clumping factor may be falsely negative in 10 to 15 percent of cases. Thus, a negative slide coagulase test with an isolate that is highly suggestive of *S. aureus* should be confirmed with a tube coagulase test for free coagulase.[120,174] A limited number of biochemical reactions can differentiate *S. aureus* from other staphylococci (Table 91–1).

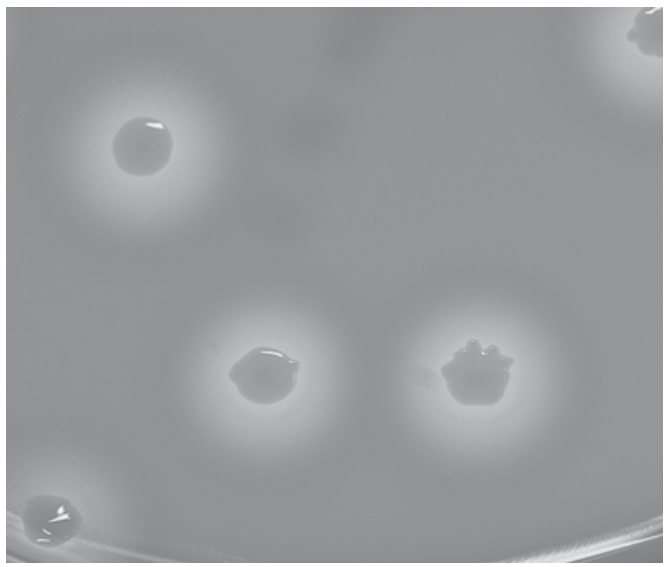

Figure 91–2 Typical hemolysis produced by *Staphylococcus aureus* on sheep blood agar. (See companion Expert Consult web site for color version.)

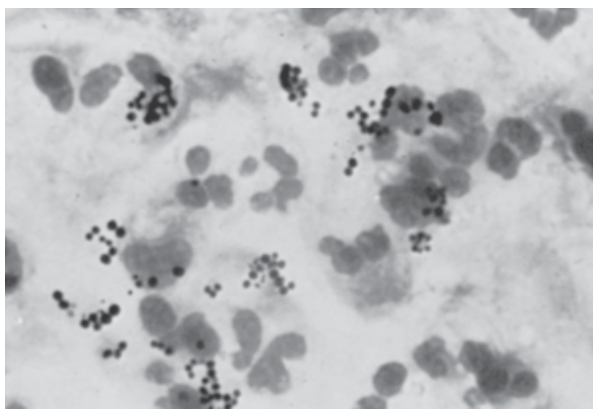

Figure 91–1 Staphylococci in pus. The organisms tend to form clusters, are round, and stain purple with Gram stain (positive), similar to bunches of grapes.

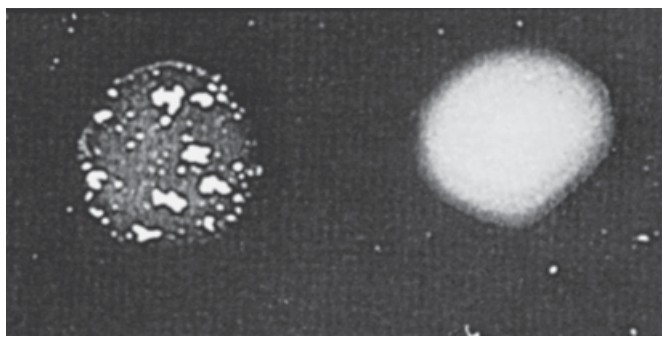

Figure 91–3 Bound (slide) coagulase test. A suspension of organisms is mixed with plasma. Immediate clumping (reaction on the *left*) indicates both the presence of bound coagulase and the fact that the organism is coagulase-positive.

STRUCTURE

CAPSULE

Capsule production often is considered a virulence factor and frequently is used by bacteria to hinder phagocytosis by the host.[159] Karakawa and colleagues described a scheme of eight *S. aureus* capsular types in 1982.[110] Subsequently, Sompolinsky and coworkers described three more serotypes, bringing the total number to 11.[199] Most *S. aureus* organisms are encapsulated to a varying degree (Fig. 91–4). Two serotypes (1 and 2) produce mucoid colonies on agar media but are rare among clinical isolates.[199] Serotypes 5 and 8 account for approximately 75 percent of strains recovered from infections in humans. In practice, strains that do not belong to serotypes 1, 2, 5, or 8 are referred to as *nontypeable*.[93] The role of capsule polysaccharide (CP) in virulence comes primarily from studies of CP5 and CP8 and is not completely clear. These studies show that inhibition of phagocytosis by capsule can result in persistence on surfaces but modulates adherence to endothelial surfaces.[159] A protein conjugate vaccine composed of CP5 and CP8 conjugated to nontoxic recombinant *Pseudomonas aeruginosa* exotoxin A (StaphVAX) initially appeared promising in prevention of *S. aureus* bacteremia in patients undergoing hemodialysis.[192] However, in a larger study, this vaccine was not found to be efficacious.[190]

PROTEIN A

Staphylococcal protein A, a major component of the cell wall of coagulase-positive staphylococci, has been found to bind to the Fc portion of immunoglobulin G (IgG). This binding is nonimmune. It differs from specific antigen-antibody reactions in that the reaction is nonspecific, although both precipitation and agglutination are observed. Protein A binds the IgG of many mammalian species. This property has rendered protein A a major reagent in many immune assays. Protein A also has been found to bind to platelets through the platelet gC1qr, a 33-kd cell protein[158] as well as to von Willebrand factor,[87] both of which may be important in the pathogenesis of endovascular infections caused by *S. aureus*. Protein A plays a central role in the pathogenesis of staphylococcal pneumonia in that TNFR1, a receptor for tumor necrosis factor-α (TNF-α), also is a receptor for protein A, and thus protein A is a principal staphylococcal proinflammatory factor in the lung.[74]

EXTRACELLULAR PRODUCTS

S. aureus elaborates a wide variety of extracellular toxins, many of which have potent biologic effects in the isolated state on intact animals, tissues, cells, and membranes. These toxins generally are thought to be responsible for the virulence of *S. aureus*, and the role of several of these products in staphylococcal infections has been proved definitively in humans. The important staphylococcal extracellular products include the following: alpha-, beta-, and delta-hemolysins; coagulases; leukocidin; hyaluronidase; staphylokinase; bacteriocins; the epidermolytic toxins; toxic shock syndrome toxin type I (TSST-I); and the enterotoxins.

Almost half of the known toxins and virulence genes in *S. aureus* are found in pathogenicity islands. These genetic clusters, commonly 15 to 20 kb in size, also contain genetic elements such as integrases and transposases. A high genetic instability is associated with many of these islands, and mosaic structures are common findings. Seven pathogenicity islands (νSa) have been associated with *S. aureus*.[68] Table 91–2 illustrates some of the features described for these islands, although allelic variations in gene content occur. All sequenced strains of *S. aureus* contain variations of the νSaα, νSaβ, and νSaγ.[47,68,94] In addition to the pathogenicity islands, virulence genes are also located on prophages (e.g., *lukS-PV* and *lukF-PV* on SLT).

HEMOLYSINS

Alpha-hemolysin is produced by most *S. aureus* isolates and is a classic pore-forming bacterial toxin. The purified toxin has impressive hemolytic, dermonecrotic, and lethal properties. Advances in protein purification have allowed pure toxin to be produced; this development, in turn, has led to a better understanding of its properties.

The protein interacts with and damages a variety of cell membranes, releases hemoglobin from erythrocytes of various mammalian and avian species, and is cytotoxic to numerous cell lines in tissue culture. It lyses rabbit and human platelets and disrupts lysosomes. It causes contraction in skeletal and vascular smooth muscle, an action that perhaps explains its property of causing localized dermal necrosis. In a rat model, alpha-toxin damages the air-blood barrier in vivo during *S. aureus* pneumonia.[143] Alpha-toxin forms pores in the membranes of endothelial cells; this process leads to vasoconstriction and increases vascular permeability, as well as having effects that cause apoptosis of numerous different cells.[49]

Injection of alpha-toxin is lethal to mammals and reptiles; death occurs within 2 to 5 minutes. Human death has been attributed to preformed alpha-toxin on at least one occasion. Anti–alpha-toxin can be demonstrated in physiologically normal persons; however, the level of anti–alpha-hemolysin is high in approximately 70 percent of patients with staphylococcal osteomyelitis.[208] In humans and experimental animals, the presence of anti–alpha-hemolysin neither modifies nor prevents staphylococcal infection.

The other hemolytic toxins, beta- and delta-hemolysin, also possess hemolytic and cytotoxic activities. In addition, beta-toxin produces lethal and dermonecrotic effects. Eighty to 100 percent of adults possess antibody to beta-hemolysin.

Despite evidence that these toxins are produced during infection, their roles in production of the typical staphylococcal tissue lesion remain unclear.[21,49] Although these toxins may be important in the establishment of infection by interacting with each other and with other biologically active staphylococcal products, this theory has not been proved; infection is not prevented by antitoxin antibody, and virulent staphylococci that lack one or more of these toxins are encountered.[197]

A recent in vitro study using proteomics (two-dimensional gel electrophoresis coupled with automated direct infusion-tandem mass spectrometry [ADI-MS/MS] analysis) showed that alpha-toxin was present in culture supernatants seven- to ninefold greater in the USA300 compared with the USA400 strain when grown at mid-exponential and stationary phases of growth.[31] Further studies of the way in which exotoxins influence strain-induced disease and host response are warranted.

LEUKOCIDIN

Although certain hemolysins are toxic to various leukocytes, the Panton-Valentine leukocidin (PVL) is the only known extracellular toxin that attacks the leukocyte exclusively.[166] It consists of two protein components, LukS-PV and LukF-PV, encoded by the genes *lukS-PV* and *lukF-PV* carried on a bacteriophage, that synergistically cause pores in polymorphonuclear leukocytes and macrophages.[26] Leukocidin injected into rabbits causes a striking fall in levels of circulating and bone marrow leukocytes, followed by marked granulocytosis; these changes occur without death of the rabbits. Leukocidin interacts with the membrane phospholipid and causes depolarization, increased permeability, and cell death. Local secretion of leukocidin may appear to confer an advantage to the staphylococcus by killing leukocytes and thereby preventing phagocytosis and intracellular killing. Levels of anti-leukocidin rise rapidly in the course of infection,[71,99] and some evidence indicates that infants and mothers with high levels of anti-leukocidin antibody are less likely to contract staphylococcal disease in high-risk epidemiologic situations.[17]

In early studies, only a few *S. aureus* isolates recovered from humans were *pvl*-positive.[171] Interest in PVL greatly increased following reports that *S. aureus* isolates carrying *pvl* genes were associated with severe furunculosis[41] and, particularly, necrotizing pneumonia in children and adolescents that frequently was fatal.[70,128] Furthermore, the independent emergence worldwide of community-acquired methicillin-resistant *S. aureus* (CA-MRSA) clones that generally carry the *pvl* genes led to further studies of the role of PVL in the pathogenesis of *S. aureus* infections.[215] The USA300 CA-MRSA clone especially has been linked to *pvl*.[150,151] In children with invasive *S. aureus* osteomyelitis, the presence of *pvl* genes was associated with greater local and systemic inflammation, longer duration of fever, greater frequency of positive blood cultures, and more frequent complications such as the development of chronic osteomyelitis or venous thrombosis.[24,140] Pulmonary manifestations also occurred more frequently among children with invasive *S. aureus* infections caused by *pvl*-positive isolates.[75] In adults with staphylococcal pneumonia, *pvl*-positive isolates were associated with increased rates of mortality.[134] Thus, the presence of *pvl* genes may be a marker for isolates capable of causing more severe disease.[56]

The contribution of PVL to the severity of *S. aureus* infections has been examined in mice using isogenic *pvl*-positive or *pvl*-negative isolates. One study found no difference in lethality for sepsis or abscess volume in a skin abscess model,[219] as well as no difference in the destruction of human neutrophils by the isogenic strains. The investigators concluded that PVL was not a major virulence determinant of CA-MRSA. The other study found that *pvl*-positive isolates caused much greater lung inflammation and necrosis in a mouse acute pneumonia model.[118] PVL was detected in the infected lung tissues. These investigators also discovered that staphylococcal protein A is more highly expressed in *pvl*-positive strains and postulated that PVL coupled with increased staphylococcal protein A could result in greater tissue inflammation than that found with *pvl*-negative strains. The discrepancy in these studies may be explained by the use of different *S. aureus* isolates as well as different models of infection.

Although the exact role of PVL in *S. aureus* infections has not been fully established, treatment measures directed against PVL have been proposed and include the preferred use of

protein-inhibiting antibiotics rather than or in addition to bactericidal antibiotics to decrease production of PVL,[51,202] as well as adjunctive administration of intravenous immunoglobulin preparations containing antibody to PVL.[67]

ENZYMES

Staphylococci elaborate a variety of enzymes, including hyaluronidase, nuclease, proteases, lipase, catalase, lysozyme, and lactate dehydrogenase, that may play a role in the spread of infection in local tissues or the establishment of a nidus of infection. Other biologically active extracellular products, as yet unidentified, undoubtedly are produced by the staphylococcus. The potency and number of these weapons in the armamentarium of the coagulase-positive staphylococcus, in contrast to the small number of extracellular products associated with the much less virulent coagulase-negative staphylococcus, suggest that the synergistic action of these toxins and enzymes may explain the superior ability of coagulase-positive staphylococci to establish infection and cause tissue necrosis. Several extracellular toxins have been proved to have specific roles in staphylococcal infection or disease: the epidermolytic toxins, TSST-I, and the enterotoxins.

EPIDERMOLYTIC TOXINS

Two biochemically and immunologically distinct exotoxins, epidermolytic toxins A and B (epidermolysins, exfoliatins), can separate adjacent cell layers within the epidermis and can cause the various skin manifestations of the staphylococcal scalded skin syndrome (SSSS). The toxin acts extracellularly; it does not induce cell death directly or lysis of the cell membrane or elicit an inflammatory response. This toxin does not damage any organ or cell, except those of the upper epidermis.[53,127,147] These low-molecular-weight (≈24,000 d) protein exotoxins now are known to hydrolyze desmoglein-1, an important structural skin protein.[9] Exfoliatin toxin D has been described but has not been associated with bullous impetigo or SSSS.[231]

TOXIC SHOCK SYNDROME TOXIN TYPE I

TSST-I was discovered independently in 1981 by two research groups. It was documented to be an excellent marker for staphylococci associated with vaginal toxic shock syndrome (TSS), in which it correctly identified more than 90 percent of strains in blinded testing. In experimental animal models, purified TSST-I can induce the major physiologic changes of TSS: fever, mucous membrane suffusion, renal impairment, hepatic damage, hypocalcemia, lymphocytopenia, and hypotension. TSST-I can be detected in blood, pus, urine, and tissues during human and experimental model TSS. USA300, the major CA-MRSA clone in the United States, does not carry the gene encoding TSST-1.[151] TSS is discussed in Chapter 71.

ENTEROTOXINS

Multiple different staphylococcal exotoxins (enterotoxins A to Q) have been identified, and most of them cause emesis in primates.[49] The toxins are heat-stable and resist boiling. Therefore, once sufficient toxin has formed within food, even heating or boiling will not inactivate the toxin. Foods involved in outbreaks of food poisoning frequently have been inoculated by a lesion on the hand of a food handler in situations in which the food is then held at temperatures that allow bacterial growth (between 25° C and 60° C) to occur for some time before the food is served. Foods implicated in particular are ham, salads with starch and mayonnaise, salami, poultry, cream sauces, pastries, and dairy products. The mode of action of enterotoxins is not understood completely, but vomiting appears to be induced through receptors in the abdominal viscera that lead to an emetic response.[29] Intravenous injection of purified enterotoxins in laboratory animals causes hypotension, cardiovascular collapse, and death. The significance of these properties of enterotoxins in naturally occurring human infections is unknown, although they may be linked to clinical syndromes, including TSS. Enterotoxin A often is elaborated with TSST-I in menstrual-associated TSS, but it also is elaborated without TSST-I in patients with septicemia in whom TSS does not develop. Staphylococcal enterotoxin B, most often isolated in phage group V organisms, is associated with local infections and pneumonia.[139] USA300 strains typically do not contain the genes encoding most enterotoxins, but they frequently have the genes for enterotoxins Q and K.[46] In contrast, USA400 isolates may carry many of the enterotoxin genes, including enterotoxin H, which is unique among the other *S. aureus* genomes.[14,156]

STAPHYLOCOCCUS AUREUS MSCRAMMs

Bacterial adherence to host tissues is mediated by numerous bacterial surface components or adhesins that recognize and bind to host extracellular matrix and cell surface molecules.[98] The subfamily of adhesins that bind to the extracellular matrix is known as Microbial Surface Components Recognizing Adhesive Matrix Molecules (MSCRAMMs). For *S. aureus*, important MSCRAMMs are protein A, fibronectin-binding proteins (A and B), clumping factors A and B (fibrinogen-binding proteins), and collagen-binding protein (cna).[63] Many other less well characterized adhesins also have been identified from the *S. aureus* genome.[181] The MSCRAMMs are linked to bacterial wall peptidoglycan following sortase cleavage of the LPXTG (LeuProX-ThrGly) motif that is a conserved C-terminal cell wall sorting signal among the adhesins.[36] Fibronectin-binding proteins play a role in *S. aureus* invasion into endothelial cells.[24,98] Collagen adhesin protein may contribute to the pathogenesis of *S. aureus* musculoskeletal infections,[52,164] although both animal studies and clinical studies are conflicting in this area.[100,184] USA300 CA-MRSA isolates do not carry the gene for cna, yet osteomyelitis is the most common CA-MRSA invasive infection in children.[140]

Clumping factor A has been the target for protective immunity in the prevention of *S. aureus* infections, and this approach has been successful in experimental models.[217] The safety and pharmacokinetics of an intravenous immunoglobulin preparation enriched for antibody to clumping factor A were established in low-birth-weight infants; however, a large randomized trial did not document efficacy in prevention of staphylococcal infections in this population.[23] A monoclonal antibody (tefibazumab [Aurexis]) directed against clumping factor A has undergone preliminary evaluation as adjunctive therapy of *S. aureus* bacteremia in adults.[224]

REGULATION

Bacterial pathogenesis is reliant on cell population, density-dependent gene expression. This quorum sensing acts to adjust the production of accessory genes (e.g., virulence genes), depending on the needs of the cell. Studies have shown that in low-density populations, when the bacterial cells are multiplying, accessory genes are either turned off or are expressed at a low level to the advantage of other genes, such as genes involved in cell wall formation. In high-density bacterial populations, expression of the accessory genes is increased. The accessory gene

regulator, agr, is genus specific, and the effector molecule is a regulatory RNA molecule, named RNAIII. Many staphylococcal toxins and virulence factors are under the regulation of agr.[1,13,28] The staphylococcal accessory regulator, sar, is another global regulator in *S. aureus*. The effector peptide, SarA, is a DNA-binding protein. In animal models of infection, both RNAIII and Sar A have been shown to affect virulence. In addition to agr and sar, several other factors have been described that affect accessory gene regulation.[22] Thus, the complex network of regulatory operons that act on each other or directly on specific genes is not completely understood.

STAPHYLOCOCCAL L-FORMS AND SMALL-COLONY VARIANTS

L-forms are staphylococcal variants with impaired or absent cell walls. L-forms can be induced in vitro by growing staphylococci in hypertonic media, in the presence of the muralytic enzyme lysostaphin, or with the addition of antibiotics that inhibit the formation of cell walls, such as the penicillin-methicillin group, cycloserine, and vancomycin. These L-forms, or protoplasts, require hypertonic environments for survival, do not accept Gram stain, and are resistant to cell wall–inhibiting antibiotics. Under favorable conditions, L-forms revert to complete bacteria with cell walls.

Clinical interest in L-forms has arisen because of concern that antibiotics may induce these forms in vivo. L-forms then could persist in the host in a latent or less virulent phase and revert to a fully virulent state at some time when antibiotics no longer are present. Identification of L-forms in specimens from human infection or in infected animals treated with antibiotics has been reported exceedingly rarely, despite considerable effort.[220] The presence of latent L-forms remains an attractive hypothesis to explain the well-known tendency of staphylococcal infections to persist and recur. Despite extensive laboratory and clinical investigation, no evidence has demonstrated that L-forms are important causes of bacterial persistence in clinical infections.

Small-colony variants of *S. aureus* are isolates with atypical colony morphology, decreased hemolysis and pigmentation, decreased growth rate, and unusual biochemical characteristics that result in difficulty isolating and identifying these organisms.[216] Small-colony variants also have been implicated in persistent and recurrent *S. aureus* infections including osteomyelitis,[172] brain abscesses, and pulmonary infections in patients with cystic fibrosis.[104,188] Small-colony variants can persist intracellularly and often are more resistant to antibiotics than is the parent strain, and antibiotics that penetrate cells (e.g., rifampin) may be advantageous in their treatment.[173]

TYPING METHODS

Staphylococcal strains were characterized historically by bacteriophage typing (World Health Organization method).[18] In the 1990s, pulsed-field gel electrophoresis (PFGE) became the gold standard for strain typing used by both reference and research laboratories.[210] The method has proven to be reliable and reproducible, and the use of digital imaging and band analysis has enhanced the quality of inter-gel comparisons. The Centers for Disease Control and Prevention (CDC) used the PFGE method to define and interrelate staphylococcal clones circulating in the United States and designated these 11 clones USA100 to USA1100 (available through the Network on Antimicrobial Resistance of *Staphylococcus aureus* [NARSA] at http://www.narsa.net).[142]

Multilocus sequence typing (MLST) is a nucleotide sequence-based method, adapted from multilocus enzyme electrophoresis (MLEE). In MLST typing, the alleles at each locus of seven housekeeping genes (*arc*C, *aro*E, *glp*F, *gmk*, *pta*, *tpi*, and *yqi*L) are determined through polymerase chain reaction (PCR) amplification, nucleotide sequencing, and submission of sequence data through computer Web site to the MLST database (http://www.mlst.net).[54] In this database, strains can be compared with strains submitted by other investigators, and within-laboratory comparisons with control strains thus have become obsolete.

spa typing was developed based on the polymorphic X or the short sequence repeat (SSR) region of the protein A gene.[194] *spa* typing has some advantages over PFGE in terms of speed, interpretation, and exportability; the main limitation is the single locus-based design.[84] Less commonly used methods include repetitive element PCR (rep-PCR), restriction fragment length polymorphism (RFLP), and toxin typing.

STAPHYLOCOCCUS AUREUS CLONES IN THE HOSPITAL AND IN THE COMMUNITY

Of the methods mentioned earlier, MLST has been especially useful in dividing *S. aureus* strains into lineages (or clonal clusters). Frequently, these clones are described in the literature by their sequence type followed by the staphylococcal cassette chromosome *mec* (SCC*mec*) type (e.g., ST8-IV). Most human *S. aureus* strains belong to 1 of 10 independent lineages. Five major clonal clusters (CCs) that have been described to contain a majority of the human MRSA strains are CC5, CC8, CC22, CC30, and CC45. Of these, MRSA clones within the CC5 and CC8 clusters have been recognized as the main causes of hospital outbreaks worldwide.[38] Examples of widespread hospital MRSA clones are EMRSA15-ST22, EMRSA16 (ST36-II), the Archaic (ST250-I or 247-I), the Pediatric (ST5-IV), and the Brazilian (ST239-III) clones.[73]

Although a few hospital MRSA clones have circulated around the world, genetically distinct community clones have been reported from different geographic areas. Commonly, these strains contain the smaller SCC*mec* elements, type IV or V.[179] Why these different clones emerged in parallel at this point in time is unknown.

In the United States, the two most commonly described community MRSA clones are USA300-ST8 and USA400-ST1. USA400, originally described as MRSA strain MW2 and responsible for four pediatric deaths in Minnesota and North Dakota, has been observed more commonly in the Midwestern States.[10] USA300 is the strain most frequently reported causing community-acquired disease in both pediatric and adult settings in the United States. Like many other epidemic strains, it has been associated with a spectrum of disease presentations ranging from simple skin and soft tissue infections[105,108] to severe sepsis syndrome,[76] sometimes with a fatal outcome. USA300 is a highly virulent strain that has been distributed across the continent and has become the most prevalent cause of community-acquired infections in less than a decade.[151] It also has become the most common source of hospital-acquired *S. aureus* infection in many hospitals, where it has acquired one or more antibiotic resistance markers.[45,77,189] The special features and adaptability of this strain are discussed further in the genome section of this chapter.

MLST typing has enabled the ancestry of many of these clones to be traced phylogenetically. For example, phage type 80/81 (ST30-MSSA) was epidemic in the 1960s and is the likely ancestor to the widely circulated Southwest Pacific clone, ST30-MRSA-IV, which has been successful both as a colonizer and as a cause of diseases ranging from skin and soft tissue infections to invasive manifestations.[180] Similarly, the USA300 (ST8-MRSA-IV) clone is postulated to have descended from an archaic ST8-MSSA.[55]

S. aureus isolates are susceptible to lysis when they are exposed to bacteriophages. The particular pattern of bacteriophage lysis

can be used to identify strains of staphylococci, but bacteriophage typing has been used primarily as an epidemiologic tool for identifying related strains in epidemics. An international system for identifying strains by bacteriophage typing has been established, but it is not widely used currently. Staphylococci of phage group 80/81 were widespread during the pandemic of staphylococcal disease in the late 1950s. At present, many different phage types are involved in staphylococcal disease.[180]

GENOMES

To date, nine genomes of *S. aureus* have been sequenced (Table 91–3). MW2,[14] FPR3757,[47] and TCH1516[90a] are the three CA-MRSA isolates with sequenced genomes, designated PFGE USA400 and USA300, respectively. *S. aureus* COL[68] is an early hospital-associated MRSA strain, and N315 and Mu50 are hospital-associated MRSA strains from Japan.[117] The Mu50 strain also has intermediate resistance to the glycopeptides(GISA/VISA). Strains 476[94] and NCTC8325[69] are methicillin-susceptible strains from the community and hospital environment, and EMRSA-16 is an MRSA strain that is a major hospital pathogen in Europe.[101] Genome sizes range from 2.8 to 2.9 Mb, and the structures of the chromosomes are well conserved. The core genome (the part of the genome that is the same in all strains) represents 75 percent of the genome.[129] Only approximately 40 to 50 percent of the predicted proteins have a known function.

EPIDEMIOLOGY

S. aureus isolates are responsible for both sporadic infections and epidemics of varying extent ranging from the intrafamily outbreaks of commonly encountered staphylococcal disease to large and often prolonged hospital-associated outbreaks, such as those emanating from a newborn nursery or a surgical service. Epidemic spread of staphylococci of phage type 80/81 was so widespread in hospitals worldwide in the period encompassing the mid-1950s through the early 1960s that it constituted a pandemic. Researchers have suggested that a few "epidemiologically virulent" strains, such as 80/81, are particularly capable of spreading widely and causing disease. Because we are largely ignorant of the factors responsible for pandemic spread, we cannot prevent or predict recurrence. Robinson and colleagues concluded that descendants of 80/81 have acquired methicillin resistance to emerge as a CA-MRSA clone, closely related to the southwest Pacific ST30 clone.[180]

Staphylococci may be transmitted by multiple routes, including contact with infected persons, contact with asymptomatic carriers, airborne spread, and contact with contaminated objects. Of these mechanisms, contact with a person who has a staphylococcal lesion appears to be particularly important in the spread of staphylococci. Persons with open draining lesions disseminate organisms into their environment and to others by direct contact. In a hospital, staphylococci may be spread from an infected patient to another on the hands of caretakers, such as physicians or nurses. Hospital personnel with mild or inapparent lesions, such as styes, furuncles, or paronychia, may themselves spread organisms. In family and small community outbreaks, multiple secondary cases frequently can be traced to an individual with a draining lesion. Secondary cases tend to appear for months after the initiating case within these small epidemiologic units.[200]

Staphylococci also may be spread by asymptomatic carriers who have staphylococci in one or more body sites, including the nose, skin, hair, nails, axillae, and perineum. At any one time, as many as 30 percent of individuals are colonized in their anterior nose with *S. aureus*.[114] The rate of nasal carriage of MRSA appears to have increased in the past decade. Nasal carriage of MRSA was 0.8 percent in 2001[157] and 9 percent in 2004[40] for children seen in an emergency center in Nashville, Tennessee. For children admitted to the hospital in Corpus Christi, Texas, in 2005, the rate of MRSA colonization was 22 percent.[6] Why nasal colonization of children by CA-MRSA has increased during the past decade is unclear but likely is related to unique properties of the major CA-MRSA clone, USA300.[47] Detailed studies have been performed to delineate factors regulating the carrier state and its establishment and perpetuation, as well as factors responsible for dispersion of organisms from carriers. Asymptomatic carriers may be a source of disease for themselves and for others. For example, a wound infection appears to be more likely to develop in a hospitalized patient who becomes a carrier than in a noncarrier.[225] Much attention has been devoted to detecting and attempting to treat nasal carriers of staphylococci; however, studies of nursery outbreaks have indicated that nasal carriage is not as important as is hand transmission in the dispersal of staphylococci.[226] Transmission by hand contact can be minimized by effective handwashing.[72] The problem of hair carriage of staphylococci in operating room personnel has been minimized by using improved head coverings.

Staphylococci are widespread in the environment and can be cultured from clothing, carpets, toiletries (e.g., hairbrushes, razors), and virtually all environmental surfaces. Airborne dissemination of organisms is possible, particularly in operating rooms with poor ventilation and heavy traffic; improved methods of ventilating operating rooms may have reduced the rates of sepsis or colonization. Environmental staphylococci may serve as an important reservoir, but direct human-to-human transfer probably is a much more important means of transmission in epidemic situations than is airborne spread or contact with contaminated objects. This means of transmission is particularly true for spread of CA-MRSA among athletes.[112] Various methods that

are used to identify epidemiologic markers in nosocomial outbreaks of staphylococcal infection include molecular typing techniques, plasmid DNA analysis, restriction endonuclease fingerprinting of chromosome DNA, and rapid-field inversion gel electrophoresis. Molecular methods of typing offer adjunctive information useful in characterizing strains involved in outbreaks.[48,54]

The neonatal nursery has been an area of particular concern in the transmission of staphylococci. Until the 1980s, *S. aureus* was the major concern. During the pandemic of strain 80/81 disease, outbreaks of serious neonatal disease were commonplace, high colonization rates were found in infants on discharge from the nursery, and the subsequent incidence of disease in some outbreaks was as high as 50 to 70 percent. Skin disease and infant and maternal mastitis usually appear within 1 to 4 weeks after discharge. Staphylococcal pneumonia, far more common during that period than at present, may not be seen for months after delivery, even though the infecting strain was acquired in a hospital. During the experience with strain 80/81 disease, a particularly high staphylococcal attack rate was seen in the families of colonized infants. The same epidemiology has been noted for the USA300 CA-MRSA clone, which has been associated with staphylococcal infections in otherwise healthy newborns up through 30 days of life.[61] The mother in approximately 20 percent of cases had a presumed or concomitant *S. aureus* infection around the time of her infant's infection in one study.[61]

Various control measures were used successfully to terminate individual outbreaks during the 1980s. Measures to protect the infant from colonization and subsequent development of disease by establishing a barrier at the site of initial colonization included hexachlorophene bathing, application of antibiotic ointment to the umbilicus and circumcision site, and application of an antiseptic dye to the umbilicus. Another approach, deliberate colonization of the umbilicus with an interfering "avirulent" strain, was successful in controlling several epidemics but itself caused skin disease and, in one case, fatal septicemia.[193] Hexachlorophene bathing became a widespread practice during the period in which nosocomial staphylococcal infections were declining.[72,169] After approximately a decade of using hexachlorophene, researchers recognized that cutaneous absorption of hexachlorophene could result in potentially toxic hexachlorophene blood levels in infants, particularly premature ones, subjected to repeated daily baths over time. Brain stem abnormalities associated with the use of hexachlorophene were demonstrated in premature infants. For these reasons, controls were placed on the sale of hexachlorophene, and its routine use was discouraged in 1973. In one neonatal nursery outbreak of MRSA, the use of 0.3 percent triclosan (Bacti-Stat) was associated with cessation of an outbreak.[233]

Coincident with the widespread discontinuation of hexachlorophene bathing, but not necessarily causally related to it, was the reported increased incidence of nursery outbreaks of *S. aureus* disease. Many of these outbreaks were caused by epidermolytic toxin-producing strains of staphylococci belonging to phage group II. In these outbreaks, limited areas of bullous impetigo developed in most children within 1 to 4 weeks after discharge, and a few children showed the more dramatic manifestations of generalized exfoliative disease. Contemporary epidemics appear to have a much lower incidence of septicemia, pneumonia, and osteomyelitis and less potential for spread to other family members.

Patterns of crowding of infants and understaffing contribute to outbreaks. Active clinical and bacteriologic surveillance and cohorting of infants may be effective in reducing the number of outbreaks.[16,83]

The frequency of bacteremia related to intravenous catheters and prosthetic devices has increased considerably.[137,138] Methicillin-resistant staphylococci have become more prevalent in the community and are responsible for widespread nosocomial outbreaks of disease in hospitals.[25,29,39,43,57,113,186,204,223]

HOST DEFENSES

S. aureus is ubiquitous in the environment, and approximately 30 percent of the population can be classified as carriers. A major defense against staphylococcal infection is intact skin. Minor wounds frequently become colonized and infected and serve as portals to deeper, more significant staphylococcal infection. In some cases, the integumentary infection may be of major importance; in others, minor skin punctures may serve to introduce infection to distant internal sites. Burns, varicella virus and cutaneous herpesvirus infections, insect bites, minor lacerations or abrasions, primary skin diseases (e.g., atopic eczema), epidermolysis bullosa, and surgical wounds are important portals of entry for staphylococci. A deficiency in peptides (defensins and cathelicidins) important for innate immunity of skin against *S. aureus* has been shown in biopsied skin of patients with atopic dermatitis and likely contributes to the increased susceptibility of the skin to *S. aureus* infections in these patients.[115,163] In hospitalized patients, intravenous needles and catheters may be sources of staphylococcal infection.[137,138]

Foreign bodies reduce local resistance to staphylococcal engraftment and are important in the pathogenesis and perpetuation of infection. Noteworthy foreign bodies are cerebrospinal fluid shunts, prosthetic cardiac valves, nonabsorbable sutures, vascular prostheses (including arteriovenous shunts for hemodialysis), and orthopedic prostheses, nails, and wires. In neonates, the umbilicus and circumcision sites, which may be colonized within the first few hours of life and from which both local and distant infections may be established, are important portals of entry.

Viral respiratory diseases such as measles and influenza[82,170] predispose the individual to development of pulmonary infection, again predominantly by damaging the integrity of the barrier at the portal of entry. Disruption of the respiratory epithelium and impairment of ciliary motion and other local defenses may allow secondary staphylococcal invasion to occur.

Once the integumentary barrier has been breached, the polymorphonuclear leukocyte appears to be the most important line of defense. Successful phagocytosis involves chemotaxis, opsonization, and intracellular killing. The incidence of difficulty with staphylococcal infection is highest in patients with defects in this area of host defense. Granulocytopenia of any origin predisposes one to the development of infection, particularly with the host's endogenous bacteria, including staphylococci.[15]

Patients with disorders of neutrophil chemotaxis are particularly subject to the development of recurrent and severe staphylococcal infections. Patients with lazy leukocyte syndrome have recurrent respiratory infections, gingivitis, and stomatitis. Their leukocytes exhibit normal phagocytosis and intracellular killing but are deficient in both motility toward a chemotactic stimulant and random motility. Leukocyte adhesion deficiency is a rare autosomal recessive disorder of leukocytes in which patients suffer recurrent skin infections. Patients with Chédiak-Higashi syndrome have recurrent infection in association with neutrophils that are morphologically abnormal, with giant lysosomes present in decreased number.[230] Hyper-IgE syndrome or Job syndrome is associated with severe, recurrent staphylococcal infections of the subcutaneous and deep skin tissues. Even for patients without defects in neutrophil chemotaxis, approximately 60 percent of *S. aureus* isolates secrete the chemotaxis inhibitory protein of staphylococci (CHIPS), and almost all have the extracellular adherence proteins that interfere with neutrophil chemotaxis and extravasation.[62]

Once the staphylococcus and the leukocyte are close to one another, opsonization of the bacterium must proceed for phagocytosis to occur. Two systems for opsonization of staphylococci have been described. Serum from normal adults has good opsonic activity when unheated but generally is inactive after heating at 56° C for 1 hour. The heat lability of normal opsonin and the observation of normal or only slightly decreased opsonic activity in unheated sera from patients with agammaglobulinemia[227] indicate that the major opsonin is complement. A few sera, generally from patients convalescing from serious staphylococcal disease, contain heat-stable opsonins, presumably antibody directed at the staphylococcal cell wall components.[121] Therefore, either complement or antibody can provide opsonins for staphylococci; specific antibody is helpful but not required. The clinical correlate to these observations may be found in patients with defective defenses; patients with agammaglobulinemia and defective antibody generally have more severe problems with organisms other than staphylococci, whereas patients with deficiencies in complement components have been reported to have repeated and severe staphylococcal infections.[3,7,8,64,149,167]

Once the bacterium has been ingested, intracellular killing proceeds normally. Coagulase-positive staphylococci can survive within polymorphonuclear leukocytes for a considerably longer period than can coagulase-negative organisms.[148] Prolonged intracellular survival may be an important virulence factor separating coagulase-negative from coagulase-positive strains and may provide a mechanism whereby surviving organisms may be carried to distant body sites to establish metastatic foci of infection. Some *S. aureus* exotoxins outlined earlier, such as PVL, contribute to the ability of *S. aureus* to evade human neutrophils. In addition, many *S. aureus* genes are regulated upward or downward after being exposed to human neutrophils, and differences exist in gene expression among various strains in response to human innate host response that may account for differences in the ability of the isolate to cause infection.[218]

Patients with chronic granulomatous disease of childhood have an inborn error in intraleukocytic killing of catalase-positive bacteria and fungi. These patients have an early onset of recurrent purulent infections of the skin, subcutaneous tissue, lungs, and reticuloendothelial organs, particularly the liver, that often are caused by *S. aureus*.[176] The response of these patients to therapy is slow and poor, a finding further demonstrating the absolute necessity of an intact polymorphonuclear bactericidal system in host defense against staphylococci. In contrast to the primacy of polymorphonuclear defense against staphylococci, evidence for an important role of specific humoral and cellular immunity in host defense against staphylococci is either lacking or contradictory.

Specific antibody is not required for opsonization of unencapsulated strains of staphylococci. The opsonic activity of serum from patients recovering from staphylococcal endocarditis or other serious disease is greater than that in physiologically normal persons.[121,228] Despite the presence of humoral antibodies to cell wall teichoic acids and to various toxins and enzymes, which are found regularly in those convalescing from serious staphylococcal infection, the patient remains susceptible to recurrence of infection with the same strain of staphylococci.

Staphylococcal infections generally occur and progress in the presence of some degree of humoral immunity. Specific antibody to one or more staphylococcal components or products does not protect against infection. Clinical evidence from patients with deficient cell-mediated immunity (combined immunodeficiency, thymic aplasia, Nezelof syndrome) suggests that staphylococcal infections are not among the most important pathogens in these patients.

Present evidence, therefore, suggests that intact local skin and mucous membrane barriers are the most important defenses against the establishment of staphylococcal infection. Once infection is established, an intact polymorphonuclear response is essential for containment of the infection and clearance of the organisms.

PATHOGENESIS

Staphylococci cause disease by two mechanisms: direct invasion of tissues with liberation of toxins, which may have effects at sites distant from the focus of infection, and colonization. The hallmark of a staphylococcal lesion is the abscess. Local tissue destruction at the site of inoculation is followed rapidly by hyperemia and a vigorous inflammatory response marked by the accumulation of large numbers of polymorphonuclear leukocytes. Tissue necrosis in the center of the lesion occurs next. At the site of intensive hyperemia surrounding the lesion, a fibrin wall is formed. Liquefaction necrosis occurs centrally; the mature lesion consists of a fibrin wall surrounded by inflamed tissues enclosing a central core of pus consisting of organisms and leukocytes. Live bacteria may persist within these lesions for a considerable period of time. As pus accumulates, it may drain toward the skin surface or into adjacent tissues, where it forms sinus tracts and secondary abscesses. In the presence of an intact host inflammatory response, this type of reaction may be seen in diverse areas, including the skin and subcutaneous tissues, lymph nodes, joints, renal tissues, liver, parotid glands, muscles, lungs, and long bones.

In addition to local extension, *S. aureus* may disseminate hematogenously from this focus of infection, even from abscesses that are trivial in size. Hematogenous dissemination may result in infection of bones, joints, and heart valves. Given the ubiquitous nature of staphylococci, skin and wounds, which are the usual ports of entry, appear to be remarkably resistant to infection. This natural resistance is affected dramatically by the presence of foreign bodies within the wound, such as sutures and bits of soil or gravel. Natural resistance also is affected by the tissue compromise that develops after ecchymosis or hemorrhage occurs and by vascular insufficiency. Poor personal hygiene also predisposes to development of staphylococcal skin infection. Moist, macerated skin is invaded more easily and thus contributes to the increased frequency of staphylococcal skin infection in intertriginous areas and in tropical climates.

Toxigenic staphylococcal disease includes SSSS, TSS, and staphylococcal food poisoning. The major manifestations of these diseases are caused by the effects of specific toxins. Clinical manifestations of infections caused by *S. aureus* in children are discussed in several chapters, and the reader is referred to the specific infection of interest.

DIAGNOSIS

The diagnosis of significant staphylococcal infections should be pursued with vigor. Collections of pus, whether superficial or deep, should be aspirated or drained surgically for diagnostic and therapeutic purposes. Gram stain and culture should be performed. An aggressive approach to establishing the diagnosis of osteomyelitis by bone aspiration and bone biopsy provides an etiologic security that is helpful during the prolonged treatment phase that necessarily follows. When infection is associated with a foreign body, such as an intravenous catheter or suture, removal and culture of the foreign body help in determining the cause, and removal almost always is required for successful resolution of infection.

At least two blood cultures should be obtained before starting therapy for all serious infections. One need not wait for fever spikes or delay therapy to obtain specimens. Blood cultures frequently are negative in serious staphylococcal infection, a finding that demonstrates the need for performing other cultures. Blood cultures are positive in most cases of staphylococcal endocarditis,

approximately half the cases of osteomyelitis and septic arthritis, and fewer than half the cases of pneumonia and deep-tissue abscesses. Measurement of nonspecific indicators of inflammation (e.g., erythrocyte sedimentation rate and C-reactive protein), although of limited value in establishing the diagnosis, can be helpful in monitoring the clinical course of infection and response to intervention. Accurate, sensitive serologic methods for determining a diagnosis of serious staphylococcal infection are not available.

Enterotoxins can be identified by a variety of methods. Immunoassay is used routinely but may lack the sensitivity required to detect levels seen in staphylococcal food poisoning. DNA oligonucleotide probes are highly sensitive, but their clinical utility is limited by the identification of nonexpressed genes.[160] Numerous molecular tests are available to identify MRSA rapidly once it is isolated in the microbiology laboratory and to detect MRSA colonization in patients at the time of hospital admission.[214]

TREATMENT

Successful treatment of staphylococcal infection depends on adequate drainage of collections of pus and the rational use of antibiotic therapy. (Strategies for clinical management of MRSA in the community are outlined in a document developed by the CDC and available at http://www.cdc.gov/ncidod/dhqp/pdf/ar/CAMRSA_ExpMtgStrategies.pdf.) Staphylococcal infections have a particular tendency to persist and recur; for these reasons, prolonged courses of antibiotic therapy usually is required for all but minor infections. Surgical drainage is extremely important and, in some patients with minor superficial abscesses, may be all that is required. In one study, an abscess less than 5 cm in diameter was associated with successful outcome of incision and drainage, regardless of whether the antibiotic administered was active against the isolated pathogen, which was CA-MRSA.[124] For most infections, a course of antibiotic therapy administered after surgical drainage better ensures that the infection has been contained. In an adult study, antibiotics active against CA-MRSA were associated with significantly greater cures than achieved with agents not active against CA-MRSA in patients who had undergone incision and drainage of skin and soft tissue infections.[183] Failure to provide surgical drainage is an important reason for persistence or recurrence of organisms. Antibiotics cannot be expected to penetrate the avascular center of abscess cavities. When abscess cavities are undrained or when antibiotic therapy is discontinued before an area is sterilized, live bacteria may persist and disseminate to cause later recurrence at that site or at distant sites.

For moderate to severe staphylococcal infection, the patient should be hospitalized initially for intravenous therapy. This strategy ensures peak antibiotic levels, which may allow greater penetration into relatively avascular areas. Intramuscular injections rarely are indicated in children. Once the patient is afebrile, has negative blood culture, and shows definite evidence of clinical improvement, therapy can be completed with home administration of antibiotics or with oral agents, as deemed appropriate by the treating physicians.

ANTIBIOTICS FOR *STAPHYLOCOCCUS AUREUS* INFECTIONS

Since the mid-1960s, most *S. aureus* isolates from most sections of North America and Europe have been penicillinase producers and, therefore, are penicillin-resistant. When *S. aureus* isolates are likely to be the cause of infection, the most appropriate agents to administer for empiric treatment are based on the relative frequency of CA-MRSA isolates in the particular community. In areas where CA-MRSA isolates are not a concern, treatment with a penicillinase-resistant penicillin or cephalosporin should be initiated before isolating the bacteria and performing susceptibility testing (Tables 91–4 and 91–5). Methicillin-resistant organisms

TABLE 91–4 Therapy for Staphylococcal Infections in Infants and Children (Excluding Neonates)

	Oral (Mild-Moderate Infection)		Parenteral (Moderate-Severe Infection)	
Agent	**Children <40 kg**	**Children >40 kg and Adults**	**Children <40 kg**	**Children >40 kg and Adults**

cannot be treated adequately with any β-lactam antibiotic, including cephalosporins. In some locations, methicillin resistance is widespread in community isolates; thus, alternative agents (discussed later) are indicated for empiric treatment. When a penicillin-resistant organism that is susceptible to oxacillin is isolated, the semisynthetic penicillinase-resistant penicillins are the drugs of choice. Oxacillin and nafcillin are available for parenteral use. Dicloxacillin and cephalexin are the preferred oral agents.

If clinical response appears to be slow, nothing is to be gained by switching to another antibiotic within this category. Instead, microbiologic data are reviewed, and the dose of antibiotic is rechecked to be certain it is correct. The patient is reassessed to be certain that all sites requiring drainage have been addressed, and compliance with therapy is addressed, especially if the antibiotics have been administered orally.

ALTERNATIVE DRUGS

The cephalosporin antibiotics are active against penicillinase-producing staphylococci and cause less irritation of veins with intravenous infusion than do penicillinase-resistant penicillins. A potential disadvantage lies in their broader spectrum of activity, which may promote superinfection with cephalosporin-resistant, gram-negative organisms in a debilitated patient with serious staphylococcal disease. Cephalosporins have been advocated widely for use in patients allergic to penicillin, but because of considerable cross-reactivity, they should be used extremely cautiously, if at all, in patients with a clear history of serious penicillin allergy or anaphylaxis. Among this group of antibiotics, cefazolin is the agent of choice for parenteral use.[168] It is well tolerated and can be administered every 8 hours intravenously. Serum concentrations of cefazolin are higher, and effective tissue levels appear to be easier to attain. Cefazolin also is associated with less bone marrow suppression than is nafcillin or oxacillin. The efficacy of the second- and third-generation cephalosporins against *S. aureus* is reduced. Therefore, these drugs, especially cefotaxime, ceftriaxone, and cefuroxime, should be given in addition to specific anti-staphylococcal agents if *S. aureus* is suspected strongly. Clindamycin and trimethoprim-sulfamethoxazole are alternative agents for patients who are seriously allergic to or intolerant of β-lactam antibiotics.[12,58,109]

The β-lactam resistance of MRSA is caused by the production of a novel penicillin-binding protein (PBP) designated PBP-2′ or 2a, which, unlike the intrinsic set of PBPs (PBP-1 to PBP-4) of *S. aureus*, has remarkably reduced binding affinities to β-lactam antibiotics. Despite the presence of otherwise inhibitory concentrations of β-lactam antibiotics, MRSA can continue to synthesize cell walls solely through the uninhibited activity of PBP-2′ or 2a.[111,141] PBP2′ or PBP2a is encoded by the *mecA* gene, which is carried by a unique mobile genetic element integrated into the *S. aureus* chromosome designated SCC*mec*.[92]

Some cases of MRSA actually may be caused by infection with *S. aureus* that lacks the *mecA* gene responsible for true methicillin resistance. The mechanism of resistance in these cases may be hyperproduction of β-lactamase.[102] Frequently in these cases, methicillin resistance is borderline, with minimal inhibitory concentrations (MICs) of 8 μg/mL or less. Hence, high doses of β-lactam antibiotics may be inhibitory. The clinical significance of these isolates is unknown.

STAPHYLOCOCCAL CASSETTE CHROMOSOME *mec*

SCC*mec* is a region spanning between 20 and 70 kilobases approximately 30 kb downstream from the chromosomal origin of replication. SCC*mec* contains the *mecA* gene encoding a PBP (PBP2a or PBP2′) with poor affinity to β-lactam antibiotics, thus allowing essential functions of cell wall formation to proceed in the presence of β-lactam antibiotics. The *mecA* gene is regulated by mecR1-mecI, in which activated mecR1 (signal transducer) inactivates mecI (repressor) through site-specific proteolytic cleavage, thereby initiating production of PBP2a or PBP2′. In vitro studies have suggested that the β-lactamase regulators blaR1-blaI may also be effective regulators of *mecA*.[146]

The SCC*mec* classification systems are based on several genetic elements including the class of *mec* and the *ccr* genes, which are recombination genes involved in the mobility of the genetic cassette. Other elements that may be present are IS431, IS1272, Tn554, pUB110, and pT181. SCC*mec* types II and III also contain other antibiotic resistance genes such as tet (tetracycline resistance). All strains contain a J(unk)-region of variable size and composition. Several schemes for SCC*mec* typing have been published.[116,161,162] Historically, nosocomial MRSA isolates contained the SCC*mec* types I to III, and when community isolates were first described, three new types (IV, V, and VI) were introduced. The smaller size (<30 kb) of SCC*mec* types IV to VI is thought to explain an increased mobility between strains. Because the community strains have been brought into the health care setting, SCC*mec* typing cannot be used reliably to predict whether an infection is related to health care or to the community.[77,88,189]

MRSA was described first within 1 year of the introduction of penicillinase-resistant penicillins.[97] Initial reports of infection appeared in England in the early 1960s and subsequently were followed by reports from other European countries.[119,203] In the United States, only sporadic cases were observed initially,[113,119] and not until 1968 was the first nosocomial outbreak described.[19] Since then, the prevalence of MRSA in the hospital setting has increased steadily. In a 1989 survey of U.S. hospitals, 97 percent reported the presence of MRSA.[25] The SCOPE (Surveillance and Control of Pathogens of Epidemiologic Importance) prospective surveillance project conducted between 1995 and 2001 identified more than 3400 episodes of nosocomial bacteremias in children. *S. aureus* accounted for 9 percent of isolates.[229] The proportion of *S. aureus* isolates that were MRSA increased from 10 percent in 1995 to 29 percent in 2001. Risk factors associated with development of infection or colonization with MRSA

include recent or prolonged hospitalization, exposure to antibiotics, and stay in an intensive care unit.[133] Nosocomially acquired MRSA appears to be fully virulent, with in vitro characteristics similar to those of methicillin-susceptible staphylococci. It has equivalent virulence in studies of experimental infection in mice, and clinical studies confirm comparable mortality rates.[90,213] These strains characteristically are multiresistant and usually show little or no susceptibility to cephalosporins, aminoglycosides, erythromycin, clindamycin, and tetracyclines.[4,222] Strains that appear to be susceptible to cephalosporins by standard disk sensitivity tests are proved resistant in quantitative dilution tests. The clinical efficacy of cephalosporins against methicillin-resistant strains has been poor.[222]

Epidemic outbreaks of nosocomially acquired MRSA have been reported. In these outbreaks, nasopharyngeal colonization with MRSA often occurs before infection develops. A high rate of nasal and hand carriage has been observed in health care workers associated with units that have MRSA outbreaks.[153] The usual approach to outbreaks has been to emphasize handwashing between examining and caring for patients. Strict isolation in a private room generally is advocated.[154] Single-room isolation usually is impractical in neonatal and pediatric intensive care units, where isolation facilities are in short supply and a single MRSA-colonized patient may occupy a room for months. Strict adherence to universal precautions (body substance isolation) with all moist body fluids and strict handwashing between seeing patients appear to be rational alternatives to "strict isolation."[135] Intranasal application of mupirocin ointment has been found to be capable of eliminating nasal and hand carriage of both colonized patients and hospital staff.[178] Interventions to control outbreaks of MRSA in intensive care or other units are multifaceted, and the reader is referred to major guidelines for recommendations.[154,196]

Occasional cases of MRSA infection apparently acquired in the community were observed sporadically in the 1970s. However, these infections were from patients who were chronically ill, and many patients had a history of nursing home residence, recent admission to acute or chronic health care facilities, previous receipt of antibiotics, or intravenous drug abuse.[125,145,185,206] Hence, in these cases, infections usually were traceable to the hospital setting. By contrast, since the 1980s, cases of true CA-MRSA infection in patients without identified risk factors have appeared in the literature. The first reports in children arose from small MRSA outbreak investigations.[85] Subsequently, Rathore and Kline described three patients with deep-seated infections caused by MRSA acquired in the community.[177] In the 1990s, reports of CA-MRSA in patients without known risk factors continued to appear sporadically in the literature. However, most of the infections described occurred in adults.[79,122,152] Four pediatric deaths in Minnesota and North Dakota in the period 1997 to 1999 demonstrated the potential for severe disease resulting from CA-MRSA infections.[10] The landmark study describing the changing epidemiology of CA-MRSA in children was published in 1998.[89] Herold and colleagues performed a retrospective review of medical records and compared the frequency of *S. aureus* isolation in hospitalized children during two time periods: between 1988 and 1990 and between 1993 and 1995. The prevalence of CA-MRSA in children without identified risk factors was 25.9 times higher in 1993 to 1995 than in 1988 to 1990.[89] After the publication of this article, several reports of CA-MRSA in children without risk factors from different parts of the United States and many regions of the world appeared.[30,37,103,108,175,187,234] This explosive increase in reporting that occurred in just a few years suggests that clones of CA-MRSA have unique properties that allow rapid spread once these pathogens are introduced into the community.[106]

All reports of the clinical characteristics of CA-MRSA infection in children without risk factors document a predominance of superficial infections, including subcutaneous abscesses and cellulitis.[30,89,108,175] However, many children with abscesses require admission to the hospital for incision and drainage with the patient under anesthesia.[108] Invasive disease with CA-MRSA, including severe, life-threatening infection, has been increasing and accounted for about 5 percent of cases in children seeking care in an emergency center of a large children's hospital in Houston.[5,10,75,76,108]

Unlike hospital-acquired MRSA, CA-MRSA isolates usually are susceptible to most non–β-lactam antibiotics, including clindamycin, gentamicin, trimethoprim-sulfamethoxazole, and doxycycline or minocycline, in addition to vancomycin, daptomycin, and linezolid.[105] Erythromycin susceptibility is somewhat more variable; the proportion of susceptible isolates varied from 29 to 80 percent in various studies.[80,89,95,155] Macrolide (erythromycin, azithromycin, clarithromycin)-resistant strains remain susceptible to clindamycin if the macrolide resistance is caused by an efflux pump (MEF). However, resistance to clindamycin, lincosamide, and streptogramin B can be constitutive (macrolide-lincosamide-streptogramin B] MLS_B]) or inducible ($iMLS_B$). Both mechanisms can be detected with molecular methods and also reliably in the routine laboratory by the "D test" (Fig. 91–5).[59] In vitro as well as some in vivo evidence indicates that, in the presence of erythromycin resistance, *S. aureus* could become resistant to clindamycin during therapy with this antibiotic.[50,144,165,221] This phenomenon, $iMLS_B$ resistance, which consists of modification of the target rRNA of *S. aureus*, is mediated by the presence of the resistance-conferring *erm* (erythromycin resistance methylase) gene, which encodes a 23S rRNA methylase.[96,123] Although 14-membered ring macrolides such as erythromycin are the most potent inducers, lincosamides such as clindamycin also can act as weaker inducers.[123] This ability may have clinical relevance in the setting of infections in which the bacteria are not eliminated quickly and may be exposed to subinhibitory concentrations of clindamycin for any amount of time. Examples include therapy for undrained deep-seated abscesses or treatment of osteoarticular infections. In patients infected with a strain having the $iMLS_B$ resistance genotype and expressing

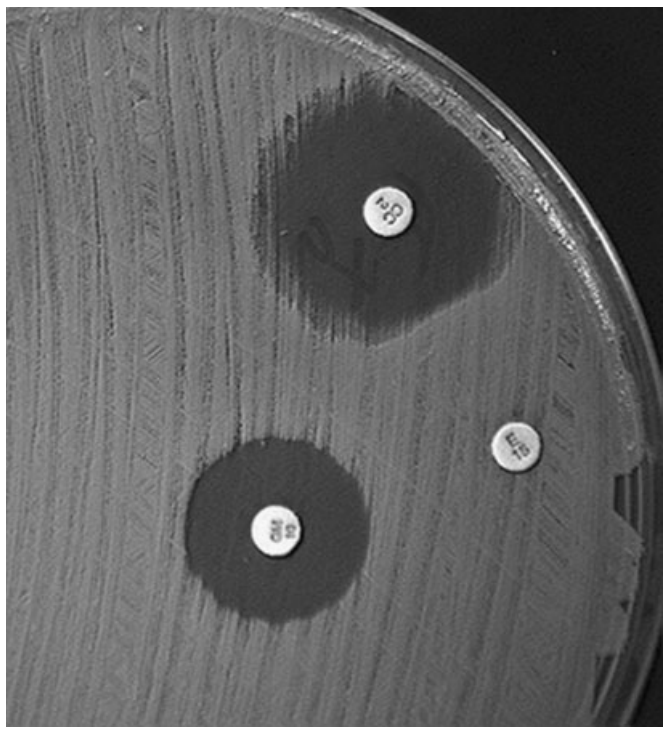

Figure 91–5 D test.

the erythromycin-resistant, clindamycin-susceptible phenotype, cases of clindamycin therapeutic failure have been reported.[66,126,195] Therefore, for MRSA isolates that are erythromycin-resistant and clindamycin-susceptible, detection of the presence of inducible MLS_B resistance should be performed by the disk approximation method, in which clindamycin- and erythromycin-impregnated disks are set 15 to 20 mm apart over Mueller-Hinton agar containing a standard inoculum of bacteria. After a 24-hour incubation period, if the zone of inhibition around the clindamycin disk is flattened or blunted (D shaped, as in Fig. 91–5) on the side facing the erythromycin disk, the isolate is classified as having an $iMLS_B$ resistance phenotype.[123]

Vancomycin, alone or together with an aminoglycoside or rifampin, is the drug of choice for serious MRSA infections. Linezolid, the first of a new family of antimicrobial agents known as oxazolidinones, has demonstrated significant activity against MRSA, vancomycin-resistant enterococci, and penicillin-resistant *S. pneumoniae*. It is available in both oral and intravenous formulations. Quinupristin-dalfopristin is an intravenous streptogramin antibiotic combination that has been found to be effective in the treatment of MRSA and vancomycin-resistant *Enterococcus faecium* infections in patients intolerant of therapy or in whom previous therapy failed. The frequent development of phlebitis with parenteral administration through a peripheral vein mandates the use of central venous access whenever possible. Both linezolid and quinupristin-dalfopristin are expensive, so their use should be restricted to situations for which other alternatives are not feasible. Daptomycin is another newer agent with the most rapidly bactericidal activity in vitro against MRSA.[27]

For severe infections caused by MRSA, the antibiotic of choice is vancomycin. In areas where CA-MRSA has been isolated from children without identified risk factors, severe, life-threatening infections suspected to be caused by *S. aureus* should be treated empirically with both nafcillin and vancomycin because nafcillin is a more active antibiotic than is vancomycin for the treatment of methicillin-susceptible isolates.[78] The addition of gentamicin should be considered for synergistic purposes. Antibiotic therapy can be adjusted subsequently after antibiotic susceptibility testing results are available. Clindamycin and linezolid are options for therapy depending on the susceptibility of the isolate, the desired route of administration, and the absence of endovascular involvement. Daptomycin is approved for serious *S. aureus* infections including bacteremia in adults, but pharmacokinetics and safety studies in children are lacking.[11,65] Tigecycline is another newer agent most useful for polymicrobial infections including MRSA in adults, but it has not been studied in children.[201] Nafcillin, oxacillin, and cefazolin are the recommended agents for treatment of severe MSSA infections.

For mild to moderate skin and soft tissue infections caused by CA-MRSA, empirical treatment may include other antibiotics such as clindamycin or trimethoprim-sulfamethoxazole. Doxycycline or minocycline are options for children older than 8 years of age.[182] If more than 90 percent of community *S. aureus* isolates are susceptible to clindamycin, this agent can be used for empiric treatment of moderately invasive infections, such as in children with osteomyelitis or pneumonia and empyema who do not require intensive care. This approach is not recommended when the clindamycin rate exceeds 10 percent of the CA-MRSA and CA-MSSA isolates combined.[44] Vancomycin or linezolid would be considerations in such circumstances.[107] Once an organism is isolated, therapy is modified based on susceptibility patterns. Nafcillin, oxacillin, and cefazolin are the preferred parenteral agents, and dicloxacillin and cephalexin are the preferred oral agents for moderate MSSA infections.

The origin of CA-MRSA is not known. The absence of health care exposure in patients harboring the bacterium, the unique antibiotic susceptibility characteristics of these isolates, and distinctive pulsed-field electrophoresis patterns that are different from the patterns of hospital-acquired MRSA isolates for a given institution suggest that the origin may be the community and that these isolates were not merely transferred from the hospital setting.[2,81] The unique combination of the gene complex and the much smaller SCC*mec* size than identified in the SCC*mec* of hospital-acquired MRSA also suggest a different origin.[136] Whether the origin is the hospital or the community, the changing epidemiology of MRSA is remarkably similar to the emergence of penicillin-resistant *S. aureus* that occurred in the 1940s and 1950s.[34] Finally, the increasing rate of isolation of MRSA will mandate the use of alternative antibiotics, which, in turn, may promote the development of additional resistance to other antibiotic classes, the most concerning of which is resistance to glycopeptide antibiotics such as vancomycin. Although vancomycin is the antibiotic of choice for severe MRSA infection, its use must remain monitored and controlled because clinical isolates with decreased susceptibility to this antibiotic, vancomycin- or glycopeptide-intermediate *S. aureus* (VISA or GISA), have been reported.[198]

In June of 2002, the first documented infection by vancomycin-resistant *S. aureus* (VRSA) in the United States was reported.[32] The isolate, obtained from a catheter exit site of a 40-year-old diabetic patient undergoing chronic dialysis, had high MICs for vancomycin (1024 μg/mL) and oxacillin (>16 μg/mL) but was susceptible to chloramphenicol, linezolid, minocycline, quinupristin-dalfopristin, and trimethoprim-sulfamethoxazole.[32,35] Since then, six additional isolates have been reported from Michigan, Pennsylvania, and New York.[33,209,212] All the VRSA strains are resistant to the glycopeptides by virtue of the *van*A gene found in the enterococci. VISA strains (MIC of 4 or 8 μg/mL) do not harbor the *van*A gene and are intermediately resistant to vancomycin because of a thickened cell wall containing vancomycin-binding dipeptides.[42,86,91] Vancomycin (and other glycopeptides) intermediate resistance detection in the laboratory is not detected by disk diffusion techniques and may not be consistently detected by automated systems.[211] In response to Clinical and Laboratory Standards Institute guidelines, microbiology laboratories have lowered the breakpoints for vancomycin susceptibility to 2 μg/mL or less, intermediate to 2 to 8 μg/mL, and resistant to 16 μg/mL or more. In actuality, very few *S. aureus* have MICs greater than 4 μg/mL.[209]

PREVENTION

Staphylococcal infections are so common that virtually everyone has had at least some minor encounters. Skin infections occur more commonly in tropical climates or during warm, humid weather in temperate areas and are likely to arise in moist areas of the body such as the axillae and skin creases. High standards of personal hygiene, careful cleaning, and adequate protection of abrasions and minor lacerations reduce the likelihood of skin infection developing.[207] Early attention given to minor infections in these small wounds with careful cleaning and antibiotic ointment may help to prevent more serious or invasive infections. We have been impressed repeatedly with the minor nature of the cutaneous source of infection in serious staphylococcal osteomyelitis, pneumonia, and endocarditis.

Person-to-person spread from an overt lesion is a major route for dissemination of infection within families, in hospitals, and in schools. A person with an infected, purulent wound should receive prompt treatment and be excused from school and from such occupations as hospital worker or food handler while the infection is open or draining. At home, special precautions should be taken in care and dressing of the wound. Disposable gauze pads should be used to wash and dry it, and towels and washcloths should not be shared with other members of the family. For children with recurrent infections or for families with multiple

family members with infections, we have found that having the patients take a bath twice a week in water to which bleach (1 teaspoon/gallon of bath water) has been added decreases the frequency of recurrences.

To date, no vaccine has been successfully developed for the prevention of *S. aureus* infections.[191] As noted earlier, a vaccine targeting types 5 and 8 polysaccharide capsule initially appeared promising but was not efficacious in a larger study.[192] One trial using immune globulin enriched for antibody to clumping factor A failed to prevent staphylococcal infections in low-birth-weight infants,[23] and a monoclonal antibody directed against clumping factor A was investigated preliminarily in adults with *S. aureus* bacteremia.[224] A polyclonal IgG preparation containing high levels of antibody to *S. aureus* capsular polysaccharides 5 and 8 has been developed by collecting plasma from healthy donors immunized with StaphVAX.[20] The pharmacokinetics and safety of this product in very low-birth-weight infants were established in a phase II trial, but further development of this antibody preparation is questionable. The safety and pharmacokinetics of human chimeric monoclonal antibody directed against the lipoteichoic acid, an integral component of the cell wall of gram-positive organisms, including *S. aureus*, were evaluated in a phase II study in very low-birth-weight infants.[23] Whether this antibody (pagibaximab) will be efficacious in preventing invasive *S. aureus* infections in these infants is to be determined.

Perhaps taking advantage of the *S. aureus* genome with a reverse vaccinology approach will lead to a safe and efficacious vaccine.[205] Until such time, however, simple measures such as washing hands frequently, giving attention to skin breaks, and avoiding contact of obviously infected skin lesions are the most effective measures to prevent *S. aureus* infections.

CHAPTER 92

Coagulase-Negative Staphylococcal Infections

David Y. Hyun ✪ Carina A. Rodriguez ✪ Christian C. Patrick ✪ Sheldon L. Kaplan

Coagulase-negative staphylococci are among the most common causative agents of nosocomial infections and are among the bacteria most frequently isolated in the microbiology laboratory. Their normal habitat includes skin and mucous membranes of humans and animals. This ecologic niche hampers studies on this group of bacteria because they also are frequent contaminants in the clinical microbiology laboratory. Coagulase-negative staphylococci infections occur mainly in immunocompromised patients, particularly those with indwelling medical devices.[160,178,203,249] New epidemiologic and molecular techniques can be useful to identify characteristics of strains in nosocomial outbreaks. Understanding the pathogenesis of infections caused by these organisms has advanced, and several possible virulence factors have been identified. The clinical spectrum of the disease is characterized by a more indolent presentation when compared with other gram-positive cocci. Removal of catheters or prosthetic devices may be necessary for patients with persistent infections. Furthermore, effective therapy can be difficult to achieve because of the high proportion of isolates resistant to antibiotics. This chapter reviews the microbiology, epidemiology, pathogenesis, clinical manifestations and diagnoses, and treatment of infections caused by these ubiquitous organisms.

HISTORICAL BACKGROUND

Staphylococcus albus was the descriptive term used to define all coagulase-negative staphylococci before 1960 because so few techniques for species definition existed. Rosenbach in 1884 used the term *S. albus* for coagulase-negative staphylococci to denote the white color imparted by the colony on an agar plate, in contrast to the pathogenic *Staphylococcus aureus*, which had a yellow colony color.

In the 1960s, coagulase-negative staphylococci clearly were identified in association with infections in certain patient populations. Coagulase-negative staphylococci were implicated as the etiologic agent of infections in patients with atrioventricular shunts and peritoneal catheters and in neonatal sepsis.[30,32,137,217]

During the 1960s, *Staphylococcus saprophyticus* was recognized as a singular species and found to be a pathogen in urinary tract infections. Additionally, *Staphylococcus epidermidis* supplanted *S. albus* as a generic term for all coagulase-negative staphylococci other than *S. saprophyticus*. The association of disease with coagulase-negative staphylococci highlighted the need for further specification. Work in the 1970s focused on coagulase-negative staphylococci biotyping (differentiation based on biochemical reactions), and this work continues. Currently, more than 32 species of coagulase-negative staphylococci are recognized. Now that individual species can be identified, *S. epidermidis* is used as a specific species term.

MICROBIOLOGY

Staphylococci are nonmotile, non–spore-forming, gram-positive bacteria. The genus *Staphylococcus* is related most closely to the

newly described genus *Macrococcus*, and it has a relatively close relationship with the genera *Bacillus*, *Salinicoccus*, *Gamella*, *Listeria*, *Planococcus*, and *Brochothrix*.[129] Members of the genus *Staphylococcus* have a low DNA G + C content (30 to 39 mol %), whereas members of the genus *Micrococcus* have a G + C content within the range of 66 to 75 mol percent.[127] Staphylococci can be divided by the ability to produce or not produce coagulase, an extracellular enzyme that promotes the congealing of rabbit plasma. The thermonuclease reaction is particularly useful for rapidly differentiating *S. aureus* (positive) from other staphylococcal species (negative) and is more accurate than are tests based on coagulase production.[101] *S. aureus* also can be differentiated from most coagulase-negative staphylococci by the fermentation of mannitol. Currently, 32 species of staphylococci are recognized, 29 of which are coagulase-negative staphylococci, and are identified by the following criteria: (1) colony morphology, (2) oxygen requirements, (3) novobiocin resistance, (4) aerobic acid production from carbohydrates, and (5) selected liability to enzymatic activities.[127,129] Susceptibility to novobiocin is a convenient assay to differentiate *S. saprophyticus* from most coagulase-negative staphylococci from human specimens, including *S. epidermidis*. *S. saprophyticus*, the uncommon pathogen *Staphylococcus cohnii*, and the rare pathogen *Staphylococcus xylosus* are novobiocin resistant.[186] Commercial kits used to identify species of coagulase-negative staphylococci have various degrees of confidence: an identification is made 60 to 95 percent of the time, depending on the species. Most systems are developed to identify especially *S. epidermidis* and *S. saprophyticus* because these are the species clearly associated with clinical diseases.[189] Additionally, DNA-pairing studies have identified intraspecies differences with strains considered to be *S. epidermidis* by biotyping.[265]

Coagulase-negative staphylococci are prototypic gram-positive bacteria. The outermost structure is a cell wall composed primarily of peptidoglycan with teichoic acid molecules and an assortment of interspersed proteins. The teichoic acid has a glycerol backbone, compared with the ribitol of *S. aureus*.[167] Approximately 20 to 30 proteins are located within the cell wall; 15 to 20 of these are surface exposed and thus are able to interact with the host.[180]

S. epidermidis and other coagulase-negative staphylococci produce a capsule that appears to be a virulence factor in animal models.[106,168,261] However, its presence has been demonstrated in only 9 percent of fresh clinical isolates.[105] A glycocalyx or slime-layer substance, produced by most strains of *S. epidermidis*, is considered a virulence factor that inhibits phagocytosis.[39,41,52,53]

TABLE 92–1 Staphylococci That Are Part of the Normal Flora, Including Common Sites of Habitation and Pathogenic Potential

Species	Common Anatomic Site of Habitation	Pathogenic Potential
S. aureus	Nares	Common
S. epidermidis	Nares; axillae; skin of head, arms, and legs	Common
S. saprophyticus	Occasionally skin	Common
S. haemolyticus	Skin of head, arms, and legs	Uncommon
S. hominis	Axillae; skin of head, arms, and legs	Uncommon
S. lugdunensis	Widely distributed on body	Uncommon
S. simulans	Occasionally skin	Uncommon
S. cohnii	Occasionally skin	Uncommon
S. warneri	Occasionally skin	Uncommon
S. saccharolyticus	Rarely skin	Uncommon
S. caprae	Occasionally skin	Rare
S. capitis	Skin of head, face, ears, and arms	Rare
S. auricularis	Ears	Rare
S. schleiferi	? Skin	Rare
S. xylosus	Occasionally skin	Rare

EPIDEMIOLOGY

Epidemiologic studies involving strain delineation of coagulase-negative staphylococci have proved difficult to perform because of the organism's commensal nature on the human body. *S. epidermidis* is the prominent species, accounting for 60 to 90 percent of all staphylococci recovered from humans. The ecologic niches of coagulase-negative staphylococci have allowed a classification, as shown in Table 92–1.

Coagulase-negative staphylococci, except for *S. saprophyticus*, cause primarily nosocomial infections. Antibiotic resistance of coagulase-negative staphylococci is a common occurrence because of selective antibiotic use in the hospital setting. In 1997, the National Nosocomial Infections Surveillance Report noted an 87 percent increase in the rate of oxacillin resistance among coagulase-negative staphylococci isolates from patients in intensive care units when compared with the same period 5 years earlier.[36] Coagulase-negative staphylococci gain access to the bloodstream primarily by breakdown of skin or mucocutaneous barriers, by following a prosthetic catheter tract, or through the hub of a central venous catheter. Two studies addressed the acquisition of *S. epidermidis* as a colonizing organism in low-birth-weight neonates.[46,90] Both reports described rapid colonization, in which 75 percent of neonates were colonized by 2 weeks of age, but differed in their findings of increased production of slime-layer or antibiotic-resistant organisms with increased colonization time.[46,90] Although most infants acquire coagulase-negative staphylococci from environmental sources, including hospital personnel, a few are colonized by vertical transmission.[89,181]

Epidemiologic techniques are of paramount importance in coagulase-negative staphylococci infections to identify a strain causing either a common-source outbreak or repeated infections within an individual.[166,189,249] Techniques currently available are divided into conventional or molecular and are listed in Table 92–2. Conventional methods are fraught with poor standardization, sensitivity, and specificity. However, a combination of these techniques has been used for strain delineation. Genotyping by pulse-field gel electrophoresis (PFGE) has been shown to be highly discriminatory when investigating patterns of transmission and sources of outbreaks.[26,134,156,238,249] Random amplification of polymorphic DNA (RAPD) by polymerase chain reaction (PCR) also has been successful in identifying clonal outbreaks and transmissions. Although it is less discriminatory than is PFGE, RAPD

Figure 92–1 Scanning electron microscopy of slime-producing coagulase-negative staphylococci. *(From Peters, G., Locci, R., and Pulverer, G.: Adherence and growth of coagulase-negative staphylococci on surfaces of intravenous catheters. J. Infect. Dis.* 146*:479-482, 1982.)*

is less costly and time-consuming.[23,195] Multilocus sequence typing (MLST) can be used to delineate clonal relationships between strains and has been used to identify predominant clones from a group of clinical isolates.[144,266]

Antimicrobial susceptibility testing is the method most readily available for typing using a phenotypic characteristic. Methicillin resistance is mediated by the *mecA* gene, which is carried on a chromosomal element called *staphylococcus chromosomal cassette mec* (SCC*mec*).[266] This mobile element is thought to be capable of horizontal transfer between species and to confer methicillin resistance in community-acquired *S. aureus*. Typing of SCC*mec* can be achieved by PCR.

PATHOGENESIS

Several risk factors for development of coagulase-negative staphylococci infection are caused by changes in host defense. Initial risk factors include a breakdown of the mucocutaneous barrier, immunosuppression,[64,119] and prior antibiotic therapy.[120,218] In addition, the presence of a prosthetic device, such as an indwelling central venous catheter, cerebrospinal fluid (CSF) shunt, or peritoneal dialysis catheter, increases the susceptibility to infection.[12,19,59,138] Opsonophagocytosis is the most important immune defense against coagulase-negative staphylococci.[64,120,227] An increased rate of infection has been noted in patients with a dysfunctional opsonophagocytosis system, including neonates[64,227] and patients receiving continuous ambulatory peritoneal dialysis.[77,120]

Biolfilm formation (Fig. 92–1 and Table 92–3) is considered to be a major virulence factor for *S. epidermidis* and other coagulase-negative staphylococci, especially in nosocomial and prosthetic device infections.[5,56,144,241,247] It consists of multiple layers of cells embedded in an amorphous extracellular material often referred to as *slime*. It provides a mechanism for staphylococci to evade antibiotics and host defense.[34,60,79,111,131,220,221,248,252]

Biofilm formation is initiated by attachment of the organism to a surface such as polystyrene.[144,145] This adhesion is mediated by cell wall teichoic acids[102] and proteins, including autolysins AltE (surface-associated autolysin) and Aae,[98,102,204,240] that interact and bind with extracellular matrix proteins such as fibronectin, fibrinogen, and vitronectin. Nonspecific electrostatic and hydrophobic interaction also promote attachment.[95,100,243] Initial

attachment is followed by accumulation of biofilm, which is primarily mediated by polysaccharide intercellular adhesin (PIA).[97,205] PIA also acts as a hemaglutinin[144,202] and protects the bacteria from phagocytosis and killing by human polymorphonuclear leucocytes.[222,252] The *ica*ADBC operon, which is found in both *S. epidermidis* and *S. aureus*, encodes enzymes necessary for PIA production.[97]

In numerous epidemiologic studies, the presence of the *ica* operon has been associated more frequently with *S. epidermidis* strains isolated from hospitalized patients with prosthetic device infections than with community strains isolated from healthy individuals. Eighty-one to 89 percent of isolates from hospitalized patients have been reported to carry the *ica* operon. In contrast, only 6 to 38 percent of community-acquired isolates were found to carry the *ica* operon.[67,130,244] The utility of *ica* operon detection in differentiating between invasive strains and commensal strains of *S. epidermidis* obtained from patients in neonatal intensive care units, bone marrow transplant units, and oncology units has been investigated. Although both groups of strains demonstrated high carriage rates of the *ica* operon, no significant difference was found.[27,51,183,198] However, higher proportions of invasive strains demonstrated biofilm production in quantitative assays compared with commensal strains.[27,198] Most of the commensal strains were biofilm-negative despite possessing the *ica* operon, a finding suggesting that regulation of gene expression plays a large role in virulence.

