CHAPTER 97

Miscellaneous Gram-Positive Cocci

Randall G. Fisher

This chapter discusses relatively uncommon gram-positive cocci that are of importance because of their unusual antimicrobial sensitivities and because of their increasing recognition as pathogens in hospitalized patients. The reader is referred to a review of these organisms for more details.[16]

LEUCONOSTOC SPECIES

BACTERIOLOGY

Leuconostoc spp. are facultatively anaerobic, gram-positive cocci that usually appear in pairs or chains. They are catalase-negative,

Vogues-Proskauer–positive, and leucine aminopeptidase–positive. In addition, colonies often are alpha-hemolytic on blood agar and also may react with group D streptococcal antiserum. These properties are shared by viridans streptococci, with which *Leuconostoc* spp. often are confused.[18] They also may resemble enterococci, except that they are pyrrolidone carboxylyl peptidase–negative. Differences include the production of gas from glucose and high-level vancomycin resistance.

EPIDEMIOLOGY

Leuconostoc spp. are found commonly on plants, especially sugar cane and leafy vegetables. They also are present in dairy products and wine.[44] They are used in the food industry as starter cultures in food production.[30,55] Studies using culture methods have suggested that, although they occasionally are recovered from vaginal swabs in healthy individuals[48] and from mucosal surfaces in some hospitalized individuals,[26] *Leuconostoc* spp. are not part of the normal human flora.[3] However, a study of the acquisition of colonizing bacteria in the newborn gut involving phylogenetic analysis of 16S recombinant DNA sequences showed that *Leuconostoc citreum* generally was acquired by newborns on their first day of life. Case reports of pediatric infection began to appear in the 1980s.[12,27,29,41,60]

PATHOPHYSIOLOGY

Leuconostocs rarely are pathogenic. Underlying disease states or compromised immune system, gastrointestinal tract disease (especially short-gut syndrome), previous or current antibiotic therapy, venous or gastrointestinal tract access devices, recent invasive procedures, and infancy are thought to be risk factors.[14,15,26,44] Frequently, leuconostocs are isolated as part of a polymicrobial infection after a patient has been treated with vancomycin.[16] Of the first 21 cases reported in the English literature, 12 were in children, 10 of which occurred in patients younger than 1 year old. Documented portals of entry include central lines,[3,27] peritoneal dialysis and urinary catheters,[6] and gastrostomy tubes.[29] Contaminated enteral formula also has been implicated.[7,29,39] Occasional sporadic cases without a known risk factor have been described,[12,26] which underscores the pathogenic potential of *Leuconostoc* infection.

CLINICAL MANIFESTATIONS

Bacteremia, heralded by fever and usually leukocytosis in patients with the risk factors outlined earlier, is by far the most common clinical manifestation of *Leuconostoc* infection. Gastrointestinal disturbances, especially diarrhea, are common manifestations.[3] Infants are prone to emesis. *Leuconostoc* bacteremia, in association with cough and chest x-ray findings consistent with pneumonia, was reported in a child with acquired immunodeficiency syndrome (AIDS).[44] *L. citreum* has been isolated from the lung tissue of a 33-year-old patient with AIDS who also had *Pneumocystis carinii* pneumonia.[21] Small necrotic cavities scattered through both lungs were associated with gram-positive cocci in tissue. Patients with dental infections,[60] peritonitis,[22] osteomyelitis,[37] and meningitis[12,19] also have been described. Meningitis has been reported in an otherwise healthy 16-year-old patient and in a neonate with fatal infection despite high cerebrospinal fluid (CSF) bactericidal antibiotic titers.[12,19] A nosocomial cluster of five cases of urinary tract infection caused by *Leuconostoc pseudomesenteroides* (strictly a species of a new genus, *Weissella*)[11] has been reported,[6] as has a cluster of three cases of *Leuconostoc* septicemia in critically ill postsurgical patients.[51]

DIAGNOSIS

Cultures usually are positive within 24 to 48 hours. Leuconostocs are somewhat fastidious. Identification of vancomycin-resistant *Streptococcus* should raise suspicion of *Leuconostoc* infection and prompt additional biochemical studies,[44] including evaluation for the production of gas in MRS broth, failure to hydrolyze arginine, and delayed esculin hydrolysis.

TREATMENT

Treatment with relatively high doses of penicillin or ampicillin frequently is successful in eradicating infection. When possible, access devices should be removed. Leuconostocs are most sensitive to the primitive β-lactam antibiotics, especially penicillin and ampicillin, although penicillin tolerance is a common finding.[29,57] They also frequently are sensitive to erythromycin, cephalothin, and the aminoglycosides. *Leuconostoc* spp. are variably resistant to clindamycin and trimethoprim-sulfamethoxazole. Resistance increases with later generations of cephalosporins.[26,57] *Leuconostoc* spp. are intrinsically vancomycin-resistant because their pentapeptide cell wall precursors end in D-Ala-lactate rather than the usual D-Ala-alanine.[25] Vancomycin cannot bind the lactate. This mode of resistance is the same as that possessed by vancomycin-resistant enterococci. However, whereas resistance in enterococci is plasmid derived and transferable, in leuconostocs it is chromosomally mediated, constitutional, and not transferable.

PEDIOCOCCUS SPECIES

BACTERIOLOGY

Pediococci also are intrinsically vancomycin-resistant, facultatively anaerobic gram-positive cocci. They appear most characteristically in tetrads on Gram stain, although they may appear in pairs or clusters.[23] The genus name *Pediococcus* is derived from the Greek word *pedium*, which means "plane." The name, therefore, suggests that they are a genus of cocci that grow in a single plane. It is a misnomer, however, because pediococci are the only lactic acid bacteria that divide in two planes.[20] They are catalase- and oxidase-negative. They do not reduce nitrates, and no gas is produced in MRS broth.[53] They are pyrrolidone carboxylyl peptidase–negative.[16] Most isolates react with Lancefield group D streptococcal antibodies.[53] They are leucine aminopeptidase–positive, which distinguishes them from *Leuconostoc* spp.[17] They produce white, opaque, nonhemolytic colonies on sheep's blood agar. A new broth medium, a combination of 90 percent Iso-Sensitest broth and 10 percent deMan-Rogosa-Sharpe broth and called LAB susceptibility test medium, has been found to provide optimal support of growth and to yield the most accurate minimal inhibitory concentration values.[33]

Pediococci produce powerful bacteriocins, which are substances that kill other bacteria. The bacteriocins of pediococci are active against other gram-positive organisms in particular[10] but also are active against *Clostridium botulinum* spores,[40] some gram-negative organisms,[54] and *Listeria monocytogenes*. Reports have suggested that some species of *Pediococcus* have antifungal activity[35]; however, this activity in other studies has been found to be present only at low pH and has been attributed to acetic acid in the medium.[5]

EPIDEMIOLOGY

Like leuconostocs and other lactic acid bacteria, pediococci are found on plants, in dairy products, and in alcohol-containing

beverages, where certain species are associated with spoilage.[58] They also are used in the formation of silage[53] and as starter cultures for some meat products. They are not thought to be part of the normal flora. They have been isolated from saliva and stool on rare occasion.[49] Though formerly thought to be nonpathogenic, they now are considered rare opportunistic pathogens with minimal virulence.

PATHOPHYSIOLOGY

Pediococci rarely are pathogenic. Many cases of blood isolates are found in patients without symptoms of infection or in polymicrobial cultures in which the significance of the isolate could not be assessed adequately.[36] One patient with a clinical picture of septic shock in whom the only organism recovered was *Pediococcus pentosaceus* has been reported.[13] Risk factors for bacteremia, with or without symptoms, appear to be the extremes of age, recent abdominal surgery or tube feeding, broad-spectrum antimicrobial therapy, and the presence of severe underlying disease states.[36] However, because the overall number of reported cases is small, the relative risks of these factors are uncertain.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Most patients either are asymptomatic or have fever as the only symptom. Six of the first 12 reported cases of *Pediococcus* bacteremia had concomitant pneumonia. Fifty-six percent of adult patients either were receiving tube feeding or had undergone abdominal surgery within 30 days of isolation of the organism.[36] The three reported pediatric cases occurred in infants, and all had underlying gastrointestinal tract anomalies. A 16-day-old infant with congenital jejunoileal atresia had undergone surgical repair just 8 days before being evaluated.[36] Her acute illness was characterized by emesis and a 200-g weight loss. She was afebrile when initially examined. The second patient was a 64-day-old infant with gastroschisis who had undergone two abdominal surgical procedures.[1] His fever reached 101.5° F, and his peripheral white blood cell count was 38,000 with a significant left shift. The third patient was a 3-month-old girl who had undergone surgical repair of gastroschisis on the first day of life.[2] Lethargy, direct hyperbilirubinemia, and a CSF pleocytosis were noted. Blood cultures grew *Pediococcus* spp., and the spinal fluid (obtained after initiation of antibiotics) was sterile. She responded to a 21-day course of ampicillin and gentamicin.

Pediococci are isolated frequently in localized infections, especially from abdominal sites, but they are virtually always part of a polymicrobial process. The relative importance of pediococci in these sites is difficult to assess. A case of *Pediococcus* bacteremic pneumonia was reported in a previously healthy pregnant woman.[50] Among 31 cases of *Pediococcus* infection submitted to the Centers for Disease Control and Prevention laboratory, 17 were from blood culture isolates (including 2 reported cases of endocarditis), and 4 strains were associated with urinary tract infections. Other sources included catheter tips, wounds, peritoneal fluid, CSF, lung, and bone.[16]

Diagnosis of infection with pediococci is established by identifying catalase-negative, vancomycin-resistant, gram-positive cocci in the characteristic tetrads. Many pediococci are misidentified initially as *Streptococcus equinus*, *Streptococcus constellatus*, or group D *Streptococcus*, not *Enterococcus*. Reported cases of pediococcal infection may, therefore, represent only a fraction of the total number of infections.

TREATMENT

Pediococci generally are susceptible to penicillin, ampicillin, imipenem, clindamycin, and first- and second-generation cephalosporins. Although both imipenem and penicillin are highly active against pediococci, they do not appear to be bactericidal. Pediococci are moderately resistant to the quinolones, tetracycline,[58] and trimethoprim-sulfamethoxazole.[47] Pediococci, like leuconostocs, are intrinsically resistant to vancomycin. Resistance is not plasmid-mediated, nor can it be transferred to other bacteria.[58] Sensitivity to ticarcillin and cefotaxime, when measured by agar dilution, is poor despite large zones of inhibition on disk susceptibility testing.[58] Occasionally, inducible resistance to erythromycin is found, although most isolates remain sensitive. Aminoglycoside sensitivity is variable.

AEROCOCCUS SPECIES

BACTERIOLOGY

The genus *Aerococcus* contains at least five species, but only two, *viridans* and *urinae*, have known clinical significance. In earlier papers, *A. urinae* was referred to as *Aerococcus*-like organism, or ALO.[9] Aerococci are catalase-negative, nonmotile, gram-positive cocci that appear preferentially in tetrads but sometimes in pairs or clusters. These relatively slow-growing organisms produce small, well-delineated, translucent, alpha-hemolytic colonies on blood agar.[8] They also are weakly bile esculin–positive and pyrrolidone carboxylyl peptidase–negative. They ferment mannose and mannitol.[45] Like enterococci, most aerococci will grow in 6.5 percent salt.[34]

EPIDEMIOLOGY

Aerococci are distributed throughout the world and are contaminants of air and dust.[28] They also have been found on meat, on raw vegetables, and in small numbers on human skin.[4] In hospitals, aerococci have been cultured from all areas, including operating suites and delivery rooms.[31] They also are found in salt water, where they cause a fatal disease in lobsters.[42]

Disease in humans is an uncommon event, and the organism usually is recovered from the bloodstream of patients with infective endocarditis. Most patients are elderly, but infection of infants and neonates also has been reported.[38,42] A rapidly fatal bacteremia has been described in patients with profound neutropenia.[32]

PATHOPHYSIOLOGY

In most circumstances, aerococci are saprophytic. The exact conditions that favor the development of infection have not been elucidated clearly. Some cases of *A. urinae* infection have occurred after genitourinary tract surgery. One case of septic arthritis developed after an elective abortion.[59] Immunocompromised patients are at higher risk, but infection in otherwise well persons has been described.[45] One report of meningitis in newborns found adherence of aerococci to inflammatory cells and suggested a role of as-yet-undefined adhesion factors.[38] Work in laboratory animals also has shown that a protease isolated from *A. viridans* cleaves the hemagglutinin of influenza virus and potentiates both viral replication and disease in mice.[52]

CLINICAL MANIFESTATIONS

Most cases of *A. viridans* bacteremia have been found in association with signs and symptoms of subacute infective endocarditis, although septic emboli and cardiac failure have not been described. In a recent series of four cases of *A. viridans* infective endocarditis, two of the patients required surgical intervention.[46] *A. urinae* causes urinary tract infection with dysuria and frequency, usually in the absence of fever.[8] *Aerococcus* infection in childhood is an uncommon occurrence. One case of bacteremia in a 1-month-old infant has been reported.[42] The patient had a 2-day history of loose stools, irritability, and drowsiness and on physical examination was noted to have mottled skin, circumoral cyanosis, and agitation. CSF and urine were normal, but blood cultures exhibited pure growth of *A. viridans*. No predisposing factors were identified.

Nathavitharana and associates[38] reported three cases of meningitis caused by *A. viridans*: a 7-month-old girl with jerking movements of the extremities, irritability, and a bulging fontanelle; a 5-month-old girl with fever, decreased appetite, and generalized convulsions; and a 24-month-old girl whose illness was manifested as fever, vomiting, and the neurologic signs of truncal ataxia, flaccidity, and hypoactive deep-tendon reflexes. All three patients had elevated CSF white blood cell counts with 55 to 93 percent segmented forms. Remarkably, all these patients had a history of prolonged illness (1 week to 2 months) before being evaluated, in contrast to patients with other causes of bacterial meningitis. No risk factors for infection were identified in any of these patients, who were thought to have normal immune function.

Swanson and colleagues[56] reported a case of penicillin-resistant *A. viridans* bacteremia in an 11-month-old girl receiving prophylactic penicillin for sickle-cell disease. The patient responded clinically to a 10-day course of therapy with cephalosporins.

Bone and joint infections and wound or other localized infections are exceedingly rare occurrences and not distinguishable from similar syndromes caused by more common organisms.

DIAGNOSIS

Careful observation of both appearance on Gram stain and growth in culture is key to establishing the diagnosis of aerococcal infection. On Gram stain, aerococci resemble staphylococci. On blood agar, they resemble viridans group streptococci. One series revealed that 1 percent of 719 cultures called streptococci actually were aerococci[43]; another study reclassified 3 percent of 168 cultures.[4] In one study of 24 alpha-hemolytic, nonenterococcal bacterial isolates from urine, standard identification methods were compared with 16S rRNA sequencing and special biochemical profiling. Thirteen of the isolates were aerococci; all were identified correctly by sequencing, but typical procedures failed to differentiate them from nonaerococcal isolates. Ciprofloxacin and trimethoprim susceptibility and the ability to grow at 45° C improved the discrimination of standard testing.[24] In their propensity toward tetrad formation, they mimic pediococci. However, all aerococci are vancomycin-sensitive. In their bile esculin hydrolysis and growth in 6.5 percent salt, they resemble enterococci; unlike enterococci, however, aerococci are pyrrolidone carboxylyl peptidase–negative and do not form chains.

TREATMENT

Aerococci generally are sensitive to penicillin, ampicillin, the cephalosporins, chloramphenicol, and the macrolides. They usually are intermediately susceptible or resistant to sulfonamides and aminoglycosides.[4,28] One report suggests that *A. viridans* and *A. urinae* have distinct antibiograms[34]; that is, *A. urinae* is more sensitive to penicillin and resistant to sulfonamides, whereas *A. viridans* is more resistant to penicillin and sensitive to the sulfonamides.[4] Individual case reports do not confirm these in vitro observations, and no large clinical trials of antimicrobial susceptibility have been conducted.

Acknowledgments

The author would like to thank Dr. William Gruber and Dr. Thomas Boyce for their invaluable assistance with earlier versions of this chapter.

SUBSECTION 2

Gram-Negative Cocci

CHAPTER 98

MORAXELLA CATARRHALIS

Barbara W. Stechenberg

Once thought to be an unimportant commensal organism in the human respiratory tract, *Moraxella catarrhalis* now is recognized as an important pathogen in respiratory tract diseases, particularly otitis, sinusitis, and lower tract disease. The initial paper by Ghon and Pfeiffer[25] published in 1902 described gram-negative cocci in sputum referred to as *Micrococcus catarrhalis*. Since then, the organism has undergone several changes in nomenclature, first to *Neisseria catarrhalis* because of its resemblance to other *Neisseria* organisms. In 1970, in recognition of the contributions of Sarah Branham, the name was changed to *Branhamella catarrhalis*.[11] More recently, that this organism should be a member of the genus *Moraxella* has become clear; thus, the name was changed to *M. catarrhalis*. With the transition in nomenclature, the last 2 decades have seen a parallel rebirth of this organism as a mucosal pathogen.

MICROBIOLOGY

M. catarrhalis is a gram-negative diplococcus that is morphologically indistinguishable from *Neisseria*. It has a tendency to resist decolorizing.[1] The organism is kidney-shaped, with the flat sides abutting each other. The size varies, but it may be larger than meningococcus or gonococcus. However, the resemblance on sputum Gram stain or conjunctival smear to gonococcus can be striking and clinically confusing.

The organism grows well on blood or chocolate agar and forms small, opaque, grayish colonies that are circular and nonhemolytic. They have poor adhesion to the agar surface, on which they act like hockey pucks when pushed over the surface of the agar plate.[17] The use of selective media such as modified Thayer-Martin or TV broth (Mueller-Hinton broth supplemented with trimethoprim and vancomycin) increases the likelihood of recovering *M. catarrhalis* from the complex flora of the mucosal surfaces.

Isolates of *M. catarrhalis* cannot use maltose, glucose, lactose, or sucrose as carbohydrate sources. *M. catarrhalis* is oxidase-positive and produces deoxyribonuclease. Valuable differentiating tests are hydrolysis of DNA and tributyrin. Several rapid tests such as butyrate hydrolysis, Tween 80 hydrolysis, and selective DNase agar have been described.[50,57] Fatty-acid analysis also has been used to identify atypical strains.

The surface of *M. catarrhalis* is composed of outer-membrane proteins, lipo-oligosaccharide, and pili. The organism does not appear to have a capsule, and the role of the pili is not defined well. Initial attempts to isolate outer-membrane proteins by detergent fractionation of cell envelopes were unsuccessful. By using a technique involving the collection of outer-membrane vesicles, which are released into the culture media, and then examination by sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE), Bartos and Murphy[6] identified eight proteins designated outer-membrane proteins A through H. The outer-membrane protein patterns of strains from diverse geographic and clinical sources were strikingly homogeneous.

Preliminary studies of the lipo-oligosaccharide of *M. catarrhalis* show that it is more antigenically conserved than are those of other gram-negative bacteria, thus rendering it a reasonable candidate for vaccine studies.[39,53] A recent study suggests that the lipo-oligosaccharide is not an adhesin, but its surface charge plays a critical role in the initial stage of attachment to human epithelial cells.[2]

Restriction endonuclease analysis has been used as an epidemiologic tool to distinguish strains of *M. catarrhalis*. Patterson and associates[42] used the technique to evaluate a nosocomial outbreak and to demonstrate the lack of association of other strains. Dickinson and coworkers[16] used a similar technique to study isolates from children with otitis media.

PATHOGENESIS

The ability of *M. catarrhalis* to produce disease, particularly in sequestered areas such as the ear and lung, indicates that this organism possesses virulence mechanisms that allow it not only to grow in these anatomic sites but also to produce pathologic effects. The presence of endotoxin in the *M. catarrhalis* outer membrane undoubtedly is important for its pathogenic potential, especially in situations in which inflammation plays a major role. Very little is known about the mechanisms involved in colonization and disease production. However, a subset of strains of *M. catarrhalis* associated with selected virulence traits suggests that some strains are more virulent than are others.[9,56]

A body of literature concerning the immune response to *M. catarrhalis* and the antigenic composition of this organism is accumulating rapidly.[12,13,34] Goldblatt and associates[26] demonstrated that children younger than 4 years old possess IgG1 and IgG2 that recognize an 82-kd outer-membrane protein exclusively but that older children mount an IgG3 response to a broad range of outer-membrane proteins. Faden and colleagues[23] developed a technique to measure opsonic antibody with the use of outer-membrane, antigen-coated beads. Convalescent sera opsonized homologous, antigen-coated sera significantly more often than acute sera did.

Unhanand and coworkers[52] used a murine model to study pulmonary clearance of *M. catarrhalis* from infected lungs. They investigated 10 strains and found marked variability in clearance rates and recruitment of phagocytic cells. With this model, Maciver and associates[36] actively immunized animals with the outer-membrane vesicles of *M. catarrhalis* and passively immunized animals with rabbit antiserum raised against these vesicles. Both experiments resulted in enhanced pulmonary clearance of both homologous and heterologous strains. The same model has been used to evaluate the role of a large, antigenically conserved protein of *M. catarrhalis* in pulmonary clearance, as well as the role of outer-membrane protein B in defense mechanisms of the lung.[30] The contribution of these proteins, as well as lipo-oligosaccharide, in host defense continues to unfold.

EPIDEMIOLOGY

M. catarrhalis is a normal inhabitant of the upper respiratory tract and is recovered exclusively from humans. The rate of colonization is highest in the early years and then declines steadily to less than 5 percent in adult life.[54] Prevalence studies report that as many as 50 percent of children are colonized with *M. catarrhalis*.[32,37] Faden and associates[22] monitored a large cohort of children from birth to 2 years of age. Sixty-six percent became colonized by the time that they reached 1 year of age, and 77.5 percent did so by 2 years of age. The frequency of nasopharyngeal colonization was higher during visits for otitis media than during well-child visits. Otitis-prone children were colonized by 6 months of age. Restriction endonuclease analysis showed marked heterogeneity, with children acquiring and eliminating many different strains over time.[22,42]

Numerous studies have documented the increased prevalence of *M. catarrhalis* as a pathogen in otitis media.[32,55] Shurin and colleagues[48] noted that isolation of *M. catarrhalis* from middle ear exudates increased from 6.4 percent between 1979 and 1980 to 26.5 percent between 1980 and 1982. A similar increase in *M. catarrhalis* as a pathogen in sinusitis has been reported.[58] In the pneumococcal conjugate vaccine (PCV7) era, a significantly higher proportion of PCV7-immunized children exhibit nasopharyngeal colonization with *M. catarrhalis*.[44]

Once colonization of the oropharynx occurs, colonization of the tracheobronchial tree may follow, but usually only if other risk factors are operative. In adults, such risk factors include previous cardiorespiratory disease, smoking, use of corticosteroids, use of immunosuppressive agents, malignancy, and intercurrent viral illnesses.[28,57] In children, many cases of pneumonia are associated with a preceding viral illness, prematurity, underlying lung disease, IgG deficiency, or other risk factors.

Nosocomial transmission has been well documented by DNA restriction endonuclease analysis.[14,42] In pediatric intensive care units, endotracheal intubation and frequent suctioning have been identified as risk factors for the development of pneumonia and bacterial tracheitis.[14,21]

Other interesting associations need to be investigated further. Seddon and associates[47] noted that colonization with *M. catarrhalis* occurred more commonly in asthmatic than in normal children. Whether the organism might be a trigger or pathogen in these children remains to be seen. Gottfarb and Brauner[27] found

a high carriage rate of *M. catarrhalis* in children with severe persistent cough.