Numerous extracellular enzymes are produced by coagulase-negative staphylococci; an extracellular metalloprotease with elastase activity; a cysteine protease that degrades human secretory immunoglobulin A, immunoglobulin M, serum albumin, fibrinogen, and fibronectin; and an extracellular serine protease involved in epidermin processing.[96,251,254] Two lipases have been postulated to facilitate skin colonization.[96,251] Unlike *S. aureus*, which is capable of producing various cytolytic and superantigenic toxins, *S. epidermidis* produces very few toxins.[251] *Delta* toxin, an enteropathogenic toxin, encoded by the *hld* component of the regulatory system agr, has been linked to necrotizing enterocolitis in infants.[215] *S. epidermidis* also produces antibacterial peptides called *lantibiotics* that may play a role in bacterial interference on skin and mucous membranes and in the creation of an ecologic niche for *S. epidermidis*.[132]

S. saprophyticus can cause urinary tract infections in the absence of indwelling catheters.[132] Several virulence factors have been described to explain its pathogenic potential to adhere and persistently grow in the urinary tract. A surface-exposed protein with hemagglutinin and adhesive properties[74] and a surface fibrillar

protein,[73] designated *ssp*, are associated with attachment to urinary tract epithelium. Urease production also has been associated with invasiveness of this organism by causing damage to bladder tissues.[71,72] The whole genome of *S. saprophyticus* has been sequenced and compared with *S. aureus* and *S. epidermidis*.[132] Analysis revealed a single, unique cell wall anchored protein with properties of hemagglutination and adherence to human bladder cells. A high population of ionic transport systems capable of providing osmotolerence in the highly variant ionic environment of urine also was demonstrated.

CLINICAL MANIFESTATIONS

Coagulase-negative staphylococci have been implicated in a variety of clinical infections in immunocompetent and immunocompromised patients (Table 92–4).[126,178,206] A basic difficulty in interpreting clinical studies of coagulase-negative staphylococci exists because of the different criteria used to define a clinically significant culture.[54] In neonates, immunocompromised patients, and patients with prosthetic implants, repeated isolation of the same phenotypic strain of coagulase-negative staphylococci from blood cultures facilitates interpretation. For catheter-related bacteremia, quantitative cultures from the catheter exhibit a five- to tenfold increase in the number of colony-forming units as compared with cultures from a peripheral vessel. The Committee on Infectious Diseases of the American Academy of Pediatrics suggested the following considerations to distinguish pathogenic from contaminant coagulase-negative staphylococci: (1) two or more positive blood cultures from different sites, (2) a positive culture from blood and another usually sterile site with identical or nearly identical antimicrobial susceptibility patterns, (3) growth in continuously monitored blood culture system within 15 hours of incubation, (4) clinical findings of infection in the patient, (5) an intravascular catheter that has been in place for 3 days or more, and (6) similar or identical genotypes among all isolates.[4]

Clinical presentation markedly differs from that of S. *aureus* infection. In general, infections caused by coagulase-negative staphylococci are more indolent and can manifest with a subacute or even chronic course.

BACTEREMIA

Coagulase-negative staphylococci, particularly *S. epidermidis*, have become the major nosocomial pathogens in most studies.[54,197] The analysis of 6290 nosocomial infections, including 110,709 patients from 61 pediatric intensive care units in the United States during 1992 to 1997, showed that bloodstream infections were the most common types of nosocomial infection; coagulase-negative staphylococcus was the causative agent in 38 percent (717 of 1887) of the cases.[197] In a large surveillance study between 1995 and 2001 among 49 hospitals in the United States, coagulase-negative staphylococci were the most common cause of nosocomial bacteremias in pediatric patients and accounted for 43 percent of the isolates.[258] These infections occur primarily with the use of indwelling vascular catheters. In febrile, immunocompromised pediatric patients with cancer, coagulase-negative staphylococci can account for 35 percent of all positive blood culture isolates.[2,11,133]

NEONATAL BACTEREMIAS

Coagulase-negative staphylococci are the single most frequent cause of late-onset septicemia among premature infants, especially in low-birth-weight infants.[16,65,80,87,88,165,179] Table 92–5 lists the salient features from six large studies.[65,88,114,115,158,179] These infections are found predominantly in premature infants with a gestational age of less than 35 weeks who have an immature immune system, particularly in quantitative and qualitative neutrophil function.[35,227,257] The presence of indwelling peripheral or umbilical catheters has been implicated in approximately half of neonatal coagulase-negative staphylococci bacteremias.[16,88,164,175]

Signs and symptoms of coagulase-negative staphylococci bacteremia *usually* are subtle and most commonly include bradycardia, apnea, and temperature instability (see Table 92-5). Skin abscesses were noted in more than 40 percent of neonates with coagulase-negative staphylococci bacteremia in one study.[179] Frequency of fulminant late-onset sepsis caused by coagulase-negative staphylococcosis bacteremia is very low (1%).[118]

Laboratory studies usually are not helpful in identifying patients with coagulase-negative staphylococci bacteremia.[161] Leukocytosis is an inconsistent finding. Reports have conflicted about production of slime, a possible virulence factor, as a marker for infection.[88,179] One study successfully correlated quantitative blood cultures with specific clinical information to distinguish a true pathogen.[233] Peripheral blood cultures yielding more than 50 colony-forming units per milliliter occurred exclusively in infants with proven septicemia. In contrast, low colony counts were observed in both septicemia and culture contamination. Those patients with low colony counts and septicemia were more likely to have a central venous line or an abnormal hematologic value (leukocytosis, decreased platelets, or increased immature to total neutrophil ratio).[233]

Persistence of coagulase-negative staphylococci bacteremia (mean duration, 12 to 13 days), despite administration of adequate antibiotic therapy, was described in neonates.[122,179] This persistence was observed in patients with and without central venous catheters and in patients with normal findings on cardiac echocardiography. Neonates with persistent bacteremia had a significantly higher incidence of severe thrombocytopenia requiring platelet transfusions than did those with nonpersistent bacteremia.[122]

Rarely, coagulase-negative staphylococci meningitis has been reported in low-birth-weight neonates with normal CSF

profiles.[85] Thus, CSF examination should be considered in neonates with coagulase-negative staphylococci bacteremia. Abnormal CSF findings or a positive CSF culture may influence the duration of therapy. Coagulase-negative staphylococci also have been implicated as etiologic agents of necrotizing enterocolitis,[84,215] although one report showed no association.[201]

LEUKEMIA AND LYMPHOMA

Immunocompromised patients with leukemia, lymphoma, or both are at risk for the development of coagulase-negative staphylococci bacteremia (Table 92–6).[2,11,69,133,190,191,219] The most common portals of entry are the gastrointestinal tract, where chemotherapy causes defects, and the skin in association with catheter devices. In several reports, coagulase-negative staphylococci were the isolates most commonly causing bacteremia in pediatric patients with cancer and accounted for 35 percent of all initial isolates.[2,11,133] One third of these patients did not have central venous catheters at the time of their bacteremia.[69]

RAPD analysis and PFGE of DNA macrorestriction fragments of blood culture coagulase-negative staphylococci isolates obtained from 40 neutropenic hemato-oncologic patients related to 61 episodes of Hickman catheter–related infections allowed the characterization of clonal coagulase-negative staphylococci types that successfully and persistently colonized patients; this finding confirmed that the skin flora was the likely source of catheter-related infections (CRIs) in 75 percent of the patients.[166]

Morbidity from coagulase-negative staphylococci bacteremia is appreciable because of the organism's acquisition of multiple antibiotic resistance, which requires the use of vancomycin or combination antibiotic therapy, with potentially toxic effects.[69,119,133,142,143,192,212] Mortality rates have varied from 0 to 11 percent.[69,133]

HEMATOPOIETIC STEM CELL TRANSPLANTATION

Coagulase-negative staphylococci have become the primary pathogen causing bacteremia in hematopoietic stem cell transplant recipients.[31,154] These episodes occur most often during periods of agranulocytosis before marrow engraftment,[31] and they can be fatal.[18] Most of these episodes are a result of the universal use of central venous catheters and the use of broad-spectrum antibiotics. Bacteremia that occurs during the neutropenic phase after hematopoietic stem cell transplantation appears to be associated with early death from invasive fungal infection.[232]

INDWELLING MEDICAL DEVICES

Central Venous Catheters

Infections associated with central venous catheters are caused primarily by coagulase-negative staphylococci, which also can cause infections in peripheral catheters composed of steel or polyethylene.[242] Central venous catheters often are used in children for long-term hyperalimentation or administration of medication.[104] Two types of devices are in common use: (1) Broviac and Hickman catheters, which have an external port, and (2) totally implanted vascular access devices.[29,99,200] Broviac and Hickman catheters have an exit site where the catheter enters the skin, whereas the totally implanted vascular devices have a subcutaneous tract; all three types have a Dacron cuff that promotes fibrosis, thereby limiting the trafficking of potential pathogens, and an insert site into the major vessel. Thus, infection can occur at the exit site, along the catheter tunnel, or at the catheter vessel insertion site. Totally implanted catheters (e.g., port-A-Cath) have the lowest rates of bacteremia (0 to 0.04 per 100 catheter days), followed by long-term Hickman or Broviac catheters (0.14 per 100 catheter days).[101] Infection at the vessel insertion site can lead to bacteremia or septic thrombophlebitis, with further complications caused by metastatic spread.[193]

Infectious complications involving central venous catheters have a variable reported frequency of 2.7 to 47 percent.[19,76,93,141,157,229,250] Coagulase-negative staphylococci are the pathogen in approximately half these cases. This variability depends on the definition of a CRI, the type of catheter used, and the presence of hyperalimentation fluid and lipid in the infusion.[146,221,223] The use of a guide wire for catheter placement or of a multilumen catheter leads to higher infection rates.[225]

S. epidermidis is the species associated most often with central venous CRIs; it is identified in approximately 70 percent of coagulase-negative staphylococci central venous CRIs.[19,93] This prevalence is not unexpected because the organism is the predominant species colonizing the skin.[128] Other implicated coagulase-negative staphylococci species include *Staphylococcus haemolyticus*, *Staphylococcus warneri*, and *Staphylococcus hominis*.[93]

Differentiating between a true infection caused by *S. epidermidis* and a contaminated specimen is difficult. Establishing the diagnosis depends on the patient's clinical status and the isolation of identical isolate strains in repeated cultures. Proper therapy, possibly including removal of a catheter, requires accurate diagnosis.[194] Additionally, distinguishing central venous catheter–related bacteremia from bacteremia not associated with a central venous catheter is important. The use of quantitative blood cultures using the DuPont isolator system has shown that catheter-related bacteremias have a 5- to 10-fold difference in bacterial concentration in blood cultures drawn through the catheter compared with peripheral cultures.[66,196] Maki and associates[147] determined that catheter-related bacteremia can be confirmed after removal of the catheter by rolling the distal 5 to 7 cm of the catheter on a culture plate and finding more than 15 colony-forming units.

Therapy for coagulase-negative staphylococci infections involving central venous catheters should include removal of the catheter if the catheter no longer is necessary. Exit-site infections usually can be managed without removing the catheter.[194] Approximately one third of tunnel tract infections can be managed without removing the catheter, but the remaining patients have continued bacteremia or relapse of their bacteremia that requires removal of their catheters. Catheters should be removed immediately if the patient's clinical status deteriorates. Duration of therapy depends on whether the catheter has been removed and on the patient's underlying immune status.

Central Nervous System Shunts

Central nervous system (CNS) shunts divert or shunt CSF to relieve hydrocephalus.[121] Other prosthetic devices within the CNS have been used to monitor ventricular pressure or to administer chemotherapy.[53] Initial shunts diverted CSF into the right atrium; this technique is used infrequently because of its high complication rate.[169] Ventriculoperitoneal shunts that divert CSF into the peritoneal cavity have been used since the 1960s because of their lower rate of mechanical complications.[121,159,169] However, the incidences of infection involving both the ventriculoperitoneal and the ventriculoatrial shunts are comparable.[121,169,224] Infection rates are higher in neonates. Coagulase-negative staphylococci account for 60 to 75 percent of all bacterial causes of shunt infections.[121,162,224]

The pathogenesis of CSF shunt infections occurs primarily at the insertion site by contamination of the catheter from the patient's skin flora[224] or during subsequent revisions, with a short-term infection rate of 13 percent and a 10-year infection rate of 27 percent.[199] Seventy percent of ventriculoperitoneal shunt infections occur within 2 months of placement of the shunt.[162] The pathogenesis of this infection appears to be similar to that of CRI, described in the pathogenesis section.

The diagnosis of CNS shunt infections caused by coagulase-negative staphylococci may be difficult to make, owing to the differentiation between a true infection and a contaminating organism. The Gram stain of ventricular fluid often is negative, but culture is sensitive. Subtle changes are noted in CSF and ventricular fluid cell counts or cytochemical findings.[262] Patients with ventriculoatrial shunts often have signs and symptoms compatible with septicemia and the additional complications of glomerulonephritis secondary to immune complexes. In patients with ventriculoperitoneal shunts, because of the distal placement of the catheter into the peritoneum, an intra-abdominal cyst may develop at the distal end of the catheter. Dysfunctions of the shunt secondary to development of infections often lead to signs and symptoms consistent with increased intracranial pressure. Standard therapy for ventriculoperitoneal shunt infections has been removal of the shunt system and administration of systemic antibiotics.[224,262,264]

Peritoneal Dialysis Catheters

Infection remains the most common complication of peritoneal dialysis, and *S. epidermidis* is the bacterial pathogen most commonly isolated,[83,187] representing as many as 50 percent of infecting organisms.[187] The pathogenesis of infections involving the peritoneal dialysis catheter is similar to that of CRIs, with infections involving the exit site, infections along the subcutaneous catheter tunnel, and peritonitis.[187] The prevalence of peritonitis in patients undergoing continuous ambulatory peritoneal dialysis is approximately 60 percent. Signs of peritonitis include fever, abdominal pain, and cloudy peritoneal dialysis; fever is variable. Removal of the catheter usually is not necessary for successful therapy but may be required in refractory cases or when the catheter malfunctions. Antibiotics are administered in the dialysis fluid, and systemic antibiotics also can be used.[62]

Prosthetic Devices

Coagulase-negative staphylococci are the second most common cause of prosthetic valve endocarditis; these pathogens account for 17 percent of contemporary cases.[255] The in-hospital mortality rate from prosthetic valve endocarditis is reported to be 26 percent. Commonly, coagulase-negative staphylococcus prosthetic valve endocarditis occurs within 60 days of implanting the device and is defined as early prosthetic valve endocarditis. It can

occur in the first year after surgery, probably caused by inoculation of the organism at the time of surgery, as noticed by the multiresistant phenotype analysis from the isolates in these patients.[26] The condition finally leads to an abscess of the mechanical valve ring. No sign or symptom is consistently diagnostic of prosthetic valve endocarditis, but fever is the most common finding. Classic endocarditis findings such as peripheral emboli and multiple positive blood cultures may be lacking in coagulase-negative staphylococci endocarditis. Anemia is the abnormality identified most commonly by laboratory tests. Obtaining blood cultures is imperative in diagnosing prosthetic valve endocarditis. Therapy should include institution of vancomycin and rifampin or an aminoglycoside, with surgical intervention as indicated.[13]

Other Indwelling Medical Devices

Coagulase-negative staphylococci are involved in an expanded spectrum of infections involving indwelling medical devices.[52,81] They include infections of prosthetic joints,[63,116] vascular grafts,[14,55] hemodialysis shunts,[174,216,217] and pacemaker pockets.[38,108,148,185] Additionally, osteomyelitis secondary to *S. epidermidis* has been reported to occur after hemodialysis and in neonates after the use of a monitoring scalp electrode.[170]

NATIVE-VALVE ENDOCARDITIS

Native-valve endocarditis, along with *S. saprophyticus* urinary tract infection, is the only non-nosocomial infection caused by coagulase-negative staphylococci.[110] Approximately 7 percent of cases of native-valve endocarditis are caused by coagulase-negative staphylococcus, and *S. epidermidis* is the most frequently isolated species.[42] These infections usually are subacute and arise from transient bacteremia. Pathogenesis is thought to involve seeding of a previously damaged valve or endocarditis that previously had not been identified.[6,17]

Staphylococcus lugdunensis can cause acute, severe, and destructive endocarditis similar to *S. aureus* endocarditis,[246] with most favorable outcomes occurring in patients who undergo valve replacement.[48] Most patients with *S. lugdunensis* endocarditis have been older than 50 years of age. Native aortic or mitral valves are involved most frequently.[245] The perineum appears to have a high colonization rate of *S. lugdunensis.*[112]

SURGICAL SITE INFECTIONS

Coagulase-negative staphylococci are the second most common cause of postoperative surgical site infections, according to National Nosocomial Infections Surveillance Report survey data.[37] Most infections probably are caused by the patient's own endogenous skin flora, but outbreaks originating from operating room personnel have been reported.[26] Outbreaks of *S. epidermidis* surgical site infections, such as mediastinitis and endocarditis, among patients who have undergone cardiac valve replacements also have been reported.[25,195]

URINARY TRACT INFECTIONS

S. saprophyticus is the most common coagulase-negative staphylococcus that causes infections in both the upper and the lower urinary tracts.[135] These infections occur predominantly in young, healthy, sexually active women,[113,135,150] during late summer and fall, with a pattern similar to that of sexually transmitted diseases.[71] Recent sexual intercourse, outdoor swimming, and occupational meat processing have been identified as risk factors.[71] *S. epidermidis* and other coagulase-negative staphylococci rarely cause urinary tract infections, but they have been noted to produce disease in older adults with urinary tract complications.[86,139,163] McDonald and Lohr[152] and Hall and Snitzer[87] described healthy children with pyelonephritis caused by *S. epidermidis*.

MISCELLANEOUS

Endophthalmitis secondary to *S. epidermidis* has been reported in patients undergoing ocular surgery or trauma.[15,28,188] Postoperative mediastinitis that develops after median sternotomy for open heart surgery can be caused by *S. epidermidis*.[24,58,82] Primary osteomyelitis secondary to coagulase-negative staphylococci is a rare occurrence in healthy children.[171] *Staphylococcus caprae*[226] and *S. lugdunensis* [211] have been linked to bone and joint infections. Coagulase-negative staphylococci have been implicated as a possible cause of toxic shock syndrome.[45]

TREATMENT

The treatment of coagulase-negative staphylococcal infections[2] depends on the patient's immunologic status, the presence of an indwelling medical device, and the results of antimicrobial susceptibility testing. Infections are more difficult to treat when they are associated with a thrombosed vessel or an intra-atrial thrombus. When an intravascular catheter becomes infected, the presence of vegetation or a thrombus in the heart or great vessels always should be considered.

Many coagulase-negative staphylococci, particularly *S. epidermidis* and *S. haemolyticus*, are resistant to many antimicrobiotics.[7,9,39,49,61,78,218,231,256] Methicillin resistance, especially, is prevalent in nosocomial infections and occurs in most cases.[208,228] Methicillin-resistant coagulase-negative staphylococcus has a high degree of resistance to other antibiotics, such as clindamycin, erythromycin, and gentamicin.[7]

The mechanism of methicillin resistance in coagulase-negative staphylococci is similar to that of *S. aureus* because of the production of an additional non-native penicillin-binding protein (PBP), PBP2a, encoded by the *mecA* gene.[96,103] PBP2a does not allow the correct binding of β-lactams to the bacterial cell wall. Phenotypic methicillin resistance can be difficult to detect because of the heterogeneous expression of the *mecA* gene by many strains of staphylococci.[103] *S. aureus* breakpoints have been seen to fail to detect many coagulase-negative staphylococci that contained the *mecA* gene involved in staphylococcal resistance. As a consequence, the Clinical and Laboratory Standards Institute in 2007 recommended specific breakpoints for coagulase-negative staphylococci (Table 92–7).[43] In some species other than *S. epidermidis*, the differentiation between *mecA*-negative and *mecA*-positive strains may not be possible by susceptibility methods,[238] and isolates may falsely be designated as oxacillin resistant. Detecting the *mec*A gene is an accurate method to predict resistance to oxacillin.[103] Testing of coagulase-negative staphylococci using oxacillin screen plate no longer is recommended because of its failure to detect many resistant strains.[238]

Coagulase-negative staphylococci (*S. haemolyticus* and *S. epidermidis*) were the first organisms in which acquired glycopeptide resistance was recognized in 1986.[218] In addition, *S. epidermidis*, *S. haemolyticus*, and *S. hominis* are more likely to be multiresistant to antimicrobial agents than are other coagulase-negative staphylococcal species. A prolonged course of vancomycin is a well-recognized risk factor for the emergence of strains with decreased susceptibility to glycopeptides.[21,260] Although they are uncommon

TABLE 92–7 Breakpoints for Antibiotic Susceptibility for Coagulase-Negative Staphylococci

MICs	Oxacillin-Susceptible	Oxacillin-Resistant	
CoNS	≤0.25 μg/mL	≥0.5 μg/mL	
S. aureus	≤2 μg/mL	≥4 μg/mL	
Zone Size	**Oxacillin-Susceptible**	**Oxacillin-Intermediate**	**Oxacillin-Resistant**
CoNS	≥18 mm	No intermediate zone	≤17 mm
S. aureus	≥13 mm	11-12 mm	≤10 mm

CoNS, coagulase-negative staphylococci; MICs, minimal inhibitory concentrations. Data from Clinical and Laboratory Standards Institute: Performance testing for antimicrobial susceptibility testing, 17th informational supplement M100-S17, 2007.

occurrences, infections caused by these strains have been described and may become more common. To prevent or delay development of resistance, the Centers for Disease Control and Prevention published recommendations for the prudent use of vancomycin.[36] Decreased susceptibility occurs more frequently to teicoplanin than to vancomycin. The minimal inhibitory concentrations of teicoplanin usually fall over a wide range, whereas vancomycin minimal inhibitory concentrations tend to remain more stable over a narrower range within the limits of susceptibility.[21] The peptidoglycan of these strains is highly cross-linked, containing additional serine in place of glycine, an alteration that may interfere with glycopeptide binding.[96]

The mechanism for vancomycin-intermediate resistance of *S. aureus* and coagulase-negative staphylococci is unknown. Vancomycin-intermediate *S. aureus* and vancomycin-intermediate, coagulase-negative staphylococcal strains have thickened cell walls, as shown by electron microscopy. Vancomycin resistance may be related to an increased ability of these organisms to bind vancomycin at sites other than those to which they normally bind.[96]

For the few isolates that are established to be penicillin susceptible and β-lactamase negative, penicillin is a suitable drug. For organisms that are resistant to penicillin but susceptible to semisynthetic penicillins, nafcillin and oxacillin are the most active antibiotics.[189,209] A degree of cross-resistance exists between the semisynthetic penicillin-resistant penicillins and cephalosporins.[208] Thus, routine susceptibility testing can indicate that a strain is susceptible to a cephalosporin when, in fact, it is resistant.[83,136] Methicillin resistance means resistance to all β-lactam antibiotics.[109]

Vancomycin is the drug of choice for methicillin-resistant organisms and is recommended for treating severe infections.[3,124] Coagulase-negative staphylococci can exhibit heteroresistance, defined as a culture population comprising two subpopulations, one susceptible to methicillin and the other resistant.[208,260] Enhanced detection of this admixture of organisms can be obtained by change in the culture conditions.[153] If these strains are incubated overnight on plates of increasing concentrations of methicillin or vancomycin, a small fraction of the total population will be able to grow at much higher antibiotic concentrations. If these highly resistant subclones are recultured, they may maintain this high level of resistance, a finding suggesting a mutant strain. However, in some cases, the highly resistant subclone will revert to methicillin or vancomycin susceptibility when it is replated, even though it was grown from a single colony. No satisfactory model can explain the mechanism governing heterogeneous resistance. Strains of coagulase-negative staphylococci and *S. aureus* with heterogeneous resistance are stable in the absence of antibiotic selective pressure. These strains may constitute 10 to 15 percent of any coagulase-negative staphylococci or *S. aureus* collection of isolates. In addition, to avoid overlooking these organisms, the clinical microbiology laboratory should attempt to optimize expression of resistance by culturing on salt-containing media at 30° C to 35° C.[207] The clinical significance of this heteroresistance in coagulase-negative staphylococci is unknown, but a study of *S. aureus* showed it did not affect outcome.[125]

The quinolones and teicoplanin have shown activity against coagulase-negative staphylococci and could be useful in therapy of highly selected multiresistant organisms.[140,221] Teicoplanin is significantly less active than is vancomycin against coagulase-negative staphylococci, in particular *S. haemolyticus*, and, to a lesser extent, *S. epidermidis*. Resistance to these agents also has been observed.[9,218,231,256]

Gentamicin and rifampin are active against coagulase-negative staphylococci, but rapid emergence of resistance has limited their use as single drugs.[39,151,209] These two antibiotics have been shown to be synergistic with vancomycin against methicillin-resistant, coagulase-negative staphylococci.[142] Additionally, rifampin has been used in neonates with persistent bacteremia to eradicate the organisms.[235] The association of vancomycin and rifampin is the mainstay of therapy for deep-seated, foreign body infections.

Excellent in vitro activity of quinupristin-dalfopristin, a streptogramin combination,[10] and linezolid, an oxazolidinone compound that inhibits bacterial growth through inhibition of protein synthesis,[206] has been shown against staphylococcal species tested, regardless of the resistance pattern, particularly resistance to methicillin. Linezolid is an option for vancomycin-intermediate susceptible isolates or for completing therapy with oral administration.[117] Daptomycin is a lipopeptide antibiotic with excellent in vitro activity against coagulase-negative staphylococci.[210]

PREVENTION

Preventing the development of coagulase-negative staphylococci infection is difficult because of these organisms' ubiquitous nature as predominant skin commensals. A 3-year analysis by molecular typing of coagulase-negative staphylococci nosocomial infections in a neonatal intensive care unit showed that many of the infections were caused by clonal dissemination and, thus, potentially were preventable by handwashing, thus reducing the transmission rate from staff to patient or from patient to patient.[249] Additionally, proper surgical techniques help to minimize these infections associated with installation of indwelling medical devices.

The effort toward developing catheters that are both inert and resistant to bacterial colonization adherence has increased; however, these attempts have been only marginally successful.[123,177,184] Catheters with antibiotics or disinfectants impregnated in their surfaces appear promising.[237] Prophylactic antibiotics are administered routinely for surgical procedures involving placement of a prosthetic device or material. However, the most appropriate agent to prevent infections caused by coagulase-negative staphylococci varies among institutions.[3] Vancomycin often is recommended for CSF shunt or prosthetic valve placement. Polyclonal antibody (intravenous gammaglobulin) and polyclonal antibody enriched for antibody to clumping factor A have not been found to be efficacious for preventing coagulase-negative staphylococcal infections in neonates.[22]

In reference to infection control policies, standard precautions should be used for methicillin-resistant, coagulase-negative staphylococci. For vancomycin-intermediate, coagulase-negative staphylococci, contact transmission precautions for multidrug-resistant organisms should be used.[4]

CONCLUSION

Coagulase-negative staphylococci, particularly *S. epidermidis*, are a major source of nosocomial infection in a variety of clinical situations. Most infections occur in patients who are immunosuppressed or have an indwelling medical device. Epidemiologic studies are difficult to perform because of the organisms' commensal existence, but newer molecular tools will help investigators to gain insight with regard to the epidemiology of these infections. The pathogenesis of coagulase-negative staphylococci infection is being defined in the context of a CRI. Therapy can be complex because of the usual presence of an indwelling medical device and the multiple antimicrobial resistance of the organisms.

CHAPTER 93

Group A, Group C, and Group G Beta-Hemolytic Streptococcal Infections

Edward L. Kaplan ✪ Michael A. Gerber

GROUP A STREPTOCOCCAL INFECTIONS

Group A beta-hemolytic streptococci (*Streptococcus pyogenes*) are common pathogenic bacteria isolated from children. They are associated with a wide variety of infections and disease states (Fig. 93–1). Although uniformly sensitive to penicillin and still exquisitely sensitive to many other antibiotics, group A streptococcal infections present formidable clinical and public health problems for pediatricians and primary care physicians. Although most group A streptococcal infections are of short duration and relatively benign, they may be fulminant and life-threatening. The importance of group A streptococcal infections was reinforced in

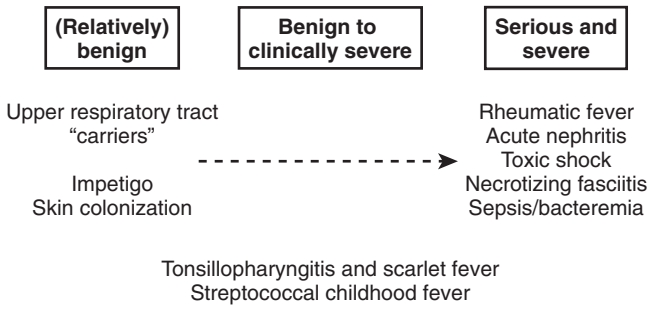

Figure 93–1 Spectrum of group A streptococcal infections.

the late 1990s by a resurgence of acute rheumatic fever in the United States[114] and the appearance of a group A streptococcal toxic shock syndrome (TSS) with very high morbidity and mortality rates.[153,154] Additionally, this bacterium is different from other pyogenic bacteria because of the potential for development of delayed, nonsuppurative sequelae (e.g., acute glomerulonephritis, acute rheumatic fever, reactive arthritis) to follow uncomplicated infections.

ORGANISM

S. pyogenes (group A streptococcus) is a gram-positive coccus, forming either short or long chains. Group A streptococci produce clear (beta) hemolysis on blood agar, a bacteriologic feature important in their recognition and in their differentiation from nonhemolytic (gamma) streptococci and from viridans (alpha) streptococci, which cause partial or green hemolysis on sheep blood agar. Although hemolysis is produced on culture plates containing blood from a variety of mammalian species, sheep or horse blood gives the clearest differentiation. Some strains of group A streptococci hemolyze red blood cells slowly or result in almost greenish hemolysis on the surface of blood agar plates incubated aerobically. These strains can be recognized by their ability to produce clear hemolysis under anaerobic conditions, which is achieved readily by routinely making a short cut or stab into the blood agar at the time of inoculation.[85] Incubation with carbon dioxide or in a candle jar also can be helpful in enhancing beta-hemolysis. Rare strains of group A streptococci are not hemolytic.[77,84]

Approximately 124 different types of group A streptococci have been recognized either on the basis of a series of serologically distinct surface proteins, the M proteins, or by sequencing of the *emm* gene, which encodes for M protein.[56,57,85,108] The M serotypes of streptococci associated with impetigo and pyoderma often are different from the serotypes associated with clinical pharyngitis, although a few M types have the capacity to produce both kinds of infection.[6] The M protein renders the group A streptococcus resistant to phagocytosis and is a major virulence factor for these organisms. Additional evidence indicates that more M-types exist that have not been identified yet; new *emm* sequences are continuing to be described (see http://www.cdc.gov/ncidod/biotech/strep/strepindex.htm).

The group A streptococcal cell is a complex structure. In rapidly dividing strains (e.g., young cultures, epidemic strains), the cell is covered with a hyaluronic acid capsule, which gives the colonies a mucoid or water drop appearance. Protruding from the cell surface and into the hyaluronic capsular layer are microscopic hairlike fimbriae, which are responsible for adherence of group A streptococci to epithelial cells. A basic chemical component of these fimbriae is lipoteichoic acid.[12] The M protein also is associated with these fimbriae.[60] Other surface proteins of interest are the T and R proteins, the serum opacity factor (SOF) proteins, and proteins that bind nonspecifically to the Fc fragment of gamma-globulins. The function and the exact location of these other proteins on the surface of the organism have not been identified precisely. Strains of a particular M type generally are associated with a particular T agglutination pattern.[82] In strains producing serum opacity, the serologically specific SOR protein usually correlates closely with the M type of the strain. At present, more than 50 opacity factor–positive types of group A streptococci have been recognized; others undoubtedly have not been identified yet. All of these characteristics are useful in epidemiologic studies of streptococcal infections, either in an individual patient or in a community.

In addition to these surface proteins, the carbohydrate moiety responsible for group specificity (e.g., group A carbohydrate) is found in the cell wall in a position sufficiently superficial to permit reaction with antibody specifically directed toward it. The group A carbohydrate is a polymer of rhamnose units with side chains of *N*-acetylglucosamine, which is responsible for its group (e.g., A) specificity.[118] The structure providing rigidity for the cell wall is another large polymer, a peptidoglycan, consisting of glycan strands cross-linked by peptide bridges. Its role in the pathogenesis of infection remains incompletely defined.

Within the cell wall of the group A streptococcus lies the cell membrane, composed mainly of lipoprotein or lipid-protein complexes. This membrane is the outer surface of the osmotically fragile protoplasts or L forms of streptococci. These wall-less forms of group A streptococci are resistant to penicillin.[62]

Intracellular constituents of the group A streptococci include, in addition to DNA and RNA, many enzymes and hemolysins.[26] Plasmids have been identified that control resistance to certain antibiotics (e.g., erythromycin).[113] Bacteriophages play an important role in the genetics of group A streptococci, including the transfer of the determinants of antibiotic resistance and the control of pyrogenic exotoxin production.[169,174]

Group A streptococci produce and release into the surrounding medium numerous biologically active extracellular products. Some of these are toxic for human and other mammalian (eukaryotic) cells. Streptolysin O (the oxygen-labile hemolysin) and streptolysin S (the oxygen-stable hemolysin) injure cell membranes, not only lysing red blood cells, but also damaging other eukaryotic cells (including myocardial cells) and membranous subcellular organelles.[15] Streptolysin O is antigenic; streptolysin S is not. The latter hemolysin is bound loosely to the streptococcal cell and is released in a complexed, stable form with a variety of carrier molecules. The pyrogenic exotoxins resemble endotoxin in exhibiting a primary or intrinsic toxicity and a secondary toxicity resulting from the acquisition of host hypersensitivity.[103] The outbreak of streptococcal TSS, which became pronounced in the late 1990s, was reported to be associated with the reappearance of strains making pyrogenic exotoxin A, but many unanswered questions remain about the precise pathogenesis.[153] Group A streptococci also produce bacteriocins,[155] low-molecular-weight proteins that can kill a variety of other gram-positive bacterial species and may play a role in promoting infection or even persistence of colonization.

Many of the other extracellular products of group A streptococci are specific enzymes that do not seem to be directly toxic for mammalian or bacterial cells, but digest or initiate the breakdown of important biologic substrates. Included are the deoxyribonucleases (nucleases A, B, C, and D), the streptokinases (which activate the fibrinolytic or plasmin-plasminogen system), a hyaluronidase, an amylase, a proteinase, an esterase, a nicotinamide adenine dinucleotidase (NADase), and C5a peptidase. Several of these enzymes are antigenic (e.g., DNAse B, streptokinase, hyaluronidase, NADase, C5a peptidase). Among group A streptococcal surface virulence factors, C5A peptidase plays a major role by inactivating the complement chemotaxin C5A, reducing the early

phagocytic response in allowing group A streptococci to become locally established. This extracellular product has been shown to be antigenic in animals and in humans.[34]

TRANSMISSION

Humans are the only known reservoir for group A streptococci. The mechanism of spread of streptococci from one person to another and from one body site to another varies according to the clinical manifestations of the infection. Epidemiologic studies of patients with streptococcal sore throat indicate that airborne routes of spread (by small droplet nuclei, dust) and environmental contamination (e.g., contaminated clothing or bedding) play little, if any, role in transmission of this kind of group A streptococcal infection.[132] Close personal contact is required for transmission of streptococcal pharyngitis to occur, apparently by direct projection of large droplets or by physical transfer of respiratory secretions containing the infectious bacteria. Spread within homes, school rooms, or crowded facilities such as military barracks is a common occurrence.[49] Residential nursing facilities also have proven to be highly susceptible to spread among staff members and patients.

Contaminated food or milk also may result in group A streptococcal infection of the throat, producing a common-source outbreak.[74] Salads containing hard-boiled eggs (e.g., egg salad) seem to be a special problem. Anal carriers have been identified as the source of contagion in several hospital outbreaks of streptococcal wound infections. Some studies have suggested that rectal or anal carriers may be more common than suspected.[104]

The period of greatest contagiousness of streptococcal pharyngitis and scarlet fever is during the acute stage of the illness. Most antibiotic therapies (especially penicillin) rapidly suppress the growth of group A streptococci and, if continued, most often eradicate them from the upper respiratory tract. A patient can be considered much less contagious after 24 hours of antimicrobial therapy. Most physicians concur that children can return to school by that time, especially if they are afebrile, with reduced risk of spread of the organism to close contacts.[150]

Although humans with active but subclinical infection also may contribute to the spread of group A streptococci, the role of throat "carriers" in the spread of this organism apparently is less important. Most secondary spread occurs during the first 2 weeks after acquisition occurs.[163] Rarely do streptococcal upper respiratory tract carriers spread the organism.[87] In contrast to carriage in the throat, which may persist for weeks or months, the prolonged presence of group A streptococci in the anterior nares is unusual.

In contrast to the upper respiratory tract, where group A streptococcus can establish infection readily on an intact epithelial surface, the production of streptococcal impetigo or pyoderma seems to be facilitated by prior disruption of the skin by trauma, insects, or some preexisting skin disorder. Group A streptococci may be found on the normal skin for several days to 2 weeks before infection develops,[59] requiring some other means of access. It does not seem likely that the source of infection for streptococcal skin infections is the upper respiratory tract. Group A streptococci causing impetigo may be found in the nose or throat, but they usually do not reach this site until several weeks after cutaneous infection has been established. One possible source is a skin lesion in another child, with spread occurring by direct contact. Some data suggest that spread may occur even by small flies that feed on such lesions.[11] The exact role of environmental contamination in the spread of streptococcal impetigo and pyoderma, and in secondary infection of wounds, burns, and eczema and other dermatoses, is unknown. The mechanism of transmission of erysipelas also is poorly understood, but may involve spread via the respiratory tract.

Measures to prevent spread of group A streptococcal infections vary in their effectiveness. Spread of throat or skin infection within a family often occurs before the index case is identified and isolated or treated. In epidemic situations, especially situations involving cases of rheumatic fever or acute nephritis, a culture survey with treatment of all individuals with positive cultures (mass prophylaxis) may be indicated. Reduction of crowding, especially in sleeping quarters, seems to be an effective long-term method of minimizing the incidence of transmission of streptococcal sore throat among some groups.

In families in which persistence or recurrence of streptococcal infection is a problem, simultaneous throat culture and culture of skin lesions of all members and treatment of all who have positive results have been successful in eradicating the organism. Some investigators have advocated a role for family pets (dogs) in transmission of streptococcal infections. Available data do not support such transmission as a common occurrence, however.[17,39,172] Control of environmental contamination would be expected to have little or no influence on the spread of group A streptococcal respiratory infections, although it possibly has an effect in controlling skin or wound infections. It also is suggested that family toothbrushes may have a role in the intrafamilial transmission of group A streptococci. More recent guidelines have suggested, however, that obtaining cultures of all family members in instances in which invasive group A streptococcal infections occur is not always necessary. Because of reported instances in which secondary cases have occurred, this guideline remains controversial.[132,136]

EPIDEMIOLOGY

Group A streptococci have a narrow range of hosts. They are one of the pathogenic bacteria identified almost exclusively in humans and only extremely rarely are found in other species.[108] In considering the epidemiology of group A streptococcal infections, one must recognize that significant differences exist between throat and skin infections.[133,164]

Streptococcal impetigo occurs with greatest frequency in preschool-aged children, whereas streptococcal pharyngitis predominantly is a disease of school-aged children. Outbreaks of streptococcal respiratory tract infections also have been observed in daycare centers.[149] On average, streptococcal respiratory infections occur at the rate of one every 3 to 5 years during childhood. One comprehensive long-term study suggested that the average child has three documented group A streptococcal infections (range of one to eight per child) before reaching age 13.[49] Among preschool and early school–aged children of certain populations, streptococcal impetigo is a recurrent problem.

The seasonal occurrence and geographic distribution are different for throat and skin infections. Tonsillitis and pharyngitis caused by streptococci are common occurrences in temperate and cold climates; streptococcal pyoderma and impetigo seem to occur with greater frequency in hot or tropical climates.[28] Streptococcal sore throat occurs more frequently in late autumn, winter, and early spring months. In tropical climates, pharyngeal colonization seems to occur more frequently during the rainy season. Streptococcal impetigo usually is a disease of the summer months in temperate climates, but it may occur with equal frequency year-round in tropical countries. In some tropical climates, groups C and G beta-hemolytic streptococci are isolated more frequently from the upper respiratory tract than is group A.[69] This finding has led some researchers to speculate about a possible etiologic role for groups C and G streptococci in the pathogenesis of rheumatic fever.[69]

PATHOGENESIS

No complete explanation is available for the predilection of certain body sites for infection by group A streptococci, or for the ability of strains of certain M types to produce pharyngitis or tonsillitis and of others to produce impetigo or pyoderma. In the establishment of throat infection, a primary requisite is a method of attachment to the epithelial cells of the pharynx. Group A streptococci attach by means of their fimbriae. To initiate an infection, group A streptococci also must compete with the resident pharyngeal flora, notably the alpha-hemolytic or viridans streptococci, which may interfere with the colonization of group A streptococci in the throat,[40] perhaps as a result of the production of a bacteriocin-like substance.[45] The relative importance of bacterial interference in preventing colonization of the human upper respiratory tract with group A streptococci is unclear, however. The influence of producers of a bacteriocin-like substance may be minimal in certain situations.[76]

In the production of impetigo, group A streptococci also must vie with other local bacterial flora. Removal of the normal flora increases the time of survival of group A streptococci applied to the skin.[3] Skin lipids, some of which are lethal for group A streptococci in vitro, also may provide a natural barrier against the establishment of streptococcal infection.

Invasion of the tissues by group A streptococci may be facilitated by a combination of bacteriologic properties. Damage to leukocytes and to fixed tissue cells may result from any of the several toxins produced, and the spread of infection may be aided by specific enzymes that attack hyaluronic acid and fibrin. M protein is antiphagocytic and contains a moiety that is cytotoxic in the presence of non–type-specific antibody.[14] The protective role of mucosal immunity remains incompletely defined. The hyaluronic acid capsule of group A streptococcus may serve as a camouflage because it resembles mammalian hyaluronic acid. In addition, several streptococcal substances (streptococcal pyrogenic exotoxins and peptidoglycan) have been shown to have endotoxin-like properties. A role for pyrogenic exotoxins has been postulated for streptococcal TSS and for necrotizing fasciitis.[152,153]

The factors responsible for the early host defense against group A streptococci (before the development of antibody) are incompletely understood. Type-specific antibody against M protein, which greatly promotes phagocytosis, usually is not detectable until 6 to 8 weeks after the infection has occurred[47]; its primary role may not be in the limitation or termination of active infection, but rather in the prevention of re-infection by the same serologic type. Reports indicate that type-specific immunity may be to specific strains within a given serotype, rather than to all strains within a given serotype.[46,161] The significance of this potentially important observation in the epidemiology of streptococcal infections and in the pathogenesis of nonsuppurative sequelae has not been defined fully. Surface phagocytosis, first by monocytes and later by polymorphonuclear leukocytes, may be the primary mechanism of defense in the early stages of infection.[141] In streptococcal skin infections, an increase in the leukotactic activity of polymorphonuclear leukocytes has been reported.[65]

Approximately 30 minutes after ingestion by a polymorphonuclear leukocyte has occurred, the streptococcus may be killed. Occasionally, the reverse occurs because of a phenomenon known as *leukotoxicity*, which apparently is related to the production of streptolysin S.[124] Degradation of the streptococcus within phagocytes or in tissues is a much slower process, suggesting that the human host may be unable to break down the streptococcal cell wall in an efficient manner.[65] This feature seems to be in contrast to the reported engulfment of group A streptococci by respiratory epithelial cells; in the latter instance, evidence suggests intracellular survival of the streptococci occurs, perhaps accounting for the persistence of these organisms in individuals thought to be carriers.[109]

Spread of streptococci to the regional lymph nodes can occur, especially in infections of the pharynx and tonsils.[45] Bacteremia occurs in the absence of underlying systemic disease, such as leukemia or other malignancies,[52,68] but it is an uncommon occurrence in older children and adults. The reason for the apparent increase in prevalence of severe systemic group A streptococcal infections beginning in the 1980s and 1990s and continuing into the 21st century remains incompletely explained. Although certain M types seem to be isolated more frequently from such severe infections (e.g., M-1, M-3), these strains apparently are no different from similar M types causing uncomplicated infections. Many M/*emm* types have been recovered from patients with severe systemic infections.

The rash and other toxic manifestations of scarlet fever have been attributed to the development of hypersensitivity to the pyrogenic toxins.[119] Toxic manifestations that have been noted in group A streptococcal TSS also may result from a direct influence of the pyrogenic exotoxins on lymphokines, such as tumor necrosis factor.[152,153] Hypersensitivity to other streptococcal products also may contribute to the manifestations of streptococcal disease.

Theories abound about the pathogenetic mechanism leading to the development of the nonsuppurative complications of streptococcal infections, acute rheumatic fever, and acute glomerulonephritis. Most of these hypotheses invoke immunologic processes in one way or another.[75,119,159] A major impediment toward clarifying the pathogenetic mechanism responsible for the development of nonsuppurative sequelae has been the lack of an appropriate animal model for study.

CLINICAL MANIFESTATIONS

Streptococcal pharyngitis or tonsillitis usually is a short-lived clinical illness with a brief incubation period (12 hours to 4 days). It varies greatly in its severity, from a subclinical or almost subclinical form, occurring in 30 to 50 percent of infections, to a very toxic form with high fever, nausea, and vomiting. Extreme toxicity may occur more frequently in epidemic situations, especially food-borne outbreaks, suggesting the importance of the rapid passage of the infecting organism from person to person in determining the severity of infection. The onset is acute and may be marked by fever, sore throat, headache, or abdominal pain (more common in children). The tonsils and pharynx may appear inflamed or infected but may look pale in the presence of marked edema. Exudate is a common manifestation (50%-90%). It usually appears by the second day and typically is discrete and whitish yellow and may become confluent by the following day. Swollen, tender anterior cervical lymph nodes (adenitis) also can be observed in 30 to 60 percent of patients.

The clinical manifestations usually subside spontaneously in 3 to 5 days, unless suppurative complications (otitis media, sinusitis, peritonsillar abscess) develop. Patients who develop nonsuppurative sequelae have a latent period of 1 to 3 weeks during which they seem completely well. After streptococcal infection of the upper respiratory tract develops, the average latent period for acute glomerulonephritis is 10 days; for acute rheumatic fever, the average latent period is 18 days.[164]

An infantile form of streptococcal infection, referred to as *streptococcal childhood fever*, may take a more prolonged course, with chronic low-grade fever, generalized lymphadenopathy, and a persistent serous nasal discharge; little or no evidence of localized inflammation is present in the pharyngeal area. The term *streptococcosis*, which sometimes has been used to refer specifically to this infantile form, should be employed more correctly to indicate the broad spectrum of clinical pictures that change with age in a manner analogous to tuberculosis.[131]

Scarlet fever is a rare disease in infants. This observation may be because of the possibility of placental transfer of maternal antibody to the pyrogenic toxins. A more complete explanation may relate to a necessity for hypersensitization to these exotoxins to develop before this manifestation of streptococcal disease can be expressed.[99] In the mid-20th century, the severe toxic form of scarlet fever was a rare occurrence in most industrialized countries; milder forms of the illness were prevalent. In the late 1980s, numerous reports of an illness characterized by scarlet fever–like rash but with severe systemic manifestations, including fasciitis, myositis, adult respiratory distress syndrome, and very high mortality rate (up to 30%), became more prevalent in the United States.[22,91]

The characteristic rash is red and finely punctate, appearing initially on the trunk and spreading peripherally within several hours to several days to cover almost the entire body in full-blown cases. A typical feature of the rash is that it fades on pressure and almost always leads to desquamation. Linear red lines may develop in the skin folds of the joints (Pastia lines) or in other areas of the extremities. The strawberry tongue of scarlet fever has a swollen, red, and mottled appearance and eventually peels. A scarlatiniform rash also may occur with streptococcal impetigo and streptococcal wound infections. An enanthema of stippled, bright red or hemorrhagic spots may appear on the soft palate or the anterior pillars of the tonsillar fossae. Exudate and tender cervical nodes may be present as in streptococcal pharyngitis without a rash, but the pharyngeal signs sometimes are minimal.

Streptococcal impetigo may develop a few days to several weeks after deposition of the infecting strain on the normal skin; the average latent period is 10 days.[59] In contrast to pharyngitis, this form of group A streptococcal infection frequently is painless, and the patient usually is afebrile. The initial lesion is a superficial vesicle with little surrounding erythema. This lesion rapidly develops into a pustule and then into a thick, honey-colored crust; this stage may last for a few days to several weeks. Secondary infection with staphylococci is a common development in the pustular and crust stages.[44,48] Removal of the crusts by trauma or as part of local therapy reveals a moist or purulent undersurface in the earlier stages. The infection does not involve the dermis. On healing, depigmentation may be seen, but permanent scarring rarely occurs. The lesions develop most frequently on the lower extremities but may occur on other exposed portions of the body, such as the upper extremities and the face.

Acute poststreptococcal glomerulonephritis may develop after impetigo or other forms of cutaneous streptococcal infection produced by a nephritogenic strain have occurred; rheumatic fever has not been proven to be associated with group A streptococcal skin infections.[166] This concept has been challenged by investigators working in populations in which group A streptococcal upper respiratory tract infections are rare compared with streptococcal pyoderma; these populations have very high incidence rates for acute rheumatic fever.[28] At present, however, a role for group A streptococcal skin infection in the pathogenesis of rheumatic fever remains unproven. The latent period for acute nephritis is longer after a skin infection (average, 3 weeks) than after a throat infection (average, 10 days).[92] The serologic types associated with nephritis after skin infection usually differ from the types causing nephritis after throat infection.[164] M-12 has been the classic nephritogenic serotype associated with pharyngitis, whereas serotypes such as M-49, M-55, and M-57 have been associated more frequently with nephritis occurring after skin infection.[164]

Impetigo and more nondescript forms of streptococcal pyoderma may be superimposed on scabies, eczema, other dermatoses, burns, and wounds, which afford a means of access through the cutaneous barrier. Ecthyma is a more deep-seated and chronic form of streptococcal pyoderma found predominantly in tropical climates.[1]

Erysipelas is an unusual type of streptococcal infection involving the skin and sometimes the adjacent mucous membranes. It is an elevated erythematous lesion, sometimes exhibiting blebs filled with yellowish fluid, which may crust over after rupture. The lesion is characterized by a well-demarcated advancing border, more reddened and edematous than is the central area, which may fade and become more normal in appearance as the lesion progresses. Erysipelas most often involves the face (especially in children), the extremities, or the body. The lesion may surround a surgical or traumatic wound, an area of dermatosis, or the umbilical stump in a newborn infant. Erysipelas tends not to spread from one body region to another. In erysipelas, the onset is acute and often is accompanied by the manifestations of systemic toxicity characteristic of other febrile forms of streptococcal infection. The lesion may last for a few days to several weeks. Relapses are common occurrences, with recurrences frequently at the same body site.

In addition to the infections described earlier, group A streptococci may produce a variety of other clinical pictures. Other infections associated with upper respiratory tract infections by these organisms include otitis media, retropharyngeal abscess, sinusitis, mastoiditis, pneumonia, and empyema. Beta-hemolytic streptococci are recoverable from approximately 50 percent of patients with peritonsillar abscess and may act in concert with anaerobic bacteria in the production of this clinical picture.[61] Acute puerperal sepsis, now a rare development, classically has been associated with group A streptococci. Outbreaks of omphalitis, bacteremia, and meningitis in nurseries continue to be reported occasionally.[156] Fatal gangrene,[66] disseminated intravascular coagulopathy,[80] and purpura fulminans[38] may be associated with infection by group A streptococci. These bacteria also are a common cause of perianal cellulitis and vaginitis in children.[4,104] Subpectoral abscesses and empyemas may develop as complications of streptococcal infections of the thumb and index finger as a result of the lymphatic drainage of that part of the hand.[4] Septic complications of varicella, including varicella gangrenosa,[25,148] osteomyelitis (especially in infants),[70] hand-foot syndrome,[71] blistering distal dactylitis,[72] necrotizing fasciitis, and TSS, are associated with beta-hemolytic streptococci. Some investigators have suggested that streptococcal infections may be responsible for episodes of acute guttate psoriasis.[8]

STREPTOCOCCAL UPPER RESPIRATORY TRACT CARRIER STATE

A puzzling aspect of the relationship of group A streptococci and the human host is the streptococcal "carrier" state. Not only does it represent a diagnostic and a therapeutic enigma for clinicians and public health authorities, but also the theoretical implications relating to pathogenesis of nonsuppurative sequelae are intriguing.[87] Data in the literature suggest that group A upper respiratory tract carriers are less dangerous to others because carriers only rarely spread the organism to close contacts. In addition, the risk of developing nonsuppurative sequelae, such as rheumatic fever, seems to be significantly reduced in carriers.[88] The epidemiologic and immunologic reasons for establishment and continuation of the carrier state are not understood.

Much of this confusion has resulted from the definition of the carrier state. In contrast to true infection, in which the patient has the presence of an organism and evidence of a host immune response, group A streptococcal upper respiratory tract carriers may harbor the organism in the upper respiratory tract for prolonged periods without evidence of an immunologic response, as measured by an increase in antibody to streptococcal antigens.[87]

The explanation for this prolonged persistence of group A streptococci in the upper respiratory tract is unknown. Whether

it is attributable to bacterial or host factors is unexplained. Hypotheses have been proposed to explain persistence of the organism in the upper respiratory tract. Bacterial data suggest that internalization of the group A streptococci into epithelial cells may explain their ability to continue to survive. Researchers have seen in vitro that stationary phase organisms are internalized easily by epithelial cells, and others have associated internalization with the presence of fibronectin-binding proteins in specific strains of group A streptococci.[109,122] Because of the inability of penicillin to penetrate the epithelial cell and to eradicate the organism from the carrier, this is an attractive explanation for clinical findings.[94]

For clinicians, the carrier has proven to be particularly problematic.[82,168] The ability to identify prospectively carriers and to separate them from individuals with bona fide upper respiratory tract infections, and the reported difficulty of eradicating the organism from the upper respiratory tract of carriers remains a perplexing and frustrating problem, especially considering that 5 to 20 percent of children may carry group A streptococci in their upper respiratory tract during the late autumn, winter, and early spring.

TABLE 93–1 Upper Limits of Normal for Anti-streptolysin O and Anti-deoxyribonuclease B for Children 2 to 12 Years Old

Rights were not granted to include this table in electronic media.
Please refer to the printed publication.

From Kaplan, E. L., Rothermel, C. D., and Johnson, D. R.: Antistreptolysin O and anti-deoxyribonuclease B titers: Normal values for children ages 2-12 in the United States. Pediatrics 101:*86-88, 1998.*

IMMUNOLOGIC RESPONSE

The numerous somatic constituents and extracellular products of group A streptococci, most of which are antigenic, accounts for the complex nature of the host immune response after group A streptococcal infection develops. Humoral and cellular immune responses have been studied, the former more thoroughly than the latter.[167]

Skin and in vitro tests suggest that most adults are hypersensitive to a variety of streptococcal antigenic preparations, whereas infants more often are nonreactive. Lymphocyte transformation responses to most streptococcal substances probably are specific in nature, resulting from prior sensitization. Some studies indicate, however, that a nonspecific (mitogenic) response may occur with certain extracellular and cellular fractions. Inhibition of migration of leukocytes has been shown with fractions of streptococcal culture supernates and with cell membrane and cell wall fractions.[135,144] Some evidence from research in humans suggests that the cellular immune response to a streptococcal extracellular antigen is controlled genetically.[67,144]

In humans, humoral immune responses have been shown to numerous somatic components of the group A streptococcal cell. Of particular interest are antibodies to the group A carbohydrate that serologically are cross-reactive with the glycoprotein of human and bovine heart valves and antibodies to protein components of the group A cell wall or cell membrane that have been reported to be cross-reactive with the sarcolemma of heart muscle.[9]

Antibody to the M protein (type-specific antibody) is of special importance because it is the basis of immunity and protection against re-infection with the same serologic type.[13,107,163] Type-specific antibody may be transferred across the placenta from mother to fetus.[176] The development of type-specific antibody can be inhibited partially by prompt administration of penicillin for the streptococcal infection.[42]

Humoral antibodies to specific streptococcal extracellular products can be shown readily by neutralization assays.[21] These assays have been especially useful as a more precise method of defining streptococcal infection in clinical and epidemiologic studies and of documenting the occurrence of a preceding streptococcal infection in patients with a suspected nonsuppurative complication.

The anti-streptolysin O assay is the streptococcal antibody test used most frequently.[145] Because streptolysin O also is produced by group C and G streptococci, the test is not specific for group A infection. The antistreptolysin O response can be feeble in patients with streptococcal impetigo or pyoderma[93]; its usefulness for this latter condition is limited. In contrast, the anti-deoxyribonuclease B (anti-DNAse B) and the anti-hyaluronidase responses are reliable after skin and throat infections have occurred.[93]

Another antibody test, the Streptozyme agglutination test, is based on antibody agglutination of erythrocytes coated with a mixture of streptococcal extracellular antigens. It has the theoretical appeal of simplicity, speed, and reaction with numerous streptococcal antigens.[78] Peak titers for an immune response as measured by the Streptozyme test have been shown within the first 7 to 10 days after onset of infection,[125] whereas neutralizing antibody titers to streptolysin O (3-6 weeks) or anti-DNAse B (6-8 weeks) do not peak until later. Because of documented problems of standardization of this reagent (variable results may be obtained with different lots) and because of problems with group specificity, this test should be interpreted with caution.[97,167] Some studies have indicated problems in interpretation of this test, and the World Health Organization has recommended that it not be used.[5]

Antibody titers reported by clinical immunology laboratories may vary. Upper limits of normal are higher for children than for adults, and these values, even for the same age group, are higher in some populations than in others. Interpretation of antibody titers for clinical purposes must take these factors into consideration.[145] Often, values given by laboratories for upper limits of normal are determined using adult sera; these values often are much too low to be used in a pediatric population. Table 93–1 gives results of normal levels of antibody titers in children 2 to 12 years old.[99]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

In patients presenting with acute pharyngitis or tonsillitis, the clinician must rely on a combination of the clinical appearance, identification of the organism, and epidemiologic findings to confirm the probability of group A streptococcal infection. The clinical difficulty is compounded because most of the clinical manifestations of streptococcal pharyngitis can be associated with a variety of other etiologic agents.[19] Group A streptococci often are found in the throats of normal children and in children whose clinical findings are due to one of these other agents (see also Chapter 10).[165] Exudative sore throat may be caused by many

viruses, *Corynebacterium diphtheriae*, gonococci, and groups C and G in addition to group A streptococci.[19] The clinical syndrome associated with *Arcanobacterium haemolyticus* can be quite similar and clinically confusing.

Viral pharyngitis may closely mimic streptococcal pharyngitis, which can be ruled out only by the absence of a positive culture for group A streptococci. In children, the white blood cell count may be elevated in viral infections, but a low count renders it unlikely that the infection is streptococcal. The C-reactive protein test is only marginally useful in the acute phase of the illness.[101]

Because most streptococcal infections are short-term illnesses and antibody responses can be slow in appearing, streptococcal antibody titers are useful only retrospectively in diagnosing acute group A streptococcal infection. Little or no reason exists to use streptococcal antibody titers in the management of acute pharyngitis. In addition to their primary role in supporting the diagnosis of nonsuppurative complications (acute nephritis and acute rheumatic fever), however, occasionally they may be useful clinically in diagnosing infections in which obtaining cultures from the primary site is difficult (e.g., streptococcal pneumonia or osteomyelitis) or the infections have been treated or partially treated with antibiotics. The presence of an elevated streptococcal antibody titer does not, by itself, confirm a diagnosis of rheumatic fever, however. A more reliable approach is to use an increase in titer to confirm group A streptococcal infection.

Numerous clinical schemes have been proposed for differentiating streptococcal from nonstreptococcal pharyngitis, but none of them is entirely satisfactory in making this distinction or in differentiating streptococcal carriers with an intervening nonstreptococcal pharyngitis from individuals with active streptococcal disease.[86,165] Clinical manifestations that are most suggestive of a group A streptococcal cause include the scarlatiniform rash (which, however, occasionally is associated with staphylococcal, rather than streptococcal, infection), excoriated nares (especially in infants), tender (not merely enlarged) anterior cervical lymph nodes, and a history of close contact with a well-documented case of group A streptococcal infection. The presence of cough, hoarseness, or conjunctivitis renders the diagnosis of streptococcal pharyngitis unlikely. Exudative pharyngitis in infants usually is nonstreptococcal in etiology.[2] In addition, numerous clinical scoring systems have been found to be helpful to the clinician in some circumstances, but even they are not entirely reliable.[168]

Cultures may yield invalid results unless they are obtained and processed carefully. For cultures of the throat, the affected areas (tonsils and posterior pharynx) should be rubbed firmly with the rayon or cotton culture swab. Impetiginous lesions should be cleansed with alcohol, and the vesicle should be punctured or the crust lifted by a sterile needle so that purulent material or the moist base can be touched by the swab.[85] Group A streptococci sometimes can be recovered even from dry crusted lesions if the swab is moistened with culture broth before touching the exposed base of the lesion. Because streptococcal impetigo lesions commonly contain secondarily invading staphylococci, which may overgrow and obscure the colonies of streptococci, cultures should be examined carefully with a hand lens; alternatively, gentian violet or other inhibitors of normal flora may be incorporated on the blood agar plates as an inhibitor of staphylococci.

Presumptive differentiation of group A from other hemolytic streptococci can be achieved by the sensitivity of group A streptococci (but relatively few of other hemolytic streptococci) to bacitracin, but only when tested by a disk designed specifically for this purpose.[85] Definite identification of group A streptococci can be accomplished by several serologic or immunologic techniques, including (1) extraction of the organism by boiling in hydrochloric acid or by several other extraction methods with examination of the resulting extract in a precipitin test, (2) fluorescent antibody test on isolated colonies or broth cultures, and (3) agglutination of the organisms by group-specific antisera bound to protein A–containing staphylococci.

Numerous rapid techniques for direct identification of group A streptococci from the upper respiratory tract are available commercially. Direct and rapid identification of group A streptococcal antigens from throat swabs (e.g., latex agglutination, enzyme-linked immunosorbent assay) has become quite popular. The specificity of these tests usually is very good, but published reports indicate that the sensitivity varies widely.[90,146] Guidelines promote a back-up throat culture if a rapid antigen detection test is negative.[20] These techniques employ extraction of the group-specific carbohydrate from the cell wall of the organism. Available data suggest that the specificity for these tests generally is greater than 90 percent, but the sensitivity ranges from less than 60 percent to greater than 90 percent.[90]

The advantages of these tests include the ability to identify group A streptococci rapidly and to treat the patient at the time the patient is in the physician's office or emergency department. This advantage has appeal, especially in view of the data suggesting that in children, the more quickly the patient is treated, the more rapid is the clinical response.[134] Studies also have shown that rapid antigen detection tests can be useful in the detection of group A streptococci in streptococcal pyoderma-like lesions.[95]

Data suggest that the sensitivity of rapid antigen detection tests is improved, leading to the suggestion that a positive rapid antigen detection test is sufficient proof of group A infection, but that a negative rapid antigen detection test should be confirmed with a conventional throat culture on sheep blood agar. The throat culture remains a "gold standard" for identifying group A streptococci in the upper respiratory tract. Although they rarely are encountered, false-positive rapid antigen detection tests also have been documented, owing to a cross-reaction with antigens present in some *Streptococcus milleri*.[88] Just as with any other laboratory test, a "learning curve effect" exists with streptococcal rapid antigen detection tests.[98]

On clinical findings alone, it generally is safer to make a diagnosis of streptococcal impetigo than it is to make a diagnosis of streptococcal pharyngitis. Impetigo in which staphylococci are the primary invader generally is bullous rather than vesicular in type, and on rupture of the vesicle a crust appears that is paper-thin and white, rather than thick and honey-colored. Some confusion may result from reports of cultures performed on patients with primary streptococcal impetigo. Staphylococci, often present as secondary invaders, may overgrow the streptococci, which consequently may be missed, unless the colonies are well isolated and the bacteriologist has an unusually sharp eye, or unless a culture medium inhibitory for staphylococci is used.

The vesicles of varicella infection may resemble those of streptococcal impetigo superficially, but they are less transient, are surrounded by a red areola, are more centripetal in distribution (tending to involve the trunk and the proximal portions of the extremities), frequently itch, occur in crops, and often are accompanied by constitutional symptoms. The crusts are not as thick as are those of streptococcal impetigo. The lesions of chickenpox can be infected with streptococci secondarily, and varicella has been identified as an important risk factor in the development of severe and invasive group A streptococcal infections.

PROGNOSIS

Patients with streptococcal sore throat or streptococcal impetigo recover spontaneously. A very few may develop suppurative complications, and an occasional patient may have a nonsuppurative sequela, particularly in industrialized countries. There is more

chance of developing complications in socially and economically disadvantaged populations.

In the general population, the risk of developing rheumatic fever after an untreated bona fide group A streptococcal infection of the upper respiratory tract has been shown to be approximately 3 percent under epidemic conditions but is apparently considerably less (about 0.3%) in endemic situations,[147] owing partly to differences in definition of infection.[100] Patients who have had one attack of rheumatic fever are at high risk of a rheumatic fever recurrence when re-infected with group A streptococci. There seems to be no risk of developing rheumatic fever after having a streptococcal infection only of the skin, but this concept has been challenged if not yet substantiated.[28]

The risk of acute glomerulonephritis depends on whether the infection is caused by a nephritogenic strain. With a nephritogenic strain, the attack rate is about 10 to 15 percent, and acute glomerulonephritis can occur after either throat or skin infection.[164]

In contrast to the usual short, often benign course of throat and superficial skin infections, streptococcal cellulitis spreads rapidly locally and to the regional lymph nodes and bloodstream. In immunosuppressed patients and patients with streptococcal infection superimposed on leukemia, lymphoma, or other malignancies, bacteremia may develop, and patients may have serious life-threatening problems. Patients with puerperal sepsis, neonatal infection, streptococcal toxic shock–like syndrome, or gangrene owing to group A streptococci also have a high mortality rate despite timely administration of and high doses of penicillin therapy.[153]

The prognosis for complete recovery in patients with group A streptococcal TSS and in patients with necrotizing fasciitis varies. Morbidity and mortality rates have been reported to be greater in adults, especially the elderly, than in pediatric patients. Several series reported a mortality rate of at least 30 percent in patients with TSS.[154] The mortality rate with necrotizing fasciitis can be even greater.[152,153]

TREATMENT

Although group A streptococci generally are susceptible to many antibiotics,[37,53,117] penicillin remains the drug of choice for treatment except in patients allergic to it.[20] No clinical isolates of group A streptococci have been identified yet that are resistant to penicillin.[112] Although tolerance to penicillin has been described in group A streptococci, its clinical significance has not been determined.[102]

Eradicating group A streptococci from the upper respiratory tract (especially from carriers) with penicillin or other antibiotics sometimes is difficult.[89,95] This observation has not been explained adequately, but possible explanations include the presence of β-lactamase–producing organisms in the upper respiratory tract, the presence of group A streptococci tolerant to penicillin, and the production by certain of the normal upper respiratory tract flora of inhibitory substances that reduce persistence of the organism. In addition, some evidence suggests that persistence frequently is associated with the upper respiratory tract carrier state.[105] The presence of intracellular group A streptococci also has been noted in this regard.

Erythromycin remains the drug of choice in patients allergic to penicillin. Resistance to erythromycin is a rare occurrence in many countries (<5%). More recent data from Europe, where macrolides are widely used, show resistance rates in some countries of greater than 30 percent. In some countries, noticeable increases in resistance to macrolide by group A streptococci has been associated with increased use of macrolides. Although the prevalence of macrolide-resistant group A streptococci generally has been low in North America and of little clinical significance,[73,173] isolated examples have shown the ability of the organism to become resistant to macrolides.[115] The incidence was high in Japan in the 1960s,[50] and this observation also has been noted in Finland.[143] The use of broad-spectrum antibiotics for group A streptococcal infections has no advantage and potential disadvantages.[6-20] Group A streptococci most frequently are resistant to tetracyclines and the sulfonamides. β-lactamase–resistant antibiotics have been advocated in some studies[23]; a role for production of β-lactamase by normal flora in penicillin treatment failures has not been clarified yet.

Some reports have pointed out that cephalosporins may be more efficacious than is penicillin, especially in carriers. This form of oral therapy has been recommended by some clinicians.[30,31]

In the treatment of bona fide streptococcal sore throat, the group A streptococcus must be eradicated to prevent the development of acute rheumatic fever.[32] Many guidelines recommend administration of 10 days of oral penicillin V, or erythromycin for a penicillin-allergic individual, as being optimal for eradication.[20] Administration of a single intramuscular injection of benzathine penicillin G (1,200,000 U in adults and in children weighing >60 lb; 600,000 U in children weighing <60 lb) is one method of accomplishing this objective. If a combination of benzathine penicillin and procaine penicillin is used, the total dosage should be based on the amount of benzathine penicillin used.

If oral medication (penicillin or erythromycin) is used, the parent must be impressed with the importance of continuing the medication for a full 10 days. Oral penicillin V (250 mg two to three times a day) has been the treatment of choice for children. Many pediatricians prefer amoxicillin because of its taste. For adolescents, 250 mg given either three or four times a day or 500 mg twice a day has been suggested.[20] More recent studies have reported that amoxicillin given once daily (750 to 1000 mg) is as effective as is amoxicillin given twice daily (two doses of 375 mg or 500 mg) in eradicating group A streptococci in children.

In patients with a suspected allergy to penicillin, erythromycin (in adults, 250 mg four times a day; in children, 40 mg/kg/day in four doses, not to exceed the adult dose) has been used.[43] Two other macrolide/azalide preparations, azithromycin and clarithromycin, have been used as substitutes for erythromycin. The exact dose of erythromycin varies with the preparation used (e.g., stearate, estolate). Other antibiotics that have been used successfully in the therapy of group A beta-hemolytic streptococcal pharyngitis or tonsillitis include clindamycin, amoxicillin, a mixture of amoxicillin with clavulanic acid, and other cephalosporins. For patients who have *not* had an immediate type reaction to penicillin, many clinicians feel safe using a first-generation cephalosporin.

The problem of patient adherence to a 10-day course of oral antibiotics is well recognized. Because of this problem, several antibiotics have been approved for short-course therapy (<10 days) for treatment of group A streptococcal pharyngitis. These antibiotics include some cephalosporins and one of the newer macrolides/azalides. Some studies show equivalence of short-course therapy to 10 full days of conventional penicillin V oral therapy. Because of conflicting data, some guidelines still promote caution in using short-course therapy for the treatment of group A streptococcal upper respiratory tract infection.[20]

In patients with strong clinical or epidemiologic evidence of streptococcal infection, the physician may decide to begin therapy before the result of the throat culture is available. If oral antibiotic therapy is used for initiating treatment, the therapy may be continued or discontinued, depending on the culture report. Alternatively, an intramuscular injection of benzathine penicillin G may be administered at that time if the laboratory culture report is positive for group A streptococci. For patients who may not return for a culture report, or who may be difficult to contact, making an immediate clinical judgment whether to prescribe penicillin therapy may be important. In these situations, the use

of the rapid direct techniques for detection of group A streptococci is advantageous. Because such patients also may be less reliable with respect to completing a course of oral therapy, the use of intramuscular benzathine penicillin G may be preferable. Even if the decision to treat or not to treat must be made on clinical grounds, throat cultures can be useful in indicating to the physician the current prevalence and clinical features of streptococcal and nonstreptococcal respiratory illnesses. Intramuscular benzathine penicillin G also is advantageous in epidemic situations.

At one time, obtaining repeat throat cultures after completion of oral therapy was thought to be appropriate to ensure that the group A streptococci had been eradicated. Studies have shown that many penicillin treatment failures seem to occur in carriers of group A streptococci in the upper respiratory tract.[87] In areas where rheumatic fever has not reappeared, re-culturing asymptomatic individuals routinely after they have received antibiotic therapy usually is unnecessary unless unusual epidemiologic circumstances (a rheumatic individual in the household or epidemic streptococcal disease in the community) exist. Other regimens that have been used for treating patients with persistently positive cultures include clindamycin, a mixture of amoxicillin and clavulanic acid, and rifampin along with either an injection of benzathine penicillin G or 10 days of oral penicillin.[20]

For patients who show a repeated clinical pattern of treatment failure, determining the serologic group and type of the strains recovered may be helpful to ascertain whether the isolates are the same or are different M protein types. Such testing is not done routinely in hospital laboratories, however, and in those circumstances contact with a state health department or streptococcal research laboratory would be required. It is important in "problem" families, in which intrafamilial spread is problematic, to culture the throats of all members of the family simultaneously and to treat all family members with positive results. The main problem of the persisting carrier is that this carrier status may complicate the interpretation of throat cultures obtained at the time of future nonstreptococcal respiratory tract infections.

Some researchers have suggested that the rapid treatment of group A streptococcal upper respiratory tract infection tends to promote recurrent streptococcal infections in the future because of the suppression of the type-specific antibody response. Some studies have shown no difference, however, in the frequency of recurrences of streptococcal infections whether therapy is started on diagnosis or delayed 48 hours.[63]

In contrast to group A streptococcal pharyngitis or tonsillitis, no authoritative guidelines have been developed for the treatment of streptococcal impetigo.[170] The effectiveness of hygienic measures and local skin care (removal of crusts and use of antibacterial soaps) probably depends on the thoroughness and perseverance with which they are carried out. These measures and the use of local antimicrobial ointments can be sufficient for the management of patients with only a few lesions. Systemic antibiotics have been associated with rapid clearing of the lesions, however. Oral or parenteral penicillin or oral erythromycin (in the amounts prescribed for the treatment of streptococcal pharyngitis) should be administered to patients with more severe or persistent infections. In the absence of microbiologic data, many clinicians use antibiotics that are effective against streptococci and staphylococci. First-generation cephalosporins and semisynthetic penicillins also are effective. Antibiotic therapy probably does help prevent the spread of streptococcal impetigo in family members. In an era when methicillin-resistant *Staphylococcus aureus* are common findings, special care must be exercised when selecting antibiotic therapy.

Whether penicillin or other antibiotic treatment reduces the risk of development of acute nephritis is unclear.[171] One study suggests that penicillin therapy may reduce the risk of this complication occurring in patients with streptococcal sore throat caused by a nephritogenic strain.[151] No definitive proof that penicillin treatment reduces the frequency of acute nephritis after treatment of skin infections exists, however. Clinical experience indicates that patients with cutaneous infections caused by a nephritogenic strain of group A streptococci may develop this complication despite receiving adequate penicillin therapy.[92]

Otitis media or cervical adenitis caused by group A streptococci usually responds to regimens prescribed for treatment of streptococcal sore throat. Patients with peritonsillar abscess require surgical drainage in addition to vigorous parenteral antibiotic therapy. Patients with more serious infections (e.g., mastoiditis, pneumonia, empyema) also should be given intensive systemic therapy. Patients with meningitis, arthritis, or osteomyelitis require high-dose intravenous penicillin administered for a long time (see Chapters 37 and 61). Patients with streptococcal TSS and patients with necrotizing fasciitis may be treated with parenteral penicillin, but more recent evidence suggests that clindamycin combined with penicillin has advantages.[152] In patients allergic to penicillin, clindamycin is an excellent alternative. Because of cross-reactions with penicillin, the cephalosporins always should be used cautiously in penicillin-allergic patients, especially in patients who have had immediate-type reactions.

PREVENTION

Antimicrobial agents have been helpful in controlling group A streptococcal infections and their sequelae, but they do not provide an encompassing solution for this group of diseases, either in industrialized countries or in the developing world—hence the "resurgence" of rheumatic fever and the appearance of streptococcal TSS in the United States during the 1980s and 1990s. Penicillin's greatest impact has been on the prevention of recurrences of rheumatic fever (see Chapter 35).[18] Prevention of first attacks of rheumatic fever is a problem of greater dimensions because it involves detection, diagnosis, and appropriate treatment in the general population. One cost-effective program can be developed from well-conceived secondary prevention programs in defined rheumatic patients and perhaps from primary prevention programs in school-aged children, especially programs in socially and economically disadvantaged populations.[127]

The prevention of spread by isolation, limiting the density of the population, and antibiotic treatment of known cases is discussed in the section on transmission (see earlier). Mass penicillin prophylaxis has been used in epidemics with a well-defined streptococcal etiology,[24] but in actual practice, the epidemic often is subsiding by the time a large-scale prophylactic effort can be mounted. Intramuscular benzathine penicillin G is very effective for this purpose.[24] The dose is the same as recommended for treating streptococcal pharyngitis. In populations in which streptococcal infections occur at epidemic or near-epidemic levels over a long period of time (e.g., certain military populations), it may be necessary to repeat the injections of benzathine penicillin at monthly intervals and to administer them to all new arrivals.

Although guidelines for management of contacts of patients with severe streptococcal infections are available, and routine surveillance cultures among family members and close contacts are not recommended universally,[132] this approach remains controversial because of documented secondary cases in families.[136] In the family studies carried out several decades ago, researchers found that approximately 25 percent of family contacts harbored the organisms in families where an index case was identified.[49] Because of documented instances in which secondary cases have occurred, some clinicians choose to culture close contacts and to use long-acting benzathine penicillin, long-acting benzathine penicillin plus rifampin, or clindamycin to treat individuals who are positive for group A streptococci. The effectiveness of such

regimens has not been studied; contacts need to be monitored closely even after being treated.

The question of the possible advantages of tonsillectomy for the prevention of streptococcal infections and their sequelae also has not been settled by well-controlled studies. Available information indicates that tonsillectomy may reduce the frequency of clinically apparent streptococcal infections,[128] perhaps rendering it less likely that these patients receive appropriate treatment.[53] One study indicates, however, that recurrences are more frequent in individuals who have had rheumatic fever and who have large tonsils.[58]

The inability of antibiotics to influence significantly the epidemiology of group A streptococcal infections and their sequelae consistently and favorably is reflected by the concentration of sequelae occurring more recently in middle-class populations with ready access to medical care.[160] Control measures would be much more effective if a group A streptococcal vaccine were available. Several different approaches to streptococcal vaccines that are being investigated include a multivalent, type-specific vaccine based on M-protein type, a vaccine based on conserved regions of the M-protein that are present in all M-protein types, and a third group of candidate vaccines that are based on immunity to extracellular or somatic antigens of the organism not associated with M protein. Early studies in animals have shown immunogenicity in several of these candidate vaccines, and some vaccines based on type-specific immunity have undergone early clinical trials in humans. Although one cannot make a prediction with certainty, the availability of a cost-effective group A streptococcal vaccine to the general public still does not seem imminent. Large-scale clinical trials in different geographic areas and among different populations are required ultimately to determine safety and efficacy.