Infection with *M. catarrhalis* exhibits seasonality in both adults and children.[28,48,55] Infection is much more likely to occur in the winter and spring months.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Otitis media caused by *M. catarrhalis* is indistinguishable clinically from otitis caused by other pathogens such as *Streptococcus pneumoniae* and *Haemophilus influenzae*. *M. catarrhalis* may be isolated as a single agent or in combination with other organisms. In one study, children with *M. catarrhalis* were less likely to have a serum C-reactive protein level greater than 1.0 mg/dL than were children with either of the other two major pathogens.[55]

Because tympanocentesis usually is not performed in routine cases, the exact cause of an episode of acute otitis media generally is not known. One study found that *Moraxella* was an unusual organism as a single agent in children in whom acute otitis media had been treated recently.[29] Nonetheless, in a study of persistent otitis, Pichichero and Pichichero[43] demonstrated *Moraxella* in 7 percent of specimens. The spontaneous resolution rate of *M. catarrhalis* may be high,[4] and this fact should be considered when therapy is planned.

The clinical manifestations of acute sinusitis caused by *M. catarrhalis* are similar to those of other organisms; therefore, selection of antibiotics should be made with consideration of this organism as a potential pathogen.

Lower respiratory tract disease caused by *M. catarrhalis* may have a broad clinical spectrum; however, because sputum samples often are not available in children, many cases documented in the literature have been severe. Berg and Bartley[7] described five premature infants, all younger than 6 months old, in whom precipitous clinical deterioration developed after 2 to 4 days of a prodrome consisting of cough, tachypnea, and intercostal retractions. They all required assisted ventilation, which is common in young infants with severe pneumonia.[7,14,20] Some cases of *M. catarrhalis* pneumonia have been associated with bacteremia.

Underlying conditions such as leukemia, acquired immunodeficiency syndrome, and trauma have been reported to predispose a patient to the development of infection with *M. catarrhalis*.[37,59] An association with immunoglobulin deficiency has been demonstrated in some patients with disease caused by this organism.[12] In adults, *M. catarrhalis* pneumonia occurs more commonly in patients with human immunodeficiency virus infection, malignancy, or chronic lung problems.[26,57] The role of this organism in less severe manifestations probably is limited.[33]

Bacterial tracheitis caused by *M. catarrhalis* has been reported in both immunocompromised hosts and those with normal immune systems.[21]

M. catarrhalis also has been responsible for a wide variety of other infections. Urethritis caused by this organism can be mistaken for infection with *Neisseria gonorrhoeae*.[49] Several cases of conjunctivitis have been reported; when present in the newborn period, *M. catarrhalis* can mimic the ophthalmia neonatorum of *N. gonorrhoeae*.[51] The relationship of neonatal infections to maternal vaginal carriage of *Moraxella* has not been established.[41]

More severe infections with *M. catarrhalis* include meningitis and bacteremia, so this organism should be considered in appropriate circumstances, especially in immunocompromised children.

Children with *M. catarrhalis* bacteremia may have many different manifestations. Some patients have petechial or purpuric rashes, thus rendering the clinical picture indistinguishable from that of meningococcemia. Others have been neutropenic and have required mechanical ventilation.[8] Baron and Shapiro[5] reported two cases of unsuspected bacteremia in children with nonspecific symptoms. Their manifestations were similar to those of children with occult pneumococcal bacteremia. An immunocompetent child with *M. catarrhalis* bacteremia and preseptal cellulitis has been reported.[46]

Meningitis can occur from hematogenous spread of *M. catarrhalis* from the nasopharynx or as a consequence of ventriculoperitoneal shunt placement or surgery. Rarely, suppurative arthritis has been seen in children and adults.[31,38] Endocarditis is a rare occurrence, as is peritonitis.

TREATMENT

In the past, *M. catarrhalis* was susceptible to all β-lactam antibiotics. In the late 1970s, however, β-lactamase–producing strains of *M. catarrhalis* were isolated in Europe. In the United States, a parallel increase in the frequency of isolation of β-lactamase–producing *M. catarrhalis* has been noted, so it is not unusual for a laboratory to report that more than 90 percent of strains are β-lactamase producers.

The β-lactamases BRO-1, BRO-2, and BRO-3 are of chromosomal origin. Laboratory detection of β-lactamase activity depends on the assay used; the chromogenic cephalosporin nitrocefin usually is recommended.[19] Polymerase chain reaction methods can be used. BRO-1 is the most common β-lactamase in North American strains.[15] The β-lactamase inhibitors clavulanic acid, sulbactam, and tazobactam are active against the enzymes produced by *Moraxella*. Most β-lactamase–positive isolates will respond to achievable concentrations of β-lactam/β-lactamase inhibitor antimicrobial combinations, cephalosporins, and cephamycins.[18,24] Because of the high prevalence of β-lactamase–producing strains, many laboratories choose not to do any such testing.

Among the oral cephalosporins active against β-lactamase–positive strains of *Moraxella*, the minimal inhibitory concentration increases twofold to fourfold in the presence of the β-lactamase BRO-1 but not the β-lactamase BRO-2; cefixime is more active than are the older cephalosporins.[40] Resistance to tetracycline (by the nontransferable tetB determinant) and erythromycin has been reported, but such resistance is a rare finding.[10,45]

In vitro, *M. catarrhalis* usually is susceptible to ampicillin-sulbactam, amoxicillin-clavulanate, erythromycin, azithromycin, clarithromycin, trimethoprim-sulfamethoxazole, tetracyclines, chloramphenicol, fluoroquinolones (e.g., ciprofloxacin), aminoglycosides, and second- or third-generation cephalosporins such as cefuroxime, cefprozil, cefpodoxime, cefixime, cefdinir, and loracarbef.[35] Levofloxacin also exhibits good activity against *M. catarrhalis*.[3] The *Moraxella* organism is resistant to clindamycin, vancomycin, and oxacillin.

PREVENTION

Prevention of nosocomial *M. catarrhalis* infection is dependent on sound practices of infection control, especially with regard to pulmonary toilet. Prevention of other infections with this organism has not been attempted, except for the use of prophylactic antibiotics for recurrent otitis media.

CHAPTER 99

Meningococcal Infections

Marsha S. Anderson ✪ Mary P. Glodé ✪ Arnold L. Smith

Epidemic meningococcal meningitis was described first by Gaspard Vieusseux in Geneva in the spring of 1805. In a monograph titled "The Disease Which Raged During the Spring of 1805," he wrote:

> It commences suddenly with prostration of strength, often extreme: the face is distorted, the pulse feeble. There appears a violent pain in the head, especially over the forehead; then there comes pain of the heart or vomiting of greenish material, stiffness of the spine, and in infants, convulsions. In cases which were fatal, loss of consciousness occurred. The course of the disease is very rapid, termination by death or by cure. In most of the patients who died in 24 hours or a little after, the body is covered with purple spots at the moment of death or very little time afterward.[200]

Today, *Neisseria meningitidis* continues to be a cause of endemic and epidemic disease. In the United States, approximately 1400 to 2800 cases occur each year, and 95 to 97 percent of these cases are sporadic.[10,170] In 2005 and 2006, 1904 and 1742 U.S. cases were reported to the Centers for Disease Control and Prevention (CDC), respectively.[35] However, epidemics in Brazil in the early 1970s and in Finland in 1975 serve as a reminder of the potential virulence of this organism. In São Paulo, Brazil, invasive meningococcal disease developed in almost 1 in every 300 inhabitants during the epidemic in a 1-year period.[49]

The reader is referred to several excellent reviews of meningococcal disease that have been published recently.[72,111,171]

MICROBIOLOGY

The *Neisseria* genus was named for Dr. Albert Neisser, who described the organism of gonorrhea in 1879. The genus *Neisseria* contains two species important in human disease, *Neisseria gonorrhoeae* and *N. meningitidis*. In addition, several species are part of the normal flora of humans and animals. *Neisseria sicca*, *Neisseria lactamica*, *Neisseria subflava*, *Neisseria flavescens*, *Neisseria mucosa*, *Neisseria cinera*, *Neisseria polysacchreae*, and *Neisseria elongate* are human commensals; they only occasionally cause human disease.[121]

N. meningitidis is a gram-negative coccus, usually less than 1 μm in diameter. It classically occurs in pairs, with adjacent sides flattened, similar to kidney beans. Occasionally, the organism divides into two planes at right angles to one another, which results in the formation of tetrads. The organisms are nonmotile and aerobic (but facultatively anaerobic), produce catalase and oxidase, and may be encapsulated. *N. meningitidis* oxidizes glucose and maltose to acid. This feature distinguishes it from *N. gonorrhoeae*, which oxidizes only glucose. However, certain rare strains of *N. meningitidis* have been reported that fail to produce acid from either glucose or maltose. Fresh isolates have complex nutritional requirements and grow best on chocolate or blood agar. Incubation in a humidified 10 percent carbon dioxide environment is not essential but enhances growth. Morphologically, the colonies are bluish gray in appearance and will produce beta-hemolysis after 48 to 72 hours of incubation on 5 percent horse blood agar.[24]

N. meningitidis can be transformed by DNA originating in other species of *Neisseria*. Thus, when a *Neisseria* spp. cohabiting the nasopharynx with *N. meningitidis* dies and releases its DNA, the co-resident meningococcus can take up the DNA and incorporate it into its genome. Although this sequence of events occurs very rarely, if the new DNA confers a selective advantage to the recipient meningococcus, the trait encoded by the incoming DNA may be retained in future progeny. This is the mechanism by which sulfonamide resistance and penicillin G resistance have arisen in *N. meningitidis*.[121] Many commensal *Neisseria*, which also inhabit the nasopharynx, are relatively resistant to penicillin G. DNA fragments from these commensal strains that encode penicillin resistance can be detected in penicillin-resistant *N. meningitidis*.[173] Transformation of new DNA into *N. meningitidis* also can introduce genes that modify the structure of the bacterium. Serotyping of groups A, B, and C meningococci has provided valuable macro-epidemiologic information.[71] Clearly, as a population develops immunity to one capsular polysaccharide, the organism is capable of acquiring DNA encoding for an alternative capsule. Switching from serogroup B to serogroup C has been observed in a population[188] and a contact of a case.[201] There also appears to be horizontal gene transfer from commensal *Neisseria* to *N. meningitidis* of genes whose products aid the bacterium in surviving in the host or are involved in housekeeping functions.[119] This phenomenon probably is responsible for the occasional report of commensal *Neisseria* causing meningitis.[6] In one case, the strain was a virulent meningococcus that acquired a gene for the synthesis of polysaccharide from sucrose; this additional property led it to be identified as *N. subflava* rather than *N. meningitidis*.

In addition to having the transformation route for varying the antigenic phenotype, meningococci also may exhibit phase variation, which allows variance of the number of surface antigens. Investigators have estimated that at least 65 genes in *N. meningitidis*, including *por*A, are subject to phase variation.[64,194] Capsule synthesis may be switched on and off by this mechanism.

Like other gram-negative bacteria, the outer and inner cell membranes of *Neisseria* are phospholipid bilayers. These membranes sandwich a layer of peptidoglycan. Lipo-oligosaccharide (LOS), which is similar to the lipopolysaccharide seen in gram-negative enteric bacteria, is associated with the outer leaflet of the outer cell membrane. Outer-membrane proteins, which function as porins, are an integral part of the outer membrane. Some of these outer-membrane proteins are opacity proteins and facilitate adherence and invasion.[138] Outside the outer membrane, meningococci possess a polysaccharide capsule that protects the organism from phagocytosis.

Meningococci also have pili, which seem to be important in some phases of adherence to host cells, colonization, and invasion. The genes that code for pili also can be turned on and off, so at times the organism may not express pili. This feature may help the meningococci detach and allow the organism to be transmitted to another site or another host.[87] Antigenic variation of pili by a cassette mechanism allows the bacterium to escape the host's immune system.[82] In addition, both outer-membrane proteins and lipo-oligopolysaccharide display antigenic differences by phase variation.

For epidemiologic purposes, meningococci are divided into serogroups, serotypes, and subtypes. Differences in capsular polysaccharides, outer-membrane proteins, and LOS constitute the basis for these classifications. The capsular polysaccharides are antigenic and the basis for serogroup designation. Thirteen

serogroups currently are recognized: A, B, C, D, H, I, K, L, X, Y, Z, W-135, and 29E.[209] Serogroups A, B, C, Y, and W-135 are the most common causes of invasive disease worldwide.

Serotyping of organisms is based on antigenic differences in outer-membrane proteins called *porins*. Porins are protein channels in the outer membrane that permit nutrients and certain antibiotics to diffuse into the periplasmic space. A single locus encodes porin B, but two mutually exclusive alleles have antigenic differences. All meningococci have either antigenic class 2 or class 3 porin B. These differences permit serotyping. Differentiation of subtypes is based on antigenic differences in porin A. This highly variable antigen is called a class 1 outer-membrane protein. Multiple serotypes and subtypes have been identified. Antigenic specificity is achieved by the generation of monoclonal antibodies to the major protein (primarily class 2 or 3), LOS, and class 1 protein. The designation B:2a:P1.1:L3,7 indicates that the serogroup B strain is an "a" subtype of class 2 proteins, is a "one" of class 1 protein, and possesses two LOS antigens: 3 and 7.[77]

Type 2 protein antigen is isolated from more than 50 percent of cases in the United States and Canada and is an antigenic determinant in group B and C strains. These protein antigens not only are important as epidemiologic markers but also can induce protective bactericidal antibodies.[70]

EPIDEMIOLOGY

The incidence of meningococcal disease varies significantly by geographic location. Endemic disease, which occurs in developed countries such as the United States and Europe, ranges in incidence from 0.35 to 3.0 cases per 100,000 population per year.[30-32,170] The U.S. Active Bacterial Core Surveillance (ABC) system tracks invasive disease caused by encapsulated organisms in selected counties of 10 states geographically dispersed throughout the country. This reporting system covers a U.S. population of 39 million people. In 2005, the overall incidence of invasive meningococcal disease for the United States was estimated to be 0.35 per 100,000 population. Fifty-six percent of cases reported through the ABC system were meningitis with a fatality rate of 1.1 percent, and 31 percent of cases were bacteremia with a fatality rate of 15.1 percent. The rate of invasive disease was the same for African Americans and whites.[32]

In developing countries, the incidence is approximately 10 to 20 times higher than that in the United States (10-25 per 100,000 inhabitants per year).[80] The highest rate of meningococcal disease is found in a multicountry belt across sub-Saharan Africa, which has been termed the *meningitis belt*. Serogroup A meningococcal disease is prevalent there and occurs in epidemics during the dry season.[128] During epidemics, the incidence of meningococcal disease is as high as 1000 per 100,000 inhabitants (1%). Spread of clonal strains of group A meningococcus may be a factor in Africa's unusually high rate of epidemic disease. Clonal strains can migrate transcontinentally and cause epidemics, such as the clonal group A meningococcus designated electrophoretic type III-1 (ET III-1), which caused epidemics in China, Nepal, Saudi Arabia, Chad, and Kenya in the 1980s.[133,152]

International outbreaks of *N. meningitidis* infection occurred in 1987 and 2000 and were associated with Muslims making the annual pilgrimage to Mecca. The disease spread to persons of all nationalities represented, some of whom returned home before becoming ill.[133,156] In some cases, close contacts of travelers were infected. Several cases in U.S. citizens were attributed to the outbreaks. The 1987 outbreak was linked to serogroup A, whereas the 2000 outbreak was caused by serogroup W-135.[28,131,156] Saudi Arabia now requires meningococcal vaccine for travelers entering the country to participate in the annual pilgrimage to Mecca.[107]

Serogroups A, B, C, and Y account for more than 90 percent of meningococcal disease worldwide. Currently in the United States, serogroups B, C, and Y each accounts for approximately a third of the cases.[21,31] Serogroup A, which causes periodic epidemics in developing countries, is responsible for only occasional cases of meningococcal disease in the United States. Serogroup B usually causes sporadic disease but occasionally is associated with outbreaks.[29] Serogroup C, though also a cause of sporadic disease, has been associated with numerous outbreaks in the United States, Canada, and Europe.[96] In addition, school-related outbreaks of serogroup C meningococcal disease have been reported.[21,134,214] The incidence of serogroup C and serogroup Y disease has increased in the United States during the last few years as a result of antigenic shifts involving outer-membrane protein genes.[86] Disease caused by serogroup W-135 occurs infrequently and, like serogroup Y, has been associated with meningococcal pneumonia.[171,203] Recently, serogroup X has been identified as a predominant serogroup causing epidemic meningitis in Niger, with a case-fatality rate of 12.2 percent.[14]

In 2006, Brooks and colleagues reported on an analysis of 69 outbreaks of meningococcal disease that occurred in the United States from 1992 to 2002. Outbreak-associated cases represented less than 2 percent of the total cases of invasive disease. Additionally, outbreak-related cases were associated with a higher case-fatality rate than sporadic cases were (21% versus 11%; odds ratio, 3.3; 95% confidence interval, 2.0 to 5.5).[21]

Meningococcal disease in the United States peaks during the months November through March.[168,171] The highest attack rate is seen in February, and the lowest attack rate occurs in September. In Africa, epidemic disease occurs during the dry season and decreases once the rainy season starts.[152] Males and females are affected equally.

The risk of acquiring meningococcal disease is related inversely to age, with the highest rates of disease occurring in children younger than 1 year old.[31] As many as 49 percent of cases occur in children younger than 2 years old.[95] However, in epidemics, an age shift occurs, with older children, adolescents, and young adults more often being affected.[29] A progressive increase in the development of protective antibodies against meningococci occurs between the ages of 2 and 12 years. Neonates usually are protected by passive IgG transfer in utero if the mother has antimeningococcal antibody. In general, the development of bactericidal antibodies to meningococci increases in children at a rate of approximately 5 percent per year.[77]

The precise epidemiology of meningococcal disease was defined elegantly in a series of observations in New Jersey military recruits. An inverse correlation was noted between the age-related incidence of meningococcal disease in the United States and the prevalence of serum bactericidal activity against three pathogenic strains of *N. meningitidis*.[77,78] The investigators prospectively studied all incoming recruits to Fort Dix and demonstrated that those who lacked bactericidal activity to case strains had a 38 percent attack rate if they were exposed and acquired a pathogenic meningococcus strain.[77] Usually, nasopharyngeal carriage was an immunizing process. Carriage induced the formation of protective antibodies against homologous strains but also produced cross-reacting antibodies to heterologous strains of pathogenic meningococci. Antibody production typically was seen within 2 weeks of the acquisition of carriage.[77,78]

In addition to nasopharyngeal carriage, other processes may contribute to meningococcal antibody formation. Certain strains of cross-reacting bacteria, such as *Escherichia coli* and *Bacillus*, produce capsular polysaccharides that are immunologically identical to the capsules of meningococci serogroups A, B, and C. They represent a potential immunizing source against invasive meningococcal disease in the general population.[77,102,198]

Nasopharyngeal carriage of *N. meningitidis* is lowest in infants and children and highest in adolescents and young adults. One study determined that 2.4 percent of asymptomatic infants and children had a positive nasopharyngeal culture for *N. meningitidis*

during a nonepidemic period.[123] A study of 1500 Norwegians found the carriage rate to be 32.7 percent in persons 20 to 24 years of age and 10 percent in individuals older than 25.[27] Other investigators have shown that approximately 20 percent of children harbor meningococcal species in their nasopharynx, but most of these isolates are atypical, nontypeable strains that ferment lactose in addition to glucose and maltose.[77,78]

Nasopharyngeal meningococcal carriage in household contacts of persons with documented meningococcal disease is approximately 10 percent.[123,144,164] Several studies have shown that the carriage rate increases if infants or children are in the home.[102,144] In one outbreak of serogroup C meningococcal disease, carriage rates were 37.8 percent in households with a case in an infant, 17.5 percent in households with a case in a child, and 6.9 percent in households with disease in an adult.[102]

Nasopharyngeal carriage is a common finding in those who have had household contact with an index case, and colonization can persist for weeks to months. Without chemoprophylaxis, as many as 35 percent of contacts become colonized by the eighth week. The median duration of carriage is 9 months.[123] However, in nearly 40 percent of individuals, it may exceed 16 months.[79] An association between smoking and an increased rate of meningococcal carriage has been demonstrated.[181,185] In addition, passive smoke has been implicated in increasing the risk for acquiring meningococcal disease in children younger than 5 years old by 7.5 times that of the general population.

The factors responsible for converting nasopharyngeal colonization to invasive disease have not been established firmly. Many people in whom invasive disease subsequently develops are colonized shortly before the illness begins. Probably, these individuals lack bactericidal antibody, and, for some reason, protective antibody does not develop after acquiring the pathogenic strain. Other risk factors associated with invasive disease include young age, crowding (new military recruits, college freshmen in dormitories),[23,127,159] lower socioeconomic class,[170] concurrent upper respiratory infections,[132,213] intimate kissing with multiple partners,[192] specific immune deficiencies (properdin or terminal complement),[65] functional or anatomic asplenia,[69] and active or passive smoking.[67,181]

Speculation regarding the role of other upper respiratory pathogens in meningococcal disease prompted several observations. The peak incidence of meningococcal infection has been noted to mirror the peaks of such agents as influenza and *Mycoplasma*. Several studies have shown an association between colonization or infection with respiratory viruses or *Mycoplasma* and an increased risk for development of meningococcal disease.[26,92,132,176] Simultaneous outbreaks of meningococcal and influenza or echovirus infections have been documented.[117,213] In addition, one study suggested that the incidence of meningococcal disease and the resultant morbidity and mortality increased in the 5 weeks after individuals had influenza-like syndromes.[132] Researchers have postulated that viral pathogens may affect the immune response temporarily and facilitate meningococcal disease. Also possible is that disruption of the normal respiratory epithelium occurs with viral infection and thereby increases the likelihood that colonizing meningococci might become invasive.[132] Preceding viral respiratory disease is not a prerequisite for the establishment of meningococcal carriage or disease; however, its occurrence may increase the risk for invasive meningococcal disease.

A variety of host genetic factors also may influence susceptibility to invasive meningococcal disease. Individuals with late complement component deficiencies (C5, C6, C7, C8, or C9) and properdin pathway deficiencies are at increased risk for acquiring meningococcal disease.[65] This defect usually is inherited, and other members of the family may have a history of meningococcal disease or repeated meningococcal infections. Acquired complement deficiencies associated with diseases such as systemic lupus erythematosus, nephrotic syndrome, and chronic liver disease also are associated with an increased risk of acquiring meningococcal disease.[113] A Russian study found the incidence of complement deficiency in first episodes of meningococcal disease to be approximately 1 percent.[154] In Italy, the prevalence of complement deficiency in patients with meningococcal meningitis was 17 percent.[45] The decision of whom to screen for complement deficiency should be based partly on the prevalence of meningococcal disease in a given country. In countries where the incidence of meningococcal disease is high, complement deficiency is less likely to be found. In countries such as the United States, where the incidence is relatively low, complement screening may be justified.

The chance of finding a complement or alternative pathway (properdin) deficiency substantially increases in patients with recurrent meningococcal disease or with uncommon serogroups. The prevalence of complement or properdin deficiency in a patient infected with an unusual serogroup was found to range from 31 to 50 percent.[66,141] Therefore, screening all individuals with unusual serogroups is reasonable. CH_{50} testing generally is available and will screen for the combined activity of C1 to C9. If complement deficiency is found, the individual should receive the meningococcal vaccine. In addition, family members should be screened for complement deficiency, and all family members should be educated about the disease and immunized with quadrivalent polysaccharide or protein conjugate meningococcal vaccine. Most experts concur that the conjugate vaccine is preferred in the age groups for which the vaccine is licensed (2 to 55 years).

Some investigators have shown that although persons with complement deficiency are more at risk for acquiring meningococcal disease, the disease that they get often is mild. Meningococcal infection activates the complement system, and the LOS present in the bacterial outer membrane probably is responsible for the activation. In fatal cases, intense activation has continued until the time of death.[20] The case-fatality rate in complement-deficient individuals is approximately 3 percent.[172] Complement-deficient individuals are thought to be unable to maintain the high-level activation of the complement pathway and, therefore, have less severe disease.