GROUP C AND GROUP G STREPTOCOCCAL INFECTIONS

ORGANISMS

The characterization of beta-hemolytic streptococci on the basis of group-specific carbohydrate antigens is complicated by the presence of similar antigens among streptococci that, on the basis of biochemical and genetic testing, have been shown to be different species. Organisms that possess either the group C or group G Lancefield antigens can be divided into groups based on colony size. The strains that produce small or minute colonies (<0.5 mm in diameter) have been placed in the *Streptococcus anginosus* group (classified as *Streptococcus milleri* by British taxonomists). Although these small-colony-forming strains of group C and group G streptococci may produce human infections, with abscesses being the most common form, they also are found as commensals and have considerably less pathogenic potential than do the large-colony-forming group C and group G streptococci. Despite the existence of these groupable, beta-hemolytic strains, members of the *S. anginosus* species group are considered to be viridans group streptococci, most of which display alpha-hemolytic or nonhemolytic reactions.

In contrast, the strains that produce large-sized colonies (≥5 mm in diameter) have been referred to as true or large-colony-forming group C or group G streptococci, depending on the nature of their carbohydrate antigen. The heterogeneity of large-colony streptococci with the Lancefield group C or group G polysaccharides has produced considerable confusion, however. The taxonomic classification of these streptococci still is unsettled, and more changes are likely to occur before a universally accepted scheme is established; however, at least three species have been found in human infections: *Streptococcus dysgalactiae* subsp. *equisimilis*, *Streptococcus equi* subsp. *zooepidemicus*, and *Streptococcus canis*.[54,137,140]

Most group C streptococci are beta-hemolytic on blood agar plates, but all types of hemolysis have been observed. Group C streptococci are aerobic, facultatively anaerobic, coprophilic, and catalase-negative organisms. Rhamnose-*N*-acetylgalactosamine is the group C antigenic determinant in the cell wall. Traditionally, four species possessing this determinant have been differentiated on the basis of their ability to ferment various carbohydrates: *S. equisimilis*, *S. zooepidemicus*, *S. equi*, and *S. dysgalactiae*. More recent genetic studies have led, however, to the reclassification of group C streptococci into two species—*S. dysgalactiae* and *S. equi*—each with two subspecies. Although most group C streptococci are resistant to bacitracin, at least a third (in one study, 62%) of group C streptococci are bacitracin-sensitive.[7]

S. dysgalactiae subsp. *equisimilis* is the species of group C streptococci and group G streptococci that most often colonizes and causes infections in humans.[54] The actual frequency is unknown, however, because clinical laboratories do not perform phenotypic tests on group C or group G streptococcal isolates other than the hemolytic reaction and the Lancefield group determinations. *S. dysgalactiae* subsp. *equisimilis* has been isolated from the nose, throat, and genital tract of asymptomatic children and adults and from the umbilicus of asymptomatic newborns. This species produces streptokinase and streptolysin O, and infection may elicit an antibody response to these extracellular antigens similar to that seen with a group A streptococcal infection.

S. dysgalactiae subsp. *equisimilis* are pyogenic streptococci that are similar to *S. pyogenes* with respect to some virulence traits. They express homologues of the M virulence protein of *S. pyogenes* that are antiphagocytic (encoded by the *emm* gene), and some strains contain superantigen genes first characterized in *S. pyogenes*.[111,129] The *emm* genes of *S. dysgalactiae* subsp. *equisimilis* isolates with either the group C or the group G Lancefield antigen can be used for sequence-based typing. Pulsed-field gel electrophoresis also can be used to identify specific stains. This organism can cause infections in a variety of domestic animals (e.g., horses, cattle, pigs, chickens). *S. dysgalactiae* subsp. *dysgalactiae* has not been found to cause human infections but does cause a serious mastitis in cows and a suppurative polyarthritis in lambs.

S. equi subsp. *zooepidemicus* possess the group C Lancefield antigen and can cause significant, often epidemic, infections in domestic animals (e.g., horses, cattle, pigs, sheep), but it is an uncommon pathogen in humans. Most human infections have been associated with consumption of homemade cheese or unpasteurized cow's milk. *S. equi* subsp. *equi* possess the group C Lancefield antigen and have not been found to cause human infections but do cause a serious and highly contagious respiratory disease in horses, known as *strangles*.

Most group G streptococci are beta-hemolytic on blood agar plates. L-rhamnose is the group G antigenic determinant in the cell wall. Most of the group G streptococci isolated from human infections are thought to be *S. dysgalactiae* subsp. *equisimilis*. *S. canis* with the group G Lancefield antigen also cause infections in humans.

Several schemes for typing group G streptococci have been described based on biochemical properties or bacteriocin typing. Although no association between particular types and infections in humans has been identified, these schemes have been useful in distinguishing human from animal strains and in epidemiologic investigations. T-typing and M-typing schemes similar to those used for group A streptococci also have been devised for group G streptococci. Newer methods, such as *emm*-typing, pulsed-field gel electrophoresis, and multilocus enzyme electrophoresis,

also are being used to type specific strains of group G streptococci.[16,129] Although most group G streptococci are resistant to bacitracin, various reports have determined that 8 to 67 percent of group G streptococci are bacitracin-sensitive.[140]

In addition to M protein, human isolates of group G streptococci share other virulence factors with group A streptococci, such as a streptokinase, a hyaluronidase, and a C5a peptidase. Group G streptococci also produce a streptolysin that is similar antigenically to the streptolysin O produced by group A streptococci. Patients with group G streptococcal infections may show a significant increase in levels of antistreptolysin O titers.

EPIDEMIOLOGY

Group C streptococci are an uncommon cause of human infections but more commonly are pathogenic in animals. Humans infected with this organism often have had some animal contact. Group C and group G streptococci often can be part of the normal human flora of the nasopharynx, skin, or genital tract. Group C streptococci also can be cultured from the umbilicus of asymptomatic newborns and from routine puerperal vaginal cultures. Group G streptococci also can be cultured from the gastrointestinal tract. The low virulence of group C and group G streptococci is indicated by the fact that most humans infected with either of these organisms have some underlying medical disorder (e.g., diabetes mellitus, malignancy, alcohol abuse, immunosuppression).[29,106]

CLINICAL MANIFESTATIONS

The clinical features of group C and group G streptococcal pharyngitis are similar to those of group A streptococcal pharyngitis and include fever, mild to moderate sore throat, pharyngeal exudate, and cervical adenitis.[110] In temperate climates, 1 to 18 percent of asymptomatic individuals have been reported to harbor group C streptococci in the upper respiratory tract. The proportion of carriers among individuals living in the tropics is even greater.[69,126] Such carrier rates render establishing the etiologic role of group C streptococci in acute pharyngitis difficult. Several earlier studies compared the isolation rates of group C streptococci from patients with acute pharyngitis with rates in asymptomatic controls; the results were contradictory.[7,35] Several more recent investigations have established a strong epidemiologic association between group C streptococci and endemic acute pharyngitis. In two investigations, group C streptococci were isolated significantly more often from college students with acute pharyngitis than from asymptomatic controls.[157,158] In the other investigation, group C streptococci were isolated significantly more often from adults who came to an emergency department with acute pharyngitis (6%) than from asymptomatic controls (1.4%).[121]

In addition to endemic pharyngitis, group C streptococci can cause epidemic food-borne pharyngitis after contaminated products, such as unpasteurized cow's milk, have been ingested. Epidemics have been reported from Great Britain, Romania, the United States, and Israel.[7,35] In one report of a milk-borne epidemic of pharyngitis caused by *S. equi* subsp. *zooepidemicus*, approximately one third of the patients developed signs of acute glomerulonephritis.[51] This outbreak was related to the consumption of unpasteurized milk from cattle with mastitis. No cases of acute rheumatic fever occurred. More recently, a large outbreak of acute glomerulonephritis in Brazil was attributed to the consumption of unpasteurized cheese containing *S. equi* subsp. *zooepidemicus*.[10] Family outbreaks of group C streptococcal pharyngitis and an outbreak in a residential school for boys also have been described.

Group C streptococci also have been reported as the cause of numerous other uncommon infections, including skin and soft tissue infections, septic arthritis, osteomyelitis, pneumonitis, infective endocarditis, bacteremia and septicemia, meningitis, epiglottitis, pericarditis, urinary tract infections, and sinusitis. These organisms also have been associated with epidemic and nonepidemic cases of puerperal sepsis and endometritis.[81] Several reports have suggested that an association exists between group C streptococci and reactive arthritis and a toxic shock–like syndrome.[54,79]

Some studies have reported that 1 to 23 percent of asymptomatic individuals may carry group G streptococci in their upper respiratory tract. As with group C streptococci, the carrier rates of group G streptococci seem to be even higher in the tropics.[69,126] Such carrier rates also render establishing the etiologic role of group G streptococci in acute pharyngitis difficult. Several studies have been performed comparing the isolation rates of group G streptococci from patients with acute pharyngitis with rates from asymptomatic controls. The results of these studies showed little difference in the isolation rates, suggesting that group G streptococci may not play an important role in endemic acute pharyngitis. Few of these studies were adequately controlled, prospective investigations, however, and in many of them, the incidence of group G streptococci in the symptomatic group was so low as to preclude any possibility of showing a statistically significant difference.

Support for an etiologic role of group G streptococci in acute pharyngitis comes primarily from anecdotes, small case clusters, and a few large outbreaks, most of which were food-borne. To date, several food-borne outbreaks of group G streptococcal pharyngitis, all of which occurred in semiclosed populations, including one outbreak at a college cafeteria, have been reported.[116] In the first reported respiratory outbreak of group G streptococcal pharyngitis in the United States, McCue[120] described 68 cases of acute pharyngitis on a college campus seen during a 9-day period in 1981. The possibility of food-borne spread could not be eliminated completely but seemed unlikely, and airborne droplet transmission seemed to be the most likely mechanism of spread.

Despite the evidence supporting the etiologic role of group G streptococci in epidemic pharyngitis, the role of group G streptococci in acute, endemic pharyngitis remains unclear. Previous outbreaks of group G streptococcal pharyngitis had been reported in college-age or older patients, and all had occurred in semiclosed communities. A community-wide, respiratory outbreak of group G streptococcal pharyngitis in a pediatric population was described, however.[64] During a 6-month period, group G streptococci were isolated from 56 of 222 (25%) consecutive children with acute pharyngitis seen at a private pediatric office. Results of DNA fingerprinting of the group G streptococcal isolates suggested that 75 percent of them were the same strain. The patients with group G streptococcal pharyngitis were comparable to patients with group A streptococcal pharyngitis with respect to clinical findings, antistreptolysin O titer response, and clinical response to antibiotic therapy. Patients with group G streptococci were significantly older, however. The findings suggested that antibiotic therapy may have an impact on the clinical course of group G streptococcal pharyngitis. These findings lend support to the belief that group G streptococci may be a more important cause of acute, endemic pharyngitis than was recognized previously.

The actual role of group C and group G streptococci in acute pharyngitis may be underestimated for several reasons. Anaerobic incubation increases the yield of these organisms, but most clinicians do not use anaerobic incubation for throat cultures routinely.[142] Because clinicians generally disregard beta-hemolytic streptococci that are bacitracin-resistant (and most strains of

group C and group G streptococci are bacitracin-resistant), many group C and group G streptococci would be missed.

Acute rheumatic fever has not been described as a complication of either group C or group G streptococcal pharyngitis, and although there have been reports attempting to link acute glomerulonephritis with group G streptococcal pharyngitis, the evidence is anecdotal, and a causal relationship has not been established.[130,137] Although acute glomerulonephritis has been reported as a complication of group C streptococcal pharyngitis, it is extremely unusual.[10,51,123] The primary reason to identify either group C or group G streptococci as the etiologic agent of acute pharyngitis is to initiate antibiotic therapy that may reduce the clinical impact of the illness. No convincing evidence as yet has emerged from controlled studies of a clinical response to antibiotic therapy in patients with acute pharyngitis and either group C or group G streptococci isolated from the upper respiratory tract.

Group G streptococci also have been reported to be an uncommon cause of puerperal sepsis, and they occasionally may cause a neonatal infection that is clinically very similar to early-onset group B streptococcal infections. Other infections occasionally caused by group G streptococci include bacteremia, endocarditis, septic arthritis, osteomyelitis, pneumonia, erysipelas and other skin and soft tissue infections, and meningitis.[55,81] Group G streptococci also have been associated with a toxic shock–like syndrome.[54,162]

TREATMENT

Penicillin is the antibiotic of choice for treating infections caused by either group C or group G streptococci.[139] Some strains of group C and group G streptococci have been shown to be tolerant to penicillin in laboratory studies, but the clinical significance of this finding is unknown.[123,138] Synergism in producing in vitro killing of group C and group G streptococci has been shown with gentamicin and various β-lactam antibiotics, but no controlled trials have been performed to establish the clinical significance of this finding. Group C and group G streptococci also are susceptible to most β-lactam antibiotics and to macrolides, vancomycin, clindamycin, and chloramphenicol. Pharyngitis usually is treated in a manner similar to that for group A streptococcal upper respiratory infections. More severe infection requires parenteral therapy.

CHAPTER 94

Group B Streptococcal Infections

Pia S. Pannaraj ✪ Carol J. Baker

HISTORY

The organism we know as group B *Streptococcus*, or *Streptococcus agalactiae*, was isolated first by Nocard in 1887[233] and for decades was recognized as a cause of bovine mastitis[220] but not human infection. Serologic techniques for differentiating beta-hemolytic streptococci were developed by Lancefield,[173] who also described isolation of group B streptococci from parturient women in 1935.[174] In that same year, Congdon[82] included one fatal puerperal case of group B streptococcal sepsis and pneumonia in a report of streptococcal infections associated with childbirth. The significance of this organism as a human pathogen was reported first by Fry[115] in 1938, who described three cases of fatal puerperal sepsis. Group B streptococcal infections continued to be reported sporadically until the 1960s, when maternal and neonatal infections increasingly were ascribed to this pathogen.[68,101,147] In the 1970s, group B *Streptococcus* emerged as the predominant organism causing bacteremia and meningitis in neonates.[12,26,113,150,241] The incidence of neonatal infection remained stable, with reported attack rates ranging from 0.2 to 5.4 per 1000 live births, until the late 1990s, when maternal intrapartum chemoprophylaxis gained wide acceptance and incidence rates fell.[33,75,280] Invasive infection also occurs beyond the neonatal period in pregnant women, nonpregnant adults with underlying medical conditions, and elderly persons.[95,103,235,311]

MICROBIOLOGY

ISOLATION AND IDENTIFICATION

Group B streptococci are facultative gram-positive diplococci that grow on a variety of bacteriologic media. Colonies are 3 to 4 mm in diameter, grayish white, flat, and somewhat mucoid. Colonies are surrounded by a narrow zone of beta-hemolysis that for some strains is detectable only when the colony is lifted from the agar. Nonhemolytic strains account for 1 to 2 percent of isolates and may cause human disease.[12,269] Definitive identification of group B streptococci relies on detection of the group B-specific antigen, a carbohydrate cell wall antigen common to all strains. The standard method, as described by Lancefield,[173] requires acid treatment of the bacteria to solubilize the carbohydrate group B antigen, followed by capillary precipitation with hyperimmune rabbit serum. Several newer methods using hyperimmune antisera have been developed, but latex agglutination is used widely because of the commercial availability of test kits, the ease of performing the assay, and the specificity of the results when organisms in pure culture are tested.[292] Other laboratory methods for presumptive identification include testing for resistance to bacitracin or trimethoprim-sulfamethoxazole, hydrolysis of sodium hippurate broth, failure to hydrolyze bile esculin, production of orange pigment when cultured under certain conditions, and CAMP (Christie, Atkinson, Munch, Peterson) testing. CAMP is an acronym of the names of the authors who first described the production of CAMP factor by group B streptococci in the presence of the beta-toxin of *Staphylococcus aureus* that results in synergistic hemolysis on sheep blood agar.[81]

SEROLOGIC CLASSIFICATION AND ANTIGENIC STRUCTURE

Group B streptococci possess two carbohydrate cell wall antigens, the group B–specific antigen and type-specific capsular polysaccharide. Group B streptococci are classified into serotypes based on type-specific capsular polysaccharides. Nine such polysaccharides are characterized: Ia, Ib, and II to VIII. The

type-specific polysaccharides of group B streptococci are repeating units of five to seven monosaccharides (glucose, galactose, glucosamine, and *N*-acetylneuraminic acid). All the characterized polysaccharides include an *N*-acetylneuraminic acid (sialic acid) residue, which is important in the pathogenesis of type III human infection and perhaps other types.[31,287,325] Despite structural relatedness, antibody directed against the capsular polysaccharide of one type does not provide cross-protection against other capsular polysaccharide types.[175,317,328] A few strains isolated from patients with systemic infection contain type-specific capsular polysaccharide genes by genotypic methods but produce very low levels of capsule or have modified capsular structures that do not react with hyperimmune sera to the characterized capsular polysaccharides.[260] These strains are called *nontypeable*.

Further differentiation of type Ia strains was based on the presence or absence of a protein antigen known as C, which led to the nomenclature of Ia and Ia/c serotypes. The C protein also is present in many other serotypes except type III strains and consists of two components, alpha (trypsin resistant), found in 70 percent of non–type III capsular polysaccharide isolates, and beta (trypsin sensitive), found in approximately 20 percent of isolates.[109,157,202]

Pili, an essential virulence factor in many gram-negative pathogens such as adhesins, was discovered in group B streptococci, and its role in pathogenesis is being studied.[179] Analyses of the group B *Streptococcus* genome sequenced in 2002 will provide further insights into its antigenic structure, genes contributing to its virulence, and targets for treatment.[123,305]

EXTRACELLULAR PRODUCTS

Several bacterial products are elaborated by group B streptococci. Type-specific capsular polysaccharide is released from cells, and the amount elaborated has been correlated with virulence.[169,338] These soluble polysaccharides inhibit opsonophagocytic killing in vitro, thereby providing a mechanism for the documented increase in virulence.[181] Most strains possess C5a-ase, an enzyme of the serine esterase class that inactivates complement component C5a.[144] Because C5a is a potent chemoattractant for neutrophils, this enzyme helps the bacteria to evade the host immune system by hindering the accumulation of neutrophils at the site of infection. The beta-hemolysin elaborated by group B streptococci was characterized in 1980, but only more recently has its role in virulence been explored through the creation of nonhemolytic and hyperhemolytic mutants.[205,322] Expression of beta-hemolysin correlated with tissue damage in an in vivo arthritis model,[256] activation of neutrophil signaling pathways in brain endothelium leading to development of meningitis,[92] and increased virulence in pulmonary infection in rats and rabbits.[140,232] Other bacterial products of group B streptococci, including CAMP factor,[163] lipoteichoic acid,[228,229] pigment,[303] hippuricase, neuraminidase, hyaluronidase,[111,213] and nucleases,[110] have been described, but the contributions of these substances to pathogenesis are not clear.

ANTIMICROBIAL SUSCEPTIBILITY

To date, human isolates of group B streptococci have remained uniformly susceptible to penicillin G. However, approximately 10-fold greater concentrations are required for inhibition and killing of group B streptococci than for group A streptococci. Group B streptococci also are susceptible to other β-lactam agents, cephalosporins, vancomycin, and carbapenems. The prevalence of resistance to the macrolides (erythromycin, clindamycin, clarithromycin) is increasing; from 1970 to 1990, it was reported in 3.4 to 7.4 percent of isolates, but more recent studies reported resistance to erythromycin in 17 to 29 percent of isolates and resistance to clindamycin in 7 to 26 percent.[55,86,107,186] Resistance is related to the presence of *ermTR*, *ermB*, or *mefA* genes.[86] Macrolide resistance is highest in type V strains.[186] Ninety-five percent of strains are resistant to tetracycline, and resistance to bacitracin, nalidixic acid, trimethoprim-sulfamethoxazole, and metronidazole is uniform.[249] Low-level gentamicin resistance is typical, but when gentamicin is combined with either penicillin G or ampicillin, synergistic killing of group B streptococci occurs in vitro and in vivo.[275,276,300]

As many as 5 to 17 percent of group B streptococcal isolates have been reported to be tolerant to penicillin.[48,167] Expression of tolerance requires laboratory conditions that promote a greater than 16-fold discrepancy between minimal inhibitory concentrations and minimal bactericidal concentrations. Tolerant strains are characterized in vitro by delayed penicillin killing, similar rates of killing by penicillin whether growth is exponential or stationary, an additive rather than a synergistic response to the combination of penicillin and gentamicin, and deficient autolysis. The clinical significance, if any, of these laboratory-induced properties remains unknown.[22,166,290]

EPIDEMIOLOGY

MATERNAL COLONIZATION

Asymptomatic colonization occurs at vaginal, rectal, urethral, and pharyngeal sites in one third of healthy young women.[52,217] Much effort has been exerted trying to define groups of women at enhanced risk for colonization with group B streptococci. Factors found to be associated with vaginal acquisition include African-American ethnicity, multiple sex partners, frequent sexual intercourse, male-to-female oral sex, tampon use, and infrequent hand washing.[52,203,217] Women younger than 20 years of age have higher prevalence of colonization.[14,29] Several studies have found significantly higher colonization rates among African Americans,[71,143,217] whereas others found higher rates in Hispanics.[263] Asians have the lowest colonization rates.[71,217]

Maternal vaginal or rectal colonization rates during pregnancy vary from 18 to 35 percent in reported studies.[19,23,59,88,93,212,249,263] These rates relate to the body sites sampled, microbiologic techniques employed, and the period of gestation in which the cultures are performed. Specimens from the distal portion of the vagina yield group B streptococci more frequently than do specimens from the proximal vagina or cervix.[197] Concomitant sampling of the rectal site results in a 10 percent increase in detection over culturing the vaginal site alone.[19,88] Several investigators have suggested the gastrointestinal tract as the principal reservoir for this organism, and, not uncommonly, the rectal site is the only one that yields group B streptococci.[19,88,148,249] The urinary tract is an important site of infection (asymptomatic bacteriuria) because it is a surrogate for a high or "heavy" ($>10^5$ colony-forming units per milliliter) genital inoculum and a marker of increased risk for development of early-onset sepsis in neonates.[225,334] Bacteriuria mandates therapy during pregnancy.[278]

The manner in which swab specimens from the vagina and rectum are processed also is important in accurately assessing colonization.[74] Anogenital culture swabs collected by patients themselves are as accurate as those performed by physicians.[307] Swabs can be placed in transport media at environmental temperatures for as long as 96 hours.[278] Specimens then should be placed in a selective antibiotic-containing broth medium, rather than on solid media, because solid media fail to detect as many as 50 percent of group B streptococcal carriers.[27,30] The addition of antibiotics to the broth limits the growth of competing flora, especially gram-negative enteric organisms, and enhances detection.[23,27,30,209] Todd-Hewitt broth with gentamicin and nalidixic

acid (selective broth medium)[27] or with colistin (Lim broth)[185] and nalidixic acid is recommended for detection of group B streptococcal colonization.[278] After overnight incubation, the broth is subcultured onto a 5 percent sheep blood agar plate and is processed conventionally.

Ninety-two percent of culture-positive women are identified if lower vaginal and rectal cultures are obtained at a single visit with correct laboratory detection methods.[94] The proximity to delivery affects the accuracy of predicting colonization at delivery. Cultures obtained at 35 and 37 weeks' gestation predict colonization at delivery with 87 percent sensitivity and 96 percent specificity.[59,248,337]

INFANT COLONIZATION

Colonization and infection in the neonate are associated significantly with the presence of group B streptococci in the maternal genital tract at delivery. Vertical transmission from colonized mothers to their infants occurs in 41 to 72 percent of cases (mean, ~50%).[7,15,23,57,93,143,212,340] Only 1 to 12 percent (mean, ~5%) of colonized infants are born to noncolonized mothers.[15,23,93,212,340] Acquisition is presumed to occur either by the ascending route through ruptured membranes or from contact with the organism in the genital tract during parturition. Heavy maternal inocula in the genital tract (>10^5 colony-forming units per milliliter) greatly increases the rates of vertical transmission to neonates and rates of heavy infant colonization.[9,15,59,148,159] Other factors associated with increased colonization rates in infants include prolonged rupture of membranes (>12 to 18 hours)[15,143] and vaginal delivery.[143] Maternal intrapartum antibiotic therapy substantially diminishes the vertical transmission of group B streptococci.[7,57,60,143,341] The body sites in neonates most likely to yield group B *Streptococcus* are the rectum and throat, findings reflecting replication of organisms at the respiratory or gastrointestinal tract sites after the ingestion of infected amniotic fluid or genital secretions.[143]

Horizontal transmission from nosocomial and community sources has been described.[1,93,118,234] Infant-to-infant or colonized staff member–to-infant spread may occur through hands of hospital personnel, but epidemics are unusual.[93,234] The rate of community acquisition, presumably by an oral-fecal route, appears to be low.[118,285] Breast milk also has been proposed as a mode of transmission for late-onset infection; most reported cases involved a mother with postpartum mastitis.[50,171,265]

INCIDENCE OF DISEASE

Before the widespread use of maternal intrapartum chemoprophylaxis to prevent early-onset disease, reported attack rates for group B streptococcal disease in infants ranged from 1.8 to 4.0 per 1000 live births.[235,323,343] Early-onset disease (onset within the first week of life) accounted for approximately 80 percent of cases.[280] Late-onset disease (onset between 7 days and 3 months of life) rates ranged from 0.3 to 1.8 per 1000 live births.[89,241] With the 2002 guidelines for universal screening of pregnant women at 35 to 37 weeks' gestation and administering of intrapartum chemoprophylaxis to carriers, the incidence of early-onset disease decreased to 0.3 cases per 1000 live births in 2004, a finding representing a decline of 81 percent from 1990.[75,280] However, the incidence of late-onset disease has remained unchanged.[75] Approximately 30 percent of cases of early-onset disease and up to 55 percent of those of late-onset and late, late-onset disease now occur in preterm infants.[188,280,283] Late, late-onset group B streptococcal disease occurs in infants older than 3 months of age and accounts for 7 to 13 percent of childhood group B streptococcal infections.[151,280,336] Affected infants typically were born before 34 weeks' gestation or have an underlying immunodeficiency or concomitant infection with human immunodeficiency virus (HIV).[87,151,336] Case-fatality rates for all infants with group B streptococcal disease have dropped from 46 percent in the 1970s to 6.5 percent in 2004.[75,156]

Group B streptococcal disease also is a common finding in pregnant women, with clinical manifestations that include urinary tract infection (usually asymptomatic bacteriuria but also cystitis or pyelonephritis), intra-amniotic infection, postpartum endometritis (often with bacteremia), and puerperal sepsis.[240,283,342] Occasionally, meningitis, septic thrombophlebitis, and other serious complications occur.[342] Attack rates of 2 per 1000 deliveries have been reported, and 28 percent of maternal cases are associated with pregnancy loss or birth of an infant with early-onset group B streptococcal disease.[240,342] Nonpregnant women and men account for 68 percent of invasive group B streptococcal disease in adults.[103] These patients typically are more than 65 years old or have underlying medical conditions, including diabetes mellitus, malignant disease (especially breast cancer), HIV infection, liver disease, stroke and other neurologic disorders, decubitus ulcers, and neurogenic bladder.[103,154,235,311]

RISK FACTORS FOR INFANT DISEASE

Vertical transmission is a prerequisite for the development of invasive, early-onset infection.[23,211,241] Evidence suggests that approximately 50 percent of late-onset infections also occur after vertical transmission.[89] The degree of colonization or inoculum also increases the likelihood of infant disease; heavily colonized mothers are more likely to have infants with invasive infection, and heavily colonized infants are more likely to have either early- or late-onset disease.[59,89,159,184] Other maternal factors associated with the development of early-onset disease include delivery before 37 weeks' gestation, premature rupture of membranes (rupture of membranes before onset of labor) or rupture of membranes more than 18 hours before delivery at any gestation, and intrapartum fever.[12,58,59,89,113,241] Women colonized with group B *Streptococcus* also have a higher incidence of premature rupture of membranes and preterm labor, a finding suggesting a causal relationship between group B streptococci and events leading to preterm birth.[6,210,214,262] Other maternal factors associated with an increased attack rate of early-onset infection are African-American ethnicity, age younger than 20 years, history of previous fetal loss, history of urinary tract infection with group B streptococci, and primiparity.[282,283] Late-onset disease also is associated with young maternal age and African-American ethnicity.[283] Siblings of infected infants who are the product of a multiple pregnancy (e.g., twins, triplets) have enhanced risk for development of early- and late-onset group B streptococcal disease.[98,242]

CAPSULAR POLYSACCHARIDE TYPES CAUSING DISEASE

Reports from the 1970s indicated that the group B streptococcal capsular polysaccharide types colonizing pregnant women and neonates were divided fairly evenly among types I, II, and III.[24,327,329] The current distribution of capsule polysaccharide types in invasive disease from multiple North American studies [84,134,187,324,342] is shown in Figure 94–1. Serotypes Ia and III are the most common cause of early-onset infection, whereas serotype III is the most common cause of late-onset infection. In Europe, type III predominates in both early- and late-onset disease.[112,308,324] Serotype III is implicated in 80 to 93 percent of meningitis cases, either as a focus of early-onset disease or as a manifestation of late-onset infection (80 to 93%).[24,26,329] Capsular polysaccharide type V emerged in the 1990s.[53,71,143,266] Type V causes both early- and late-onset infant disease and is the

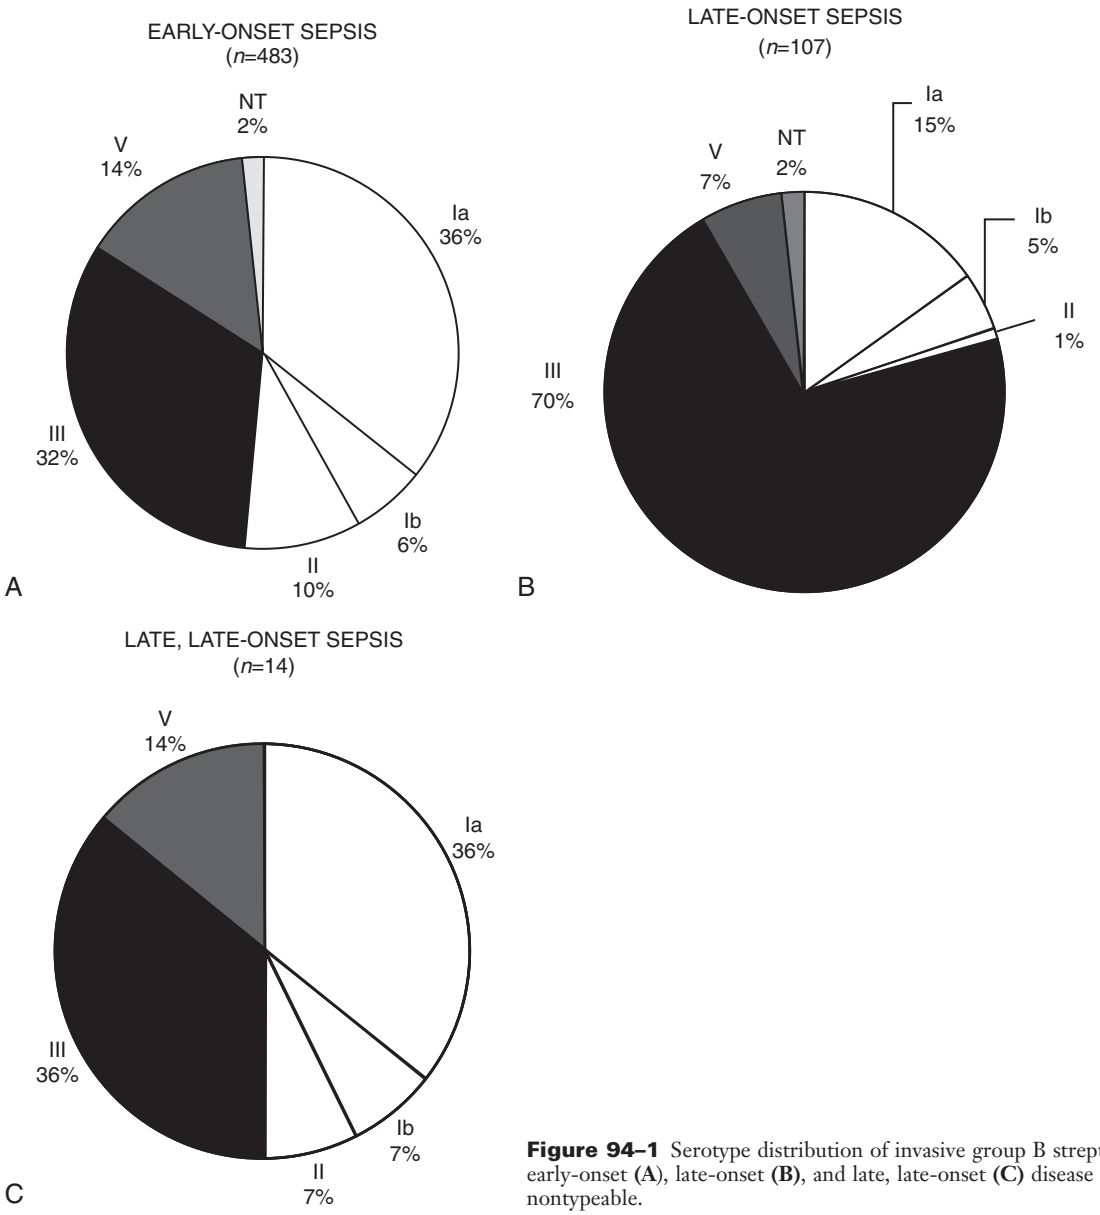

Figure 94–1 Serotype distribution of invasive group B streptococcal strains causing early-onset **(A)**, late-onset **(B)**, and late, late-onset **(C)** disease in infants.[53,84,134,187,342] NT, nontypeable.

type most commonly isolated from adults with invasive disease.[53,266] In Japan, types VI and VIII are the most common isolates from pregnant women.[172] The least common serotypes causing human disease are types Ib/c, IV, VI, VII, and VIII.

PATHOGENESIS

For pediatricians, group B streptococcal disease predominantly afflicts neonates, a predilection that results from a unique combination of maternal, bacterial, and host factors. Figure 94–2 shows a simplified flow chart of group B streptococcal transmission. First, an organism carried by an asymptomatically colonized mother is transmitted vertically to her neonate. Evidence suggests that this transmission may occur in utero shortly before birth or during parturition. This continuum in time of acquisition is reflected in the time of onset of symptoms; infected neonates often are ill at or within 12 hours of birth (≤90% of cases), whereas others may not have evidence of disease for a few days.[26,283] The organism successfully colonizes approximately 50 percent of all infants born to group B streptococcal carriers, yet disease develops in only 1 to 2 percent of these infants.[12,281,325] A breach in the delicate interplay of maternal, infant, and bacterial factors allows the organism to invade. Once invasion occurs, a combination of host defenses and therapeutic interventions may halt the progression of disease, or the infant's defenses may fail and the disease may progress and result in tissue damage or death.

MATERNAL FACTORS

The bacterial inoculum in the maternal genital tract determines the likelihood that the organism will be transmitted vertically. Infants born to heavily colonized women are more likely to be colonized themselves and are more likely to have early-onset disease.[9,15,59,89,148,159] Infants delivered before 37 weeks of gestation have an increased risk for development of early-onset disease. Heavy maternal colonization may induce preterm delivery,[211,262] and disease is more likely to develop in the infant in this setting

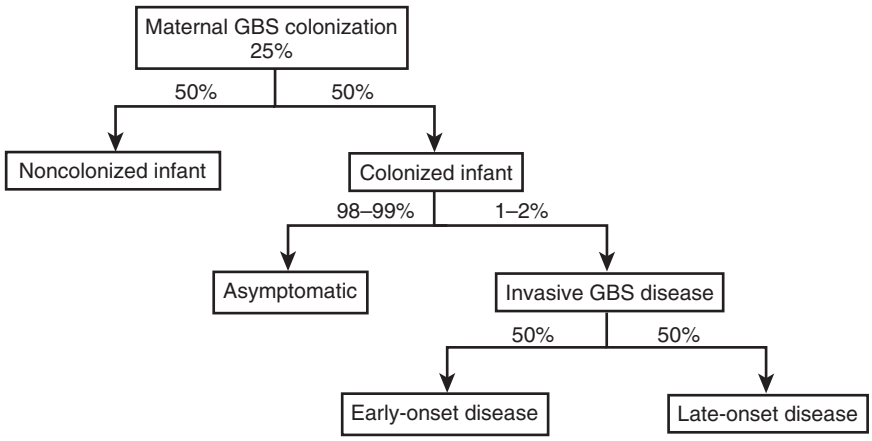

Figure 94–2 Flow chart of vertical transmission and disease manifestation of group B streptococcal disease in the era of intrapartum chemoprophylaxis.

of high bacterial inoculum and immunologic immaturity. Invasive disease also has been reported in term neonates delivered by elective cesarean section with intact membranes, but this is a rare event.[12,101,240]

In addition to bacterial inoculum, another critical maternal factor is the concentration of serum antibody to the serotype-specific polysaccharide capsule of the colonizing strain of group B *Streptococcus* at delivery. Antibody to the type-specific capsular polysaccharide is protective against the homologous serotype in the mouse model of lethal infection; antibody to the group B polysaccharide is not.[176] Baker and associates[28,32] determined that invasive disease with type III group B streptococci occurred primarily in infants born to women with low serum concentrations of antibodies directed against the type III capsular polysaccharide. Several other investigators also reported a correlation between low concentrations of antibody to types Ia, Ib, II, and III capsular polysaccharide in maternal delivery sera and the occurrence of early- and late-onset group B streptococcal infant disease.[125,127] A correlation between antibody concentration and maternal age may explain the epidemiologic association of young maternal age and increased likelihood of neonatal disease.[13] Animal models have demonstrated that antibody directed against the alpha or beta determinants of C protein is protective,[176,218] but definitive human studies are lacking. Invasive disease, but not colonization, elicits immunoglobulin M (IgM) and IgG antibodies to beta C protein in humans.[236] Antibody to other protein determinants in some serotypes has been postulated to be partially protective. Titers of antibody to R protein were found to be higher in maternal serum from mothers colonized with R protein–bearing strains whose infants were healthy than from mothers whose infants were ill; such antibodies were protective in a mouse model against type II, but not type III strains.[189,190] Presence of maternal antibody to Rib also was associated with protection in neonates against Rib-expressing group B streptococcal strains.[178]

BACTERIAL FACTORS

To colonize the genital tract or cause disease effectively, the organisms must be able to adhere to host tissue. Group B streptococci adhere well to many types of epithelium, including vaginal epithelium and chorioamnionic membranes.[116,196,293,302] Type III strains adhere more avidly to vaginal cells than do other serotypes in vitro.[56] Furthermore, invasive strains adhere better to epithelial tissue than colonizing strains do.[138] This capacity to adhere to and possibly invade chorioamnionic cells may explain the association of group B streptococcal colonization with preterm labor and premature rupture of membranes.[145] If a breach occurs in the membranes, the bacteria can multiply in amniotic fluid.[139] After transmission and colonization occur, the capacity of the bacteria to adhere to neonatal epithelial cells may allow them to invade and disseminate. The lung, after aspiration of infected maternal fluids, is a frequent initial site of infection in a newborn with early-onset disease. Group B streptococci can adhere to and invade respiratory epithelial cell lines.[272] In addition, they can invade endothelial cells, which may be a mechanism for some of the pathologic features of disseminated disease.[121]

Several different factors may confer adherence properties of group B streptococci including bacterial cell wall component lipoteichoic acid[229] or surface proteins.[67,302] One study showed that translocation across epithelial barriers was mediated by alpha C protein binding to host cell surface glycosaminoglycan.[42] Several proteins with potential roles in adherence and invasion were identified by detecting up-regulation during cell invasion using proteomics and include an undefined surface antigen, penicillin-binding protein 2b, glyceraldehydes-3-phosphate dehydrogenase, and an iron-binding protein.[158] Mouse antisera to these five proteins inhibited binding of group B streptococci to cervical epithelial cells. Translocation also may occur by a paracellular route.[296] Adherence to and invasion of the microvascular endothelial cells of the blood-brain barrier has been associated with proper anchoring of lipoteichoic acid,[91] beta-hemolysin/cytolysin,[92] fibrinogen binding protein FbsA,[304] and the newly discovered pilus proteins.[199]

A well-defined virulence structure of group B streptococci is the capsular polysaccharide. Mouse virulent strains are able to synthesize greater amounts of surface-bound type-specific polysaccharide than avirulent strains.[169,338] An unencapsulated mutant, created by inserting a transposon into the gene regulating capsule expression, has significantly less virulence in neonatal rats than does the parent type III strain.[273] As with other encapsulated organisms, the capsule is thought to confer virulence primarily by interfering with opsonophagocytosis.[181] In vitro, the capsule of type III group B streptococci has been shown to prevent the deposition of C3,[207] and the presence of the terminal sialic acid residue on the repeating unit of the polysaccharide is crucial to this interference.[99] Removal of sialic acid residues from the polysaccharide leads to diminished virulence, and a desialylated mutant loses virulence when compared with the parent strain.[326] Furthermore, the presence of this sialic acid moiety prevents activation of the alternative complement pathway, the predominant pathway used by the human host when minimal type-specific antibody is present.[99] In addition, when bacteria grow in the presence of human serum, the quantity of sialic acid increases, thereby potentiating its contribution to virulence.[244] Opsonization may be affected by cell surface components other than capsular sialic acid. C protein also lends relative resistance to

opsonization to strains bearing the antigen.[157,244] Beta-hemolysin/cytolysin contributes to cytolysis and apoptosis of phagocyte while protecting group B streptococci by the linked carotenoid pigment against oxidative damage.[194]

Sialic acid residues on the capsule may interfere with another component of the immune system. In a serum-free system, the desialylated mutant of type III group B streptococci elicited much larger quantities of leukotriene B_4 from macrophages than did the parent strain.[270] Leukotriene B_4 is a potent neutrophil chemoattractant, so this effect may result in diminished influx of effector cells. Similarly, C5a-ase may disable C5a, another host product capable of eliciting neutrophil influx. By enhancing phagocytosis and killing of group B streptococci, C5a also has direct stimulatory effects on neutrophils.[301] Bacterial elaboration of C5a-ase may affect both the accumulation of neutrophils and the efficiency of neutrophil function.

Once invasive infection is established, ongoing replication and digestion of bacteria can instigate host inflammatory responses that may be deleterious. Neonates recovering from group B streptococcal disease have circulating immune complexes for a prolonged period of time, and immune complexes can contribute to end-organ damage.[312] Additionally, immune complexes containing group B streptococcal components elicit inflammatory mediators such as leukotriene B_4 and interleukin-6 (IL-6). The cytokine response to gram-positive pathogens is not delineated as clearly as is that to gram-negative bacteria, partly because of the greater heterogeneity in structure of the latter.[54] Both group B and type III capsular polysaccharides induce the release of IL-6 from monocytes[296]; group B antigen also causes the release of tumor necrosis factor-α (TNF-α).[314] As with other gram-positive pathogens, the cell walls of group B streptococci contain peptidoglycan and lipoteichoic acid. Peptidoglycans from other gram-positive organisms elicit a variety of proinflammatory cytokines such as TNF-α, IL-1, IL-6, and granulocyte colony-stimulating factor.[90,142,264] Lipoteichoic acid also induces the release of IL-1β, IL-6, and TNF-α.[49,164] Group B streptococcal cell wall components likewise exert similar effects. Elaboration of these cytokines has been implicated in the clinical and hemodynamic effects of sepsis.[54] Specifically, blockade of IL-1 activity by administration of an IL-1 receptor antagonist in a piglet model of group B streptococcal sepsis ameliorated systemic hypotension and prolonged survival.[315]

INFANT HOST FACTORS

Neonates have several domains of immune dysfunction that affect their ability to mount a sufficient defense against group B streptococci. Neutrophils are the primary effector cell in host defense against extracellular bacterial pathogens, and neutrophils from neonates have many functional abnormalities.[182] The generation of chemotactic activity in neonatal serum in response to group B streptococci is diminished, as is the release of chemotactic factors by neonatal monocytes.[10,11,271] Thus, the diminished ability of neutrophils to migrate is amplified by a diminished level of chemotactic stimulation. Phagocytosis and bacterial killing also are impaired when opsonic activity is poor, as is the usual pattern in neonates with sepsis.[182] The neutrophil storage pools of neonates rapidly become depleted during invasive infection, thereby leading to profound neutropenia,[80] an ominous prognostic indicator.[245] These defects in neonatal neutrophils are even more pronounced in infants born prematurely.[182]

Cells of the monocyte/macrophage lineage also may play a role in host defense against group B streptococci, especially in the lungs, where the alveolar macrophage is the first effector cell to encounter pathogens. Defects in the functions of these cells have been described in neonates. Cord blood monocytes have impaired phagocytosis and killing of group B streptococci.[206] In animal models, oxidative metabolism, bacterial uptake, and migration to the site of infection by neonatal macrophages are diminished in response to group B streptococci.[208,284,286]

Humoral immunity is compromised in neonates. Both the alternative and classic complement pathways are affected, and preterm neonates are impaired more severely than are term neonates.[85,97] Both pathways are important in the opsonization of group B streptococci.[33] The concentration of type-specific antibody passively acquired from the mother is an important protective factor. Because passive transfer of IgG increases dramatically during the final 8 weeks of pregnancy, premature neonates are again at a disadvantage because they may not receive sufficient amounts of antibodies if they are born before protective levels are transferred.[79]

The pattern of production of cytokines by neonatal immune cells frequently is altered when compared with that of adults. For example, in response to group B streptococci, the level of TNF-α and IL-6[313] released by neonatal monocytes is increased relative to adults,[314,330] and IL-6[313] but levels of IL-8 and leukotriene B_4 are decreased.[271,277] IL-12 and interferon-γ are associated with improved outcome in an animal model of group B streptococcal infection, but lower quantities of these mediators are released by neonatal mononuclear cells.[162,201] Cytokine networks are important both in the manifestations of sepsis and in the stimulation of an appropriate immune response, so alterations in expression of cytokines may affect the neonate's response to this pathogen both clinically and immunologically.

CLINICAL MANIFESTATIONS

EARLY-ONSET DISEASE

Group B *Streptococcus* remains the leading cause of neonatal sepsis, and it accounts for 40 to 50 percent of early-onset sepsis cases.[40,51,152] The bimodal distribution of group B streptococcal infections corresponding to age of neonates and young infants was described first in 1973 and now is divided into two types, termed *early-* and *late-onset disease*.[26,113] The syndromes of early- and late-onset disease differ in epidemiologic characteristics, pathogenesis, clinical findings, and prognosis. Their major clinical features are detailed in Table 94–1. Early-onset disease is defined as onset of infection in the first 6 days of life, but most neonates (61-95%) become ill within the first 24 hours of life (median, 1 hour).[58,64,283] Premature infants often are ill at birth or within 6 hours of birth and account for 17 to 32 percent of neonates with early-onset group B streptococcal disease.[20,75,257,280,283] In very-low-birth-weight infants, group B *Streptococcus* has dropped to the second most common cause of early-onset sepsis, after *Escherichia coli*, since the implementation of intrapartum antibiotic chemoprophylaxis.[298]

Early-onset disease often occurs in the setting of maternal complications, including labor before 37 weeks' gestation, prolonged rupture of membranes for more than 12 hours, intrapartum fever greater than 100.4° F, chorioamnionitis, and early postpartum febrile morbidity.[25,45,58,59,89,323] In one study, infants born to a mother with one or more of these risk factors were 12.5 times more likely to develop early-onset group B streptococcal disease compared with those born to a mother with no risk factors.[58] Term infants can develop group B streptococcal disease without definable maternal risk factors except vaginal/rectal colonization.[33] In another study, 76 percent of mothers of infants with early-onset disease had deliveries complicated by at least one of the foregoing identifiable risk factor or was known to be a group B *Streptococcus* carrier.[257]

The three most frequent clinical manifestations are bacteremia without a focus, pneumonia, and meningitis.[12,323,336] The

TABLE 94–1 Features of Group B Streptococcal Disease in Infants

Feature (References)	Early-Onset Disease	Late-Onset Disease	Late, Late-Onset Disease
Age at onset (58, 64, 283)	≤6 days; mean, 8 hr; median, 1 hr	7-89 days; mean, 36 days; median, 27 days	≥90 days
Infants affected (75, 132, 283, 323)	Premature neonates, births after maternal obstetric complications	Term infants predominate	Premature neonates <32 wk gestation, immunodeficiency
Clinical findings (33)	Acute respiratory distress, apnea, and hypotension common	Fever, irritability, nonspecific signs, occasionally fulminant	Fever, irritability, nonspecific signs
Manifestations (12, 21, 96, 113, 323, 336)	Bacteremia (40-55%), pneumonia (30-45%), meningitis (6-15%)	Bacteremia without a focus (55%), meningitis (35%), osteoarthritis (~5%), cellulitis/ adenitis (~2%)	Bacteremia without a focus, focal infections as in late-onset disease
Case-fatality rate (75, 280, 283, 323, 336)	5-15%	2-6%	<5%

presentation for each may range from shock and respiratory failure at delivery to a healthy infant who has infection detected during evaluation because of maternal risk factors known to increase the risk for development of invasive infection.[257,323] Respiratory distress, including apnea, grunting respirations, tachypnea, and cyanosis, is the most common initial manifestation in all forms of early-onset group B streptococcal disease.[20,26,113,316,336] Other signs include lethargy, poor feeding, abdominal distention, pallor, jaundice, tachycardia, and hypotension. Fever usually is present in term neonates, but preterm infants often are normothermic or hypothermic.[323] Administration of intrapartum antibiotic prophylaxis to the mother does not alter the findings in infants, in whom early-onset disease develops despite administration of prophylaxis; most still become clinically ill in the first 24 hours of life.[40,64]

Bacteremia without a focus is present in 27 to 87 percent of neonates with early-onset disease.[283,323,336] Signs of septicemia, such as respiratory distress and poor perfusion, often are present, especially in neonates born at less than 37 weeks' gestation.[323] Bacteremia in healthy-appearing term infants also may develop, and in one series it occurred in 22 percent of cases.[150,323,336] These infants probably remained healthy because of early evaluation and institution of empiric antimicrobial therapy.[323] More often, bacteremic infants are mildly ill and have fever and nonspecific signs that should prompt bacteriologic evaluation. Bacteremia also frequently accompanies pneumonia and meningitis.

Radiographic findings of pulmonary involvement include infiltrates suggestive of congenital pneumonia, small pleural effusions, a pattern similar to that of hyaline membrane disease or respiratory distress syndrome, and increased vascular markings as seen in transient tachypnea of the newborn; radiographs also may appear normal despite abnormal pulmonary signs.[183,192,316] In preterm neonates, the findings frequently are identical to those of respiratory distress syndrome, and at autopsy, hyaline membranes containing bacteria and minimal inflammatory infiltrates have been described.[2,316]

Meningitis is documented in 6 to 15 percent of neonates with early-onset disease (Fig. 94–3).[283,323,332] As a rule, no signs specifically indicate its presence; this situation underscores the need to evaluate all neonates with presumed early-onset disease for the possibility of meningeal involvement.[323,332] Early in the course, the cerebrospinal fluid (CSF) white blood cell count may be normal despite isolation of group B streptococci.[14] Again, respiratory distress is the most frequent clinical finding.[26,323] Seizures rarely are the initial feature but do occur in as many as 50 percent of affected neonates early in the course of therapy; often these seizures are focal and subtle.[26] Postmortem evaluation of infants who die of early-onset group B streptococcal meningitis reveals hemorrhage, prominent basilar involvement, and abundant bacteria with relatively sparse inflammation.[113]

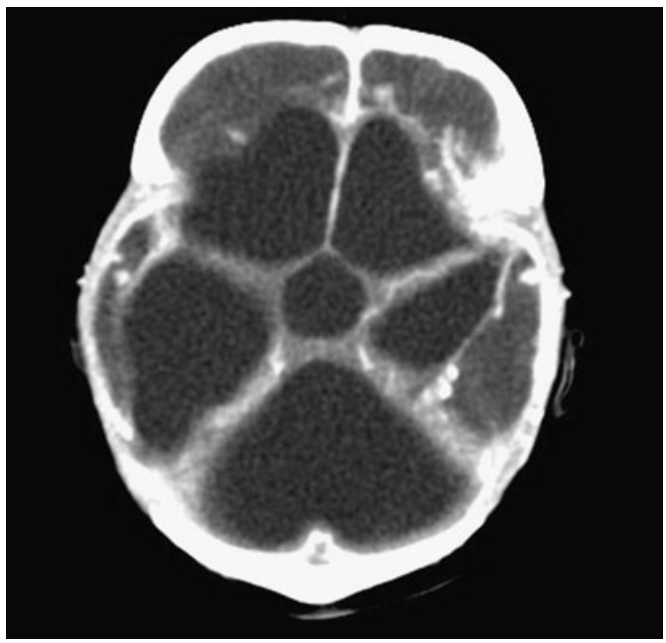

Figure 94–3 Head computed tomography scan at 6 weeks of age from a term infant with early-onset group B streptococcal (GBS) meningitis shows significant loss of normal brain matter.

LATE-ONSET DISEASE

Late-onset disease is defined as infection in infants 7 to 90 days of age, and it primarily affects term infants with an unremarkable maternal history and early neonatal course.[26,89] However, more recent case series suggested that late-onset infection develops in a larger proportion of infants born quite prematurely (<34 weeks' gestation).[188] Bacteremia without a focus and meningitis are the two most common manifestations of late-onset disease.[113,117,336] Osteoarticular infections and cellulitis are additional clinical foci.[21,96,336] Whereas early-onset disease most frequently occurs acutely with apnea and hypotension, late-onset disease often is manifested by fever, irritability, and other nonspecific signs.[33] More fulminant, rapidly progressive cases do occur, however.[26]

Meningitis is a frequent complication, occurring in 35 to 40 percent of late-onset disease cases.[26,323,336] Late-onset meningitis most typically manifests with fever and lethargy, although respiratory distress, coma, and shock also may occur.[26] Classic signs of meningitis, such as a bulging fontanelle and nuchal rigidity, occur more commonly in neonates with late-onset than early-onset meningitis. Subdural effusions develop in as many as 20 percent of cases, but subdural empyema is a rare occurrence.[12,26,242] Infants who die of late-onset meningitis have purulent leptomeningitis at postmortem examination.[113]

Sequelae occur in 20 to 30 percent of survivors of early- and late-onset meningitis. These sequelae include mental retardation, spastic quadriplegia, cortical blindness, deafness, uncontrolled seizures, hydrocephalus, and speech and language delay.[100,318] Signs at admission that are correlated with a high likelihood of a poor outcome include hypotension, coma or semicoma, status epilepticus, neutropenia, CSF protein levels greater than 300 mg/dL, and high concentrations of bacterial capsular polysaccharide antigen in CSF.[39,100,245]

LATE, LATE-ONSET DISEASE

Contemporary studies show increasing incidence of group B streptococcal infection in infants older than 3 months of age, defined as late, late-onset disease.[151,280,336] These infections tend to occur in infants who were born extremely prematurely and whose corrected age is less than 3 months.[151,280,336] Late, late-onset disease also occurs in children co-infected with HIV and those with immunodeficiencies,[87,151,336] a finding supporting the recommendation that immunodeficiency be considered in any child infected beyond the usual period of risk.[87] The clinical manifestations in these older infants are similar to those in patients with typical late-onset infection; bacteremia without a focus and meningitis are the most common clinical features.[87,151] Endocarditis and central venous catheter infection also have been noted.[151]

SEPTIC ARTHRITIS AND OSTEOMYELITIS

Osteoarthritis occurs in approximately 5 percent of infants with late-onset infection.[336] Among neonates and young infants with osteomyelitis, group B streptococci have been identified as the causal agent in 7 to 38 percent of cases.[96,333] The osteoarticular disease usually is more indolent than is the osteomyelitis caused by other etiologic agents in young infants. Diagnosis usually is established after a mean of 9 days of findings at a mean age of 31 days.[33,96] Decreased motion of the involved extremity and pain with manipulation are common signs. Warmth and redness are uncommon findings but have been described.[96] Systemic signs and symptoms, including fever, are unusual manifestations.[96,214]

Group B *Streptococcus* has a predilection for the proximal humerus.[96] The femur is the second most commonly affected bone. Involvement of more than one bone is an unusual finding.[96] However, involvement of the adjacent joint is described.[214] Blood cultures infrequently are positive, unlike neonatal osteomyelitis caused by other etiologic agents. A lytic lesion often is seen on radiographs at first evaluation (Fig. 94–4). This observation suggests that lytic lesions may be a late phenomenon that develops after seeding of the metaphysis during an episode of asymptomatic, early-onset bacteremia several weeks before presentation.[33]

The mean age at diagnosis in infants who have septic arthritis without osteomyelitis is 20 days. The clinical picture typically is acute, with a mean of 2 days of abnormal findings before diagnosis is established. The lower extremities are involved most often, with the hip joint predominating. Infants typically present with local joint signs in the absence of systemic symptoms.[215]

Figure 94–4 Radiograph of the right arm of a 26-day-old infant with a 2-day history of diminished movement of that extremity. A well-defined, lytic lesion is present in the proximal end of the humerus. Necrotic material from this area was débrided surgically and grew group B streptococci on culture. *(Courtesy of Morven S. Edwards, M.D.)*

CELLULITIS/ADENITIS

In one case series, 2 percent of late-onset group B streptococcal infections were associated with cellulitis/adenitis syndrome.[336] Diagnosis is made at a mean age of 5 weeks, with a preponderance of cases in male patients.[21] Typical presentation includes fever, irritability, poor feeding, and swelling of the affected soft tissue area. Enlarged adjacent lymph nodes become palpable within a few days. The most frequent sites of cellulitis are the face and neck,[21,136,243] with enlarged lymph nodes in the submandibular area. Ipsilateral otitis media was noted in four of five infants with facial or submandibular cellulitis in one case series.[139] Less commonly affected areas reported include the genital or inguinal region (Fig. 94–5), the hand, and the prepatellar bursa.[21,33,61] Aspiration of the affected area of cellulitis often yields group B streptococci, and concomitant bacteremia almost always is present.

OTHER MANIFESTATIONS

Nearly every organ has been reported to be a site of group B streptococcal infection in young infants. Table 94–2 lists these reported unusual manifestations of early- and late-onset disease.

RECURRENT INFECTIONS

Second (and sometimes third) episodes of group B streptococcal infection occur in approximately 1 to 2 percent of cases after early- and late-onset infection.[128] In a case series from Houston, the mean age at recurrence was 44 days, and the mean duration between the first course of therapy and recurrence was 19 days.[128] Molecular epidemiologic techniques have indicated that most, but not all, of these recurrent infections are caused by the strain implicated in the first episode; this finding suggests that persistent mucosal colonization after treatment of the first episode is followed by invasion of the bloodstream.[227] Contaminated breast

milk also has been implicated as a source of recurrent infection.[171] No specific risk factors are evident in these infants, but most of them are born prematurely.[128]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

LABORATORY STUDIES

The diagnosis of group B streptococcal infection is confirmed by isolation of this pathogen from a normally sterile body site including blood, CSF, pleural fluid, bone aspirate, joint fluid, or soft tissue. Cultures of the skin, umbilicus, or mucous membranes do not have clinical significance. Tracheal aspirate cultures that grow group B streptococci indicate neonatal colonization but do not prove pulmonary invasion (pneumonia). Rather, isolation of the organism from blood (or in rare circumstances, lung tissue or the pleural space) is required.

Meningitis in early-onset disease is clinically indistinguishable from bacteremia without a focus, and 10 to 38 percent of neonates with meningitis have negative blood culture results,[332] so lumbar puncture is necessary to determine the presence or absence of meningeal involvement. Lumbar punctures also are indicated in patients with a focal site of group B streptococcal infection resulting from its propensity for involving the CNS. For example, group B streptococci grew from CSF cultures in 24 percent of infants with cellulitis/adenitis who underwent lumbar puncture.[5] One study found that if selected criteria were used instead of routine lumbar punctures, the diagnosis of bacterial meningitis would have been missed or delayed in 17 percent of infants.[332]

Several methods for detecting group B polysaccharide antigen in body fluid specimens have been developed. These techniques include countercurrent immunoelectrophoresis, latex particle agglutination, and enzyme immunoassay.[39,131,226,247,267]

The advantages of these methods are their simplicity, rapidity, and ability to detect antigen, even after cultures are rendered sterile by antimicrobial therapy. The disadvantage is the frequency of false-positive results, especially when they are used to "screen" asymptomatic infants for sepsis.[247] Studies also have shown false-negative results from specimens from infants with subsequent death from group B streptococcal disease.[231]

CSF has had detectable group B antigen in 72 to 89 percent of neonates with meningitis; serum is much less likely to be positive. The only specimens recommended for antigen testing are blood and CSF; urine specimens should not be tested because they are unreliable. Antigen testing should not be used as a substitute for bacterial culture. Their proper use should be limited to the setting of symptomatic infants in whom rapid diagnosis may alter therapy or allow proper tailoring of antibiotic choice, for example, a sick neonate with CSF pleocytosis and previous antibiotic administration. These tests are never useful in infants who appear healthy.

A limited study of real-time polymerase chain reaction (PCR) to detect DNA in blood of eight neonates with culture-proven group B streptococcal sepsis showed positive corresponding results.[160] However, larger, prospective studies are required to evaluate sensitivity and specificity.

The white blood cell count of a neonate with proven group B streptococcal sepsis may reflect leukopenia, neutropenia, or leukocytosis.[204,245,316] Manroe and associates[204] found the ratio of absolute immature neutrophils to absolute total neutrophils (I:T index) to be the most reliable index for distinguishing respiratory distress caused by group B streptococcal infection from that with a noninfectious origin. Most infected neonates had an elevation greater than 0.20 (91% versus 4% of uninfected infants). Other markers of inflammation such as C-reactive protein may also rise with acute infection and decrease in response to therapy.[250,255]

DIFFERENTIAL DIAGNOSIS

The signs and symptoms of early-onset group B streptococcal disease are clinically indistinguishable from neonatal sepsis caused by other bacterial pathogens such as *E. coli* and *Listeria monocytogenes*. The timing may be somewhat different, with group B streptococcal disease appearing earlier and leading to death earlier in fatal cases.[267] The prominence of respiratory signs in early-onset disease has led to confusion with noninfectious causes of respiratory distress such as transient tachypnea of the newborn, persistent fetal circulation, and respiratory distress syndrome.[2,20,245,316] Clinical features that suggest group B streptococcal infection include a history of prolonged rupture of membranes, apnea, shock in the first 24 hours of life, a 1-minute Apgar score of 5 or less, and rapid progression of pulmonary disease.[2,20,316]

The differential diagnosis of late-onset disease depends on the focus of infection. Meningitis in infants of this age also is caused by *Streptococcus pneumoniae*, *Neisseria meningitidis*, *Listeria monocytogenes*, *Haemophilus influenzae* (type b and nontypeable), and viruses. If the results of Gram stain analysis of CSF are inconclusive, other potential pathogens should be considered when therapy is selected. The findings of osteomyelitis may be subtle; refusal to move the arm may be ascribed to neuromuscular disease or Erb palsy.[96] Careful physical examination usually reveals tenderness over the involved area, and radiographs generally show a lytic defect in the metaphyses.[96] If the organism is isolated from a bone aspirate, the diagnosis is definitive. Finally, as seen in Table 94-2, many unusual manifestations of group B streptococcal infection have been described, so this organism should be included in the differential diagnosis of any focal infection occurring in the age group at risk.

TREATMENT

EMPIRIC TREATMENT

The antimicrobial regimens recommended for the treatment of group B streptococcal infection in infants are summarized in Table 94–3. Penicillin G remains the drug of choice because susceptibility is uniform. In the usual circumstance, however, antimicrobial therapy for group B streptococcal infection is started before culture results are known. Initial empiric therapy for early-onset disease would include ampicillin and gentamicin for the treatment of neonatal pathogens in addition to group B streptococci. Irrespective of gestational age, neonates with suspected meningitis and those whose clinical condition will not permit lumbar puncture should receive high doses of ampicillin (300 mg/kg/day) plus gentamicin.[12] This combination is more effective than is either ampicillin or penicillin G alone in killing most group B streptococcal strains in vitro[275] and in vivo.[300] For suspected late-onset disease, the usual initial therapy includes intravenous ampicillin in combination with cefotaxime or ceftriaxone.[252] If an infant is receiving empiric vancomycin therapy and group B streptococcal meningitis has not been excluded, penicillin G or ampicillin should be added to the regimen because vancomycin is inhibitory in vitro rather than bactericidal, and CSF concentrations may not exceed the minimal inhibitory concentration if a high inoculum of group B streptococci is present.[33]

TABLE 94–3 Treatment of Group B Streptococcal Infections in Infants

Focus of Infection	Antibiotic	Daily Dose	Duration
Suspected meningitis (initial empiric therapy)	Ampicillin *plus* gentamicin	300-400 mg/kg 7.5 mg/kg	Until cerebrospinal fluid is sterile
Suspected sepsis* (initial empiric therapy)	Ampicillin *plus* gentamicin	150-200 mg/kg	Until bloodstream is sterile
Meningitis	Penicillin G	450,000-500,000 units/kg	14 days minimum†
Bacteremia	Penicillin G	200,000 units/kg	10 days
Arthritis	Penicillin G	200,000-300,000 units/kg	2-3 wk
Osteomyelitis	Penicillin G	200,000-300,000 units/kg	3-4 wk
Endocarditis	Penicillin G	400,000 units/kg	4 wk‡

**Assumes that lumbar puncture has been performed and the cerebrospinal fluid has no abnormalities.*
†Should be extended to 21 days or longer if ventriculitis, cerebritis, subdural empyema, or other suppurative complications occur.
‡In combination with low-dose gentamicin for the first 14 days.

SPECIFIC TREATMENT

Once group B streptococci have been identified in cultures of blood, CSF, or other normally sterile body sites and blood and CSF cultures are shown to be sterile, penicillin G alone should be used to complete therapy. Recommendations concerning the optimal dose and duration have varied, but they should be dictated by the focus and severity of the infection (see Table 94–3). Several issues should be considered when selecting the appropriate dose: (1) the usual minimal bactericidal concentration of penicillin for group B streptococci ranges from 0.04 to 0.8 μg/mL,[165] (2) only 10 percent of penicillin serum levels reach the CSF, (3) the inoculum of group B streptococci in the CSF of infants with meningitis may reach 10^7 to 10^8 colony-forming units per milliliter,[105] and (4) high doses of penicillin G and ampicillin are safe in neonates.[33] To ensure rapid bacterial killing, especially in infants with meningitis, relatively high doses of penicillin are recommended for both early- and late-onset infections.

The infant with meningitis should undergo a second lumbar puncture 24 to 48 hours into therapy to document CSF sterility.[33] Infants with continued positive CSF cultures may have very high inoculum, ventriculitis with obstruction, severe infection with cerebritis and vasculitis, subdural empyema, or septic thrombophlebitis, or they may be receiving an insufficient dose of antibiotics; in this circumstance, appropriate studies should be initiated to determine which of these conditions is present. When CSF sterility and penicillin G susceptibility are verified, penicillin G alone is given for a minimum of 14 days.[252] Longer treatment is indicated if the course is severe, the infant has ventriculitis, or CSF sterilization is delayed. Another lumbar puncture to evaluate CSF cell count and protein should be considered at the anticipated completion of therapy. Findings of polymorphonuclear cells greater than 30 percent or protein higher than 200 mg/dL may warrant further diagnostic evaluation and longer duration of therapy.[33] In addition, a contrast-enhanced computed tomography scan of the head should be performed near completion of therapy in complicated cases, including infants who have prolonged fever (>5 days), cerebritis, abscess, subdural empyema, or venous thrombosis. Such complications often correlate with neurologic abnormalities that lead to a poor prognosis for complete central nervous system recovery.[100,318]

Infants with bacteremia without a focus should receive intravenous therapy for a total of 10 days.[252] A shorter duration has not been documented to be efficacious, and relapses, although rare, have been reported in these circumstances.[65,320] Patients with septic arthritis, osteomyelitis, or endocarditis should be treated for the durations summarized in Table 94–3. Oral therapy has no place in the management of infants with group B streptococcal disease.[33,252] Alternative agents such as the cephalosporins and vancomycin are active against group B streptococci in vitro.[107,186] The efficacy of these agents is unknown, however, and these drugs are not recommended in most circumstances.

SUPPORTIVE TREATMENT

The importance of prompt, vigorous, and careful supportive therapy in the successful treatment of infant group B streptococcal infections cannot be overemphasized. Neonates with early-onset disease accompanied by pneumonia should be suspected of having early respiratory failure, and ventilatory support should be initiated before the onset of apnea, septic shock, or frank respiratory failure occurs. Persistent metabolic acidosis and delayed capillary refill should prompt treatment for shock. All patients with signs of impending respiratory or circulatory failure or meningitis should be treated in an intensive care unit. When present, hypoxemia, severe anemia, and acidosis should be corrected, and seizures should be controlled with anticonvulsants. In addition, fluid and electrolyte status should be monitored meticulously. Surfactant should be used as per nursery protocol; improved gas exchange is seen in infected premature neonates who receive surfactant, although the response is slower than in patients with respiratory distress syndrome.[141] Finally, if an infant has persistent pulmonary hypertension or if conventional ventilatory therapy has failed, extracorporeal membrane oxygenation may be considered, if available.

ADJUNCTIVE TREATMENT

Adjunctive treatment of life-threatening group B streptococcal disease is aimed at correcting poor host defenses and is being investigated. Such treatment includes intravenous human immunoglobulin, monoclonal antibodies to group B streptococcal polysaccharide antigen, leukocyte transfusion, and growth factors such as granulocyte colony-stimulating factor and granulocyte-monocyte colony-stimulating factor for neutropenia.[69,78,122] The efficacy of these agents has not been established, and, although they may be used occasionally, they should be considered experimental.

RECURRENT INFECTIONS

In the few infants who experience a recurrence, suppurative foci, HIV infection, or humoral immune deficiency should be excluded or treated. Immunoglobulin levels should be determined to exclude humoral immune deficiency. Although it may be too early to document humoral immune deficiency unequivocally, total IgG usually is significantly lower than would be expected for age in weeks.[128] Tube dilution susceptibility of isolates from the first and recurrent episodes should be determined to ensure in vitro susceptibility to penicillin. If the reason for the recurrence remains unknown, persistent mucous membrane colonization with group B streptococci probably is the source.[227] β-Lactam antibiotics, even when administered by the parenteral route, do not eradicate group B streptococcal colonization reliably.[239] Some studies have shown the benefit of rifampin (20 mg/kg/day) to eradicate mucosal group B streptococcal colonization when given orally during the last 4 days of parenteral therapy.[128,219] However, a more recent study showed failure of rifampin to eradicate group B streptococcal colonization in infants.[108]

PROGNOSIS

The outcome of group B streptococcal disease is related closely to the severity and site of infection at initial evaluation. Improved outcomes after early-onset infection have resulted from greater awareness among pediatricians and improved obstetric management. Improvements in obstetrics include the use of intrapartum antibiotic prophylaxis in women at risk for delivering an infant with early-onset group B streptococcal infection. However, the mortality rate remains substantial at 2 to 8 percent, especially in neonates born at less than 37 weeks' gestation, in whom the mortality rate often exceeds 20 percent.[75,281]

Little information is available on the long-term prognosis of survivors of group B streptococcal sepsis without meningitis. In infants with septic shock, the development of periventricular leukomalacia has been reported and associated with neurodevelopmental sequelae.[102] However, the frequency of this association is not known.

For infants with early- or late-onset meningitis, 20 to 30 percent will have permanent neurologic sequelae, and 20 percent of these impaired survivors have global mental retardation, cortical blindness, hearing loss, spasticity, or paresis.[100,135,318] Whether

these rates reported over 20 years ago can be applied to infants currently being treated is unknown. Improvements in both specific and supportive therapy may have diminished the frequency of lasting impairments.

To date, the prognosis for infants with osteoarticular or soft tissue infections with group B streptococci has been excellent.[21,96] However, omission of early surgical intervention for infections that involve either the hip or shoulder joints may result in epiphyseal injury.

PREVENTION

The continuing magnitude and severity of group B streptococcal disease and its attendant mortality and morbidity have led to investigations aimed at its prevention. Several general approaches have been proposed: maternal chemoprophylaxis to decrease transmission, infant chemoprophylaxis to decrease colonization, and immunoprophylaxis to increase protection against disease.

CHEMOPROPHYLAXIS

Maternal Chemoprophylaxis

Epidemiologic studies during the 1980s showed that women with group B streptococcal colonization during pregnancy had greater than 25 times likelihood of delivering infants with early-onset disease compared with women with negative prenatal cultures.[278] The idea to give antibiotic therapy to the mother to prevent vertical transmission to her fetus was suggested first by Franciosi and colleagues.[113] The first strategy to be evaluated was antenatal treatment of group B streptococcal maternal carriers with oral or intramuscular penicillin. This method temporarily suppresses colonization density but does not eradicate it or interrupt vertical transmission of group B streptococci to neonates.[119,130,258]

The next strategy, maternal intrapartum chemoprophylaxis, has been demonstrated to be efficacious in the prevention of vertical transmission of group B streptococci from colonized mothers to their neonates, the development of early-onset disease, and maternal febrile morbidity. Infants are less frequently colonized with group B *Streptococcus* if they are born to mothers treated with ampicillin during labor than to mothers not given antibiotics.[59,60,341] Several controlled trials involving thousands of deliveries indicated that intrapartum penicillin G or ampicillin given intravenously to group B streptococcal carriers during labor prevents early-onset disease in neonates.[57,211,309] Early-onset infection occurred in 0 to 1.1 percent of infants whose mothers received intrapartum ampicillin compared with 5 to 9 percent of infants of mothers in the groups not receiving treatment. A large trial involving more than 50,000 live births in Australia showed similar results.[120]

In 1996, guidelines supported by the Centers for Disease Control and Prevention (CDC), the American College of Obstetricians and Gynecologists, and the American Academy of Pediatrics recommended a risk-based approach or culture-based approach.[278] The risk-based approach was based on the presence of one of more of the following: premature labor at less than 37 weeks' gestation, prolonged rupture of membranes (>18 hours), group B streptococcal bacteriuria, intrapartum fever (≥100.4° F [38° C]), or delivery of a previous infant with group B streptococcal infection. The culture-based approach required intrapartum chemoprophylaxis for all women with positive vaginal and rectal cultures routinely obtained at 35 to 37 weeks' gestation regardless of risk factors. Use of these methods to define women who were candidates for intrapartum chemoprophylaxis led to a 70 percent decline in the incidence of early-onset group B streptococcal disease.[75,280]

In 2002, a population-based study compared the two approaches and found the culture-based approach to be 50 percent more effective than the risk-based approach in preventing early-onset group B streptococcal disease.[279] Sixty-two percent of infants with early-onset disease were born to mothers who did not have any clinical risk factors. Therefore, revised guidelines published by the CDC in 2002 recommended universal vaginal and rectal screening cultures of all pregnant women between 35 and 37 weeks of gestation, with intrapartum chemoprophylaxis for all women identified as group B streptococcal carriers.[278] The risk-based approach was to be reserved for any women in labor whose colonization status is unknown. Colonization during a previous pregnancy is not an indication for intrapartum chemoprophylaxis. Women with group B *Streptococcus* isolated from urine in any concentration during pregnancy should receive intrapartum chemoprophylaxis, because these women usually are heavily colonized. Women who previously gave birth to an infant with invasive group B streptococcal disease always should receive chemoprophylaxis. An algorithm of these current guidelines is shown in Figure 94–6.

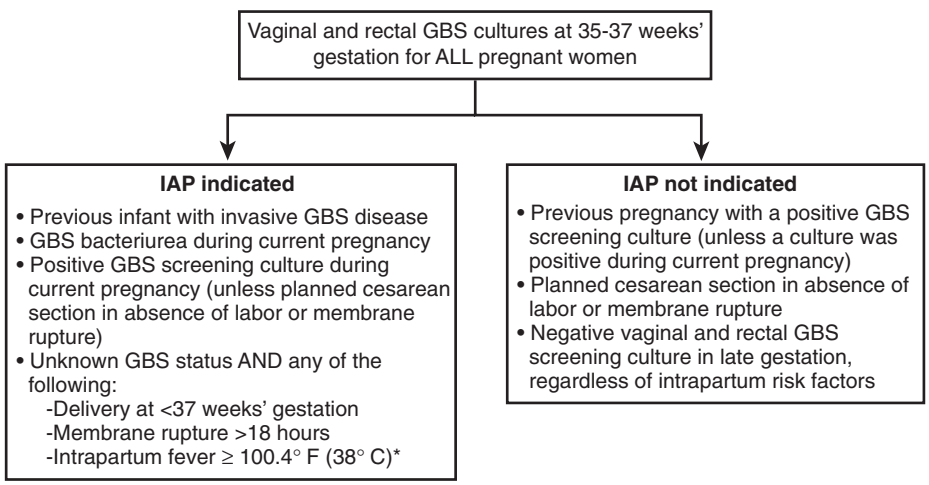

Figure 94–6 Recommendations for intrapartum antimicrobial prophylaxis (IAP) to prevent early-onset group B streptococcal (GBS) disease using a universal culture screening strategy. *(Adapted from Centers for Disease Control and Prevention: Prevention of perinatal group B streptococcal disease: Revised guidelines from CDC. M. M. W. R. Morb. Mortal. Wkly. Rep.* 51:*1-22, 2002.)*

Optimal culture techniques are discussed earlier in the chapter. Many rapid tests are being studied because they offer the advantage of detecting colonization status in women who present for preterm labor or who have not had prenatal care. These tests include latex agglutination, optical immunoassay, DNA hybridization, enzyme immunoassay, Islam starch medium tests, and PCR.[146] With the exception of PCR, all tests showed poor sensitivity or specificity compared with the standard culture method and are not sufficiently accurate to aid in decision making concerning intrapartum antibiotic prophylaxis. None of these tests can replace routine culture at this time. A prospective multicenter study evaluated a real-time PCR assay that gave results in 40 minutes.[83] Compared with intrapartum culture, the PCR assay had a sensitivity of 94 percent and a specificity of 96 percent.