Properdin deficiency, which impairs activation of the alternative complement pathway, is X-linked and has been associated with fulminant meningococcal disease.[51,66] The case-fatality rate in one kindred was 75 percent for persons with meningococcal disease.[12] Screening of individuals with exceptionally fulminant disease or those who have a family history of meningococcal infection should be considered. AP_{50} will screen for properdin deficiency in the alternative complement pathway. If a deficiency is documented, those individuals and their family members should receive the quadrivalent meningococcal vaccine to prevent disease caused by serogroups of meningococcus in the vaccine (conjugate vaccine is preferred in the age groups for which the vaccine is licensed, 2 to 55 years).

Mannose-binding lectin (MBL) is a pattern recognition receptor and a component of the innate immune system. Patients with meningococcal disease during childhood have a significantly increased incidence of structural mutations in the genes coding for MBL; such mutations lead to deficient MBL function when compared with healthy age-matched controls.[62] Similarly, mutations in genes coding for toll-like receptor 4 also may increase susceptibility to meningococcal disease. Human toll-like receptor 4 mutations are associated with susceptibility to invasive meningococcal disease in infancy.[61]

PATHOLOGY AND PATHOGENESIS

The mechanisms by which meningococci invade humans are understood only partially. We do know that encapsulated, type-

able meningococci are virulent, whereas nonencapsulated strains are relatively nonpathogenic. Even among encapsulated strains, differences in virulence between case and carrier strains of *N. meningitidis* have been demonstrated in an animal model.[91] The presence of a polysaccharide capsule enhances invasiveness by resisting opsonization and subsequent phagocytosis.

The human nasopharynx is the only natural reservoir of *N. meningitidis*.[183] Once pathogenic meningococci have colonized the respiratory tract of susceptible persons, either they become invasive or antibody to the organism develops and confers immunity. Meningococci adhere to nonciliated, columnar epithelial cells in the nasopharynx via pili. Binding induces endocytosis of the organism into the epithelial cell, and the bacteria may penetrate the epithelial barrier via phagocytotic vacuoles.[182] If antibody is insufficient and invasion occurs, the individual may become bacteremic. Occasionally, unsuspected meningococcal bacteremia has been detected on blood culture and spontaneously cleared on a follow-up culture without antibiotics.[186] However, in most cases, such clearance does not occur, and the individual becomes progressively ill. Bacteria in blood may seed the meninges and cause meningitis.

Meningococci are gram-negative organisms, and LOS is a major component of the bacterial cell membrane. Meningococci release blebs from their surfaces that contain outer membrane laden with LOS. LOS is a potent endotoxin, and concentrations of LOS correlate with the severity of disease.[18-20] LOS induces the release of a host of inflammatory and anti-inflammatory mediators whose concentrations also are correlated with the severity of disease: tumor necrosis factor-α (TNF-α), interferon-γ, interleukin-1 (IL-1), IL-6, IL-8, IL-10, and IL-1 receptor antagonist.[75,114,195,196,205] TNF-α down-regulates thrombomodulin expression on endothelial cells, thereby leading to decreased activity of proteins S and C.[39,139] Like TNF-α, many of the mediators directly or indirectly contribute to the formation of a procoagulant state, which results in the formation of microthrombi characteristically found in the skin, digits, extremities, and organs.

Cytokines play an important role in development of the shock frequently seen in meningococcemia. Release of cytokines causes activation of neutrophils and up-regulation of adhesion molecules that may promote endothelial damage and capillary leakage.[59] Vasodilation also may occur secondary to increased production of nitric oxide by endothelial cells.[130] Subsequent compensatory vasoconstriction of splanchnic, skin, and renal vessels may not be sufficient to maintain adequate blood pressure. Endotoxin-related or cytokine-mediated cardiac dysfunction also may contribute to the development of heart failure and hypotension.[146] Profound capillary leakage in the pulmonary bed may lead to the development of acute respiratory distress syndrome.

The disseminated intravascular coagulation (DIC) commonly seen in meningococcemia also is thought to be a consequence of activation of the coagulation system by endotoxin.[167] Experimental work in animals has suggested a synergistic effect of meningococcal endotoxin and materials egested from leukocytes containing meningococci in the initiation of DIC.[53]

The pathologic purpuric lesions seen in fulminant meningococcal disease are similar to those that the generalized Shwartzman reaction induces in rabbits by endotoxin. Pathologically, these lesions show evidence of microthrombi in small dermal vessels, endothelial damage, and hemorrhage. Inflammatory vasculitis is mediated by up-regulation of endothelial adhesion molecules, activation of neutrophils, and effects of cytokines and bacterial endotoxin.[4,44,90] Circulating concentrations of endotoxin in patients with meningococcemia may be 50 to 100 times that of other gram-negative infections.[155] In addition, meningococcal endotoxin is more potent than is endotoxin from enteric bacilli.[46]

A pathologic study of 200 fatal meningococcal infections[85] illustrates the ability of the meningococcus to affect virtually any organ, either directly or indirectly. Approximately 40 percent of the patients had both meningococcemia and meningitis. Except for adults with meningitis, the average survival for all patients was 72 hours or less. The major organ systems involved at autopsy in these 200 cases were the heart, central nervous system (CNS), skin, mucous and serous membranes, and adrenals. Myocarditis developed in 78 percent of cases. Cutaneous hemorrhage occurred in 69 percent of the fatal infections and ranged from isolated petechiae to diffuse purpura. Acute meningitis was noted at autopsy in 68 percent, with brain abscesses found in two patients. In almost half the patients with acute meningococcemia, *N. meningitidis* was isolated from otherwise normal cerebrospinal fluid (CSF). Adrenal hemorrhage and necrosis were found in 48 percent of autopsy cases. Diffuse adrenal hemorrhage occurred in approximately 50 percent of adult cases and in more than 80 percent of pediatric cases. Focal areas of inflammation and petechial hemorrhage were seen in many other tissues, including the synovium, skeletal muscle, and the tracheobronchial tree. An association was noted between the pathologic findings and the infecting serogroup of *N. meningitidis*. Serogroup A infections most frequently were associated with encephalitis; serogroup B and C infections were associated with necrotizing myocarditis.

CLINICAL MANIFESTATIONS AND DIFFERENTIAL DIAGNOSIS

The spectrum of disease caused by *N. meningitidis* ranges from asymptomatic transient bacteremia, which clears spontaneously, to fulminant sepsis resulting in death only a few hours after the first symptoms occur.[186] In 2006, Kaplan and colleagues (U.S. Multicenter Meningococcal Surveillance Study Group) reviewed 159 episodes of invasive meningococcal disease seen at 10 children's hospitals in the United States between January 2001 and March 2005.[101] Meningitis was the most common manifestation of disease, seen in 70 percent of cases. Twenty-seven percent of children had bacteremia alone, and 4.4 percent had fulminant disease. Fifty-five percent of the children had petechiae, and 38 percent had purpura. Hypotension was present in 10 percent and thrombocytopenia in 6 percent on admission. The overall mortality rate was 8 percent, and it was significantly higher in children who were 11 years of age or older than in children younger than 11 years ($p < 0.001$). Hearing loss occurred in 12.5 percent of children with meningitis. Skin necrosis occurred in 9.4 percent of children, and 2.4 percent required skin grafts. One percent of children underwent amputations; one child lost all four limbs. Only one penicillin-intermediate isolate was identified in this study, and no penicillin-resistant isolates were found.

MENINGOCOCCEMIA/MENINGITIS

Serious or invasive disease usually is manifested in one of two ways: meningococcemia or meningitis (either with or without meningococcemia). It is important to consider other causes in the differential diagnosis of meningococcemia (Table 99–1).

The signs and symptoms of meningococcemia are variable. Early in the course, evidence of an upper respiratory infection, including coryza, pharyngitis, tonsillitis, and laryngitis, may be present. Patients generally are febrile, with complaints of headache, lethargy, and vomiting. Severe myalgia with muscle tenderness and joint pain also may be the initial complaint.[93] The typical patient with meningococcemia has a short history of upper respiratory symptoms, fever, and a hemorrhagic rash. Signs of severe circulatory collapse often develop. It is not unusual for purpura and shock to develop within hours of the onset of symptoms.

The skin manifestations of meningococcemia range from diffuse mottling to extensive purpuric lesions (Figs. 99–1 and

Figure 99–1 Petechial lesions are seen on the face and neck of a young child with meningococcemia.

TABLE 99–1 Differential Diagnosis of Meningococcemia

INFECTIOUS
Rocky Mountain spotted fever
Ehrlichia
Streptococcal pneumoniae sepsis
Haemophilus influenzae type b sepsis
Group A *Streptococcus* sepsis
Other bacterial sepsis with disseminated intravascular coagulation (i.e., enteric gram-negatives)
Subacute bacterial endocarditis
Gonococcemia
Rat-bite fever
Typhus
Secondary syphilis
NONINFECTIOUS
Henoch-Schönlein purpura
Idiopathic thrombocytopenic purpura
Collagen vascular disease
Neoplastic processes

99–2). Unfortunately, some variation in the type of rash is seen. Petechiae or purpura is present in 50 to 60 percent of patients.[103,212] Maculopapular rash alone is reported in 10 to 13 percent of patients.[124,212] Twenty to 30 percent of children may have no rash at initial evaluation.[212] This variance renders differentiating meningococcemia from a viral exanthem particularly difficult. A pink macular rash resembling early varicella is another variant sometimes seen in children with meningococcemia; these lesions often are tender. They may occur in crops, as do petechiae, and are seen most frequently on the trunk and extremities.[55,89]

The finding of petechiae or purpura in a febrile child should increase the index of suspicion for meningococcemia or other serious disease (e.g., infectious, neoplastic, immunologic). Acral distribution of a rash, in particular, is worrisome for meningococcemia or another infectious vasculitic process. In two studies involving more than 200 patients with fever and petechiae (not purpura), 8 percent to 20.2 percent had invasive bacterial disease.[199,212] Seven to 10 percent of the total group had infections

Figure 99–2 Extensive purpuric lesions occurring in a child with overwhelming meningococcemia and disseminated intravascular coagulation.

caused by *N. meningitidis*. Therefore, obtaining blood cultures for most febrile patients with petechiae seems reasonable. Lumbar puncture should be performed if clinically indicated or if the blood culture ultimately is positive. Antibiotic therapy in these patients should include coverage for meningococcus.

Purpura is noted in 16 to 24 percent of patients.[157,168,212] When the purpura is extensive and accompanied by shock, it is referred to as *purpura fulminans*. Acquired deficiencies of protein S and protein C have been described in some patients with purpura fulminans.[157,158] One study showed a mortality rate of 50 percent in patients in whom purpura developed. Progressive purpura was accompanied by declining protein C levels, and the protein C level was related inversely to the clinical severity of the disease.[157]

Patients with meningitis often are febrile, with headache, vomiting, irritability, stiff neck, and sometimes seizures. They may have a history of lethargy, or they may be obtunded at initial evaluation. In neonates, physical findings of meningismus, such as the Kernig and Brudzinski signs, often are absent. The anterior fontanelle, if open, may be full and tense.

The most common neurologic complications of meningitis are hydrocephalus, cranial nerve palsy (especially hearing loss), subdural effusion or empyema, cerebral edema, cortical vein thrombosis, and cerebral infarction. Neurologic sequelae occur much more commonly in patients with meningitis, but complications such as cerebral infarction also can be seen in children with meningococcemia and shock.[145]

Cerebral edema and cranial nerve palsies may be seen initially or develop shortly thereafter. Sixth nerve or third nerve palsies

are suggestive of increased intracranial pressure (ICP) and impending herniation, respectively. The development of either of these signs is indicative of an urgent intracranial process. Hearing loss occurs in 5 to 10 percent of patients with meningitis. Auditory testing should be performed after recovery on all patients with meningitis.

Subdural effusion or empyema should be considered in patients with fever persisting after 8 days of therapy, vomiting, or the development of signs of increased ICP after the initial few days of treatment. Drainage is recommended only if the effusion is infected (empyema) or is large enough to produce either focal neurologic signs or increased ICP.[145]

Vascular thrombosis, cerebral infarction, or both can be caused by arterial or venous thrombosis. Venous thrombosis is more common and generally is not seen before the second week. Hemorrhagic infarction of the brain then may occur. Cerebral infarction also may be seen in patients without arterial or venous thrombosis who present in shock with prolonged hypotension and cerebral ischemia. Cerebral infarction in these individuals is an early event.

Hydrocephalus occurs most frequently in young children and those with a delayed diagnosis or severe disease. It tends to occur 3 to 4 weeks after the onset of illness. Inflammation, with collagen deposition and proliferation of fibroblasts in the meninges, produces an obstruction to the flow of CSF. A progressive increase in head circumference should alert the clinician to the possibility of hydrocephalus.[145] Imaging (computed tomography, magnetic resonance imaging) studies are diagnostic.

Neonatal meningococcemia or meningitis (or the presence of both) is an uncommon finding but has been reported. In one report, a 2-week-old infant died after having a brief febrile illness with both CSF and blood cultures positive for meningococcus. Maternal endocervical colonization was documented. In addition, the mother's pharyngeal culture grew *N. meningitidis*.[99] If endocervical colonization by *N. meningitidis* is detected prenatally, treatment with antibiotics probably should be initiated in an attempt to eradicate colonization before delivery, or intrapartum antibiotics should be given. Ceftriaxone would seem to be a reasonable choice. Rifampin and ciprofloxacin are not advocated for use during pregnancy.

CHRONIC MENINGOCOCCEMIA

Chronic meningococcemia, first described in 1902, is defined as meningococcal septicemia without meningeal symptoms in which fever has persisted for at least a week before any antibiotic therapy is initiated.[57,143] Benoit[8] reviewed 148 cases of chronic meningococcemia in the United States in 1963; patients ranged in age from 3 months to 62 years. The major symptoms included fever and chills (present in 100% of patients), rash (93.2%), arthralgias (70.3%), and headache (61.5%). The patients generally did not appear toxic and were in good health before becoming infected. The mean duration of illness before diagnosis was 6 to 8 weeks (range, 1 to 40 weeks). Symptoms tended to be intermittent; the rash often appeared in association with fever and then disappeared over the next several days. Bacteremia also was intermittent in some patients. In the Benoit study, five blood cultures were obtained for the average patient before meningococci were isolated. However, after a blood culture yielded the organism, most subsequent cultures were positive. In children, some investigators report that the organism frequently is isolated in the first blood culture.[115] The arthralgias also tended to be intermittent in nature.

In Benoit's series,[8] localizing complications developed in almost 40 percent of the patients with chronic meningococcemia. The meninges were the most common site of localization, and meningitis developed in 15.5 percent of these patients. Other localized infections included carditis, nephritis, epididymitis, conjunctivitis, iritis, and retinitis. In only one instance was an organism recovered from the joint. The average duration of meningococcemia in patients with complications was 10.2 weeks, as opposed to 4 to 8 weeks in patients without any localization.

The diagnosis is established by identifying the organism in blood cultures. Antibiotic therapy results in prompt defervescence and dramatic recovery.

The pathophysiologic mechanisms permitting chronic meningococcemia remain unclear. No evidence exists that the organisms are less virulent than other meningococci are; thus, a defect in host immunity has been suggested. A hypersensitivity basis for this disease has been postulated, and researchers have theorized that the skin changes and arthritis may be secondary to antigen-antibody complexes.[143] In contrast to acute meningococcemia, bacteria almost never are found by biopsy or culture of skin lesions. The histology of the skin lesion is distinct from that seen in skin lesions of patients with acute meningococcemia.[8,85,143]

MENINGOCOCCAL PNEUMONIA

Meningococcal pneumonia occurs in conjunction with meningococcemia or meningitis in 8 to 15 percent of cases.[106] However, the meningococcus also can play a role as a primary respiratory pathogen.

Primary meningococcal pneumonia, once considered a rare disease, now is recognized as the most common form of meningococcal disease in certain military recruit populations and has been reported to be responsible for 4.5 percent of all cases of bacterial pneumonia in a general hospital population.[106,118]

Patients with preceding viral pneumonias are at risk for the development of meningococcal pneumonia; more than 100 cases of meningococcal pneumonia occurred during the influenza pandemic of 1918 and 1919. In addition to disease among military recruits, nosocomial acquisition of meningococcal pneumonia in hospitalized patients has been reported.[38]

The diagnosis of meningococcal pneumonia is difficult to establish because isolation of the organism from sputum does not distinguish a meningococcal carrier from an individual with meningococcal pneumonia. In addition, routine sputum cultures do not include media selective for the meningococcus. Blood cultures are positive in only 15 percent.[106]

Koppes and associates[106] reported on 68 cases of meningococcal pneumonia; diagnostic criteria included a compatible clinical syndrome and isolation of *N. meningitidis* from pleural fluid or blood. All 68 meningococcal pneumonia cases were group Y; during the same period, 10 cases of meningococcemia and 6 cases of meningitis caused by group Y occurred. The high ratio of pneumonia to meningitis in this study suggested that group Y organisms may be more likely than are other serogroups to cause pneumonia, and this finding has been substantiated by other investigators.[160,170] Pneumonia caused by group B or C meningococci has been reported, usually in association with meningococcemia or meningitis.[210]

Primary meningococcal pneumonia usually is associated with a gradual onset of symptoms and a history of an antecedent upper respiratory infection. Rales and fever are found in most patients, and 80 percent have pharyngitis. The radiograph often shows involvement of the lower lobes with patchy alveolar infiltrates. More than one lobe is involved in 40 percent of these patients. Twenty-five percent of them have pleural effusions. Petechiae, purpura, or shock was not present in any of the patients with pneumonia reported by Koppes and colleagues.[106]

The pathogenesis of this disease is thought to be pulmonary infection via inhalation of droplets. The epidemiologic importance of meningococcal pneumonia was emphasized in a report

from the CDC that discussed nosocomial transmission of group Y *N. meningitidis* in oncology patients.[38] The index case had meningococcal pneumonia. Meningococcal bacteremia developed in one other patient in an adjacent room; in three additional patients, group Y *N. meningitidis* was isolated from nasopharyngeal cultures. Airborne dissemination seemed to be the mode of transmission. Respiratory isolation is indicated for a patient with suspected meningococcal pneumonia.

Penicillin therapy for penicillin-sensitive meningococcal pneumonia results in a prompt clinical response. Ninety-three percent of the patients reported by Koppes and colleagues[106] were afebrile after 3 days of therapy. Third-generation cephalosporins, such as ceftriaxone and cefotaxime, may be the current drugs of choice pending definitive identification.

OTHER MENINGOCOCCAL SYNDROMES

Conjunctivitis

Primary meningococcal conjunctivitis is indistinguishable clinically from acute bacterial conjunctivitis caused by other organisms. Usually, it is manifested in children as an acute onset of unilateral purulent conjunctivitis.[7] It has been reported in individuals aged 2 days to adulthood.[8] Gram stain of the purulent material typically shows gram-negative diplococci that sometimes may be confused with gonococcal conjunctivitis. Barquet and colleagues[7] showed that 44 percent of the isolates were serogroup B meningococci.

The complications of primary meningococcal conjunctivitis reported by Barquet and associates[7] included sepsis or meningitis in approximately 18 percent. The symptoms of systemic meningococcal disease occurred 3 to 96 hours after onset of the conjunctivitis (mean, 41 hours). In patients treated only with topical therapy when initially evaluated for conjunctivitis, systemic disease was 19 times more likely to develop than in patients treated with systemic therapy ($p = 0.001$). Ocular complications occurred in 15.5 percent of patients and included corneal ulcers (10.7%), keratitis, hemorrhage, and iritis.

Pharyngitis

The diagnosis of meningococcal pharyngitis is difficult to establish because, like group A beta-hemolytic streptococci, isolation of meningococcus from the pharynx does not establish that this organism is the etiologic agent. In fact, most individuals who harbor meningococci in their nasopharynx are asymptomatic carriers. However, Banks[5] noted overt nasopharyngitis in a third of patients with meningococcal sepsis or meningitis. Pizzi,[153] in describing a severe epidemic of meningococcal meningitis, noted that individuals with sore throats often had a pure culture of meningococci. Olcen and associates[144] performed cultures on family members of 21 consecutive patients with meningococcal disease and found that 61 percent of family members with a sore throat or other upper respiratory symptoms were meningococcal carriers, as opposed to 14 percent of asymptomatic family members.

On occasion, individuals in the community with symptomatic pharyngitis have cultures performed and the laboratory reports the growth of *N. meningitidis*. If the patient is febrile but otherwise appears well, we recommend obtaining blood for culture and administering intramuscular or intravenous ceftriaxone. If the blood culture is negative, the patient should be treated with an antibiotic that will eradicate the meningococcus (see "Chemoprophylaxis"). If the patient is afebrile and asymptomatic at the time that the culture results are obtained, we recommend eradication of the organism with one of the antibiotics suggested for chemoprophylaxis.

Arthritis

Meningococcal arthritis occurs primarily in adults. The overall incidence, as a complication of bacteremia, is approximately 2 to 14 percent.[81,212] There are two forms of meningococcal arthritis. The first is seen within the first few days of treatment and is characterized by severe arthralgias and few objective signs of joint inflammation. The pathogenesis of this arthritis has been suggested to be an inflammatory response to viable organisms that have seeded the synovium during the initial bacteremia. The second, more common form appears to be an immune complex phenomenon. It usually is noted 3 to 7 days after recognition of meningococcemia, often at a time when the patient appears to be improving from the meningitis or sepsis. The knee, wrist, elbow, and ankle joints are involved most commonly.[81]

In both forms, the arthritis usually is monarticular or oligoarticular with an effusion, minimal pain, erythema, and limitation of motion. Organisms seldom are cultured from the effusion; culture of joint fluid yields meningococci in less than 10 percent of cases. The exception is a child with suppurative arthritis on initial evaluation. In one study, 8 percent of patients with meningococcal infection had arthritis; 75 percent were culture-positive when culture was performed before receiving antibiotics.[210,212]

Synovial fluid leukocyte counts vary widely, but counts greater than 100,000/mm^3 have been reported.[151] The appearance of arthritis often is accompanied by a rise in temperature; in 7 of 47 patients with arthritis, a characteristic skin lesion appeared at the same time.[82] These lesions began as skin hyperpigmentation but progressed to vesiculation and ulceration; biopsy showed vasculitis. Additional evidence of concurrent vasculitis is suggested by reports of episcleritis and mild proteinuria developing simultaneously with arthritis.[82]

On histologic examination, the synovium is infiltrated by mononuclear cells that contain IgM, C3, and meningococcal antigen,[82] which strongly suggests an immune complex–mediated disease. No specific therapy is indicated, and the arthritis resolves spontaneously. Controversy exists regarding the role of intermittent closed drainage of the joint space.[13] Permanent joint deformity is an uncommon feature of this disease that occurs in approximately 10 percent of cases.[175] Edwards and Baker[58] reported allergic complications of meningococcal disease in 10 percent of the 86 children monitored prospectively. More than 83 percent were serogroup B, although late-onset arthritis and vasculitis also have been reported with serogroup A and C disease.

Permanent joint damage is an unusual event that occurs in approximately 1.5 percent of patients with arthritis. Potential sequelae include ankylosis, decreased range of motion, and bone necrosis.[113]

Pericarditis and Myocarditis

Pericarditis occurs in 3 to 5 percent of cases as a complication of meningococcal disease, although one series reported a 19 percent incidence in 32 patients with meningococcal meningitis.[56,135] It generally occurs in patients with meningococcemia but has been reported as an isolated event without septicemia or meningitis.[88]

Pericarditis is presumed to be a late complication of meningococcal disease because clinical symptoms such as fever, dyspnea, or substernal chest pain (or even cardiac tamponade) usually do not appear until the fourth to seventh day of illness. However, several investigators have noted early evidence of pericarditis based on the electrocardiographic or roentgenographic data of patients examined at the time of hospital admission.