Maternal chemoprophylaxis begins at hospital admission for delivery or at rupture of membranes and consists of intravenous penicillin G (initial dose, 5 million units; subsequent doses, 2.5 million units every 4 hours recommended for intrapartum chemoprophylaxis).[278] Although penicillin is preferred because of its narrow spectrum of activity, ampicillin (initial dose, 2 g; subsequent doses, 1 g every 4 hours) can be given as an alternative. For women who are allergic to penicillin, intrapartum chemoprophylaxis must take into account increasing resistance rates to clindamycin and erythromycin.[55,86] Women at low risk of developing anaphylaxis should be given cefazolin (initial dose, 2 g; subsequent doses, 1 g every 8 hours). Women at high risk of developing anaphylaxis should have susceptibility testing performed on their isolates obtained during screening at 35 to 37 weeks of gestation. If the isolate is susceptible, clindamycin (900 mg every 8 hours) or erythromycin (500 mg every 6 hours) can be used. If susceptibility testing is not available, the results are not known, or the isolate is resistant to clindamycin and erythromycin, vancomycin (1 g every 12 hours) can be given as the alternative. The efficacy of the latter two regimens is not known.

Since the widespread adoption of chemoprophylaxis, the incidence of early-onset disease has plummeted.[75,280] Racial disparities in early-onset disease have declined significantly.[73,280] Opportunities to prevent early-onset disease still are missed, however, because of laboratory practices,[74] hospital or procedural errors in communication of the screening results, or failure to administer intrapartum chemoprophylaxis to a mother known to be colonized.[257] The incidence of late-onset disease remains unaffected by intrapartum chemoprophylaxis.[75]

Management of an infant born to a mother given intrapartum penicillin G prophylaxis depends on the clinical findings at birth, the gestational age, and the timing of doses administered to the mother (Fig. 94–7). Amniotic fluid levels of penicillin that will kill group B streptococci are not achieved until at least 3 hours after administration of the first dose.[62] If the infant appears healthy, has a gestational age of 35 weeks or more, and has a mother given at least one dose of intrapartum chemoprophylaxis at least 4 hours before delivery, neither diagnostic evaluation nor empiric antimicrobial therapy will be required. However, to ensure their ongoing stability, such infants should be observed in the hospital for at least 48 hours. Keeping the infant hospitalized through day of life 2 has been challenging because the associated expense affects the cost-to-benefit ratio of intrapartum prophylaxis.[223] However, an analysis of all live births in the state of Florida for the years 1992 through 1994 demonstrated a 115 percent increase in the rate of readmission for group B streptococcal infection in infants discharged on day of life 1; this finding supports the recommendation to observe infants for 48 hours.[126]

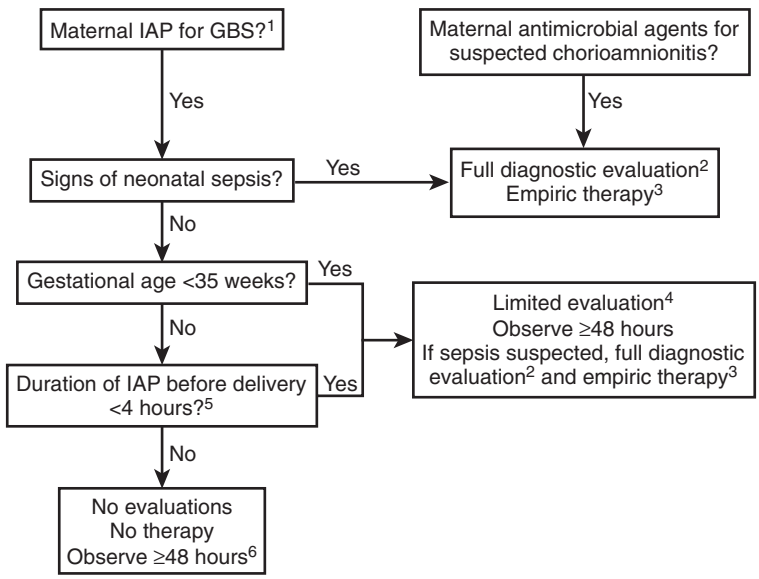

Figure 94–7 Empiric management of a newborn exposed to intrapartum antimicrobial prophylaxis (IAP) for group B streptococcal (GBS) infection. *1*, When no maternal intrapartum prophylaxis for GBS was administered despite the presence of an indication, data are insufficient on which to recommend a single management strategy. *2*, Includes complete blood cell count (CBC) and differential, blood culture, and chest radiograph if respiratory abnormalities are present. When signs of sepsis are present, a lumbar puncture, if feasible, should be performed. *3*, Duration of therapy varied depending on results of blood culture, cerebrospinal fluid findings, if obtained, and clinical course of the infant. If laboratory results and clinical course do not indicate bacterial infection, duration may be as short as 48 hours. *4*, CBC and differential and blood culture. *5*, Applies only to penicillin, ampicillin, or cefazolin and assumes recommended dosing regimens. *6*, A healthy-appearing infant who was at least 38 weeks' gestation at delivery and whose mother received at least 4 hours of IAP before delivery may be discharged home after 24 hours if other discharge criteria have been met and a person able to comply fully with instructions for home observation will be present. If any one of these conditions is not met, the infant should be observed in the hospital for at least 48 hours and until criteria for discharge are achieved. *(Adapted from Centers for Disease Control and Prevention: Prevention of perinatal group B streptococcal disease: Revised guidelines from CDC. M. M. W. R. Morb. Mortal. Wkly. Rep.* 51:*1-22, 2002.)*

Neonates with signs of sepsis are evaluated and treated empirically for sepsis. Healthy-appearing neonates who either are born at less than 35 weeks' gestation or are born to women given no intrapartum chemoprophylaxis or a single dose of intrapartum chemoprophylaxis less than 4 hours before delivery should undergo limited laboratory evaluation (complete blood count and blood culture) and observation in the hospital for 48 hours without therapy. However, if the subsequent clinical course or the laboratory results suggest infection, full diagnostic evaluation and therapy is initiated.

Concern that widespread use of intrapartum ampicillin use will result in a greater incidence of ampicillin-resistant neonatal infection has been supported by some case series.[161,216] Development of penicillin- or ampicillin-resistant group B streptococci has not been seen.[77] In most studies, incidence rates of *E. coli* and other gram-negative pathogens have remained stable.[4,161,216,268] The rate of ampicillin-resistant *E. coli* infections is increasing in preterm infants. However, rates of ampicillin resistance in term neonates before and after widespread intrapartum chemoprophylaxis are the same.

Infant Chemoprophylaxis

The two controlled trials evaluating neonatal prophylaxis reached contradictory conclusions.[256,289] In the first trial, more than 16,000 newborns received either intramuscular penicillin G or topical tetracycline (prophylaxis for gonococcal ophthalmia neonatorum) within an hour of birth during alternating weeks.[289] In penicillin-treated newborns, the incidence of proven early-onset group B streptococcal disease was less common, but death rates were similar, and an increase in the number of penicillin-resistant infections in the penicillin group was noted. In the second controlled study, blood cultures were obtained before initiation of penicillin therapy, and rates of group B streptococcal bacteremia were similar in the treatment and control groups.[256] In this study of nearly 1200 neonates weighing 2000 g or less at birth, intramuscular penicillin (or no treatment) was given in the first hour of life and was continued for 3 days. Rates of group B streptococcal bacteremia were similar in the treatment and control groups. Penicillin prophylaxis probably was ineffective because almost 90 percent of neonates with early-onset group B streptococcal disease were bacteremic immediately after birth. The results of the second study are supported by numerous observations, thus indicating that early-onset disease often begins in utero.[60,241,253,281,282] Infant chemoprophylaxis currently is not recommended.[278]

IMMUNOPROPHYLAXIS

Although efforts to implement intrapartum chemoprophylaxis further are ongoing, the most promising and potentially lasting method for prevention of both early- and late-onset infant infections is immunoprophylaxis. This approach remains investigational, and several reviews have summarized the rationale.[25,137,237] It is based on the observation that immunity to group B streptococci correlates with antibody directed against the type-specific capsular polysaccharides of these organisms. These IgG class antibodies and complement promote opsonization, phagocytosis, and bacterial killing of group B streptococci and protect animals against lethal challenge.[238,325] Thus, provision of protective levels of type-specific immunity to the infant could be achieved through active immunization of the mother. Baker and associates[36] immunized women at a mean gestation of 31 weeks with purified type III polysaccharide vaccine. Although the immune response was not optimal (63%), placental transport of maternal antibodies was 90 percent in neonates born to women who did respond to vaccination, and most of these infants had protective levels of antibodies in their sera at 3 months of age. A more recent study immunizing women with a type III polysaccharide-tetanus toxoid conjugate reported a 95 percent immune response, with persistence of opsonophagocytic antibodies at 2 months of age in 100 percent of infants born to maternal responders.[38] Other studies immunizing nonpregnant adults with purified capsular polysaccharide-tetanus toxoid conjugate vaccines showed the safety and immunogenicity of these vaccines.[34,35,37]

Availability of the complete genome sequences for group B *Streptococcus* has led to the discovery of many potential surface proteins and secreted proteins that can be expressed in recombinant form and used for production of antibodies.[200,306] A set of proteins shared by the disease-causing serotypes theoretically can be used in combination to create a vaccine capable of providing protection against multiple serotypes. Group B streptococcal pili with at least one of the pilus islands present in all sequenced group B streptococcal genomes may be included in a future vaccine.[66]

Because most pregnant women (estimated at 85-90%) have nonprotective levels of these antibodies in their sera at delivery, active immunization of childbearing-age women before or during pregnancy would optimize strategy to induce high maternal antibody levels. Human studies have demonstrated efficient antibody transfer to the neonate.[36,38] Transfer of high levels of maternal antibody would provide protection of the neonates from early- and late-onset group B streptococcal disease. In addition, immunization also would offer protection for the mother against preterm deliveries and fetal loss caused by group B streptococcal infection. Finally, vaccination of elderly or nonpregnant adults with defined medical conditions could reduce the disease burden significantly. Because immunoprophylaxis should be the most cost-effective and beneficial prevention strategy for group B streptococcal disease,[224,291] it should be promoted by physicians, public health officials, parents, pharmaceutical manufacturers, and legislators.

CHAPTER 95

Enterococcal and Viridans Streptococcal Infections

B. Keith English ✪ Jerry L. Shenep

ENTEROCOCCAL INFECTIONS

The enterococci are gram-positive ovoid bacteria that are related closely to the streptococci but now are known to be phylogenetically distinct and make up the genus *Enterococcus*. These organisms are found in the normal bowel flora of humans and many animals and commonly are isolated from environmental sources. Enterococci generally are considered to be of low virulence but have been known to cause human infection for more than 100 years (reviewed by Murray[164]). These ubiquitous bacteria have become recognized increasingly as important causes of both nosocomial and community-acquired infection in adults[62,152,153,164,166,168,180,185] and children,* yet the role of *Enterococcus* spp. as a pathogen (or co-pathogen) in certain clinical settings, particularly intra-abdominal and pelvic infections, often remains uncertain.

Enterococci are intrinsically resistant to many antimicrobial agents (including the cephalosporins, oxacillin, clindamycin, and the aminoglycosides). Since the emergence of high-level aminoglycoside resistance in *Enterococcus* spp. more than 35 years ago,[157] increasing percentages of these organisms have acquired clinically significant resistance to β-lactam antibiotics and to vancomycin and other glycopeptides, as well as to aminoglycosides. Vancomycin-resistant enterococcal (VRE) infections, especially those caused by vancomycin-resistant *Enterococcus faecium* (VREF), are of particular concern because VREF isolates frequently are resistant to other bactericidal antimicrobial agents.[166,168] The dramatic increase in nosocomial VRE infections[62,166,180] has resulted in failure of antimicrobial therapy[125] and has inspired comparisons with the pre-antibiotic period[5] and even speculation about a "post-antimicrobial era."[44] Fortunately, new classes of antimicrobials active against most VRE isolates have become available recently, but pediatric experience with these agents is limited, and enterococci resistant to these agents already have been detected (see later). Concern about the continued nosocomial spread of VRE isolates and the documented transfer of vancomycin resistance determinants to *Staphylococcus aureus*[27,28,242,252] has led to the development of stringent hospital infection control guidelines designed to interrupt the spread of vancomycin-resistant organisms.[193] Although the impact of VRE infections in children has been less dramatic, increasing numbers of pediatric centers are reporting infections caused by these organisms.*

MICROBIOLOGY

The genus *Enterococcus* consists of gram-positive cocci that are catalase-negative and occur singly, in pairs, and in short chains. Morphologically, enterococci are indistinguishable from streptococci and traditionally were classified as members of the genus *Streptococcus*. Sherman's early classification scheme[222] divided the streptococci into four groups: pyogenic, viridans, lactic, and enterococcal. By the Lancefield criteria, enterococci were classified as group D streptococci, along with the "nonenterococcal" *Streptococcus bovis* group. However, recent genetic evidence has indicated that the enterococci are sufficiently different from the streptococci to merit establishment of a separate genus.[68]

Figure 95–1 is a scheme for the differentiation of enterococci from other gram-positive cocci. Catalase-negative gram-positive cocci that have been isolated from human sources include the streptococci, the enterococci, *Lactococcus* spp., *Leuconostoc* spp., *Pediococcus* spp., and *Gemella* spp. Most enterococci produce no (gamma) or partial (alpha) hemolysis on blood agar; differentiation between enterococci and certain alpha-hemolytic or nonhemolytic streptococci and other nonstreptococcal gram-positive cocci may require a series of biochemical tests.[67,68] Clinical laboratories may identify an organism presumptively on a primary isolation plate as an enterococcus based on colony morphology, Gram stain, and the pyrrolidonyl arylamidase (PYR) test. Most enterococci produce PYR, as do *Streptococcus pyogenes* and nutritionally variant streptococci (*Abiotrophia*), but not other streptococci. The PYR test is particularly useful for differentiating enterococci from group D streptococci and *Leuconostoc* spp. (see Fig. 95–1). *S. pyogenes* and *Abiotrophia* spp. are distinguished easily from enterococci by colony morphology, hemolysis, and special growth requirements.

Enterococci are able to hydrolyze esculin in the presence of 40 percent bile salts; of the true streptococci, only group D streptococci (*S. bovis* group) and approximately 5 to 10 percent of viridans streptococci share this characteristic.[68] Enterococci are facultatively anaerobic and grow under harsh conditions that inhibit the growth of streptococci; growth in 6.5 percent sodium chloride at 45° C is a useful confirmatory test. Enterococci produce leucine aminopeptidase, as do streptococci, lactococci, pediococci, and some *Gemella* strains. The presence of group D streptococcal antigen is of limited value because the *S. bovis* group, most pediococci, and half of the clinical *Leuconostoc* spp. isolates share this antigen.[68]

Occasional clinical isolates of *Leuconostoc* spp., *Pediococcus* spp., and *Lactococcus* spp. may be difficult to distinguish from the enterococci. Some strains of *Leuconostoc* spp. and *Pediococcus* spp. may grow in 6.5 percent NaCl at 45° C, but they are PYR-negative. Lactococci are PYR-positive, and some isolates will grow in 6.5 percent NaCl; however, most lactococci fail to grow (or grow very slowly) at 45° C. Consequently, definitive confirmation of an organism as an enterococcus may require complete identification to the species level. Molecular techniques allow rapid, reliable identification and speciation of enterococci,[50,57,60] but currently they are available only in the research setting.

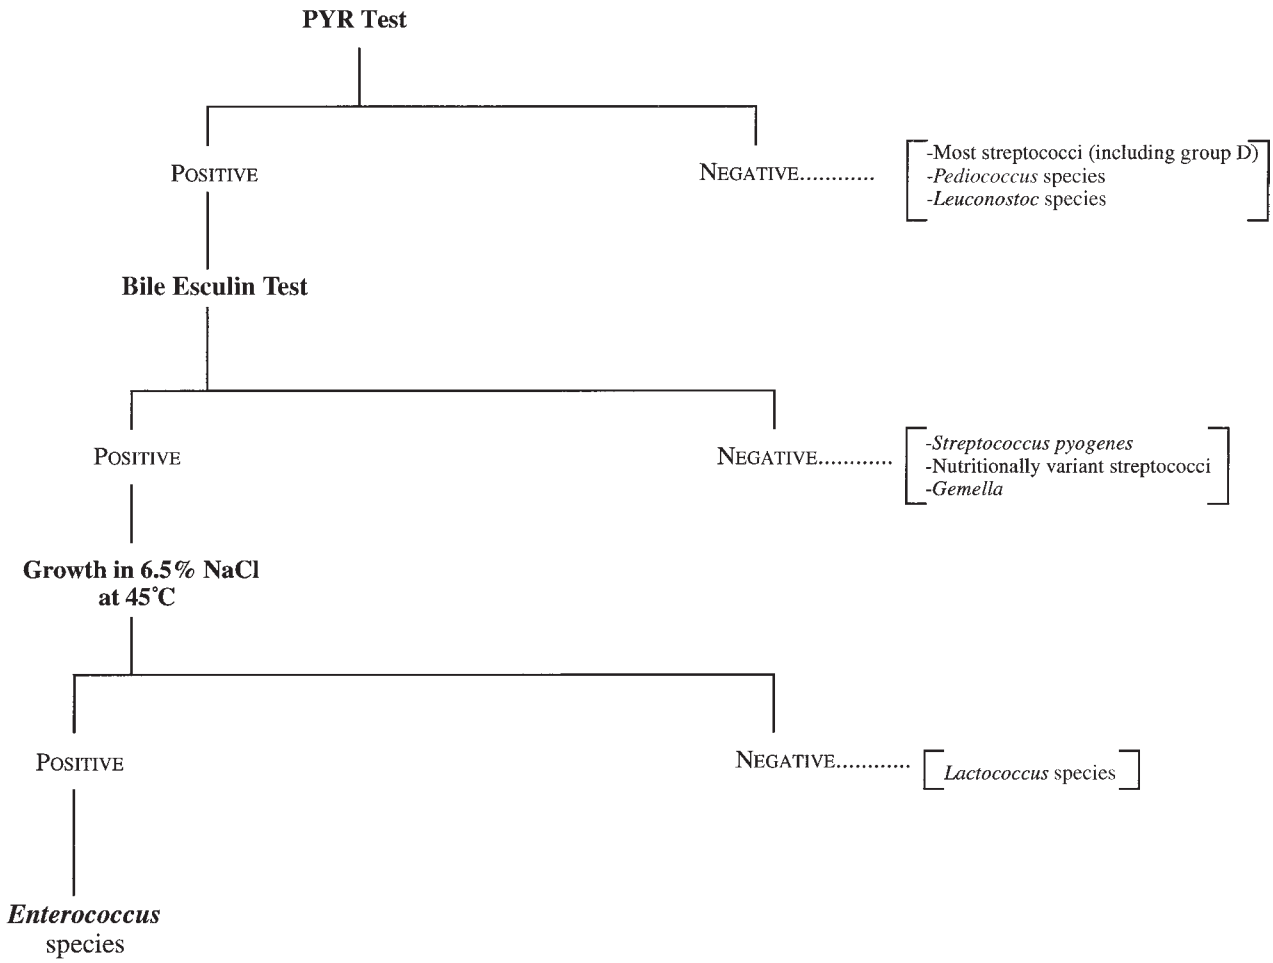

Figure 95–1 Differentiation of enterococci from other catalase-negative, gram-positive cocci. PYR, pyrrolidonyl arylamidase.

TABLE 95–1 *Enterococcus* Species

Typical Enterococci (PYR$^+$)
E. faecalis
E. faecium
E. avium
E. casseliflavus
E. durans
E. raffinosus
E. gallinarum
E. malodoratus
E. hirae
E. mundtii
E. pseudoavium
E. dispar
E. flavescens
E. sulfureus
Atypical Enterococci (PYR$^-$)
E. cecorum
E. columbae
E. saccharolyticus

PYR, pyrrolidonyl arylamidase.

The genus *Enterococcus* now includes at least 14 "typical" species and 3 additional "atypical" species (the latter are PYR-negative and grow very slowly in the presence of 6.5% NaCl) (Table 95–1). However, most human clinical isolates are either *Enterococcus faecalis* (50-90%) or *E. faecium* (5-37%), although clusters of human infection caused by *Enterococcus raffinosus*,[33] *Enterococcus casseliflavus*,[172] *Enterococcus avium*,[184] and *Enterococcus durans*[216] and occasional human infections attributable to *Enterococcus gallinarum*, *Enterococcus mundtii*, and *Enterococcus flavescens* have been reported.[66] Even though *E. faecalis* and *E. faecium* continue to account for most clinical isolates, the percentage of *E. faecium* isolates has been increasing, and relatively more "other" (non-*faecalis*, non-*faecium*) enterococci are being identified by clinical laboratories.[110,112,138]

Speciation of enterococci has been useful primarily for epidemiologic purposes, but distinction between the more antibiotic-susceptible *E. faecalis* and the more antibiotic-resistant (see later) *E. faecium* may be helpful in selecting optimal therapy for endocarditis and other serious enterococcal infections. A panel of biologic tests can differentiate these two common enterococcal species readily.[68,118,164] Most *E. faecalis* isolates (unlike those of *E. faecium*) grow in the presence of 0.04 percent tellurite, reduce tetrazolium to formazan, and produce acid from sorbitol and glycerol.

A variety of molecular techniques, including a modification of pulsed-field gel electrophoresis known as the CHEF (contour-clamped homogeneous electric field electrophoresis) technique[39,40,56,160,255] and polymerase chain reaction (PCR), are available to assist in the identification of enterococci and determination of the relatedness of enterococcal isolates.[60] These molecular techniques have been particularly valuable in investigations of possible nosocomial transmission of multiresistant enterococci.[39,40,57,60,68,160,182,205,255]

EPIDEMIOLOGY

Enterococci are normal flora of the gastrointestinal tract of most humans and have been found in as many as 97 percent of fecal samples from adults in Europe, Asia, and North America (reviewed by Murray[164]). Approximately half of newborn infants have become colonized with enterococci by the time they are 1 week of age.[175] Enterococci are isolated less commonly (<20% of specimens) from other sites, including the vagina, oral cavity, and skin. These organisms also are common inhabitants of the bowel flora of many animals and frequently are present in soil, water, and food. Enterococci are hardy organisms and may persist for long periods on environmental surfaces, thereby contributing to potential nosocomial spread of these bacteria.

Human infection caused by enterococci was reported before the beginning of the 20th century, but the initial reports included patients with infections that seldom are associated with enterococci today: enteritis, meningitis, and appendicitis (reviewed by Murray[164]). The ubiquitous presence of enterococci in fecal samples led to the mistaken impression that these organisms cause enteritis and food poisoning. Enterococci are isolated commonly as part of mixed flora in intra-abdominal and pelvic infections, but the contribution of these organisms to the pathogenesis of such infections remains uncertain.[81,173] However, enterococci were identified as pathogens causing urinary tract infection and endocarditis as early as 1906,[4] with later confirmation by many studies. Subsequently, enterococci have been documented to cause invasive infection in neonates,[56,77,121] patients with malignancies,[85,86,159,221] recipients of bone marrow and solid organ transplants,[9,116,119,183,210] burn victims,[127] patients with indwelling catheters,[9,51,153,164,185,199] and other immunosuppressed or debilitated patients.[30,153,164,185,199]

In general, enterococcal infections occur less frequently in children (outside the neonatal period) than in adults, and enterococci are less common causes of pediatric (versus adult) urinary tract infection[259] and endocarditis.[231] Much of the published experience with enterococcal infection in children focuses on the neonatal period,[47,56,140,194] and some evidence suggests that late-onset (but not early-onset) neonatal enterococcal infection may be increasing in frequency.[39,56] Relatively few series of pediatric enterococcal infection have been published.[14,17,22,39,51,85,202]

Enterococci recently have emerged as important nosocomial agents, and they rank as either the second or third most common hospital-acquired pathogens in this country.[62,103,152,180,200,211,261,262] Evidence of nosocomial spread of enterococci is relatively recent. Initially, all enterococci isolated from hospitalized patients were thought to have originated from the patient's endogenous bowel flora. However, the emergence of multiantibiotic-resistant enterococci prompted the performance of careful epidemiologic studies that documented the nosocomial spread of these organisms.* Many groups have reported that VRE and other enterococcal isolates may persist for long periods of time in the environment and may be spread either by direct patient-to-patient contact via the hands of colonized health care personnel[194] or from contaminated beds or other hospital material or contaminated patient equipment, including thermometers.[18,117,132,153]

The growing problem of nosocomial infection by VRE organisms is multifactorial; the diversity of isolates found in many hospitals indicates that resistant organisms may be introduced via multiple sources.[39,61,78,161,167,199,221] Consequently, outbreaks of VRE infection in institutions may be caused by single or multiple clones, although the first recognized outbreak of VRE infection or colonization in a hospital usually is associated with a single clone.[30,78]

In many reports, distinguishing risk factors for VRE colonization from those for invasive disease caused by these organisms has not been possible, and certain factors probably increase the risk for both colonization and development of infection caused by VRE organisms. Major risk factors for VRE colonization or the development of infection, or for both, appear to be the severity of the underlying illness or immunosuppression; the proximity to patients colonized with VRE organisms (e.g., admission to an intensive care unit [ICU] or a transplant unit); receipt of a bone marrow or solid organ (especially liver) transplant; increasing length of hospital stay; recent cardiothoracic or abdominal

*See references 10, 11, 40, 87, 93, 194, 199, 200, 202, 229, 251, 262.

surgery; the presence of indwelling central venous or urinary catheters; and previous treatment with vancomycin, broad-spectrum antibiotics (particularly those lacking appreciable anti-enterococcal activity, such as the third-generation cephalosporins), or agents with broad anti-anaerobic activity.* Patients infected with human immunodeficiency virus (HIV) also appear to be at higher risk for the development of VRE bacteremia.[9] Factors contributing to nosocomial spread of these organisms probably differ from those responsible for the gradual overall increase in resistant strains.[199]

Since the first report of a vancomycin-resistant isolate in 1988,[128] infection and colonization with VRE bacteria in the United States have been observed primarily in the ICUs of large teaching hospitals.[166,168,180] For example, data reported to the National Nosocomial Infection Surveillance (NNIS) system of the Centers for Disease Control and Prevention (CDC) from January 1989 through March 1993 revealed no vancomycin resistance in hospitals with fewer than 200 beds, a resistance rate of 1.8 percent in hospitals with 200 to 500 beds, and a rate of 3.6 percent in hospitals with more than 500 beds.[180] A 1995 report from the multicenter *Enterococcus* Study Group analyzed 1936 isolates collected from 97 laboratories in 47 states during the last quarter of 1992 and generally confirmed the findings of the NNIS survey.[110] However, VRE infections are not limited to ICUs. A 1999 report from the Surveillance and Control of Pathogens of Epidemiologic Importance (SCOPE) group's ongoing surveillance of nosocomial bloodstream infections in 49 U.S. hospitals revealed no overall differences in rates of vancomycin resistance in enterococci isolated from patients located in critical care versus hospital ward settings.[62] Fortunately, VRE infections have occurred much less frequently in children than in adults, and overall rates of vancomycin resistance in enterococci isolated from children's hospitals remain very low. However, increasing numbers of pediatric centers have reported VRE infections.*

In the United States, VRE isolates generally have not been detected in environmental sources or in patients who have not had exposure to hospitals,[166] with rare exceptions.[30] However, the ecology of VRE organisms in Europe differs: they have been detected in the feces of nonhospitalized patients and healthy volunteers in several European studies, with rates of VRE colonization as high as 28 percent in adults living in some parts of Belgium (reviewed by Murray[166,168]). The more widespread occurrence of VRE strains in Europe probably was related to the use of oral glycopeptides such as avoparcin in animal feed and the oral administration of bacterial preparations (possibly contaminated with resistant enterococci) to humans and animals for therapeutic purposes.[166-168]

Initial reports of VRE organisms in the United States were clustered in the northeast region, particularly New York, Maryland, and Pennsylvania,[180] and geographic differences in rates of VRE colonization and infection persist. However, subsequent reports indicate that VRE strains are found in most parts of the United States[109,138] and that rates of vancomycin resistance among enterococci isolated from patients in this country generally are higher than those found in isolates from Canada, western Europe, or Latin America.[108,111,138] The reasons for these geographic differences remain uncertain, but the high rates of resistance in the United States may be related to the marked increase in the use of vancomycin in this country during the past 3 decades.[120]

PATHOGENESIS AND VIRULENCE

Enterococci are organisms of low virulence, and their ubiquitous presence in the human gastrointestinal tract probably has contributed to both the spurious association of these organisms with some illnesses (e.g., enteritis) and the failure to recognize other situations in which enterococci are true pathogens (e.g., immunosuppressed and debilitated patients, neonates). When compared with organisms such as *S. pyogenes* and *S. aureus*, enterococci are much less virulent in animal models of infection,[104,152] but they are capable of causing disease at a higher inoculum.

Enterococci rarely cause primary cellulitis or abscesses, although these organisms are isolated frequently as components of polymicrobial wound infections and intra-abdominal and pelvic infections. The contribution of enterococci to the pathogenesis of these polymicrobial infections remains uncertain.[81,173] In animal models, synergy between enterococci and a variety of other organisms (particularly anaerobes) can be demonstrated, but enterococci injected alone have little propensity to cause either peritonitis or subcutaneous infection.[104,105,164,181] Many clinical trials have concluded that provision of anti-enterococcal therapy generally is not necessary to effect a cure of human intra-abdominal and pelvic infections, even though *Enterococcus* frequently (14-33% of cases) is isolated from primary peritoneal cultures.[81]

Enterococci are an important cause of urinary tract infections in adults (particularly in elderly men, patients with structural abnormalities of the urinary tract, and those with indwelling urinary catheters), but they are associated less frequently with urinary tract infections in children.[7,259] Enterococci also are important but less frequent (than in adults) causes of bacterial endocarditis in children.[151,231]

Adherence of bacteria to tissue is a necessary first step in the pathogenesis of both urinary tract infection and endocarditis, and evidence suggests that pathogenic enterococci produce factors that mediate adherence to urinary epithelial cells and endocardial tissue (reviewed by Jett and colleagues[104] and Johnson[105]). Enterococcal adhesins include an enterococcal surface protein known as aggregation substance[36,123] and surface carbohydrates. Lipoteichoic acid, an important adhesin for *S. pyogenes*, does not appear to mediate adherence of enterococci,[228] but it may trigger the host inflammatory response to these organisms.[238] Recent studies have implicated an enterococcal surface protein, Esp, in biofilm formation by *E. faecalis*.[24,240] In addition, many virulent *E. faecalis* isolates express a cytolysin in the presence of target cells.[43,48]

Nosocomial enterococcal bacteremia in adults frequently is associated with urinary tract and wound infections, but catheter-related bacteremia is of increasing importance. Enterococcal bacteremia without a source occurs relatively more commonly in children,[17,199] although Bonadio[14] reported that many children with enterococcal bacteremia had an identifiable focus of infection. Enterococcal bacteremia occurs more frequently in patients with severe underlying disease and may be life-threatening. However, the precise contribution of enterococcal bacteremia to morbidity and mortality in severely ill patients remains controversial. Adult ICU patients with enterococcal bacteremia have a very high mortality rate,[83] and some early studies suggested that isolation of *Enterococcus* from blood merely serves to identify a very high-risk group of patients.[164] In several studies, clearance of VRE organisms from blood was not associated with a reduced mortality rate in this high-risk population. In other studies, spontaneous resolution of VRE bacteremia has been reported, thus suggesting that transient VRE bacteremia or pseudobacteremia (or both) may occur.[246] However, a series of recent studies has clearly associated vancomycin resistance with an increased risk for mortality in certain patients and has demonstrated that effective anti-enterococcal therapy reduces the mortality rate in patients with VRE bacteremia.[53,54,61,97,168,185] Taken together, these findings indicate that at least a subset of high-risk patients with VRE bacteremia are at risk for the development of significant morbidity and mortality directly related to the infection.

CLINICAL MANIFESTATIONS

Enterococcal infections generally occur less frequently in children than in adults, but *Enterococcus* is a relatively frequent cause of neonatal infections.[56] The types of infections caused by enterococci in children are similar to those in adults,[14,17,51,199] although enterococcal bacteremia may be associated with fewer sequelae in children.[51] In children, as well as in adults, enterococci have become increasingly important nosocomial pathogens.[17,39,147,152,180,200,262] They are important causes of endocarditis, urinary tract infection, and bacteremia (particularly catheter-related bacteremia) in pediatric patients, and these organisms commonly are isolated as components of polymicrobial wound, intra-abdominal, and pelvic infections in children.[14,17,153,164] Meningitis[234] and septic arthritis[192] are rare manifestations of enterococcal infection. Respiratory infections caused by enterococci are extremely uncommon occurrences, although many neonates with enterococcal infection have pulmonary symptoms.[55]

URINARY TRACT INFECTION

Urinary tract infections are the most common enterococcal infections in adults,[153] and enterococci are important urinary pathogens in children.[52] Most enterococcal urinary tract infections occur in elderly men after they have undergone urinary catheterization, instrumentation, or both.[70,162] Enterococci are infrequent (<5% of isolates) causes of cystitis and pyelonephritis in otherwise healthy children, infants, and neonates[7,259] and are infrequent causes of urinary tract infection in young women.[164] However, some centers are reporting an increasing incidence of both community-acquired and nosocomial urinary tract infection caused by enterococci.[70]

Most enterococcal urinary tract infections in children[7,52,134] and adults[70,152] are nosocomial. Risk factors for the development of urinary tract infection by *Enterococcus* include indwelling urinary catheters, instrumentation of the urinary tract, structural abnormalities of the urinary tract, and previous broad-spectrum antimicrobial therapy.[162,164] The increasing problem of nosocomial enterococcal urinary tract infection[70] is compounded by the growing problem of multiantibiotic-resistant enterococci.[180]

The genitourinary tract reportedly is the most common entry site leading to enterococcal bacteremia in adults,[83,124] but it is implicated much less frequently in the cause of enterococcal bacteremia in children.[14,17,51] Christie and colleagues reported that urosepsis was the cause of 12 percent of episodes of nosocomial enterococcal bacteremia in one children's hospital,[39] but Das and Gray[51] failed to detect any cases of urosepsis in 75 consecutive cases of enterococcal bacteremia in another pediatric hospital during a 3-year period. Other complications of enterococcal urinary tract infection in adults include prostatitis and perinephric abscess.[153]

ENDOCARDITIS

Enterococcal endocarditis was reported first in 1906,[4] and these organisms are important causes of native- and prosthetic-valve endocarditis in children and adults.[2,150,197] Either normal or previously damaged valves may be involved. Enterococci cause approximately 5 to 20 percent of cases of native-valve endocarditis in adults (excluding cases in intravenous drug users),[150] approximately 6 to 7 percent of prosthetic-valve endocarditis,[150,243] and approximately 5 to 10 percent of endocarditis in intravenous drug users.[164] Enterococcal endocarditis in intravenous drug users generally involves the aortic or mitral valves, unlike staphylococcal endocarditis in this setting, which usually involves the tricuspid valve.[164] As with other enterococcal infections, *E. faecalis* causes most cases of endocarditis.

Enterococcal endocarditis primarily is a disease of older men, and the genitourinary tract is the most commonly identified source of the initial bacteremia. Enterococci are relatively less frequent causes of endocarditis in children—less than 5 percent of cases in most series.[106,107,230,231,239,263] Typically, enterococcal endocarditis occurs after a subacute course that is clinically indistinguishable from that caused by streptococci.[150] Although the enterococcus is a common neonatal pathogen,[56] reports of neonatal enterococcal endocarditis are extremely rare.[239] The prognosis of enterococcal prosthetic-valve endocarditis is somewhat better than that of native-valve endocarditis caused by these organisms.[2,197] Aortic-valve involvement is associated with increased rates of morbidity and mortality.[150] Endocarditis rarely complicates nosocomial enterococcal bacteremia.[142,164,185] Consequently, VRE-associated endocarditis is a rare development, although a number of cases have been reported recently.[233]

BACTEREMIA

Enterococcal bacteremia often represents a conundrum. Bacteremia in severely ill hospitalized patients, particularly that caused by VRE organisms, is associated with considerable morbidity and mortality. However, only a portion of that morbidity and mortality can be attributed directly to enterococcal bacteremia *per se*. Nosocomial enterococcal bacteremia frequently occurs as a component of polymicrobial bacteremia, with 21 to 45 percent of bloodstream isolates of *Enterococcus* being accompanied by one or more other pathogens.[51,142,185,224] As many as half of cases of catheter-related enterococcal bacteremia are polymicrobial.[147,185] Many,[90,142] but not all,[96,147] series of patients with enterococcal bacteremia have reported increased mortality rates in patients with polymicrobial bacteremia (including *Enterococcus*) versus isolated enterococcal bacteremia. Mortality in adults with nosocomial enterococcal bacteremia has ranged from 23 to 46 percent,[142,143,185] but patients at risk for the acquisition of nosocomial enterococcal bacteremia are severely ill and have a poor prognosis independent of the bacteremic event. However, hospital-acquired enterococcal infections can be life-threatening,[61,164,185,189] and specific therapy does appear to reduce the overall mortality rate.[61,97,185] Furthermore, a recent meta-analysis concluded that vancomycin resistance is independently correlated with increased mortality in patients with enterococcal bloodstream infections.[53,54] Nonetheless, many episodes of enterococcal bacteremia in high-risk patients apparently resolve in the absence of specific therapy.[97,246] The mortality rate associated with enterococcal bacteremia in children has been lower than that reported in adults in most studies but has ranged from 7.5 percent[51] to 12 percent[17] to 20 percent[14] to 26 percent,[39] depending on the population studied.

In adults, many cases of enterococcal bacteremia are associated with a primary focus, most commonly a urinary tract infection.[55,85] In contrast, few children with enterococcal bacteremia have urosepsis, and most episodes of enterococcal bacteremia in children have not been associated with any identifiable focus.[17,199] However, Christie and coworkers identified a primary focus in 21 of 57 children (37%) with nosocomial enterococcal bacteremia, including 7 patients with urosepsis and 6 with peritonitis.[39] Many children with enterococcal bacteremia do have underlying disease involving the gastrointestinal or respiratory tract.[14,17] Central venous catheter–related enterococcal bacteremia is a growing problem in both children[14,17,39,51,56,185] and adults.[82,185] In earlier series, infections of vascular catheters were reported to account for only 2 to 14 percent of cases of enterococcal bacteremia (reviewed by Graninger and Ragette[83]), but more recent

reports have implicated intravascular devices in as many as 22 to 28 percent of these episodes in adults and children.[51,185]

Most episodes of enterococcal bacteremia do not lead to endocarditis,[142,164,185] and endocarditis is particularly uncommon in the setting of nosocomial enterococcal bacteremia. Maki and Agger[142] identified only one case of endocarditis in 118 episodes of hospital-acquired enterococcal bacteremia, whereas endocarditis was diagnosed in 12 of 35 patients with community-acquired enterococcal bacteremia.

INTRA-ABDOMINAL INFECTIONS

Most of the published information about the role of *Enterococcus* in intra-abdominal and pelvic infections comes from series of adult patients. Enterococci commonly are isolated as components of polymicrobial infections involving the abdomen or pelvis,[81] and animal models suggest that these organisms can play a synergistic role in the pathogenesis of such infections.[104] However, evidence that the addition of specific anti-enterococcal therapy improves the outcome of human intra-abdominal and pelvic infections, even when enterococci are isolated from peritoneal cultures, is not compelling.[81]

Children with enterococcal bacteremia frequently have underlying conditions related to the gastrointestinal tract.[14,17,39] Bonadio reported five cases of enterococcal bacteremia in previously healthy infants with gastroenteritis, six cases associated with bowel obstruction, and one case associated with acute appendicitis without perforation.[14] Boulanger and coworkers[17] identified underlying conditions affecting the gastrointestinal system in 8 of 32 pediatric patients, but they were unable to specifically implicate any of these conditions as the source of the bacteremia. Das and Gray detected underlying chronic gastrointestinal pathology (short-gut syndrome, congenital anomalies of the gastrointestinal tract, ulcerative colitis, chronic liver disease) in fully a third (25 of 75) of pediatric patients with enterococcal bacteremia.[51]

MENINGITIS

Enterococci are rare causes of bacterial meningitis in adults and children. Stevenson and colleagues[234] found only four cases of enterococcal meningitis among 493 episodes (0.8%) of bacterial meningitis in adults, and they identified an additional 90 cases in a literature search of the interval from 1966 to 1992. These authors reviewed 16 published cases of enterococcal meningitis in children: 11 of these 16 pediatric cases were complications of central nervous system (CNS) trauma or surgery, but 4 children (3 of the 4 were neonates) had primary meningitis.[234] Enterococci are uncommon but well-recognized causes of infection involving cerebrospinal fluid (CSF) shunts and related devices.[122,170,214] Meningitis rarely complicates nosocomial bacteremia in adults,[142,185] but it has been reported more frequently in children (particularly neonates) with bacteremia. For example, meningitis developed in 7 percent (4 of 57) of episodes of nosocomial enterococcal bacteremia in children in Cincinnati[39] and in 15 percent (4 of 26) of premature neonates with late-onset enterococcal sepsis in Houston.[56]

Stevenson and associates found that most adults with enterococcal meningitis were immunocompromised (most were receiving steroids) or had a history of CNS trauma or surgery (or both).[234] Enterococcal meningitis has been reported in an adult patient with HIV infection who had completed a course of steroids for presumed *Pneumocystis* pneumonia.[187] Although many children with enterococcal meningitis do have a history of CNS trauma or surgery or are premature infants, most do not have other identifiable predisposing conditions or a history of immunosuppressive therapy.

As with the majority of enterococcal infections, most isolates from CSF are *E. faecalis*, but meningitis and ventriculoperitoneal shunt infections caused by *E. faecium* also have been reported in children.[170,171]

NEONATAL INFECTIONS

Enterococci are important neonatal pathogens,* and the published experience with neonatal enterococcal infections constitutes much of the pediatric experience with these organisms. Although several large series of neonatal sepsis included few cases of enterococcal infection (reviewed by Klein and Marcy[121]), many centers have reported that *Enterococcus* is a relatively frequent cause of neonatal bacteremia. Siegel and McCracken[226] found that enterococci were second only to group B streptococci as causes of neonatal sepsis at Parkland Hospital in Dallas from 1974 to 1977, with an incidence rate of approximately 1.0 case per 1000 live births. Gladstone and colleagues[77] reported that *Enterococcus* caused 18 of 270 (6.7%) episodes of neonatal sepsis at Yale–New Haven Hospital during the period 1979 to 1988, which ranked fourth in incidence behind group B streptococci (64 cases, 23.7%), *Escherichia coli* (46 cases, 17.0%), and coagulase-negative staphylococci (36 cases, 13.3%). During the 1990s, reports from Houston,[57] Cincinnati,[39] and New York City[147] documented sharp increases in the rate of late-onset neonatal infection with enterococci in both hospitalized high-risk premature neonates and infants[57,147] and otherwise healthy term newborns with "community-acquired" infection.[57]

Enterococci cause both early-onset (<7 days of age) and late-onset (>7 days of age) neonatal sepsis. Early-onset disease is indistinguishable from that caused by other neonatal pathogens, but it tends to be less severe.[56] Rates of early-onset disease have remained relatively stable; however, several centers are reporting increasing rates of late-onset infection. Dobson and Baker identified 56 neonates with enterococcal sepsis during a 10-year period at Jefferson Davis Hospital in Houston; 18 of 56 (32%) had early-onset sepsis, 26 of 56 (46%) had late-onset sepsis, and 12 of 56 (21%) had sepsis associated with necrotizing enterocolitis (2 early onset, 10 late onset).[56] In this study 25 of the 26 (96%) infants with late-onset enterococcal sepsis were premature infants. Christie and colleagues[39] identified 83 cases of enterococcal bacteremia between 1986 and 1992 at Children's Hospital of Cincinnati; 58 of the 83 episodes occurred in neonates. Most cases (57 of 83, 68.7%) were nosocomial, but many (26 of 83, 31.3%) were community acquired. Young infants (<3 months of age) accounted for almost all (24 of 26, 92.3%) of the community-acquired episodes and for many (34 of 57, 59.6%) of the nosocomial infections. Bonadio[14] and Boulanger and colleagues[17] also have reported community-acquired enterococcal bacteremia in young infants.

McNeeley and associates[147] identified 138 episodes of enterococcal bacteremia in a New York City neonatal ICU during a 20-year period and reviewed 100 of the episodes in detail. These authors noted a sharp increase in the rate of enterococcal bacteremia during the second decade (1984 to 1994) of this study and found that most cases occurred in older infants; during this decade, the mean age at onset was 44.7 days (versus 16.1 days during the first decade of the study), and 65 percent (51 of 78) of the episodes occurred after the infants reached 30 days of age. Most of the infections occurred in neonates with indwelling central venous catheters (77%), and more than half of the patients had evidence of gastrointestinal disease (necrotizing enterocolitis in 33% and abdominal distention in an additional 21%). The

*See references 5, 29, 30, 32, 47, 61, 69, 78, 89, 91, 117, 129, 139, 153, 161, 164, 166, 168, 174, 196, 199, 202.

overall mortality rate in this study was 28 percent, although many of the deaths were not attributed to the enterococcal infection. Most (64%) of the episodes of enterococcal bacteremia in this series were polymicrobial.[147]

Nosocomial outbreaks of enterococcal infection, including VRE infection, have been reported in several neonatal units in the United States.[39,47,140,194] Indwelling central venous catheters, necrotizing enterocolitis, and intra-abdominal surgery are important predisposing factors for the development of nosocomial enterococcal bacteremia in neonates, whereas the genitourinary tract is implicated much less frequently as a source.[39,147]

Enterococcal bacteremia in neonates and young infants has been associated with diarrhea[14,56] and with respiratory disease,[14,56] although a causative role for *Enterococcus* in the pathogenesis of gastroenteritis or pneumonia remains undefined. Enterococci rarely cause urinary tract infections in neonates,[14,39,56,147] but nosocomial and community-acquired cases have been reported. Enterococci have been noted to cause a variety of other neonatal infections, including focal skin and soft tissue infections such as scalp abscess,[56] brain abscess,[201] omphalitis,[56] and conjunctivitis.[250]

Most enterococcal infections in neonates are caused by *E. faecalis*, but outbreaks of infection with *E. faecium* have been reported.[47] In the series from Cincinnati reported by Christie and associates and consisting largely of neonates, 82 percent of enterococcal isolates were *E. faecalis* and 14 percent were *E. faecium*.[39] McNeeley and colleagues reported the isolation of *E. faecalis* from 94 of 100 patients and *E. faecium* from 15 of 100 patients in their series (both organisms were isolated from 9 of the patients).[147] Six of the *E. faecium* isolates were resistant to vancomycin, and all six patients with VRE bacteremia died, although only one death appeared to be related directly to the VRE infection.

SEPTIC ARTHRITIS

Enterococci rarely have been reported to cause septic arthritis, but they can infect native or prosthetic joints. Raymond and colleagues[192] reported a case of enterococcal septic arthritis involving a prosthetic hip and reviewed an additional 18 cases from the literature. Eleven of these 19 episodes involved prosthetic joints (2 hips, 9 knees), and 8 involved native joints; only 1 of the 8 individuals with native-joint arthritis had an underlying abnormality of the joint. In 7 of the 19 episodes, enterococcus was isolated from synovial fluid along with a second organism (3 with coagulase-negative staphylococci, 1 with group B streptococci, 1 with *Pseudomonas*, 1 with *Streptococcus*, and 1 with *Kingella kingae*). Only one pediatric case was identified: a 21-month-old girl with septic arthritis of the wrist whose joint aspirate grew *Enterococcus* spp. and *K. kingae*.[225]

DIAGNOSIS

Enterococcal infections usually are diagnosed by isolation of *Enterococcus* from a culture of blood or another normally sterile site. As discussed earlier, enterococci are ubiquitous inhabitants of the human gastrointestinal tract, and isolation of these organisms from stool or surface cultures is not evidence of invasive infection. Although enterococci are uncommon blood culture contaminants, transient bacteremia or pseudobacteremia (or both) may be caused by these organisms.[97,246]

More problematic is the interpretation of a positive culture for enterococcus as a component of polymicrobial infections, particularly intra-abdominal and pelvic infections. In this setting, the role of the enterococcus in pathogenesis is uncertain, and therapeutic regimens that do not include anti-enterococcal agents usually suffice to effect a clinical cure.[81] However, rare cases of breakthrough enterococcal bacteremia have been reported with these regimens, and one study found a decreased rate of abdominal surgical wound infections when anti-enterococcal coverage was provided in a prophylactic regimen.[253]

ANTIMICROBIAL SUSCEPTIBILITY AND RESISTANCE

The increasing importance of *Enterococcus* as a human pathogen, especially in the nosocomial setting,[62,112,147,152,164,180,200,261,262] is of particular concern because of the concomitant development of antimicrobial resistance by these organisms. Furthermore, antibiotic resistance probably has played a critical role in allowing the organism to persist and eventually cause disease in high-risk patients despite its relatively low virulence.

Some enterococci have acquired high-level resistance to all three classes of antimicrobial agents that have been used to treat life-threatening enterococcal infections—β-lactams, aminoglycosides, and glycopeptides. This acquired resistance has occurred in the context of intrinsic (usually lower-level) resistance of enterococci to many antibiotics, and physicians have been confronted with the possibility that invasive disease caused by these organisms might not respond to any available antibiotics. Some enterococci also have acquired resistance to recently developed agents (e.g., quinupristin-dalfopristin, linezolid, daptomycin) that are active against most antibiotic-resistant gram-positive cocci (see later).

INTRINSIC RESISTANCE

β-Lactam Antibiotics

Relative resistance to β-lactam antibiotics is an intrinsic characteristic of enterococci that occurs even in human populations without previous exposure to antibiotics[154]; such resistance is due to the lower affinity of enterococcal (versus streptococcal) penicillin-binding proteins, especially PBP-5.[153,256] In general, the minimal inhibitory concentration (MIC) of penicillin for most *E. faecalis* isolates (2 to 8 μg/mL) is at least 10 to 100 times higher than that of most streptococci, and *E. faecium* is even more resistant (MIC of 8 to 32 μg/mL or higher).[164] Ampicillin is the most active of the β-lactam antibiotics against enterococci, with average MIC values approximately twofold lower than those for penicillin.[153,164] Nafcillin generally is less active than is penicillin, and methicillin is much less active (MIC > 50 μg/mL for *E. faecalis*), as are carbenicillin and ticarcillin. Importantly, enterococci exposed to β-lactam antibiotics rapidly become tolerant of the killing effects of these agents.[153,164] Along with intrinsic resistance to these agents, tolerance limits the utility of β-lactam monotherapy for the treatment of endocarditis or other severe enterococcal infections.

Imipenem has some activity against *E. faecalis* but is much less active against *E. faecium*.[153,164] None of the cephalosporins currently available has clinically useful activity against the enterococci, and frequent use of broad-spectrum cephalosporins and imipenem has been identified as a risk factor for the acquisition of nosocomial enterococcal infection.

Aminoglycosides

Enterococci are intrinsically resistant to all aminoglycosides because of diminished uptake of these drugs. For most *E. faecalis* isolates, the MIC for gentamicin or tobramycin ranges from 8 to 64 μg/mL, and that for streptomycin ranges from 12 to 250 μg/mL.[149,186,244] Moellering and colleagues first demonstrated that the addition of a cell wall–active antibiotic results in dramatically

increased aminoglycoside uptake by enterococci[156,266] and that combinations of β-lactam and aminoglycoside antibiotics can lead to synergistic killing of these organisms. All *E. faecium* strains exhibit higher MICs (than *E. faecalis* does) to certain aminoglycosides, including tobramycin, netilmicin, kanamycin, and sisomicin, and these aminoglycosides do not exhibit synergy with β-lactam antibiotics against *E. faecium*.[34,164]

Other Antibiotics

Under carefully standardized laboratory conditions, enterococci are inhibited by the combination of trimethoprim and sulfamethoxazole (TMP-SMX). However, *Enterococcus* isolates should be considered resistant to TMP-SMX because these organisms are capable of using exogenous folinic acid to evade the antimicrobial action of TMP-SMX.[265] TMP-SMX fails to eradicate enterococci in animal models of infection,[31,88] and breakthrough enterococcal bacteremia has occurred in patients being treated with TMP-SMX for enterococcal urinary tract infection.[80] Enterococci also are intrinsically resistant to clindamycin, a drug with excellent activity against many other gram-positive cocci. Most enterococci have a clindamycin MIC of 12.5 to 100 μg/mL.[164] As with low-level β-lactam resistance, clindamycin resistance is found in enterococcal isolates from human populations with no previous antibiotic exposure.[154]

ACQUIRED RESISTANCE

Enterococci have acquired resistance to antibiotics by the acquisition of both narrow– and broad–host range plasmids and via the exchange of conjugative transposons (reviewed by Murray[164]). Resistance mediated by broad–host range plasmids is of particular concern because glycopeptide resistance encoded by broad–host range plasmids has been transferred to staphylococci in vitro[176] and in vivo.[27,28,242,252]

High-Level Resistance to Aminoglycosides

Intrinsic resistance of enterococci to aminoglycosides is caused by poor drug uptake by these organisms and can be overcome effectively both in vitro and in vivo by the addition of cell wall–active antibiotics. In contrast, high-level resistance to aminoglycosides is mediated either by the acquisition of plasmids encoding aminoglycoside-modifying enzymes (affecting all aminoglycosides via several different enzymes) or by ribosomal mutations (streptomycin only). High-level aminoglycoside resistance is of great clinical importance because it eliminates synergism between the affected aminoglycoside or aminoglycosides and β-lactam or glycopeptide antibiotics.[34,164,186] All *E. faecium* strains produce a chromosomally encoded aminoglycoside acetyltransferase that eliminates synergistic killing between cell wall–active antibiotics and certain aminoglycosides (including tobramycin, kanamycin, netilmicin, and sisomicin),[34] but it does not result in high-level resistance to these compounds. Consequently, these particular aminoglycosides should not be used to treat infections caused by *E. faecium*.

Enterococci with high-level resistance (MIC usually ≥2000 μg/mL) to streptomycin, kanamycin, and several other aminoglycosides (excluding gentamicin) were identified more than 35 years ago[157] and were widely prevalent in the United States by the mid-1970s.[23] High-level resistance to streptomycin occurs via two mechanisms, ribosomal mutation or enzymatic modification by 6′-adenylyltransferase. Initial reports of high-level resistance to kanamycin were associated with the production of 3′-phosphotransferase.[34,164]

Horodniceanu and colleagues first reported high-level resistance to gentamicin in *E. faecalis* in 1979,[99] and this resistance was shown later to be mediated by a fusion enzyme containing both 6′-acetyltransferase and 2″-phosphotransferase activity. Expression of this fusion enzyme conferred resistance to all clinically useful aminoglycosides except streptomycin.[129,130] Enterococci expressing this fusion protein usually have gentamicin MICs that are 2000 μg/mL or higher. Thus, enterococci expressing this fusion enzyme and the 6′-adenylyltransferase mediating streptomycin resistance (or chromosomally mediated streptomycin resistance) are highly resistant to all available aminoglycosides and generally fail to be killed synergistically by any combination of β-lactam antibiotics and aminoglycosides. Strains of *E. faecalis* resistant to both streptomycin and gentamicin (and thus to all aminoglycosides) were detected first in Houston, Bangkok, and Santiago in 1983.[149,164] Subsequently, strains of *E. faecalis*, *E. faecium*, and other enterococci resistant to gentamicin, streptomycin, or both (or all) aminoglycosides have become increasingly prevalent[82,108,110,111,138,186] (Table 95–2). Although high-level resistance to both streptomycin and gentamicin was described first in *E. faecalis*, it now is at least as common in *E. faecium*.[110]

Enterococci resistant to all aminoglycosides have been isolated at an increasing rate from clinical specimens. Jones and colleagues and the *Enterococcus* Study Group[109] found that fully 20 percent of 1936 enterococcal isolates from late 1992 (from 97 participating laboratories in 47 states) exhibited high-level resistance to both gentamicin and streptomycin. Low and associates and the SENTRY Antimicrobial Resistance Surveillance Program[138] reported similar rates of high-level resistance to both gentamicin and streptomycin from 1997 to 1999 (see Table 95–2). Almost a third (32.8%) of enterococci collected by the SENTRY group from 1997 to 2005 were highly resistant to gentamicin.[111] Many medical centers in the United States now report that most enterococcal isolates exhibit high-level resistance to all aminoglycosides.[168]

Several new aminoglycoside-resistant genes were identified in enterococci during the late 1990s (reviewed by Chow[34]). Some enterococci produce three or more enzymes. Strains expressing some of the recently described resistant genes may fail to exhibit synergy between gentamicin and β-lactams despite MICs below those usually associated with high-level resistance. For example, the aph (2″)-Ic gene[37] found in clinical isolates of both *E. faecalis* and *E. faecium* results in gentamicin MICs of approximately 256 to 384 μg/mL, lower than the standard screening cutoff for high-level resistance to gentamicin (500 μg/mL). Nonetheless, these organisms are resistant to ampicillin-gentamicin synergism and would not be detected by standard screening methods.

High-Level Resistance to β-Lactams and Production of β-Lactamase

The mechanisms of resistance to penicillin, ampicillin, and other β-lactam antibiotics differ among enterococcal species. The high-level β-lactam resistance (ampicillin MIC ≥ 16 μg/mL) of *E. faecium*[19,87,146] and some other non-*faecalis* enterococcal strains[19] has increased considerably during the past decade and is mediated by additional alterations in PBPs, particularly PBP-5.[71,87,198] Thus, high-level resistance to ampicillin and other β-lactams in *E. faecium* (and other non-*faecalis* strains) represents an exaggerated form of intrinsic β-lactam resistance. *E. faecalis* isolates also are intrinsically resistant to β-lactams (though less so than *E. faecium*), but little change has occurred in the level of this resistance in recent years. However, some strains of *E. faecalis*[110,165,169] and *E. faecium*[46] have acquired clinically significant resistance to ampicillin and penicillin via the plasmid-mediated, constitutive production of a β-lactamase enzyme identical to that of *S. aureus*.[267] β-Lactamase–producing strains of *E. faecalis* and *E. faecium* will not be detected by routine susceptibility testing because of a pronounced inoculum effect. Therefore, enzymatic methods

such as the nitrocefin test must be used to screen for β-lactamase–producing strains.[118,165] Fortunately, such strains remain very uncommon.[153]

Glycopeptide Resistance

Enterococci resistant to vancomycin were identified first in 1988[128,247] and rapidly have become a major nosocomial problem. Data collected by the NNIS of the CDC revealed a dramatic increase in the rate of vancomycin resistance in nosocomial isolates of *Enterococcus* during the interval 1989 to 1993.[180] The NNIS survey documented a 26-fold increase in vancomycin resistance among all nosocomial isolates (from 0.3% of enterococcal isolates in 1989 to 7.9% in 1993) and a 34-fold increase in vancomycin resistance among isolates obtained from adult patients in ICUs (from 0.4% of isolates in 1989 to 13.6% in 1993). Rates of vancomycin resistance in enterococci continued to increase during the next decade (see Table 95–2). The NNIS reported that fully 25 percent of enterococci associated with nosocomial infections in adult patients in ICUs in the United States were resistant to vancomycin in 1999 and 2000; by 2003 to 2004, approximately 30 percent of the enterococcal isolates from these patients were vancomycin-resistant (*http://www.cdc.gov/ncidod/dhqp/pdf/ar/ICU_RESTrend1995-2004.pdf*). Isolates of *E. faecium* are particularly likely to be vancomycin-resistant. Jones and colleagues in the SENTRY Antimicrobial Resistance Surveillance Program reported that 69.4 percent of 1512 U.S. bloodstream isolates of *E. faecium* collected between 1997 and 2005 were resistant to vancomycin.[111] Similarly, Wisplinghoff and colleagues in the SCOPE surveillance study found that 60 percent of U.S. bloodstream isolates of *E. faecium* collected between 1995 and 2002 were resistant to vancomycin, whereas only 3 percent of *E. faecalis* bloodstream isolates were vancomycin-resistant.[261]

Enterococci were the second most common organisms associated with pediatric bloodstream infections in both the 1992-1997 NNIS database[200] and in the pediatric component of the 1995-2001 SCOPE survey.[261] However, VRE organisms were detected much less frequently in these pediatric patients; only 11 percent of *E. faecium* and 1 percent of *E. faecalis* bloodstream isolates (of 357 total enterococcal isolates) obtained from pediatric patients in the SCOPE study were vancomycin-resistant.[262] This finding is important because vancomycin-resistant isolates, particularly those of *E. faecium*, also may exhibit high-level resistance to both β-lactam antibiotics and aminoglycosides, thus rendering treatment of these infections extremely challenging.*

Vancomycin resistance among enterococci is phenotypically and genotypically heterogeneous[6,78,167,168] and may or may not be associated with resistance to other glycopeptides, including teicoplanin. Five major phenotypes of vancomycin resistance (VanA, VanB, VanC, VanD, and VanE) have been characterized. The VanA and VanB phenotypes are most common, and both are transferable. The VanA phenotype is characterized by high-level resistance to vancomycin and teicoplanin, whereas strains with the VanB phenotype exhibit variable levels of resistance to vancomycin but not teicoplanin.[6,78,167,168] The VanC phenotype is limited to *E. gallinarum* and *E. casseliflavus* and is associated with constitutive, low-level, chromosomally mediated (nontransferable) resistance to vancomycin but not teicoplanin and is not transferable.[78,167,168,199] VanD and VanE phenotypes occur uncommonly and are not transferable.

High-level resistance to both vancomycin and teicoplanin (the VanA phenotype) is found primarily in strains of *E. faecium*, whereas most vancomycin-resistant strains of *E. faecalis* express the VanB phenotype and remain susceptible to teicoplanin. Jones and associates and the *Enterococcus* Study Group found that 10 of 11 (91%) vancomycin-resistant strains of *E. faecalis* remained susceptible to teicoplanin (VanB phenotype) whereas 49 of 62 (79%) vancomycin-resistant strains of *E. faecium* were resistant to teicoplanin (VanA phenotype).[110]

The biochemical mechanisms responsible for the major vancomycin-resistant phenotypes are the subject of intense study (reviewed by Murray[168] and Gold[78]). Both VanA and VanB phenotypes are mediated by homologous enzymes that catalyze the formation of an altered, vancomycin-resistant depsipeptide that is incorporated into cell wall peptidoglycan.[6,168,199] The *vanA* and *vanB* gene clusters share functional similarities but are regulated quite differently.[78,168] VanA resistance is transferable by either transposition (e.g., via the transposon Tn1546) or conjugative plasmids. VanB resistance often is encoded by chromosomal DNA but may be transferred by at least two different transposons (Tn1547 and Tn5382).[78,168] Vancomycin induces the production of enzymes encoded by both the *vanA* and *vanB* gene clusters, whereas teicoplanin induces VanA but not VanB enzymes.[78]

The peculiar phenomenon of infection caused by vancomycin-dependent enterococci has been described. Fraimow and colleagues[72] reported a urinary tract infection attributable to a strain of *E. faecalis* that would grow only in the presence of vancomycin, and Green and coworkers[89] reported breakthrough bacteremia with a vancomycin-dependent strain of *E. faecium* occurring during therapy for bacteremia. These organisms are progeny of VanA or VanB enterococci that undergo mutations preventing them from growing in the absence of glycopeptides.

Other Antibiotics

Recently licensed antimicrobials active against most antibiotic-resistant, gram-positive cocci (including VRE organisms) include

quinupristin-dalfopristin, linezolid, and daptomycin. Enterococcal isolates resistant to each of these new agents already have been identified, although overall resistance rates remain very low in the United States.

Streptogramins are protein synthesis inhibitor antibiotics and are natural combinations of two chemically unrelated molecules (referred to as streptogramin A and B, respectively).[137] Quinupristin-dalfopristin is a streptogramin agent that is active against *E. faecium* (including most strains of VREF) but lacks activity against *E. faecalis* at clinically achievable concentrations.[45] An early study found that more than 95 percent of 875 initial patient isolates of VREF were susceptible to quinupristin-dalfopristin,[65] but both emergence of resistance to this agent[155,207] and superinfection with *E. faecalis* and other organisms[35,260] have been reported during therapy with this drug. Multiple molecular mechanisms, including the expression of modifying enzymes (acetyltransferases), active transport via an efflux pump, and activation of the target site, account for resistance to quinupristin, dalfopristin, or both.[96] In the United States, overall rates of enterococcal resistance to quinupristin-dalfopristin remain low, in the range of 1 to 2 percent in most areas.[96] However, resistance to quinupristin-dalfopristin was observed in 10 percent of *E. faecium* isolates obtained from European patients in one recent survey.[55]

The oxazolidinones are a novel class of synthetic protein synthesis inhibitors that act to inhibit the formation of ribosomal initiation complexes in bacteria.[41] Linezolid, the first oxazolidinone antimicrobial approved for human use, is active against both *E. faecalis* and *E. faecium*, including VRE isolates. Initial studies demonstrated virtually uniform activity of this agent against clinical isolates of enterococci,[16,64,179] with 100 percent of 180 strains (representing multiple resistance profiles) inhibited by linezolid concentrations of 1 to 4 μg/mL in one study.[64] Furthermore, initial in vitro studies suggested that the development of resistance would occur very rarely.[41,112,268] However, resistance to linezolid has been reported in several patients receiving prolonged courses of therapy with this drug[79,144,151,217] and in some patients who have not previously received the agent,[15] and it has been associated with clinical failures.[79] Resistance to linezolid is conferred by single nucleotide changes in varying numbers of copies of the bacterial genes encoding 23S ribosomal RNA.[151] Resistance increases in strains containing multiple copies of these mutations.[144,151] Although some centers have reported increasing rates of linezolid resistance in VRE isolates[151] and nosocomial spread of linezolid-resistant VRE strains,[95] overall rates of linezolid resistance in enterococci remain low. For example, only 0.9 percent of 1512 U.S. bloodstream isolates of *E. faecium* collected from 1997 to 2005 by the SENTRY group were resistant to linezolid.[111]

Daptomycin is a novel cyclic lipopeptide antimicrobial that exhibits rapid, concentration-dependent bactericidal activity against gram-positive pathogens, including methicillin-resistant *S. aureus* (MRSA) and VRE strains.[26,232] Daptomycin has a novel method of action in which binding to bacterial membranes and triggering of rapid depolarization of membrane potential lead to inhibition of protein and nucleic acid synthesis.[1,74] Daptomycin was found to have potent activity against a panel of VRE isolates from the United States and Europe—all 75 VRE isolates tested (55 *E. faecium*, 20 *E. faecalis*) were susceptible to this agent.[206] Daptomycin also was reported to be active against a collection of VRE strains resistant to linezolid or quinupristin-dalfopristin.[3] However, daptomycin resistance has developed during therapy with this agent,[135,163,204] although resistance rates remain very low. The mechanism or mechanisms responsible for daptomycin resistance are not known.

TESTING FOR ANTIMICROBIAL RESISTANCE IN ENTEROCOCCI

All enterococci isolated from cultures of blood, CSF, or other normally sterile sites (with the possible exception of urine) should be tested for resistance to β-lactam antibiotics (ampicillin or penicillin, or both, including a test for β-lactamase production), vancomycin, and high levels of aminoglycosides (streptomycin and gentamicin)[68,193,199] by using the methodology and interpretative guidelines published by the Clinical and Laboratory Standards Institute (CLSI).[42] For multiantibiotic-resistant isolates, testing for susceptibility to alternative agents, including linezolid and daptomycin, should be performed.

Testing of enterococci for ampicillin (or penicillin) resistance must involve determination of the MIC of these agents and a test for β-lactamase production.[42] Jones and colleagues and the *Enterococcus* Study Group compared three techniques that are used commonly to determine the ampicillin MIC of enterococcal isolates—disk diffusion, broth microdilution, and E-test strips—and found excellent agreement among the three methods.[109] Enterococcal isolates with an ampicillin or penicillin MIC of 16 μg/mL or greater are considered resistant to these agents.[42] β-Lactamase-producing enterococci cannot be detected by these methods but are identified routinely by performance of the chromogenic nitrocefin assay.[237]

High-level resistance to gentamicin and streptomycin usually may be detected by either agar dilution (high-level resistance to gentamicin, MIC > 500 μg/mL; high-level resistance to streptomycin, MIC > 2000 μg/mL) or broth microdilution (high-level resistance to gentamicin, MIC > 500 μg/mL; high-level resistance to streptomycin, MIC > 1000 μg/mL).[42,235,237] These isolates also may be identified by disk diffusion with the use of high-content aminoglycoside disks (120-μg gentamicin disk, 300-μg streptomycin disks, ≥10-mm zone = susceptible)[237] or high-range E-test strips.[109,209] However, the recent identification

of novel genes encoding gentamicin resistance in both *E. faecalis* and *E. faecium* has raised concern about continued use of the 500-μg/mL cutoff for detection of high-level resistance to gentamicin (reviewed by Chow[34]). These enterococcal isolates are not killed synergistically by combinations of ampicillin/penicillin and gentamicin, even though gentamicin MICs are 256 to 384 μg/mL. If these isolates become more widely prevalent, modification of the standard screening procedures for high-level aminoglycoside resistance may be required.

Commercially available automated antimicrobial susceptibility testing methods may fail to detect vancomycin resistance in enterococci, particularly the VanB phenotype of moderate resistance,[241] although newer versions of these systems appear to be much more reliable.[76,248] Routine disk diffusion testing is more dependable but requires an extended incubation time and the use of transmitted light for examination of zone size to be highly accurate.[236,241] Agar dilution screening using brain-heart infusion agar supplemented with 6 μg/mL vancomycin reliably identifies VRE strains,[42,237,254] as does the standard broth microdilution method.[110,241] E-test glycopeptide strips are a useful alternative to the more cumbersome broth dilution methodology.

THERAPY FOR ENTEROCOCCAL INFECTIONS

Before the emergence of VRE infection as a major nosocomial problem in high-risk patients, the optimal management of serious enterococcal infections (especially endocarditis) was well established. Successful treatment of enterococcal endocarditis required the administration of combination therapy consisting of a cell wall–active agent (usually ampicillin) and an aminoglycoside (gentamicin or streptomycin). Combination therapy also was recommended for other potentially life-threatening enterococcal infections (e.g., sepsis, meningitis) based on the extensive experience with endocarditis. Other enterococcal infections, including urinary tract infections, responded well to monotherapy with a variety of antimicrobials.

In contrast, the optimal therapy for many infections caused by VRE strains remains uncertain. Older agents such as chloramphenicol are no longer used.[177,188,195] Several new agents (quinupristin-dalfopristin, linezolid, daptomycin) have been used for the treatment of VRE infections in adults. However, only one of these antibiotics (linezolid) has been approved for use in children, and enterococci resistant to these new agents already have been detected.[96,150,163] In addition, the prognosis for patients with VRE infections (including bacteremia) often is related more closely to the underlying disease than to the infection, thus complicating the management of these high-risk patients.

TREATMENT OF INFECTIONS CAUSED BY ANTIBIOTIC-SUSCEPTIBLE ENTEROCOCCI

Any discussion of the treatment of serious enterococcal infection must begin with a review of the large experience in the treatment of enterococcal endocarditis. The difficulty of treating enterococcal endocarditis has been apparent since early reports showed that penicillin alone failed to cure as many as two thirds of patients with enterococcal endocarditis but was highly effective in the treatment of streptococcal endocarditis (reviewed by Murray[164]). The early failures of penicillin therapy stimulated studies of the in vitro and in vivo effects of β-lactam antibiotics on enterococci; these studies led to the discovery that enterococci were "tolerant" of the killing effects of cell wall–active agents and provided evidence that bactericidal therapy was required to cure bacterial endocarditis reliably.

For more than half a century, standard therapy for enterococcal endocarditis has included an aminoglycoside plus a cell wall–active agent. Hunter[101] first reported clinical evidence of synergism between penicillin and streptomycin in the treatment of enterococcal endocarditis in 1947, and this synergism subsequently was confirmed for combinations of penicillin or ampicillin and streptomycin or gentamicin both in vitro and in vivo (reviewed by Murray[164]). Moellering and Weinberg[156] first demonstrated that synergy between β-lactams and aminoglycosides was a consequence of increased aminoglycoside uptake by enterococci exposed to cell wall–active agents. Glycopeptides and aminoglycosides also exhibit in vitro and in vivo synergy against "susceptible" (not expressing high-level resistance) strains of enterococci.[98,151]

The preferred therapy for endocarditis caused by "susceptible" strains of enterococci in both adults[13,151,153,197,257] and children[49,231] consists of combination therapy with parenteral ampicillin (or penicillin G) plus parenteral gentamicin (or streptomycin) for a minimal duration of 4 to 6 weeks. Patients with severe penicillin allergy should be treated with vancomycin plus gentamicin or streptomycin. Selected adult patients with a short duration of symptoms and an uncomplicated course may be treated with 4-week regimens[257,258]; most other patients, including those with mitral-valve involvement, a longer duration of symptoms (especially those with symptoms for >3 months), or prosthetic-valve endocarditis, probably should receive 6-week courses of therapy.[151,257] Interestingly, several reports indicate that the prognosis of enterococcal prosthetic-valve endocarditis is better than that of native-valve disease, perhaps because of the generally shorter duration of symptoms before the diagnosis is made.[151,197] Many patients with prosthetic-valve endocarditis caused by enterococci can be cured without surgery. Rice and colleagues[197] reported a 69 percent cure rate with medical therapy in patients with enterococcal endocarditis involving prosthetic valves.

The general consensus, based on experience with enterococcal endocarditis, is that other life-threatening enterococcal infections, including meningitis and septicemia, should be treated with bactericidal regimens.[152,164,234] The duration of therapy for uncommon enterococcal infections such as meningitis must be individualized, although 2- to 3-week courses of antibiotics have been reported to cure enterococcal meningitis.[234] The optimal treatment of enterococcal bacteremia, particularly that occurring in the nosocomial setting, remains controversial.

The prognosis for these patients varies widely and often is related more closely to the underlying disease than to the enterococcal infection. In adults, single-drug regimens generally are successful in the treatment of enterococcal bacteremia, thus indicating that bactericidal therapy often is not required in all cases.[152,164]

Considerable clinical experience supports the routine use of single-drug therapy for uncomplicated enterococcal urinary tract infection and for soft tissue infection caused by enterococci. Urinary tract infections by susceptible strains of enterococci generally respond promptly to ampicillin, penicillin, nitrofurantoin, or vancomycin.[152,162,164]

TREATMENT OF INFECTIONS CAUSED BY ANTIBIOTIC-RESISTANT ENTEROCOCCI (INCLUDING VANCOMYCIN-RESISTANT ENTEROCOCCI)

Unfortunately, the emergence of enterococci with clinically significant resistance to aminoglycosides, β-lactams, and glycopeptides has complicated the management of endocarditis and other serious infections caused by these organisms to a considerable extent. This discussion focuses on the management of endocarditis caused by drug-resistant enterococci because the need to provide bactericidal therapy has been well established in this setting. The general principles probably apply to the management of other life-threatening enterococcal infections (see earlier).

Endocarditis caused by enterococci with high-level resistance to either streptomycin or gentamicin may be treated by substitut-

ing the other aminoglycoside in a combination regimen, but isolation of strains with high-level resistance to both aminoglycosides means that no available aminoglycoside will provide synergistic killing in concert with cell wall–active agents.[151,164] No reliably bactericidal regimen is available for the treatment of endocarditis caused by these strains, even if the isolates remain susceptible to other classes of antimicrobials. Based on animal studies, some experts recommend prolonged treatment (8 to 12 weeks or more) with high-dose intravenous ampicillin given by continuous infusion in this situation (if the isolate is susceptible).[63,153] Surgical excision of infected valves may be required in such patients.[197]

Endocarditis and other serious infections caused by enterococci resistant to β-lactam antibiotics also are increasing in frequency.[87] Endocarditis caused by enterococci (usually *E. faecium*) highly resistant to β-lactams may be treated with vancomycin plus an aminoglycoside (if the strain is susceptible to vancomycin). Endocarditis caused by β-lactamase–producing strains of *E. faecalis* (or rarely, *E. faecium*) would be expected to respond to ampicillin-sulbactam because this combination is highly effective in animal models.[63] Higher-dose or continuous-infusion ampicillin may be effective in the treatment of endocarditis caused by some strains of enterococci that are "resistant" to ampicillin by current guidelines (MIC ≥ 16 μg/mL) because sustained plasma concentrations in excess of 100 μg/mL may be achieved with these regimens.[168] However, even high-dose ampicillin therapy probably will fail to cure endocarditis caused by enterococci with ampicillin MICs greater than 64 μg/mL.[21,78]

Enterococci resistant to vancomycin may remain susceptible to teicoplanin (VanB phenotype). Teicoplanin with or without the addition of an aminoglycoside has been used successfully in the treatment of serious enterococcal infections caused by susceptible isolates,[213] including some cases of endocarditis[190,213] and meningitis.[136] However, teicoplanin is not available in the United States, treatment of endocarditis with this agent has been associated with both treatment failure and relapse,[190,213] and high-level teicoplanin resistance may develop even without exposure to the drug.[92] Endocarditis caused by VanB strains of enterococci should be treated with high-dose ampicillin plus gentamicin or streptomycin if resistance to these agents is not present.

Similarly, endocarditis caused by enterococci highly resistant to both vancomycin and teicoplanin (VanA phenotype) but susceptible to β-lactams should be treated with ampicillin plus an aminoglycoside (if high-level resistance to aminoglycosides is not present). Unfortunately, the VanA phenotype is associated primarily with strains of *E. faecium*, which increasingly are resistant to β-lactams.[71,87,109] Endocarditis caused by enterococci highly resistant to both glycopeptides and β-lactams is especially difficult to treat. Combinations of ampicillin and vancomycin are not bactericidal against these isolates but may[223] or may not[29] provide additive or synergistic inhibition in vitro. If high-level resistance to aminoglycosides is not present, triple-combination therapy with a β-lactam, a glycopeptide, and an aminoglycoside may achieve bactericidal activity; such combinations are reported to be highly effective in animal models of endocarditis caused by ampicillin- and vancomycin-resistant *E. faecium*.[25] For endocarditis caused by enterococci exhibiting high-level resistance to both gentamicin and streptomycin along with resistance to β-lactams and glycopeptides, no proven effective therapies are available.