Because most symptomatic pericardial effusions develop late in the course of the illness, are serous in nature, and are sterile, the pathophysiologic mechanism is presumed to be an immune

complex reaction. Uncontrolled studies report the successful use of steroids for the treatment of this complication.[101] However, one report documented pericarditis and the development of tamponade in a patient receiving steroids.[147]

The clinical course of meningococcal pericarditis usually is benign, but pericardial compression requiring pericardiocentesis can occur.[147] Early relapses also have been reported, but they were self-limited. Cases of constrictive pericarditis requiring pericardectomy have been reported.[147,177,204]

Myocarditis was noted at autopsy in 78 percent of patients with fatal meningococcal disease.[85] Myocarditis was seen most often in adults but was more severe when it occurred in children. Rosenblatt and colleagues[168] noted myocarditis at autopsy in 10 of 12 children with fatal meningococcal infection. Pathologic examination revealed collections of inflammatory cells in the myocardial interstitium and focal extravasation of erythrocytes with acute vasculitis. Abscesses and endocarditis were not seen. Inflammation occasionally may involve the atrioventricular node and has been reported as a cause of sudden death in a patient recovering from meningococcal meningitis.[166]

Miscellaneous Meningococcal Infections

Several unusual syndromes, including primary meningococcal pericarditis,[199] mesenteric adenitis,[109] peritonitis,[109] and genitourinary infections, have been reported.[63]

LABORATORY FINDINGS AND DIAGNOSIS

Wong and colleagues[212] reviewed 100 cases of meningococcal infection in children seen at their institution between 1985 and 1988. Leukopenia (white blood cell count <5000/mm^3) was present in 21 percent, and thrombocytopenia was noted in 14 percent. Fifty-five percent of patients had meningitis. Eleven percent of those with culture-positive meningitis had no CSF abnormalities detected on chemistry panels or examination.

Hyponatremia is seen in some patients with meningitis. Inappropriate secretion of antidiuretic hormone is the mechanism. In one study of 43 children with meningococcal meningitis, the syndrome of inappropriate secretion of antidiuretic hormone developed in 7 percent.[60]

Other laboratory abnormalities seen in patients with sepsis or shock include abnormal coagulation panels (DIC), acidosis, and abnormal liver function studies.

The gold standard for diagnosis is based on recovering the organism from blood, CSF, or petechiae. Blood culture alone is positive approximately 50 percent of the time in patients who have not received antibiotics.[212] Rapid diagnosis often can be made by Gram stain of CSF in patients with meningitis. Characteristic gram-negative diplococci are seen. Caution should be exercised in relying solely on the Gram stain to determine initial antibiotics. Broad-spectrum antibiotic therapy should be initiated pending identification of the organism by culture. Overdecolorized gram-positive cocci of *Streptococcus pneumoniae*, on occasion, have been confused with meningococci on Gram stain.

In patients who have skin lesions, a rapid presumptive diagnosis of meningococcemia frequently can be made by needle aspiration and Gram stain of a skin lesion. Needle aspiration yields gram-negative diplococci on the Gram-stained specimen in approximately 50 percent of patients with acute meningococcal infections.[197] Culture of the aspirate increases the yield further. Correlation of the Gram stain with clinical findings is important because disseminated gonococcal infection also may be accompanied by skin lesions that yield gram-negative diplococci on Gram stain.

Counterimmunoelectrophoresis and latex agglutination have been used to detect circulating antigen in the serum, CSF, and urine of patients with meningococcal disease.[207] Latex agglutinin tests using serum and urine are not recommended.[2] Cross-reactions with certain *E. coli* K1 (cause of neonatal meningitis) or *Bacillus* strains may occur. Latex agglutinin tests using CSF may be helpful in patients pretreated with antibiotics and with a compatible clinical syndrome.[2] These tests are of particular benefit in cases of partially treated meningococcal meningitis, in which culture and Gram stain may be negative.

Polymerase chain reaction (PCR), one of the newer tests for detection of *N. meningitidis*, may be very helpful in establishing the diagnosis in patients with partially treated meningococcemia or meningitis. Once antibiotics have been given, the chance that a blood culture will be positive decreases to less than 5 percent.[25] One study showed the sensitivity and specificity of PCR for *N. meningitidis* to be 91 percent with CSF specimens. Treatment with antibiotics before the test did not decrease the test's sensitivity or specificity.[140] Use of this test in confirming meningococcal infections in patients pretreated with antibiotics may be valuable in subsequent patient management, follow-up, and prompt institution of chemoprophylaxis in contacts. One report from the United Kingdom describes the use of a multiplex PCR assay for the simultaneous detection of *N. meningitidis*, *Haemophilus influenzae*, and *S. pneumoniae* from clinical samples of CSF and whole blood. Corless and colleagues[41] found that sensitivity for detection of the three organisms ranged from 88.4 percent to 91.8 percent with 100 percent specificity. Commercially available assays such as this would greatly facilitate establishing the etiologic diagnosis in children with sepsis or meningitis. Currently, meningococcal PCR is in use in the United Kingdom, but it is available in the United States only as a research test.

MORTALITY AND PROGNOSIS

The overall mortality associated with invasive meningococcal disease in the United States is 7 to 19 percent.[101,142,169,184] Numerous different scoring systems have been devised in an attempt to predict prognosis in patients with meningococcal disease. These scoring systems were reviewed in an article by Kirsch and colleagues.[105]

The Glasgow Meningococcal Septicaemia Prognostic Score (GMSPS) is a validated scoring system developed to assess clinically patients and facilitate admission of the most severely ill children to intensive care units.[178,189] This scoring system, which evaluates seven key items (hypotension, difference in skin core temperature, coma, acute deterioration, absence of meningismus, progressive purpura, and base deficit), has been used by many investigators to define criteria for entry into clinical trials.

In a review of 100 cases of meningococcal disease at the Los Angeles Children's Hospital, five features were identified that correlated with poor prognosis: shock or seizures on initial evaluation, hypothermia, total white blood cell count less than 5000/mm^3, platelet count less than 100,000/mm^3, and the development of purpura fulminans. The overall mortality in this series was 10 percent.[212]

Most prognostic scoring systems and clinical reviews agree that purpura fulminans and shock uniformly are poor prognostic signs. Individuals with only meningitis have a case-fatality rate lower than that of those with bacteremia or an isolate from another source (2% vs. 12%).[169] Presumably, this is a function of virulence of the organism, ability of the immune system to contain the infection, or both. Case-fatality rates also differ by serogroup and are higher in W-135 disease (21%) than in serogroups C (14%), Y (9%), or B (6%).[169]

Evidence suggests that a genetic component of host cytokine production may be associated with the severity of disease. Westendorp and coworkers[206] reported that families with low TNF production or high IL-10 production are at increased risk for

having fatal outcomes of meningococcal disease. Recently, investigators have been studying variants of proinflammatory host genes (TNF-α, IL-1) to see whether polymorphisms in these genes might be linked to the severity of disease. Read and associates[163] found that homozygosis of certain alleles at the IL-1 locus increased the risk of death occurring in individuals with meningococcal disease and suggested that the IL-1 genotype may be associated with fatal outcomes.

TREATMENT

Therapy for meningococcal disease has evolved during the last century. In the early 1900s, treatment consisted of the administration of intravenous and intrathecal horse serum and CSF drainage. The mortality rate associated with this therapy was 26 percent.[89] The use of sulfonamides lowered the death rate to 5 or 10 percent.[83] With the emergence of sulfa-resistant strains, penicillin was added to the regimen and still may be used for susceptible meningococcal infections. In the late 1980s, reports began to appear of meningococci relatively resistant to penicillin. The mechanism of resistance is reduced binding affinity of penicillin-binding proteins. Relatively resistant strains have been reported in the United States, Canada, Europe, South Africa, Romania, and Croatia.[16,97,148,187,213] Isolates that are absolutely resistant to penicillin (minimal inhibitory concentration >1.0 μg/mL) have been documented from Spain and the United Kingdom.[148,187] Strains with resistance to fluoroquinolones also have been reported on rare occasion.[42,122] Non–ceftriaxone-susceptible strains have been reported from India.[122] Routine susceptibility testing of meningococcal strains is not currently recommended.

Genotypic and phenotypic studies of penicillin-resistant isolates from Spain revealed that the strains were genetically diverse and did not arise from a single clone.[215] In addition, Mendelman and colleagues[126] demonstrated that these strains have a penicillin-binding protein (PBP-3) with less penicillin-binding capacity than seen in sensitive strains. These strains appear to have arisen by the acquisition of segments of genes (by transformation) from the naturally resistant *Neisseria* commensals *N. flavescens* and *N. lactamica*.[180] The gene encoding PBP-2, *penA* in commensal *Neisseria*, encodes a protein that has less avidity for penicillin G. Transformation of *N. meningitidis* with *penA* from these strains leads to a slight decrease in penicillin G susceptibility; repeated transformation will yield a penicillin-resistant strain.

In 1988, penicillin-resistant meningococci also were reported from South Africa and the United Kingdom; these strains had acquired a gonococcal plasmid encoding for the production of β-lactamase.[187]

Prompt institution of antibiotic therapy for suspected meningococcal infection may be lifesaving. Children with fever and purpura should be considered to have meningococcemia until proved otherwise while recognizing that other pathogens may cause fever and purpura. A purpura fulminans–like manifestation also has been reported rarely to be caused by *Staphylococcus aureus*,[108] group A *Streptococcus*,[54] group B *Streptococcus*, and overt sepsis, with other organisms causing DIC. Antibiotics should be administered as soon as possible. A systematic review of the effectiveness of antibiotics given before admission concluded that "the data are consistent with benefit when a substantial proportion of cases are treated."[84] If possible, blood should be drawn for culture before antibiotics are administered, but collection of specimens should not delay such administration. A lumbar puncture can be performed in stable patients, but the procedure also should not delay the administration of antibiotics. CSF obtained after antibiotic therapy has been administered may be sterile, but pleocytosis will be apparent. In patients who are unstable or have significant coagulopathy, lumbar puncture should be deferred. Shortly after receiving bactericidal antibiotics, some patients exhibit marked clinical deterioration, including hypotension and sometimes death. Rapid liberation of endotoxin (and resultant stimulation of cytokine release) from lysing organisms may be the cause of this phenomenon.[125]

The clinical features of *N. meningitidis* meningitis may be similar to those of meningitis caused by *S. pneumoniae* or *H. influenzae*. Empiric antibiotic therapy should, therefore, take into consideration the most likely pathogens. In children older than 1 month with meningitis, vancomycin plus cefotaxime (or vancomycin plus ceftriaxone) is an appropriate regimen until a definitive diagnosis has been established. Similarly, empiric therapy for children younger than 1 month includes ampicillin and cefotaxime, with consideration given to the addition of vancomycin.[171]

For penicillin-susceptible meningococcemia or meningitis, intravenous penicillin G, 250,000 to 300,000 U/kg/day (maximum, 12 million U/day) given in divided doses every 4 to 6 hours for 7 days, is effective.[2] Third-generation cephalosporins, ceftriaxone (100 mg/kg/day intravenously in two divided doses) or cefotaxime (200 mg/kg/day intravenously in three or four divided doses), also are effective. Cefotaxime or ceftriaxone is recommended for travelers from Spain, Italy, and parts of Africa because of reports of penicillin resistance in these areas.[2]

In confirmed cases of meningococcal disease, comparisons of penicillin G with ceftriaxone have shown ceftriaxone to be as efficacious. Necrotic skin lesions were seen more commonly in the penicillin group, but otherwise, complication and mortality rates were equivalent.[193] Meningococcal disease has been treated successfully with ceftriaxone intravenously in both once-a-day (80 to 100 mg/kg/day) and twice-a-day (100 mg/kg/day in two divided doses) dosing regimens.[193] Chloramphenicol is an alternative for penicillin-allergic patients. Currently, routine susceptibility testing of meningococcal isolates is not recommended. However, in selected cases in which the patient is not responding as expected, susceptibility testing may be warranted. With all cases of meningococcal disease, eradicating colonization of the index case is important (see "Chemoprophylaxis").

Administration of steroids to patients with septic shock and meningococcemia is controversial, but several studies have reported adrenal insufficiency (or partial adrenal insufficiency) in 10.3 to 16.9 percent of severely ill children with meningococcemia.[15,48,50,165] In those patients with Waterhouse-Friderichsen syndrome, treatment with steroids is indicated. However, treatment of meningococcal meningitis with steroids has been debated in the literature for years. Steroid proponents point to *H. influenzae* type b meningitis and *S. pneumoniae* studies, in which treatment with steroids decreases hearing loss and may reduce neurologic sequelae. They postulate that steroids, through anti-inflammatory effects, may decrease polymorphonuclear neutrophils, macrophages, and cytokines in the CNS and thus decrease CNS immune-mediated damage and hearing loss. Steroid opponents say that no conclusive studies show steroids to be of benefit in meningococcal meningitis and that risks include gastrointestinal ulceration, decreased penetration of antibiotics into the CNS (because of decreased meningeal inflammation), and steroid psychosis. If steroids are used, it seems prudent to administer them early (preferably close to the time that the first dose of antibiotics is administered). However, antibiotics should never be withheld while waiting for steroids to be given.

EXPERIMENTAL/ADJUNCTIVE THERAPIES

Many adjunctive and experimental therapies have been tried or are being evaluated presently. Anti-endotoxin therapies and infusion of protein C concentrate are the most recent additions (Table 99–2). Two anti-endotoxin therapies have been evaluated

TABLE 99–2 Recent Studies of Alternative Therapies for Severe Meningococcemia or Sepsis Syndrome

Year	Study	Authors	Randomized/Placebo Controlled	Eligible Patients	Patient Number (*N*)	Results
1997	Activated protein C	Smith, White, Vaughan, et al.[179]	No/No	3 months to 27 years old, severe meningococcemia with septic shock and purpura fulminans	12	0 deaths, 2 patients with amputations. Favorable results in comparison to the historical mortality rate of 50% in patients with shock, purpura fulminans, and Glasgow meningococcal septicemic prognostic score indicating an expected mortality of >80%
1999	HA-1A	Derkx, Wittes, and McCloskey[52]	Yes/Yes	3 months to 18 years old, petechiae or purpura, hypotension, toxicity, or end-organ dysfunction	269	No statistically significant reduction in 28-day mortality demonstrated. Mortality rate with HA-1A, 18%; with placebo, 28% ($p = 0.11$)
2000*	rBPI	Levin, Quint, Goldstein, et al.[116]	Yes/Yes	2 weeks to 18 years, petechiae or purpura, and severe disease	393	No statistically significant reduction in mortality (7.4% with rBPI, 9.9% with placebo). The treatment group had fewer amputations and a trend toward improved outcomes
2001†	Activated protein C	Bernard, Vincent, Laterre, et al.[9]	Yes/Yes	Severe sepsis (any organism, known or suspected) with organ dysfunction	1690	Significant reduction in mortality (30.8% with placebo versus 24.7% in the treatment group) and increased risk of bleeding in the treatment group
2005‡	Activated protein C	Nadel, Goldstein, Williams, et al.[137]	Yes/Yes	Pediatric patients with severe sepsis	477	Study stopped after review by Data Safety and Monitoring Committee. No difference in mortality or time to resolution of complete organ failure

**Fifty-seven patients died before receiving drug or placebo (after randomization) and were not included in this analysis.*
†This study enrolled adults with severe clinical sepsis (meningococcemia not a criterion for entrance).
‡This study enrolled pediatric patients with severe clinical sepsis of all types.
rBPI, recombinant bactericidal/permeability increasing protein.

in clinical trials: HA-1A and recombinant bactericidal/permeability increasing protein (rBPI). HA-1A, a human monoclonal antibody to endotoxin, was evaluated in a randomized, double-blind, placebo-controlled trial in 269 children with severe meningococcemia. Although the 28-day mortality rate in the treatment group was 18 percent as compared with 28 percent in the placebo group, this difference was not statistically significant ($p = 0.11$).[52] BPI is a naturally occurring protein in neutrophil azurophilic granules. BPI binds to and neutralizes the effects of endotoxin. Administration of rBPI was studied in 393 children with presumed meningococcal disease. There was no difference in mortality rates (7.4% with rBPI versus 9.9% with placebo). A trend in reduction of amputations in the treatment group that approached statistical significance ($p = 0.067$) was noted.[116]

Infusions of recombinant protein C concentrate have been studied in adults in a large randomized, placebo-controlled trial of 1690 patients with severe sepsis. A reduction in the mortality rate was demonstrated, but the treatment group had an increased risk of bleeding.[9] Smith and colleagues[179] compared 12 children with severe meningococcemia and purpura fulminans treated with protein C concentrate and historical controls. No deaths occurred in the treated patients versus a 50 percent rate in historical controls. A large study published in 2007 compared activated protein C with placebo in children with presumed meningococcal infection. The study was terminated by the Data and Safety Monitoring Board because of a low likelihood of improved outcome in the treatment group.

Additional supportive measures such as prophylactic low-dose heparin are used by some clinicians.[208] Many investigators have studied the effect of heparin on survival and DIC in patients with meningococcemia, but no consistent beneficial effect on these parameters has been noted. Serious side effects directly attributed to heparin therapy have been reported rarely.[73] Difficulty adjusting the dose in small infants may lead to heparin intoxication. A retrospective chart review of 24 patients with purpura fulminans showed less necrosis of the digits and extremities in patients treated with heparin, but the results were not statistically significant.[110]

Many other experimental therapies have been attempted in patients with fulminant meningococcemia. Anecdotal reports or small case series describe the use of tissue plasminogen activator,[1,136] antithrombin III infusion,[37] topical nitroglycerin,[94,129] plasmapheresis,[36] and extracorporeal membrane oxygenation.[112] Continuous caudal block has been used to restore lower extremity perfusion.[190] Evidence is insufficient to state that any of these therapies has a significant impact on outcomes in meningococcal disease. Larger, multicenter studies are needed to evaluate efficacy.

CHEMOPROPHYLAXIS

The ability of *N. meningitidis* to spread from person to person and cause epidemic disease has been recognized since the 1800s. The secondary attack rate in households with an index case is approximately 1000 times the attack rate in the general population.[3,181] Household crowding and young age are factors that increase the secondary attack rate. The mode of transmission is direct contact with respiratory droplets or secretions. For these reasons, chemoprophylaxis is recommended for household contacts of an index case and for young daycare center contacts. Persons who have had significant contact with the oral secretions of an index case also should be considered for prophylaxis. Several epidemiologic studies suggest that casual acquaintances (such as school-aged classmates) are not at increased risk, although a number of authors have reported secondary cases in this population.[98,100] Prophylaxis is indicated for health care workers who have had intimate exposure to nasopharyngeal secretions (e.g., mouth-to-mouth resuscitation).[74] The period of communicability of the index patient is not well established. Most public health authorities recommend that persons in contact with the patient up to 7 days before the onset of illness be considered for prophylaxis. Prophylaxis should be instituted as soon as possible after identification of the index case. It is not necessary to wait for laboratory confirmation of a case if the clinical picture is most consistent with meningococcal infection. Nasopharyngeal cultures are not recommended because many nonpathogenic *Neisseria* spp. may colonize the nasopharynx.

The index patient should receive chemoprophylaxis before being discharged unless the patient has been treated with ceftriaxone (or cefotaxime). Bilukha and Rosenstein[9] reported that 4 of 14 (29%) patients with meningococcal infection treated with intravenous penicillin had positive cultures of the respiratory tract 1 week after completion of therapy.

Secondary cases originally were defined as cases occurring more than 24 but fewer than 31 days after onset in the index case. According to this definition, approximately 50 percent of secondary cases will develop in the first 7 days after occurrence in the index case. Prophylaxis must be initiated as soon as possible based on clinical findings in the index case (e.g., fulminant meningococcemia) or on laboratory culture data if the infection is manifested as bacterial meningitis, septic arthritis, or other disease.

The original drug used for chemoprophylaxis was sulfadiazine. However, a large percentage of strains now are resistant to sulfa. Table 99–3 lists four antibiotics that are highly effective in eradicating meningococcus from the nasopharynx. Rifampin generally is the drug of choice for chemoprophylaxis of children. It usually is tolerated well but has a number of side effects, including orange urine and sweat, orange staining of contact lenses, and stimulation of liver microsomal enzymes leading to a reduction in levels of other concurrent medications (e.g., oral contraceptives, anticoagulants, digoxin, phenytoin). The development of resistant strains has been reported rarely.[40] Ciprofloxacin, ceftriaxone, and rifampin have been evaluated in a randomized, comparative study.[43] All three drugs were highly effective in eradicating carriage. Ceftriaxone probably is the drug of choice for a pregnant contact and also may be indicated for children because a single intramuscular injection may result in greater compliance than do four doses of rifampin. Ciprofloxacin is contraindicated in individuals younger than 18 years old because of evidence of cartilage damage in juvenile beagles. Three cases of fluoroquinolone-resistant *N. meningitidis* disease were recently reported in North Dakota and Minnesota.[35a] Azithromycin was studied in a randomized, controlled trial that compared 500 mg of azithromycin given once orally with rifampin, 600 mg given twice daily orally for 2 days. Carriage was eradicated in 56 of 60 (93%) colonized adults treated with azithromycin versus 95 percent of the 59 colonized adults treated with rifampin.[76]

TABLE 99–3 Chemoprophylaxis Regimens for Eradication of *Neisseria meningitidis*

Drug	Age	Dose/Duration
Rifampin*	Children <1 month	5 mg/kg per dose PO bid for 2 days (4 doses)
	Children ≥1 month	10 mg/kg per dose PO bid for 2 days (4 doses)
	Adults	600 mg PO bid for 2 days (4 doses)
Ceftriaxone	Children <15 years	125 mg IM, single dose
	Children >15 years	250 mg IM, single dose
	Adults	250 mg IM, single dose
Ciprofloxacin†	Children	Not recommended
	Adults	500 mg PO, single dose
Azithromycin‡	Adults	500 mg PO, single dose (only studied in adults)

**Rifampin is not recommended for pregnant women (teratogenicity in laboratory animals). The reliability of oral contraceptives may be affected by rifampin therapy; therefore, alternative contraceptive measures should be used during and for the month after rifampin administration.*

†Ciprofloxacin is not recommended for children, pregnant women, or lactating women. Three cases of fluoroquinolone-resistant N. meningitidis disease were reported in North Dakota and Minnesota. The CDC recommends the use of an alternative agent for chemoprophylaxis in affected counties.[35a]

‡Azithromycin is not currently listed in the Centers for Disease Control and Prevention's recommendations for prophylaxis.

As mentioned in the section on meningococcal vaccines, secondary disease also can be prevented by immunization of contacts. We recommend both immunization and chemoprophylaxis whenever possible (realizing that no protection against group B meningococci currently is provided by immunization).

The single most important element of chemoprophylaxis is education of contacts regarding the need for immediate medical attention if signs or symptoms of a febrile illness develop. No prophylactic strategy is 100 percent effective, and ill contacts should be evaluated medically with maintenance of a high suspicion for meningococcal disease.

MENINGOCOCCAL VACCINES

Primary prevention of meningococcal disease is essential for several reasons. The manifestation may be fulminant, with no opportunity for antibiotics to influence the course of the disease. Antibiotic-resistant strains now are recognized, and chemoprophylaxis of contacts is a cumbersome and often ineffective public health measure. Mass immunization offers the opportunity to prevent both endemic and epidemic disease worldwide.

Two vaccines, meningococcal polysaccharide vaccine and meningococcal conjugate vaccine, currently are licensed for prevention of meningococcal disease in the United States. Both vaccines are quadrivalent and contain antigens from serogroups A, C, Y, and W-135.

MENINGOCOCCAL POLYSACCHARIDE VACCINE

Meningococcal polysaccharide vaccine (MPSV4, Menomune) is a capsular polysaccharide vaccine licensed for use in individuals older than 2 years who are at increased risk for acquiring meningococcal disease. This vaccine was licensed in 1981 and has been the only meningococcal vaccine widely available in the United States until the licensing of meningococcal conjugate vaccine. MPSV4 has several limitations. First, children younger than 2 years old do not develop high levels of antibody to most pure polysaccharide antigens, so MPSV4 vaccination in young

children is not reliably protective. Second, like other polysaccharide antigen–based vaccines, MPSV4 is unable to stimulate T-cell–dependent immunity to produce memory cells. Third, repeated boosting with MPSV4 has resulted in blunting of the antibody response, termed *hyporesponsiveness*.[17,120] Finally, meningococcal polysaccharide vaccines do not substantially decrease nasopharyngeal carriage. For these reasons, although MSPV4 remains licensed and available, most experts agree that meningococcal conjugate vaccines have significant advantages in indicated groups. MSPV4 is given subcutaneously as a single dose.

MENINGOCOCCAL CONJUGATE VACCINES

Meningococcal conjugate vaccines have been developed via technology similar to that used for the highly effective pneumococcal conjugate and *H. influenza*e type b conjugate vaccines. This technology couples polysaccharide antigens to a protein carrier. The United Kingdom has developed a monovalent serogroup C conjugate vaccine, and the U.S. vaccine is quadrivalent.

MENINGOCOCCAL CONJUGATE VACCINE IN THE UNITED KINGDOM. Meningococcal C conjugate vaccination in the United Kingdom has demonstrated efficacy,[161,191] ability to produce herd immunity (67% disease reduction in unvaccinated 1- to 17-year-olds),[162] and a 66 percent reduction in adolescent nasopharyngeal carriage. These studies and the dramatic reduction of disease in the United Kingdom after rollout of a comprehensive meningococcal vaccine program in children bolstered hopes that the MCV4 vaccine would have similar results.

MENINGOCOCCAL CONJUGATE VACCINE IN THE UNITED STATES. A meningococcal conjugate vaccine (MCV4, Menactra) was licensed by the U.S. Food and Drug Administration in 2005 for use in persons aged 11 to 55 years. This vaccine is a conjugate vaccine that couples polysaccharide capsular antigens (serogroups A, C, Y, W-135) to a diphtheria toxoid protein carrier. Protein conjugate vaccines stimulate both B- and T-cell–dependent immunity. The T-cell response leads to a good amnestic response.

The safety and immunogenicity of MCV4 were evaluated in adolescents and adults by several studies. In the United States, adolescent and adult immunogenicity studies comparing MCV4 and MPSV4 demonstrated no difference in the number of subjects (80%) achieving a fourfold rise in serum bactericidal antibody for all four serogroups.[104] Efficacy was inferred by demonstration of the development of serum bactericidal antibodies to each of the A, C, Y, and W-135 antigens at a level that was not inferior to the response generated by the polysaccharide vaccine (MPSV4).

The safety of MCV4 was evaluated before licensure in six clinical studies and included more than 7500 MCV4 vaccine participants and more than 3000 MPSV4 recipients. In general, the overall safety profile is similar to that of MPSV4. Local reactions occurred more commonly in the MCV4 group in both adolescents and adults; most reactions were graded as mild. The frequency of local reactions after MCV4 was similar to that reported after vaccination with tetanus and diphtheria toxoids (Td).[10,68] Some systemic symptoms (fever, headache, arthralgia, fatigue) were slightly more common in the MCV4 group than in the MPSV4 group, and most were mild in severity.

Close monitoring for potential adverse events has suggested a possible association between recent meningococcal conjugate vaccine receipt and Guillain-Barré syndrome (GBS). As of March 2007, 17 cases of GBS with onset occurring 2 to 33 days after administration of the vaccine have been reported through the Vaccine Adverse Event Reporting System since licensure of MCV4 in June 2005.[34] Researchers calculated the rate of GBS after MCV4 administration to be 0.20 per 100,000 person-months as compared with a background incidence rate of 0.11 per 100,000 person-months.[47] This study suggests that there *may* be a slightly higher risk of GBS developing in MCV4 recipients than in the general population. Because GBS is such a rare event, this association is difficult to study. The Advisory Committee for Immunization Practices (ACIP) and the American Academy of Pediatrics continue to recommend MCV4 because if the risk does exist, it is small. The observation that GBS has been reported rarely after meningococcal conjugate vaccine has been added to the Vaccine Information Statement for this vaccine.

Concomitant administration of Td and MCV4 produced similar frequencies of adverse events as did sequential administration (in which Td and MCV4 were separated by 28 days). Concomitant administration of Td and MCV4 did not result in decreased antibody titers of diphtheria, tetanus, or the meningococcal antibody responses. However, bactericidal antibody titers for serogroups C, Y, and W-135 were higher when MCV4 and Td were administered concomitantly versus sequentially (MCV4 given 28 days after Td). The clinical significance of this finding is unknown.[174] Diphtheria antibody titers were observed to be higher with concomitant administration of Td and MCV4 than with sequential administration. The clinical significance of this finding also is unknown.[174]

Meningococcal conjugate vaccine is administered intramuscularly (as opposed to MPSV4, which is administered subcutaneously). Since MCV4 has been licensed, there have been numerous reports of misadministration of it. The CDC studied 100 such cases and found that misadministration of MCV4 by the subcutaneous route still resulted in a protective immune response. Although this route of administration is not recommended for MCV4, persons who received the vaccine by this route do not need to be revaccinated.[33]

The duration of protection afforded by MCV4 is unknown. However, a study in adolescents compared persistence of serum bactericidal antibody for each of the four vaccine serogroups 3 years after vaccination with MPSV4 versus MCV4. MCV4 was associated with greater persistence of antibody titers to serogroups C and W-135 at 3 years than MSP4 was.[202]

Meningococcal conjugate vaccine studies are currently being conducted and analyzed in younger children. A U.S. study of the immunogenicity and safety of MCV4 in 2- to 10-year-old children showed higher seroconversion and antibody titers against all four vaccine serogroups in MCV4 recipients than in MPSV4 recipients ($p < 0.001$).[149] A follow-up study of these children at 23 to 36 months after receipt of MCV4 showed persistence of antibody activity, and a booster response was demonstrated by exposure to meningococcal polysaccharide antigens (small amount of MPSV4).[150]

RECOMMENDATIONS FOR USE OF MENINGOCOCCAL VACCINES

Table 99–4 summarizes recommendations of the ACIP for the use of vaccines to prevent meningococcal disease. Meningococcal vaccine is recommended for all U.S. children (who have not previously received it) at the 11- to 12-year-old pre-adolescent visit, with catch-up immunization of all older teens who have not received vaccine yet. The ACIP recommends that MCV4 be used as the preferred vaccine, but MPSV4 is an alternative.[10]

Entering college students who will be living in dormitories are at increased risk for acquiring meningococcal disease and should receive a dose of MCV4 if they have not been immunized previously (MCV4 preferred, MPSV4 is an alternative).[22] Other persons at increased risk for acquiring meningococcal disease and recommendations for vaccination are listed in Table 99–4.

TABLE 99–4 Current Recommendations for Meningococcal Vaccines in the U.S.

Age Group (Yr)	Recommendations for Healthy Persons	Recommendations for "At Risk Persons"*
0 to <2	No meningococcal vaccines are licensed in the U.S. for this age group. Phase III clinical trials of conjugate vaccines in progress.	No meningococcal vaccines are licensed in the U.S. for this age group.
2-10	Not routinely recommended	MCV4 intramuscularly† (preferred product) *or* MPSV4 subcutaneously†
11-18	Routine administration at 11-12 years recommended (catch up vaccination for older teens that have not previously been vaccinated): MCV4 intramuscularly (preferred product) or MPSV4 subcutaneously	MCV4 intramuscularly† (preferred product) *or* MPSV4 subcutaneously†
19-55	Not routinely recommended	MCV4 intramuscularly† (preferred product) *or* MPSV4 subcutaneously†

MCV4, meningococcal conjugate vaccine; MPSV4, meningococcal polysaccharide vaccine.

**"At risk persons" include: individuals with functional or anatomic asplenia, complement or properidin deficiency, travelers to areas where meningococcal disease is epidemic or hyperendemic, military recruits, college freshmen living in dormitories, persons infected with HIV, and military recruits.*

†*MCV4 is licensed for a single dose. Second doses of MCV4 are not currently recommended (studies pending). Persons who previously received MPSV4 and who continue to be "at risk"* for meningococcal disease should receive a single dose of MCV4 three years after prior MPSV4 administration.*

Persons 2 to 55 years of age who are at continued increased risk for acquiring meningococcal disease and previously have received MPSV4 should be vaccinated with a single dose of conjugate vaccine 3 years after receiving the last MPSV4 dose. Studies are currently under way regarding the issue of reimmunization with a second dose of conjugate vaccine in persons who remain at increased risk of acquiring meningococcal disease. Development of an immunogenic serogroup B meningococcal vaccine has been problematic because the polysaccharide capsule of group B meningococcus is not immunogenic in animals or humans. In 1983, Finnish investigators reported that horse antiserum to meningococcus group B reacted with glycoproteins isolated from human and rat brain.[11] Therefore, good immunogenic responses may not be achievable with group B polysaccharide antigen vaccines because the body may see these antigens as "self" antigens (similar to neural tissue). However, a serogroup B outer-membrane vesicle vaccine has been studied recently in 16- to 24-month-old children in New Zealand, and 75 percent demonstrated seroconversion after receiving three doses.[211]

Deeper understanding of the pathophysiologic mechanism of meningococcal disease and the bacterial structures critical for antigenicity and immunogenicity in humans is needed. A safe and effective vaccine that could induce protection against all encapsulated meningococci in all age groups is the ultimate goal.

CHAPTER 100

Gonococcal Infections

Charles R. Woods, Jr.

Gonorrhea, the foremost manifestation of human disease caused by *Neisseria gonorrhoeae* (the gonococcus), is one of the oldest known human diseases. Hippocrates called the disease "strangury" in the fifth and fourth centuries BCE. Galen coined the name *gonorrhea*, meaning "flow of semen," in the second century CE. The association of the disease with sexual activity was recognized, and sexual abstinence plus washing of the eyes of newborns was prescribed by Greco-Roman physicians for treatment of the disease. Gonorrhea also has been known as *clap* since the late 1300s. The origin of this term is unclear but may have derived from the Les Clapier district of Paris, where prostitutes were housed during the Middle Ages.[186,229]

After syphilis appeared in Europe in the late 15th century, the two diseases were thought to represent different manifestations of the same infection, and they often coexisted then as today. The description by Neisser of *N. gonorrhoeae* in stained smears of urethral and other exudates in 1879 and culture of the organism by Leistikow and Löffler in 1882 provided the foundation for modern understanding of the clinical spectrum of gonococcal diseases. The advent of safe and effective antimicrobial agents, first sulfonamides in 1936 and then penicillin in 1943, was the next major advance in combating gonorrhea.[186,229] Further understanding of the clinical aspects of the disease was facilitated by development of the Thayer-Martin medium in 1964.[322] Modern knowledge of the molecular pathogenesis of *N. gonorrhoeae* infection began in 1963 with the observation by Kellogg and colleagues that gonococcal strains with differences in colony morphology also varied in virulence.[188]

The potential reproductive sequelae of gonococcal infections (e.g., infertility), the ever-growing resistance to antimicrobial agents, and disproportionate case burdens in public clinics continue to cast *N. gonorrhoeae* infection as a major international public health problem.[57,213,276] The purpose of many current investigations remains the development of an effective vaccine.[81,308]

In infants, the gonococcus causes primarily ophthalmia neonatorum. Wound infections, including scalp abscess (often associated with fetal monitoring), funisitis, and vaginitis may occur. Infection can disseminate from any colonized or infected skin or mucous membrane site and may result in sepsis, meningitis, septic arthritis, or endocarditis. In prepubertal children, gonococcal infection usually involves the genital tract and almost always is transmitted sexually. Vaginitis is the most common manifestation. Extension to the upper genital tract in girls does occur but very seldom. Urethritis can develop in boys but rarely does so. Anorectal and tonsillopharyngeal infections also can occur in prepubertal children.

In adolescents, as in adults, the most common clinical manifestations are urethritis, endocervicitis, and salpingitis in females and urethritis in males. Epididymitis, bartholinitis, pelvic inflammatory disease (PID), and perihepatitis can occur as a result of extension from primary genital infections. Rectal and pharyngeal infections and disseminated disease, which may include reactive or septic arthritis, also are seen. Additional information on gonococcal infections is provided in Chapter 48.

EPIDEMIOLOGY OF GONOCOCCAL INFECTION

Gonococcal infections remain second only to *Chlamydia* infections in incidence among reportable diseases for 15- to 24-year-olds in the United States.[60,68] Gonococcal infections are relatively rare occurrences in Canada and much of western Europe but remain common in developing countries.[164] Rates of gonococcal infection in the United States and western and central Europe declined steadily in the 1980s and 1990s. Rates of gonorrhea increased in eastern Europe in the early 1990s.[326] These rates have declined but remain above those in other European regions.[342] Regions with higher rates of adult disease have higher numbers of pediatric cases,[109,131] a finding that reflects the adult origin of virtually all pediatric cases.

An estimated 1 million new cases of gonococcal infection occur annually in the United States, only approximately a third of which are reported. The 339,593 reported cases in the United States in 2005 (115.6 cases per 100,000 population) represented a slight increase in the national rate for the first time since 1999 (Fig. 100–1). This rate remains well above the Healthy People 2010 goal of 19 per 100,000. At least half the cases are thought to go undiagnosed or unreported. After World War II, reported cases of gonorrhea in the United States declined from 204 per 100,000 in 1950 to 129 per 100,000 in 1958. Rates rose in the 1960s and early 1970s, in association with changing sexual mores, before peaking at 472 per 100,000 in 1975. Gonococcal infections rarely are fatal (approximately four deaths per year in the United States), with death being caused by gonococcal sepsis.[58,60,65,213,276]

Adolescent females 15 to 19 years of age have the highest reported incidence of infection in the United States (625 cases per 100,000 in 2005). Among those aged 25 years and younger (including children), rates of gonorrhea are higher for females than for males. Rates for males are higher in those aged 25 years and older. Rates in African American adolescents of both genders greatly exceed those of white adolescents, and this trend continues into adulthood. The disparity between African Americans and non-Hispanic whites narrowed slightly from 26-fold in 2001 to 18-fold in 2005.[60,65]

Low socioeconomic status, early onset of sexual activity, unmarried marital status, and past gonococcal infections are risk factors for acquiring gonococcal infection, as are prostitution and illicit drug use.[16,39] Limited access to quality health care also may contribute to an increased prevalence of disease in impoverished populations.[65] The prevalence of gonococcal infection in adolescents attending private clinics probably is lower than that in those seeking care in publicly funded settings.[22] For women, the use of

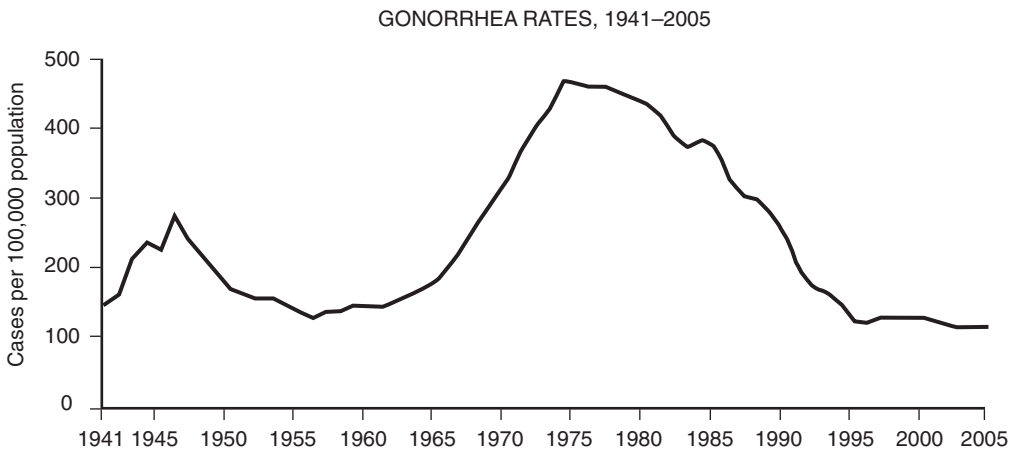

Figure 100–1 Rates of gonorrhea in the United States, 1941 to 2005. After a 74 percent decline from 1975 through 1997, overall gonorrhea rates have plateaued in recent years. Gonorrhea is substantially underdiagnosed and underreported. About twice as many new infections are estimated to occur each year as reported. *(From Centers for Disease Control and Prevention: Trends in reportable sexually transmitted diseases in the United States, 2005. December 2006. Available at* http://www.cdc.gov/std/stats/05pdf/trends-2005.pdf.*)*

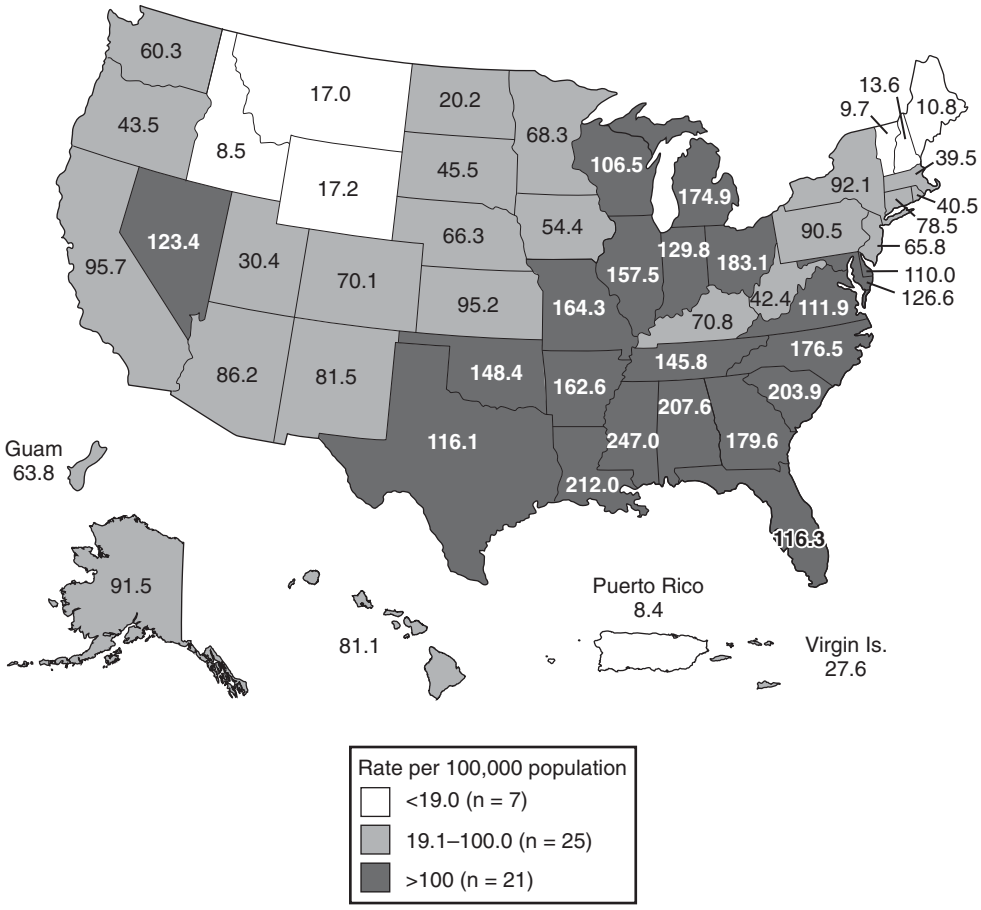

Figure 100–2 Rates of gonorrhea by state in the United States and outlying areas, 2005. *(From Centers for Disease Control and Prevention: Sexually Transmitted Disease Surveillance 2005 Supplement, Gonococcal Isolate Surveillance Project (GISP) Annual Report 2005. Atlanta, U.S. Department of Health and Human Services, Centers for Disease Control and Prevention, January 2007.)*

hormonal contraceptives may increase the risk of acquiring infection, whereas the use of spermicides or diaphragms appears to be at least partially protective.[210,211]

Rates of gonococcal infection among men who have sex with men (MSM) are lower than those in past years but remain higher than those among males who are exclusively heterosexual.[196] Among human immunodeficiency virus (HIV)-infected persons included in the Adult/Adolescent Spectrum of HIV Disease Project in the United States from 1991 to 1998, 9.5 cases occurred per 1000 person-years. A trend toward increasing rates of gonorrhea was noted during that period among MSM, whereas a decline occurred in those with heterosexual contact as their HIV exposure risk.[112] In a prospective study from 2001 to 2003, the prevalence of pharyngeal gonorrhea among HIV-negative MSM was 5.5 percent; 92 percent of cases were asymptomatic.[227]

The southeastern United States continues to have rates of gonorrhea higher than those of other regions of the country, but rates per 100,000 population in the Southeast fell from 175 to 140 between 2001 and 2005 (Fig. 100–2). Rates in the western United States increased during this period from 72 to 82 per 100,000.[65] This increase occurred in all age, gender, and racial/ethnic groups, regardless of sexual orientation, and was explained only in part by increased testing and the use of more sensitive tests.[66]

Rates of gonorrhea are based primarily on detection of symptomatic infection. Asymptomatic chronic infection in adults is well documented and may account for 5 percent of cases.[164] Such persons can transmit the infection. Some untreated cases will resolve over the course of time. Data also indicate that asymptomatic infection occurs in children, including prepubertal children.[3,123,158,171]

Humans are the only reservoir of *N. gonorrhoeae*. Exudate and secretions from infected mucosal surfaces allow transmission to occur during the intimate contact of sexual acts, parturition, and, rarely, household exposure. The incubation period usually is 2 to 7 days. No evidence of airborne transmission of gonococci exists; contact with viable microbes is required for transmission. Gonococci survive on surfaces outside the human body for only short periods of time (probably minutes). Although organisms can be cultured from environmental sources (e.g., toilet seats) for up to 3 hours after artificial inoculation in large numbers, viable gonococci have not been recovered from random samplings in public restrooms.[133]

Gonococcal conjunctivitis can be acquired nonvenereally.[203] Vulvovaginitis potentially could be acquired when a child sleeps in the same bed with an infected family member,[133] and sharing of bath towels and other similar objects has been suspected as the cause of epidemics in prepubescent girls living together.[308] However, nonsexual transmission rarely occurs and never should be presumed without extensive investigation of the social setting of the infected child.[239] Although persistence of apparently perinatally acquired gonococcal infection for up to 1 year of age has been reported and fomite or maternal nonsexual transmission to young infants is plausible,[34] these possibilities should not be generalized beyond infancy.

The risk of a male acquiring urethral infection after a single episode of vaginal intercourse with an infected female is estimated to be 20 percent. With four exposures, the risk increases to 60 to 80 percent. The prevalence of infection in females named as sexual contacts of males with gonococcal urethritis has been reported to be 50 to 90 percent.[162,167]

The annual direct medical cost of treating sexually transmitted diseases (STDs), including HIV, in the United States alone has been estimated at $11 to $17 billion in 2003 U.S. dollars. Almost half of these costs accrue to persons aged 15 to 24 years. The reduction in gonorrhea and syphilis rates in the United States between 1990 and 2003 has been estimated as being equivalent to $5 billion during this period.[78]

MICROBIOLOGY

Neisseria spp. are aerobic, gram-negative, nonmotile, non–spore-forming cocci that occur in pairs (diplococci), with adjacent sides flattened. They have the typical gram-negative microbial outer membrane overlying a thin peptidoglycan layer and cytoplasmic membrane. The species lacks a true polysaccharide capsule but produces a surface polyphosphate that provides a hydrophilic, negatively charged surface.[246] In Gram stains of clinical specimens, the microbes frequently are observed within phagocytes.[303]

Gonococci are able to use glucose, lactate, and pyruvate as carbon sources but cannot use other carbohydrates, which is the basis for the carbohydrate utilization tests for speciation of *Neisseria* (Table 100–1). Catalase and cytochrome oxidase are produced by the gonococcus, as in most *Neisseria* spp., but gonococci do not produce appreciable amounts of superoxide dismutase. Growth is optimal in a 5 percent CO_2 atmosphere at 35° C to 37° C and a pH of 6.5 to 7.5. Gonococci do not survive below pH 6.0, grow poorly below 30° C, and do not survive above 40° C.