Newer Options for Treatment of Vancomycin-Resistant Enterococcal Infections

Three new antimicrobials with activity against most VRE strains recently have been licensed: quinupristin-dalfopristin, linezolid, and daptomycin. Of these drugs, only linezolid has been approved for use in children.

The streptogramin antibiotic quinupristin-dalfopristin[137] was approved by the Food and Drug Administration (FDA) in September 1999 for the treatment of adults with infections caused by VREF. This agent is not approved for the treatment of *E. faecalis* infections, nor for pediatric use. Although time-kill curves indicate that quinupristin-dalfopristin is not reliably bactericidal against strains of *E. faecium*,[45] it may provide bactericidal activity against some multiresistant clinical isolates.[141,170,207] Quinupristin-dalfopristin has been reported to effect clinical cures of several serious infections caused by multiresistant *E. faecium*, including ventriculoperitoneal shunt infections in two patients,[170,245] an infected aortic graft in one patient,[210] and VREF peritonitis in a series of adults.[141] Several case series suggest that treatment with quinupristin-dalfopristin reduces the mortality rate associated with VREF bacteremia in adults[131,155,260] and children.[84,133,249] Clinical response to quinupristin-dalfopristin has been reported in approximately 74 to 80 percent of patients with VREF bacteremia.[84,155,249,260] The lack of a consistent bactericidal effect may limit the utility of this agent in the treatment of endocarditis and other life-threatening infections. Therapy with quinupristin-dalfopristin for 10 weeks was reported to cure one patient with VREF endocarditis, although bacteremia persisted until the eighth week of therapy.[75] A second patient with VREF endocarditis failed treatment with 2 weeks of quinupristin-dalfopristin monotherapy but was cured by treatment with a combination of quinupristin-dalfopristin, doxycycline, and rifampin.[145] Other patients with VREF endocarditis have failed to respond to quinupristin-dalfopristin.[8,155]

Quinupristin-dalfopristin therapy generally has been tolerated fairly well in both adults and children, although a high rate of venous phlebitis in recipients has led to a recommendation that the agent be administered through a central venous catheter. Myalgias and arthralgias are other commonly reported side effects of this agent. The potential utility of quinupristin-dalfopristin for the treatment of pediatric patients is limited by its venous toxicity, its lack of a consistent bactericidal effect against VREF, and its lack of clinically useful activity against *E. faecalis*.[45]

Linezolid, the first oxazolidinone antibiotic, was approved by the FDA in April 2000 for the treatment of selected infections caused by antibiotic-resistant, gram-positive bacteria in adults, including those caused by VRE strains (*E. faecium* or *E. faecalis*). In December 2002, the FDA approved this agent for the treatment of pediatric patients with pneumonia, skin and skin structure infections, and VREF infections. Linezolid is available in both parenteral and oral formulations (with comparable bioavailability). Linezolid is active against many antibiotic-resistant, gram-positive pathogens, including MRSA, penicillin-resistant *S. pneumoniae*, and vancomycin-resistant isolates of both *E. faecium* and *E. faecalis*.[16,41,64,179] This agent is bacteriostatic against most susceptible organisms, including the enterococci, but it does exhibit bactericidal activity against some strains of pneumococci. Initial studies demonstrated virtually uniform activity of linezolid against clinical isolates of enterococci.[16,64,179]

Linezolid has been reported to effect both bacteriologic and clinical cure in patients with life-threatening VRE infections, including endocarditis,[8,12,32,233] bacteremia,[32,148,178] and meningitis,[219,264] although clinical experience with this agent in the treatment of endocarditis or meningitis remains limited. Several patients, including those with endocarditis[8] and persistent VREF bacteremia, who responded to linezolid therapy previously had failed therapy with quinupristin-dalfopristin.[148] Linezolid therapy has been reported to cure several patients with VRE endocarditis,[8,12,32,233] including 10 of 22 patients in one study[12] and all of 3 patients who received at least 6 weeks of the drug in another report.[233] These results are encouraging, but enthusiasm for the use of linezolid to treat serious VRE infection must be tempered by its generally bacteriostatic activity and the potential for increasing resistance to this agent. Pediatric experience with line-

zolid is limited, but the drug was demonstrated to be well tolerated and as effective as vancomycin in the treatment of children with serious gram-positive infections in a large multicenter trial.[114]

Linezolid generally has been tolerated well in both adults and children,[41,73,208] with fewer side effects occurring than with quinupristin-dalfopristin. Adverse effects most frequently reported in patients receiving linezolid have included nausea, diarrhea, and headache in adults and diarrhea and vomiting in children.[73] Reversible myelosuppression has been reported in adults.[73] Longer courses of linezolid therapy have been associated with more serious adverse effects, including optic neuropathy that usually is reversible and peripheral neuropathy that may be irreversible.[102,203]

Daptomycin is a novel cyclic lipopeptide antimicrobial that exhibits rapid, concentration-dependent bactericidal activity against enterococci, including VRE strains.[26,232] It was approved by the FDA in September 2003 for the treatment of adult patients with complicated skin and soft tissue infections caused by gram-positive bacteria, including staphylococci, streptococci, and vancomycin-susceptible strains of *E. faecalis*. Daptomycin is available in an intravenous formulation. It is not approved for use in children, and pediatric experience with the drug is very limited. Daptomycin should not be used for the treatment of pneumonia because it is inactivated by pulmonary surfactant.[227]

The published experience with daptomycin therapy in patients with VRE bloodstream infections is limited. Half (11 of 22) of the patients with VRE bacteremia or endocarditis treated with daptomycin summarized in three recent reports were cured.[126,189,218] Additional studies are under way, and pediatric trials are needed.

Numerous other promising new antibiotics with in vitro activity against VRE isolates recently have been licensed for use in adults (e.g., the glycylcycline antibiotic tigecycline) or are being evaluated in clinical trials. Agents in clinical trials include the lipoglycopeptides oritavancin and telavancin, as well as new members of the oxazolidinone and streptogramin classes of antibiotics.

PREVENTION OF ENTEROCOCCAL INFECTIONS

The explosive increase in nosocomial infections caused by vancomycin-resistant and multiantibiotic-resistant enterococci[61,180] has rendered prevention of enterococcal infections, particularly those caused by VRE strains, a public health priority in the United States.[30,78,168,193,220] In 1995, the Hospital Infection Control Practices Advisory Committee (HICPAC) recommended a series of overlapping strategies designed to prevent the development of serious enterococcal infections.[193] These strategies are aimed at simultaneous interruption of the considerable increase in vancomycin resistance in enterococci and prevention of nosocomial infection with these organisms. Implementation of such strategies has been reported to reduce or eliminate the transmission of VRE organisms in health care facilities.[182] However, overall rates of nosocomial infection by VRE continued to increase in the United States from 1995 to 2004 (*http://www.cdc.gov/ncidod/dhqp/pdf/ar/ICU_RESTrend1995-2004.pdf*), perhaps because the HICPAC guidelines have been followed inconsistently (reviewed by Cetinkaya and colleagues[30]).

REVERSING THE TREND TOWARD VANCOMYCIN AND MULTIPLE-ANTIBIOTIC RESISTANCE IN ENTEROCOCCI

The use of vancomycin[193,212,220] and treatment with broad-spectrum antibiotics, including the third-generation cephalosporins and carbapenems,[61,86,161,166,173,196] are risk factors for colonization and the development of infection with VRE strains. Consequently, the HICPAC and the CDC have recommended that all hospitals, even those at which VRE organisms have not been isolated, should (1) develop a comprehensive antimicrobial utilization plan, (2) oversee surgical prophylaxis, and (3) develop institution-specific guidelines for the proper use of vancomycin.[193]

Efforts to eliminate unnecessary use of vancomycin are of critical importance[193,220] but may be inadequate unless the use of other classes of antimicrobials is reduced as well (see later). In 1995, the HICPAC provided recommendations regarding the acceptable and appropriate use of vancomycin (Table 95–3), as well as recommendations regarding situations in which vancomycin use should be discouraged[193] (Table 95–4). These recom-

TABLE 95–3 Situations in Which Vancomycin Use Is Appropriate or Acceptable

Treatment
Treatment of serious infections caused by β-lactam–resistant, gram-positive microorganisms
Treatment of gram-positive infections in patients with serious allergies to β-lactams
Treatment of antibiotic-associated colitis only when it fails to respond to metronidazole or is severe and potentially life-threatening
Prophylaxis
Endocarditis prophylaxis after certain procedures in high-risk patients according to the American Heart Association guidelines
Prophylaxis for major surgical procedures involving implantation of prosthetic materials or devices (single-dose prophylaxis usually is adequate)

Modified from Recommendations for preventing the spread of vancomycin resistance: Recommendations of the Hospital Infection Control Practices Advisory Committee (HICPAC). M. M. W. R. Recomm. Rep. 44*(RR-12):1-13, 1995.*

TABLE 95–4 Situations in Which Vancomycin Use Should Be Discouraged

Treatment
Empiric therapy for febrile neutropenic patients (unless there is presumptive evidence of an infection caused by gram-positive organisms, such as a Hickman catheter exit-site infection, and the local prevalence of methicillin-resistant *Staphylococcus aureus* strains is substantial)
Treatment of an isolated, single blood culture positive for coagulase-negative *Staphylococcus*
Treatment (chosen for dosing convenience) of infections caused by β-lactam–susceptible, gram-positive microorganisms in patients with renal failure
Continued empiric use of presumed infection in patients whose cultures are negative for β-lactam–resistant gram-positive microorganisms
Primary treatment of antibiotic-associated diarrhea
Eradication of methicillin-resistant *S. aureus* colonization
Prophylaxis
Routine surgical prophylaxis except in patients with life-threatening allergy to β-lactams
Systemic or local prophylaxis for infection of indwelling intravascular catheters
Routine prophylaxis for very-low-birth-weight infants
Routine prophylaxis for dialysis patients
Use of vancomycin solution for topical application or irrigation
Selective decontamination of the gastrointestinal tract

Modified from Recommendations for preventing the spread of vancomycin resistance: Recommendations of the Hospital Infection Control Practices Advisory Committee (HICPAC). M. M. W. R. Recomm. Rep. 44*(RR-12):1-13, 1995.*

mendations remain useful, but the recent emergence of community-acquired MRSA infections[94,100,115] has resulted in increased empiric and definitive use of vancomycin for a HICPAC-approved indication: "treatment of serious infections caused by β-lactam–resistant, gram-positive microorganisms."[193]

In addition, efforts should be undertaken to reduce the unnecessary use of broad-spectrum antibiotics and certain agents with potent anti-anaerobic activity, particularly in settings with high rates of nosocomial infection (such as ICUs). These efforts are necessary because many studies indicate that nonglycopeptide antibiotics also exert selective pressure for VRE strains and that limitation of the use of vancomycin alone has only a modest effect on reducing VRE colonization and infection (reviewed by Rice[196]). Exposure to agents with broad-spectrum activity (but lacking anti-enterococcal activity), such as the extended-spectrum cephalosporins, appears to predispose to colonization with VRE organisms,[59,196] whereas exposure to antimicrobials with potent anti-anaerobic activity (even if they are also active against enterococci) may promote high-density, prolonged VRE colonization (by eliminating gut anaerobes that may interfere with colonization by VRE strains).[58,191,196]

PREVENTING AND CONTROLLING THE SPREAD OF NOSOCOMIAL INFECTION BY VANCOMYCIN-RESISTANT ENTEROCOCCI

The increasing prevalence of *Enterococcus* in nosocomial infections is related to the intrinsic and acquired antimicrobial resistance of these organisms, but the factors leading to increased antibiotic resistance in enterococci are not identical to those that predispose to enterococcal colonization or infection, or both. Enterococcal infections are concentrated increasingly in debilitated and immunocompromised patients, including those with malignancies, recipients of bone marrow and solid organ transplants, burn victims, premature neonates, and critically ill patients with indwelling intravascular catheters. Consequently, special attention should be paid to potential outbreaks of VRE infection in hospital wards caring for these high-risk patients.[30]

Efforts to prevent the spread of VRE colonization or infection (or both) probably will be more successful if the VRE isolates are confined to a few patients in a single area of the hospital. Widespread colonization with VRE strains may precede identification of infections by these organisms. Therefore, all hospitals should implement active VRE surveillance and formulate a multidisciplinary plan to prevent nosocomial spread of VRE strains if such organisms are identified. In hospitals that have not isolated VRE strains, periodic antimicrobial susceptibility testing should be performed on enterococcal isolates from all sources, particularly from high-risk patient populations such as those in intensive care or transplant units. If VRE organisms are identified, a comprehensive plan to prevent nosocomial spread of these bacteria should be instituted immediately. The HICPAC guidelines summarized the essential elements of such a plan.[193] Hospital infection control staff and clinical staff must be notified promptly when VRE strains are isolated from a clinical sample, and isolation precautions should be implemented immediately to prevent patient-to-patient transmission of VRE organisms. These precautions include gown and glove isolation, vigorous handwashing, dedicated use of noncritical patient items such as thermometers and stethoscopes, and prompt surveillance of any possibly exposed patients for VRE colonization. Additional measures may be necessary in hospitals with endemic or continued VRE transmission despite implementation of the aforementioned measures.[193] Ostrowsky and colleagues[182] reported that an active infection control program that included surveillance cultures and prompt isolation of infected patients successfully reduced the spread of VRE strains in health care facilities throughout the Sioux land region of Iowa, Nebraska, and South Dakota.

Once VRE organisms become endemic in a hospital unit, achieving complete eradication is very difficult. The duration of VRE colonization in individual patients may be weeks or months,[30,159] although spontaneous resolution of colonization occurs frequently.[30,158] Attempts to eradicate colonization in individual patients generally have been unsuccessful.[30,158] Consequently, the measures recommended by HICPAC and others are directed at preventing the initial establishment of VRE strains in hospitals. Implementation of these policies will require the involvement of hospital pharmacy and therapeutics committees, quality assurance programs, and medical staff. Ongoing monitoring of the efficacy of these programs will be required.

VIRIDANS STREPTOCOCCAL INFECTIONS

A group of *Streptococcus* spp. known as viridans, alpha-hemolytic, or oral streptococci are ubiquitously present on the oral mucosa of virtually all humans. These organisms are important pathogens in children and adults alike and cause infections ranging from caries and bacterial endocarditis in immunocompetent hosts to fatal sepsis in neutropenic persons.

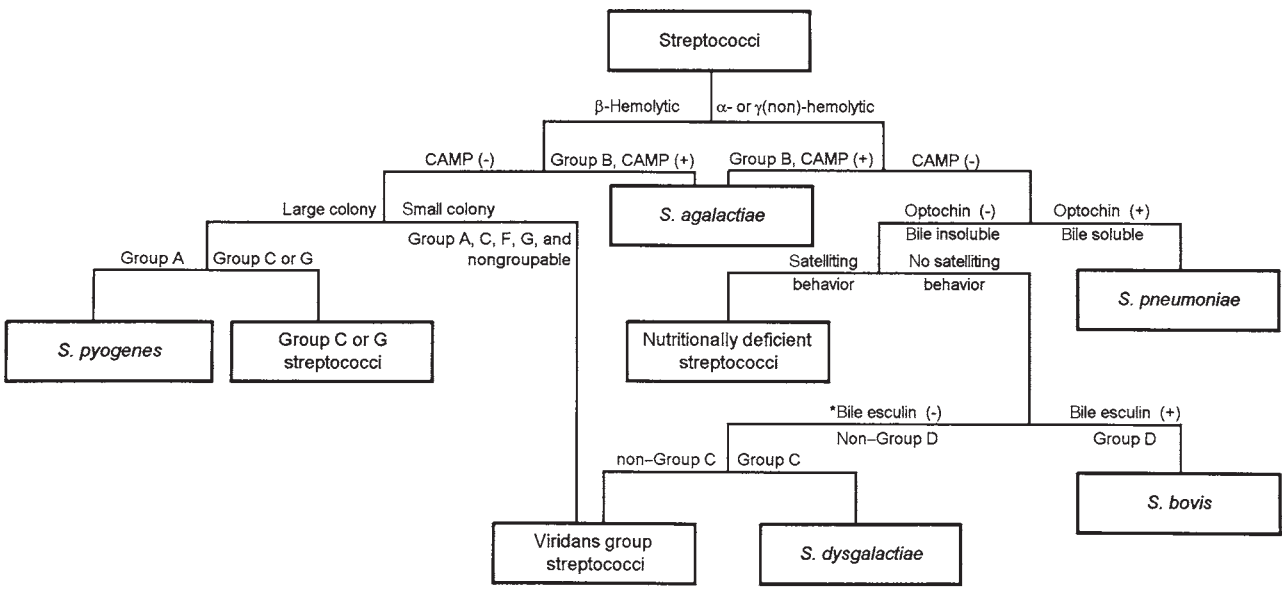
Each of the terms applied to this group is wanting. Not all members of the *alpha-hemolytic* streptococci are alpha-hemolytic, some being gamma-hemolytic (nonhemolytic) or even beta-hemolytic. *Streptococcus pneumoniae*, which is alpha-hemolytic, is considered to be a separate group. The term *viridans streptococci* likewise is inadequate because it is derived from the Latin *viridis*, or green, and refers to the sheen caused by partial hemolysis around alpha-hemolytic colonies on sheep blood agar. The term *oral streptococci* circumvents the dilemma of outliers in the hemolytic classification schema, but it also is confusing because viridans streptococci are found in sites other than the oral cavity and nonviridans streptococcal species frequently are present in the oral cavity. In accordance with the American Society for Microbiology's most recent efforts in this field,[219] the term *viridans streptococci* will be used here in referring to this diverse group of bacteria in recognition that the member organisms typically, but not invariably are alpha-hemolytic. Also of emphasis is that viridans does not refer to a species of streptococci but rather to a group of species, erroneous references to "*Streptococcus viridans*" notwithstanding.[238]

Streptococci have been reclassified on the basis of molecular and genetic studies[55,219]; this reclassification adds to the clinical confusion, at least temporarily. For example, under the new classification system, certain small-colony, beta-hemolytic streptococci, including some that are in Lancefield group A, now are considered to be viridans streptococci. The hope is that classification based on molecular relatedness eventually will lead to a clearer understanding of the infectious diseases associated with these organisms. One should recognize, however, that the current knowledge of viridans streptococcal infections is based predominantly on study of the alpha-hemolytic members of the viridans group.

MICROBIOLOGY

Streptococci are gram-positive, catalase-negative bacteria that are spherical or ovoid and less than 2 μm in diameter. They are facultatively anaerobic and nonmotile and do not produce spores or gas. Some strains require an atmosphere enriched with carbon dioxide (5%). The enterococci (distinguished by their ability to grow in 6.5% sodium chloride) and lactococci (formerly Lancefield group N streptococci) once were considered to be streptococci but now are classified as separate genera.

Figure 95–2 is a schema for classifying the clinically important streptococcal species. Hemolysis of blood agar remains a key tool



*Occasional viridans streptococcal strains are positive or weakly positive.

Figure 95–2 Schema for the identification of clinically important streptococcal species. Viridans group species are, in general, those remaining after identification of other streptococcal species. CAMP, Christie, Atkins, and Munch-Peterson test.

for classifying streptococci. Strains that are beta-hemolytic are characterized further according to colony size and Lancefield group (a serologic classification system based on cell wall carbohydrate). Group B *Streptococcus agalactiae* strains typically can be identified by beta-hemolysis and a positive result of the CAMP (Christie, Atkins, and Munch-Peterson) test[219]; however, some strains of *S. agalactiae* that are alpha- or gamma-hemolytic also are recognized by a positive CAMP test result.

Large-colony, beta-hemolytic, group A streptococci make up the species *Streptococcus pyogenes*. Other large-colony, beta-hemolytic streptococci occasionally are pathogenic, and most of them are group C or G streptococci. Small-colony, beta-hemolytic streptococci, including groups A, C, G, and F and nongroupable strains, partially constitute the *Streptococcus milleri* group of organisms within the viridans streptococci group. Among the alpha- or gamma-hemolytic streptococci, *S. agalactiae* (group B streptococci) and *S. pneumoniae* generally are identified by positive results on the CAMP test and optochin test, respectively. Bile solubility confirms an optochin-susceptible isolate as *S. pneumoniae*.

Nutritionally deficient streptococci are recognized by a requirement for the presence of a second bacterial species (*Staphylococcus aureus* typically is used in testing) to maintain growth on agar. These streptococci generally will grow in blood culture media in the absence of the reduced form of nicotinamide adenine dinucleotide (NADH) produced by a second bacterial species and may demonstrate some growth on agar in the absence of other bacteria. Nutritionally deficient streptococci once were classified as viridans streptococci, but more recent studies have classified these organisms in a new genus: *Abiotrophia adjacens* and *Abiotrophia defectiva*.[132] Excluding *Enterococcus* spp., streptococci that are alpha- or gamma-hemolytic, possess Lancefield group D antigen, and are bile esculin–positive may be identified tentatively as *Streptococcus bovis*. Though once included among viridans streptococci, this species now is classified separately from the viridans group.

Strains of one species of group C streptococci, *Streptococcus dysgalactiae*, are alpha- or gamma-hemolytic. These strains also must be distinguished from the viridans group of streptococci. A former streptococcal species included in the viridans group, *Streptococcus morbillorum*, was reclassified as *Gemella morbillorum*.[136] The remaining streptococcal organisms tentatively may be identified as viridans group streptococci. Thus, in practice, viridans streptococci continue to be characterized by the absence of features that distinguish the other major streptococcal pathogens. No characteristics can be used to confirm the identity of viridans streptococci definitively in the standard microbiology laboratory.

Classification of species within the viridans streptococci group also has been challenging. Over the years, several schemata that have been developed include those of Carlsson,[41] Coleman and Williams,[51] Facklam,[85] Ruoff and Kunz,[220,221] and Coykendall.[55] All these classification schemata lack reliable markers for member species and therefore result in inconsistent classification of clinical isolates. Consequently, efforts to characterize the clinical features of infections according to individual species of viridans streptococci have had marginal results. Molecular and polymerase chain reaction (PCR)-based taxonomies have been used to classify viridans streptococci,[4,55,183,218,290] but these techniques generally are not available in the clinical laboratory. Given the current flux in the taxonomy of these organisms, a simplified, practical approach to classifying viridans streptococci as outlined in Table 95–5 has been advocated.[219] The biochemical tests available in many clinical microbiology laboratories can be used to assign clinical isolates to one of five groups that encompass the 14 clinically important viridans streptococcal species listed in Table 95–5. Rapid molecular and PCR-based tests are available for tentative identification of individual viridans streptococcal species[89,98,189,221]; however, at this time, identification of precise species has little clinical significance except as an epidemiologic tool.

EPIDEMIOLOGY

Viridans streptococci are the predominant microorganisms in the oral flora of humans. These organisms also are found commonly in other areas of the upper respiratory tract, throughout the gastrointestinal tract, and in the female genital tract. Occasionally, viridans streptococci are found as members of the skin flora.

Viridans streptococci begin colonizing neonates shortly after birth. By 1 month of age, virtually all infants are colonized with at least one species of viridans streptococci.[186] The mix of colonizing viridans streptococcal species varies with ontogeny. For example, *Streptococcus mutans*, a species that plays an important role in the development of caries, rarely is found in predentate children but commonly is present after the eruption of teeth.[42,73,256] The ecology of other viridans streptococcal species also appears to be affected by the eruption of teeth.[43,73,239,256] In addition to these temporal factors in the colonization of infants and children, viridans streptococci have species-specific predilections for

TABLE 95–5 Simplified Classification Schema for Viridans Streptococci

Group	Species	Hemolysis	Sorbitol	Arginine	Voges-Proskauer	Mannitol	Esculin
S. milleri	*S. anginosus*	α, β, γ	–	+	+	±	±

Data from Coykendall, A. L.: Classification and identification of the viridans streptococci. Clin. Microbiol. Rev. 2:315-328, 1989; and Ruoff, K. L.: Streptococcus. In *Murray, P. R., Baron, E. J., Pfaller, M. A., et al. (eds.): Manual of Clinical Microbiology. 6th ed. Washington, D.C., American Society for Microbiology, 1995, pp. 299-307.*

certain anatomic areas of the oral cavity and pharynx. For example, *Streptococcus sanguis* is the predominant isolate of the buccal mucosa but rarely is found on the dorsum of the tongue, where *Streptococcus mitis* is the predominant species.[93] Diet also may affect the viridans streptococcal ecology. For example, consumption of sugar-containing beverages and the low pH that can result from carbohydrate intake favor colonization with caries-producing *S. mutans*.[106,254]

Little is known about the transmission of viridans streptococci, but studies of the transmission of *S. mutans* within families indicate that intrafamily transmission commonly occurs.[3,110,222] Toothbrushes may be an important vehicle of transmission of viridans streptococci in children.[153] The hands of hospital personnel, especially those with skin disorders such as eczema, also may be a vehicle of transmission of viridans streptococci.[48] In addition, dental records have been suggested as a vehicle in the transmission of viridans streptococci.[56]

Viridans streptococci have an important role in the ecology of the oral flora in that they protect against potentially more invasive pathogens by resistance to colonization with these organisms.[17,97] This mechanism has been demonstrated by a double-blind study in which patients who had received antibiotic therapy for group A streptococcal pharyngitis were treated with either a preparation that contained four species of viridans streptococci or a placebo. In the treated group, none of 17 patients experienced recurrence of group A streptococcal pharyngitis. In contrast, pharyngitis recurred in 7 (37%) of 19 patients in the placebo group.[211] A second double-blind, placebo-controlled multicenter trial by the same group confirmed the finding of the first study.[212] Viridans streptococci also may have a role in resistance to colonization by pathogens such as methicillin-resistant *S. aureus* (MRSA) in the oral cavity of infants[269]; nontypeable *Haemophilus influenzae*, *S. pneumoniae*, and *Moraxella catarrhalis* at the eustachian tube orifice[255]; and *Neisseria gonorrhoeae* in the female genital tract.[162] In addition to competition for mucosal adherence sites, viridans streptococci produce hydrogen peroxide and bacteriocins that are bactericidal to certain competing bacteria and may contribute to resistance to colonization.[57,59,270,275] Conversion of hydrogen peroxide to ozone in the oral cavity may play a role in the resistance to colonization by other bacterial species and *Candida*.[268]

PATHOGENESIS

Viridans streptococci are organisms of low virulence that usually cause nonpyogenic infection when they do cause infection. They are involved most often in localized infections of the sinuses and oral cavity, including the teeth, in which the tissues are invaded directly by colonizing organisms. Caries is a disease of teeth that develops over a period of years, often in association with *S. mutans* infection. Viridans streptococci also have a role in a variety of gingival diseases, possibly including gingival hyperplasia accompanying the chronic administration of phenytoin. In an experimental animal model, phenytoin-induced gingival hyperplasia was enhanced in rats infected with *Streptococcus sobrinus* when compared with uninfected control animals.[175] Occasionally, viridans streptococci, usually organisms of the *S. milleri* group, cause pyogenic infections, including abscesses in the brain, lung, and abdomen. An intriguing, but preliminary study suggested that viridans streptococcal–related dental disease is associated with the subsequent development of coronary artery heart disease.[146] Viridans streptococci are among the microorganisms isolated from atherosclerotic plaque, although the role of these microbes in the pathogenesis of atherosclerosis has not been determined.[47] Typically, viridans streptococci cause life-threatening infection only in settings in which the oral mucosa is disrupted and the host's mechanisms of clearance are compromised, such as in patients with neutropenia or cardiac-valve disease.

The preponderance of viridans streptococci in the oral flora rather than its virulence accounts for the domination of viridans streptococci in infections originating from the mouth. In a study of 36 children who underwent extraction of normal or abscessed teeth, 11 (30%) had postextraction positive blood cultures.[245] In all 11, viridans streptococci were isolated exclusively. Bacteremia occurred more commonly after removal of diseased teeth (37%), but it also occurred after removal of normal teeth (23%).

A separate study of 58 children who underwent dental extraction included 26 who received penicillin, amoxicillin, or erythromycin prophylaxis because of a risk of endocarditis developing.[54] Bacteremia was detected in only 9 (35%) of the 26 children who received prophylaxis and in 20 (63%) of 32 children who did not ($p < 0.05$). In this study, viridans streptococci accounted for 37 percent of the blood isolates, strict anaerobes accounted for 26.5 percent, and a variety of organisms accounted for the remainder. The number of colony-forming units per milliliter of blood ranged from 2 to 12. Even within a single colony-forming unit, more than one bacterial species sometimes was found after subculture.

Although these two studies were dissimilar in the diversity of organisms isolated, both indicated that viridans streptococci are the organisms most likely to invade the blood after trauma to the oral cavity. Also reflecting the predominance of these organisms in oral and salivary flora, bacteremia with viridans streptococci occurs commonly during orthodontic banding[84] and dilation of esophageal strictures.[296]

The ability of viridans streptococci to bind to oral mucosa, tooth surfaces, and dental plaque via interaction of specific microbial and host "receptors" accounts for the preferential colonization of the oral cavity by these organisms.[273] This interaction also helps explain localization of the various viridans streptococcal species to distinct anatomic sites, as well as the involvement of ontologic factors in colonization. The precise nature of bacterial adherence to the oral mucosa is not defined but appears to involve streptococcal lipoteichoic acid.[118] Through release of modulin protein I/II, viridans streptococci induce the expression of adhesion molecules such as E-selectin and intercellular (ICAM-1) and vascular cell (VCAM-1) adhesion molecules on endothelial cells, promote transendothelial migration of neutrophils in vitro, and induce release of cytokines in epithelial (interleukin-6 [IL-6]) and endothelial cells (IL-6 and IL-8).[277,278] The host's immunologic status also may be an important determinant of adherence and subsequent invasion. For example, immunocompetent persons produce secretory IgA to *S. mutans*,[11] and such antibody is capable of preventing caries.[169] Viridans streptococci within the biofilm present in dental plaque are at least 500 times more resistant to antibiotic treatment than predicted on the basis of their susceptibility in culture medium; therefore, this finding suggests that antibiotic treatment cannot eradicate viridans streptococci from dental plaque, even temporarily.[140]

At the University of Texas M. D. Anderson Cancer Center in Houston, the incidence of viridans streptococcal bacteremia increased extraordinarily between 1972 and 1989, from 1 to 47 cases per 10,000 admissions.[75] Analysis of risk factors associated with viridans streptococcal bacteremia indicated that prophylactic administration of trimethoprim-sulfamethoxazole (TMP-SMX) or a fluoroquinolone, profound neutropenia, and the administration of antacids or histamine type 2 receptor antagonists each significantly predisposed patients to the development of bacteremia.[75] Presumably, administration of the implicated antibiotics and antacids favored the overgrowth of viridans streptococci and their proliferation throughout the gastrointestinal tract, which in turn would favor the development of viridans streptococcal bacteremia in an immunocompromised host, especially if the mucosal barrier was disrupted by cytotoxic

chemotherapy and the host was neutropenic. Of note, administration of cytarabine (cytosine arabinoside or ara-C) was not associated with viridans streptococcal sepsis in this study despite being identified as a major risk factor in many other studies.[28,29,39,67,123,157,167,205]

The ability to adhere to damaged cardiac valves and vegetations is a principal factor in the predominance of viridans streptococcal endocarditis. Strains of viridans streptococci carried by healthy children adhered less well to buccal and endocardial cells than did disease-producing strains isolated from children with endocarditis.[229,230] Lipoteichoic acid is thought to help mediate adhesion of viridans streptococci to endocardium, and penicillin prophylaxis may be effective in part because of its reduction of lipoteichoic acid on the bacterial cell surface.[148]

The ability of antibiotics to alter the surface properties of bacteria, even when the bacteria are resistant to the bactericidal action of the drug, may be an important determinant in the effectiveness of prophylactic antibiotics.[148,236] In the host, fibronectin is an important determinant of binding of viridans streptococci to damaged endothelium. Viridans streptococci do not bind to soluble fibronectin, but a reactive domain becomes available for binding when the fibronectin molecule is immobilized, as is the case in endocarditis.[147] Mutant viridans streptococci that cannot bind to fibronectin were significantly less virulent in an animal model of endocarditis.[147]

The ability of viridans streptococci to induce platelet aggregation also may be involved in the pathogenesis of endocarditis.[90,154] In viridans streptococci–challenged, anticoagulated rabbits, only microscopic vegetations developed despite fulminant sepsis. In contrast, viridans streptococci–challenged, non-anticoagulated animals tended to have large vegetations and a subacute course.[121] These findings are concordant with those of a separate study in which viridans streptococci–challenged thrombocytopenic rabbits had a greater density of bacteria within vegetations than did nonthrombocytopenic control animals; these results suggest that platelets limit progression of the disease.[250] Surprisingly, neutropenia appears to have little effect on susceptibility to endocarditis in animal models but affects containment of the infection.[165,166]

In neutropenic patients with cancer and in patients who have received bone marrow transplants, viridans streptococci cause septic shock and adult respiratory distress syndrome (ARDS). Viridans streptococci also induce nephritis.[5,259] In these circumstances, little is known about the mechanisms involved. Viridans streptococci produce no endotoxin, and specific exotoxins have not been identified. Nonetheless, products of these organisms can activate complement[173] and induce the production of tumor necrosis factor-α (TNF-α) and TNF-β; IL-1, IL-2, IL-6, and IL-8; interferon-γ; and nitric oxide.[18,80,112,161,182,240,242,253] Strains isolated from patients with sepsis were found to be more active in inducing TNF-β and IL-8 production than were colonizing strains isolated from healthy subjects.[243] In a study of two neutropenic patients with fatal viridans streptococcal sepsis, high blood levels of IL-6 were detected, especially late in the course, whereas IL-1 and TNF-α blood levels were not remarkable.[78] Viridans streptococcal lipoteichoic acid induces cytokine and nitric oxide production in vitro,[80,173] but the clinical significance of these observations is not known. In contrast to group A streptococci isolated from patients with septic shock, viridans streptococci isolated from the blood of pediatric cancer patients with septic shock do not express superantigens in vitro.[180] Thus, intravenous immunoglobulin, which has been suggested as an adjuvant therapy for group A streptococcal shock, may not be effective in patients with viridans streptococcal sepsis.

CLINICAL MANIFESTATIONS

The viridans streptococcal species are a diverse group of bacteria, and consequently, a variety of clinical manifestations are associated with the infections that they cause. Typically, the viridans streptococci cause nonpyogenic infections such as bacteremia and endocarditis, whereas the *S. milleri* group, also referred to as the *Streptococcus intermedius* group, tends to cause invasive pyogenic infections, including bone infections, brain abscesses, appendicitis, and pulmonary and abdominal abscesses.[176]

SEPSIS IN IMMUNOCOMPROMISED HOSTS

For obscure reasons, during the past 2 or 3 decades the relative incidence of gram-positive bacterial infections, especially viridans streptococcal infection, has increased in immunocompromised hosts. In 1978, viridans streptococci first were perceived as an important cause of sepsis in neutropenic patients with cancer when 29 episodes in adults and children at the National Cancer Institute[192] and 6 episodes in children at the M. D. Anderson Cancer Center[117] were reported. Before these reports, the significance of blood isolates of viridans streptococci in this setting generally was not appreciated. The fact that no deaths occurred in the original National Cancer Institute series or in a subsequent series from that center[216] suggested that viridans streptococci produce a benign bacteremia similar to that seen with coagulase-negative staphylococci. In contrast, three of the six children at M. D. Anderson died. Several other centers in Europe and North America have reported fulminant, sometimes fatal viridans streptococcal sepsis in patients with cancer and in those who have received transplants.* Overall, the death rate associated with viridans streptococcal sepsis has ranged from 0 to 50 percent, with most centers reporting mortality rates of approximately 10 percent. In some centers, viridans streptococci are the most common cause of fatal sepsis.[21,28,105] The incidence of viridans streptococcal sepsis appears to be higher in children than in adults.[160,248]

The oral cavity is the most common portal of entry in immunocompromised hosts. Catheter-related viridans streptococcal bacteremia is an unusual occurrence. However, because administration of antacid is a risk factor,[75] the lower gastrointestinal tract probably is a portal of entry in some patients. Several factors predispose patients to the development of viridans streptococcal sepsis. Profound neutropenia clearly is a predisposing factor,[28,75] although viridans streptococcal bacteremia occasionally develops in patients with cancer and absolute neutrophil counts greater than 1000 cells/mm^3. Mucositis, especially oral mucositis, is a definitive risk factor.[28,29,75,105,157,167] Cytarabine appears to be a risk factor even beyond its predisposition to produce clinically evident mucositis,[28,29,39,67,79,123,157,167,205] although at least one study has not found this association.[99] The use of prophylactic TMP-SMX or quinolones also is an important risk factor.[28,29,49,75,105,188] The observation that the administration of acyclovir may decrease the incidence of viridans streptococcal bacteremia in transplant patients suggests that herpes simplex virus infection may be a risk factor as well.[206] Allogeneic bone marrow transplantation likewise has been associated with an increased risk for the development of viridans streptococcal sepsis, with a greater than fourfold increase in the mortality rate.[157] An association between the development of viridans streptococcal sepsis and menstruation has been noted.[75]

The hallmark clinical feature of viridans streptococcal sepsis in an immunocompromised host is fever that typically is high, occurs in the presence of neutropenia and mucositis, and frequently lasts for several days after viable organisms are cleared from the blood. Most patients recover uneventfully. However, fulminant septic shock may occur. Shock may appear early,

*See references 10, 13, 21, 28, 29, 39, 50, 52, 75, 105, 107, 114, 141, 157, 160, 188, 203, 205, 235, 241, 248, 281.

although it often is delayed for 2 or 3 days after the onset of sepsis, and it occurs despite prompt sterilization of blood by effective antibiotics.[248] ARDS frequently occurs in severe cases, usually 2 or 3 days after the initial bacteremia.[10,75,120,257] Focal complications, including pneumonia and meningitis, are uncommon occurrences. Rash and palmar desquamation may be present but are not common manifestations.[75] For unexplained reasons, the incidence of aspergillosis is increased after the development of viridans streptococcal sepsis in children with cancer.[181]

Several studies have implicated *S. mitis* as a more pathogenic species of viridans streptococci with a predilection to cause shock and ARDS in patients with cancer,[10,29,50,71,111,163,248,257] but other studies have not found a clear relationship between clinical features and species.[75] *S. mitis* isolated from cancer patients with sepsis also has been found to be more resistant to antibiotics than other species of viridans streptococci isolated from the same patient population are.[111]

NEONATAL SEPSIS, MENINGITIS, AND OTHER INFECTIONS

Viridans streptococci are normal inhabitants of the female genital tract and are a common cause of chorioamnionitis and subsequent abortion,[9] as well as a frequent cause of neonatal sepsis and meningitis.[1,25,34,94,145,174,284] Viridans streptococci ordinarily do not colonize newborns' skin and should not be dismissed as contaminants when isolated from normally sterile sites.[1] In some newborn centers, the incidence of viridans streptococcal bacteremia and meningitis has approached or exceeded that attributable to group B streptococci, although viridans streptococcal infections tend to be less severe.[34,174] *Streptococcus oralis* (*S. mitis*) caused more than half of the cases in one study.[284] The portal of entry of the organism generally is unknown in this setting, but a fetal scalp electrode was implicated in one case.[95] Unusual manifestations in newborns include pharyngitis and epiglottitis,[31] endocarditis,[164] and conjunctivitis.[138]

ENDOCARDITIS

Viridans streptococci are a common cause of endocarditis at all ages because of the organism's ability to adhere to diseased endocardium and its frequent implication in bacteremia during dental procedures and routine mouth care. A recent study at a teaching hospital in Finland found that starting in 1995, *S. aureus* became more prevalent than viridans streptococci as a cause of endocarditis[113]; however, a study from Minnesota found no significant change in the etiology of endocarditis from 1970 to 2000, with viridans streptococci being the most common cause throughout.[263] Viridans streptococci tend to cause subacute endocarditis; blood cultures may be positive only intermittently. *S. sanguis* and *S. mitis* are the species identified most commonly.[68,201,207,251,286] Complications of viridans streptococcal endocarditis include septic pulmonary emboli, congestive heart failure, pericarditis, myocardial abscess, meningitis, osteomyelitis, and glomerulonephritis.[139,201] The shock and ARDS that develop in immunocompromised patients do not occur in immunocompetent patients with endocarditis.

PNEUMONIA

Pulmonary infiltrates frequently complicate viridans streptococcal sepsis in neutropenic hosts. In most cases, these infiltrates represent ARDS, not primary pneumonia. However, several cases of primary viridans streptococcal pneumonia that developed in previously healthy persons have been reported.[96,104,155,177,198,226] In some cases the diagnosis was supported by multiple isolates of viridans streptococci obtained from blood in the absence of endocarditis. The incidence of viridans streptococcal pneumonia may be underestimated significantly because tracheal isolates of viridans streptococci usually are discounted as contaminants and tracheal isolates probably do represent contamination of the specimen with oral flora in many cases.[213] Given the increasing incidence of viridans streptococcal infection and the escalating prevalence of antibiotic resistance among these organisms, clinicians should consider viridans streptococci as a potential cause of pneumonia when they are isolated in the absence of other pathogens.

OSTEOMYELITIS AND SEPTIC ARTHRITIS

Viridans streptococci are unusual causes of osteomyelitis and septic arthritis. Extension of an oral infection into the mandible or maxilla is the most common circumstance in which viridans streptococci cause osteomyelitis,[185] but vertebral osteomyelitis caused by these organisms has been described on several occasions.[2,38,62,217,271,282] Infection of the long bones[204] and septic arthritis[14] occur infrequently.

CARIES

Although caries was recognized as an infectious disease in 1890 by workers trained in Robert Koch's laboratory, its infectious nature still is not accepted universally.[8,12,72] Evidence that *S. mutans* is the major cause of caries in children and adults alike is substantial,[8,12,32,233,258,267,274] but other viridans streptococci and *Actinomyces* spp. also have cariogenic potential.[233,274] *S. mutans*, which colonizes the oral cavity only after the eruption of teeth, has a predilection for the dental surfaces, metabolizes sucrose, and produces a strong acid that weakens the mineral matrix of teeth and allows the organisms to penetrate the structure of the teeth.[44,233] Fluoridation of the water supply has been credited with strengthening tooth enamel, thereby fostering resistance to the harsh acids produced by *S. mutans*.[233] Fluoride has potent antibacterial action against *S. mutans*, particularly at low pH.[44,276] Thus, fluoridation of water supplies may represent, albeit in a unique form, the most widespread and successful use of antibacterial prophylaxis. Topical treatments also provide protection against the cariogenic actions of *S. mutans* and in some circumstances depend on the antibacterial action of fluoride.[116,262,272,294] Short courses of oral antibiotics can reduce colonization with *S. mutans* substantially and may be an important adjunct to the treatment of caries.[247] Specially designed culture systems are available to detect the presence and measure the concentration of *S. mutans* in plaque and thus permit the effects of therapy to be monitored.[32,283] Because the development of cavities typically requires a few years of infection, opportunity to interrupt the pathogenesis of this disease is ample.[8]

ABSCESSES AND OTHER INFECTIONS

The suppurative infections produced by viridans streptococci typically are caused by the *S. milleri* group: *Streptococcus anginosus*, *Streptococcus constellatus*, and *S. intermedius*. Like *S. aureus*, members of this group resist killing by polymorphonuclear leukocytes and stimulate less chemotaxis than other viridans streptococci do.[280] Because *S. milleri* bacteria inhabit the upper respiratory tract and the gastrointestinal tract and are relatively invasive, these organisms cause sinusitis, otitis media, meningitis, and abdominal abscesses and often are present in brain abscesses.[24,53,77,170,172,176,224] *S. milleri* group organisms may infect the brain via a hematogenous route that originates in the oral

cavity or intestinal tract or by direct invasion through the upper respiratory tract. Sepsis in non-neutropenic patients occurs uncommonly, usually in association with an intra-abdominal source.[151,224]

Among other unusual infections caused by viridans streptococci was a large outbreak of pharyngitis caused by *S. mitis* accompanied by a toxic shock–like syndrome in half of the cases.[150] Meningitis resulting from both hematogenous and direct spread has been observed in healthy adults.[149] Iatrogenic meningitis caused by contamination with oral viridans streptococci may complicate lumbar puncture or other central nervous system procedures.[82,228,291] Lung abscesses caused by viridans streptococci may result from the aspiration of saliva.[128,198] Empyema and mediastinitis are other reported thoracic infections associated with viridans streptococci.[19,128] Myositis complicated by rhabdomyolysis in children with leukemia has been reported.[225] Viridans streptococci also are found occasionally in liver abscesses,[16,91,100] peritonitis,[23] and appendicitis.[193]

DIAGNOSIS

Infections caused by viridans streptococci cannot be distinguished clinically from infections caused by other gram-positive and gram-negative bacteria. Collection of adequate culture specimens is essential for establishing the diagnosis. Viridans streptococcal infections typically are diagnosed by culture of blood or other normally sterile tissue. The organisms may be present in low concentration. A volume of 30 mL of blood has been suggested as the optimal volume for culture in an adult-sized patient.[232] The addition of agents that neutralize the antibacterial effects of fresh blood, such as sodium polyanethole sulfonate, significantly improves the yield of blood cultures.[231] Chemotherapeutic agents may interfere with the detection of viridans streptococci in blood.[187]

Viridans streptococci normally are not part of the skin flora and ordinarily should not be considered contaminants. Viridans streptococci have been reported to cross-react with *S. pneumoniae* Omniserum, and this cross-reaction has the potential to lead to false-positive results of the Omniserum test.[120]

ANTIBIOTIC SUSCEPTIBILITY

In the past, viridans streptococci have been considered penicillin-sensitive. Today, penicillin-resistant and penicillin-tolerant viridans streptococci are found worldwide as causes of sepsis, endocarditis, meningitis, and other infections, including conjunctivitis of the newborn.* Penicillin resistance occurs commonly, particularly in patients receiving long-term penicillin therapy,[7,26,184,246,249] although even short courses of antibiotics may predispose patients to colonization with resistant viridans streptococci.[83,101,171] Infection with penicillin-resistant viridans streptococci is associated with a higher mortality rate than infection with penicillin-susceptible strains is.[64,244] Antibiotic resistance may develop in all species of viridans streptococci, although *S. mutans* rarely exhibits resistance.[127]

Resistance to a variety of antibiotic classes has developed during the past 2 decades,[196] although resistance still is an uncommon finding in patients who live in the community and have not been treated recently with antibiotics.[292] Resistance to cephalosporins is widespread, with the general pattern of susceptibility being the following: cefotaxime and ceftriaxone usually are more active than cefepime and cefuroxime, both of which are more active than ceftazidime and cephalexin.[65,156,190,287] Previous cephalosporin therapy is a risk factor for cephalosporin resistance, an observation with particular relevance for patients with cancer.[36,133] Resistance to fluoroquinolones, especially ciprofloxacin and ofloxacin, is a common finding.[46,60,63,134,227,290] Levofloxacin has better activity against viridans streptococci than the older fluoroquinolones do, and the newer agents garenoxacin, gatifloxacin, and moxifloxacin have enhanced activity against most gram-positive pathogens, including viridans streptococci.[208-210] However, resistance develops rapidly when patients receive quinolones prophylactically—levofloxacin, gatifloxacin, and moxifloxacin included.[197,260] At the Mayo Clinic in Rochester, Minnesota, viridans streptococcal sepsis developed in 6 (16%) of 37 transplant patients receiving levofloxacin prophylaxis (3 experienced shock); blood isolates were resistant to levofloxacin, as well as the newer quinolones gatifloxacin and moxifloxacin.[202] Resistance was associated with mutations in the quinolone resistance-determining region of GyrA or ParC. Resistance of viridans streptococci to aminoglycosides,[131] tetracycline,[60,65,290] TMP-SMX,[60,63,65,290] clindamycin,[63,266,290] erythromycin,[33,60,63,65,290] other macrolide antibiotics,[6] and vancomycin[237] also has been reported.

Resistance of viridans streptococci to penicillin appears to involve chromosomally mediated alterations in the organisms' PBPs.[200,295] Initially, researchers suspected that genes conferring penicillin resistance might have been acquired from *S. pneumoniae*.[70] Subsequent studies, however, indicated that penicillin resistance may have evolved first in *S. mitis* and that *S. pneumoniae* acquired genes mediating penicillin resistance from this and other closely related viridans streptococcal species.[45,69,195] Quinolone resistance determinants also are transmitted efficiently between viridans streptococci and *S. pneumoniae*,[126] and the *mef*(E) gene that confers resistance to macrolides is transmitted readily from viridans streptococci to *S. pyogenes*.[129]

The clinical impact of the development of penicillin resistance among viridans streptococci has been far-reaching. The emergence of penicillin-resistant viridans streptococci incidentally may be encouraging the development of vancomycin-resistant enterococci because of the increased use of vancomycin to prevent and treat viridans streptococcal infection in patients with cancer.

Overall, vancomycin is the antibiotic with the most reliable activity against viridans streptococci. Teicoplanin also has been used successfully to treat patients with endocarditis caused by viridans streptococci.[288] Daptomycin, dalbavancin, quinupristin-dalfopristin, and linezolid are active in vitro against most clinical isolates of viridans streptococci.[137,223,285]

TREATMENT

Empiric antibiotic therapy for viridans streptococci should be based on the local pattern of antibiotic susceptibility among recent clinical isolates. Antimicrobial susceptibility testing of viridans streptococcal isolates is necessary. Limited data indicate that antibiotic susceptibility testing performed with the E-test correlates well with agar dilution susceptibility testing.[214] Although vancomycin-resistant clinical isolates currently are very rare findings, inclusion of vancomycin in susceptibility testing is advisable. For infections other than endocarditis and meningitis, single-antibiotic therapy usually is preferred. An exception is infection in neutropenic patients with cancer because restricting antibiotic therapy to drugs active against gram-positive bacteria exclusively may predispose these patients to the development of gram-negative bacterial infections.[191] Some investigators have advocated reserving vancomycin for neutropenic patients with shock or ARDS,[265] whereas others have advocated inclusion of vancomycin in the initial empiric therapy for patients with fever and neutropenia.[76,235] Viridans streptococcal sepsis may occur in neutropenic

*See references 30, 35, 74, 87, 103, 119, 138, 144, 194, 200.

patients despite ongoing antibiotic therapy with β-lactam agents to which the infecting organisms are susceptible in vitro[235]; the fact that this phenomenon has not been observed with vancomycin therapy supports the use of this antibiotic for the treatment of viridans streptococcal sepsis in neutropenic patients.

Combination therapy often is advocated for the treatment of viridans streptococcal endocarditis[27,92,159,279] and may be considered for the treatment of meningitis, especially when the infecting organism is tolerant of penicillin.[81] Combinations of either penicillins and aminoglycosides or vancomycin and aminoglycosides are used most commonly. Penicillin and vancomycin are thought to increase uptake of aminoglycosides, thereby leading to synergistic bactericidal activity.[293] However, a recent meta-analysis of five clinical trials failed to identify any overall improvement in the outcome of patients who had endocarditis and were treated with β-lactam and aminoglycoside combination therapy versus β-lactam monotherapy.[86] Vancomycin monotherapy has been used to treat patients with penicillin-resistant viridans streptococcal endocarditis successfully,[122] and endocarditis also has been treated successfully with linezolid[179] or ceftriaxone[234] monotherapy.

Frequent dosing of antibiotics generally has been recommended; however, viridans streptococci exposed to penicillin or cephalosporin plus aminoglycoside combinations appear to be susceptible to a post-antibiotic effect.[40,135,142] Consequently, longer dosing intervals may be satisfactory, but data are insufficient currently to support a recommendation. Viridans streptococcal endocarditis usually is treated for 4 to 6 weeks; the duration of therapy for infections at other sites has not been studied but generally can be guided by site-specific practice and individual clinical response.

In the treatment of endocarditis, penetration of antibiotics into the fibrin vegetation may be impeded markedly. Viridans streptococci produce an exopolysaccharide composed predominantly of dextran, which may limit penetration. Experimental studies indicate that the degree of exopolysaccharide production by viridans streptococcal strains affects the success rate of antimicrobial therapy.[199] In accord with this observation, administration of dextranase to animals with experimental viridans streptococcal endocarditis enhances antibiotic efficacy.[168] In the future, such adjuvant therapies designed to reduce the size or density of valvular vegetations may offer promise for patients not helped by conventional antibiotic therapy for endocarditis.

Another setting in which adjuvant therapy may be considered is viridans streptococcal sepsis in neutropenic patients who have received cytarabine chemotherapy. One uncontrolled trial suggested that the early addition of high doses of corticosteroids to the antimicrobial therapeutic regimen may reduce the incidence of associated ARDS and death.[66] However, data are insufficient to recommend this approach routinely.

PREVENTION

Attempts to prevent viridans streptococcal infection have focused on three distinct settings: prevention of caries, prevention of endocarditis, and prevention of sepsis in neutropenic patients with cancer. Efforts have been successful in the former two settings. However, the emergence of penicillin-resistant viridans streptococci and concern about the possible emergence of vancomycin resistance highlight the need for new approaches to prevent infection with these ubiquitous organisms. In developing such methods, investigators should not forget that the resistance to colonization provided by viridans streptococci can protect the host from more virulent pathogens (see "Epidemiology").

The incidence of caries in the United States has been reduced sharply by fluoridation of water supplies, inclusion of fluoride in toothpaste, and modification of diet (e.g., use of sugar substitutes). Fluoride acts as an antibacterial agent that also strengthens resistance of the teeth to invasion by bacteria. The use of dental varnishes, gels, and rinses that contain fluoride or other antibacterial agents such as chlorhexidine or vancomycin may be beneficial in selected cases.[88,130,158,178]

The American Heart Association has led a successful effort to prevent the development of endocarditis by systemic antibiotic prophylaxis of patients with known endocardial defects who are undergoing dental procedures.[58] These efforts are aimed especially at preventing viridans streptococcal endocarditis, and penicillin is the antibiotic used most commonly. The mechanism or mechanisms by which antibiotic prophylaxis prevents endocarditis are not understood completely. In animals, endocarditis can be prevented by the administration of bacteriostatic antibiotics and by maintenance of serum levels of bactericidal antibiotics that are well below the minimal inhibitory concentration for the colonizing viridans streptococci.[102] Vancomycin has been observed to prevent the development of vancomycin-tolerant *S. sanguis* endocarditis in experimentally challenged animals without reducing the incidence or level of bacteremia; thus, antibiotics may prevent endocarditis by reducing bacterial adherence to endocardium.[20] This hypothesis is supported by a study in which bacteremia, in some cases with antibiotic-resistant organisms, developed in 21 percent of children receiving antibiotic prophylaxis, but endocarditis rarely occurred.[115] However, studies in animals have indicated that the probability of preventing endocarditis is correlated with the antibiotic susceptibility of the challenging streptococcal strains.[115]

Prophylaxis should be targeted carefully[264] and administered immediately before dental procedures are initiated. Increased numbers of antibiotic-resistant viridans streptococci can be detected within 6 hours of administration of antibiotic treatment, and they persist for 9 days or longer.[143] Experimental studies of the prevention of endocarditis by the administration of antibiotics *after* challenge with bacterial inocula have yielded inconsistent results,[22,125,152] and the clinical utility of this approach is not known. Topical treatment with vancomycin or chlorhexidine has been advocated as an adjuvant to prevent the development of endocarditis, but the efficacy of this approach has not been proved.[252,289]

In recent years, viridans streptococcal infections have become a major problem in neutropenic patients with cancer and in recipients of bone marrow transplants. Because penicillin-resistant viridans streptococci are widespread, some cancer centers include vancomycin in the initial empiric antibiotic regimen for neutropenic patients with unexplained fever.[235] In addition, despite concern about the possibility of inducing vancomycin-resistant bacterial strains, physicians managing bone marrow transplant units are administering intravenous vancomycin prophylactically to high-risk patients in an effort to prevent the development of viridans streptococcal sepsis; the results of an observational cohort study support this practice.[124]

Two noncontrolled trials of oral vancomycin paste[15] or vancomycin mouthwash[37] in children who were receiving cytotoxic chemotherapy suggested efficacy in the prevention of viridans streptococcal infection. However, increased colonization and infection with vancomycin-resistant enterococci are a predictable consequence of increased vancomycin use, which has prompted the Centers for Disease Control and Prevention (CDC) to recommend that empiric vancomycin therapy be avoided when feasible and has led investigators to explore alternatives to the empiric or prophylactic use of vancomycin.

In a comparative trial, penicillin prophylaxis was superior to TMP-SMX prophylaxis in preventing viridans streptococcal infections in patients with cancer despite extensive colonization with penicillin-resistant streptococci.[109] In other studies, oral administration of penicillin or roxithromycin, a macrolide antibiotic, also appeared to reduce the incidence of viridans strepto-

coccal infection in patients with cancer in comparison to historical controls.[61,215,244] In contrast, in a study of prophylactic administration of ampicillin to patients receiving autologous bone marrow transplants, no reduction in the incidence of viridans streptococcal sepsis occurred, whereas the incidence of penicillin resistance increased.[26] Increased penicillin resistance associated with penicillin prophylaxis has been noted in other prophylactic trials as well.[244] The CDC does not recommend the routine use of penicillin prophylaxis in patients receiving bone marrow transplants.[108]

Levofloxacin prophylaxis currently is used commonly to prevent bacterial infections in adults with cancer, but viridans streptococci rapidly develop quinolone resistance, a point of concern.[261] Innovative prophylactic methods and carefully designed clinical trials are needed to identify effective prophylactic measures, especially for patient cohorts at high risk such as children receiving chemotherapy for acute myeloid leukemia.

CHAPTER 96

Pneumococcal Infections

Ronald Dagan ✪ David Greenberg ✪ Michael R. Jacobs ✪ Brandon Lane Phillips

The pneumococcus (*Streptococcus pneumoniae*) continues to be a leading cause of morbidity and mortality in persons of all ages. Most children experience some form of pneumococcal infection (e.g., otitis media or pneumonia), and sepsis or meningitis develops in some cases. Despite more than a century of research, many of the aspects of pneumococcal disease remain obscure. The continued frequency and severity of pneumococcal disease, coupled with the knowledge that antimicrobial therapy invariably does not prevent illness or death, and the high and still increasing prevalence of strains of pneumococci resistant to antimicrobial agents serve to underscore the need for better understanding of pneumococcal infections. Currently, attention is concentrated on efforts to prevent these infections by the development and use of appropriate vaccines.

HISTORY

Pasteur and Sternberg, working independently in 1880 and 1881, discovered the pneumococcus. Pasteur called the organism *microbe septicémique de la salive*, and Sternberg called it *Micrococcus pasteri*. Each researcher recovered pneumococci from rabbits injected with human saliva. Friedlander demonstrated pneumococci in tissue from humans with pneumonia in 1882 and, in the following year, found them in most cases of acute pneumonia. Friedlander described both the characteristic capsule and colonial morphologic features of pneumococci and, in 1884, recovered pneumococci from the blood of patients with pneumonia for the first time. During the next few years, pneumococci were found in virtually all types of infection, including meningitis and otitis media. By 1890, researchers had established the pneumococcus as the most common cause of acute pneumonia, and, hence, the term *pneumococcus* emerged. In addition, the pneumococcus became recognized as a principal cause of meningitis and other serious infections.

During the next decade, researchers immunized animals with cell-free filtrates of pneumococci, demonstrated that serum from immune animals could protect against experimental pneumococcal infection, deduced the role of immunity in promoting phagocytosis, and noted agglutination of pneumococci by serum from immune animals. In 1897, Pane treated humans suffering from pneumonia with serum from such animals. By 1900, researchers had laid the foundation for immunotherapy for pneumococcal pneumonia, the only effective treatment until the advent of chemotherapy.

During the next few years, investigators noted that agglutination of pneumococci appeared to depend on the strain isolated. In 1910, Neufeld and Haendel classified pneumococci into several discrete serotypes on the basis of the appearance of capsular swelling (the quellung reaction). Only strains exposed to homologous serum showed capsular swelling. Their work made possible all subsequent epidemiologic investigations of pneumococcal infection, immunotherapy with type-specific serum, and the development of vaccines.

After these discoveries were made, researchers concentrated on several aspects of pneumococcal disease, including identification of additional serotypes and their roles in disease, production and clinical use of antisera, and development of pneumococcal vaccines.

In 1926, the pneumococcus was called *Diplococcus pneumoniae* because it usually appears in pairs. In 1974, it was renamed *Streptococcus pneumoniae* because it forms long chains when grown in liquid medium. The original classification of pneumococci was limited to types I, II, III, and IV (others). Currently, 90 serotypes have been identified, and certain serotypes have proved to be more virulent than others, with virulence depending, to some extent, on the species of animal infected.

The use of antisera for the treatment of pneumococcal pneumonia proved strikingly effective when type-specific sera were administered. As early as 1913, Cole and associates showed that treatment with antisera lowered fatality rates from 25 to 30 percent to 10.5 percent. In addition to allergic reactions, difficulties associated with this treatment included the necessity of identifying the causative serotype, the need for the earliest possible administration of antisera, and the availability of antisera to only types I, II, and III. White compared the efficacy of early antisera therapy and found that 403 of 1614 (25.0%) who did not receive any therapy died, 32 of 377 (8.5%) who received therapy within 3 days of onset died, and 24 of 127 (18.9%) who received therapy 4 or more days after onset died. Unfortunately, therapy with antisera had no beneficial effect on other pneumococcal infections such as meningitis and endocarditis. Despite these

drawbacks, the use of antisera soon became widespread. The advent of chemotherapy—first sulfa compounds, then penicillin—was followed by a precipitous decline in the use of antisera. Antimicrobial agents killed or inhibited pneumococci, regardless of serotype, and cured patients with previously incurable localized infections.[778]

Coincident with research resulting in the general use of antisera came research into the efficacy of pneumococcal vaccines. Proof of efficacy lagged, and indisputable evidence of protection induced by vaccination was not available until 1945. The ability of pneumococci to cause epidemic pneumococcal pneumonia in young men crowded into army camps or gold mines allowed large-scale trials to be performed. Highlights of the development of effective vaccines include the trial of Wright and associates[789] in South Africa beginning in 1911. Using a vaccine made with whole, killed pneumococci, this trial produced inconclusive results. Many trials followed, with some showing trends toward protection. In 1923, Heidelberger and Avery[317] published their classic article in which they stated that protective antibodies were reactive with surface capsular polysaccharides. In 1930, Francis and Tillett[238] showed capsular polysaccharides to be immunogenic for humans. Ekwurzel and colleagues[203] used a vaccine containing such polysaccharides during 1933 to 1937 and showed it to be effective. Smillie and associates used a preparation of serotype 1 polysaccharide to abort a hospital epidemic of pneumonia at State Hospital in Worcester, Massachusetts.[694]

Although many of these studies suggested that specific pneumococcal polysaccharide antigens could confer protection against severe pneumococcal infection, not until 1945, in a trial performed on U.S. Army and Air Force recruits, were they finally proved by MacLeod and associates[485] to do so. This trial showed vaccination to be strikingly effective in preventing pneumococcal pneumonia caused by serotypes contained in the vaccine but not in preventing disease caused by other serotypes, thus showing serotype-specific protection.

Regrettably, interest in vaccination waned rapidly with the general availability of penicillin, and manufacturers voluntarily withdrew their vaccines from the market. This unfortunate attitude persisted for the next 2 decades until the inability of chemotherapy to prevent many deaths from pneumococcal disease was recognized.[42] The rapid development and spread of antibiotic resistance among many clinically important strains further emphasized that prevention could be more effective than treatment for pneumococcal disease. Fortunately, a few farsighted individuals continued to maintain surveillance of the serotypes causing human disease, and their work allowed the reintroduction of pneumococcal vaccines. The current status of vaccines is discussed later in this chapter.

Interested readers should consult both White's *The Biology of Pneumococcus* and Heffron's *Pneumonia, with Special Reference to Pneumococcus Lobar Pneumonia*, as well as a comprehensive review by Watson and colleagues, for a complete account of the long and fascinating history of this organism.[316,774,778]

THE ORGANISM, HOST DEFENSE MECHANISMS, AND PATHOGENESIS

STRUCTURE OF THE PNEUMOCOCCUS

Pneumococcal cells are surrounded by a trilamellar, lipopolysaccharide, cytoplasmic membrane that has two electron-dense bands, each 25 to 30 Å wide. A cell wall surrounding the plasma membrane has two bands—an inner 30- to 40-Å-wide band and an outer 60- to 80-Å-wide band. Numerous bridges connect the cell wall and the plasma membrane. The polysaccharide capsule covers the cell wall in encapsulated strains and is seen as a wider, less structured band.[735] A schematic representation of the major structural components and selected cell wall components is shown in Figure 96–1.

Cell Wall Structure

The predominant structural components of the pneumococcal cell wall are peptidoglycan, teichoic acid (TA), lipoteichoic acid (LTA), and several choline-bound proteins. Choline is a lipid that is an essential growth factor for *S. pneumoniae*.

PEPTIDOGLYCAN. Peptidoglycan, which accounts for approximately half of the cell wall mass, is a cell wall polymer

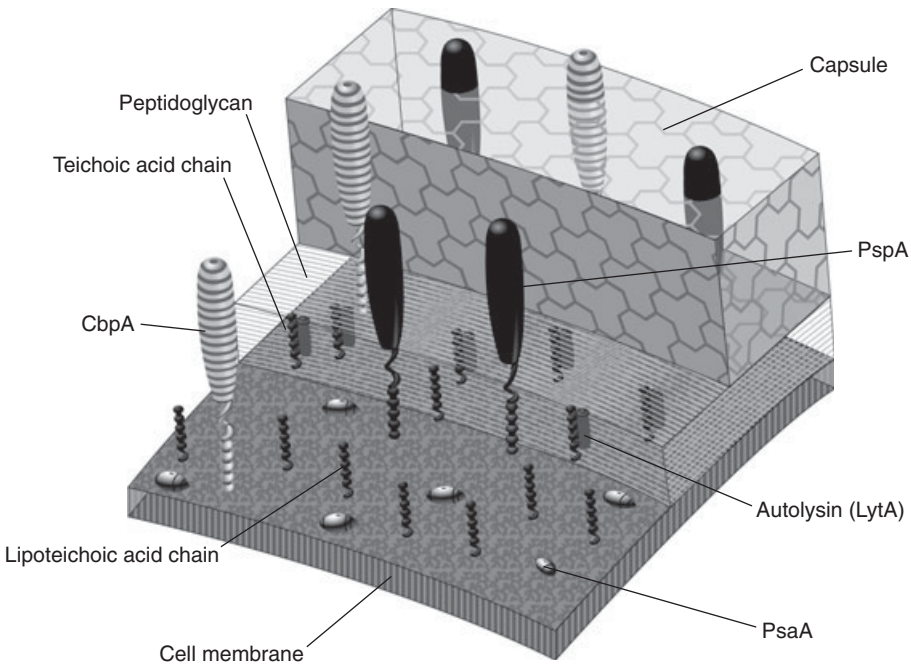

Figure 96–1 Schematic three-dimensional representation of the major structural components of the cell membrane, cell wall, and capsule of *Streptococcus pneumoniae*. The locations of selected major virulence factors of the organism are shown as well. Chains of lipoteichoic acid are attached to cell membrane glycolipid, whereas surface proteins, such as PspA and CbpA, in turn are attached to the lipoteichoic acid chains via phosphocholine links. Chains of teichoic acid are attached to the peptidoglycan layer via phosphodiester bonds. Autolysin (LytA) is attached to teichoic acid chains via phosphocholine links. PsaA is found on the outer surface of the cell membrane. *(Adapted from references 229, 349, 740. Copyright Michael R. Jacobs, used with permission.)*

linked by stem peptides to form a complex, three-dimensional structure.[670] Stem peptides are formed when transpeptidases (also known as *penicillin-binding proteins* [PBPs]) link pentapeptide chains into linear stem peptides in penicillin-susceptible strains.[670] However, in non–penicillin-susceptible strains, branched and other variant stem peptides are produced.

LIPOTEICHOIC ACID. LTA also is known as *pneumococcal Forssman* (*F*) *antigen*. The LTA of pneumococci possesses identical repeat and chain structures linked to a cell membrane glycolipid that anchors LTA to the cell.[229,230] Phosphocholine is attached to saccharide residues. PspA and other proteins (see later) also are attached to choline residues on LTA.

TEICHOIC ACID. TA, also known as *pneumococcal C polysaccharide*, has a chain structure similar to that of LTA, except that the saccharide differs. TA chains are attached to the cell wall peptidoglycan. Some phosphocholine residues of both LTA and TA are expressed on the cell wall surface, where they are thought to serve three functions: (1) activation of the pneumococcal autolysin (LytA) enzyme, which is responsible for the autolysis of pneumococci; (2) binding of the choline-binding domain of LytA to choline on TA, which may regulate the activity of LytA; and (3) a function associated with transformability (choline-deficient cells lack transformability).[683]

SURFACE PROTEINS. Pneumococci have several surface proteins, with the four most important being *pneumococcal surface protein A* (PspA), *pneumococcal surface adhesin A* (PsaA), *choline-binding protein A* (CbpA), and *hyaluronate lyase* (Hyl).

PspA is a cell wall protein with a molecular size of 67 to 99 kd that is bound to TA and LTA by phosphocholine links.[373] This protein extends through the cell wall and capsule to the surface of the organism.[794] PspA exists in various antigenic forms, and epitopes within one PspA molecule can recombine into different types.[97] However, PspA variants usually are sufficiently cross-reactive that immunization with one PspA serotype elicits immunity to other PspA serotypes.

PsaA is a 37-kd surface protein thought to be anchored to the cell membrane and associated with magnesium and zinc transport.[187] It appears to be a lipoprotein and is common to virtually all *S. pneumoniae* isolates.[606] Considerable variation in the amino acid sequences of PsaA from different strains has been detected.[570] The relationship of this protein to other cell wall components has not been determined.[721]

CbpA is a protein similar to PspA and has a mass of 75 kd. It is an adhesin involved in the adherence of pneumococci to cytokine-activated human cells.[632] Several other choline-binding proteins also have been identified.

Hyl is a hyaluronidase that results in breakdown of the hyaluronan and chondroitin sulfate present in the extracellular matrix of human tissues.[373] It is bound to peptidoglycan in the cell wall.

Capsule

The capsule of pneumococci consists of polysaccharides that vary in the make-up of monosaccharides, the sequence of monosaccharides in polysaccharides, the linkage of monosaccharides to each other, and the presence of nonsaccharide components.[732] Currently, 90 serotypes consisting of 25 individual serotypes and 65 serotypes grouped into 21 serogroups are known (see the section "Microbiology" later) (Table 96–1). Each serotype has a specific capsular structure, and serotypes within a serogroup often have the same oligosaccharide sequences linked differently. The capsular structure of many serotypes has been determined.[250] Several epidemic clones have been shown to have different serotypes, and extensive genetic changes involving the replacement of entire cassettes of genes related to capsule production are required for capsular switching to take place.[604]

Genetics and the Pneumococcal Genome

The pneumococcal genome has been mapped recently, and 90 to 95 percent of its DNA sequences are known. The genome has been estimated to be 2.0 to 2.1 megabases (Mb) in size, approximately half that of *Escherichia coli*.[51,192] The locations of more than 100 genes, including 20 tRNA synthetase and 20 ribosomal protein genes, have been mapped. Genes involved in cell wall synthesis also have been identified.

S. pneumoniae is a naturally transformable bacterium, which means that it is able to take up single-stranded DNA from its environment and incorporate this exogenous DNA into its genome. This process is known as *transformational recombination*.[521,703] Recombination is a powerful means of genome evolution and provides a great degree of genome flexibility to this organism. Transformation occurs only at high cell densities (10^5 to 10^8 colony-forming units per milliliter), and a peptide pheromone quorum-sensing signal called *activator* or *competence factor* is required.[602] This factor also is termed *competence-stimulating peptide*.

The genes associated with capsule synthesis have been characterized for several serotypes as well. The complete nucleotide sequence of 24 of these genes of several *S. pneumoniae* serotypes has been determined,[35,249] as has the genetic basis for the structural diversity of capsule polysaccharides within *S. pneumoniae* serogroups.[517,518] The abundance of transposable elements at the gene locus favors genetic variability of the capsule.[249]

VIRULENCE FACTORS

Animal models of pneumococcal infection have provided considerable insight into the pathogenesis of disease and the association of virulence factors with disease. However, the pneumococcus is primarily a human pathogen, and the host defenses of animal models can vary significantly from those in humans. For example, pneumococci adhere to human but not to rabbit polymeric immunoglobulin receptor (pIgR).[802] Additionally, virulence in mice varies considerably with the strain of pneumococcus: pneumococci belonging to serogroups 6, 14, 19, and 23 rarely are virulent in mice, whereas serotypes 1, 2, and 3 usually are virulent.[60,95,434] Virulence also may vary according to the mouse strain.[1,45,729] Some serotypes can be virulent to one species of animal but not to others. An example is serotype 19F, which rarely is virulent in mice[45] but is highly virulent in guinea pigs.[40] In addition, penicillin resistance appears to be linked to decreased virulence by virtue of the fact that isogenic mutants of a virulent, penicillin-susceptible strain were reduced significantly when transformed into a penicillin-resistant strain with an abnormal *pbp2x* gene.[614] Therefore, many animal models of pneumococcal virulence may not be representative of virulence in humans or representative of all pneumococcal serotypes or antimicrobial-resistant strains.

Although the polysaccharide capsule has been recognized as the major determinant of virulence, relatively little is known about the molecular basis of the pathogenesis of pneumococcal disease. A library of 1786 pneumococcal mutants created by insertion-duplication mutagenesis was analyzed for their ability to survive and replicate in murine models of pneumonia and bacteremia.[440] One hundred eighty-six mutant strains exhibited attenuated virulence; 56 of these strains were genetically characterized, and genomic DNA inserts were sequenced and subjected to database searches. Most of the insertions were in probable operons, but no pathogenicity islands were found. Forty-two novel virulence loci were identified. Five strains showed

mutations in genes involved in gene regulation, cation transport, or stress tolerance; the virulence of these strains was shown to be highly attenuated in a murine respiratory tract infection model. Additional experiments also suggest that induction of competence for genetic transformation has a role in virulence.[440] This approach has revealed several previously unrecognized genes required for virulence.

A similar genomic approach was used to look for genes coding for surface-localized proteins that could be targets for protective humoral immunity. By exploiting the whole genome sequence of *S. pneumoniae*, researchers found 130 open-reading frames encoding proteins with secretion motifs or similarity to predicted virulence factors.[787] Mice were immunized with 108 of these proteins, and 6 conferred protection against disseminated pneumococcal infection. Each of the six protective antigens showed broad strain distribution and immunogenicity in human infections. Some of these proteins have been identified as LytB, LytC, and a cell wall–anchored serine protease. Another genomic-based study used a genomic expression library of *S. pneumoniae* screened with convalescent-phase serum for immunoreactive proteins.[805] Six known and 17 unknown pneumococcal proteins were detected. Five of the known proteins, including PspA and SpsA (CbpA), were surface-located virulence factors, and 8 of the unknown proteins were putative membrane proteins. Use of these genomic approaches for the identification of novel microbial targets to elicit a protective immune response has been validated, and these new antigens may play roles in the development of improved vaccines against *S. pneumoniae*.

CAPSULE. The capsule is the major determinant of virulence in pneumococci. It prevents phagocytosis by polymorphonuclear leukocytes (PMNs) and macrophages, thereby allowing unrestricted extracellular multiplication of the organism. Because the pneumococcus has 90 antigenically distinct serotypes, production

of anticapsular antibody in response to one serotype provides protection against only that serotype or serogroup, whereas nonencapsulated strains are considerably less virulent.[527] The importance of the capsule as a virulence factor is emphasized by the fact that protection from pneumococcal infection can be achieved by capsular-specific antibodies. Despite the large number of additional virulence factors (see the following paragraphs), the capsule remains the single most important determinant of virulence in avoiding host defenses after the epithelial barriers have been breached. Other virulence factors are important in breaching host defenses such as epithelial barriers.

NEURAMINIDASES. Neuraminidases are enzymes that cleave terminal sialic acid residues from glycolipids, glycoproteins, and oligosaccharides on eukaryotic cell surfaces; such cleavage may unmask cell surface receptors for pneumococcal adhesins.[570] The neuraminidase NanA has been implicated in the ability of *S. pneumoniae* to colonize and persist in the nasopharynx and middle ear.[736] A second neuraminidase, NanB, has much weaker activity than NanA does but exhibits optimal activity at pH 5, whereas NanA is most active at pH 7.[570]

PNEUMOLYSIN. Pneumolysin is a 53-kd cytoplasmic protein produced by all pneumococci. It is essential for the initial binding to membrane cholesterol and the interaction leading to subsequent membrane damage.[46] Functions of pneumolysin include the following:

1. Pore formation in host epithelial cell membranes. Pneumolysin binds to cholesterol in host epithelial cell membranes, where oligomers of pneumolysin molecules assemble to form 35- to 45-nm pores in the cell membrane, which results in lysis of the targeted cell. Pneumolysin is, therefore, cytotoxic to epithelial cells, and it also slows ciliary beating of bronchial epithelial cells and disrupts the tight junctions between epithelial cells. In addition, pneumolysin disrupts alveolar epithelial cells and the alveolar-capillary boundary, thereby facilitating entry of pneumococci into the bloodstream and through the blood-brain barrier.[269,806]
2. Effects on phagocytic and immune cell function. Pneumolysin attracts neutrophils in the early phases of disease and lymphocytes at a later stage.
3. Direct activation of the complement system. Expression of pneumolysin by pneumococci reduces serum complement levels and serum opsonic activity.[11]
4. Promotion of nitric oxide (NO) production by macrophages. NO is produced by an inducible NO synthase (iNOS) during inflammation as an essential element of antimicrobial defense, but it also can contribute to host-induced tissue damage.[93]

SURFACE-LOCATED CHOLINE-BINDING PROTEINS. The virulence of members of the choline-binding protein (Cbp) family and two recently described cell wall hydrolases, LytB and LytC, has been characterized.[281] Cbp-, LytB-, and LytC-deficient mutants show significantly reduced colonization of the nasopharynx. The following proteins of the Cbp family and their virulence mechanisms have been described:

1. *PspA* is a serologically variable protein that has undergone extensive recombination.[332] It is thought to exert its virulence function in systemic infection by interfering with deposition of the complement component C3b onto pneumococci or by blocking recruitment of the alternative pathway, thereby reducing the effectiveness of complement receptor–mediated pathways of clearance.[739] PspA recently has been shown to bind to lactoferrin, an iron-sequestering glycoprotein found in mucosal secretions, when the level of free extracellular iron is not sufficient for the growth of pneumococci. This binding is thought to overcome the iron limitation at mucosal surfaces and might represent a potential virulence mechanism for colonization of mucosal surfaces.[303]
2. CbpA, or *SpsA*, is a surface protein adhesin that acts as a bridging element between pneumococci and host-cell glycoconjugates on cytokine-activated host cells.[304] This process is thought to be associated with change from nasopharyngeal colonization to invasion of epithelial and endothelial cells.[632] One mechanism by which this process occurs, wherein CbpA binds to the pIgR of human epithelial cells, has been described.[800] The pneumococcus co-opts the transcytosis machinery and gains entry into and across airway epithelial cells. This process is a novel example of a pathogen co-opting the transcytosis machinery to promote translocation across a mucosal barrier.[384]
3. *PsaA* is a surface protein that also is associated with virulence via adhesion to epithelial cells.[605]
4. *Pneumococcal histidine-containing protein A* (*PhpA*) is a 20-kd protein with putative proteolytic activity against the human complement component C3. PhpA is a potential candidate for use as a vaccine against systemic pneumococcal disease and otitis media.[802]
5. The *pneumococcal histidine triad* (*Pht*) proteins PhtA, PhtB, PhtD, and PhtE constitute a novel family of homologous surface proteins associated with virulence; they are also potential vaccine candidates.[7] Although antibodies targeting PhtA, PhtB, or PhtD are protective, the function of these proteins remains unknown. The number of histidine and tyrosine residues in these proteins suggests that they may be involved in metal or nucleoside binding.