Neisseria spp. require enriched media, including free iron, to support their growth. Multiple colony types are evident when a single isolate is grown on clear agar. Small convex glistening colonies are piliated, whereas larger, flatter colonies are nonpiliated. In vitro passage usually results in loss of pili. Under low-power microscopy, some colonies appear opaque or granular and others are transparent. The former represent colonies in which most cells express one or more opacity-associated proteins (Opa), whereas in the latter colonies, most cells do not express these proteins.[37,42,188,310,318,319,331]

CULTURE FROM CLINICAL SPECIMENS

The organisms usually are cultured on chocolate blood agar in an atmosphere enriched by carbon dioxide. If the clinical specimen has been obtained from a highly contaminated site (e.g., rectum, cervix), a selective medium containing nystatin, vancomycin, trimethoprim, and colistin (e.g., modified Thayer-Martin medium) to suppress contaminating flora allows the growth of most *Neisseria* spp. A few strains of gonococci can be inhibited by vancomycin (see later).[37,225] Chocolate agar without antimicrobial agents is preferred if the culture is taken from a usually sterile area such as blood, cerebrospinal fluid (CSF), synovial fluid, or a skin lesion. Gonococcal colonies usually are evident on agar plates within 24 to 48 hours after inoculation. Frequent propagation is necessary to maintain isolates because viability is lost rapidly after 48 hours of growth.

Because gonococci cannot tolerate drying, clinical specimens must be plated as soon as possible onto appropriate media. Transport bottles that contain medium and a CO_2-enriched atmosphere should be used if definitive processing of the specimen must be delayed. Transport bottles should be maintained upright to preserve the CO_2 atmosphere.

In addition to sugar fermentation patterns (see Table 100–1) and oxidase positivity, other biochemical reactions also can be used to differentiate between *Neisseria* spp. or confirm that an isolate is *N. gonorrhoeae*.[71] Enzyme substrate tests that identify the presence or absence of 1-hydroxyprolylaminopeptidase, gamma-glutamyl aminotransferase, and beta-galactosidase are available as an adjunctive means of confirmation.[97] Gonococci possess only the former. These reactions alone will not distinguish *N. gonorrhoeae* from several commensal *Neisseria* spp. Antigen-detection–based tests, including fluorescent antibody staining, also have been used to confirm the identity of an isolate as *N. gonorrhoeae*.[189] Tests based on detection of gonococcal nucleic acid sequences, which are being used increasingly for diagnostic purposes, also can be used to confirm the identify of gonococcal isolates from cultures (see "Diagnostic Testing" and "Medicolegal Issues" later).

GENETIC CHARACTERISTICS

Gonococci have a circular chromosome consisting of 2219 kilobases (kb), which is about half the size of the *Escherichia coli* genome.[107] The gonococcal genome has approximately 2250 predicted open-reading frames (ORFs).[35] The entire *N. gonorrhoeae* strain FA1090 has been sequenced. A macrorestriction map with the positions of many genetic markers has been available since 1991.[199,257] More than 1300 ORF sequences have been validated.[35]

Piliated gonococcal cells (the natural in vivo state) are competent for genetic transformation by exogenous DNA at all stages of growth.[25] Only homologous DNA is taken into the cell.[114] Gonococci are highly autolytic and release DNA in a biologically active form. Thus, different strains are able to exchange genetic material readily. Such exchange can lead to further genetic and phenotypic diversity, which helps maintain the species in its human hosts and facilitates transfer of chromosomal antibiotic resistance genes.[291]

A 36-kb conjugal plasmid is present in many gonococci. It efficiently mobilizes its own transfer and other non–self-mobilizable plasmids (e.g., the 4.5- and 7.5-kb penicillinase plasmids), but not chromosomal genes.[24,253,279] Extrachromosomal, non-plasmid DNA circles recently have been identified in wild-type gonococcal isolates. They may play a role in gene recombination, amplification of chromosomal genes, and transformation.[18]

Gonococci possess multiple restriction endonucleases and their corresponding DNA methylases.[317] No bacteriophages for *N. gonorrhoeae* are known, and no drug resistance transposon systems have been identified.[308] The species is relatively nonmutagenic and lacks photoreactivation and error-prone repair systems.[48]

STRAIN TYPING

The ability to differentiate one strain from another allows researchers to investigate the epidemiology of transmission of gonorrhea and assessment of virulence factors. Numerous methods have been applied to gonococci.

Auxotyping classifies strains according to their ability to grow or not grow in the absence of 11 specific compounds, including amino acids (e.g., arginine, proline), purines, pyrimidines (e.g., hypoxanthine, uracil), and other nutrients (e.g., thiamine). Approximately 20 auxotype phenotypes are recognized. Genetic studies have shown that multiple mutations in the same biochemical pathway can lead to the same phenotype, such that a single auxotype can represent many genotypes.[298] Auxotypes are stable in vitro, however, and organisms cultured from sexual partners are of a similar auxotype.[51,55] The auxotype of greatest epidemiologic importance is designated arginine-, hypoxanthine-, and uracil-negative (AHU^-). Such strains are unable to grow in the absence of these compounds. AHU^- strains typically are more resistant to killing by normal human serum, are more likely to cause asymptomatic infections in males, and are found more frequently in patients with disseminated infection.[117] AHU^- strains often are susceptible to vancomycin.[225]

Numerous serotyping schemes have been attempted,[72] but the best and most widely available serologic technique is based on antigenic heterogeneity of the porin protein (formerly called protein I) contained in the outer membrane of the gonococcus.[10,179,192,288,289] Two immunochemically distinct serogroups, PorA and PorB, exist and can be subdivided into serovars by using sets of monoclonal antibodies. Serovars remain stable in vitro and are designated IA-x or IB-x, where *x* is the numeral of the serovar. At least 26 IA and 31 IB serotypes have been identified.[62] Serotyping can be combined with auxotyping to further discriminate among gonococcal strains.[166,263] Limitations of auxotype-serovar classification include restricted supplies of reagents and batch-to-batch variation in monoclonal antibodies. In addition, common serovars can have such significant genetic diversity that this typing method may not provide sufficient discrimination for some epidemiologic evaluations.

Antimicrobial susceptibility patterns (antibiograms) have been used in the past as an adjunctive tool, but the usefulness of this method for long-term epidemiologic studies has been compromised by the ability of gonococci to transfer genetic elements for antibiotic resistance between strains.[308]

Genotyping methods have been applied to *N. gonorrhoeae* in the past 2 decades. Simple restriction endonuclease methods with rare cutting enzymes[122,262] have been supplanted by polymerase chain reaction (PCR)-based methods and pulsed-field gel electrophoresis (PFGE). Arbitrarily primed PCR (AP-PCR) has been used, but the reproducibility of this method can be problematic.[47,208] PFGE and Opa typing, which involves PCR primers that are able to generate DNA bands from each of the 11 *opa* genes, followed by restriction enzyme digestion, each appear to be able to produce higher discrimination among gonococcal isolates than does serotyping combined with AP-PCR.[208]

Sequencing of the *por* gene also appears to be highly discriminatory among strains,[87] and PCR amplification of the *por* gene with restriction enzyme digestion provides discrimination similar to that of combined auxotyping-serotyping.[111] Repetitive-element sequence-based PCR (rep-PCR), which uses longer primers than AP-PCR does and is a more reproducible method, correlates well with PFGE for analysis of gonococcal strains.[263] Rep-PCR is a rapid method that can be performed directly on colonies without having to purify microbial DNA, which is required with most other genotyping methods.[341]

PATHOGENESIS

A continuously expanding body of literature is devoted to the pathogenesis of *N. gonorrhoeae*. Gonococci are able to survive in the urethra in the face of hydrodynamic forces that tend to wash other microbes away and persist there despite close proximity and even attachment to the hoards of neutrophils that respond to their presence. These observations suggest that they have an ability to adhere to mucosal epithelia and evade the host's acute innate immune response. Individuals also can have repeated infections by the same gonococcal strain, thus suggesting that the organism can thwart established local immune responses, probably through frequent antigenic variation. The tissue damage that occurs in the fallopian tubes during salpingitis implies that one or more directly toxic moieties or factors can trigger a deleterious host response.[124,308] Much progress has been made in understanding the mechanisms that account for these properties.

Clinical studies have focused largely on the adaptation of organisms to specific anatomic areas (e.g., rectum, blood, endocervix) in older adolescents and adults. This information probably holds true for most infections in infants and children. Recent insight into the molecular pathogenesis of gonococcal infection has been derived from in vitro molecular studies involving cell lines and fallopian tube organ cultures and experimental infections in human males.[81,215,216,272] Currently, no adequate animal models of gonococcal infection exist.

After adhering to host epithelial cells, some gonococcal microbes are able to invade, replicate intracellularly inside phagosomes/vacuoles, and exit the basal (but not lateral) surface of the cell via exocytosis[216,221,237] (Fig. 100–3). Adjacent nonepithelial cells are sloughed, probably because of the toxicity of lipo-oligosaccharide (LOS) and peptidoglycans.[142] Mucosal cell damage and submucosal invasion are followed by an influx of neutrophils along with the formation of submucosal microabscesses and exudation of purulent material into the lumen of the infected organ.[339]

The vast majority of invading gonococci are ingested and killed by neutrophils. Gonococci are susceptible to the oxidative burst products of phagocytes, as well as to nonoxidative products such as cathepsin G.[52,296] A few gonococci are able to escape the innate and early adaptive immune responses such that infection and contagion can persist for weeks and sometimes months in the absence of treatment.

Adherence of gonococci to mucosal epithelial cells causes activation of nuclear factor κB and activator protein 1, which in turn leads to up-regulation and release of multiple cytokines and chemokines, including macrophage colony-stimulating factor, tumor necrosis factor-α (TNF-α), tumor growth factor-β, monocyte chemoattractant protein 1, interleukin-1β (IL-1β), IL-6, and IL-8.[238,266]

The initial steps in pathogenesis may result from the synergistic effects of pili, Opa proteins, and porin proteins.[19,144] Close interactions of *N. gonorrhoeae* with mucosal cells, erythrocytes, spermatozoa, and polymorphonuclear cells are well described. Species specificity is demonstrated by greater adherence of gonococci to human cells than to nonhuman cells. The best-characterized microbial factors are listed in Table 100–2 and discussed in the following sections.

**Data were provided in which the outcomes of pregnancies of mothers not infected with N. gonorrhoeae were shown to be significantly more favorable.*
†Percentages in all columns may sum to greater than 100 because pregnancies could have more than one of the listed outcomes.

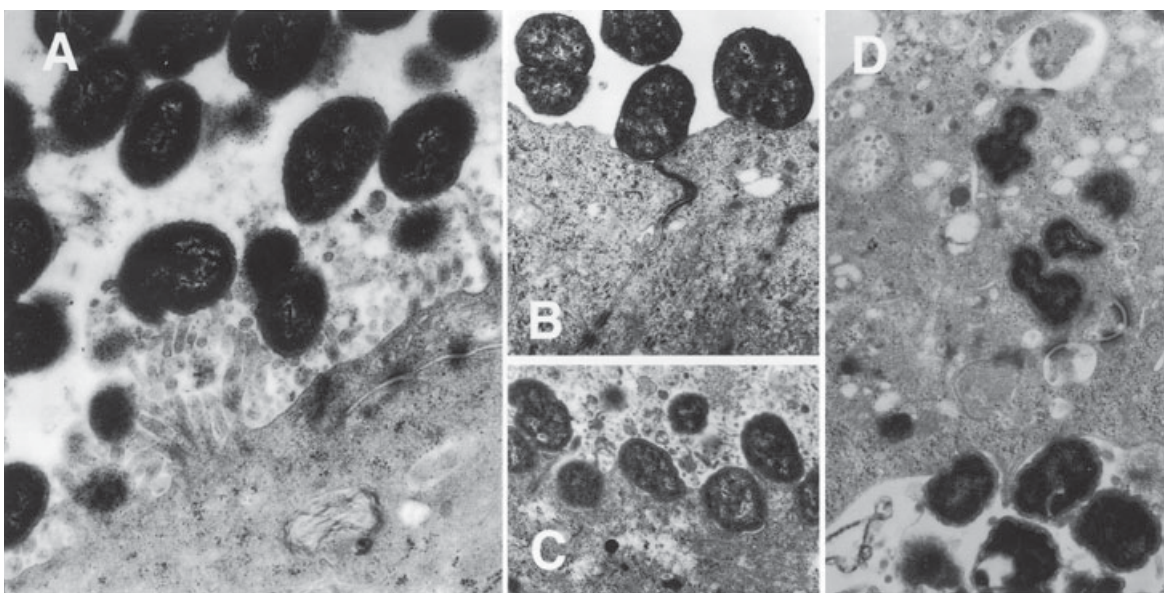

Figure 100–3 Electron micrographs of *Neisseria gonorrhoeae* (strain MS11) interactions with polarized T84 human epithelial cell monolayers. At early stages of infection, the microbes adhere to the apical plasma membrane as microcolonies. Adherent bacteria are surrounded by a matrix of microvilli (**A**). Bacteria subsequently disperse from the microcolony and adhere as a monolayer in which bacterial and host-cell membranes are tightly apposed (**B** and **C**). The region of contact between the bacteria and the host-cell membrane enlarges (**C**), with subsequent internalization of the microbes (**D**). Bacteria then traverse the host cell and exit via the basolateral membrane (**D**). *(Photographs by Magdalene So, from the* Annual Review of Cell and Developmental Biology, *Volume 16. © 2000 by Annual Reviews.* www.AnnualReviews.org.*)*

VIRULENCE FACTORS

Characteristics of *N. gonorrhoeae* strains that appear to have a role in virulence include (1) pili, (2) opacity proteins, (3) porin protein, (4) the ability to survive in low iron environments, (5) IgA protease, (6) LOS, (7) cell wall peptidoglycan, and (8) reduction modifiable protein (Rmp). Many other gonococcal gene products and molecular systems have been identified, and a more detailed and complex understanding of virulence at the molecular level probably is forthcoming.

THE PRESENCE OF PILI. Gonococci are piliated predominantly in vivo and express type IV pili. Pili cover essentially the entire surface of the cell and are arranged in individual fibrils or fibrillar aggregates. Pili consist primarily of polymers of an 18-kd subunit now denoted as PilE. A single pilus is approximately 6 nm in diameter and up to several microns in length.[221] Each may contain thousands of PilE subunits.[44] The PilC protein is present in lower numbers in the pilus but appears to be the key pilus adhesin. PilC interacts with CD46 molecules, which are present on most human cells and serve as receptors for C3b, C4b, and measles and other viruses. PilC-CD46 attachment appears to be a key step in the initiation of microbial adherence to host cells.[45,185,190,283,285]

Binding of pili to a host-cell membrane induces at least two responses in the host cell: release of Ca^{2+} from intracellular stores[184] and cytoskeletal rearrangements with the formation of cortical plaques that represent an accumulation of actin, ezrin, and other phosphotyrosine-containing proteins.[219,220] The latter results in elongation of the microvilli that embrace the microbe. Formation of plaque appears to be induced by retraction of the attached pilus, and retraction is dependent on another pilus protein designated PilT.[222]

Gonococcal pili undergo both phase variation (switching from piliated to nonpiliated states) and high-frequency antigenic variation.[44] These variations occur during natural infection and in vitro passage.[293] Pili have a common N-terminal domain, semivariable domains in the midportion, and two hypervariable regions in the carboxyl-terminal of the pilin protein subunit.[309] Relatively invariant regions occur between the variable domains. The pilin protein consists of 159 to 160 amino acids. A disulfide bridge is formed by cysteine residues at amino acids 121 and 151.

The genetic mechanism of pilus antigenic variation has been studied extensively. The chromosome contains either one or two complete pilin genes. The expressed gene contains an intact promoter region, a ribosome binding site, and a seven–amino acid signal sequence in addition to the pilin sequence. Scattered around the chromosome are six to eight loci that contain varying portions of the pilin sequence without the promoter region or the 5′ end of the structural gene. Some loci may contain many incomplete pilin sequences arranged head to tail that differ slightly from one another. Movement of these sequences into the active expression site through nonreciprocal combination events results in antigenic variation of the pilus protein. If recombination leads to a faulty pilin subunit product that cannot be processed into a mature pilus, the progeny of that organism become nonpiliated (phase variation). Subsequent recombination events can allow reversion back to the piliated phase.[150,223,224,243,292,309,320]

In addition to promoting adhesion to epithelial cells, pili also provide a twitching motility, are involved in DNA transformation, and may play a role in resistance to ingestion by phagocytic cells.[221] The presence of pili, perhaps mediated through their promotion of adhesion, affects the activation of $CD4^+$ T-lymphocytes and the production of IL-10. This property may help gonococci diminish the T-cell response to their presence.[259]

OPACITY-ASSOCIATED PROTEINS. Opa proteins also influence adherence of the gonococcus to host cells. The isolation of particular Opa protein phenotypes from different anatomic sites or at different times during the menstrual cycle has suggested that these proteins contribute to the ability of the organism to succeed in a given niche. Opa proteins (formerly designated *protein II*) are a set of as many as 12 related proteins that are variably present in gonococcal outer membranes. Opa proteins are 24 to 28 kd in size and confer increased opacity to colonies of organisms by promoting adherence of the organisms to one another. A given strain has the capacity to make at least 10 different Opa proteins but appears to express no more than 5 at the same time. Some cells express no Opa proteins. Like pili, Opa proteins undergo both antigenic and phase variation. Both types of variations can occur within a single colony, so sector variations in opacity can be seen.[27,308,318,319]

Each *opa* gene is present as a complete gene with its own promoter and is transcribed at all times. Phase variation in expression occurs at the translational level. Each gene has a varying number of pentameric CTCTT repeat units adjacent to the ATG start codon. When the number of repeats is divisible by three, the transcribed mRNA is translationally in frame and the Opa protein is expressed. The number of pentameric repeats is subject to high-frequency variation. Antigenic variation results from recombinations between the two hypervariable regions in each of the *opa* genes.[86,313-315]

Two classes of host-cell receptors for Opa proteins have been identified. Heparan sulfate–proteoglycan (HSPG) receptors are present on epithelial cells and interact with one particular Opa protein variant (Opa_{50}). HSPG binding can stimulate the lipid hydrolysis enzymes phosphatidylcholine-specific phospholipase C and acid sphingomyelinase and thereby lead to clathrin-independent endocytosis. HSPG-Opa binding also can lead to interactions with serum factors such as vitronectin and fibronectin, which then mediate endocytosis via host-cell integrin receptors. The CD66 family is present on epithelial cells and neutrophils, recognizes many different Opa proteins, and mediates nonopsonic phagocytosis, a process distinct from antibody- and complement-mediated phagocytosis.[102,103,140,197,221,328]

PORIN PROTEIN. Formerly designated protein I, porin protein is the most common gonococcal outer-membrane protein. Porin is 34 to 36 kd, is exposed on the surface, exists as a trimer in the membrane, and is physically proximate to LOS and Rmp.[28,159] The trimer forms an anion-specific pore in the bacterial membrane that allows small water-soluble molecules to enter the cell.[343] The *por* locus has two alleles that encode chemically and immunologically distinct classes of porin protein—PorA and PorB—that are similar to porin proteins in other gram-negative bacteria. A given strain expresses only PorA or PorB, and many antigenic variants of both exist (thereby forming the basis for serotyping).[50,192]

The porin trimer appears to translocate into the host-cell membrane and is able to disrupt neutrophil degranulation, the oxidative burst, and phagosome maturation,[151,209,230] in addition to induction of apoptosis in epithelial cells and neutrophils in vitro.[234] Exposure to gonococcal porin protein induces the typical structural and biochemical changes seen in apoptotic cells.[233] Porin translocation permits rapid influx of Ca^{2+} into the host cell from the external environment.[234] Porin proteins also may play a role in endocytosis mediated by the binding of HSPG and Opa protein[19] and in down-regulation of complement by binding with C4b-binding protein.[265]

THE ABILITY TO USE IRON. Iron is an essential nutrient for *N. gonorrhoeae*, and in host tissues, iron is sequestered in hemin compounds as ferritin or is bound to lactoferrin or trans-

ferrin. The species does not produce any siderophores but relies on an iron-repressible system that scavenges iron from transferrin, lactoferrin, and hemoglobin. This system is composed of numerous proteins, some of which serve as receptors for the aforementioned iron-bearing ligands.[26,75,92,333] The ability to use iron from transferrin is a general property of pathogenic *Neisseria* spp. Transferrin- and lactoferrin-binding proteins are required for gonococci to cause experimental urethritis.[91]

IgA PROTEASE. All gonococci (and meningococci, but not nonpathogenic *Neisseria*) make a protease that cleaves both serum and secretory IgA1 (but not IgA2) at the hinge region with the release of Fab and Fc fragments. This protease may help the organism evade host IgA at the mucosal surface, especially early in secondary infections, when preexisting antibodies may be present. However, mutant strains without the IgA protease have limited ability to grow inside epithelial cells. The protease appears to cleave a host-cell intracellular protein (LAMP1) involved in phagosome compartmentalization.[205] IgA1 protease is not required for gonococci to cause experimental urethritis,[178] thus suggesting that its intraphagosome function may be more important in pathogenesis.

LIPO-OLIGOSACCHARIDE. Gonococci express LOS complexes of 3 to 7 kd on their cell surface. LOS consists of a lipid A moiety and a core polysaccharide composed of ketodeoxyoctanoic acid, heptose, glucose, galactose, glucosamine, galactosamine, or any combination of these constituents.[146] The lack of a long polymeric sugar attached to the core distinguishes LOS from the lipopolysaccharides of other gram-negative bacteria. The core sugar antigens of LOS are subject to intrastrain and interstrain variation, and a single strain may express as many as six variants of LOS.[105,145] Numerous genes are involved in LOS synthesis; these genes undergo high-frequency phase variation similar to *opa* genes.[139] LOS terminal sugars mimic the structure of certain human glycosphingolipids.[146]

Gonococci with predominately short LOS molecules appear to be more sensitive to killing by human serum but also more able to invade eukaryotic cells. Strains with longer LOS are more serum-resistant but noninvasive.[329] Longer LOS moieties are sialylated readily with host neuraminic acid by a bacterial sialyltransferase that appears to shield both LOS and porin molecules from antibody binding, thus providing protection from complement-mediated killing in serum.[33,334]

LOS from serum-sensitive strains is able to activate the classical complement pathway and may do so in the absence of antibody.[295] LOS induces the production of cytokines (TNF-α, IL-1β, IL-6, IL-8) by urethral epithelial cells[157] and can mediate host defensin-enhanced adherence to epithelial cells.[138]

CELL WALL PEPTIDOGLYCAN. Gonococci shed membrane fragments with peptidoglycan into their environment during exponential growth. Peptidoglycan monomers have numerous biologic properties, including activation of complement and modulation of mononuclear cell proliferation. These fragments also damage fallopian tube mucosa in organ culture, thus suggesting a pathogenic role for the compounds in invasive disease.[142,216]

REDUCTION MODIFIABLE PROTEIN. Rmp (formerly designated protein III) is an antigenically conserved, 30- to 31-kd protein that is present in all pathogenic *Neisseria*. Rmp is located proximate to LOS and porin in the outer membrane. Antibodies that bind to Rmp epitopes block the bactericidal effect of the complement-fixing IgM antibodies that recognize LOS. Women with preexisting anti-Rmp antibodies appear to be more susceptible to the development of infection than do those without such antibodies.[274,275,308]

RIBOSOMAL PROTEIN L12. Ribosomal protein L12 mimics the structure of human chorionic gonadotropin, the natural ligand for lutropin receptors. It is able to bind to lutropin receptors in the upper female genital tract, which may facilitate ascending infection in females.[115,312]

CHARACTERISTICS OF STRAINS CAUSING DISSEMINATED DISEASE

The increased virulence of some strains is suggested by observations such as a micro-epidemic of gonorrhea involving one asymptomatic infected male and eight female contacts.[154] Seven of the women were infected symptomatically, and four experienced disseminated infection. Clinical data repeatedly have shown that most infected women have asymptomatic infection and dissemination occurs relatively rarely.