PHASE VARIATION. Phase variation in the colonial opacity of *S. pneumoniae* has been implicated as a factor in bacterial adherence, colonization, and invasion.[776] On clear media, colonies can appear as opaque or translucent when viewed under magnification with oblique, transmitted light. All strains of *S. pneumoniae* are thought to be capable of phase variation. Opaque colonies are less likely to autolyze, contain less TA but more PspA in their cell walls, and colonize the nasopharynx poorly in animal models but are more virulent when inoculated into sterile sites. Conversely, translucent colonies are more likely to autolyze, contain more TA but less PspA in their cell walls, and colonize the nasopharynx well but are less virulent when inoculated into sterile sites. Translucent colonies become umbilicated as a result of autolysis, whereas opaque colonies remain domeshaped.

PHOSPHORYLCHOLINE ESTERASE. This enzyme has activity that removes phosphorylcholine residues from cell wall TA and LTA.[759] Inactivation of the gene encoding for the enzyme in pneumococcal strains caused a change in colony morphology from translucent (colonizing) to opaque (virulent) and a striking increase in virulence in the intraperitoneal mouse model. Phosphorylcholine esterase therefore appears to be a regulatory element involved in the interaction of *S. pneumoniae* with its host.[759]

PNEUMOCOCCAL AUTOLYSIN. Pneumococcal autolysin (LytA) is a 36-kd cell wall protein attached to choline residues on TA and LTA. It is associated with unlinking of cell wall glycan from stem peptides during cell remodeling and division. Autolysin initially was considered to be a significant virulence factor, but more recent work has shown that it plays only a minor role and that immunization with autolysin does not provide protection.[570]

CELL WALL STEM PEPTIDES. The peptidoglycan of gram-positive bacteria triggers the release of cytokine from peripheral

blood mononuclear cells.[489] However, 100 to 1000 times more gram-positive peptidoglycan than gram-negative lipopolysaccharide endotoxin is required to release the same amount of cytokine. Simple stem peptides were 10-fold less active than was undigested peptidoglycan in stimulating tumor necrosis factor (TNF). In contrast, complex branched peptides such as tripeptides were at least 100-fold more potent than was the native material. These complex branched peptides represented 2 percent or less of the total material, but their activity in stimulating TNF was almost equal to that of endotoxin.

IRON TRANSPORT. The availability of iron is a major requirement for the growth and survival of many organisms, including *S. pneumoniae.* Two *S. pneumoniae* genetic loci, *pit1* and *pit2*, which encode homologues of ABC iron transporters, are required for uptake of iron by this organism.[105] Virulence in mouse models of pulmonary and systemic infection is attenuated moderately with a *pit2*-disrupted strain and attenuated strongly with a *pit1/pit2*-disrupted strain.

IgA PROTEASE. IgA proteases belong to a family of proteins used by a diverse group of bacteria, including *S. pneumoniae*, for colonization and invasion. IgA1 protease allows bacteria to cleave human IgA1 in the hinge region. The exact role of these enzymes in bacterial pathogenesis is not understood completely, but they are important in bacterial colonization of mucosal membranes in the presence of secretory IgA antibodies by causing local IgA deficiency.[401] The IgA protease genes of *S. pneumoniae* and *Streptococcus mitis* show extensive polymorphism, which results in enzymes with considerable antigenic diversity.[591]

PHOSPHOGLUCOMUTASE. Phosphoglucomutase is an enzyme that is necessary in one of the early steps in capsular polysaccharide synthesis, and *S. pneumoniae* mutants lacking this enzyme do not produce a capsule and are avirulent in immunocompetent but not in immunosuppressed mice.[307] Other metabolic pathways also are thought to be affected by this enzyme.

FREE OXYGEN RADICALS. Release of free oxygen radicals has been implicated in the pathogenesis of otitis media by *S. pneumoniae*, and antibiotic killing of bacteria leads to the release of further free oxygen radicals, which results in tissue damage despite the administration of appropriate antibiotic therapy.[719] Reactive oxygen intermediates also mediate brain injury in bacterial meningitis.[38,477]

NADH OXIDASE. Reduced nicotinamide adenine dinucleotide (NADH) oxidase has been shown to be a virulence factor necessary for *S. pneumoniae* infection. The basis of NADH oxidase as a virulence factor is the conversion of O_2 to H_2O. If O_2 is not reduced fully, it can form superoxide anion (O_2^-) and hydrogen peroxide (H_2O_2), both of which can be toxic to cells.[796]

PYRUVATE OXIDASE. Pyruvate oxidase decarboxylates pyruvate to acetyl phosphate plus H_2O_2 and CO_2 and appears to be associated with regulation of the multiple adhesive properties of pneumococci.[702] A pneumococcal mutant lacking the gene encoding pyruvate kinase showed a greater than 70 percent loss of the ability to attach to all cell types.

PLASMINOGEN BINDING AND PENETRATION OF THE BASEMENT MEMBRANE. Binding of plasminogen plus penetration of the basement membrane is thought to be an essential step in the pathogenesis of bacterial meningitis.[199] Most strains adhere to reconstituted basement membrane, as well as to its purified laminin and collagen IV components, and to bound plasminogen. Penetration of the basement membrane was achieved within 3 to 4 hours in the presence of plasminogen, whereas without plasminogen, no penetration occurred.

HYALURONIDASE. Virtually all pneumococcal strains produce the enzyme hyaluronidase, a 107-kd protein. Models used to simulate human meningitis generally involve the direct intracerebral route of infection. However, intranasal inoculation would provide a more realistic model, and it recently was achieved by intranasal administration of *S. pneumoniae* with hyaluronidase. This model induced meningitis in 50 percent of inoculated mice, whereas meningitis did not develop in any of the mice inoculated without hyaluronidase. Hyaluronidase was found to facilitate pneumococcal invasion of the bloodstream after colonization of the upper respiratory tract. This murine model mimics important features of human disease, which allows the model to be used to study issues related to the pathophysiology and treatment of pneumococcal meningitis.[804]

PEPTIDOGLYCAN *N*-ACETYLGLUCOSAMINE DEACETYLASE A. The glucosamine and muramic acid residues of the pneumococcal cell wall traditionally are regarded as being *N*-acetylated. However, more than 80 percent of the glucosamine and 10 percent of the muramic acid residues have been shown to be deacetylated, thereby explaining the resistance of peptidoglycan to the hydrolytic action of lysozyme, a muramidase that cleaves the glycan backbone.[758] A gene that encodes for peptidoglycan *N*-acetylglucosamine deacetylase A has been identified. This gene may, therefore, contribute to pneumococcal virulence by providing protection against host lysozyme, which is known to accumulate in high concentration at sites of infection.

PHAGES. Whereas transformation is recognized as occurring in pneumococci, another mechanism of DNA transfer in pneumococci is transduction of DNA carried by bacteriophages (lysogeny). A high proportion (76% of 791 isolates) of clinical isolates of pneumococci were found to carry multiple copies of LytA, thus indicating the widespread occurrence of lysogeny in pneumococci.[603] The LytA hybridization pattern of a strain has been found to be stable during extensive serial culturing; it is specific for the clonal type of the strain and can be used as a molecular epidemiologic marker.[671] In addition, phage DNA integrated into the pneumococcal genome acts as an integrase to facilitate the introduction of foreign genes into the pneumococcal chromosome.[270]

TOLERANCE. The ability of *S. pneumoniae* to escape lysis and killing by vancomycin and penicillin, a property termed *tolerance*, has been described recently.[324] Among 116 clinical isolates of pneumococci, 3 percent and 8 percent were tolerant to vancomycin and penicillin, respectively. Tolerance may contribute to treatment failure, particularly in meningitis, in which bactericidal activity is critical for eradication. A vancomycin- and cephalosporin-tolerant strain of *S. pneumoniae*, the Tupelo strain, has been isolated from the cerebrospinal fluid (CSF) of a patient in whom recrudescence of meningitis developed despite treatment with vancomycin and a third-generation cephalosporin.[503] The defect leading to tolerance in this strain involves the control pathway for triggering of autolysis.

HOST DEFENSE MECHANISMS

Although anticapsular antibody is the most prominent protective mechanism against pneumococcal infection, many host responses to infection occur and many other factors are associated with protection against disease.[527] Pneumococcal infection and disease have been modeled in several animal species. Most are models of sepsis arising from intravenous or intraperitoneal inoculation of

bacteria, and only a few were designed to study disease arising from intranasal infection. Chinchillas provide the only animal model of middle ear pneumococcal infection in which the disease can be produced by very small inocula injected into the middle ear or intranasally. This model, developed at the University of Minnesota in 1975, has been used to study pneumococcal pathogenesis at a mucosal site, the immunogenicity and efficacy of pneumococcal capsular polysaccharide vaccine antigens, and the kinetics and efficacy of antimicrobial drugs.[265]

ANTICAPSULAR SERUM IgG ANTIBODY. IgG to the capsular polysaccharide of *S. pneumoniae* is thought to provide the greatest degree of protection against systemic pneumococcal disease, as well as limited protection against colonization. The reference method for measurement of antibody is the opsonophagocytosis assay, which involves serial dilutions of serum, viable pneumococci, complement, and viable PMNs incubated together for 1 hour.[626] An infant mouse assay system for assessment of protective concentrations of human serum pneumococcal anticapsular antibodies correlated well with opsonophagocytic titer but not with naturally occurring IgG antibody concentrations or IgG produced in response to nonconjugated polysaccharide vaccines, as determined by enzyme-linked immunosorbent assay (ELISA).[379,532] However, the ELISA method of serotype-specific antibody assay with absorption of cross-reacting antibody to cell wall polysaccharides does correlate well with protection after vaccination with conjugated vaccine, and it is the method used most commonly to predict serotype-specific immunity.[27,749,750] The development of a phagocytosis assay based on flow cytometry has not overcome the limitations of the ELISA method and is inferior to the opsonophagocytosis method.[371] Investigation of polymorphisms in the variable region of IgG that affect protective function has indicated that the capsular polysaccharide antibody repertoire in adults is derived from memory B-cell populations that have switched class and undergone extensive hypermutation.[483] Functionally disparate anticapsular polysaccharide antibodies can arise within individuals both by activation of independent clones and by intraclonal somatic mutation, which illustrates the complexity of assaying and interpreting serum capsular polysaccharide antibody levels.

ANTICAPSULAR IgA ANTIBODY. The role of IgA in the control of invasive mucosal pathogens such as *S. pneumoniae* is understood poorly. Human pneumococcal capsular polysaccharide–specific IgA initiates dose-dependent killing of *S. pneumoniae* in the presence of complement and phagocytes. The majority of specific IgA in serum is of the polymeric form, and the efficiency of killing initiated by this polymeric form exceeds that of monomeric IgA–initiated killing. In the absence of complement, specific IgA induces minimal bacterial adherence, uptake, and killing. Killing of *S. pneumoniae* by resting phagocytes with immune IgA requires complement, predominantly via the C2-independent alternative pathway, which in turn requires factor B but not calcium. Pneumococcal capsule–specific IgA may have distinct roles in effecting the clearance of pneumococci in the presence or absence of inflammation, and the polymeric form may control pneumococcal infections locally and after the pathogen's entry into the bloodstream by several mechanisms.[367]

PHAGOCYTOSIS AND LEUKOCYTE IgG RECEPTORS. IgG-mediated phagocytosis by PMNs is the main defense against *S. pneumoniae*. Two leukocyte IgG receptors, FcγRIIa and FcγRIIIb, are expressed constitutively on PMNs. Blocking experiments have shown that FcγRIIa is crucial for opsonophagocytosis of serum-opsonized *S. pneumoniae*. In adults, serum-induced phagocytic activity depends mainly on antipneumococcal IgG2 antibodies.[370,623] However, in infants and young children, the main response to pneumococcal conjugate vaccines occurs in the IgG1 subclass.[26,205,755] Investigators have suggested that IgG1 subclass antibodies are at least as highly functional as is IgG2.[205] Recruitment and function of neutrophils also are important host defenses. In a pneumococcal infection model in immunocompetent and immunodeficient mice intranasally infected with *S. pneumoniae* type 2, immunocompetent BALB/c mice were resistant and immunodeficient CBA/Ca mice were susceptible to infection. BALB/c mice recruited significantly more neutrophils in the lungs, and inflammatory lesions were visible much earlier than in CBA/Ca mice.[271]

ANTIBODIES TO SURFACE PROTEINS AND PNEUMOLYSIN. PspA, PsaA, and pneumolysin are common to virtually all pneumococcal isolates. The development of antibodies to PspA, PsaA, and pneumolysin as a result of pneumococcal infection and carriage in young children was determined by measurement of serum antibodies to these proteins by ELISA in children at ages 6, 12, 18, and 24 months and in their mothers. All age groups were shown to produce antibodies to the three proteins, which increased with age and were associated strongly with pneumococcal exposure as a result of carriage or acute otitis media (AOM).[605] IgA to PspA, PsaA, and pneumolysin has been detected by ELISA in the saliva of children aged 6 to 24 months.[685] This finding was associated with pneumococcal carriage and otitis media.

Serum antipneumolysin IgG at the time of hospital admission has been found to be higher in patients with nonbacteremic pneumococcal pneumonia than in those with bacteremic pneumococcal pneumonia or uninfected control subjects.[531] Serum antipneumolysin IgG levels also rose significantly during convalescence in patients with bacteremic pneumonia, and the levels attained were equal to those observed in nonbacteremic patients. Children aged 6 to 24 months were shown to produce antibodies to pneumolysin, and antibody concentrations increased with age and were associated strongly with pneumococcal exposure, whether by carriage or infection such as AOM.[605] Infants also have been shown to mount a specific antibody response to pneumolysin during AOM.[606]

DEFENSE MECHANISMS OF THE SPLEEN. The spleen is the principal organ that clears pneumococci from the bloodstream.[527] Opsonized particles are removed from the circulation by the liver, but with decreasing opsonization, the spleen increasingly assumes the role of clearance. The slow passage of blood through the spleen and the prolonged contact time with reticuloendothelial cells in the cords of Billroth and the splenic sinuses allow time for the removal of nonopsonized particles. Overwhelming pneumococcal infection occurs in children and adults whose spleens have been removed or do not function normally. Pneumococcal disease progresses so rapidly in such individuals that pneumonia is not detectable clinically or by chest radiographs, although it is seen at autopsy. The increase in the incidence of pneumococcal bacteremia and meningitis in children with sickle-cell disease is due largely to splenic dysfunction.

VITAMIN A. The association of nasopharyngeal colonization with *S. pneumoniae* and vitamin A supplementation in infants in an area with endemic vitamin A deficiency in southern India showed that neonatal vitamin A supplementation delayed the age at which colonization occurs; therefore, it may play a role in lowering morbidity rates associated with pneumococcal disease.[139]

C-REACTIVE PROTEIN. C-reactive protein (CRP) is a normal constituent of human serum that is synthesized by hepatocytes and induced by proinflammatory cytokines. The function of this acute-phase reactant includes activation of complement and enhancement of opsonophagocytosis. CRP binds to phos-

phorylcholine, a constituent of eukaryotic membranes that also is found on the cell surface of the major bacterial pathogens of the human respiratory tract, including *S. pneumoniae* and *Haemophilus influenzae*. CRP is present in inflamed (0.17 to 42 mg/mL) and uninflamed (<0.05 to 0.88 mg/mL) secretions from the human respiratory tract in sufficient quantities to have an antimicrobial effect. In addition, the CRP gene was expressed in human respiratory epithelial cell cultures. The complement-dependent bactericidal activity of normal nasal airway surface fluid and sputum was abolished when the secretions were pretreated to remove CRP. Human respiratory epithelial cells are capable of expressing CRP, and this protein may contribute to bacterial clearance in the human respiratory tract.[282]

PLATELET-ACTIVATING FACTOR RECEPTORS OF AIRWAY EPITHELIAL CELLS. Adherence of pneumococci to cultured human tracheal epithelial cells increased after exposure to acid and decreased after exposure to a specific inhibitor of the receptor for platelet-activating factor.[348] Exposure to acid thus may stimulate the adherence of *S. pneumoniae* to airway epithelial cells via increases in platelet-activating factor receptors. The clinical significance of these findings is not clear.[348]

CYTOKINES. Polymorphonuclear granulocytes, which provide a major defense against *S. pneumoniae* infection, are attracted to and activated by various cytokines, including interleukin-1β (IL-1β), IL-6, TNF-α, IL-8, IL-10, IL-12, interferon-γ, and granulocyte-macrophage colony-stimulating factor.[36] The inflammatory response in bacterial meningitis also is mediated by TNF-α and IL-1, which are produced in the subarachnoid space by cells such as leukocytes, astrocytes, and microglia.[559] Inoculation of pneumococcal cell wall components directly into the CSF of rabbits also results in the induction of an inflammatory response with pleocytosis and increased levels of CSF TNF-α and IL-1.[283] Both TNF-α and IL-1α have been shown to increase mucosal adhesion of pneumococci to tracheal epithelium in a chinchilla trachea whole-organ perfusion model.[737]

Respiratory Viral Infections. The role of respiratory viral infection in predisposing the host to secondary bacterial infection, including pneumonia, empyema, and lung abscess, is well recognized.[462] The lungs of immunocompetent mice infected with influenza A virus on day 1 and *S. pneumoniae* on day 8 demonstrate greater *S. pneumoniae* colony counts, more extensive neutrophil infiltration, and higher lung levels of IL-1β and TNF-α after exposure to *S. pneumoniae* than do the lungs of control mice not pre-infected with influenza virus.[462]

L-ASCORBIC ACID (VITAMIN C). Degradation of the connective tissue component hyaluronic acid by the hyaluronate lyase produced by *S. pneumoniae* is inhibited competitively by L-ascorbic acid (vitamin C).[465] One L-ascorbic acid molecule was found to bind to the active site of the enzyme. The high concentration of L-ascorbic acid in human tissues probably provides a low level of natural resistance to pneumococcal invasion by this mechanism.

LEUKOTRIENES. Leukotrienes are produced by macrophages and are considered important for antibacterial defense in the lung. Leukotrienes comprise a group of highly potent lipid mediators synthesized by the enzyme 5-lipoxygenase. Multidrug-resistance protein 1 (mrp1) is a transmembrane protein responsible for the cellular extrusion of leukotrienes from macrophages. In a mouse pneumonia model, mrp1-deficient mice display diminished growth of pneumococci in the lungs and low mortality by a mechanism that involves increased release of leukotriene B_4.[661] Pneumococci also induce the production of leukotrienes in the middle ear, which has been related to up-regulation of two genes that govern the lipoxygenase pathway.[469]

HUMAN ALVEOLAR MACROPHAGE BINDING AND PHAGOLYSOSOMES. Human alveolar macrophages are the major resident phagocytic cells of the lung. After contact with macrophages, bacteria enter phagosomes, which gradually acquire the characteristics of terminal phagolysosomes, with incorporation of lysosome-associated membrane protein. Opsonization with serum containing immunoglobulin resulted in significantly greater binding of pneumococci to macrophages than did opsonization with immunoglobulin-depleted serum.[279] Binding, intracellular localization, and killing of pneumococci by macrophages all are increased significantly by opsonization with serum containing immunoglobulin, complement, or both.

INTRACELLULAR KILLING. Once pneumococci undergo phagocytosis by "professional" phagocytes (leukocytes and macrophages), they are killed.[527] However, researchers have shown that pneumococci can enter and survive inside A549 cells, a human lung alveolar carcinoma (type II pneumocyte) cell line.[720] Not all clinical *S. pneumoniae* isolates were capable of penetrating these cells, and the presence of a polysaccharide capsule also reduced their capacity to penetrate A549 cells significantly. The intracellular activity of various antibiotics against pneumococci in A549 cells showed that in the presence of antibiotics for 18 hours, more than 98 percent of the A549 cells were viable and less than 3 percent of the pneumococci that initially were phagocytosed could be detected intracellularly after exposure to peak serum concentrations of penicillin G, azithromycin, moxifloxacin, trovafloxacin, rifampin, and telithromycin.[494] In the absence of antibiotics, pneumococci were phagocytosed efficiently but then paradoxically went on to kill all the A549 cells within 18 hours. The clinical significance of these findings is unknown.

COMPLEMENT. The second component of complement (C2) is an important factor associated with host defense against encapsulated organisms. Homozygous deficiency of C2 is the deficiency of complement most commonly inherited. Although C2 deficiency can be asymptomatic, patients usually have either autoimmune disease or recurrent pyogenic infection caused by encapsulated bacteria such as *S. pneumoniae*, *H. influenzae* type b (Hib), and *Neisseria meningitidis*. An association between C2 deficiency and IgG subclass deficiency also has been described previously.[37] *S. pneumoniae* challenge of mice deficient in the third component of complement (C3) results in a 2000-fold increase in organism load in the bloodstream in comparison to controls.[130] Binding of pneumococcal CbpA to epithelially produced C3 results in adhesion of pneumococci to type II pulmonary epithelial cells. CbpA-deficient pneumococcal mutants and lysates, therefore, fail to bind C3 and demonstrate a moderate decrease in adhesion to type II pulmonary epithelial cells, thus confirming the interaction of CbpA and C3 in adhesion.[696]

POLYMERIC IMMUNOGLOBULIN RECEPTOR. pIgR plays a crucial role in mucosal immunity against microbial infection by transporting polymeric immunoglobulins such as IgA across the mucosal epithelium. Polymeric IgA consists of two IgA molecules joined by a small polypeptide J chain. The J chain shows high affinity for the glycoprotein pIgRs of epithelial cells, which are responsible for externalization of polymeric IgA across cell membranes.[376] However, pIgR also can act as a "Trojan horse" and participate in the pathogenesis of invasive pneumococcal disease as pIgR binds to a major pneumococcal adhesin, CbpA.[800] Expression of pIgR in human nasopharyngeal cells greatly enhances pneumococcal adherence and invasion; this effect is abolished either by insertional knockout of CbpA in pneumococci or by antibodies against either pIgR or CbpA.

BASIC FIBROBLAST GROWTH FACTOR. Basic fibroblast growth factor is a neurotrophic factor in the central nervous system that is expressed at high levels in response to seizure or stroke. It also occurs in pneumococcal meningitis, as shown in experimental bacterial meningitis in mice and in children with bacterial meningitis.[341] Patients with meningitis in whom major sequelae or death occurred had much higher levels of CSF basic fibroblast growth factor than did those who survived. In patients with bacterial meningitis who survived, basic fibroblast growth factor decreased significantly in CSF after 24 to 50 hours of administration of antibiotic therapy. However, its biologic role in the pathophysiology of bacterial meningitis is not known.

GRANULOCYTE COLONY-STIMULATING FACTOR. In a limited study of 22 non-neutropenic adult patients with pneumococcal meningitis, granulocyte colony-stimulating factor (G-CSF), in addition to cefotaxime and dexamethasone, was administered subcutaneously for 6 days. All patients survived, and in only one patient did a complication develop (bilateral hearing deficit). Improvement of inflammation indices in CSF was rapid.[182] However, controlled clinical trials are needed. In a rabbit meningitis model, G-CSF increased the percentage of granulocytes in blood but not in CSF and increased CSF TNF-α and IL-1β concentrations.[658] However, G-CSF did not reduce the density of apoptotic neurons in the dentate gyrus of the hippocampus. A second study in a rabbit meningitis model used longer pretreatment with G-CSF and showed more positive results.[558] G-CSF pretreatment attenuated meningeal inflammation and enhanced systemic killing of bacteria. Pretreatment with recombinant human G-CSF in a murine model of pneumococcal pneumonia resulted in improved survival with low, but not high, bacterial inocula. Therefore, the benefits of using G-CSF are limited inasmuch as pneumococci already have recruited large numbers of neutrophils in the lungs by this time.[176]

INTRACELLULAR SIGNALING PATHWAYS. Pneumococcal cell walls activate multiple intracellular signaling pathways in microglial brain cells, with induction of an outwardly rectifying K^+ channel; suppression of the constitutively expressed inwardly rectifying K^+ current; and release of TNF-α, IL-6, IL-12, and other inflammatory mediators.[596] The presence of serum strongly facilitated these effects. The mechanisms involved in microglial activation by pneumococcal cell walls were different from those activated by gram-negative lipopolysaccharide.

LACTOFERRIN. Human lactoferrin is an iron-binding glycoprotein that is particularly prominent in exocrine secretions and leukocytes and also is found in serum, especially during inflammation. It is able to sequester iron from microbes and has immunomodulatory functions, including inhibition of both activation of complement and production of cytokines. Binding of human lactoferrin to the surface of *S. pneumoniae* depends entirely on PspA.[298] Prevention of the binding of lactoferrin to pneumococcal PspA could be an important host defense mechanism.

MANNOSE-BINDING LECTIN. Mannose-binding lectin (MBL) is a key mediator of innate host immunity that activates the complement pathway and directly opsonizes some infectious pathogens. Mutations in three codons in the MBL gene have been identified, and individuals homozygous for a mutant genotype have very little or no serum MBL. In a study conducted in the United Kingdom of 229 patients in whom *S. pneumoniae* was isolated from sterile sites, 28 (12%) were homozygous for MBL codon variants versus only 18 of 353 (5%) controls (odds ratio, 2.59; 95% confidence interval, 1.39 to 4.83).[638]

PATHOGENESIS OF DISEASE

To cause disease, pneumococci, like other extracellular bacterial pathogens, must adhere to mammalian cells, replicate in situ, be carried to and replicate in parts of the body that normally are free of them, escape phagocytosis, and damage tissue by causing inflammation or producing substances that directly damage cells and, in some cases, invade the bloodstream.[527] As discussed earlier, the vast array of virulence mechanisms available to pneumococci are countered by numerous host defense mechanisms, although some host responses facilitate infection.

Even though colonization with a pneumococcal strain can progress to disease, it usually does not occur, and the development of anticapsular type-specific antibodies occurs within 30 days,[287,288,529,530] at least in older children and adults. If organisms find their way into the eustachian tubes, sinuses, or bronchi, clearance mechanisms, chiefly ciliary action, lead to their rapid removal. After the development of humoral immunity, colonization with a strain may persist for 1 to 12 months, during which time disease may occur in contiguous sites, but the host is protected from invasive disease by circulating type-specific anticapsular IgG. Loss of colonization with a strain is followed, after a variable colonization-free interval, by colonization with a different serotype. Because 90 antigenically distinct serotypes exist, this cycle of colonization accompanied by the development of humoral immunity occurs many times.

Progression of colonization to disease usually requires the combination of two events: first, acquisition of a serotype to which the host is not immune and, second, a concurrent respiratory viral infection, chronic damage to respiratory epithelium (e.g., smoking or occupational exposure), allergy, or other conditions that result in the development of disease rather than just colonization.[527] Many of these concurrent conditions initiate cytokine activation of the respiratory epithelium, which facilitates increased adhesion of pneumococci to respiratory epithelial cells, as well as invasion of these cells.[462] Mechanisms by which cytokine activation results in these effects include expression of platelet-activating factor and pIgR as discussed earlier. This combination of factors leads to a higher density of colonizing organisms and enables pneumococci to cause infection, including pneumonia, acute exacerbations of chronic bronchitis, sinusitis, otitis media, and mastoiditis, in contiguous respiratory tract sites. Adherence of *S. pneumoniae* to host cells involves an array of surface adhesin molecules such as CbpA, PspA, PspC, Hyl, Ply, PsaA, and both neuraminidases. As discussed earlier, these proteins are involved in interactions with the host complement system (PspA), degradation of hyaluronan of the extracellular matrix (Hyl), lysis of cholesterol-containing membranes (pneumolysin), and binding of metals (divalent cations) such as Mn^{2+} or Zn^{2+} (PsaA), followed by their transport inside the cytoplasm of pneumococci.

Additionally, transepithelial and transendothelial transport of organisms into the bloodstream results in bacteremia, and subsequent transport across other epithelial cells leads to infection of noncontiguous sites such as the leptomeninges, peritoneum, and joint spaces. Such infection occurs in nonimmune hosts by virtue of the fact that pneumococci are able to escape ingestion and killing by host phagocytic cells in the absence of type-specific antibody because the capsule is the major determinant of virulence. *S. pneumoniae* produces few toxins and largely causes disease by its capacity to replicate in host tissues and generate an intense inflammatory response. Cell wall TA and peptidoglycan stimulate the production of cytokines (IL-1, IL-6, IL-8, and TNF) and activate complement by the alternative pathway. The polysaccharide capsule also activates the alternative complement pathway in vitro. Such activation is associated with the release of C5a, a potent attractant for PMNs. The classic complement pathway also is activated by antibody to cell wall polysaccharides

in the absence of anticapsular antibody, and an intense inflammatory response fueled by vigorous activation of both the alternative and classical complement pathways accompanies pneumococcal infection of an immunologically naive host.[527] The disease process is largely a result of this inflammation, and its severity is in direct proportion to its intensity. Pneumolysin also is associated with the severity of disease, and injection of pneumolysin into rat lung causes all the histologic findings of pneumonia, whereas immunization of mice with pneumolysin before infection or challenge with pneumolysin knockout pneumococci is associated with a significant reduction in virulence.[49,221] Numerous other factors contribute to the ability of strains to cause disease and to the severity of disease, as discussed under virulence mechanisms.

A 2006 study evaluated 189 isolates from blood or CSF, 3200 isolates from middle ear fluid, and 348 isolates from the conjunctiva of children aged younger than 36 months with pneumococcal infection. A positive association with invasive pneumococcal disease was demonstrated for serotypes 1, 5, and 12F; with AOM for serotypes 1, 3, 5, 12F, 19A, and 19F; and with acute conjunctivitis for serotype 3 and nontypeable *S. pneumoniae*.[678]

Although pneumococci most commonly cause bacteremia, otitis media, pneumonia, and meningitis, they can produce disease in virtually any organ. Before the advent of immunotherapy and chemotherapy, such "unusual" infections were relatively common. Today, they are less so.

Survival of a patient with a pneumococcal disease depends on numerous variables, including the site of infection, the underlying disease, and the patient's age. Before the advent of chemotherapy, pneumococcal meningitis was universally fatal, whereas pneumococcal pneumonia killed approximately 25 percent of patients. Austrian and Gold[42] in 1964 dramatically illustrated the role of age and underlying disease when their survey of mortality associated with bacteremic pneumococcal pneumonia destroyed the complacency produced by the use of antimicrobial agents. The aged and infirm were likely to die despite receiving immediate and appropriate therapy with penicillin. Today, normal children rarely die of pneumococcal disease; thus, the prognosis must be related to the likelihood of permanent sequelae occurring. Pneumococci do not cause necrosis in pulmonary tissue, and survivors rapidly regain normal pulmonary function.[372] Many children recovering from pneumococcal meningitis are found to have neurologic sequelae. Some investigators suggest that the first attack of pneumococcal otitis media in some way predisposes the individual to subsequent attacks of otitis media.[338]

Before the availability of antimicrobial agents, recovery of a patient with pneumococcal pneumonia depended on the development of type-specific antibody. Although serum and white blood cells (WBCs) from nonimmune children kill pneumococci, probably by activation of the alternative complement pathway, they do so slowly. The importance of this pathway is illustrated best by the inability of children with sickle-cell disease to handle pneumococcal infection.[186,378,572] These children and others with asplenia may die rapidly despite the administration of prompt, vigorous therapy.[382,406,666]

MICROBIOLOGY

S. pneumoniae is a gram-positive coccus that replicates in pairs and chains in liquid medium. The shape of the individual organism is a lanceolate coccus, usually in pairs with the long axis forming a straight line. Elongated or pointed forms are common findings.

Pneumococci are cultured readily on blood and chocolate agar media, as well as in suitable liquid culture media for isolation from blood. Isolates are facultative anaerobes, and most strains require atmospheric enrichment with 5 to 10 percent CO_2 for primary isolation[41]; occasional strains are strict anaerobes. Strains can be adapted for growth without CO_2 supplementation by repeated subculture. Detection of nasopharyngeal carriage of pneumococci is a problem because of the presence of other flora; the use of antimicrobial-containing media, such as blood agar supplemented with gentamicin (5 μg/mL), has led to improvements in isolation of pneumococci, particularly resistant strains.[574,599] However, the sensitivity of current in vitro methods is poor in comparison to the sensitivity of mouse inoculation, although not all serotypes are virulent in mice.[330,423]

IDENTIFICATION OF PNEUMOCOCCI

Pneumococci usually are identified readily by standard features such as colonial morphology, alpha-hemolysis, negative catalase reaction, optochin susceptibility, bile solubility, and specific reactions with antisera to capsular polysaccharides.[353] *S. pneumoniae* produces an autolytic intracellular enzyme, LytA, that causes the organism to autolyze rapidly when grown on artificial media. Bile salts accelerate this natural autolytic process by combining with the pneumococcal cell and activating its autolysin. Strains with atypical features, such as rounded rather than flat or concentrically ringed colonies, optochin resistance, or lack of capsules, do occur and can result in misidentification of such strains as viridans streptococci. Atypical strains are more likely to be encountered from normal flora sites and with penicillin-resistant strains.

Strains with optochin zones greater than 14 mm can be identified presumptively as pneumococci, strains with 7- to 14-mm zones require confirmation by bile solubility, and strains with no zone usually are not *S. pneumoniae*. However, incubation in carbon dioxide has been recognized for a long time as decreasing the size of the zone around optochin disks, and incubation in room air generally results in an increase in zone size if the strain is a pneumococcus or a decrease if the strain is a member of the viridans group of streptococci.[600] Optochin-resistant variants of pneumococci can occur and usually are seen as a subpopulation within the zone of inhibition of an optochin disk, and optochin-resistant mutants can be selected by passage of strains in the presence of optochin.[525] Strains with equivocal optochin zones or atypical colonial morphology can be tested for bile solubility, either directly by placing a drop of bile salt solution (10% sodium deoxycholate) onto colonies and observing for lysis of the colonies or by suspension of organisms in a bile salt solution with a bile salt–free control. Care must be taken in the tube bile solubility test to avoid obtaining false-positive results, which can be caused by the organism suspension being too light or by organisms being suspended in broth rather than saline.[353]

Identification of the capsular polysaccharide serotype or serogroup also is useful in characterizing strains and confirming the identity of problem strains. Such identification is performed by the capsular swelling technique, in which equal volumes of an organism suspension, 0.3 percent methylene blue dye solution, and antiserum are mixed on a glass slide, covered with a coverslip, and read at 1000× magnification by phase-contrast microscopy. Alternatively, organism suspensions can be dried on slides and antiserum and methylene blue dye solution mixed on a coverslip, which then is placed on the slide. The polysaccharide capsule of the pneumococcal organism binds with type-specific antiserum, and organisms can be seen to clump or agglutinate; the resulting change in the refractive index of antibody-coated capsule causes the capsule to appear swollen. Currently, antisera to each serotype or serogroup are available commercially, and factoring antisera to subtype serogroups are available from Statens Serum Institut, Copenhagen, Denmark. The numbering system for the 90 pneumococcal serotypes is shown in Table 96–1.

Currently, 90 serotypes have been identified and are divided into 25 individual serotypes and 21 serogroups in the Danish

classification, which now is used universally.[323] Most serotypes have one antigenic determinant, whereas serogroups have one or more antigenic determinants common to the group and one or more determinants unique to each serotype. Serotypes within a serogroup usually are identified by the serogroup number followed by a letter indicating the serotype to which a strain belongs in the Danish system, or they are identified by a unique number in the U.S. system. Except for serogroups 6 and 9, the letters in the Danish system are F for the first subtype, followed by A, B, and so on. Each serogroup contains 2 to 5 related types, and the 21 serogroups include 65 individual subtypes. Serotype numbers 26 and 30 are not in use. Omniserum containing antibodies to all 90 serotypes is available and can be used to confirm the identity of isolates as pneumococci. Because many serotypes or serogroups are included in this reagent, reactions may not always be optimal and usually are stronger in pool or monovalent reagents. Nine antiserum pools classified from A to I, each containing four to seven serotypes or serogroups, also are available and can be used to identify strains in a group of serotypes before individual serotype or serogroup reagents are tested. Other methods of capsular typing, such as latex agglutination, coagglutination, and capillary precipitation, can be used, but these methods are not available commercially.

The ability of a polymerase chain reaction (PCR) method to identify the capsular serotype of pneumococci has been developed on the basis of polymorphisms in two genes common to the different capsule loci.[441] In a limited study, the correct serotype or serogroup was identified in 92 of 93 strains, but this method did not differentiate serotype 6A from 6B strains. PCR holds promise as a noncultural method for determining serotype.

DETECTION OF CLONALITY

In addition to phenotypic features, such as serotype and antimicrobial resistance markers, the various DNA fingerprint methods for epidemiologic typing of *S. pneumoniae* that have been applied include ribotyping, BOX fingerprinting with the BOX repetitive sequence of *S. pneumoniae* used as a DNA probe, PCR fingerprinting with a primer homologous to the enterobacterial repetitive intergenic consensus sequence, pulsed-field gel electrophoresis of large DNA fragments digested by restriction enzymes, and restriction fragment end labeling to detect restriction fragment length polymorphisms of small DNA fragments.[325,504] The discriminatory power of the individual techniques differed significantly. BOX fingerprinting, pulsed-field gel electrophoresis, and restriction fragment end labeling provided the highest degree of discriminatory power. Ribotyping, BOX fingerprinting, and restriction fragment end labeling were very suitable techniques for computerized data analysis. Pulsed-field gel electrophoresis of large DNA fragments digested by restriction enzymes such as Sma1 is the method used most frequently. Descriptions and nomenclature for the 16 major pneumococcal clones that have contributed to the increase in antimicrobial resistance worldwide were published recently.[504]

DIAGNOSIS OF PNEUMOCOCCAL DISEASE

Definitive diagnosis of pneumococcal infection is based on recovery of pneumococci from the site of infection or documentation of pneumococcal bacteremia, whereas presumptive diagnosis is based on detection of pneumococcal cellular components, such as capsular polysaccharide, and on species-specific DNA and RNA sequences from the site of infection or from remote sites such as urine.[353] Definitive diagnosis is confounded in many instances by the need for invasive procedures to obtain specimens (e.g., from the middle ear space) and by nasopharyngeal carriage of pneumococci when sputum is cultured. Pneumococci almost invariably are isolated from CSF in pneumococcal meningitis, even in patients receiving oral antibiotics.[635] However, establishing the diagnosis of pneumococcal pneumonia is more challenging because sputum rarely is available from children and direct lung puncture is performed very infrequently. Detection of pneumococcal bacteremia to confirm the diagnosis of pneumococcal pneumonia or other localized infection is valuable, but it does not occur frequently and the actual prevalence of bacteremic pneumococcal pneumonia in children is not known,[728] although a recent study suggests that the prevalence is approximately 17 percent (11/64).[509] Therefore, pediatricians must use other methods to diagnose pneumococcal pneumonia. Signs and symptoms significantly associated with bacteremic pneumococcal pneumonia in children include high temperature (>38.9° C [>102° F]), leukocytosis (>15,000/mm^3), and lobar or segmental consolidation.[728] However, the frequency with which these findings are associated with nonbacteremic pneumococcal pneumonia is not known.

With the widespread deployment of pneumococcal vaccine, occult bacteremia caused by *S. pneumoniae* occurs less commonly. The likelihood that a positive blood culture will be a false-positive result is increased if the WBC count is less than 15,000/mm^3, the time for the blood culture to become positive exceeds 24 hours, or the Gram stain result is suggestive of a contaminant.[655] Overall, the frequency with which positive blood cultures are obtained from children with occult bacteremia has declined in comparison to the pre-pneumococcal vaccine era and has declined precipitously since the era before the deployment of vaccine for Hib.

Direct examination of Gram-stained smears of clinically appropriate material remains the fastest diagnostic method and can be augmented if necessary by direct demonstration of capsular swelling of organisms in the presence of anticapsular antisera. The availability of antigen-detection systems that can be used in urine, serum, CSF, and other specimens, such as capsular antigen detection by counterimmunoelectrophoresis and latex agglutination with polyvalent pneumococcal reagent, generally has not improved patient management because of the low sensitivity and specificity of these methods and the fact that they usually are positive only when a Gram stain also is positive. The concentration of pneumococcal capsular antigen in saliva was evaluated by latex agglutination in a study consisting of children with community-acquired pneumonia and healthy controls. None of the children with pneumonia in this study had a positive blood culture, and pneumococcal capsular antigen was detected in the saliva of 27 percent of children with pneumonia versus 17 percent of controls. More cases (20%) than controls (2%) had a pneumococcal capsular antigen titer of 10 or greater ($p < 0.01$). Quantitative measurement of pneumococcal capsular antigen in saliva may be valuable in helping make an etiologic diagnosis in children with pneumonia, but its sensitivity is poor and it is confounded by false-positive results caused by pneumococcal carriage.[233]

A rapid (15-minute) immunochromatographic membrane test to detect pneumococcal polysaccharide capsular antigen in urine samples (Binax NOW) has been developed and was evaluated in the diagnosis of bacteremic and nonbacteremic pneumococcal pneumonia. Urine samples were studied in 51 patients with bacteremic and nonbacteremic pneumonia caused by *S. pneumoniae*; the pneumonia was diagnosed by blood culture, and pneumococcal polysaccharide capsular antigen was detected by counterimmunoelectrophoresis in urine samples. Pneumococcal antigen was detected in urine by the immunochromatographic membrane test in 41 of 51 patients with pneumococcal pneumonia (80.4%), including 23 of 28 bacteremic cases (82.1%) and 18 of 23 nonbacteremic cases (78.3%). Antigen also was detected in 7 of 16 patients with a diagnosis of presumptive pneumococcal pneumonia (43.7%) and in 1 of the 16 patients with pneumonia but in

whom no pathogen was identified. The specificity of the immunochromatographic membrane test was 97.2 percent, but its sensitivity was only approximately 80 percent, thus limiting its value.[191] Furthermore, the usefulness of this test is questionable because the antigen was detected in the urine in 30 of 138 (22%) healthy children with nasopharyngeal carriage of *S. pneumoniae* versus only 3 of 71 (4%) noncarriers ($p < 0.001$).[302] Thus, the test was shown to be often positive in healthy pneumococcal carriers.

One recent study found that immunochromatographic testing for *S. pneumoniae* in CSF was both 100 percent sensitive and specific. The simplicity of the test and the longevity of the CSF antigen even after treatment suggest potential utility of this method in identifying *S. pneumoniae* meningitis in resource-poor countries with widespread prehospital antimicrobial use.[646] Another study showed immunochromatographic testing to be more sensitive than culture in detecting *S. pneumoniae* as the causative agent in thoracic empyema.[587]

Newer molecular-based methods for establishing the diagnosis of pneumococcal disease include the use of DNA probes to detect pneumolysin, autolysin, and PsaA protein, but considerable practical problems must be overcome before these methods will be applicable clinically.[173] Examples include a commercial method involving real-time PCR for simultaneous detection of *N. meningitidis*, *H. influenzae*, and *S. pneumoniae* in patients suspected of having meningitis and septicemia. This method is based on detection of the pneumolysin gene for *S. pneumoniae* and uses a single-tube, 5′-nuclease multiplex PCR assay on samples of CSF, plasma, serum, and whole blood. Amplified products are monitored with sequence-specific, fluorescent dye–labeled probes. The sensitivity of using clinical samples (CSF, serum, plasma, and whole blood) from culture-confirmed cases of *S. pneumoniae* infection was 91.8 percent. The multiplex assay also was used to test a large number of culture-negative samples, which resulted in the detection of numerous cases of meningococcal, *H. influenzae*, and pneumococcal disease that had not been detected by culture.[141] However, whether these results are true positives or false positives is not known, and in another study, although the sensitivity of PCR amplification of the pneumolysin gene in the serum and CSF of infants and children with culture-proven pneumococcal bacteremia and meningitis was 100 percent, the specificity was poor, with 17 percent of healthy controls having positive results.[173] The prevalence of false-positive reactions was highest (33%) in 2-year-old children, the age group with the highest rate of nasopharyngeal carriage of pneumococci. Therefore, although PCR of serum and CSF is a sensitive test for the detection of *S. pneumoniae* in these sites, its high rate of positivity in healthy controls as a result of nasopharyngeal carriage limits its utility in detecting systemic pneumococcal infection.[173]

Another rapid PCR method involving the use of a set of primers that amplify 273 base pairs of the autolysin gene has been developed to identify *S. pneumoniae*. In addition, three sets of primers were designed to amplify a 240–base pair fragment of the PBP-2B gene (*pbp2b*) of penicillin-susceptible *S. pneumoniae* and two common *pbp2b* mutations present in penicillin-resistant *S. pneumoniae* in order to simultaneously identify the penicillin susceptibility of strains. The autolysin gene was identified in all 1062 clinical isolates of *S. pneumoniae* evaluated. In addition, 98.9 percent of 621 penicillin-susceptible isolates were shown to have DNA fragments amplified by the penicillin-susceptible primers, whereas 72.1 percent of 441 penicillin-resistant isolates were detected by the penicillin-resistant *S. pneumoniae* primers.[741] Although further refinement of this method is required, this study has shown that it is possible to identify pneumococci and differentiate penicillin-susceptible from penicillin-resistant *S. pneumoniae* by applying PCR and a combination of primers to detect the susceptible *pbp2b* gene, resistant *pbp2b* gene mutations, and the autolysin gene. In another study, a 208–base pair region of the pneumolysin gene was amplified by PCR in blood specimens from hospitalized children with pneumonia. Whole blood, buffy coat, or plasma samples from 67 children (44%) tested positive by PCR. The sensitivity was 100 percent in 11 culture-confirmed children, and the specificity was 95 percent in control subjects. Age, previous administration of oral antibiotic therapy, and pneumococcal nasopharyngeal colonization did not influence the PCR results, which were more specific than were serologic and urinary antigen testing.[509]

A gene probe for the gene encoding the PsaA protein also has been developed on the basis of PCR assay. PsaA was confirmed to be present in representative strains of all 90 serotypes of *S. pneumoniae*. The specificity of the assay was verified by the lack of signal from analysis of heterologous bacterial species ($n = 30$) and genera ($n = 14$), including viridans group streptococci. The potential of the assay for clinical application was shown by its ability to detect pneumococci in culture-positive nasopharyngeal specimens.[520]

SUSCEPTIBILITY TESTING

Susceptibility testing of pneumococci has been well standardized, and testing can be performed by determination of the minimal inhibitory concentration (MIC) and, for selected agents, by disk diffusion.[356] MICs can be performed by macrodilution or microdilution in cation-supplemented Mueller-Hinton broth enhanced with 5 percent whole defibrinated sheep or horse blood or 5 percent lysed and centrifuged horse blood.[537] If sulfonamides are tested, only the latter supplement should be used to avoid the presence of sulfonamide antagonists. MICs also can be determined by dilution in Mueller-Hinton agar supplemented as just described; agar dilution generally is regarded as the reference method for pneumococci and often is used for developmental work.[353]

Many systems based on frozen or dried microdilution trays are available commercially and used extensively for surveillance testing.[354] As with any system, commercial microdilution panels should be validated and used with appropriate quality controls.

A new method for determination of MICs, the E-test (A. B. Biodisk, Solna, Sweden), is much simpler to use than are the other methods for MIC determination. The E-test consists of a calibrated antibiotic-impregnated plastic strip that is applied to the surface of an inoculated agar plate. An antibiotic gradient is produced that results in an elliptical zone of inhibition after incubation. The MIC is read at the point where the ellipse of inhibition meets the strip. Evaluation of the E-test has shown that this method generally is reliable, although problems are encountered with some agents because acidification of the medium occurs during incubation of the plates in CO_2, which is required to ensure the growth of clinical isolates. Agents particularly affected are macrolides and some quinolones.

Disk diffusion also has been standardized well for testing pneumococci against selected agents. Distinction between susceptible and resistant strains is accomplished readily by using the current National Committee for Clinical Laboratory Standards (NCCLS) method involving macrolides, tetracycline, chloramphenicol, trimethoprim-sulfamethoxazole, and clindamycin.[353] For testing penicillin and other β-lactams, disk diffusion is used best as a screening method with 1-μg oxacillin disks that have a susceptible cutoff zone of 20 mm or larger. Strains with zones of 20 mm or larger are fully susceptible to penicillin and other β-lactams. However, strains with zones that are less than 20 mm need to have MICs of penicillin and other appropriate β-lactams determined.[537] Penicillin-susceptible strains with MICs of 0.06 μg/mL usually screen out with resistant strains.

Although interpretative categories for clarifying the significance of MIC values are available, many limitations to the

currently available NCCLS pneumococcal breakpoints exist, particularly for agents that can be administered in multiple-dosing regimens and by multiple routes of administration and that are used for infections in different body sites. Breakpoints for parenteral β-lactam agents generally are based on the use of agents in meningitis, whereas those of oral β-lactam agents are based on nonmeningeal infections such as otitis media.[537] Nonmeningeal breakpoints for some parenteral β-lactam agents were introduced in 2002, which to some extent will avoid the use of non–β-lactam agents for serious nonmeningeal pneumococcal infections. These breakpoint changes classify strains previously interpreted as intermediate in sensitivity to penicillin G, cefotaxime, and ceftriaxone as susceptible if the agents are administered parenterally to treat pneumonia and other nonmeningeal infections. Pharmacokinetic and pharmacodynamic parameters recently have been shown to correlate with clinical outcome and offer a more rational approach to predicting antimicrobial efficacy and determining clinically relevant susceptibility breakpoints.[145,150,361]

ANTIBIOTIC RESISTANCE

Mechanisms of Antibiotic Resistance

RESISTANCE TO β-LACTAM DRUGS. Widespread resistance to β-lactam and other drug classes has evolved in the most common pathogens, including *S. pneumoniae*. Although pneumococci are naturally transformable organisms, β-lactamase production never has been described in this organism. Instead, a much more complex resistance mechanism has evolved in *S. pneumoniae* that is mediated by sophisticated restructuring of the targets of the β-lactams, the PBPs, and by other newly described mechanisms.[300] The PBP targets in penicillin-resistant strains of *S. pneumoniae* are modified, low-binding affinity versions of the native PBPs. PBP targets may be modified by mutation or by transformation and homologous recombination with DNA from the PBP genes of viridans streptococci. The level of resistance is determined by how many and to what extent targets are modified.[120] Restructuring of PBPs is mediated by stepwise alterations in PBPs. The high-molecular-weight PBPs—types 1A, 2X, and 2B—that usually are detected in *S. pneumoniae* are involved in transpeptidase activity and play an important role in resistance.[301] Alterations in PBP-2B are associated with low-level resistance to penicillin, and alterations in PBP-2X mediate low-level resistance to cephalosporins. The additional alterations in PBP-1A raise penicillin MICs to 1 μg/mL or greater and cefotaxime MICs to 0.5 μg/mL or greater. Genomic comparison between *S. pneumoniae* and commensal *S. mitis* and *Streptococcus oralis* strains has documented the mosaic nature of PBPs among these species, with pneumococci acquiring their altered PBP genes from *S. mitis* and *S. oralis*.[299] Many other mosaic gene clusters not associated with penicillin resistance also have been found.[255] The capacity to produce branched cell wall stem peptides encoded by altered *murM* and *murN* genes, as well as altered PBPs, is required for expression of penicillin resistance in *S. pneumoniae*.[224] The *fibA* and *fibB* genes, which are homologous to the *Staphylococcus aureus femA/B* genes required for expression of methicillin resistance in this organism, encode proteins involved in the formation of interpeptide bridges and also are required for expression of PBP-mediated penicillin resistance.[775] Other mechanisms of β-lactam resistance have been described in laboratory mutants and in a clone of Hungarian pneumococcal strains with notably high levels of β-lactam resistance (penicillin MIC, 16 μg/mL; cefotaxime MIC, 4 μg/mL).[300,695]

RESISTANCE TO NON–β-LACTAM DRUGS. The molecular and genetic mechanisms of resistance to macrolides, chloramphenicol, tetracycline, fluoroquinolones, and trimethoprim-sulfamethoxazole in *S. pneumoniae* also have been determined. Resistance genes for several agents are carried on a transposon, Tn1545.[144] It confers resistance to three antimicrobial classes—kanamycin (*aphA-3*), macrolide-lincosamide-streptogramin B–type antibiotics (*ermB*), and tetracycline (*tetM*). This transposon has been conjugated and transposed to the chromosome of *Enterococcus faecalis*, oral streptococci, and *Listeria monocytogenes*. The properties of this transposon account for the sudden emergence, rapid dissemination, and stabilization of resistance to multiple antibiotics in *S. pneumoniae* in the absence of plasmids.

Resistance mechanisms include the production of chloramphenicol acetyltransferase, an enzyme capable of catalyzing the conversion of chloramphenicol to nonfunctional derivatives. Chloramphenicol acetyltransferase is encoded by a chloramphenicol acetyltransferase (*cat*) gene identical to the *cat* gene from the *S. aureus* plasmid pC194. Tetracycline resistance occurs through ribosomal protection encoded by the genes *tetM* and *tetO*. The tetM and tetO proteins are thought to cause tetracycline to be released from the ribosome. Resistance to fluoroquinolones primarily involves mutations in the DNA gyrase gene *gyrA* and in the topoisomerase IV genes *parC* and *parE*, as well as an efflux mechanism that affects some fluoroquinolones. Resistance to trimethoprim is mediated through a single amino acid substitution in the chromosomal dihydrofolate reductase gene of *S. pneumoniae*, which is thought to disrupt the bond with trimethoprim without affecting the action of dihydrofolate reductase. Sulfonamide resistance appears to result from repetitions of one or two amino acids in the chromosomal dihydropteroate synthase.[782]

Two major mechanisms have been described for resistance to erythromycin. Co-resistance to macrolides, clindamycin, and streptogramin B–type antibiotics is a result of modification of the ribosome through methylation of an adenine residue in domain V of the 23S rRNA. Methylation is encoded by a methylase gene, *ermB* (previously called *ermAM*). Resistance to 14- and 15-membered macrolides (erythromycin, azithromycin, and clarithromycin) but not to 16-membered macrolides (roxithromycin, josamycin, and spiramycin), ketolides, or clindamycin is a result of efflux of the antibiotic from the cell; such resistance is encoded by the gene *mefE* in *S. pneumoniae* and appears to be emerging rapidly as the predominant mechanism of resistance to erythromycin in many countries.[255] Other macrolide resistance mechanisms that have been described recently include mutations in position 2059 of the 23S rRNA and in genes encoding ribosomal protein L4.[717]

VANCOMYCIN TOLERANCE. Although vancomycin resistance has not been described in pneumococci, antibiotic tolerance, or the ability of bacteria to survive but not grow in the presence of antibiotics, has been described. It has been shown to be caused by loss of function of the VncS histidine kinase of a two-component gene expression sensor-regulator system in *S. pneumoniae* that produces tolerance to vancomycin and other classes of antibiotics.[543]

Evolution of Antibiotic Resistance among Pneumococci

Pneumococci initially were susceptible to many antimicrobial agents, but they became resistant with varying degrees of rapidity to many of these agents. The earliest example was the development of resistance to optochin (ethylhydrocupreine) when this agent was used experimentally in mice in the early part of the 20th century. With the introduction of sulfonamides in 1939, pneumococci similarly exhibited an ability to acquire resistance in experimental infections in mice, as well as in a human case of meningitis.[418] Sulfonamide resistance was identified sporadically

thereafter, and a trimethoprim-sulfamethoxazole–resistant strain was recognized first in 1972. Trimethoprim-sulfamethoxazole resistance subsequently has become widespread in virtually all serotypes throughout the world, including developing countries, and resistance to this agent is greater than that to any other antimicrobial class worldwide.[328] Tetracycline resistance emerged in the 1960s and chloramphenicol resistance in 1970. However, little attention was paid to the development of resistance in this species until 1977, when isolates resistant to several antimicrobial classes, including penicillins, chloramphenicol, tetracyclines, macrolides, clindamycin, and trimethoprim-sulfamethoxazole, were detected in South Africa.[29,360] Subsequently, multiresistant clones of pneumococci have spread throughout many regions of the world. Noteworthy is that multiresistant clones are confined mostly to serotype 14 and serogroups 6, 9, 19, and 23.[179] Whereas resistance to penicillins occurs in a stepwise fashion and can be overcome by using β-lactams with appropriate pharmacokinetics, resistance to other drug classes usually is absolute, and distinct populations of strains are found to be susceptible and resistant to agents such as macrolides, clindamycin, tetracyclines, trimethoprim-sulfamethoxazole, and chloramphenicol. Unlike enterococci, resistance to vancomycin has not developed in pneumococci yet, although vancomycin-tolerant strains have been detected.[52,324]

Cross-resistance among *S. pneumoniae* to macrolides and other classes of antibiotics usually increases with increasing MICs to penicillin[357] (Fig. 96–2). Whereas only 6 percent of penicillin-susceptible pneumococci are resistant to macrolides and 14 percent to trimethoprim-sulfamethoxazole, approximately half of the penicillin-intermediate isolates were resistant to these agents. In the case of penicillin-resistant strains, three quarters were resistant to macrolides, 90 percent to trimethoprim-sulfamethoxazole, and 28 percent to clindamycin. However, this pattern is not the case in all countries, and at least one multiresistant clone resistant to chloramphenicol, tetracycline, erythromycin, clindamycin, and trimethoprim-sulfamethoxazole has remained susceptible to penicillin.[184,716]

Strains of *S. pneumoniae* were exquisitely susceptible to penicillin (MICs of 0.01 to 0.03 μg/mL) when this agent initially was used clinically in the 1940s and 1950s, and this MIC range is referred to as the baseline activity of penicillin against *S. pneumoniae*.[353] Evolution of resistance to this class of agents was noted first when a few strains of *S. pneumoniae* were isolated in the 1960s in Australia and New Guinea. These strains had decreased susceptibility to penicillin, with MICs of 0.1 to 0.25 μg/mL, approximately 10-fold higher than the MICs of baseline strains. Strains with penicillin MICs of 2 to 4 μg/mL, approximately 100-fold higher than, the baseline strains, were isolated in South Africa in 1977, and, subsequently, strains with even higher MICs (16 μg/mL, approximately 1000-fold higher than baseline strains) were described in Hungary.[695] Pneumococci conventionally are classified as penicillin-susceptible if the MICs are 0.06 μg/mL or less, intermediate if the MICs are 0.12 to 1.0 μg/mL, and resistant if the MICs are 2.0 μg/mL or greater. This classification is useful mainly in characterizing strains as fully susceptible to β-lactams if susceptible or as having decreased susceptibility if intermediate or resistant. Strains with such decreased susceptibility are better referred to as β-lactam drug-challenged because the mechanism of resistance can be overcome if the pharmacokinetics of the β-lactam drug used in serum or at the site of infection exceeds the MIC for 40 to 50 percent of the dosing interval.[146] Similar variations in MIC ranges are seen with all β-lactams, although MIC ranges for many β-lactams are much higher than that for penicillin itself. Agents such as ampicillin, amoxicillin, cefotaxime, and ceftriaxone have MIC ranges similar to that of penicillin, whereas agents such as cefazolin, cefaclor, cefprozil, ceftazidime, and cefixime have much higher MIC ranges. For example, the baseline activity of cefaclor against *S. pneumoniae* is 0.5 to 1 μg/mL, which is a concentration approximately 20- to 30-fold higher than that required for penicillin to inhibit the most susceptible strains. Changes in susceptibility that occur over the course of time were illustrated in a study of recent versus archived otitis media strains. In this study, the MIC_{90} for cefaclor against archived isolates was 1 μg/mL, whereas the MIC_{90} against recent isolates was greater than 64 μg/mL.[355] A few agents, such as imipenem and meropenem, have slightly lower MIC ranges than those of penicillin. Currently, 50 to 60 percent of pneumococci in the United States are penicillin-susceptible, 15 to 20 percent are penicillin-intermediate, and 20 to 30 percent are penicillin-resistant. The proportions of strains in each group vary considerably throughout the world.

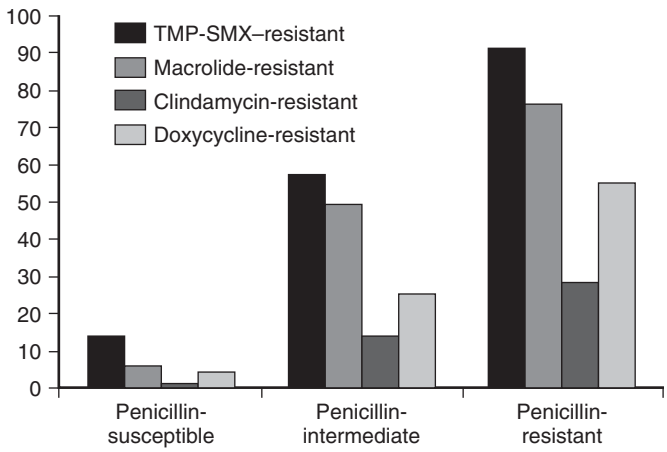

Figure 96–2 Pneumococci often are resistant to several drug classes, and cross-resistance to macrolides and other classes of antibiotics increases as minimal inhibitory concentrations of penicillin increase. TMP-SMX, trimethoprim-sulfamethoxazole.[357,687]

Resistance to macrolides in strains of *S. pneumoniae* was noted first in 1964 and was detected sporadically in the United States until it became widespread in the latter half of the 1990s.[328,344,418] The baseline activity of macrolides (0.03 μg/mL) and MIC distributions (1000-fold concentration range, 0.03 to >32 μg/mL) against *S. pneumoniae* are somewhat similar to those of penicillin. The MIC distribution of macrolides is trimodal, with strains being exquisitely susceptible (erythromycin MIC, ≤0.03 μg/mL) or highly resistant (erythromycin MIC, ≥32 μg/mL) or demonstrating intermediate resistance (MICs of 1 to 16 μg/mL).[216] These distributions closely correlate with macrolide ribosomal methylase and efflux resistance mechanisms. The prevalence of macrolide resistance and reports of clinical failure resulting from strains with efflux and ribosomal methylase resistance mechanisms continue to increase.* Some authors, however, have argued that isolates with efflux-mediated resistance could be susceptible to the high intracellular concentrations that these agents achieve in phagocytic cells and in epithelial lining fluid of the alveoli.[18,398] However, no clinical or animal data support these arguments for extracellular pathogens such as *S. pneumoniae*, whereas considerable clinical and animal data support the use of current breakpoints.[50,145,146,512] The rising incidence of macrolide-resistant pneumococci was directly proportional to the increasing use of macrolides in various communities and age groups.[251,344,586] In a recent report, 18 to 23 percent of pneumococci from the United States were macrolide-resistant[328,733] as compared with 10 percent from Canada, 11 percent from Latin America, 20 percent from Europe, and 39 percent from the Asia-Pacific region.[328]

Strains with multiple antibiotic resistance have greater selective advantages than do strains resistant to just one antibiotic because the opportunity for positive selection is increased as the

*See references 80, 232, 351, 399, 479, 480, 516, 586, 651, 773.

number of drug classes to which isolates are resistant increases.[419] Exposure to different classes of antibiotics allows more opportunity for selective advantage to a multiple antibiotic–resistant organism than to a monoresistant strain, which must wait to encounter the one antibiotic to which it is resistant and is likely to be killed by agents of other antibiotic classes. Thus, the increasing prevalence of antibiotic-resistant pneumococci is associated with the increasing prevalence of multidrug-resistant strains.[779] Therefore, one is not surprised that the use of one class of antibiotics (mainly macrolides and trimethoprim-sulfamethoxazole) can be associated with an increase in resistance to other classes of antibiotics (mainly β-lactam drugs).[5,30,169,277] Many authorities now think that antibiotic agents such as the newer macrolides (e.g., clarithromycin and azithromycin) and trimethoprim-sulfamethoxazole are stronger promoters of antibiotic resistance among *S. pneumoniae* strains than are the β-lactam drugs.[30,169,251,277,586] Researchers also have suggested that among the β-lactam drugs, cephalosporins are stronger promoters of resistance in *S. pneumoniae* than are the aminopenicillins.[251,650]

Although many strains are resistant to tetracyclines and macrolides, they are susceptible to the new tetracycline derivatives, the glycylcyclines, as well as to streptogramins, ketolides, glycopeptides, and rifampin. Many strains are resistant to trimethoprim-sulfamethoxazole worldwide, with more than 40 percent being resistant in the United States. Fluoroquinolones with antipneumococcal activity (e.g., gatifloxacin, levofloxacin, moxifloxacin) are active against most strains of *S. pneumoniae*; however, in several countries where fluoroquinolones have been prescribed widely, clinically relevant levels of resistance have been described.[122,328,613] No doubt, antibiotic resistance will continue to evolve and challenge us.

EPIDEMIOLOGY

Pneumococcal infection remains a serious problem at the beginning of the 21st century in both the developed and developing worlds. It still is a leading cause of death worldwide and a very important cause of morbidity in all countries.

In the United States, since the introduction of Hib vaccination, *S. pneumoniae* has become the leading cause of bacteremia and bacterial meningitis and has remained a major cause of otitis media. This organism causes more deaths than does any other vaccine-preventable organism.[252] The burden of pneumococcal disease in the United States has been estimated to be 125,000 to 500,000 cases of pneumonia, 50,000 cases of bacteremia, 3000 cases of meningitis, and 7 million cases of otitis media, with 40,000 deaths occurring annually.[56,315,594] In the developing world, pneumococcal infections are among the leading causes of death in children younger than 2 years old, with the estimated 1.2 million deaths per year accounting for 9 percent of all deaths.[409]

The only reservoir of *S. pneumoniae* is the human nasopharynx. From there, the organism can (1) enter the bloodstream and cause invasive infections such as sepsis and meningitis and infections in remote foci such as joints, bones, and soft tissues; (2) spread to adjacent mucosal tissue and cause mucosal infections such as otitis media, sinusitis, and pneumonia; and (3) be transmitted by direct contact and through aerosols to other individuals.[154] Acquisition and nasopharyngeal carriage of *S. pneumoniae* are associated with the occurrence of pneumococcal AOM,[210,442,478,799] bacteremia,[286,448,473,497] and pneumonia.[330]

The most common diseases caused by *S. pneumoniae* are related to the upper respiratory tract (mainly otitis media, conjunctivitis, and sinusitis). The least common are invasive infections such as bacteremia and meningitis, whereas pneumonia is of intermediate frequency. Figure 96–3 shows the difference in the order of magnitude of these diseases. The yearly incidence of invasive infections is reported to be less than 10 to greater than 1000 per 100,000 children younger than 5 years old in various populations. The incidence of pneumonia usually is reported as a few dozen to a few thousand per 100,000 children younger than 5 years of age. Pneumococci are responsible for 25 to 50 percent of cases of otitis media in children, which translates to more than 10,000 per 100,000 children younger than 5 years old. Thus, pneumococcal otitis media is roughly up to 1000-fold more common than is invasive pneumococcal infection, and pneumococcal pneumonia is 10- to 100-fold more common than is invasive infection.

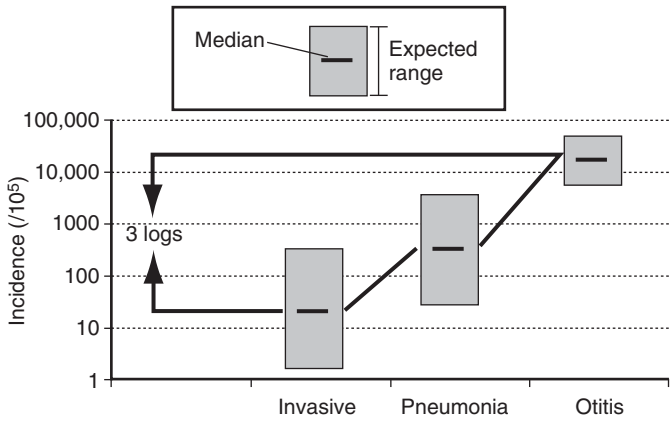

Figure 96–3 Relative incidence of pneumococcal invasive infections, pneumonia, and otitis media in children. The figure is based on estimates from global data that have been published or presented at meetings. The *horizontal line* in each box presents the estimated average value and the upper and lower limits of the presumed range.

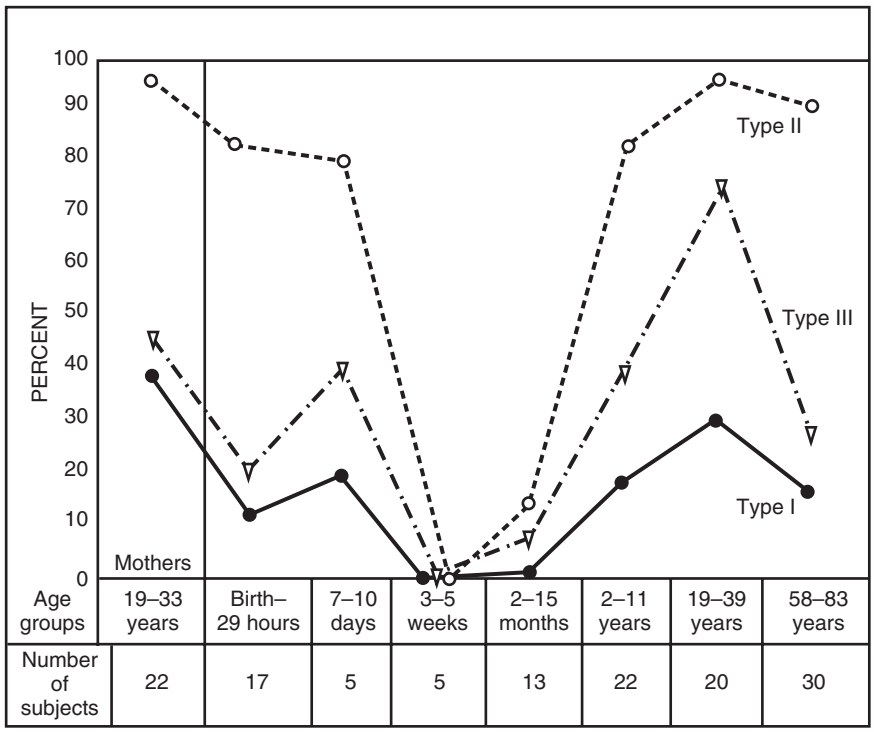
RISK FACTORS FOR PNEUMOCOCCAL INFECTION

In general, decreased host defenses, especially in humoral immunity, or increased exposure to the organism can be considered the main risk factors for acquiring pneumococcal infection. Risk factors can be divided into various categories, although such division is arbitrary because numerous predisposing conditions can be present.

YOUNG AGE. Young age is perhaps the most important risk factor for acquiring pneumococcal infection because natural immunity is highly age-dependent. One of the best demonstrations of the relationship between age and immunity to pneumococcal infection was published in 1932 by Sutliff and Finland (Fig. 96–4). Immunity in the first few months of life, derived from maternal antibody passively transferred to the fetus, protects against invasive infection. These antibodies disappear rapidly, and, within a few months, the incidence of invasive infection increases. The incidence then starts to decline sharply after the child is 18 months of age and able to mount an immune response to most pneumococci, coupled with cumulative exposure to the various pneumococcal strains.

ABSENCE OR MALFUNCTION OF THE SPLEEN, INCLUDING HEMOGLOBINOPATHIES. The spleen is the principal organ that clears pneumococci from the bloodstream.[710,769] Patients in whom the spleen has been removed or does not function normally are at risk for the development of overwhelming pneumococcal infection. Children with invasive *S. pneumoniae* from eight children's hospitals in the United States were studied during the period 1993 to 1999. Of 2581 cases, 1 percent occurred either in children with congenital asplenia or in children who had undergone surgical splenectomy.[662] The mortality rate was high (6/22 [27%]), especially in those with meningitis.



Age groups	19–33 years	Birth–29 hours	7–10 days	3–5 weeks	2–15 months	2–11 years	19–39 years	58–83 years
Number of subjects	22	17	5	5	13	22	20	30

Figure 96–4 Percentage of subjects in different age groups whose blood is pneumococcidal.

Splenic malfunction is considered to be the most important reason for the increased incidence and severity of pneumococcal bacteremia in sickle-cell disease and other sickle hemoglobinopathies (e.g., hemoglobin SC disease or S-β-thalassemia).[569,571,662,797] Although the incidence of pneumococcal infection in children with hemoglobin SC disease is lower than in persons with sickle-cell disease, it is higher than in healthy children.[439,738] The incidence of overall bacterial sepsis in other hemoglobinopathies (e.g., S-β-thalassemia) is estimated to be intermediate between that for hemoglobin SC and hemoglobin SS disease.[560] The high risk for the development of pneumococcal infection in persons with sickle-cell disease is thought to be due to the combination of low levels of circulating antibodies, splenic dysfunction, and complement deficiency, which results in decreased clearance of encapsulated bacteria from the bloodstream.[571,784] Although the use of prophylactic penicillin has reduced the risk for acquiring pneumococcal disease, children younger than 5 years old with sickle-cell disease still have increased rates of invasive disease (range, 1230 to 1500/100,000 population).[226,569,788,797]

DEFECTIVE ANTIBODY FORMATION. As reviewed in the "Pathogenesis" and "Prevention" sections of this chapter, defective antibody production against pneumococcal polysaccharides is the rule for most serotypes in individuals younger than 18 months old and may be seen at even older ages for some serotypes. However, at all ages, conditions associated with reduced antibody formation constitute a high risk for acquiring pneumococcal infection in comparison to peers. Such conditions are congenital agammaglobulinemia, acquired common variable hypogammaglobulinemia,[147] selective IgG subclass deficiency,[746] and secondary defective antibody production in diseases such as malignancies and human immunodeficiency virus (HIV) infection. HIV infection predisposes individuals to the acquisition of secondary bacterial infection by several mechanisms, but defective antibody production is the most important factor in pneumococcal infection. The ability to produce antipneumococcal capsular antibody is inversely proportional to the peripheral blood $CD4^+$ lymphocyte count, especially if it falls below $500/mm^3$.[368,625] *S. pneumoniae* is the most common cause of invasive bacterial infection in HIV-infected children; it accounts for 35 to 50 percent of such episodes, with the relative risk of acquiring disease being 3- to 22-fold higher than that in children without HIV infection.[22,64,214,239,487,515] In one study, the incidence of invasive pneumococcal disease was 6.1 cases per 100 patient-years in HIV-infected children through the age of 7 years.[495]

DEFECTS IN COMPLEMENT. Congenital or acquired deficiencies in C1, C2, and C4 may be associated with increased susceptibility to pneumococcal infection, although cases documenting these associations are rare.[222]

NEUTROPENIA OR NEUTROPHIL DYSFUNCTION. The primary neutropenias, such as cyclic neutropenia, as well as secondary ones, such as drug-induced neutropenia and aplastic anemia, are associated with an increased incidence of severe pneumococcal infection. In some neutrophil dysfunction states, such as seen in alcoholism, liver cirrhosis, glucocorticoid treatment, and renal insufficiency, an increased incidence of pneumococcal infection is found. However, the incidence is not increased in other granulocyte dysfunction syndromes such as leukocyte adhesion deficiency syndromes[19] and chronic granulomatous disease.[248] In chronic granulomatous disease, although intracellular bacterial killing by polymorphonuclear WBCs is defective, the absence of catalase renders the pneumococcus susceptible to interaction between its endogenous H_2O_2 and myeloperoxidase and the halides present in PMNs.

DIABETES MELLITUS. Diabetes is associated with a high incidence of pneumococcal infection in adults.[113,213,601,772] However, because diabetes can predispose to pneumococcal infection by several mechanisms, some of which are found only in adults, whether diabetes mellitus in children also is a risk factor for the development of pneumococcal infection is not clear.

CONDITIONS ASSOCIATED WITH DECREASED PULMONARY CLEARANCE. Inflammatory conditions such as

asthma, chronic bronchitis, and chronic obstructive lung disease predispose to the development of bacterial infections of the lung, including pneumococcal pneumonia. Both active smoking and passive smoking are associated with chronic lung damage and inflammation and have been shown to be important risk factors for development of serious pneumococcal infection.[545] Respiratory viral infections also contribute to decreased pulmonary clearance. However, as described in the "Pathogenesis" and "Prevention" sections of this chapter, viral infections contribute to pneumococcal infection by several additional mechanisms.

CROWDING. Crowding contributes to many factors that increase the risk for acquiring pneumococcal infection, including viral infections, poor hygiene, and increased person-to-person transmission of *S. pneumoniae*. Attendance at daycare centers was the most important risk factor for acquiring invasive pneumococcal infection in children and infants in several studies.[68,124,261,463,608,718] In a recent population-based, case-control study, adults aged 18 to 64 years who lived in households that included children attending daycare were at greater risk of acquiring invasive pneumococcal infection.[545] In developed countries, attendance at daycare centers is also the most important risk factor for acquiring AOM, including pneumococcal otitis.[535,637,744]

NON–BREAST-FEEDING. Breast-feeding may be protective against pneumococcal infection. Human milk has been shown to block the attachment of pneumococci to pharyngeal cells, whereas bovine milk demonstrated only a weak effect.[305] This antibacterial effect could be mediated through several components of the immune system, including secretory IgA, lactoferrin, and lysozyme. Some authors have suggested that breast-feeding protects against otitis media,[24,104,197,744] but others have failed to show this effect.[58] Studies in the United States demonstrated a protective effect of breast-feeding against invasive pneumococcal infection in children in the general population[463] and in Alaskan natives.[261] In Finland, in contrast, no such protective effect was seen.[718]

GENETIC VARIATION IN MANNOSE-BINDING LECTIN. Approximately 5 percent of the population in Europe and North America and an even larger population in many developing countries are homozygous for MBL codon variants. These subjects have a greater than 2.5-fold increased risk for the acquisition of pneumococcal infection than do those who do not have this variant or are only heterozygous for this variant.[638]

MALE GENDER. Males are affected more often than are females in most studies on pneumococcal disease, including studies on pneumococcal bacteremia, pneumonia, meningitis, and otitis media.* The reason for the male preponderance is not understood.