Strains of *N. gonorrhoeae* obtained from adult patients with disseminated disease usually are less susceptible to the bactericidal activity of sera[38,83,272,273,297] (see discussion of LOS earlier). These strains have an atypical growth pattern on agar[226] that reflects the absence of Opa protein expression, which suggests that the genetic variation capacity described earlier allows adaptation to different niches and probably helps organisms elude the host response.[23] Unlike most gonococcal strains, many invasive strains (designated AHU^-) require arginine, uracil, and hypoxanthine for growth.[191] A high degree of sensitivity to penicillin also has been characteristic of most strains from patients with disseminated disease.[338] *Many also are susceptible to vancomycin*, which may prevent them from being detected in selective media but not in the usual media used for blood culture.

HOST RESPONSE

The adult response to local and systemic infection with *N. gonorrhoeae* has been investigated extensively, but no such studies have been performed on infected children. Gonococcal infections usually are characterized by intense inflammation that involves neutrophilic and mononuclear granulocytes. The vast majority of gonococcal cells ingested by neutrophils are killed.[52] Gonococci are susceptible to the oxidative products produced by neutrophils but also can be killed efficiently by nonoxidative products such as cathepsin G.[296]

An intact complement system is essential for successful eradication of the organism. Persons with inherited or acquired complement deficiencies may be predisposed to contracting disseminated gonococcal infection, as is the case with meningococcal infection. Approximately 13 percent of patients with disseminated disease have complement deficiencies.[119,246]

Adherence of gonococci in vitro induces the activation of nuclear factor κB and activator protein 1, which leads to up-regulation of mRNA for and release of numerous cytokines and chemokines: macrophage colony-stimulating factor, TNF-α, tumor growth factor-β, monocyte chemoattractant protein 1, IL-1β, IL-6, and IL-8.[238] Intra-urethral challenge leads to increased levels of IL-8, IL-6, and TNF-α in urine before the onset of symptoms and in plasma at the onset of symptoms.[266]

Multiple episodes of gonorrhea may occur in a single individual in a short period of time and even may be caused by the same strain. The antigenic diversity and ease of altering the antigenicity of both pili and opacity proteins undoubtedly contribute to the insufficiency of the host response in preventing reinfection.

Circulating humoral antibody to the infecting strain is measured by an assay of bactericidal antibody and is present in most persons who have prolonged mucosal colonization with *N. gonor-*

rhoeae.[172,187] In addition, women in whom PID develops usually produce bactericidal antibody during the infection. IgA- and IgG-blocking antibodies against some gonococcal antigens appear to block killing of the bacteria mediated by otherwise bactericidal IgG and IgM antibodies (see Rmp information earlier).[272] Serum antibody responses are greater in patients with invasive disease (e.g., bacteremia, salpingitis).

Secretory IgA antibody is present in the urethral exudate of men with gonorrhea and in the genital secretions of women with gonorrhea.[247] The development of local IgA antibody occurs more rapidly and is more transient than is development of the serum bactericidal response. Microbial IgA1 protease is not required for infection but may play a role in reinfection.

A cellular immune response to gonococcal antigens in patients with uncomplicated gonorrhea has been demonstrated in vitro.[200] The significance of this response in controlling or preventing infection is unknown.

PERINATAL GONOCOCCAL INFECTIONS

Since the 1970s, health clinics have encouraged the routine screening of sexually active women for gonorrhea. Such screening is especially important during pregnancy, and rates of gonorrhea in pregnant women range from exceedingly low to approximately 10 percent. Adolescent girls have a higher prevalence of gonorrhea than do older women of child-bearing age, and this prevalence probably translates into higher rates of gonorrhea in pregnant adolescents. Rates of gonococcal infection in neonates reflect the frequency of infection in pregnant women. Recognition of gonorrhea early in pregnancy identifies a population at risk that should be monitored sequentially for reinfection throughout pregnancy.[180]

The spectrum of infection with *N. gonorrhoeae* appears to be similar in pregnant and nonpregnant women. Most women are asymptomatic. Pharyngeal infection seems to occur more commonly during pregnancy, perhaps reflecting altered sexual practices. One study reported that 39 percent of patients with *N. gonorrhoeae* at any site had concurrent involvement of the pharynx and that 30 percent had pharyngeal infection as the sole manifestation.[90] In adolescent girls, pregnancy and menstruation are associated with disseminated disease.[161]

Gonorrheal infection puts both the mother and infant at risk for the development of other forms of gonococcal disease. Pregnant women have an increased risk for the development of gonococcal septic arthritis, and most such cases occur during the third trimester or in the immediate postpartum period.[40,161] Although the incidence of gonococcal arthritis is low, many cases have occurred in pregnant adolescents.

Gonococcal PID and acute salpingitis also may complicate the pregnancy of an infected woman.[132] These complications usually occur during the first trimester and have been associated with a high rate of fetal loss. An increased incidence of postpartum fever in women with untreated gonorrhea likewise has been noted. A new mother with complications of peripartum gonorrhea may have difficulty providing care for her child.[175]

Maternal gonococcal infection has been associated with abnormalities in labor and delivery that may affect the infant adversely. Prolonged rupture of membranes, premature delivery, chorioamnionitis, funisitis, and a clinical diagnosis of sepsis occur frequently in infants with *N. gonorrhoeae* detected in the gastric aspirate during delivery.[7,116,153,280]

Hazards to the fetus posed by maternal gonorrhea include septic abortion, perinatal death, prematurity, perinatal distress, and premature rupture of membranes. Table 100–2 tabulates the proportions in six studies of infants born to infected mothers who experienced these problems. A controlled study in an area with a high prevalence of gonorrhea found that maternal infection with *N. gonorrhoeae* was associated significantly with preterm birth and that 14 percent of preterm births in this population were attributable to gonococcal infection.[118]

GONOCOCCAL OPHTHALMIA NEONATORUM

Epidemiology

Researchers have recognized for centuries that ophthalmia neonatorum occurs in infants born to women with a vaginal discharge. Recommendations for flushing the eyes of a newborn commonly were given before the 20th century.[218] In the late 1800s, Neisser helped establish the relationship between the gonococcus and neonatal ophthalmia.

By 1881, Dr. Carl Sigmund Franz Credé had recognized that asymptomatic disease in the mother was a potential source of infection.[96] Gonorrhea was highly prevalent in Europe, and Credé described an increased incidence in patients from lower socioeconomic backgrounds. Mechanical cleansing of the birth canal failed to protect the infant from gonococcal ophthalmia neonatorum (GON), which was occurring in approximately 10 percent of newborns in major cities. The infection was the cause of a large proportion of admissions to schools for the blind.[17] Credé described the technique of instillation of 2 percent silver nitrate ($AgNO_3$) into the infant's conjunctival sac, which remains one method recommended for preventive procedures today.

By 1930, most states in the United States required that all newborns receive $AgNO_3$ prophylaxis (i.e., the Credé procedure). At present, prophylaxis of some form is required by most states. GON decreased as a cause of admission to schools for the blind in the United States, from an average of 24 percent from 1906 to 1911 to 0.5 percent from 1951 to 1955.

The worldwide decline in adult gonorrhea in the 1950s probably contributed to the decreased recognition of disease in newborns during that period. The incidence of GON rose in the 1960s and 1970s along with the increased incidence of gonorrhea in the general population and was very high in some developing nations.[197] In Los Angeles, California, the rate rose from 9 per 100,000 live births in 1957 to 1958 to 56 per 100,000 live births in 1962 to 1963. In a New York hospital between 1970 and 1973, a rate of 145 per 100,000 births was reported, and in a hospital in North Carolina during 1969 and 1970, a rate of 265 per 100,000 live births was proved by culture.[307] In the late 1970s and 1980s, GON again subsided in developed countries, but it has remained a major problem in underdeveloped nations.

Factors associated with higher rates of GON include lower socioeconomic class of the mother. An increased incidence of GON in infants of unwed mothers and mothers who have not had prenatal care also may exist.[304] Previous treatment of gonorrhea during pregnancy likewise is associated with an increased incidence of GON.[180]

The incidence of prematurity in infants with GON often is reported to be higher. Whether it is due to an adverse effect of gonorrhea on the pregnancy or because GON may be recognized more readily in premature infants has not been established. Premature rupture of membranes appears to increase the risk of GON occurring.

Prevention

Prophylaxis for GON has been accomplished mainly through the local instillation of either 1 percent $AgNO_3$ or one of several antimicrobial agents. In the United States, prophylaxis for GON is recommended for all infants immediately after birth and is required by law in most states. Prophylaxis regimens using a 1 percent solution of $AgNO_3$, 1 percent tetracycline ointment, or 0.5 percent erythromycin ophthalmic ointment have been con-

sidered equally effective for GON. Each is available in single-dose units, which are preferred over multidose tubes. One unit should be instilled into the eyes of every neonate as soon as possible after delivery. Instillation may be delayed for as long as 1 hour to facilitate parent-infant bonding. Povidone-iodine 2.5 percent solution also may be effective, but this agent is not recommended for use in the United States at this time.[5] Bacitracin is not effective for prevention of GON.[141]

The efficacy of tetracycline and erythromycin in the prevention of tetracycline-resistant *N. gonorrhoeae* ophthalmia is unknown. Both probably are effective because of the high concentration of drug in these preparations. Studies of these agents for prevention of *Chlamydia trachomatis* ophthalmia have been conflicting. Povidone-iodine may be more effective in preventing *C. trachomatis* ophthalmia than is topical $AgNO_3$ or erythromycin is. None of these agents prevents chlamydial colonization of the nasopharynx. Some Western countries with low rates of gonococcal and chlamydial infection do not recommend routine ophthalmic prophylaxis.[5,149]

CURRENT PROPHYLAXIS RECOMMENDATIONS IN THE UNITED STATES. In the United States, the 2006 version of the Sexually Transmitted Diseases Treatment Guidelines of the Centers for Disease Control and Prevention (CDC) no longer includes the use of silver nitrate. This change reflects the lack of availability of this agent in the United States at that time and not concerns about safety or effectiveness. The recommended agents are erythromycin 0.5 percent ophthalmic ointment or tetracycline 1 percent ophthalmic ointment, either one administered as a single application to each eye as soon as possible after delivery. None of the topical agents prevents mother-to-infant transmission of *C. trachomatis*.[64]

SILVER NITRATE AND GONOCOCCAL OPHTHALMIA NEONATORUM. Numerous studies have compared the efficacy of $AgNO_3$ and no prophylaxis or prophylaxis with another agent in the prevention of GON, and these studies have been reviewed elsewhere.[76,248,281] Until the late 1900s, most studies of the efficacy of $AgNO_3$ were not randomized and did not document rates of perinatal gonococcal exposure in the infants studied. Such studies involved large numbers of infants and consistently have shown lower rates of GON in treated groups than in untreated controls. Observations of a decreased frequency of blindness from GON in the population during the last half century, even during periods of increased rates of gonorrhea in women of child-bearing age, further support the benefits of $AgNO_3$ prophylaxis.

In a randomized trial of Kenyan infants born to mothers with gonorrhea reported in 1988, rates of GON were 42 percent in the control group, 7 percent in the group treated with 1 percent $AgNO_3$ (83% reduction), and 3 percent in the group treated with 1 percent tetracycline (93% reduction). The two treatment arms were not statistically different.[199] In a randomized trial in the United States involving infants born to women without gonococcal infection, infants treated with 1 percent $AgNO_3$ had a 39 percent lower rate (statistically significant) of conjunctivitis of any type in the first 2 months of life than did infants receiving no prophylaxis. Infants treated with 0.5 percent erythromycin ointment in this trial had a 31 percent reduction in comparison to control infants, but this result was not statistically significant.[20]

The major advantages of the use of $AgNO_3$ for prophylaxis are the lack of allergic potential, the absence of development of bacterial resistance to the compound, and very low cost. Two outbreaks of erythromycin-resistant staphylococcal conjunctivitis in newborn nurseries have been associated with the use of erythromycin eye ointment as ocular prophylaxis, but the outbreaks remitted when $AgNO_3$ was substituted. Disadvantages include the occurrence of conjunctival irritation along with the development of exudate in many babies and lack of effectiveness if infection already is established before drops are instilled into the eye. A solution of $AgNO_3$ that becomes concentrated may cause ophthalmic injury, but this problem largely has been alleviated by dispensing doses in ampules, which prevents evaporation.

Failure of $AgNO_3$ prophylaxis (as well as other agents for prevention of GON) does occur. Improper administration of $AgNO_3$ such that the solution does not reach the conjunctival sac, irrigation performed too quickly after instillation, and inadvertent omission of prophylaxis can lead to apparent failure. When gonococcal infection of the eye has begun before birth, $AgNO_3$ is not expected to prevent further progression. The increased risk of GON associated with premature rupture of membranes is due to exposure to and establishment of infection before actual delivery. In some cases of premature rupture of membranes, clinically apparent GON can be present at the time of birth.

Despite these problems, the use of 1 percent $AgNO_3$ remains a widely accepted, carefully evaluated, and safe form of GON prophylaxis. The occasional failure of $AgNO_3$ prophylaxis emphasizes that it is preferable to prevent GON through identification and treatment of pregnant women.

Clinical Features

The newborn eye is subject to colonization with numerous bacterial organisms that cause infections that usually are clinically mild, nonprogressive, and characterized by conjunctival discharge. The bacteria most commonly associated with conjunctival discharge are *Haemophilus influenzae*, *Streptococcus pneumoniae*, *Staphylococcus aureus*, *Neisseria cinerea*, *Klebsiella pneumoniae*, enterococci, and *C. trachomatis*.[110,195] Viral causes include herpes simplex virus and adenoviruses. In contrast, infection of the eye of a newborn with *N. gonorrhoeae* results in disease of a severity that, despite frequently being mild, can be rapidly destructive and lead to scarring and blindness. The chemical conjunctivitis that can result from $AgNO_3$ prophylaxis typically starts within 6 to 24 hours after administration and disappears within 24 to 48 hours.

Colonization during delivery is followed by an incubation period of 2 to 5 and usually less than 3 days, but cases occasionally may be recognized for 2 to 3 weeks after delivery.[130] A discharge typically develops that initially is watery but usually becomes thick and mucopurulent within a short time and may contain blood (Fig. 100–4). The disease generally is bilateral. Early findings include prominent edema of the conjunctivae and lids, followed by edema and later ulceration of the cornea or spread to wider areas in severe cases. Rapid arrest of the disease is essential because the degree of corneal involvement determines whether vision will be preserved. Some cases are self-limited and have benign outcomes, and occasional cases of asymptomatic GON have been discovered during routine screening.[261] Perforation of the globe and panophthalmitis can result from extensive local disease. The conjunctivae may serve as a portal of entry for gonococcal septicemia, arthritis, or other manifestations of invasive disease, but such events seldom occur.

A presumptive diagnosis may be made by demonstrating typical gram-negative diplococci by Gram stain of conjunctival exudate. Because other organisms also may cause exudative infection of the conjunctivae, laboratory confirmation of the diagnosis of GON depends on culture results of *N. gonorrhoeae*.

Invasive disease rarely occurs in association with GON. However, in the United States, the recommendation is that neonates with GON or any other manifestation of gonococcal infection have cultures performed on blood and CSF (as well as any local sites of infection) and be hospitalized pending culture results.[5]

GONOCOCCAL SCALP ABSCESS AND OTHER LOCAL INFECTIONS

Gonococcal infections of scalp wounds occur especially after fetal monitoring electrodes have been used on infants born to infected mothers.[99] The lesions may produce extensive local inflammatory disease and necrosis and can be a focus for disseminated infection. A scalp wound in a neonate should be cultured for gonococci, as well as other likely pathogens, which include *Staphylococcus* spp., group B streptococci, *H. influenzae*, and gram-negative enteric flora. Herpes simplex also may be present in areas of injury to the scalp of newborns. Overall, approximately 1 in 200 births that are monitored with fetal scalp electrodes has been complicated by infection at the monitoring site.[260]

Neonatal gonococcal vulvovaginitis, proctitis, rhinitis, funisitis, and urethritis have been described but are infrequent findings.[149] Gonococcal colonization of the oropharynx, gastric fluid, or both occurs relatively frequently in perinatally exposed infants, however. Pharyngeal colonization is present in as many as 35 percent of neonates who have GON.[127] A summary of selected studies on the incidence of neonatal gonococcal colonization and disease in exposed infants is presented in Table 100–3.

Infants with localized gonococcal infection at any site should have cultures obtained of blood and CSF, as well as the local site, and should be hospitalized pending the availability of culture results (see "Treatment" later).

Figure 100–4 Gonococcal ophthalmia neonatorum. The usual clinical finding is bilateral conjunctivitis that becomes progressively purulent if untreated. *(From Gutman, L. T.: Gonococcal infections. Semin. Pediatr. Infect. Dis.* 16*:4, 2005.)*

SYSTEMIC DISEASE IN THE NEONATE

Disseminated disease occurs in 1 percent or less of infants who are perinatally exposed to gonococcal infection[13] (see Table 100–3). Septic arthritis is the most common form of disseminated gonococcal infection in neonates. Gonococcal arthritis of the newborn was described extensively between 1900 and 1930 by Cooperman[88,89] and Wehrbein,[332] and recent case reports suggest that the disease remains similar. Clinical findings usually become evident when the infant is 1 to 4 weeks old. Although a few infants with gonococcal arthritis will have evidence of GON or other sites of mucosal or skin infection at the time of onset of arthritis, most do not.

The signs and symptoms of gonococcal septic arthritis are similar to those of joint infection caused by other microbes in the neonatal period, including a predominance of polyarticular involvement. Infection most frequently involves the ankles, knees, wrists, and hands.[88] The hip may be infected with minimal signs other than pseudoparesis. Involvement of a joint may include suppurative arthritis, inflammatory disease of the periarticular structures, and tenosynovitis. Leukocytosis usually occurs, and most infants have a positive culture and compatible Gram stain results from the synovial fluid of the involved joint.[135]

In a hospital-associated outbreak of gonococcal polyarthritis that occurred in 1927, involvement of the joint was noted in 53 of 67 infected infants (79%). Other studies of outbreaks have indicated that perhaps 15 percent of children with gonorrhea acquire gonococcal arthritis. These rates probably are considerably higher than the estimated 1 to 3 percent incidence in adults and suggest an increased risk of dissemination in infants and children. For example, case reports have described gonococcal arthritis in both mother and newborn infant.[143] Prompt drainage of septic hips, along with initiation of antimicrobial therapy, is necessary because of the risk of development of aseptic necrosis of the femoral head. Long-term dysfunction from gonococcal infection of other joints seldom occurs.[89,149,163,193]

Although gonococcal sepsis can develop in neonates with or without associated septic arthritis, the bacteremic phase of spread to the joints from the initial sites of infection generally is clinically silent. Premature infants seem to be more at risk for the development of sepsis with bacteremia than term infants are. Meningitis has been documented but appears to be an exceedingly rare manifestation of neonatal gonococcal infection.[32,149,153] In the newborn period, the gastric aspirate may be cultured to determine colonization from a maternal source.

GONOCOCCAL DISEASE BEYOND THE NEONATAL PERIOD

LOWER GENITAL TRACT INFECTION IN PREPUBERTAL GIRLS

Gonococcal vaginitis or vulvovaginitis is the most common form of gonorrhea in prepubertal girls beyond the neonatal period. In

TABLE 100–3 Incidence of Neonatal Gonococcal Disease in Exposed Infants

Site of Neonatal Infection	Rate of Positive Cultures (%)	Population	Reference
Conjunctiva	0-10	Exposed infants who underwent $AgNO_3$ ocular prophylaxis	Edwards et al.,[116] Allen and Barrere,[4] Armstrong et al.,[11] Laga et al.[197]
	2-48	Exposed infants who had no ocular prophylaxis	Rothenberg,[281] Fransen et al.,[127] Laga et al.[197]
Orogastric fluid	26-40	Infants of infected mothers	Handsfield et al.,[153] Edwards et al.[116]
Oropharynx	35	Infants with gonococcal ophthalmia	Laga et al.[197]
Disseminated disease as a proportion of all neonatal gonorrhea	0-1 (rare)	Reported series of neonatal gonococcal disease	Folland et al.,[125] Tomeh and Wilfert,[323] Wald et al.,[330] Edwards et al.,[116] Fransen et al.[127]

contrast to that of postpubertal females, the anestrogenic vaginal mucosa of prepubertal girls creates an alkaline environment that is colonized and infected more readily with *N. gonorrhoeae*. Infection of the endocervix, urethra, paraurethral and Bartholin glands, and upper genital tract occurs only rarely.

Gonococcal vaginitis in prepubertal girls almost always is symptomatic, with vulvar erythema and a profuse vaginal discharge. The girl may complain of dysuria, urinary frequency, vulvar discomfort, or pain while walking.[235,297,300] Asymptomatic cases may occur but are uncommon.

Symptoms and signs should resolve promptly within a few days after treatment is initiated, but acute manifestations may persist for several weeks if the child is not treated. The natural course of disease is for the inflammation to subside and the discharge to become scant and seropurulent. Infection may resolve spontaneously but occasionally may persist until the girl reaches puberty.

Prepubertal vulvovaginitis can be caused by numerous irritative and infectious agents, including pinworms, foreign bodies, group A streptococci, *Neisseria meningitidis*, *Neisseria sicca*, and *Moraxella catarrhalis* (see also Chapter 48). Vulvovaginitis can mimic urinary tract infection, and pyuria can be seen on urinalysis with gonococcal and other causes of vulvovaginitis.[128,207]

Although ascending infection seldom occurs, it may result in salpingitis or peritonitis. One study found that 10 percent of girls with gonorrhea had signs compatible with peritonitis, including fever, diffuse abdominal pain, leukocytosis, and decreased bowel sounds.[46] Salpingitis and periappendicitis may cause findings similar to those of appendicitis. Therefore, perineal examination for vaginal irritation or discharge should be done before performing abdominal surgery in young girls.[12]

In children with gonorrheal infection of the genitourinary tract, concomitant anorectal and tonsillopharyngeal colonization is a common findng[240] because sexual abuse usually is the means of infection.

LOWER GENITAL TRACT INFECTION IN POSTMENARCHEAL FEMALES

Gonococcal infections in adolescent girls are similar to those in adults. The endocervix is the primary site of urogenital infection, although the external genitalia, urethra, vulvar mucosa, and vestibular glands also may be infected. Symptoms of acute infection usually begin 3 to 5 days after exposure with the development of a profuse, purulent vaginal discharge. The vulvar tissues are inflamed, with resultant pruritus and a burning sensation. Urethritis often is present initially and can lead to dysuria with urinary frequency and urgency. Urethral discharge can be seen but is much less prominent than in males. A purulent discharge from the vestibular and paraurethral glands also may be noted.

The endocervical mucosa is edematous, inflamed, and often friable. A profuse yellow-green discharge is present and detaches easily from the surface. The zone of endocervical ectopy that normally is present in as many as 50 percent of adolescents may appear bright red, does not bleed easily when touched with swabs, and should not be mistaken for cervicitis. Ectopy that appears swollen and friable suggests cervicitis. Nabothian inclusion cysts (transparent and grayish) also are normal findings.

Infection of the Bartholin (major vestibular) gland or paraurethral (Skene) gland ducts may develop during acute gonorrhea. Bartholin gland abscesses appear as large, circumscribed painful swellings of the dorsal aspect of the labium minus (see Fig. 48–12). They occur in 5 percent of females with endocervical gonorrhea.[269] Paraurethral duct abscesses (see Fig. 48–11) appear as small painful swellings in the urethrovaginal septum and may cause dysuria. Rupture into the urethra can create a urethral diverticulum. Bartholin gland or paraurethral duct abscesses should be incised and drained, but small asymptomatic nodules do not require drainage.