SEASONALITY. The occurrence of pneumococcal infection is related to season. Clustering of invasive infections, pneumonia, and otitis media occurs from September to October through April to May in the Northern Hemisphere (with the opposite picture in the Southern Hemisphere), with peaks usually occurring from December through February.† Variation in the seasonality of carriage of pneumococci also occurs and is lowest in the summer months.[290,476] This seasonality probably is related, at least in part, to two factors: (1) it parallels the seasonal variations in viral respiratory infections, which play an important role in predisposing to pneumococcal carriage and infection, and (2) the peak pneumococcal infection season coincides with attendance at school and daycare centers, which often excludes the summer months. However, many issues regarding seasonality remain unclear, as exemplified by data from an ongoing surveillance of invasive infections in southern Israel, where two different populations live side by side and have two distinct seasonal patterns (Fig. 96–5). In this example, the Jewish population in southern Israel, with a lifestyle equivalent to that of a middle/lower social class Western population, has a seasonality of invasive pneumococcal infection similar to that of developed populations, as represented in Figure 96–5 by children from Houston, Texas.[413] In contrast, the Bedouin population in southern Israel, a population in transition from semi-nomadism to a Western lifestyle and who live in crowded and poor hygienic conditions with a high birth rate and a disease pattern similar to that in the developing world,[464] does not demonstrate a clear pattern of seasonality. The relative abundance of cases in the spring and summer is speculated to be related to the peak of diarrheal illness in this population.[464] Further understanding of seasonality patterns may contribute to prevention of pneumococcal disease in the future.

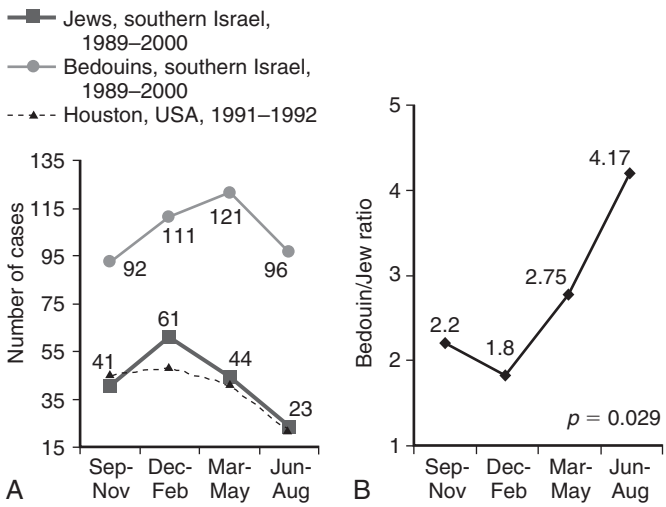


Figure 96–5 Seasonality of invasive pneumococcal infection in children from two populations in southern Israel during the years 1989 to 2000 and in Houston during the years 1991 to 1992.[405] **A,** Average number of cases for each season. **B,** Ratio of the average number of cases per season among Bedouin versus Jewish children in southern Israel.

NASOPHARYNGEAL CARRIAGE

Because acquisition and carriage of *S. pneumoniae* are associated with infection, that the higher incidence of pneumococcal infection in children than adults is associated with a higher incidence of nasopharyngeal carriage is not surprising. In various parts of the world, the carriage rate is approximately 5 to 10 percent in adults but can reach levels greater than 90 percent under various circumstances in infants and young children. Virtually all individuals carry pneumococci belonging to several serotypes during their lifetime. In a study conducted in the United States,[321] the prevalence of nasopharyngeal carriage in preschool children was 38 to 60 percent versus 29 to 35 percent and 9 to 25 percent in elementary school and junior high-school students, respectively. The prevalence in adults with no children at home was 6 percent. In studies in closed populations such as kibbutzim in Israel[87] or a poor and crowded black community in southern Israel,[160] the same differences between children and adults were noted.

Contact with young carriers increases the carriage rates in older children and adults. In the United States, although adults

*See references 92, 103, 112, 153, 207, 240, 350, 360, 701, 726.
†See references 98, 153, 207, 243, 285, 286, 288, 387, 405, 411, 522, 706, 754.

with no children had a carriage rate of 6 percent, the carriage rate increased to 29 percent when children were present at home. Similarly, primary school–aged children who have siblings younger than 2 years old carried *S. pneumoniae* more often than did those without young siblings.[481] In a study in Costa Rica, mother-child paired cultures showed an increased prevalence of carriage: from 6 percent at 1 month of age to 39 percent at 12 months of age. At the same time, carriage in mothers increased from 0 to 9.8 percent, thus confirming the influence of infants on adult carriage.[757] In Finland, the increased prevalence of carriage in mothers, fathers, and siblings when the index child grew older resulted in increased rates of pneumococci in the family.[459] In a Swedish study, the observed average duration of carriage was longer in children who had family carriers of the same serotype and, therefore, was suggestive of rapid recirculation in the family.[202]

Acquisition of *S. pneumoniae* may occur during the very first days of life. In infants aged 2 months, the prevalence of carriage ranges from less than 15 percent in some developed countries[23,82,171,286,459,476] to greater than 60 percent in developing countries.[138,241,284,498,514] Colonization peaks toward the second to third year of life.[171,290,320] The relationship of age to carriage is not understood, but it depends, at least in part, on the development of specific anticapsular antibodies.[288,289] In toddlers vaccinated with a pneumococcal conjugate vaccine, nasopharyngeal acquisition of new *S. pneumoniae* serotypes was related inversely to serum levels of specific antipolysaccharide IgG antibodies.[158] In another study, the presence of both circulating IgG and secretory IgA antibodies to the surface pneumococcal protein PsaA was associated with a lower prevalence of nasopharyngeal pneumococcal carriage.[397,605,685] A 2004 study showed that mucosal anticapsular IgA developed in response to colonization in preschool-aged children, regardless of vaccination status.[83,800] This phenomenon has been hypothesized to contribute to the falling carriage rates observed with increasing age.[801] The relative role of innate immunity with increasing age is not clear.

Crowding is an important factor that facilitates the spread of *S. pneumoniae*. Therefore, one is not surprised that in the developed world, the nasopharyngeal carriage rate and spread are highest in infants and toddlers attending daycare centers, with levels exceeding 90 percent in some studies,* followed by those living with one or more sibling at home.[23,171,481,595,753] In addition, the viral infections that are very prevalent in infants and toddlers attending daycare centers enhance colonization of the nasopharynx with *S. pneumoniae*.[290,476,763] The combination of young age, poor hygienic behavior, and increased incidence of respiratory viral infections renders daycare centers the ideal site for promotion and spread of *S. pneumoniae*. In addition, because of widespread antibiotic use, carriage of antibiotic-resistant *S. pneumoniae* is highest in daycare center attendees.† Daycare centers, thus, are a nucleus of high carriage of *S. pneumoniae*, particularly antibiotic-resistant strains. This nucleus is then responsible for the dissemination of such resistant organisms to other children, mainly to young siblings of daycare center attendees.[156,171]

The duration of carriage depends on age and serotype and may be related to additional factors such as antibiotic treatment, the immune status of the child, and other unknown factors. Carriage lasts longer in infants and young toddlers than in older children and adults.[159,202,288] In a study in Sweden,[202] infants were colonized for an average of 30 days, and after 3 months, 17 percent were carrying the same organism. In a study in the United States in adults, individual serotypes usually persisted for 2 to 4 weeks. The study showed that the first pneumococcal

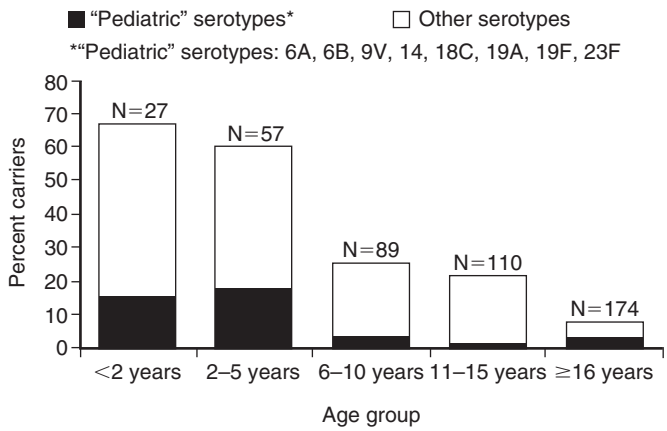

Figure 96–6 Nasopharyngeal carriage of *Streptococcus pneumoniae* in a closed black community living in crowded conditions in southern Israel. *(Adapted from Dagan, R., Gradstein, S., Belmaker, I., et al.: An outbreak of Streptococcus pneumoniae type 1 in a closed community in southern Israel. Clin. Infect. Dis.* 30*:319-321, 2000.)*

serotype that colonizes infants (typically before they reach 6 months of age) can be detected for as long as 12 months (mean, 4 months).[288]

The relationship between the ability of a specific serotype to colonize the nasopharynx of a child and its ability to cause respiratory or invasive infection is not clear. Some serotypes, such as 6A, 6B, 9V, 14, 18C, 19A, 19F, and 23F, are among the most frequent colonizers in infants and young children in most parts of the world and thus often are considered "pediatric" serotypes.[90,160] Some of these "pediatric" serotypes, such as serotypes 6B and 23F, also are less immunogenic than are others, especially in children younger than 2 years old, but some can show a reduced response even late in childhood. These serotypes are acquired frequently by infants and young children and often are carried for a prolonged period. After the child reaches the age of 2 years, carriage of these "pediatric" serotypes declines rapidly. Although pneumococcal carriage decreases overall with age, the proportion of the "nonpediatric" serotypes increases with age. This phenomenon is demonstrated in Figure 96–6.

In contrast to the "pediatric" serotypes, serotypes such as 1, 5, 7F, and 12 are carried infrequently and are eliminated from the nasopharynx rapidly. However, these serotypes are able to cause disease and even epidemics.[160,331,526,529,694] The different distribution of serotypes among colonized children, children with invasive infections, and adults with pneumonia is exemplified in Figure 96–7.

Although most colonization occurs without the development of disease, some prospective, longitudinal studies have suggested that most systemic infections develop soon after colonization by a new pneumococcal serotype.[210,286,288] Carriers are protected from invasive disease by the development of circulating antibodies. However, such antibodies do not always protect against invasion of contiguous sites, and other studies have shown that a substantial number of pneumococcal otitis media cases occur at any time during nasopharyngeal colonization by a specific serotype.[43,714]

The epidemiology of nasopharyngeal carriage of antibiotic-resistant pneumococci is important. The most significant promoter of carriage of antibiotic-resistant *S. pneumoniae* is antibiotic use.* Prolonged carriage of azithromycin-resistant *S. pneumoniae* was observed after a single dose of azithromycin was administered to Australian aboriginals for the treatment of trachoma.[443]

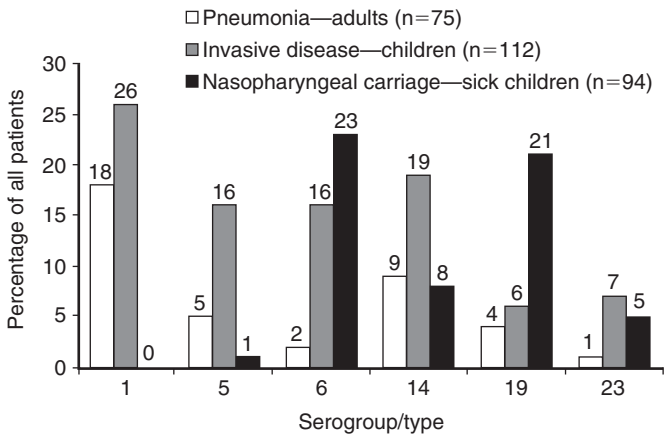

Figure 96–7 Distribution of selected serogroups/serotypes in *Streptococcus pneumoniae* isolates from adults with pneumonia, children with invasive infection, and nasopharyngeal specimens from sick children in Kenya. *(Adapted from Scott, J. A. G., Hall, A. J., Hannington, A., et al.: Serotype distribution and prevalence of resistance to benzylpenicillin in three representative populations of Streptococcus pneumoniae isolates from the coast of Kenya. Clin. Infect. Dis. 27:1442-1450, 1998.)*

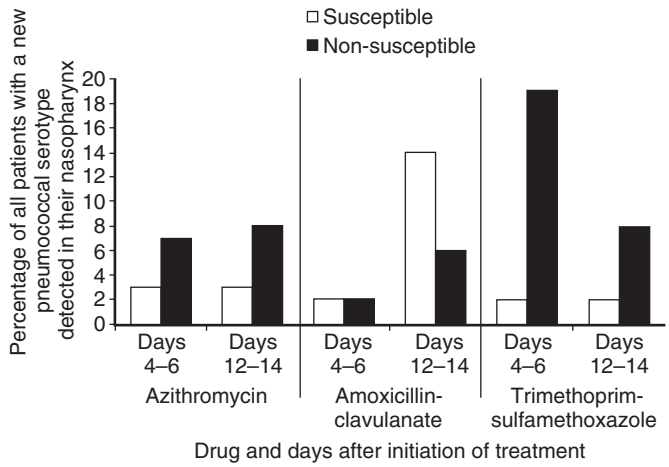

Figure 96–8 Nasopharyngeal acquisition of new pneumococcal serotypes during antibiotic treatment of acute otitis media based on susceptibility or resistance to the antimicrobial that was administered. Material for culture was obtained 3 to 5 days and 11 to 13 days after initiation of treatment. The regimens were azithromycin, 10 mg/kg as a single dose on day 1, followed by 5 mg/kg once daily for an additional 4 days; amoxicillin-clavulanate, 45/6.6 mg/kg/day in two divided doses for 10 days; and trimethoprim-sulfamethoxazole, 8/40 mg/kg/day in two divided doses for 10 days.[169]

Prophylaxis with amoxicillin increased the carriage of penicillin-resistant *S. pneumoniae*.[101] An association between trimethoprim-sulfamethoxazole prophylaxis and nasopharyngeal colonization with both trimethoprim-sulfamethoxazole– and penicillin-resistant *S. pneumoniae* has been demonstrated.[5,30,169]

A series of prospective studies revealed some of the early processes that occur in the nasopharynx during and in the immediate post-treatment period in cases of AOM caused by antibiotic-resistant *S. pneumoniae*.[133,137,148,167,169] These events can be summarized as follows: (1) most drugs studied had a substantial effect on the nasopharyngeal flora and eradicated or reduced the carriage of pneumococci that were susceptible to the drugs; (2) little, if any effect was seen when the organism had reduced susceptibility to the drugs administered; (3) some drugs, such as azithromycin and trimethoprim-sulfamethoxazole, appeared to promote colonization with resistant *S. pneumoniae*; and (4) β-lactam drugs with higher activity against *S. pneumoniae* in general and against non-penicillin-susceptible *S. pneumoniae* in particular, such as amoxicillin-clavulanate and cefuroxime axetil, decreased colonization better than did drugs with poor antipneumococcal activity, such as cefaclor, cefpodoxime, and cefixime.

Even more intriguing than the differential effect of various drugs on carriage of *S. pneumoniae* is the ability of these agents to alter nasopharyngeal colonization. Such alteration occurs by selection of pneumococcal strains that were masked by other organisms or selection of strains that were acquired after initiation of treatment, as was exemplified when children suffering from trachoma received one dose of azithromycin and were monitored for nasopharyngeal carriage of *S. pneumoniae*.[443] Before treatment, 68 percent were colonized with *S. pneumoniae*, but only 1 percent had azithromycin-resistant *S. pneumoniae*. Within 2 to 3 weeks after they received treatment, colonization decreased to 29 percent, but 16 percent were colonized with azithromycin-resistant *S. pneumoniae*. Two months later, 78 percent were colonized with *S. pneumoniae* and 27 percent with azithromycin-resistant *S. pneumoniae*. The prevalence of pneumococcal colonization and azithromycin susceptibility returned to pre-exposure values only after 6 months. In another study, cultures performed shortly after initiation of treatment and immediately after cessation of treatment showed that new serotypes, either susceptible or resistant to the treatment drug, appeared in 21, 24, and 31 percent of those treated with azithromycin, amoxicillin-clavulanate, and trimethoprim-sulfamethoxazole, respectively[169] (Fig. 96–8). The proportion of new strains of pneumococci resistant to these drugs was 15, 8, and 27 percent, respectively.

A study looking at more than 31,000 *S. pneumoniae* isolates between 2000 and 2003 found that 29.4, 22.5, and 0.9 percent were resistant to erythromycin, penicillin, and levofloxacin, respectively. Thirty-one percent of the isolates exhibited multidrug resistance. Among macrolide-resistant isolates, *mefA* was the most prevalent resistant gene identified. Ninety percent of isolates that contained both the *mefA* and the *ermB* resistance genes were resistant to penicillin, tetracycline, or trimethoprim-sulfamethoxazole. However, 98.6 percent of those isolates were susceptible to levofloxacin.[374]

Prolonged and low-dose antibiotic regimens are suggested to be important contributors to promotion of carriage and spread of antibiotic-resistant *S. pneumoniae*.[136,294,329,482,659]

One of the serious problems with pneumococcal strains clearly is the emergence of resistance to more than one antibiotic class.[355] This phenomenon explains why the use of one antibiotic may result in carriage of *S. pneumoniae* resistant not only to the antibiotic to which the host was exposed but also to other, unrelated classes of antibiotics. In 1993, approximately a fifth of the pneumococcal strains in Iceland were not penicillin-susceptible and 80 percent of them were multidrug-resistant. When the risk for carriage of penicillin-resistant *S. pneumoniae* was investigated, a clear association was found not only with use of β-lactam drugs but also with the use of trimethoprim-sulfamethoxazole and erythromycin.[30] Other authors likewise have shown an association between the use of trimethoprim-sulfamethoxazole and carriage of penicillin-resistant *S. pneumoniae*.[82,507]

When a group of children who did not carry trimethoprim-sulfamethoxazole–resistant *S. pneumoniae* were studied longitudinally during therapy for AOM,[169] carriage of trimethoprim-sulfamethoxazole–resistant *S. pneumoniae* was found in 23 percent of patients by day 6 and in 33 percent by day 40. Additionally, non–penicillin-susceptible *S. pneumoniae* was carried at these times by 26 and 43 percent of children, respectively. This remarkable promotion of colonization with penicillin-resistant strains by trimethoprim-sulfamethoxazole

treatment occurred because many strains were resistant to both penicillin and trimethoprim-sulfamethoxazole.

Mass chemoprophylaxis and therapeutic campaigns now are being conducted in different regions against a variety of diseases, which raises concern about the widespread development of resistance. Examples are mass azithromycin treatment campaigns to eradicate trachoma, mass sulfadoxine-pyrimethamine (Fansidar) treatment (shown to be associated with an increased rate of resistance to trimethoprim-sulfamethoxazole in pneumococci),[218] increasing use of trimethoprim-sulfamethoxazole for prophylaxis of patients infected with HIV, and mass treatment with fluoroquinolones and tetracyclines after exposure to *Bacillus anthracis*.

The dramatic change in nasopharyngeal flora after initiation of antibiotic therapy has two important consequences. First, the phenomenon described earlier predisposes patients to new acquisition of infection with more resistant organisms.[157] Antibiotic treatment not only can increase nasopharyngeal carriage of antibiotic-resistant *S. pneumoniae* but also can induce superinfection of the middle ear with a resistant strain within a few days.[167] Second, the increased prevalence of antibiotic-resistant *S. pneumoniae* in the nasopharynx may increase transmission in crowded conditions such as extended families and daycare centers.[171,262,274,320,595,627,791] A recent study found that reducing the number of antibiotic prescriptions written in a French community resulted in an 18 percent decrease in colonization ($p < 0.05$). Physicians participating in the study were instructed not to write prescriptions for presumed viral respiratory tract infections even with purulent rhinitis. In addition, the physicians were asked to document actual streptococcal pharyngitis with an antigen test.[295] Therefore, the widespread use of antibiotics is likely to be responsible for the increase in antibiotic-resistant *S. pneumoniae*, especially in crowded populations, thus creating a vicious cycle that is difficult, if not impossible, to overcome (Fig. 96–9). The presence of this vicious cycle poses a real challenge to society.

Since the use of pneumococcal vaccine has become widespread in the United States, the serotypes found most commonly in nasopharyngeal colonization have been replaced by nonvaccine serotypes. A study evaluating nasopharyngeal colonization in 16 Massachusetts communities during 2001 to 2004 showed a decrease in serotypes found in the PCV-7 vaccine from 36 percent to 14 percent along with an increase in non–PCV-7 serotypes from 34 percent to 55 percent.[342] Another study showed that 25 percent of children colonized with pneumococci carried antibiotic-resistant, nonvaccine serotypes, including serotypes 19A and 35B, rarely detected before introduction of the pneumococcal conjugate vaccine. Seven percent of the 19A isolates tested in the study were resistant to all oral agents tested (penicillin, amoxicillin, cefuroxime, ceftriaxone, azithromycin, and trimethoprim/sulfamethoxazole), and 12 percent of the 35B isolates were not susceptible to penicillin or cefuroxime.[359]

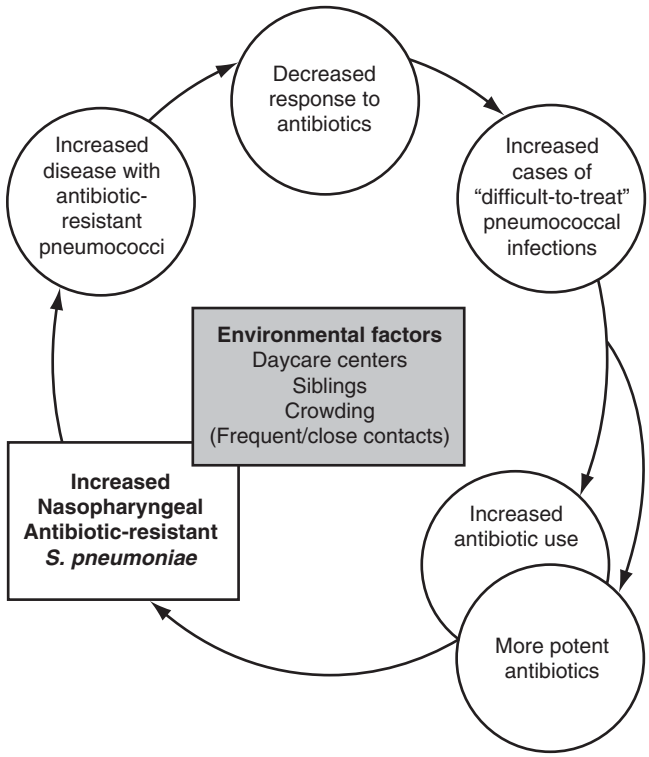

Figure 96–9 Chain of events that create a vicious cycle in which antibiotic treatment increases the carriage of antibiotic-resistant pneumococci, which cause more disease with resistant organisms. This situation results in reduced response to antibiotic treatment and an increase in the number of "difficult-to-treat" cases. As a result, the use of antibiotics is increased, especially more potent ones, thus again promoting a further increase in nasopharyngeal carriage of antibiotic-resistant pneumococci.

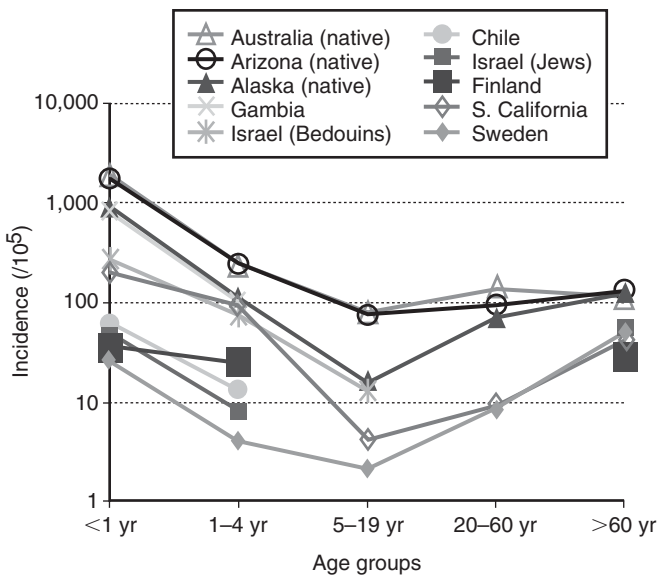

Figure 96–10 Age-specific incidence of invasive pneumococcal disease in various populations. Data were obtained from various presentations and publications.

INVASIVE PNEUMOCOCCAL DISEASE

Although invasive pneumococcal infections occur far less commonly in early childhood than does pneumonia or otitis media, they are an important cause of morbidity and mortality during childhood worldwide. Pneumococci are more common than are Hib and *N. meningitidis* as causes of bacteremia in most countries and rank second after Hib or third after *N. meningitidis* in causing bacterial meningitis. Pneumococci are estimated to be responsible for 25 to 50 percent of cases of bacterial meningitis in children in the United States,[660] Europe,[140] and Africa.[575]

The incidence and severity of invasive pneumococcal disease vary in different populations. Figure 96–10 exemplifies the differences in incidence in various populations by age group. Several important points can be drawn from this figure: (1) an age-dependent pattern exists that is similar in all populations: the highest rate is in infants, the rate decreases rapidly toward the age of 5 years, and then it increases again toward the age of 60 years, with a second peak occurring in persons older than 65; (2)

a marked difference exists among various populations in the incidence of invasive infection, and this difference can be up to 100-fold; and (3) in general, the incidence in the more industrialized countries is lower than that in less industrialized countries or in less privileged populations, but the U.S. figures seem to be higher than those of other developed populations.

Because invasive pneumococcal infections are detected by blood culture in most cases, variations in rates of performing blood cultures in young children could be responsible, at least in part, for differences in the reported incidence of invasive pneumococcal infection.[217,312] In contrast to Europe, where most pediatric blood isolates were obtained from hospitalized children, many blood cultures are performed on outpatients in the United States.[312] This difference arises because U.S. practice guidelines recommend blood cultures for children aged 3 to 36 months with high fever and WBC counts of 15,000/mm^3 or greater.[53] Indeed, several European investigators have noted that the recent rises in reported invasive pneumococcal disease rates might be related to an increasing likelihood of taking blood for culture.[48,387,539,697] Preliminary evidence from Chile also suggests that a considerable proportion of relatively mild invasive infections routinely go unrecognized.[438] This hypothesis can be supported by the fact that the incidence of meningitis is similar in the United States and Europe.[312]

Thus, the incidence of invasive infection in children younger than 5 to 6 years in western Europe (e.g., Finland, the United Kingdom, Germany, Switzerland, Denmark, Spain) was lower than 25 cases per 100,000 population per year in various studies; in Chile, Australia, and New Zealand, it was 25 to 60 per 100,000; and during the same period in the United States, the range was approximately 65 to 75 cases per 100,000.[312] In contrast, the incidence of pneumococcal meningitis in these countries was similar: 3.6 per 100,000 in the United States versus a mean of 4.6 per 100,000 in Europe (range, 2.1 to 7.0).[312]

Differences in the incidence of invasive pneumococcal infection among populations are not due solely to different blood culture practices because true significant differences can be found within the same country. This difference can be exemplified by comparing the incidence of invasive pneumococcal disease in different ethnic groups in the United States, where a higher incidence of invasive pneumococcal disease occurs in African Americans, Alaskan Natives, and specific American Indian populations than in whites (Table 96–2). The incidence of pneumococcal bacteremia and meningitis in Alaskan Native children younger than 5 years ranges from 598 cases per 100,000 population in those 6 to 11 months of age to 56 cases per 100,000 population in those 36 to 47 months of age, which is approximately four times the incidence in similarly aged non–Alaskan Native/non–American Indian children.[115] The highest incidence for any ethnic group in the United States is found in Navajo and Apache populations living on reservations in the southwestern United States. The incidence in children aged 1 to 2 years in these populations is 557 to 2396 per 100,000.[142,549] Among children younger than 5 years, the incidence of invasive pneumococcal disease in African American children in the United States is two to three times higher than that in white children of the same age.[61,94,309,622] In a case-control study of risk factors for the development of invasive disease in young children, the association of race with disease risk was not statistically significant in an analysis that controlled for socioeconomic status.[463] However, other studies have reported persistence of increased risk even when controlling for income.[94,123,223,309,322] The reasons for the increased incidence in some populations in comparison to others in the United States are unclear.

In other geographic regions, differences among populations also can be observed, again being higher in populations that live in underprivileged conditions, which raises the question of the importance of genetic versus environmental risk factors. In southern Israel, the incidence of pneumococcal invasive infection during the first year of life in Bedouin infants (a population with a lifestyle, birth rate, and general disease incidence similar to that of the developing world) was 270 cases per 100,000 versus 53 per 100,000 in Jewish infants (a population with standards of living comparable to the middle/low social class in the developed world) ($p < 0.001$).[240] This difference also was found in children aged 1 to 4 years: 75 and 21 cases per 100,000, respectively ($p < 0.001$). In New Zealand, when Maoris, Pacific Islanders, and others were compared, incidence rates of invasive pneumococcal disease in the first year of life per 100,000 population were 153, 276, and 52, respectively. The respective rates in children younger than 5 years were 67, 117, and 36 per 100,000, respectively.[760]

Studies on the incidence of invasive pneumococcal infection in developing regions are scanty. In one study in The Gambia, the annual incidence in children younger than 1 and 5 years was 554 and 240 per 100,000, respectively.[554] Another study in The Gambia documented the incidence of invasive pneumococcal infection to be 224, 139, and 82 cases per 100,000 children during the first, second, and third years of life, respectively.[747] *S. pneumoniae* plays a more important role in the acquisition of meningitis in developing countries than in developed countries. Reports from several African countries show that *S. pneumoniae* accounts for 20 to 50 percent of all cases.[575] Data from many other developing populations, especially from countries in Southeast Asia, are lacking but are needed because data from Africa cannot be extrapolated to other developing parts of the world.

TABLE 96–2 Incidence (Cases/100,000 Population) of Invasive Pneumococcal Disease in Selected U.S. Pediatric Populations—Selected Years

The fatality rate of pneumococcal meningitis is higher than that of meningitis caused by other organisms.[575] Mortality rates for invasive pneumococcal infection in developed populations vary between less than 2 percent and 6.6 percent.[153,180,293,511,622,760] In contrast, in the developing world, mortality rates for invasive pneumococcal infection, including meningitis, vary from 19 percent in South Africa[343] to as high as 67 percent in Mali and Niger.[573,575]

Most invasive pneumococcal diseases in children are caused by a limited number of pneumococcal serotypes. However, despite the many studies reporting on serotypes or serogroups published or presented thus far, the data are not yet complete. Data on serotypes are important, especially with regard to the question of coverage of the various conjugate vaccines, as discussed in the section on prevention in this chapter. The extensive literature was summarized by Hausdorff and colleagues[310,311] in two review articles. The results of their exhaustive review, despite showing many gaps in our knowledge, did lead to certain conclusions (Fig. 96–11): (1) in children younger than 5 years, the great majority of invasive infections are covered by the 11 serotypes that will be included in future conjugate vaccines (or the cross-reacting serotypes in the same serogroup [serogroups 1, 3, 4, 5, 6, 7, 9, 14, 18, 19, 23]); (2) in some regions, 4 serogroups not present in the 7-valent vaccine (serogroups 1, 3, 5, and 7) are of great importance; (3) in older children and adults (mainly those older than 18 years), the 7-valent vaccine often covers only a minority of cases, whereas the 11-valent vaccine covers a greater percentage; and (4) the 23-valent nonconjugate vaccine provides considerably wider coverage than the conjugate vaccines do, although it may not be immunogenic in infants, young children, or immunocompromised hosts.

A recent study evaluating the invasiveness of different *S. pneumoniae* serotypes found that serotypes 4, 14, 7F, 9V, and 18C were associated with rates of greater than 20 invasive pneumococcal disease cases per 100,000 acquisitions, whereas serotypes 23F, 6A, 19F, 16F, 6B, and 15B/C were associated with fewer than 10 invasive pneumococcal disease cases per 100,000 acquisitions. The study also found an inverse relationship between the duration of carriage and the likelihood of causing invasive disease ($p < 0.0001$).[690]

Since the PCV-7 vaccine was introduced, the rate of invasive pneumococcal disease in young infants has decreased significantly.[588] In a study involving eight U.S. children's hospitals, the incidence of invasive pneumococcal disease has decreased more than 75 percent in children younger than 24 months. Replacement of vaccine serotypes by nonvaccine serotypes was noted, particularly serogroups 15 and 33.[278,393] Furthermore, penicillin resistance has increased among nonvaccine serogroups.[393] A study in northern California clinics showed an 84 percent reduction in *S. pneumoniae* bacteremia and a 67 percent reduction in overall bacteremia since routine vaccination was implemented. In this same study, a third of the pathogens identified in positive blood cultures were *E. coli*, a third were nonvaccine serotype *S. pneumoniae*, and the remaining third were mostly *S. aureus*, *Salmonella*, *N. meningitidis*, or *Streptococcus pyogenes*.[326] Despite the use of pneumococcal vaccine, children younger than 1 year and children with comorbid illnesses such as malignancy, HIV infection, immune deficiency, or nephrotic syndrome continue to remain at risk for acquiring invasive pneumococcal disease.[340]

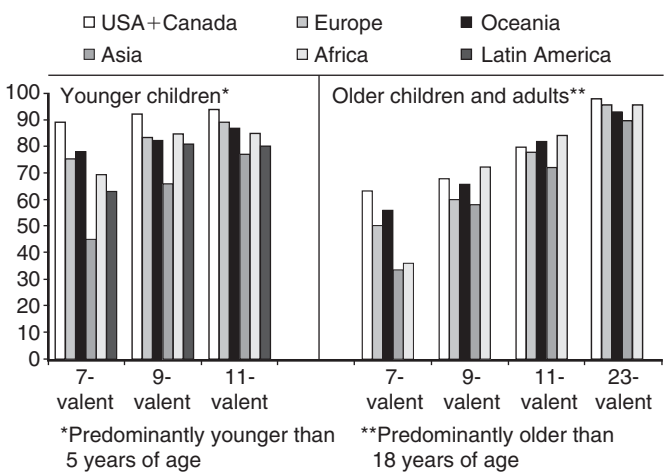

Figure 96–11 Coverage of 7-valent, 9-valent, and 11-valent conjugate pneumococcal vaccines and 23-valent nonconjugated pneumococcal polysaccharide vaccine in younger children (predominantly 5 years of age) and older children and adults (predominantly >18 years of age) in various regions of the world.[310,311]

Serotype 19A is, at present, the most important cause of invasive pneumococcal disease by replacement serotypes since the widespread use of pneumococcal vaccine, and it is becoming increasingly drug-resistant. Between July 1999 and June 2004, the overall rate of invasive pneumococcal disease decreased from 23.3 to 13.1 cases/100,000 population ($p < 0.00001$); during this same period, the rate of invasive pneumococcal disease caused by serotype 19A in children younger than 5 years old increased from 2.6 to 6.5 cases/100,000 population.[562]

In the first 3 years after routine vaccination with heptavalent pneumococcal conjugate vaccine was introduced, the incidence of overall invasive pneumococcal disease decreased 67 percent in Alaska Native children younger than 2 years old. However, between 2001 to 2003 and 2004 to 2006, an 82 percent increase occurred in the rate of invasive disease in Alaska Native children younger than 2 years old. Since 2004, the invasive pneumococcal disease rate caused by nonvaccine serotypes has increased 140 percent in comparison to the prevaccine period.[686]

Many reasons, such as differences in living conditions and socioeconomic status and genetic differences among populations, can be cited for the diversity of serotype/serogroup distribution in populations. However, Hausdorff and associates[312] suggest that the differences in serotype/serogroup distribution among various geographic regions may be related to differences in the testing and reporting practices of various countries. Some serotypes/serogroups may be associated with more severe disease than others are. In regions where blood cultures are performed for mildly ill children, such as the United States, the predominance of serogroups such as 6, 9, 14, 18, 19, and 23 can be accentuated, whereas serotypes such as 1, 3, 5, and 7F, which are found in more severe disease, appear to be less important. The importance of having local data on serotype coverage for evaluating disease burden that can be prevented by vaccination always should be considered.

PNEUMONIA

In adults, *S. pneumoniae* is by far the predominant cause of community-acquired bacterial pneumonia. However, this cause is more difficult to assess in children because obtaining bacteriologic specimens such as sputum from infants and young children is difficult. Blood cultures usually are positive in less than 5 percent of the children with any pneumonia and, thus, cannot provide an accurate representation of the pathogens in childhood pneumonia. Nasopharyngeal cultures, as well as antigen detection and PCR, also are difficult to correlate with bacterial pneumonia (see the section on diagnosis). Studies using lung aspirates are helpful but scant,[761] and most of the recent studies were performed in one developing country (The Gambia). However, data derived from these studies show an important role of *S. pneumoniae* as a causative agent of pneumonia in children.[8,234-236,673]

In a recent study conducted in Finland, transthoracic needle aspiration disclosed an etiology in 18 of 26 patients from whom a representative sample specimen was obtained.[762] Of these patients, 10 of 26 (38%) had lung aspirate cultures positive for *S. pneumoniae*, and 1 additional child had a positive blood culture for *S. pneumoniae*. An additional six patients (23%) had a positive PCR test. Thus, in total, 17 of 26 (65%) had at least one test that was positive for *S. pneumoniae*.

Studies with the newly developed pneumococcal conjugate vaccines in children suggest that the role of *S. pneumoniae* in lower respiratory infections in general and pneumonia in particular may be more important than previously demonstrated. In a study in California,[71] administration of a 7-valent conjugate pneumococcal vaccine reduced the number of cases of clinical pneumonia in children younger than 3.5 years by 6.0 percent ($p = 0.13$) (intention-to-treat analysis). A reduction in the incidence of pneumonia of 8.9 percent ($p = 0.03$) was found in patients who had clinical features of pneumonia and had a chest radiograph performed, regardless of the findings. The incidence of pneumonia was reduced by 22.7 percent in patients with a positive finding on the chest radiograph (defined as parenchymal infiltrates, consolidation or effusion [or both], but not perihilar infiltrates only). In South Africa, administration of three doses of 9-valent conjugate pneumococcal vaccine reduced the incidence of radiologically proven pneumonia by 22.1 percent ($p = 0.049$) in children younger than 2 years old (Klugman, K., and Madhi, S.: Data presented at the Third International Symposium on Pneumococci and Pneumococcal Diseases, May 2002, Alaska). This ability of a pneumococcal vaccine to reduce the incidence of clinical and radiologically documented pneumonia suggests that (1) *S. pneumoniae* is the causative agent in most cases of pneumonia, with consolidation being seen in infants and toddlers in the population studied, and (2) *S. pneumoniae* is a causative agent in many cases usually considered to be viral. Supportive evidence for the latter suggestion can be derived from a study conducted in Israeli toddlers attending daycare centers.[174] In these toddlers, a 9-valent pneumococcal vaccine reduced the incidence of lower respiratory disease, including bronchiolitis, cough, and pneumonia, by 16 percent and reduced antibiotic treatment days for these entities by 47 percent. More studies are being undertaken to investigate the potential of pneumococcal conjugate vaccines to reduce the incidence of pneumonia and other lower respiratory tract infections in developing populations (Native Americans and those in The Gambia and the Philippines).

Although pneumonia usually is not a fatal disease in developed countries, it is an important cause of morbidity and hospitalization. Pneumococcal infections are thought to be rare causes of serious lower respiratory tract disease requiring hospitalization in children younger than 6 months.[181] However, *S. pneumoniae* is an important cause of hospitalization for community-acquired pneumonia in older children.[131,189,258,429,542,640]

In developing countries, acute respiratory infections in general and pneumonia in particular are the leading causes of morbidity and mortality.[505] The mortality rate from respiratory infections in developing countries is estimated to be 10- to 30-fold higher than that in developed countries.[6,461] In addition, of the 15 million children younger than 5 years old who die annually, an estimated 4 million die of pneumonia.[296,461] When obtained, rates of positive sputum culture for *S. pneumoniae* in developing countries can be as high as 88 percent in children.[63] Using a variety of methods, including antigen detection, cultures from blood, sputum, and pleural and lung aspirates, and antipneumococcal antibody testing, a series of investigations in The Gambia associated *S. pneumoniae* with severe acute lower respiratory tract infection in 20 percent of hospitalized infants and in 61 percent of children aged 1 to 9 years.[235,236] In another study in The Gambia[234] conducted on ambulatory children younger than 5 years old with lower respiratory tract infections, *S. pneumoniae* was associated with 8.6 percent of all cases of clinical acute lower respiratory tract infection, 12.3 percent of episodes of radiologically proven acute lower respiratory tract infection, and 28.0 percent of episodes of lobar pneumonia. Despite the limitations of these diagnostic tests, these results demonstrate the importance of *S. pneumoniae* in severe respiratory infection.

No accurate information exists about the pneumococcal serotypes involved in pneumonia in infants and young children. The only accurate data are for bacteremic pneumococcal pneumonia. In these cases, the serotype distribution is not different from that for other invasive infections. However, the bacteremic cases represent only a minority of pneumococcal pneumonia cases, and one cannot extrapolate these data to nonbacteremic cases. The finding of an impressive reduction in pneumonia after the use of a conjugate pneumococcal vaccine, as reviewed earlier, suggests that most pneumonia cases in the population studied are pneumococcal and caused by serotypes included in the vaccine.

OTITIS MEDIA

Otitis media is the diagnosis that accounts for most office visits in pediatric clinics in the United States. It results in more than 15 million visits per year.[425,706] In the United States, 10 percent of children have one or more episodes of otitis media by the time that they are 3 months of age, approximately 60 percent by 1 year of age, and more than 80 percent by 3 years of age.[412,727] More recent statistics show even higher figures: a study involving 2253 infants in the Pittsburgh area showed that 48 percent had one or more episodes of otitis media between 2 and 6 months of age, 79 percent between 2 and 12 months of age, and 91 percent by 24 months of age.[566] Finnish studies in the 1980s showed an incidence of 0.47 to 1.05 episodes per year in infants aged 0 to 12 months.[394,598,688] Otitis media often is not perceived as a severe problem in developing countries, but community studies have shown perforation of the tympanic membrane in 0.4 to 6.1 percent and mastoiditis in 0.19 to 0.74 percent of all children.[62] Although serious complications rarely occur, the economic cost of otitis media is estimated at more than $3.5 billion each year in the United States.[254,706] During 1996, approximately 500,000 tympanostomy tubes were placed in children's ears in the United States.[536] AOM also is the leading reason for prescribing antibiotics to children.[593]

In a prospective study conducted in southern Israel that examined the burden of AOM on patients and their families,[291] the average number of days of severe crying, temperature higher than 38° C, loss of appetite, and insomnia was 2.9, 7.8, 7.0, and 6.6, respectively. An average of 18.6 days was required for a family to return to normal activity. The number of visits, use of emergency rooms, and care by otolaryngologists averaged 2.6, 0.3, and 0.35 per episode, respectively. The average antibiotic and over-the-counter drug treatment days per episode were 9.1 and 6.6, respectively. Parents lost an average of 1.6 working days, and children lost an average of 3.5 daycare days per episode. The parents thought that during a 1-month follow-up period, an average of 18.6 days were nonroutine days versus only 3.4 such days in controls.

The role of *S. pneumoniae* in otitis media has been studied extensively. During the last decades, numerous studies with various designs have been performed in many geographic regions. *S. pneumoniae* was the major bacterial cause of otitis media and accounted for 25 to 60 percent of cases.* However, in some recent studies, *H. influenzae* was found more commonly than was *S. pneumoniae* in AOM.[161,257,402] *H. influenzae* is a rare finding in

*See references 72, 77, 162, 183, 195, 206, 264, 358, 377, 402, 410, 484, 528, 629.

first episodes of AOM, but it becomes increasingly common from the third episode onward, whereas *S. pneumoniae* is a common finding in all episodes.[402]

Although the cost of each AOM episode may be relatively low when compared with other infections caused by *S. pneumoniae*, the highest overall cost in all pneumococcal infections is due to otitis media because of the large number of episodes.[466] The estimated cost for meningitis was 11,081 U.S. dollars per case in 1997, for bacteremia it was $2313, and for pneumonia with consolidation it was $1464. In contrast, for simple otitis media, the cost was $294 per episode, and for complex otitis media it was $1339 per episode. The cost of tympanostomy tube placement was $2390 per case. The estimated annual cost in the United States was $3 to $5 billion for simple pneumococcal otitis media and approximately $1.3 billion for complex pneumococcal otitis media. In contrast, the annual cost of pneumococcal meningitis was approximately $9 million, that of pneumococcal bacteremia was $35 million, and that of pneumococcal pneumonia was $113 million.

Antibiotic resistance in *S. pneumoniae* strains causing otitis media is rising sharply, and in some countries, resistance to at least one antibiotic class (in most cases penicillin and other β-lactams) is now the rule, not the exception. Figure 96–12 exemplifies the rapidity of the increase in antibiotic resistance among *S. pneumoniae* isolates from the middle ear fluid of children with AOM in France and Israel in the last decade. A well-established fact is that higher antibiotic resistance rates are found in pneumococci from patients with nonresponsive AOM and recurrent AOM, in whom recent antibiotic treatment is common, as well as in daycare center attendees.[55,73,135,157,164,458,583,799] In children younger than 18 months old, the prevalence of antibiotic-resistant *S. pneumoniae* in AOM is higher than that in older age groups.[55,73,159,358]

Studies of pneumococcal serotypes causing AOM in the last 60 years have demonstrated relatively similar patterns, with the most common serotypes being 6A, 6B, 9V, 14, 19A, 19F, and 23F.[43,73,114,157,225,257,556,577,680] (Fig. 96–13). As mentioned in the section on bacteriology, these serotypes also are the most frequent antibiotic-resistant serotypes. Furthermore, the great majority of highly penicillin-resistant and multiply-resistant *S. pneumoniae* belong to five serotypes (6B, 9V, 14, 19F, 23F) and, to a lesser extent, to related serotypes (6A and 19A).[157,380] This finding is somewhat reassuring with regard to vaccination because the serotypes most frequently associated with otitis media are included in the PCV-7 vaccine. The serotypes included in the PCV-7 vaccine are 4, 6B, 9V, 14, 18C, 19F, and 23F. A recent study found that 60 to 70 percent of all *S. pneumoniae* isolates that caused AOM in children in the 6- to 59-month age range were represented in the PCV-7 vaccine.[313] Most of the data with regard to AOM are obtained from studies involving middle ear puncture (tympanocentesis or myringotomy) or spontaneously draining ears; therefore, the spectrum of cases studied probably could be skewed toward the most severe cases or treatment failures.

Immunization with conjugate pneumococcal vaccine is associated with replacement of vaccine serotypes by other serotypes. Widespread immunization with conjugate vaccine may increase the importance of some nonvaccine serotypes while decreasing that of the serotypes included in the vaccine. A study in children showed a shift in pneumococcal colonization toward nonvaccine serotypes (11, 15 and 23B)[86] and an increase in *S. aureus*–related AOM after immunization.[85]

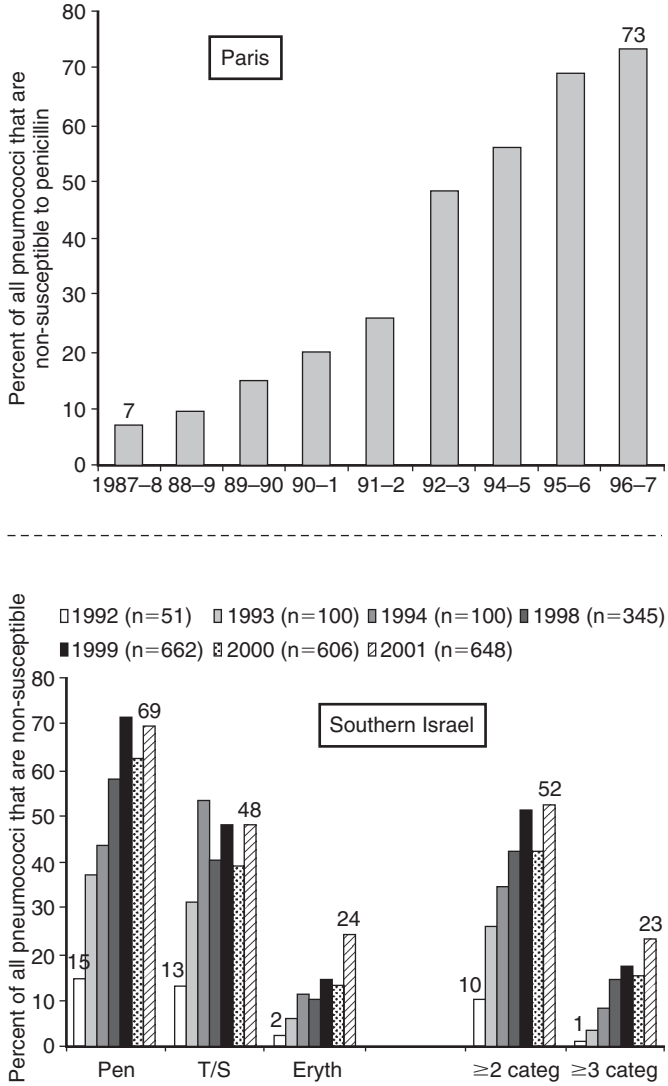

Figure 96–12 Rate of increase in non–antibiotic-susceptible pneumococci isolated from middle ear fluid during acute otitis media episodes in France and Israel during a 10-year period. **Top,** Non–penicillin-susceptible *Streptococcus pneumoniae* in Paris from 1987 through 1997. A 10-fold increase in resistance to penicillin occurred during this period.[259] **Bottom,** Non–penicillin-susceptible *S. pneumoniae* isolated from middle ear fluid during acute otitis media episodes in children in southern Israel from 1992 through 2001.[168] Categ, antibiotic drug category; Eryth, erythromycin; Pen, penicillin; T/S, trimethoprim-sulfamethoxazole. (Data from 1999 to 2001 are unpublished.)

CLINICAL SYNDROMES

S. pneumoniae can spread from the nasopharynx, which is its natural niche, to adjacent mucosal surfaces and cause mucosal infections such as AOM, sinusitis, and pneumonia, or it can invade the bloodstream. Infection may spread from the bloodstream to other sites and cause sepsis or meningitis or result in focal infection in heart valves, bones, joints, and soft tissues and within the peritoneal cavity. In rare cases, such as after penetrating trauma or fracture of the base of the skull, pneumococci can invade the brain directly from the upper respiratory tract. Organisms also can spread through the fallopian tubes to the peritoneal cavity after colonizing the perineum.

The clinical signs and symptoms of patients with pneumococcal infection are diverse. In general, invasive diseases such as bacteremia and meningitis are manifested as fever with temperatures that can exceed 40° C.[47] A peripheral blood leukocyte count of greater than 15,000/mm^3 can be found in most patients with bacteremia, and in one study, the average WBC count was 20,000/mm^3, with a range of 16,100 to 24,600/mm^3.[47] In patients

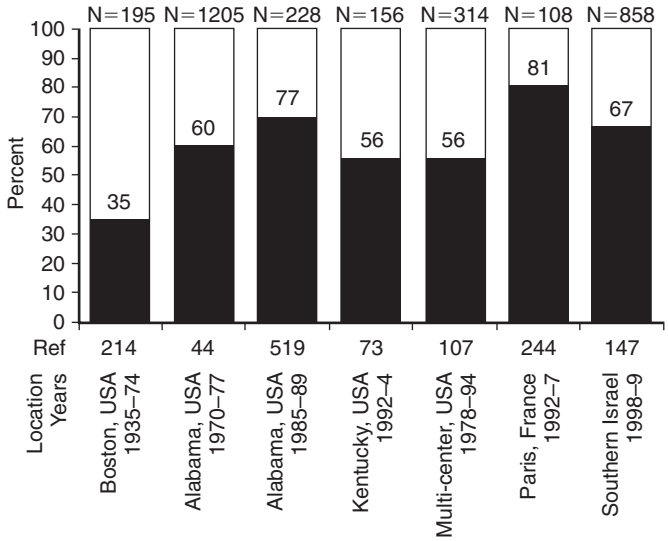

Figure 96–13 Relative proportion of serotypes 6A, 6B, 9V, 14, 19A, 19F, and 23F as a group in relation to all other serotypes causing acute otitis media.

with pneumococcal pneumonia, cough and tachypnea are the most common manifestations besides high fever.[722] Pneumococcal pneumonia and other focal infections such as cellulitis, peritonitis, and bone and joint infections often cause similar high temperatures and elevated WBC counts. Other infections such as AOM and sinusitis frequently have minimal systemic manifestations.

BACTEREMIA. The most common clinical manifestation of invasive pneumococcal disease in children younger than 3 years old is *occult bacteremia*, defined as a positive blood culture without a known focus of infection. *S. pneumoniae* caused an estimated 90 percent of all cases of occult bacteremia after the introduction of Hib conjugated vaccine.[446] Severe complications such as meningitis or sepsis are relatively rare occurrences after occult bacteremia—approximately 6 percent of all cases.[10] The risk for the development of occult bacteremia is related to age, with approximately 75 percent of all patients being between 3 and 24 months of age.[362] Signs and symptoms vary among patients with occult bacteremia. In most patients with pneumococcal bacteremia, fever appears within 24 hours after the diagnosis has been made. In one study, initial diagnoses at the time of occult bacteremia were AOM in 43 percent of patients, fever without a source in 30 percent, and viral infection in 22 percent.[47] Forty-one (8.7%) patients had complications: persistent bacteremia developed in 4 percent, meningitis in 1.7 percent, pneumonia in 1.7 percent, and cellulitis in 2.5 percent.

Febrile patients with focal infections such as otitis media or upper respiratory tract infection have a lower incidence of bacteremia than do febrile patients without an obvious source of infection (3.3% vs. 9.9%, respectively).[501] The height of the fever is associated with a greater risk for the development of bacteremia, with temperatures above 40° C being associated with a 25 percent risk.[57] A higher peripheral WBC count (>15,000/mm^3) also is associated with the presence of occult bacteremia.[365,437] These findings can help in categorizing high- and low-risk patients for the presence of occult bacteremia.

Occult bacteremia resolves spontaneously without complication in most children. However, complications such as meningitis, pneumonia, osteomyelitis, arthritis, cellulitis, and fulminant sepsis develop in approximately 10 percent of patients.[446] The case-fatality rate usually is low and generally less than 1 percent in children without underlying immunologic problems.[392,622]

Persistent bacteremia and new focal infections were associated with higher temperature (mean of 38.8° C vs. 37.7° C), greater elevation in WBC count (18,900/mm^3 vs. 14,900/mm^3), age younger than 20 months, and no antibiotic treatment being prescribed during the initial visit.[47]

MENINGITIS. *S. pneumoniae* is either the most frequent or the second most frequent (after *N. meningitidis*) cause of bacterial meningitis in countries in which routine vaccination against Hib has been introduced. *S. pneumoniae* most commonly invades the meninges via the bloodstream.[198] However, in rare cases it can invade the meninges directly, especially after penetrating trauma or fracture of the base of the skull.[660] Patients with underling conditions such as CSF leak, HIV infection, sickle-cell anemia, or asplenia are predisposed to the development of pneumococcal meningitis.[31]

The initial signs and symptoms are variable, and a rapid onset (<24 hours of illness) occurs in less than 20 percent of children with pneumococcal meningitis.[89] Patients commonly have the typical signs of meningitis, including fever, nuchal rigidity, irritability or lethargy, and poor feeding. The anterior fontanelle often is bulging. The duration of meningeal signs before admission averages 28 hours but can be as short as 4 hours and as long as 52 hours. Seizures develop in approximately a quarter of patients. Decreased consciousness and septic shock occur in 11 and 16 percent, respectively.[31]

In one study, the mean total CSF WBC count was 1136/mm^3, whereas it was 4612/mm^3 with Hib disease and in *N. meningitis* disease it reached 5476/mm^3.[657] In another study, significantly higher median blood leukocyte counts, lower median CSF protein concentrations, and higher CSF glucose concentrations were found in children with meningitis caused by penicillin-resistant *S. pneumoniae* isolates than in patients with penicillin-susceptible *S. pneumoniae*.[227] However, in a different study, patients with penicillin-susceptible *S. pneumoniae* did not differ from those with non–penicillin-susceptible *S. pneumoniae* with regard to blood and CSF leukocyte counts and CSF glucose or protein concentrations.[110]

Children with CSF pleocytosis are admitted routinely to the hospital and treated with antibiotics, although few have bacterial meningitis. Patients are at very low risk for acquiring bacterial meningitis in the post–pneumococcal vaccine era if they lack all of the following criteria: (1) positive CSF Gram stain, (2) CSF absolute neutrophil count of at least 1000 cells/μL, (3) CSF protein of at least 80 mg/dL, (4) peripheral absolute neutrophil count of at least 10,000 cells/μL, and (5) a history of seizure before or at the time of evaluation.[540]

The course of pneumococcal meningitis can be associated with prolonged fever that can last for more than 10 days or with secondary fever higher than 38° C that occurs at least 1 day after the primary fever has resolved.[89] This course can be attributed to complications of the primary infection, such as subdural effusion or empyema, but these events are now relatively rare. More commonly, secondary fever is related to intercurrent conditions such as urinary tract infection, otitis media, phlebitis, pneumonia, drug fever, or a nosocomial viral infection.[177] In patients treated with corticosteroids in the first 2 to 4 days, a second spike of fever can be seen after discontinuation of the steroids.[582,597] The outcome of patients with prolonged or secondary fever is similar to that of other patients with pneumococcal meningitis.[208]

The outcome and long-term complications of pneumococcal meningitis include severe hearing loss (in as many as 46% of patients), seizures, learning or mental difficulties, or paralysis (in as many as 22%).[31] Patients with *S. pneumoniae* meningitis have a higher mortality rate and are at greater risk for the development of neurologic sequelae than are patients with *N. meningitidis* or Hib infection.[389,538] The mortality rate varies from 6.3 to 20 percent.[198,392,660] A peripheral WBC count of less than 5000/mm^3

at initial evaluation was recognized as a poor prognostic factor with a high mortality rate.[428] A trend toward a higher mortality rate also was noted if the CSF WBC count was less than 1000/mm^3.[428] A similarly poor outcome can be predicted in patients with pneumococcal meningitis when low CSF glucose concentrations (<1.11 mmol/L)[237] or high CSF protein concentrations (>250 mg/dL) are present.[428]

A recent study evaluating outcomes of pneumococcal meningitis in pediatric patients in the intensive care unit over a 12-year period revealed a hospital mortality rate of 49 percent (24 of 49 patients) and neurologic deficits in 47 percent of survivors.[770]

Recent studies have shown that patients who have severe to profound hearing loss with cochlear implants are more than 30 times more likely than children in the general U.S. population to acquire pneumococcal meningitis. Children with implants with positioners were at a higher risk than were those with other implant models. The higher risk of bacterial meningitis developing continued for 24 months after implantation.[66,610]

Delayed sterilization of CSF cultures after antimicrobial treatment also has been associated with a poorer outcome.[444]

PNEUMONIA. Pneumococcal pneumonia in its classic form is manifested as an acute illness with rigors, fever with temperatures often exceeding 40° C, general malaise with a productive cough, dyspnea, and chest pain. However, the signs and symptoms may be subtle in young infants. Fever and cough occur in 90 and 70 percent of all patients, respectively. Lethargy, emesis, rhinorrhea, abdominal pain, and chest pain occur in 10 to 50 percent of patients.[722] Pneumococcal pneumonia can have an atypical and incomplete course, without respiratory symptoms, and in some cases even an absence of fever or the presence of extrathoracic manifestations. Severe abdominal pain with or without vomiting may be the only initial symptom, especially in left lower lobe pneumonia. Irritation of the meninges in cases of upper lobe pneumonia may elicit meningeal signs without meningitis.

When serologically diagnosed pneumococcal pneumonia was compared with pneumonia caused by respiratory syncytial virus (RSV), the serologically diagnosed pneumococcal pneumonia overlapped with RSV pneumonia. However, pneumococcal pneumonia was associated significantly less often with tachypnea (17% vs. 45%, respectively) and a high WBC count (mean of 20,800/mm^3 vs. 12,000/mm^3, respectively), as well as a higher CRP level (mean of 137 vs. 28 mg/L, respectively). Alveolar infiltrates were found in 76 versus 15 percent of chest radiographs, respectively.[381] Children with bacteremic pneumococcal pneumonia appeared ill more often than did those with serologically proven pneumococcal pneumonia without bacteremia (79% vs. 50%, respectively), and they had typical pneumococcal pneumonia with high fever, leukocytosis, and lobal infiltrates on chest radiographs more often (70% vs. 34%, respectively).

Pleural effusion can be found in as many as 40 percent of patients with pneumococcal pneumonia, but only approximately 10 percent have a significant amount of effusion and only approximately 2 percent exhibit empyema.[467] These patients can have a pleural friction rub, abdominal pain, chest pain, and dullness on percussion. In patients with pleural effusion, fever persists longer than in patients with pneumonia but without pleural effusion despite adequate treatment.[722]

In one study conducted in Salt Lake City during the years 1993 to 1999, 153 of 540 (28%) children hospitalized with community-acquired pneumonia had empyema.[117] Pathogenic bacteremia, 26 (41%) cases of which were caused by *S. pneumoniae*, was detected in 64 (42%) of the patients. In nine additional patients, gram-positive cocci were revealed by Gram stain but did not grow in culture. *S. pneumoniae* was the most common pathogen identified in patients with empyema. When compared with patients who had pneumonia only, patients with empyema were more likely to be aged 3 years or older, to have had fever for 7 days or longer, to have varicella, and to have received antibiotics and ibuprofen before admission to the hospital.

Another study in Utah after widespread use of the PCV-7 vaccine found that pneumococcal parapneumonic empyema was more common. Serotype 1 was the most common cause, but serotypes 3 and 19A also were prevalent.[116]

CRP, the erythrocyte sedimentation rate, and the peripheral blood absolute neutrophil count are significantly higher in pneumococcal pneumonia than in viral pneumonia.[430] Blood culture is positive in no more than 10 percent of patients with pneumococcal pneumonia.[773] Children with bacteremic pneumococcal pneumonia usually have a high temperature and leukocytosis on admission, with peripheral WBC counts exceeding 15,000/mm^3, similar to those without bacteremia.[734] Body temperature, CRP, the erythromycin sedimentation rate, and leukocyte counts are of limited value in differentiating pneumococcal from nonpneumococcal pneumonia in individual patients.

No strict radiologic definition of pneumococcal pneumonia in children is accepted broadly. The classic chest radiographic finding in pneumococcal pneumonia is thought to be an alveolar infiltrate, usually confined to one lobe or a part of it.[557] Such infiltrates are thought to be present in approximately 85 percent of all cases. In studies performing lung aspiration in cases of radiologically proven lobar infiltrates, the proportion of patients in whom *S. pneumoniae* was detected was high.[212,761,768] In most instances in which patients with lobar consolidation were studied, the predominant bacterial pathogen was *S. pneumoniae*.[8] In addition, a 63 percent reduction in incidence of pneumonia with alveolar infiltrates was demonstrated in a study using this definition when children were vaccinated with a 7-valent pneumococcal conjugated vaccine versus placebo,[71] thus suggesting a major role of *S. pneumoniae* when alveolar infiltrates are present.

A recent study found that the incidence of human metapneumovirus (hMPV) lower respiratory tract infection was reduced by 45 percent ($p < 0.002$) and the incidence of clinical pneumonia was reduced by 55 percent ($p < 0.003$) in non–HIV-infected children who had received three doses of conjugate pneumococcal vaccine. In fully vaccinated HIV-infected children, the incidence of hMPV-associated lower respiratory tract infection was reduced by 53 percent and that of clinical pneumonia by 65 percent.[486]

In the pre-antibiotic era, the natural course of pneumococcal pneumonia consisted of 7 to 9 days of a stationary phase of symptoms followed by worsening of the systemic signs ("pre-crisis") and subsequently, in those who recovered, defervescence, sweating, polyuria, and a brief febrile attack ("post-crisis").[39,557] Today, long-term complications are rare developments, and the mortality rate is extremely low—less than 1 percent even in cases of bacteremic pneumonia.[392]

OTITIS MEDIA. *S. pneumoniae* causes 25 to 60 percent of cases of AOM.* The bacteriologic outcome of *S. pneumoniae* AOM is less favorable than is the outcome of AOM caused by other organisms when untreated or treated inappropriately.[414,528,555] A recent study found that as many as 79 percent of patients with pneumococcal AOM developed the disease in association with newly acquired carriage of pneumococcus.[713] Also recognized is that commonly used oral antibiotics are not as effective as they were in the past because of the increased antibiotic resistance among *S. pneumoniae* isolates.[149,150,152]

Some studies have suggested that pneumococcal AOM is more severe than that caused by other pathogens. In addition, a suggestion was made in 1970 that AOM caused by *S. pneumoniae*

*See references 72, 77, 162, 195, 206, 264, 358, 377, 402, 410, 484, 528, 629.

was accompanied more frequently by pain and fever than was AOM caused by other pathogens.[337] Moreover, on the first day of diagnosis, WBC counts in the middle ear fluid of patients with *S. pneumoniae* AOM were significantly higher than those in the case of AOM caused by other bacterial pathogens.[100] *S. pneumoniae* AOM was associated with significantly higher fever and more redness of the tympanic membrane than was AOM caused by *H. influenzae* or *Moraxella catarrhalis*.[624] The presence of *S. pneumoniae* in the nasopharynx during a case of otitis media was associated with a higher tympanic membrane severity score and higher rates of persistent symptoms on day 5, persistence of tympanic membrane abnormalities on day 28, and recurrence before day 28.[211,306] Spontaneous remission of the infection occurs less commonly in patients with pneumococcal AOM than in those with other pathogens.[335]

MASTOIDITIS. In the pre-antibiotic era, acute mastoiditis was the most common complication of otitis media and was observed in as many as 20 percent of cases without appropriate treatment. The infectious process may lead to reabsorption of the bony septa of mastoid air cells and subsequently to the formation of empyema and anatomic loss of the air-cell system.[231] *S. pneumoniae* is the most common cause of acute mastoiditis in children and accounts for 25 to 46 percent of all culture-proven cases.[272,333] A recent international study suggested that in countries in which otitis media cases are seldom treated with antibiotics, the rate of mastoiditis is greater than in those in which antibiotic treatment of otitis is the rule.[752]

SINUSITIS. The true incidence of pneumococcal sinusitis in children is unknown. It is estimated to be present in 10 percent of all upper respiratory tract infections, but the diagnosis usually is subjective.[765] *S. pneumoniae* is the pathogen most commonly isolated from patients with sinusitis, and it causes 35 to 42 percent of all bacterial cases.[767] The disease can occur at any age, and clinical signs and symptoms depend on the maturation of the different sinuses affected. The ethmoid and maxillary sinuses are the sites most commonly involved in children younger than 5 years old. Sinusitis is manifested initially as a viral infection, followed by a nasal discharge that frequently is purulent and accompanied by cough. The symptoms are aggravated at night because of postnasal drip from the sinus to the pharynx and larynx. Malodorous breath can be noted, as can vomiting.[347,385] In cases of sinusitis, isolation of *S. pneumoniae* from the nasal discharge strongly suggests its involvement at the site of infection.

CONJUNCTIVITIS. Bacterial conjunctivitis often is purulent and tends to be bilateral more frequently than is the case with viral conjunctivitis.[764] *S. pneumoniae* causes 12 to 32 percent of all cases of bacterial conjunctivitis.[75,268,777]

The syndrome of "conjunctivitis-otitis" was described first in 1982.[81] *H. influenzae* is the most common pathogen and can be isolated in as many as 73 percent of cases from the conjunctiva and the middle ear concomitantly. This rate is higher than the rate when conjunctivitis is present without AOM.[81]

In one study in the United States, the rate of non–penicillin-susceptible *S. pneumoniae* in isolates taken from children with bacterial conjunctivitis was 28 percent, with most isolates being fully resistant.[75]

A recent study in Minnesota evaluated 735 children with conjunctivitis in two cities. Forty-nine percent of positive cultures were *S. pneumoniae*. All isolates were nontypeable. Pulsed-field gel electrophoresis identified three clonal groups, with 84 percent of the isolates belonging to one clonal group. Multilocus sequence typing revealed that isolates had the same multilocus sequence type as that of isolates from a 2002 pneumococcal disease outbreak at a New England college. It has been suggested that certain pneumococcal strains have a predilection for causing conjunctivitis.[108] Another study suggested that the absence of a capsule might provide *S. pneumoniae* with a selective virulence advantage in conjunctivitis.[590]

BONE AND JOINT INFECTIONS. Septic arthritis caused by *S. pneumoniae* is a relatively rare condition that accounts for 2.2 to 9.7 percent of all cases.[297,641] Its main initial clinical features are single or multiple swollen, warm, and painful joints. The joints most commonly involved are the knee and the ankle.[349] In one study, the mean duration of symptoms before hospitalization was 2 days, and patients were hospitalized for an average of 11 days. The mean peripheral WBC count was 20,600/mm^3, the erythrocyte sedimentation rate usually was greater than 90 mm/hr, and the CRP concentration generally was higher than 100 mg/L. *S. pneumoniae* can be isolated from synovial fluid or blood in most patients.[641] The outcome is favorable in the majority of cases unless underlying diseases or sepsis occurs concomitantly.[349]

SOFT TISSUE INFECTIONS. *S. pneumoniae* is an uncommonly recognized etiologic agent of soft tissue infections, but it can cause serious infections of soft tissues, especially in patients with connective tissue diseases such as systemic lupus erythematosus. Other risk factors are HIV infection and corticosteroid treatment. The organism can be isolated from the infected tissue, as well as from blood.[188] *S. pneumoniae* can cause facial cellulitis as well. Periorbital infection can spread and cause infection of the orbit (orbital cellulitis or abscess) manifested as proptosis and ophthalmoplegia, but these sequelae are rare occurrences and usually a complication of purulent sinusitis, or they occur after bacteremia in infants and young children without another apparent source.[674] Most patients are younger than 3 years of age and previously were healthy. Fever and peripheral WBC counts higher than 15,000/mm^3 can be observed in most patients, and blood cultures frequently are positive. Overall, response to therapy generally is good, and patients usually recover.[273]

PERITONITIS. The term *primary peritonitis* is associated with organisms that spread from the blood or via the lymphatic system to the peritoneal cavity and cause infection. Primary peritonitis is a rare condition that accounts for only 17 percent of all cases of peritonitis, and *S. pneumoniae* is the major pathogen in primary peritonitis and is responsible for 38 percent of all cases.[280] Primary pneumococcal peritonitis should be considered in the differential diagnosis of children with an acute abdominal syndrome.[242] This condition can be associated with underlying medical conditions such as nephrotic syndrome, immunocompromised status, or sickle-cell disease.[280] Colonization of the perineum and subsequent spread via the fallopian tube to the peritoneal cavity have been suggested to be important sources in young girls.[689] Indeed, 87 percent of all patients with pneumococcal primary peritonitis are females,[669] in contrast to other invasive infections, for which a male preponderance is observed.[3,15,92,103,112,207,240,350,701,726] Most of the patients are between 4 and 10 years of age.[669] Symptoms include diffuse abdominal pain, fever, vomiting, and diarrhea. Abdominal tenderness can be maximal in the right lower quadrant, which can lead to confusing it with acute appendicitis. In some cases, *S. pneumoniae* can be isolated as the only cause of peritonitis secondary to appendicitis.[319] Cultures should include blood, peritoneal fluid, and a vaginal swab. Some patients need laparotomy or laparoscopy to exclude other pathologies such as appendicitis or a tubo-ovarian abscess.[689] Morbidity and mortality rates can be high when the period without treatment exceeds 1 week, but in most cases the outcome is favorable when treated adequately.[669]

ENDOCARDITIS. Infection of native valves can lead to distal embolization and heart failure as a result of valve destruction. Cases of *S. pneumoniae* endocarditis, including those caused by

non–penicillin-susceptible strains, were reported with involvement of the aortic and mitral valves.[683] The triad of pneumococcal meningitis, pneumonia, and endocarditis was described first by Osler, but this triad also is known as *Austrian syndrome*. Today, this entity is an uncommon occurrence because the incidence of *S. pneumoniae* endocarditis has decreased significantly from 10 to 15 percent of all endocarditis cases in the pre-antibiotic era to less than 3 percent today.[352,522,724]

Only 32 cases of pediatric pneumococcal endocarditis have been reported in the English medical literature since 1900. A fourth of them have been reported since 1990. Clinical features differed from adult cases, with mitral-valve involvement being more frequent and Osler's triad rarely present in children. A history of congenital heart disease was the only identifiable risk factor. Medical therapy alone resulted in a high mortality rate that was improved in a group of patients receiving combined medical and surgical interventions.[127]

PERICARDITIS. In the pre-antibiotic era, *S. pneumoniae* was the pathogen most commonly isolated from purulent pericarditis in children. These infections were common complications of pneumococcal pneumonia. After the introduction of antibiotics, pneumococcal cases decreased from 51 to 9 percent of all pericarditis cases and occurred mainly in adults.[275,643] Currently, infections of the pericardium are rare findings in children and often are related to underlying medical conditions such as immunodeficiency.[578]

INFECTION IN IMMUNOCOMPROMISED HOSTS. Patients with functional asplenia, including those with hemoglobinopathies, are at high risk for the acquisition of invasive pneumococcal infection. In a study of 19 asplenic patients with invasive pneumococcal infection, the clinical findings included fever (86%), shock (27%), petechiae or purpura (27%), disseminated vascular coagulopathy (18%), and respiratory distress (18%). Clinical illness included bacteremia alone (52%), meningitis (26%), bacteremia with otitis/sinusitis (13%), and bacteremia with pneumonia (9%). The mortality rate was 32 percent. No association was noted between antimicrobial resistance and mortality.[662]

HIV-infected children with pneumonia usually have the typical symptoms of fever, shortness of breath, and productive cough associated with pleuritic pain. The chest radiograph shows unilobar or multilobar infiltrates, and peripheral WBC counts often are elevated. A comparison between HIV-infected and non–HIV-infected children with community-acquired pneumonia showed no significant differences between groups with regard to the duration of hospitalization and mortality rates.[488] In contrast, when only patients from the aforementioned groups infected with isolates belonging to the "pediatric serotype group" (see the sections on epidemiology and prevention) were compared, marked differences, such as a higher rate of pneumonia with or without concurrent meningitis in the HIV-infected group and a higher rate of septic shock without focus in the non-HIV-infected group, were observed.[488] Recurrence of pneumococcal infection within 6 months from the initial episode is common in patients infected with HIV, particularly children.[260] Most HIV-infected patients recover without significant sequelae, and the clinical course of their systemic infection does not appear to be markedly different from that in healthy children.[369]

Patients with immunodeficiency disorders consisting of antibody and complement deficiencies are at high risk for acquisition of invasive and recurrent pneumococcal infection.[369] Children with nephrotic syndrome have a particularly increased risk for the development of pneumococcal peritonitis, mainly during relapse of their renal disease.[220] Other underlying diseases such as hematologic malignancies, diabetes mellitus, and cirrhosis, as well as conditions such as alcoholism, are associated with an increased risk for the development of pneumococcal bacteremia and other invasive diseases, mainly in adults.[369]

Children with sickle-cell disease are prone to the development of overwhelming *S. pneumoniae* bacteremia and sepsis; in children younger than 3 years of age, the incidence of bacteremia is 6.1 events per 100 patient-years, and the case-fatality rate is 24 percent for *S. pneumoniae* sepsis.[798]

Transplant recipients have been recognized for some time as being at high risk for the development of invasive pneumococcal disease. Of 42 children who had undergone bone marrow or solid organ transplantation and became infected with *S. pneumoniae*, 8 (19%) had two or more pneumococcal infections.[663] Solid organ recipients were more likely to have recurrent invasive disease than were recipients of bone marrow transplants. Death occurred in 2 of 42 recipients (5%). Cardiac transplant patients have an incidence of 39 cases of invasive pneumococcal infection per 1000 patients per year,[709] the highest risk of which occurs in African American heart transplant recipients who undergo transplantation because of idiopathic dilated cardiomyopathy.

TREATMENT

Penicillin G is the parenteral drug of choice for disease caused by penicillin-susceptible *S. pneumoniae* strains (defined as those with a penicillin MIC < 0.1 μg/mL). The usual doses of penicillin G result in serum concentrations that exceed this level in blood and most other body fluids for an adequate period. Penicillin G is the most common parenteral drug used for the treatment of pneumococcal infection, with doses ranging from 50,000 U/kg/day for minor infections to 300,000 U/kg/day for meningitis. For penicillin-susceptible strains, other parenteral β-lactams such as ampicillin, cefuroxime, cefotaxime, and ceftriaxone provide no advantage over penicillin G, even for serious infections. Macrolides and cephalosporins are an alternative treatment for penicillin-allergic patients if regional data do not show macrolide and cephalosporin resistance. Other agents such as clindamycin, tetracycline, and trimethoprim-sulfamethoxazole are active against *S. pneumoniae*, but resistance to these agents is increasing rapidly in most parts of the world.

In many regions, treatment of non–penicillin-susceptible *S. pneumoniae* has become a challenge, and reports of treatment failure have increased, especially in patients with invasive multidrug-resistant *S. pneumoniae* infection.[691] Rates of antibacterial resistance are highest in infants and decrease with increasing patient age.[106] Because isolates of *S. pneumoniae* that are resistant to penicillin frequently are resistant to other drug classes such as cephalosporins (mainly oral), macrolides, and trimethoprim-sulfamethoxazole,[779] the challenge of treatment is becoming complex.

The critical time for treatment of severe pneumococcal infection is during the first few hours after initial evaluation of the patient, before culture results are available and, thus, before knowledge of the presence or susceptibility of the pathogen is obtained. Therefore, the choice of antibiotics must rely on considerations based on the most recent epidemiologic data and the clinical status of the child, as well as the site of infection. Furthermore, because treatment is empiric, the choice of antibiotics must take into account other potential pathogens. Knowledge of the patient's antimicrobial use in the 3 months before infection developed is crucial for determining the appropriate therapy for a patient who has a possible pneumococcal infection.[751]

The proportion of *S. pneumoniae* isolates from U.S. pediatric patients covered by the PCV-7 vaccine decreased substantially in the 4 years after the vaccine was introduced. Resistance to commonly used antibiotics, including β-lactams and macrolides, as well as multidrug-resistant strains, also increased significantly among respiratory tract isolates of nonvaccine serotypes.[215]

Because treatment of pneumococcal infection is not necessarily similar in each of the clinical entities, specific details are provided for each clinical entity separately.

BACTEREMIA. Results of studies are conflicting with regard to the role of antibiotic treatment of occult pneumococcal bacteremia. In one study, the bacteremia resolved without any need for parenteral antibiotic treatment in 95.7 percent of patients.[12] No significant difference was found between amoxicillin and placebo recipients regarding complications such as meningitis in bacteremic patients, but faster reduction of fever and improvement in clinical appearance were observed in the group treated with amoxicillin.[366] A meta-analysis showed that rates of serious bacterial infection and meningitis did not differ between children treated with oral antibiotics and those treated with parenteral antibiotics.[634] In contrast, in another meta-analysis conducted by the same authors, treated patients had fewer serious bacterial infections than did untreated patients (3.3% versus 9.7%), and meningitis developed in only 0.8 percent of the treated group versus 2.7 percent of the untreated group.[636] In one study, the rate of persistent pneumococcal bacteremia was significantly higher in patients receiving no therapy for pneumococcal bacteremia than in those receiving either oral or parenteral treatment. A higher prevalence of persistent bacteremia in the orally treated group than in the parenterally treated group also was noted.[47] Thus, in patients suspected of having occult bacteremia, treatment with a β-lactam drug can be initiated, especially if the patient looks toxic or has a high fever. However, if the patient has been immunized with both Hib and pneumococcal conjugate vaccines, does not look toxic, and has no predisposing risk factors such as immunodeficiency, the risk of significant bacteremia resulting in complications is extremely low, and in this case, withholding treatment is reasonable.[792]

For proven *S. pneumoniae* bacteremia in a previously healthy child who is not critically ill, treatment, including oral amoxicillin, amoxicillin-clavulanate, second-generation oral cephalosporins, or parenteral third-generation cephalosporins such as ceftriaxone, can be initiated at the usually recommended dosages.[91] In most cases of penicillin-susceptible and penicillin-intermediate *S. pneumoniae* (penicillin MICs ≤1.0 μg/mL), most parenteral and some oral β-lactam antibiotic agents achieve serum concentrations that exceed the MIC of the organism for an adequate period.[421] The exceptions are drugs such as loracarbef, cefaclor, and cefixime, which have little activity against non–penicillin-susceptible *S. pneumoniae*.

In studies looking at the outcome of children with bacteremia caused by non–β-lactam–susceptible *S. pneumoniae* (not susceptible to penicillin, cefuroxime, or ceftriaxone), no difference in outcome was observed when compared with those with susceptible organisms.[126,392,684] However, in critically ill infants and children with invasive *S. pneumoniae* infection, initial antimicrobial therapy should include a third-generation cephalosporin (cefotaxime or ceftriaxone) alone or with vancomycin. Vancomycin should be discontinued as soon as antimicrobial susceptibility test results demonstrate effective alternative agents.[14,731] For children with severe hypersensitivity to β-lactam antibiotics (i.e., penicillins and cephalosporins), initial management of a potential pneumococcal infection could include clindamycin or vancomycin, in addition to antimicrobial drugs for other potential pathogens, as indicated.

MENINGITIS. Penicillin G, 250,000 to 400,000 U/kg/day, is an excellent treatment regimen for meningitis caused by penicillin-susceptible pneumococci, and ceftriaxone, 100 mg/kg/day, or cefotaxime, 300 mg/kg/day, is an excellent choice for meningitis caused by *S. pneumoniae* susceptible to these drugs.[14] However, treatment failures have been reported in penicillin- and ceftriaxone-nonsusceptible pneumococcal meningitis in patients, as well as in animal models.[245,246] Therefore, because of the increased prevalence of penicillin-, cefotaxime-, and ceftriaxone-resistant *S. pneumoniae*, combination therapy consisting of vancomycin (60 mg/kg/day) and cefotaxime (300 mg/kg/day) or ceftriaxone (100 mg/kg/day) should be administered initially to all children 1 month of age or older with definite or probable bacterial meningitis. One recent study showed that delaying administration of the first dose of vancomycin until 2 or more hours after the first dose of parenteral cephalosporin has been administered was associated with a decrease the incidence of hearing loss related to the use of vancomycin.[111] This finding requires confirmation. However, vancomycin does not need to be used if compelling evidence indicates that the cause is an organism other than *S. pneumoniae* (e.g., gram-negative diplococci on a CSF smear or during an outbreak of meningococcal disease).[14] Vancomycin should not be given alone because bactericidal concentrations in CSF are difficult to sustain, clinical experience to support its use as monotherapy is minimal, and clinical failure and inadequate CSF drug concentrations have been reported.[9,756] Therapy should be modified after the organism has been isolated and based on the results of susceptibility testing. If the organism is susceptible to the β-lactam agent being used, vancomycin use should be discontinued. Antibiotic treatment in proven pneumococcal meningitis should not be shorter in duration than 10 days, and in complicated cases with a suspected focus, it may need to be provided for an even longer period.

When appropriately treated, the clinical manifestations and outcomes of meningitis caused by non–antibiotic-susceptible pneumococci are not significantly different from those caused by antibiotic-susceptible pneumococci.[31,110,227,723]

The combination of ceftriaxone and rifampin in an animal meningitis model had a bactericidal effect in meningitis caused by ceftriaxone-resistant *S. pneumoniae*.[567] The addition of rifampin to vancomycin after 24 to 48 hours of therapy should be considered in the following cases if the isolate is susceptible to rifampin: (1) when the patient's clinical condition has worsened despite therapy with vancomycin and cefotaxime or ceftriaxone, (2) when the subsequent Gram-stained smear or culture of CSF indicates failure to eradicate or substantially reduce the number of organisms, or (3) when the organism has an unusually high cefotaxime or ceftriaxone MIC (>4 μg/mL).[14] Although rifampin resistance is a rare event, rifampin should not be given as monotherapy because resistance may develop during therapy.[731]

Other β-lactam antimicrobial agents that can be used for the treatment of pneumococcal meningitis include meropenem (120 mg/kg/day) and cefepime (150 mg/kg/day).[390,644,645]

In patients with severe hypersensitivity to β-lactam antibiotics (i.e., penicillins and cephalosporins), the combination of vancomycin and rifampin should be considered.[246]

Chloramphenicol (75 to 100 mg/kg/day) is an acceptable alternative to β-lactam antibiotics in patients hypersensitive to these drugs. However, for unknown reasons, failure occurred in a patient with non–penicillin-susceptible pneumococcal meningitis treated with chloramphenicol.[244] Thus, treatment with chloramphenicol should be reserved for patients with β-lactam hypersensitivity who have pneumococcal meningitis caused by penicillin-susceptible strains.

Much debate has ensued on the role of dexamethasone as adjunctive therapy for pneumococcal meningitis. On the one hand, it might exert a positive effect in decreasing inflammatory reactions, but on the other hand, the same decrease in inflammation may reduce penetration of antibiotic agents into CSF. A meta-analysis of three randomized, double-blind, placebo-controlled studies combined with one retrospective study demonstrated a potential benefit of reducing hearing loss and neurologic sequelae after having pneumococcal meningitis.[656] Some studies had suggested a beneficial effect on pneumococcal meningitis when dexamethasone was given for 2 days with or

before administration of parenteral antibiotics.[506] Thus, for infants and children aged 6 weeks and older, adjunctive therapy with dexamethasone should be considered after weighing the potential benefits and potential risks. When given in the recommended dosages to children with meningitis treated with dexamethasone, CSF concentrations of vancomycin, ceftriaxone, cefotaxime, and rifampin usually are adequate to treat meningitis caused by most strains of *S. pneumoniae*, but in some parts of the world, the CSF concentration of the drugs might be inadequate because of the high MIC values of ceftriaxone and cefotaxime. Dexamethasone may lead to decreased fever and a misleading impression of clinical improvement, even though CSF sterilization may not have been achieved. In some cases, after discontinuation of the steroids, secondary fever may develop, which also can be misleading and give the impression of a nonresponsive case and lead to use of additional lumbar punctures or other procedures.[208]

Repeat lumbar puncture should be considered after 24 to 48 hours of therapy if the following apply: (1) the organism is not susceptible to penicillin, (2) the results of cefotaxime and ceftriaxone susceptibility testing are not yet available, (3) the patient's condition has not improved or has worsened, or (4) the child has received dexamethasone, which might interfere with the ability to interpret a clinical response, such as the resolution of fever.[14,208]

PNEUMONIA. *S. pneumoniae* accounts for most cases of bacterial pneumonia in children. Thus, empiric treatment of pneumonia should cover this pathogen despite the fact that an organism-specific diagnosis seldom is established in children with pneumonia. Oral treatment with a β-lactam antibiotic such as amoxicillin, cefuroxime axetil, or amoxicillin-clavulanate is an appropriate option for the first-line treatment of ambulatory community-acquired pneumonia in children younger than 5 years old in most countries.[315]

In most cases of pneumonia caused by non–penicillin-susceptible *S. pneumoniae*, the outcome is favorable if the penicillin MIC is between 0.1 and 2.0 μg/mL and treatment consists of standard doses of parenteral penicillin G (100,000 to 300,000 U/mg/day), oral amoxicillin or amoxicillin-clavulanate (40 to 50 mg/kg/day), or cefuroxime (30 to 50 mg/kg/day).[315,722] No difference in outcome was found between patients with community-acquired pneumococcal pneumonia treated with oral amoxicillin-clavulanate and those treated with parenteral ceftriaxone.[633]

For immunocompetent hospitalized patients who are not critically ill on admission, parenteral treatment with β-lactam antibiotics such as cefuroxime, cefotaxime, or ampicillin (with or without β-lactamase inhibitors) is an appropriate option because both *S. pneumoniae* and most other potential organisms are covered.[315]

In adult and pediatric patients with pneumococcal pneumonia treated with standard regimens of parenteral penicillin G or a cephalosporin, the outcome was similar when patients infected with penicillin- or cephalosporin-resistant organisms were compared with those infected with susceptible organisms.[91,119,209,219,391,519,563,771,790]

In one retrospective cohort study, adult patients with bacteremic pneumonia caused by isolates that were not penicillin-susceptible had a significantly greater risk of dying in the hospital and of having more suppurative complications than did patients with susceptible isolates.[508] However, the mortality rate was not significantly different after adjustment for baseline differences in severity of illness. A population-based active surveillance study of pneumococcal disease in the United States found that 12 percent of 5837 cases were fatal.[219] In this study, a higher mortality rate was noted after the fourth hospital day in patients with invasive pneumococcal pneumonia caused by isolates with penicillin MICs of 4 μg/mL or greater. However, potential limitations of this study included absence of data on the severity of illness at initial evaluation, as well as lack of information on the antibiotics used.

Treatment failure and breakthrough meningitis were reported in a patient who was infected with highly resistant *S. pneumoniae* (penicillin MIC of 2 μg/mL, cefuroxime MIC of 2 μg/mL, and cefotaxime MIC > 8 μg/mL) and treated with cefotaxime and cefuroxime.[109] Because of such cases, some authorities recommend that in critically ill patients with highly resistant *S. pneumoniae*, vancomycin (or in older patients, fluoroquinolones active against *S. pneumoniae*) be added initially to third-generation cephalosporins.[315]

In a series of 32 children with pleural empyema caused by *S. pneumoniae*, those with non–penicillin-susceptible strains were significantly younger and more frequently had been treated previously with antibiotics than were children with penicillin-susceptible strains.[561] However, no significant differences were found between the two groups in the duration of fever and tachypnea, need for surgical treatment, presence of bacteremia, mean duration of therapy, or length of hospital stay.[561] In cases of pleural fluid or empyema in patients infected with highly resistant organisms, vancomycin or rifampin may be added if no clinical response is achieved within 48 to 72 hours.[91]

For β-lactam–allergic patients, macrolides are favored.[390] However, in some areas, macrolide resistance occurs commonly and may lead to treatment failure.[232,344,399,479,480,516,711,773] Breakthrough pneumococcal bacteremia has been reported during treatment with clarithromycin or azithromycin for community-acquired pneumonia.[399]

Drugs that are not appropriate for treating critically ill patients with pneumococcal pneumonia are the first-generation cephalosporins, ceftazidime, and ticarcillin because most penicillin-resistant *S. pneumoniae* also are resistant to these drugs.[190,565] Trimethoprim-sulfamethoxazole is not recommended because of the high prevalence of resistance to this drug.[315]

The duration of treatment is related to the clinical findings, clinical response to treatment, and underlying diseases of the patient and generally is 7 to 14 days. For hospitalized patients, 5 to 7 days of parenteral treatment followed by 7 days of oral therapy is recommended,[91,364] but many clinicians use a shorter course of 7 to 10 days total.

OTITIS MEDIA. Antibiotics are the standard of care for the treatment of AOM in the United States and in many other countries. Although antibiotic therapy is required in only 20 to 30 percent of all cases of AOM, most patients are treated with antibiotics because these cases cannot be identified quickly and easily.[415] As with other infections, the main goal of antibiotic therapy is to eradicate the causative pathogens from middle ear fluid.[166,386,453,631]

S. pneumoniae is responsible for 30 to 50 percent of all cases of acute bacterial otitis media, and it is the least likely pathogen to resolve without the administration of appropriate antibiotic treatment.[624] After 2 to 7 days, if not treated, approximately 50 percent of all *H. influenzae* organisms are eradicated spontaneously, but less than 20 percent of pneumococci are eradicated spontaneously in AOM.[334] Therefore, *S. pneumoniae* generally is considered the most important organism against which antibiotic treatment should be directed in AOM.

Studies in which tympanocentesis is performed before treatment and a second tympanocentesis procedure during treatment to document bacteriologic efficacy ("double-tympanocentesis" bacteriologic outcome studies) have demonstrated that pharmacodynamic models can predict bacteriologic outcome.[146,163] Studies have shown that the increasing resistance of *S. pneumoniae* to various drugs has increased the complexity of antibiotic treatment of otitis media. In addition to having activity against antibiotic-resistant pneumococci, a drug appropriate for empiric treatment of AOM should be active against the two other main

pathogens of otitis media, namely, *H. influenzae* and *M. catarrhalis*. Table 96–3 summarizes the activity of drugs used commonly against otitis media pathogens, with the pharmacodynamic properties (the relationship between the drug concentration in plasma and the concentration at the site of infection) and the MIC of the drug to the infecting organism taken into account. The in vitro activity of oral agents has not always been predictive of their in vivo activity because of incorrect or unavailable interpretative breakpoints, but this deficiency has been rectified for *S. pneumoniae* in the United States since 2000.

Most of the drugs used for the treatment of AOM belong to the β-lactam and macrolide classes; these drugs act against pathogens by a "time-dependent killing" mechanism,[79,146] which means that an effective dosing regimen for AOM would require that the unbound plasma concentration exceed the MICs of the drug against the causative pathogens for at least 40 to 50 percent of the dosing interval. Although the drug exerts its effect in the middle ear cavity, penetration of the drug into this space is driven by the unbound plasma concentration, which is in equilibrium with the extracellular fluid compartment of tissues and sites such as the middle ear space.

For penicillin-susceptible *S. pneumoniae*, most β-lactam drugs (with the exception of penicillin V and the first-generation oral cephalosporins) reach that goal and are appropriate drugs for otitis media caused by penicillin-susceptible *S. pneumoniae*.

In the case of non–penicillin-susceptible *S. pneumoniae*, on the other hand, the picture is different. The most active oral β-lactam drugs against penicillin-intermediate isolates are amoxicillin and amoxicillin-clavulanate (clavulanate has no effect on pneumococci, but it is used often to empirically add coverage against β-lactamase–producing organisms). However, most of the oral cephalosporins, with the exception of cefuroxime axetil, cefpodoxime proxetil, and cefprozil, cannot reach the goal of unbound plasma concentrations exceeding the MIC_{90} values for most penicillin-intermediate organisms for 40 to 50 percent of the dosing interval and thus are not appropriate for the treatment of AOM in areas where penicillin-intermediate strains occur commonly.[146,195] For fully penicillin-resistant *S. pneumoniae* strains, of the β-lactam drugs commonly used against AOM, only high-dose amoxicillin (80 to 100 mg/kg/day), amoxicillin-clavulanate (80 to 100 mg/kg/day of the amoxicillin component), and intramuscular ceftriaxone (50 mg/kg/day) reach plasma or middle ear fluid concentrations that are above the MIC values for an appropriate duration. A recent study found that 90 mg/kg of amoxicillin (given as amoxicillin-clavulanate) significantly decreased nasopharyngeal colonization when compared with 45 mg/kg

TABLE 96–3 In Vivo Activity of Antibiotic Drugs in Common Use for the Treatment of AOM That Are Effective against the Major AOM Pathogens*

	Antimicrobial Activity

**In vitro activity, pharmacodynamic properties, and, if available, the results of bacteriologic outcome studies are taken into account.*
†Penicillin-susceptible (MICs ≤ 0.06 μg/mL), penicillin-intermediate (MICs of 0.1 to 1 μg/mL), penicillin-resistant (MICs ≥ 2 μg/mL).
‡When Streptococcus pneumoniae is not penicillin-susceptible, the prevalence of macrolide, clindamycin, and TMP-SMX resistance among the strains is higher than in penicillin-susceptible ones. This rate can be very high in penicillin-resistant S. pneumoniae. (See "Bacteriology.")
+++, Appropriate; ++, may not be appropriate for some strains; +, frequent bacteriologic failures are likely; –, usually associated with bacteriologic failure.
AOM, acute otitis media; MICs, minimal inhibitory concentrations; TMP-SMX, trimethoprim-sulfamethoxazole.

($p = 0.0261$).[102] To eradicate *S. pneumoniae* with penicillin MICs of 2.0 μg/mL or higher, an amoxicillin or amoxicillin-clavulanate dose of 80 to 100 mg/kg/day (divided into two or three doses) is necessary.[161,453,667]

Among the parenteral cephalosporins, ceftriaxone and cefotaxime have the lowest MICs, but high-level resistance of *S. pneumoniae* to these agents has been reported.[700] Intramuscular ceftriaxone (50 mg/kg/day) given once daily for 1 to 3 days is effective for pneumococcal otitis caused by penicillin-susceptible strains. For otitis caused by non–penicillin-susceptible *S. pneumoniae*, 3 days of treatment may be required.[456,457]

Resistance to macrolides is significant and affects bacteriologic and clinical outcomes in AOM.[28,52,165] All macrolides are efficacious against otitis caused by macrolide-susceptible *S. pneumoniae*. Efficacy was shown for erythromycin,[336] clarithromycin,[334] and azithromycin.[165] However, when the organism is resistant to macrolides, these drugs are not effective because the MIC is too high to be exceeded by drug concentrations at the site of infection, which has been demonstrated best for azithromycin[162,165] but can be generalized to other macrolides. In one child, pneumococcal bacteremia and meningitis were reported to have developed during azithromycin therapy for otitis media.[351]

Clindamycin is active against most non–penicillin-susceptible *S. pneumoniae* strains and may be used to treat pneumococcal AOM that does not respond to β-lactam antibiotics. However, prospective, controlled studies on the bacteriologic and clinical efficacy of clindamycin in the treatment of AOM have not been performed. Furthermore, as described in the section on microbiology, an increasing proportion of *S. pneumoniae* isolates resistant to macrolides also are resistant to clindamycin.

Trimethoprim-sulfamethoxazole no longer is an appropriate choice for empiric treatment of AOM because of the high prevalence of resistance to this drug among *S. pneumoniae* strains in many regions. In the case of AOM caused by *S. pneumoniae* resistant to trimethoprim-sulfamethoxazole, the effect of this drug is no better than that of placebo.[452]

Treatment of nonresponsive AOM (cases refractory to one or more courses of antibiotics) was studied in double-tympanocentesis studies, with bacteriologic outcome being the major endpoint.[415] Cefaclor, cefixime, loracarbef, ceftibuten, azithromycin, and trimethoprim-sulfamethoxazole clearly have been shown to be ineffective against nonsusceptible pneumococci and no longer can be recommended for the empiric treatment of nonresponsive AOM.[195] Second-line treatment preferably should be based on the results of middle ear fluid cultures and pathogen susceptibility tests.

For patients with clinically defined treatment failure after receiving 3 to 5 days of initial therapy, suitable second-line agents active against non–penicillin-susceptible pneumococci, as well as β-lactamase–producing *H. influenzae* and *M. catarrhalis*, should be administered. Three antibiotic drugs fulfill these criteria: amoxicillin-clavulanate, intramuscular ceftriaxone, and, to a lesser extent, cefuroxime axetil.[72,195,502] In these cases, amoxicillin-clavulanate should be given at 80 to 100 mg/kg/day of the amoxicillin component. Intramuscular ceftriaxone given for 3 days was found to be superior to a 1-day regimen in cases caused by penicillin-resistant *S. pneumoniae*.[457] A recent study found that gatifloxacin, 10 mg/kg once daily, was as effective and well tolerated in children with AOM treatment failure or recurrent otitis media.[675] Use of gatifloxacin was not associated with the development of arthropathy, and, in fact, an observational study of more than 6000 children treated with fluoroquinolones found the incidence of joint disorders comparable to that after treatment with erythromycin.[793]

Erythromycin-sulfisoxazole, clarithromycin, and azithromycin may be used as alternatives in penicillin-allergic patients.[454] One recent study found that azithromycin was as effective as was high-dose amoxicillin for the treatment of children with AOM and that rates of adverse events were lower and compliance improved with the simplified single dosing regimen.[32] However, macrolide resistance among middle ear *S. pneumoniae* isolates has been increasing steadily.[496] Therefore, in such cases, tympanocentesis is recommended either before initiation of treatment or after 48 to 72 hours of treatment if no clinical response is observed.

The recommended duration of treatment usually is 10 days for most antibiotic drug regimens in children younger than 2 years.[416] Recent studies suggest that a shorter treatment course (5 to 7 days) may be adequate, at least for a subgroup of children older than 2 years of age with uncomplicated otitis.[435,580,584] However, data evaluating the bacteriologic outcome and clinical efficacy of shortened antibiotic treatment of AOM are not complete in children younger than 2 years old, children with severe or complicated AOM, and those with a history of recurrent or chronic otitis media, although such studies are being undertaken. Clinical studies suggest that 5 to 7 days of treatment may not be adequate for these groups of patients.[134,136,196,585] Children attending daycare centers are at particular risk of having a poor response and recurrence if treated for 5 rather than 10 days.[135] Therefore, until the results of more studies are available, shortened antibiotic treatment in AOM cannot be recommended for children younger than 2 years old, children with severe or complicated AOM, children with chronic or recurrent AOM, and children attending daycare centers.[136,151]

Prophylactic use of amoxicillin or trimethoprim-sulfamethoxazole at half the therapeutic dose may reduce the number of new episodes significantly in patients with recurrent AOM.* However, this approach may promote carriage of drug-resistant *S. pneumoniae* and lead to the development of new infections with resistant organisms.[164] Thus, antibiotic prophylaxis is not recommended except in children with frequently recurrent AOM episodes, defined as three or more documented episodes in 6 months or four or more in 12 months.[455]

Although most non–penicillin-susceptible *S. pneumoniae* are included in PCV-7, AOM caused by these strains will not disappear completely. Therefore, clinicians must continue to consider non–penicillin-susceptible pneumococci when prescribing antibiotics for AOM.[308]

SINUSITIS. Although studies on the bacteriology of acute sinusitis are sparse, they suggest that the pathogens causing sinusitis are similar to those causing AOM. Acute bacterial sinusitis usually is a complication of viral rhinosinusitis and occurs in 0.5 to 2 percent of cases. In a study comparing antimicrobial therapy with placebo for the treatment of children with a clinical and radiographic diagnosis of acute bacterial sinusitis, children receiving antimicrobial therapy recovered more quickly and more often than did those receiving placebo.[766] Thus, antimicrobial agents that are effective for the treatment of AOM also are likely to be effective and are recommended for acute sinusitis.[14,550,687,765]

In the selection of appropriate therapy for bacterial sinusitis, physicians should consider the following parameters: (1) the severity of disease: mild (healthy patients with 10 days of persistent anterior and posterior rhinorrhea and fatigue), moderate (patients with 10 days of nasal congestion in whom a low-grade fever developed during the past 3 days, as well as increasing unilateral tenderness over the frontal or maxillary sinuses that becomes aggravated while the patient bends forward), or severe (life-threatening infection); (2) antibiotic use during the 4 to 6 weeks before the onset of infection, which is an important risk factor for the selection of resistant organisms; (3) age younger than 5 years; (4) attendance at a daycare center; and (5) underlying condition predisposing to invasive infection, such as immunocompromised status.

*See references 65, 318, 413, 493, 499, 579, 592, 618, 630, 783.

Amoxicillin is recommended for the initial treatment of children who have uncomplicated acute bacterial sinusitis that is of mild severity, do not attend daycare centers, and have not been treated recently with an antimicrobial.[132] If the patient is allergic to amoxicillin, cefdinir, cefuroxime axetil, or cefpodoxime can be used (if the allergic reaction was not a type I hypersensitivity reaction). In children with serious allergic reactions, macrolides or clindamycin can be used in an effort to select an antimicrobial of an entirely different class.[132] In patients with disease moderate in severity or those attending daycare, therapy should be initiated with high-dose amoxicillin-clavulanate. Parenteral antibiotic treatment should be considered in patients with severe disease. For patients with mild or moderate disease who are not improving after receiving 72 hours of treatment, therapy should be changed to amoxicillin-clavulanate unless this agent was used initially, in which case treatment options are very limited.[132,363] In addition, re-evaluation of deteriorating or nonresponsive patients may include computed tomography, fiberoptic endoscopy, or sinus aspiration with culture.[687]

Acute sinusitis should be treated for 7 days after improvement is noted and for at least 10 to 14 days.[550] However, the duration of treatment has not been studied adequately and, therefore, is arbitrary.

CONJUNCTIVITIS. When compared with placebo, topical therapy with polymyxin-bacitracin ointment has been shown to reduce the duration of symptoms by half and to achieve a 2.5-fold increase in the rate of bacteriologic eradication after 8 to 10 days of therapy (31% vs. 79%, respectively).[267] Polymyxin B–trimethoprim, applied four times daily for 1 week, also can be an effective broad-spectrum therapy for nonsevere conjunctivitis, although the coverage against gram-positive organisms provided by trimethoprim is less than optimal for some species. Aminoglycoside drops (0.3% gentamicin or 0.3% tobramycin) are inherently less active against gram-positive organisms and have a low therapeutic-to-toxic ratio as topical agents. Neomycin–polymyxin B–gramicidin drops or neomycin–polymyxin B–bacitracin ointment provides broad-spectrum coverage, but neomycin poses a 10 percent risk for hypersensitivity reactions such as contact dermatitis.[764]

Most organisms causing conjunctivitis are susceptible to chloramphenicol.[75,621] However, significant public and professional concern regarding the use of chloramphenicol eyedrops has been raised because of the associated risk of development of bone marrow aplasia.[99,125]

Increased resistance to polymyxin B–sulfamethoxazole for the treatment of conjunctivitis caused by *S. pneumoniae* in children was reported recently. Topical tetracycline and fluoroquinolones are active against penicillin-resistant *S. pneumoniae* and are considered suitable for the treatment of patients with conjunctivitis that is not responsive to the other treatment.[75]

BONE AND JOINT INFECTIONS. In a review of 13 cases of septic arthritis or osteomyelitis caused by penicillin-susceptible *S. pneumoniae*,[4] the drug used most commonly was penicillin, followed by ampicillin. Nafcillin and cefotaxime also were used to treat these patients. In addition, three patients with non–penicillin-susceptible *S. pneumoniae* were treated with combinations of vancomycin and cefotaxime or ceftriaxone for septic arthritis and osteomyelitis.

Rifampin and clindamycin also were used to treat a patient with septic arthritis of the left hip and osteomyelitis of the proximal end of the femur caused by highly resistant *S. pneumoniae* (penicillin and cefotaxime MICs of 8 μg/mL); this patient also experienced prolonged fever (21 days). The patient had been treated initially with cefotaxime and nafcillin, as well as with drainage and irrigation of the infected site.[4]

The duration of treatment with parenteral antibiotics in patients with *S. pneumoniae* bone infection varied from 14 to 196 days and, in those with joint infection, from 12 to 67 days.[4,54] Parenteral treatment may be followed by oral antibiotic therapy once the patient has improved considerably.

ENDOCARDITIS. *S. pneumoniae* endocarditis is a rare event that accounts for less than 3 percent of all cases of endocarditis.[352,524,724] Cases caused by penicillin-resistant *S. pneumoniae* have been reported exclusively in adults.[683] Treatment is based on a combination of antibiotics and surgery because *S. pneumoniae* endocarditis is associated with rapid destruction of heart valves. Parenteral second- or third-generation cephalosporins are recommended as initial treatment, and the addition of vancomycin is advised in patients with penicillin- or cephalosporin-resistant organisms.[420] Newer fluoroquinolones may serve as an alternative treatment in older patients.[683]

TREATMENT OF PNEUMOCOCCAL INFECTION IN IMMUNOCOMPROMISED HOSTS. Children with underlying conditions such as HIV infection, nephrotic syndrome, sickle-cell disease, other congenital hemoglobinopathies, or congenital immunoglobulin deficiencies, as well as children receiving immunosuppressive drugs and those with congenital or acquired asplenia, are at increased risk for acquiring *S. pneumoniae* infection in general and infection with drug-resistant organisms in particular.[346,488,664,731] The results of two studies[665,740] suggested that in HIV-infected adults, the outcome is worse in patients with nonsusceptible *S. pneumoniae* than in those with susceptible *S. pneumoniae*. However, both studies had limitations that preclude arriving at firm conclusions. In regions where penicillin-resistant *S. pneumoniae* occurs commonly, consideration should be given to initiating therapy with vancomycin and cefotaxime or ceftriaxone in critically ill patients until susceptibility results are available; subsequent therapy should be based on these results and the patient's clinical course.

For infants with sickle-cell anemia, oral penicillin prophylaxis against invasive *S. pneumoniae* disease should be initiated as soon as the diagnosis is established, preferably by the time that the infant is 2 months of age. Although the efficacy of antimicrobial prophylaxis has been proved only in patients with sickle-cell anemia, other asplenic children at particularly high risk, such as those with malignant neoplasms or thalassemia, also should receive daily chemoprophylaxis. In general, antimicrobial prophylaxis (in addition to immunization) should be considered strongly for all asplenic children younger than 5 years old and for at least 1 year after they undergo splenectomy.[13]

The age at which chemoprophylaxis is discontinued often is empiric. Based on a multicenter study, prophylactic penicillin can be discontinued in children with sickle-cell anemia who are receiving regular medical attention and have not had a severe *S. pneumoniae* infection or surgical splenectomy when they reach approximately 5 years of age.[13] The appropriate duration of prophylaxis for children with asplenia caused by other conditions is unknown. Some experts continue administering prophylaxis throughout childhood and into adulthood for high-risk patients with asplenia.[13]

For antimicrobial prophylaxis, oral penicillin V (125 mg twice a day for children younger than 5 years old and 250 mg twice a day for children 5 years and older) usually is recommended. Some experts recommend amoxicillin (20 mg/kg/day). Breakthrough infections caused by drug-resistant *S. pneumoniae* may occur. Therefore, parents should be aware that all febrile illnesses are potentially serious in immunocompromised children and that immediate medical attention should be sought because the initial signs and symptoms of fulminant bacteremia can be subtle.[13]

In addition to receiving chemoprophylaxis, children aged 2 years and older who are at increased risk of acquiring invasive *S. pneumoniae* infection should be immunized with a pneumococcal conjugate vaccine followed by a 23-valent nonconjugate polysaccharide vaccine 2 months or longer after the last dose of the conjugate vaccine is taken.[593] Indications for immunization are the following: (1) sickle-cell disease; (2) functional or anatomic asplenia; (3) nephrotic syndrome or chronic renal failure; (4) conditions associated with immunosuppression, such as organ or bone marrow transplantation, drug therapy, or cytoreduction therapy (including long-term systemic corticosteroid therapy); (5) HIV infection; and (6) CSF leaks.[14] For details on immunization, see the section on prevention.

MISCELLANEOUS INFECTIONS. Other infections, such as primary peritonitis and orbital cellulitis, should be treated with antibiotic agents that are recommended for bacteremia. Parenteral penicillin, ampicillin and cefotaxime, or ceftriaxone is suitable treatment in most cases, and the addition of vancomycin for drug-resistant *S. pneumoniae* is recommended. Treatment should be adjusted according to susceptibility results.[731]

PREVENTION

Prevention of pneumococcal infection in all ages is, without doubt, a more effective approach to reducing the burden of pneumococcal disease than any successful treatment modality is. In general, prevention can be divided into nonimmunologic and immunologic strategies (immunoprophylaxis).

NONIMMUNOLOGIC STRATEGIES

This category includes interventions that aim at (1) reducing risk factors predisposing to the development of pneumococcal infection, (2) providing chemical substances (e.g., antibiotics) to abort or prevent pneumococcal colonization or disease, and (3) modifying anatomic abnormalities that predispose to the development of pneumococcal infection.[417]

A factor that is important not only for pneumococcal infection but also for many other serious bacterial infections is the need to improve general health and nutrition worldwide, particularly in developing countries. Many risk factors for the acquisition of pneumococcal infection that can be alleviated include poor living conditions, overcrowding, poor hygiene, malnutrition, and a high prevalence of viral infections, particularly respiratory viruses, measles, and HIV. In the developed world, carriage of pneumococci, especially antibiotic-resistant strains that result in sporadic infections as well as outbreaks, is related to daycare attendance and is proportional to the number of children per group.[124,135,168,171,463,608,718] Therefore, reducing the number of children per group in daycare centers and developing alternative forms of childcare may reduce the rate of pneumococcal morbidity.

The importance of passive smoking (namely, being in close contact with smokers in the same household) has been highlighted as a risk factor for the development of pneumococcal disease.[545] Thus, effort to prevent smoking in the home may have an important role in the prevention of pneumococcal infection. Breast-feeding may protect against some infections related to *S. pneumoniae*, such as otitis media.[23,104,197,628,744] Therefore, breast-feeding should be encouraged, especially in families in which otitis media occurs commonly, although the precise role of prolonged breast-feeding in protecting against pneumococcal infection has not been established.

Antimicrobial chemoprophylaxis is used predominantly for two indications: prevention of recurrent AOM and prevention of pneumococcal sepsis in children with anatomic or functional asplenia. Data now exist to support the common practice of prescribing regular doses of penicillin for children with asplenia or sickle-cell disease.[253] Chemoprophylaxis is used commonly for the prevention of middle ear infections. Controlled clinical trials have compared antimicrobial chemoprophylaxis with placebo, surgery, or historical controls.[76] Various antibiotics were tested (either as ongoing daily prophylaxis or as intermittent treatment during viral infections). Most of the studies, but not all, showed a benefit of chemoprophylaxis over controls, especially for amoxicillin, ampicillin, sulfonamides, and trimethoprim-sulfamethoxazole.* However, those studies were performed before the era of increased antibiotic resistance in *S. pneumoniae*. The dosing schedule recommended for prophylaxis usually is half the daily therapeutic dose given once a day, but the optimal dosing regimen has not been defined.

The potential benefits of otitis media chemoprophylaxis have been weighed against the ability of chemoprophylaxis to alter the nasopharyngeal flora, foster colonization with resistant organisms, and thereby compromise the long-term efficacy of the prophylactic drug and contribute to the propagation of resistant organisms throughout the community. As a result, the practice of otitis media chemoprophylaxis has been reduced greatly. In one study,[101] prophylaxis with amoxicillin induced a dramatic increase in the carriage of penicillin-resistant *S. pneumoniae*, as well as increased carriage of other resistant pathogens. The fear of increasing resistance led the Committee on Infectious Diseases of the American Academy of Pediatrics to issue a warning against the widespread use of otitis media prophylaxis and to state in its recent report that "Antimicrobial prophylaxis should be reserved for control of recurrent acute otitis media, defined by 3 or more distinct and well-documented episodes during a period of 6 months or 4 or more episodes during a period of 12 months."[15]

Surgical otitis media prophylaxis by myringotomy and insertion of tympanostomy tubes or adenoidectomy (with or without tonsillectomy) has been recommended for otitis-prone children.[411] Some authorities now prefer this modality to the chemoprophylactic approach because it is not associated with altered flora. However, surgical risks also need to be considered.

A novel approach to prevention of pneumococcal disease is the potential use of oligosaccharides to prevent attachment of organisms, including *S. pneumoniae*, to the respiratory mucosa. Because colonization of the respiratory mucosa can result in local and systemic disease, as well as spread to other individuals, prevention of colonization is a reasonable approach to prevent disease. Human milk oligosaccharides can prevent attachment of *S. pneumoniae* and other organisms to the mucosa of the respiratory tract[19,803] and have been shown to interfere with the establishment and progression of experimental pneumococcal pneumonia in infant rats.[345] Natural oligosaccharides act as decoys in mucosa (also in saliva, tears, urine, sweat, and breast milk) and bind the carbohydrate-binding proteins of the microbial pathogens and thereby prevent mucosal attachment.[417] Despite this promise, a large-scale study examining the efficacy of such an oligosaccharide (3′-sialyllacto-*N*-neoteratose) given intranasally as prophylaxis for AOM and nasopharyngeal carriage of bacteria failed to show any beneficial effect on either outcome.[745]

Other experiments conducted in Finland showed that xylitol (a five-carbon sugar alcohol used extensively as a sweetener in toothpaste, chewing gum, and various foods) inhibited the growth of streptococci, including *S. pneumoniae*, in vitro[426,427] and prevented the development of otitis media in daycare center attendees when provided as chewing gum, lozenges, or syrup.[742,743]

*See references 65, 318, 413, 493, 499, 579, 592, 618, 630, 783.

Whether this approach eventually will develop into a practical strategy to prevent respiratory infections caused by *S. pneumoniae* and other organisms is not clear. Obviously, the concept of reducing nasopharyngeal colonization and thereby the number of episodes of bacterial respiratory infection through competitive inhibition remains "cutting-edge" medicine. Additional new agents, altered doses, or the existing agents or different methods of administration still should be studied.[576]

IMMUNOPROPHYLAXIS

As discussed in the section on pathogenesis in this chapter, *S. pneumoniae* infections typically are opportunistic infections complicating viral respiratory infection. Recent advances in the development of vaccines against respiratory viruses, especially influenza virus, RSV, and parainfluenza virus, could, therefore, reduce the incidence and severity of pneumococcal infection by reducing these preceding viral infections. Some of these vaccines are expected to be licensed and widely used in the next decade. Inactivated influenza vaccines are licensed already and used in children. The expected addition of live attenuated influenza vaccines may herald a new era in the prevention of influenza disease in children.

The reader is referred to the sections on the structure of the pneumococcus, virulence factors, and host defense mechanisms in this chapter for an understanding of the basis for the immune-based strategy of prevention of disease.

Unconjugated Capsular Polysaccharide Vaccines

Efforts to prevent pneumococcal infection by providing specific immunity started more than 100 years ago, as described in the section on history. That both passive immunization (administration of specific antibodies) and active immunization can protect against many pneumococcal infections is well established.

Passively administered serotype-specific antibodies can protect animals and humans against diseases caused by pneumococci. Administration of antisera was associated with improved clinical outcome, including reduced mortality rates.[118] Human immunoglobulins can prevent experimental pneumococcal bacteremia in mice[128,639] and otitis media in chinchillas.[679] The finding of low cord blood IgG antibodies, mainly of the IgG1 subset, is predictive of early-onset AOM in infancy.[59,474,647] In several clinical studies, bacterial polysaccharide immune globulin (BPIG) obtained by immunizing healthy adults with a 14-valent pneumococcal vaccine (in addition to group C meningococcal and Hib polysaccharide vaccines) decreased the prevalence of AOM[654,680] and invasive infection[682] in children. High-dose BPIG administered to infant rats resulted in high serum concentrations of serotype-specific IgG against serotype 3 (geometric mean concentrations of 8.2 and 1.4 μg/mL on days 1 and 7, respectively) and, consequently, protection against nasopharyngeal carriage of this serotype.[492]

Immunization with pneumococcal polysaccharide antigens, mainly in adults, has been studied for a long time. First, hexavalent polysaccharide vaccines were introduced in the late 1940s, followed by 14-valent vaccines in the late 1970s and 23-valent vaccines in the early 1980s. The last, produced by several manufacturers, contains 25 μg of purified, nonconjugated polysaccharide antigens per dose for serotypes 1, 2, 3, 4, 5, 6B, 7F, 8, 9N, 9V, 10A, 11A, 12F, 14, 15B, 17F, 18C, 19A, 19F, 20, 22F, 23F, and 33F. These 23 serotypes account for approximately 90 percent of the serotypes responsible for invasive pneumococcal infection in all age groups in both developed and developing countries.[17,310,311,619,698] The 23-valent polysaccharide vaccines are tolerated well by healthy children for primary[447,668] or repeated immunization.[88] However, the presence of preexisting antibodies was associated with an increased incidence of adverse events at the site of infection in adults but less pronounced effects in children.[78,432,552]

Generally speaking, these bacterial polysaccharide-based vaccines are poorly immunogenic in infants and toddlers for important disease-causing serotypes, which is to be expected because bacterial capsular polysaccharides induce antibody production primarily by T-cell–independent mechanisms that still are not fully developed in this age group.[615] Polysaccharide-specific IgG concentrations are relatively high in very young infants because they are acquired transplacentally and consist mainly of IgG1. Nasopharyngeal colonization with various serotypes of *S. pneumoniae* results in the natural production of serotype-specific antibodies.[107,314,730,786] The immune response to pneumococcal polysaccharides is serotype-dependent, and some serotypes commonly associated with disease are especially poor immunogens until the child reaches the age of approximately 5 years.[194] Serotypes 6A, 6B, 12, 19A, 19F, and 23F are examples of this phenomenon.[170,194,431,447,460,599,699,730,786] As for other species, the IgG subclasses that are produced after exposure to polysaccharide antigens are mainly IgG2 and IgG4.[468] A second dose of polysaccharide vaccine does not provide a booster effect and even may result in a reduced immune response when compared with the response after the first dose, which may suggest an antigenic tolerance effect.[78,754]

Children with certain underlying conditions that predispose to the development of pneumococcal infection respond more poorly to pneumococcal polysaccharide vaccines than do otherwise normal children. Published studies of children with recurrent respiratory tract infections,[204,327,652,653] HIV infection,[34,263,581] sickle-cell disease,[67,754] splenectomy,[3,612] malignancies,[609] and chronic renal disease[247,630,642,703] all have demonstrated this phenomenon.

In addition to a relatively poor systemic immune response, the polysaccharide vaccines have been shown to induce only minimal mucosal immune responses. Serotype-specific antibodies to pneumococcal serotypes 6A, 14, 18C, and 23F were measured in the sera and middle ear effusions of 14 children who had received a 14-valent pneumococcal capsular polysaccharide vaccine and in controls.[431] Serotype-specific antibody concentrations in middle ear effusions correlated with serum concentrations and generally were higher in pneumococcal vaccine recipients than in control vaccine recipients. IgM class antibodies frequently were seen only in the serum samples, thus suggesting that antibodies diffuse into the middle ear space rather than being synthesized in situ in response to the vaccine. This finding refutes previous theories that local production of antibodies occurs in the middle ear after vaccination.[433,692,693]

Limited data exist regarding the efficacy of polysaccharide pneumococcal vaccines in preventing disease in infants and children. A large study conducted in Papua New Guinea on more than 7000 children showed a reduction in mortality rates from acute lower respiratory tract disease.[449,616,617] In this study the effect was dramatic: a 59 percent reduction in mortality rates in all children vaccinated (5 months to 5 years of age) and a 50 percent reduction in children vaccinated before they reached 2 years of age. However, the vaccine did not protect against nonfatal disease. In the United States, researchers have suggested that the polysaccharide vaccines would be 62 percent effective in preventing invasive pneumococcal disease caused by vaccine serotypes in children aged 2 to 5 years.[226] The effectiveness of polysaccharide pneumococcal vaccines in preventing otitis media is not clear. Several studies have shown some reduction in the incidence of otitis media in vaccinated children,[339,490] but other studies have failed to show this effect.[193,394,725] No effect of the use of polysaccharide pneumococcal vaccine on pneumococcal nasopharyngeal carriage could be demonstrated.[160,170]

The aforementioned data on T-cell–independent polysaccharide pneumococcal vaccines clearly show that the benefit in children was at best marginal.

Conjugated Capsular Polysaccharide Vaccines

In contrast to the T-cell–independent nature of the immune response that occurs after the administration of bacterial polysaccharides, when these polysaccharides are conjugated to protein, the antibody response changes to a T-cell–dependent one.[44,200,396,620,681,705] These conjugate vaccines induce helper T cells to stimulate polysaccharide-specific B cells that not only produce antibodies but also mature into memory cells (Fig. 96–14). Polysaccharide–protein conjugate products characteristically are immunogenic in infancy and result in the production of high concentrations of antibodies. These antibodies have improved functional capacity (determined by avidity and opsonization assays), are long lasting, and induce a brisk and rapid elevation in highly functional antigen-specific antibodies with re-exposure (booster effect).[205]

The development of pneumococcal conjugate vaccines initially used the technology developed for Hib conjugate vaccines. Increasing experience and challenges have led to modifications of that technology, the development of new technologies, and the addition of new protein carriers. Studies were initiated first on monovalent pneumococcal conjugate vaccines. Currently, this technology has brought about vaccines with 7 to 13 different conjugated pneumococcal polysaccharide antigens. Table 96–4 shows the pneumococcal conjugate vaccines that are licensed in at least one country, are being tested in phase III efficacy studies, or are in advanced phase II (safety and immunology) stages. The rationale for choosing among the 7-, 9-, 11-, or 13-valent conjugate vaccines is presented in the section on epidemiology in this chapter.

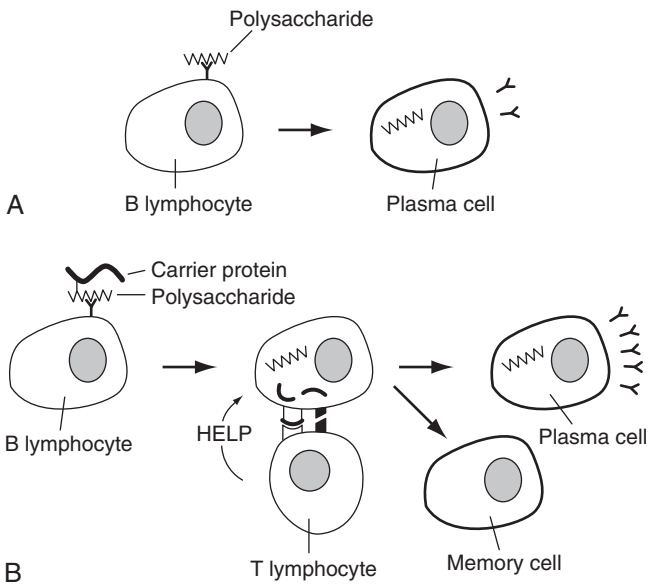

Figure 96–14 T-cell–independent **(A)** and T-cell-dependent **(B)** antibody responses to polysaccharide or polysaccharide–protein conjugate antigens. *(From Eskola, J., and Anttila, M.: Pneumococcal conjugate vaccines. Pediatr. Infect. Dis. J.* 18*:543-551, 1999.)*

The main target populations for the development of conjugate pneumococcal vaccines were infants and young children. Conjugate pneumococcal vaccines have been studied in these target populations since the early 1990s. Pneumococcal conjugate vaccines have been found to be safe and well-tolerated. The reactions reported usually were local ones, such as pain, redness, and swelling at the injection site. The incidence of fever and irritability was somewhat higher than reported in studies with the Hib conjugate vaccines or hepatitis B vaccines, perhaps because these vaccines represent 7 to 11 separate monovalent vaccines administered together as opposed to the monovalent Hib conjugate vaccine or hepatitis B vaccine. The 7-valent pneumococcal vaccine conjugated to CRM_{197} protein (PnCRM7) was found to be safe even when administered to low-birth-weight and preterm infants.[677]

The conjugate vaccines tested were able to elicit a T-cell–dependent immune response in normal infants and toddlers, namely, priming with immunologic memory and maturation of the functional antibody response, as measured by the predominance of IgG1 subclass antibodies, opsonophagocytic activity assays, and antibody avidity assays.[205,217] The immunogenicity of one vaccine (PnCRM7) also was studied in various high-risk groups. It was immunogenic in children with sickle-cell disease,[544,552,754] HIV infection,[407,408,419,534] solid organ transplants,[471] or allogeneic bone marrow transplants,[513] as well as in Alaska Natives and American Indians.[510] A 9-valent CRM (PnCRM9) pneumococcal vaccine also was immunogenic in children with sickle-cell disease.[276]

Determining the efficacy of pneumococcal vaccines is complex. Pneumococci cause a range of clinical diseases, and, therefore, several end-points of efficacy trials should be considered. The end-points thought to be of most importance in evaluating pneumococcal vaccines have been (1) prevention of invasive pneumococcal disease as defined by isolation of pneumococci from a normally sterile site (e.g., bacteremia or septicemia, meningitis, osteomyelitis/septic arthritis, and soft tissue infections); (2) prevention of mucosal infections such as otitis media, sinusitis, and nonbacteremic pneumonia; and (3) reduction of nasopharyngeal colonization, which in turn results in a reduction in spread of the organisms (the biologic basis for indirect effects, also known as *herd immunity*).

TABLE 96–4 Pneumococcal Conjugate Vaccines That Are Licensed in at Least One Country, Are Being Tested in Phase III Trials, or Are in Advanced Stages of Phase II Development

Vaccine	Valency	Pneumococcal Polysaccharides	Carrier Protein	Manufacturer
PnOMPC7	7-valent	4, 6B, 9V, 14, 18C, 19F, 23F	Meningococcal outer-membrane protein complex	Merck Research Laboratories
PnCRM7	7-valent	4, 6B, 9V, 14, 18C, 19F, 23F	CRM_{197} protein	Wyeth Pharmaceuticals
PnCRM9	9-valent	1, 4, 5, 6B, 9V, 14, 18C, 19F, 23F	CRM_{197} protein	Wyeth Pharmaceuticals
PncT/D	11-valent	1, 3, 4, 5, 6B, 7F, 9V, 14, 18C, 19F, 23F	A mixture of tetanus and diphtheria toxoids	Aventis Pasteur
Pn-PD	11-valent	1, 3, 4, 5, 6B, 7F, 9V, 14, 18C, 19F, 23F	*Haemophilus influenzae*—protein D	GlaxoSmithKline
PnCRM13	13-valent	1, 3, 4, 5, 6A, 6B, 7F, 9V, 14, 18C, 19A, 19F, 23F	CRM_{197} protein	Wyeth Pharmaceuticals

By mid-2001, the 7-valent pneumococcal CRM vaccine had been licensed in the United States and in more than 30 other countries. The vaccine's trade name is Prevnar in the United States and Prevenar in other countries. In the United States, the Committee on Infectious Diseases of the American Academy of Pediatrics has made the following recommendations with regard to pneumococcal conjugate vaccines. PCV-7 is recommended for routine administration as a four-dose series for infants at ages 2, 4, 6, and 12 to 15 months; catch-up immunization is recommended for all children up to 23 months of age. The PCV-7 vaccine may given along with other age-appropriate childhood immunizations in a separate syringe and at a separate injection site. Infants of very low birth weight may be immunized when they reach a chronologic age of 6 to 8 weeks, regardless of their calculated gestational age. The PCV-7 vaccine also is recommended for all children younger than 60 months who are at high risk of acquiring invasive pneumococcal infection (patients with sickle-cell disease, asplenia, HIV/acquired immunodeficiency syndrome, diabetes, cancer, liver disorders, lung diseases, and cardiac diseases). For some high-risk children, supplemental protection should be given by administration of the PPV23 vaccine. The only contraindication to receiving the vaccine is a serious allergic reaction to a previous dose of this vaccine or one of its components. Children with minor illnesses such as colds may be vaccinated.[16]

In the United States, the practice of giving three primary doses and a booster dose is known as a "3 + 1 schedule." Some countries routinely immunize with fewer doses. Some countries give two primary doses and a booster, a "2 + 1 schedule," whereas others give three primary doses without a booster, a "3 + 0 schedule." Some serotypes, namely serotypes 6B and 23F,[395] produce less antibody when a two–primary dose series is used as opposed to a three–primary dose series.[475] One study found that three infant doses with a booster were more protective against vaccine-type disease than were two doses alone ($p = 0.0323$).[781] The booster dose may play a role in reducing nasopharyngeal carriage; therefore, absence of a booster dose may decrease indirect protection.[475]

Widespread use of the vaccine in the United States began in the first half of the year 2000. Such widespread use has provided additional data on the safety of PnCRM7. Common side effects of the vaccine include redness, tenderness, or swelling at the site of injection, fever, fussiness, drowsiness, rashes, and urticaria.[785] Furthermore, the incidence of invasive pneumococcal disease has decreased sharply in infants and toddlers and even in their household contacts.[70,676,780]

Three efficacy studies with the end-point of a reduction in the number of invasive infections were completed by mid-2002, two with PnCRM7 and one with the PnCRM9 vaccine. The first study was a prospective double-blind study of 37,868 healthy infants in northern California to whom either the PnCRM7 vaccine or a control vaccine was administered at 2, 4, 6, and 12 to 15 months of age.[69] The vaccine was 97.4 percent efficacious (95% confidence interval, 82.7-99.9%) against invasive disease caused by the serotype included in the vaccine in fully vaccinated infants and 93.9 percent efficacious (95% confidence interval, 79.6-98.5%) in partially vaccinated infants. No evidence of an increase in invasive disease caused by serotypes that were not included in the vaccine was detected, and thus the overall effect was a reduction in total invasive pneumococcal disease by 89.1 percent (95% confidence interval, 73.7-95.8%). This trial was the pivotal efficacy one that led to U.S. licensure of the vaccine by the Food and Drug Administration in February 2000 and subsequent licensure in many other countries. Additional analysis[677] has shown that the vaccine was as effective in the subset of low-birth-weight and premature infants as it was in the full study cohort.

A second large-scale efficacy study with the PnCRM7 vaccine was conducted among American Indian (Navajo and White Mountain Apache) children in the United States. This population has rates of invasive pneumococcal infection that are approximately five times those of the general U.S. population.[142,549] In a double-blind, community-randomized study, infants and young children aged 2 months to 2 years received the PnCRM7 vaccine or a control vaccine.[551] A total of 8292 infants from 43 communities were enrolled; of these, 8091 lived in 38 communities that were randomized to the pneumococcal or the control vaccine. During the study period, two cases of invasive pneumococcal infection caused by the serotypes included in the vaccine occurred in the vaccine group versus eight in the control group. After controlling for community randomization, the primary efficacy of the vaccine was 76.8 percent (95% confidence interval, 9.4-95.1%), and the intent-to-treat efficacy was 86.4 percent (95% confidence interval, 11-96.1%). These results are not statistically different from those of the trial in northern California.

A third efficacy study was conducted with the PnCRM9 vaccine among black infants in South Africa. In a double-blind, randomized, placebo-controlled study, PnCRM9 was administered to children at the ages of 6, 10, and 14 weeks according to the World Health Organization's Expanded Programme on Immunization. The infants were monitored until they reached 2 years of age, and the study was completed by the end of 2001. The intent-to-treat analysis showed a reduction of 82.5 percent (95% confidence interval, 39.0-96.7%) in the number of invasive infections caused by the serotypes included in the vaccine for children not infected with HIV and a reduction of 65.4 percent (95% confidence interval, 23.8-85.7%) in children infected with HIV.[424]

Otitis media is caused by various organisms in addition to *S. pneumoniae* (mainly *H. influenzae* [usually untypeable], *M. catarrhalis*, and, less frequently, *S. pyogenes* and enteric bacteria). Therefore, a positive evaluation of conjugate pneumococcal vaccines must demonstrate not only a reduction in the incidence of disease caused by the pneumococcal serotypes included in the vaccine but also a parallel increase in episodes caused by other pathogens, especially the pneumococci of serotypes not present in the vaccine. The latter were shown to be isolated with increased frequency from the nasopharynx of children vaccinated with conjugate pneumococcal vaccine (the so-called replacement phenomenon), as will be discussed further in the section.

Pneumococci are found in 25 to 50 percent of cases of AOM occurring in children.[77,378,484] The serotypes causing otitis media are not always identical to those causing invasive infection, but the most common serotypes found in otitis media worldwide are included in the 7-, 9-, or 11-valent conjugate vaccines. They include serotypes 3, 6B, 9V, 14, 19F, and 23F.[74,114,157,394] Serotypes 6A and 19A also are important causes of otitis media.[157,206] These two serotypes are not included in the vaccine, but cross-protection of serotype 6A by antibodies to serotype 6B has been demonstrated.[2,25,159,206,266,548,568] The pneumococcal serotypes included in the various vaccine formulations would account for 50 to 85 percent of all serotypes causing otitis media. Assuming 100 percent efficacy of pneumococcal conjugate vaccines against the serotypes included in the vaccines and no increase in otitis media caused by other pneumococcal serotypes or other pathogens, conjugate pneumococcal vaccines could reduce the incidence of all causes of otitis media by at most 10 to 25 percent. The results of analysis of four efficacy/effectiveness studies confirmed these expectations.

The northern California study, conducted primarily to determine efficacy of the PnCRM7 conjugate vaccine against invasive pneumococcal infection,[69] also looked at the reduction in the number of clinic visits for otitis media in 18,927 pneumococcal vaccine recipients and 18,941 control meningococcal vaccine

recipients at the ages of 2, 4, 6, and 12 to 15 months. During the 30-month follow-up period, a total of 73,041 visits related to otitis media and 52,789 distinct episodes of otitis media had occurred in the study population. Of those, 5451 subjects had frequent episodes of otitis media (three episodes in 6 months or four episodes in 1 year). The pneumococcal vaccine reduced the number of clinically diagnosed otitis media episodes by 7 percent (95% confidence interval, 4.1-7.9%). The effectiveness of the PnCRM7 vaccine against frequent otitis media was 9.3 percent (95% confidence interval, 3.0-15.1%) when three episodes in 6 months or four in 12 months were counted, and it was 22.8 percent (95% confidence interval, 6.7-36.2%) when a frequency of five episodes in 6 months or six in 12 months was considered. Children who received the pneumococcal conjugate vaccine were 20.1 percent (95% confidence interval, 1.5-35.2%) less likely to require placement of a pressure-equalizing tube than controls were. This study was not designed to evaluate the effect of conjugate pneumococcal vaccine on otitis media as a primary outcome, and, therefore, no attempts were made to standardize or validate the clinical diagnoses of otitis media. Hence, the study was able to assess only the effect of PnCRM7 vaccine on otitis media as it is diagnosed and managed in the routine clinical setting. As a result, the authors were not able to examine the efficacy of the vaccine against otitis media caused by pneumococcal serotypes included in the vaccine, except for cultures performed on fluid obtained from spontaneously draining ears. In 23 children, culture of fluid from spontaneously draining ears was positive for pneumococci of the vaccine serotypes, with a 66 percent calculated efficacy against disease caused by serotypes included in the vaccine. However, its efficacy against clinically diagnosed otitis media indicated that the vaccine reduced morbidity attributed to otitis media and medical services used for the management of clinical otitis.

A second study, conducted in Finland, looked at the efficacy of PnCRM7 vaccine against AOM in general and more specifically against otitis media caused by serotypes in the conjugate pneumococcal vaccine under study.[206] A total of 1662 infants were enrolled and randomized in a double-blind manner to receive either the PnCRM7 vaccine or a hepatitis B vaccine at the ages of 2, 4, 6, and 12 months. The clinical diagnosis of AOM was based on predefined criteria, and bacteriologic diagnosis was based on culture of middle ear fluid obtained by myringotomy. The children were monitored through 24 months of age. A total of 2596 episodes of AOM occurred in children who had received three doses of vaccine by the time that they reached 6 months of age. The efficacy of the vaccine in reducing cases caused by the serotypes included in the vaccine was 57 percent (95% confidence interval, 46-67%). The PnCRM7 vaccine also provided cross-protection against serotypes 6A and 19A. The efficacy of the vaccine in reducing all culture-confirmed pneumococcal infections (including serotypes not included in the vaccine) was 34 percent (95% confidence interval, 24% to 45%). However, the vaccine was not effective against nonvaccine pneumococcal serotypes that are not cross-reactive with the ones included in the vaccine. The vaccine also was ineffective against otitis media caused by *H. influenzae* and *M. catarrhalis*, and a trend toward an increase in the incidence of otitis media among vaccinated children (replacement disease phenomenon) was noted. Thus, the overall high protection provided against the serotypes included in the vaccine was offset partially by an increase in the number of episodes of otitis media caused by other serotypes of pneumococci and other pathogens. The overall reduction in the number of episodes of AOM of any cause in the pneumococcal vaccine group was 6 percent (95% confidence interval, –4-16%). This difference did not reach statistical significance, but it was within the expected range when all theoretical considerations listed earlier were taken into account, and it also was strikingly similar to the 7 percent reduction in the number of cases of otitis media observed in the California study.[69] In addition, similar to the California study, by the time that they reached the age of 4 to 5 years, the vaccinated subjects had undergone tympanostomy tube placement at a rate that was reduced by 39 percent (95% confidence interval, 4% to 61%) in comparison to controls.[564]

A third study was conducted by the same Finnish group in parallel with the study just described, but this time with a different 7-valent vaccine (serotypes 4, 6B, 9V, 14, 18C, 19F, and 23F conjugated to the meningococcal outer-membrane protein complex [OMPC]—PnOMPC7).[403,404] In this randomized, double-blind, controlled trial, 1666 children were randomized to receive either PnOMPC7 or hepatitis B vaccine at 2, 4, and 6 months of age. At 12 months of age, approximately 22 percent of the PnOMPC7 conjugate vaccine recipients received a nonconjugate 23-valent polysaccharide vaccine as a booster, and the others received a fourth dose of PnOMPC7. Follow-up continued through 24 months of age. The methodology was similar to that described earlier for the PnCRM7 conjugate vaccine, including cultures for the diagnosis of otitis media episodes. A total of 2709 otitis media episodes occurred in evaluable children who had completed their three-dose schedule, 360 of which were caused by pneumococci of the serotypes included in the vaccine. The efficacy of the vaccine in reducing the number of cases of otitis media caused by the serotypes included in the vaccine was 56 percent (95% confidence interval, 44-66%). In reducing the number of all pneumococcal otitis media episodes, the efficacy was 25 percent (95% confidence interval, 11-37%). However, no overall reduction in the number of episodes of otitis media was seen because of an increase in the number of episodes caused by nonvaccine serotype pneumococci and other nonpneumococcal organisms (replacement disease).

The results of the two studies in Finland and the study in northern California are strikingly consistent. They all have shown that (1) the efficacy of the two conjugate vaccines tested thus far in the prevention of otitis media caused by pneumococcal serotypes included in the vaccine was greater than 50 percent and that efficacy on the order of magnitude observed for invasive infections (i.e., 90%) cannot be achieved against otitis media, (2) replacement otitis media with pneumococci not included in the vaccine and other organisms such as *H. influenzae* and *M. catarrhalis* occurs and reduces the overall efficacy of the pneumococcal conjugate vaccines against otitis media, and (3) better protection is provided against episodes of more severe otitis media and recurrent otitis media than against simple otitis media. The more severe and recurrent otitis media episodes often are associated with pneumococcal serotypes 6B, 9V, 14, 19F, and 23F, which tend to persist both in the nasopharynx and in the middle ear. These serotypes also tend to be more resistant to antibiotics.[157,380]

A fourth study was conducted in toddlers attending daycare centers in southern Israel. In this double-blind study, the efficacy of a 9-valent CRM conjugate pneumococcal vaccine (PnCRM9) in reducing nasopharyngeal carriage of *S. pneumoniae* and respiratory infections was compared with that of a control vaccine. This study showed, in conjunction with an extensive reduction in carriage of the serotypes included in the vaccine, especially serotypes 6B, 9V, 14, 19F, and 23F,[155,159,174] a 17 percent (95% confidence interval, –0.2-33%) reduction in the number of cases of otitis media and a 20 percent (95% confidence interval, 14-36%) reduction in antibiotic use for otitis media.[174] These findings support the notion that conjugate pneumococcal vaccines can reduce the morbidity of otitis media, not only by reducing the number of episodes or reducing the severity of otitis media in general but also by selectively reducing otitis media in high-risk groups such as attendees at daycare centers.

TABLE 96–5 Studies* on the Effect of Conjugate Pneumococcal Vaccine on Carriage of *Streptococcus pneumoniae* and Antibiotic-Resistant *S. pneumoniae*

Author	Conjugate Vaccine (Valence)	Site	Age (mo) at Vaccination	Reduction in Serotypes Included in the Vaccine	Reduction in Resistant Pneumococci	Increase in Nonvaccine Serotypes

PnOMPC, 7-valent pneumococcal vaccine conjugated to the outer-membrane complex of Neisseria meningitidis B; PnT, pneumococcal vaccine conjugated to tetanus toxoid; PnD, pneumococcal vaccine conjugated to diphtheria toxoid; PnT/D, pneumococcal vaccine conjugated to a mixture of tetanus and diphtheria toxoid; PnCRM, pneumococcal vaccine conjugated to CRM_{197} protein (PnCRM5, 5-valent; PnCRM7, 7-valent; PnCRM9, 9-valent).

Since the use of PCV-7 has become common practice, several studies have shown that the PCV-7 vaccine is not extremely efficacious in decreasing the total number of children who have AOM because of an increase in cases caused by nonvaccine serotypes or other organisms.[707,708] The vaccine should be promoted because of its primary indication of preventing invasive pneumococcal disease and not decreasing the incidence of AOM.[375] However, some papers have reported a decline in the number of visits to primary care physicians for AOM[292] by up to 19 percent.[475] Another study found that the incidence of tympanostomy tube placement decreased by 24 percent after introduction of the vaccine.[228]

Protection against pneumococcal pneumonia by the conjugate pneumococcal vaccines was shown in the PnCRM7 vaccine efficacy trial conducted in northern California.[69,71] However, pneumococcal pneumonia cases are associated only infrequently with bacteremia, and the PnCRM7 vaccine should provide protection against these invasive episodes to the same degree as they do against all other invasive episodes. Because most cases of pneumonia are nonbacteremic, the great majority remain without a clear bacteriologic diagnosis. In these cases, the role of *S. pneumoniae* can be demonstrated indirectly if the use of a vaccine significantly reduces the occurrence of pneumonia cases. Thus, the conjugate pneumococcal vaccines can be used as surrogates to estimate more accurately the proportion of pneumonia cases attributable to vaccine serotype pneumococci.

In the northern California study conducted on 37,868 infants given the PnCRM7 vaccine, all clinically diagnosed episodes of pneumonia identified through hospital, outpatient, and emergency records were collected.[71] In total, 3711 clinical episodes of pneumonia that occurred before the children reached the age of 3.5 years were identified; the efficacy of the PnCRM7 vaccine in reducing the incidence of disease (intent-to-treat analysis) was 6.0 percent (95% confidence interval, 1.5-11.0%). Of the 3711 clinical episodes, a chest radiograph was obtained in 2249 episodes, and among these children, vaccine efficacy was 8.9 percent (95% confidence interval, 0.9-16.3%). Of the 2249 children in whom a chest radiograph was obtained, 737 had a positive chest radiograph (defined as parenchymal infiltrates, consolidation or effusion [or both], but not perihilar infiltrates alone). In these 737 patients, efficacy was 22.7 percent (95% confidence interval, 8.7-34.5%). These findings have some limitations because they were not derived from a study in which the primary objective was to evaluate protection against pneumonia. However, the findings suggest two important points: (1) many cases of clinically and radiologically proven pneumonia in children are caused by *S. pneumoniae* by virtue of the fact that vaccination was associated with a marked reduction in not only the "classic" lobar pneumonia usually associated with *S. pneumoniae* but also clinical pneumonia, with negative or minimal findings on the chest radiograph, and (2) the 22.7 percent efficacy observed for pneumonia with radiologically documented findings suggests that at least in the developed world where Hib vaccines are used widely, *S. pneumoniae* causes a high proportion of pneumonia with parenchymal infiltrates.

A recent study from South Africa showed that administration of three doses of PnCRM9 at the ages of 6, 10, and 14 weeks reduced the incidence of radiologically proven pneumonia by 22.1 percent (95% confidence interval, 0.1-39.5%) in children who were not infected with HIV.[424]

Additional supportive evidence that *S. pneumoniae* may play a more important role in respiratory infections than usually attributed to this pathogen can be derived from a study in southern Israel involving toddlers aged 12 to 35 months who attended daycare centers.[174] In this study, 263 children were randomized to receive either PnCRM9 vaccine or a control vaccine (meningococcus CRM conjugate) in a double-blind fashion. The children were monitored for 5556 child-months. A total of 906 episodes of non–otitis media upper respiratory tract infection were reported, for an efficacy estimate of 15 percent (95% confidence interval, 4-24%); 596 episodes of lower respiratory tract problems occurred, including bronchiolitis, cough, and pneumonia, and the efficacy of pneumococcal vaccine was 16 percent (95% confidence interval, 2-28%). For these two clinical illness categories, children received a total of 3678 days of antibiotics. A reduction of 10 percent in the number of days that antibiotics were given for upper respiratory tract infections was achieved, as was a reduction of 47 percent for lower respiratory tract problems in the pneumococcal vaccine group ($p < 0.001$ versus control children). The incidence of bronchiolitis and pneumonia, often regarded as viral in this age group, was decreased significantly by the administration of this conjugate pneumococcal vaccine, thus suggesting that *S. pneumoniae* plays a role as a pathogen or co-pathogen for these entities.

As stated earlier, control of nasopharyngeal carriage of pneumococci is the key to managing pneumococcal disease and person-to-person spread of *S. pneumoniae*. The nonconjugate pneumococcal vaccines do not have a significant effect on carriage of *S. pneumoniae* in children and adults.[170,485] In contrast, the conjugate vaccines do have a significant effect on carriage.* Table 96–5 shows the studies conducted and published thus far to

*See references 155, 159, 170, 172, 175, 201, 436, 500, 546, 548.

document the effect of pneumococcal vaccines on carriage of *S. pneumoniae*. Despite variations in the nature of the conjugate vaccines, populations, and the ages at which the vaccines were administered, a significant reduction in carriage of the serotypes included in the vaccine clearly was observed in all studies. However, in most of the studies, a "replacement" phenomenon occurred: an increase in the carriage of *S. pneumoniae* serotypes not included in the vaccine was observed in conjunction with a decrease in the carriage of serotypes included in the vaccine. Although this replacement phenomenon is remarkable, its clinical significance is not clear. In theory, such a phenomenon could be simply an artifact of "unmasking," in which nonvaccine serotypes are detected more readily in vaccinees than in controls because the vaccine serotypes are not present. However, the use of mathematic modeling and testing in controlled vaccine studies strongly suggests that a true "replacement phenomenon" does exist in which non–vaccine-type pneumococci truly are replacing vaccine-type pneumococci.[472] This suggestion is supported by the observation of an increase in the incidence of otitis media caused by organisms not included in the vaccine after vaccination with PnCRM7 and PnOMPC7 in Finland.[206,403]

The reduction in nasopharyngeal carriage of vaccine serotypes of pneumococci is important because it certainly will reduce the spread of these serotypes. Two studies in different settings clearly have shown the existence of this phenomenon. In one double-blind comparative study conducted in southern Israel, toddlers attending daycare centers were vaccinated with a PnCRM9 vaccine or a control vaccine.[156] In this study, attendees at daycare centers and their younger siblings who stayed home were monitored after the daycare attendees were vaccinated. A marked reduction in the incidence of vaccine-type pneumococcal carriage was seen in the young siblings of those who were vaccinated with the PnCRM9 vaccine when compared with siblings of the controls.[156]

In a second study, Navajo and White Mountain Apache children younger than 2 years old were randomized according to their community of residence to receive either PnCRM7 or meningococcus C conjugate vaccine. Nasopharyngeal swabs were cultured for *S. pneumoniae* from 598 nonimmunized infants residing in both vaccinated (by PnCRM7 vaccine) and control communities.[547] A 24 percent reduction in carriage of vaccine-associated serotypes was noted in vaccinated infants residing in the PnCRM7 communities versus those living in control vaccine communities. The reduction was found both in infants who lived with a PnCRM7-vaccinated sibling and in those who did not have direct contact with a PnCRM7-vaccinated child. This study demonstrated the indirect protective effect of pneumococcal vaccination on those in the household.

Because most antibiotic-resistant *S. pneumoniae* strains belong to only a few serotypes that are included in the conjugate pneumococcal vaccines or are related to these serotypes (see the section on epidemiology and microbiology), vaccines are expected to reduce disease, carriage, and spread of antibiotic-resistant *S. pneumoniae* and may have an impact on the use of antibiotics. Indeed, in all vaccine studies that investigated the effect of conjugate vaccines on nasopharyngeal carriage of antibiotic-resistant *S. pneumoniae*, a reduction in carriage of such strains was observed[155,170,172,175,500] (Table 96–5). Furthermore, the use of conjugate vaccines reduced the use of antibiotics in two prospective double-blind studies. In a study conducted in northern California, administration of the PnCRM7 vaccine reduced the use of antibiotics by 5.3 percent in patients given vaccines versus controls; the reduction was 5.0 percent for drugs generally used as first-line agents (such as amoxicillin and ampicillin) and 11.2 percent for those often used as second-line agents (cephalosporins, amoxicillin-clavulanate, and azithromycin) (Black, S., Shinefeld, H.: Presented at the 19th Annual Meeting of the European Society for Pediatric Infectious Diseases, April 26 to 28, 2001, Istanbul, Turkey). In another study performed in toddlers attending daycare centers in southern Israel, the PnCRM9 conjugate vaccine reduced the use of antibiotics in vaccine recipients versus controls by 20 percent,[174] in parallel with the reduction in carriage of antibiotic-resistant *S. pneumoniae* and respiratory diseases. The reduction in both these factors may contribute to reducing antibiotic resistance in the community. However, the overall effect remains to be determined.

Although invasive infections are the most dramatic part of the pneumococcal disease spectrum, respiratory infections such as otitis media occur far more frequently.[466] In a study investigating current estimates of pneumococcal disease burden, clinical outcome, and vaccine efficacy, researchers estimated that for each annual U.S. birth cohort, routine use of a 7-valent vaccine could prevent 12,000 cases of pneumococcal bacteremia and meningitis, 53,000 cases of pneumococcal pneumonia, and more than 1 million clinical cases of otitis media per year.[466]

Pneumonia has a greater impact globally than do otitis media or even invasive infections because of the high mortality rate in children in the developing world.[63,296,461] However, it is more difficult to study because it does not occur as commonly as does otitis media, and bacteriologic documentation rarely is available for this entity in children.

Thus, the protection conferred by the conjugate pneumococcal vaccines with regard to reduction in the number of episodes of otitis media, pneumonia, and other mucosal infections, if proven by additional studies, could have an even greater impact on the burden of disease than on prevention of invasive infections.

Potential Future Vaccines and Future Strategies

Studies have been conducted to determine whether immunization of pregnant women with pneumococcal conjugate or nonconjugate vaccines can protect their offspring from acquiring pneumococcal diseases during their first few months of life, before they achieve immunity through active vaccination. This suggestion is based on studies that have shown that naturally acquired IgG antibodies are transferred transplacentally to the fetus readily,[21,129,143] and clinical studies of maternal immunization with pneumococcal polysaccharide vaccines have resulted in similar observations.[450,553,672] In experimental studies, a correlation has been demonstrated between higher concentrations of vaccine-specific antibodies at birth and greater response to specific serotypes after subsequent active immunization in the offspring of vaccine recipients.[445,470] In one study, administration of a conjugate pneumococcal vaccine to pregnant women[523] resulted not only in efficient transplacental passage of vaccine-induced pneumococcal antibodies (mainly of the IgG1 subtype) but also in prevention of pneumococcal carriage in the offspring of vaccinated mothers. A recent Cochrane review found no evidence that pneumococcal vaccination administered during pregnancy reduces the risk for neonatal infection. Although the data did suggest an effect in reducing pneumococcal colonization in infants by the time they reached 16 months of age, no evidence was found of this effect in infants at 2 months of age or by 7 months of age.[121] A recent study in New Guinea found that breast milk IgA was 1.1 to 1.8 times higher in women immunized with pneumococcal polysaccharide vaccine than in unimmunized women for 6 months post partum.[451] Thus, maternal immunization during pregnancy may prove to be a successful strategy to protect against pneumococcal infection in early infancy, but additional serotypes need to be included in these vaccines.

Adding more polysaccharide capsular antigens to the conjugate pneumococcal vaccines to increase serotype coverage is being investigated. In addition, much effort is being invested in combining the present conjugate pneumococcal vaccine with other childhood vaccines to be given in the same syringe in

order to reduce the number of injections needed to immunize infants.

Despite the great potential benefit of the pneumococcal conjugate vaccines, they have two important limitations: (1) inclusion of a limited number of serotypes, which results not only in noncoverage of some other important serotypes causing disease but also in potential replacement disease by serotypes not related to the vaccine, and (2) their high price as a result of complex production and quality control processes.

Many of the proteins mentioned in the section on pathogenesis appear to be suitable antigens for candidate vaccines, and such vaccines that include proteins immunogenic in infants are being developed. The main drawback of protein vaccines is the antigenic variability of many pneumococcal proteins. However, some of the most important proteins considered essential for bacterial virulence have epitopes that are common to many pneumococcal strains. Among these proteins are pneumolysin, PspA, and PsaA.[96] Plasma concentrations of antibodies to these proteins increase with age and are associated strongly with pneumococcal exposure, whether by carriage or infection such as AOM.[605] One suggestion is that antibodies to PsaA may prevent pneumococcal otitis media,[607] but such prevention has not been confirmed. Preliminary studies show that PspA and PsaA given as single antigens or as a mixture of antigens are immunogenic and protective in mice and safe and immunogenic in humans.[533] Further studies in humans were expected to begin in 2002. Other candidate protein vaccines are being investigated in animals, but as of mid-2002, they had not yet been administered to humans. An additional novel approach to providing immunization against *S. pneumoniae* infection is to immunize subjects with killed whole-cell *S. pneumoniae* intranasally with an adjuvant. This approach was studied in animal models and showed promising results.[491]

During the next decade, other pneumococcal vaccine prototypes probably will be discovered and developed. Whether they will equal or surpass the beneficial effects of the pneumococcal conjugate vaccines remains to be seen.