If the gonococcal infection goes untreated, the acute symptoms generally subside in 8 to 10 weeks. Persisting acute symptoms are more likely to represent reinfection than chronic infection. Chronic urethritis, thickening of the vestibular glands and paraurethral ducts, and chronic cervicitis can occur. A secondary nonspecific vaginitis can develop as a result of irritation of the mucosa from persisting profuse endocervical discharge.

Mucopurulent cervicitis can be caused by *N. gonorrhoeae*, *C. trachomatis*, *Gardnerella vaginalis*, *Mycoplasma hominis*, *Ureaplasma urealyticum*, and group B streptococci. The overlap in clinical manifestations of infections caused by these microbes and the frequency of infection by two or more simultaneously preclude establishing the diagnosis by clinical findings alone.

Adolescents may be unaware of their infection, especially if they have a preexisting profuse discharge as a result of nonspecific vaginitis or trichomoniasis. Early recognition and treatment of lower genital tract gonococcal infection may prevent extension to and complications of upper genital tract infection. Therefore, sexually active adolescent females should be examined for gonococcal infection as part of their routine health care.[158,286]

A review of reported complications in 1232 cases of gonococcal vaginitis in the pre-antibiotic era revealed that 35 percent had urethritis, 19 percent had proctitis, and 6 percent had peritonitis.[21]

Urinalysis may provide clues to gonococcal infection in some cases. In a cross-sectional study of 296 sexually active females 14 to 22 years of age, gonorrhea or trichomoniasis was present in 65 percent who had sterile pyuria.[168]

UPPER GENITAL TRACT INFECTION IN POSTMENARCHEAL FEMALES

PID will develop in 10 to 17 percent of females with endocervical gonococcal infection. Conditions encompassed by the term PID include endometritis, parametritis, salpingitis, oophoritis, tuboovarian abscess, and pelvic peritonitis. PID can be caused by a variety of bacteria. Anaerobes, including *Bacteroides*, *Peptococcus*, and *Peptostreptococcus* spp., are the organisms usually recovered. *N. gonorrhoeae* is present in 25 to 50 percent of cases, similar to the proportion of cases from which *C. trachomatis* is recovered. Coliform organisms, *G. vaginalis*, *M. hominis*, *U. urealyticum*, and various streptococcal species also may be involved. PID develops when these organisms are able to ascend into the uterus, fallopian tubes, and beyond from the lower genital tract. Multiple species may be involved in a single episode. Gonococcal PID often occurs during or just after menses.[130,161] Identification of the specific microbial cause or causes of PID is complicated by the difficulty of obtaining fallopian tube specimens before initiating therapy.

Common findings in PID include an acute onset of lower abdominal pain with tenderness, fever, tenderness on lateral motion of the cervix, adnexal tenderness that generally is bilateral, and adnexal fullness. Vaginal discharge, urinary symptoms, and irregular vaginal bleeding also may be present. In moderate to severe cases, abdominal pain frequently is bilateral, exacerbated with movement, and continuous. Nausea, vomiting, marked abdominal tenderness, an abdomen that appears tense, and fever exceeding 39° C may be present. Such patients often appear to be ill and may have tachycardia consistent with the height of fever.[294] Leukocytosis and elevated erythrocyte sedimentation rates are common findings. Alternatively, PID may be clinically silent or cause only mild pain without discernible tenderness, vaginal discharge, or leukocytosis. Such mild cases can go unrecognized by patients and physicians.

Establishing the diagnosis of PID may be difficult, and the differential diagnosis includes numerous other lower abdominal conditions such as appendicitis, ectopic pregnancy, cholecystitis, mesenteric adenitis, pyelonephritis, and septic abortion. Sonography and pregnancy testing may be helpful in diagnostic decision making. No single symptom, sign, or laboratory finding is sensitive and specific for the diagnosis of PID. Combinations of findings can improve the sensitivity but do so at the expense of reduced specificity, and vice versa.

Initiation of empiric therapy for PID should be considered if the minimal criteria of lower abdominal tenderness, adnexal tenderness, and cervical motion tenderness all are present and no other cause for these findings is readily apparent. More elaborate evaluation may be needed in some cases because incorrect diagnosis and management might lead to unnecessary morbidity. Additional criteria that support the diagnosis of PID include an oral temperature higher than 38.3° C (101° F), an abnormal cervical or vaginal discharge, elevated erythrocyte sedimentation rate, increased C-reactive protein level, and laboratory documentation of cervical infection with *N. gonorrhoeae* or *C. trachomatis*. Some cases may require pursuit of definitive criteria for diagnosing PID, which include histopathologic evidence of endometritis on endometrial biopsy, transvaginal or abdominal ultrasonography or other imaging studies that show thickened fluid-filled fallopian tubes with or without free pelvic fluid or a tubo-ovarian abscess, and laparoscopic abnormalities consistent with PID.[59,176]

The outcome for fertility probably is improved with prompt and vigorous therapy. In the past, physicians have recommended that all adolescents suspected of having PID be hospitalized for therapy. More recently, inpatient observation and treatment have been recommended when a surgical emergency (e.g., ectopic pregnancy or appendicitis) cannot be excluded; when compliance with or tolerance of an outpatient treatment regimen and follow-up within 72 hours cannot be ensured; when the illness appears to be severe (e.g., pelvic or tubo-ovarian abscess, overt peritonitis); or when the patient is immunocompromised, is pregnant, or has failed to respond to outpatient therapy.[5] All courses of therapy should include treatment that is appropriate for *C. trachomatis* and other causes of PID, in addition to *N. gonorrhoeae*.

Complications of PID include tubo-ovarian abscess, perihepatitis (Fitz-Hugh-Curtis syndrome), future ectopic pregnancy, and infertility. Perihepatitis is characterized by right upper quadrant abdominal pain that may radiate to the shoulder. Nausea, fever, and other symptoms and signs of PID may be present as well. Leukocytosis occurs commonly, and liver enzymes are elevated in some cases. The differential diagnosis of perihepatitis includes pleuritis, cholelithiasis, subphrenic abscess, and perforated ulcers.[206]

An estimated 15 percent of women may become sterile after a single episode of PID and 50 percent after three infections. Because of scarring and fibrosis in the fallopian tube, patency is compromised and fertility is jeopardized.[53,120,121] PID in adolescents is particularly likely to result in infertility and ectopic pregnancy, and PID is the single most common cause of infertility in young women.[43,231] Between 1970 and 1980, the rate of ectopic pregnancies per 1000 live births increased from 4.8 to 14.5, and between 1975 and 1981, the rate of hospitalization of females 15 to 19 years of age for salpingitis was 4 per 100,000.[330] These increases correlated with rising rates of gonococcal infection in the affected populations. Data from several studies of gonococcal disease in adolescents are presented in Table 100–4.

Risk factors for the development of PID include young age at the time of acquisition of gonococcal disease or other STDs, a history of previous PID, multiple sexual partners, and the use of an intrauterine device (IUD) for contraception. The immature cervix may be at particular risk for progression to upper tract disease.[302] Disseminated gonococcal infection may accompany asymptomatic infection of an IUD,[84] and the rate of acute PID in those who use IUDs may be increased.

GENITAL TRACT INFECTION IN MALES

Gonococcal urethritis in prepubertal boys is a less frequent event than is vaginitis in girls because of gender differences in rates of sexual abuse. In children with gonorrheal infection of the genitourinary tract, concomitant anorectal and tonsillopharyngeal colonization is a frequent finding.[240]

Urethritis is the primary manifestation of gonococcal infection in males of all ages beyond the neonatal period. Even in young boys, the disease usually is symptomatic and resembles gonococcal urethritis in men.[95,132] Dysuria, purulent discharge, or both develop 2 to 7 days after exposure. Patients generally are afebrile. Purulence typically is greater than with nongonococcal urethritis, but symptoms often are mild enough that patients (or their parents) may delay seeking medical care for weeks. Associated inguinal adenopathy occurs rarely.

At least 5 percent of cases of gonococcal urethritis in males are asymptomatic, and asymptomatic infection can occur at all ages. Asymptomatic pyuria is a manifestation with which the pediatrician should be familiar.[100] It may be the only finding in some cases and should raise suspicion of gonococcal or chlamydial infection in boys who may have been sexually abused or in sexually active adolescent males.

Males with asymptomatic infection are a major reservoir for transmission to their sexual partners.[100,125] Untreated male urethral infection may persist for as long as 6 months.

Complications of gonococcal infection in males now occur much less frequently than in the pre-antibiotic era. Epididymitis is the most common complication. Unilateral swelling, pain, and erythema in the posterior aspect of the scrotum are the usual features. Fever may occur. If untreated, the infection may progress to involve the ipsilateral testis. Hydrocele may result from secretion of fluid into the potential space of the tunica vaginalis. Epididymitis can lead to testicular infarction, abscess, infertility, prostatitis, paraurethral abscesses, and penile lymphangitis, but these local complications are rare findings. Perihepatitis in males has been described but occurs extremely infrequently.[194]

TABLE 100–4 Prevalence of Gonorrhea and Other Sexually Transmitted Diseases in Clinics for Adolescents

Reference	Location	Total Clinic Population Studied	Gonorrhea (%)	*Chlamydia* Infection (%)	Other

DISSEMINATED DISEASE

Dissemination requires invasion of the bloodstream from local infection of the mucous membranes of the genital tract, rectum, pharynx, or conjunctiva. Bacteremia then can lead to infection of other sites. The risk of dissemination in children after mucosal infection appears to be higher than the 1 to 3 percent rate in adults. Dissemination in adults seems to be more common with asymptomatic infections, many of which are caused by AHU$^-$ gonococcal strains (see "Pathogenesis" earlier).[189] Deficits in the complement system have been associated with disseminated disease in adults, but the frequency of such deficiencies in children is unknown.

As in neonates, gonococcal arthritis is the most common form of disseminated disease in older children, adolescents, and adults. The ankles, knees, wrists, and hands are involved most frequently. The clinical findings are not distinct from those of other microbial causes of septic arthritis. Polyarticular involvement occurs less frequently than in neonates.[93] Gram stain and synovial fluid cultures often are negative. Therefore, empiric coverage for *N. gonorrhoeae* must be considered when septic arthritis develops in a sexually active adolescent or a child who may have been sexually abused.

Typically, the patient has a single most severely affected joint, and associated myositis and tenosynovitis may be prominent findings. Gonococcal arthritis in older children and adolescents resembles that in adults and may be accompanied by cutaneous lesions (Fig. 100–5).[4] Osteomyelitis rarely occurs but has been reported in all age groups, usually in association with septic arthritis.[9]

Treatment of gonococcal arthritis depends on prompt recognition of the disease. Cultures of all mucous membranes (nasopharyngeal, rectal, vaginal or endocervical, conjunctival), blood culture, and aspiration of the involved joint should be performed. The local signs of gonococcal arthritis may not respond to antibiotic therapy for several days. Serial needle aspiration rather than open drainage usually is sufficient for relief of pain and recovery without sequelae (the hip may be an exception).

Gonococcemia is clinically silent generally but can cause a syndrome of migratory polyarthralgia, fever, and rash that precedes the onset of arthritis by several days to a week. The symptomatic course normally is only mild to moderate in severity. Blood cultures often are negative by the time that care is sought. Gonococcemia-related symptoms may resolve after several days, even without treatment. Rare cases can resemble meningococcemia with purpura and fulminant sepsis with disseminated intravascular coagulopathy. These cases sometimes can be fatal.[253]

The skin lesions associated with gonococcemia usually are pustules on an erythematous base (Fig. 100–5), but petechiae, papules, and hemorrhagic bullae can develop. The development of skin lesions in conjunction with septic arthritis also has been called the arthritis-dermatitis syndrome. The lesions usually arise on the extremities and are fewer than 20 in number. Low-grade fever is most common, but high fever with shaking chills may occur. Tenosynovitis is present in a fourth of these patients. Leukocytosis, pyuria, and elevated liver enzyme test results may be seen. The resultant septic joints generally become clinically apparent during the second week after the onset of disseminated infection.

ANORECTAL GONORRHEA

Gonococcal anorectal infection (proctitis) frequently is asymptomatic but can be associated with pruritus, tenesmus, purulent discharge, or rectal bleeding. Rectal infection can occur as a result of rectal intercourse or inoculation from vaginal secretions. Approximately 40 percent of females with genital gonococcal infection have positive anorectal cultures. Rectal infection is an unusual finding in males who have not engaged in rectal intercourse.[311]

PHARYNGEAL GONORRHEA

Pharyngeal gonococcal infection in all age groups beyond the neonatal period is acquired by orogenital contact. Pharyngeal gonorrhea may be asymptomatic, without evidence of inflammation, or may cause an exudative tonsillopharyngitis that can mimic group A streptococcal or viral infection. Cervical adenopathy also may be present in some cases. In sexually abused children, the pharynx may be the only site of infection. It may be the sole culture-positive site in some cases of disseminated gonococcal infection, and pharyngeal infection possibly is a factor predis-

Figure 100–5 Skin lesion typical of the arthritis-dermatitis syndrome of disseminated gonococcal infection: necrotic pustule with an erythematous halo. *(Courtesy of Daniel P. Krowchuk, M.D.)*

posing to dissemination. Pharyngeal infection usually resolves spontaneously within 10 to 12 weeks but should be treated when recognized.

Throat cultures for *N. gonorrhoeae* should be considered in sexually active adolescents with pharyngitis, asymptomatic orogenital contacts of infected persons, patients with disseminated disease in whom other sites of initial infection are not readily apparent, and children who have been sexually abused.

Current treatment regimens for genital gonococcal infection are effective in eradicating gonococcal infection from the pharynx. Routine throat cultures for screening all sexually active adolescents are not cost-effective, but throat culture may be considered for those who give a history of frequently engaging in orogenital sexual activity.*

CONJUNCTIVITIS BEYOND INFANCY

Gonococcal ophthalmia occasionally is seen in children and adults. Direct inoculation of the eye can occur as a result of transmission of fomites from infected persons. Clinical findings typically include a profuse purulent discharge, chemosis, eyelid edema, keratitis, and fever. The initial ocular discharge may be watery before turning purulent. The acute phase may mimic orbital cellulitis. Untreated infection, as with neonates, can lead to corneal opacification, ulceration, and rupture of the globe with resultant visual loss. Some cases may be minimally symptomatic with a minimal inflammatory response and spontaneous resolution.[203,207,261]

OTHER FORMS OF GONOCOCCAL DISEASE

Gonococcal meningitis is a rare condition that may occur with or without associated signs of gonococcemia or septic arthritis. Pyomyositis of the biceps and soft tissue abscesses remote from the genital area have been reported. A gonococcal abscess arising in an area of blunt trauma to a hand has been described in an adolescent with associated endocervical infection.[137] Ventriculoperitoneal shunt–associated infection, endocarditis, and myocarditis caused by *N. gonorrhoeae* have been reported in adults and can be expected to occur occasionally in children and adolescents.[161] These manifestations of gonococcal infection seldom are seen in children.

DIAGNOSTIC TESTING

Isolation of *N. gonorrhoeae* in culture remains the standard for diagnosing gonococcal infection, but non-culture, DNA-based tests have become widely used in recent years. Uses of these tests are listed in Table 100–5. Only culture should be used for rectal or pharyngeal specimens. Serologic tests based on complement fixation, latex agglutination, enzyme-linked immunosorbent assays, and other techniques have been developed, but the sensitivity of these methods is only about 70 percent, which limits their use primarily to studies of immune response and pathogenesis.[160,164,287]

A diagnosis of *N. gonorrhoeae* infection at any site should prompt evaluation for the presence of other common STDs, if not already done[286] (see also Chapter 48).

CULTURE

In adults, culture of clinical specimens is 80 to 95 percent sensitive when promptly inoculated and incubated. Cultures of adult male urethral specimens, blood, and other normally sterile body sites tend to have sensitivities in the higher range.[164] Because false-positive cultures (with appropriate laboratory confirmation; see later) are not thought to occur, specificity and positive predictive values are 100 percent. Culture in adolescents and children probably has sensitivity similar to that of adults. Vaginal specimens are adequate for diagnosis in prepubertal girls, for whom obtaining endocervical specimens is unnecessary.

The use of selective media such as modified Thayer-Martin (which contains nystatin, vancomycin, and trimethoprim, and colistin) is required for culture of endocervical, rectal, and pharyngeal specimens to suppress contaminating flora. Selective or nonselective media (chocolate agar) can be used with equal sensitivity for male urethral cultures. Plating of specimens on both types of media may improve the sensitivity, but the incremental yield is small and probably not cost-effective for routine practice.[30,98,270]

Gonococcal colonies become evident on agar plates within 24 to 48 hours after inoculation. Isolates are considered presumptively positive if Gram stain shows gram-negative diplococci and colonies are oxidase-positive. Further testing that demonstrates the gonococcal phenotypic pattern of acid production from selected carbohydrates or a positive result by a nucleic acid method (or both; see later) is required for confirmation as *N. gonorrhoeae* (Table 100–5).[63]

Gonococci do not tolerate drying, so clinical specimens must be plated onto appropriate media as soon as possible. Transport bottles containing medium and a CO_2-enriched atmosphere should be used if definitive specimen processing will be delayed. Transport bottles should be maintained upright during inoculation to preserve the CO_2 atmosphere.

In sexually active females with endocervical gonococcal infection, the urethra, Bartholin gland ducts, and Skene gland ducts usually are infected also. Cultures of these sites may improve the overall yield/sensitivity, in part by avoiding the sampling errors that can occur with any single culture. However, the incremental yield is small enough to render obtaining such cultures unnecessary in routine clinical settings. Culture of the rectum and pharynx in females can be considered optional except when evaluating for sexual abuse.[30,182]

In sexually active males, sites to be cultured depend on the sexual practices and the anatomic sites exposed. Among MSM, rectal infection occurs almost as frequently as urethritis, and pharyngeal infection is not an uncommon finding.[36,164,217,227]

GRAM-STAINED SMEARS

In symptomatic males, a Gram stain of a urethral specimen that demonstrates polymorphonuclear leukocytes with intracellular gram-negative diplococci can be considered diagnostic of infection with *N. gonorrhoeae*. Gram stain in this population has greater than 99 percent specificity and greater than 95 percent sensitivity.[64] Negative Gram stain results are not sufficient to exclude the diagnosis of gonorrhea. Although nonpathogenic *Neisseria* spp. and *N. meningitidis* are morphologically indistinguishable from gonococci, the former rarely are cell-associated.

Gram stains of endocervical, pharyngeal, and rectal specimens are not recommended because of lower sensitivity in detection of infection at these sites. The specificity of a negative Gram stain appears to be at least 95 percent for specimens from the endocervix and rectum.[164,282]

Gram stains of eye exudates, joint fluid, and pustular fluid should be performed because the presence of gram-negative diplococci may help guide initial therapeutic interventions pending culture results.

*See references 1, 41, 73, 94, 104, 147, 165, 240, 250, 301, 335, 339.

TABLE 100–5 Laboratory Testing of Specimens for the Presence of *Neisseria gonorrhoeae*

Clinical Indication for Testing	Testing Method and Specimen Type
Suspected female genitourinary tract infection	1. Culture performed on an endocervical swab specimen (adolescents or adults) or vaginal swab specimen from prepubescent females* *If transport and storage conditions are not conducive to maintaining the viability of* N. gonorrhoeae, *a nucleic acid amplification test (NAAT) or nucleic acid hybridization test (NAHT) can be performed on an endocervical swab specimen*† (NAAT or NAHT generally is not acceptable for prepubescent children undergoing evaluation for sexual abuse) 2. NAAT performed on urine (generally not acceptable for prepubescent children undergoing evaluation for sexual abuse)
Suspected male urethral infection	1. Culture performed on an intraurethral swab specimen if collecting such a specimen is acceptable and transport and storage conditions are suitable for culture†,‡ 2. Gram stain of urethral discharge (positive if intracellular gram-negative diplococci are seen) 3. NAAT or NAHT performed on an intraurethral swab specimen if collecting such a specimen is acceptable 4. NAAT performed on urine
Suspected male or female rectal or pharyngeal infection	1. Culture performed on rectal or pharyngeal swab specimens* 2. No other tests recommended
Suspected gonococcal ophthalmia (neonatal or childhood) or disseminated infection	1. Culture performed on conjunctival exudate specimens, blood, synovial fluid, cerebrospinal fluid, or pustular skin lesions with the use of nonselective media (e.g. chocolate agar) 2. Gram stain on exudates or fluid samples (synovial, cerebrospinal fluid) can be useful as an initial point-of-care test that can help guide early treatment considerations pending culture results. Should be accompanied by culture
Scenario for Confirmatory Testing	**Recommendations and Comments**
Presumptively positive culture (identification in the laboratory of typical gram-negative, oxidase-positive diplococci consistent with *N. gonorrhoeae*)	1. Preferred methods for confirmation of *N. gonorrhoeae* are (a) acid production from carbohydrates§ or (b) positive NAHT results (use of molecular method to confirm culture results) 2. Requiring both methods to be positive ensures high specificity 3. If an isolate cannot be conclusively identified as *N. gonorrhoeae* at a local laboratory, it should be sent to a reference laboratory for confirmation (especially in cases of alleged sexual abuse, sexual assault, or rape)
Positive non-culture test (e.g., NAAT, NAHT)	1. Culture with confirmation as above is the preferred additional test after a positive non-culture test if specimen transport and storage conditions are suitable. Confirmatory testing is not routinely required unless medicolegal issues exist or there is need for antibiotic susceptibility testing 2. Competitive probe format after a positive NAHT (probe) test, but this approach theoretically is less likely to detect a false-positive result 3. A different NAAT as an additional test after NAAT or NAHT has received limited evaluation; certain NAATs sometimes cross-react with nongonococcal *Neisseria* species 4. Antibody tests that detect gonococcal antigens are not recommended for detection of *N. gonorrhoeae*

**A selective medium (e.g., modified Thayer-Martin) should be used for culture of specimens from these sites.*
†*Transport cultures with an enriched CO_2 atmosphere can be used in some situations.*
‡*Selective or nonselective media may be used.*
§*N. gonorrhoeae produces acid reactions with glucose but not maltose, lactose, sucrose, or fructose. The species also does not reduce nitrates or hydrolyze tributyrin.*
Compiled from Centers for Disease Control and Prevention: Screening tests to detect Chlamydia trachomatis and Neisseria gonorrhoeae infections—2002. M. M. W. R. Recomm. Rep. 51(RR-15):1-38, 2002.

NON-CULTURE DIAGNOSTICS

Non-culture diagnostic tests have become widely used in the United States for establishing a rapid diagnosis of gonococcal (and chlamydial) infection. Many offer the advantage of using urine samples rather than the more invasive swabs and also allow *C. trachomatis* to be evaluated with the same specimen. Numerous gonococcal antigen-detection tests have been developed, but they have been supplanted largely by nucleic acid detection methods.

Nonamplified DNA-DNA hybridization probe tests have been the non-culture tests used most commonly in the United States in recent years. These tests are based on a single-stranded DNA probe complementary to gonococcal rRNA. Sensitivities are about 95 percent (less than culture), with a specificity of 99 percent.[152,164,204,252] Nucleic acid amplification tests (NAATs) use standard PCR-based assay and actually are more sensitive than is culture (Table 100–5). False-positive reactions can occur as a result of the carry-over contamination that occurs during processing or because of occasional cross-reactions with commensal

Neisseria spp. that may be present in some clinical specimens. Specificities are generally greater than 98 percent. False-negative results can occur as a result of target sequence differences (or absence) in some gonococcal clones. NAATs can be used to evaluate first-void urine specimens, which permits screening for gonococcal infection in males and females when genital examination is impractical.[79,256,306,325,327,336]

NAATs and DNA probe tests can detect the presence of nonviable gonococcal microbes, thereby possibly reducing need for the stringent transport conditions often required for culture. Currently available NAATs are multiplex tests that also can detect *C. trachomatis*. NAATs generally are approved by the U. S. Food and Drug Administration for use with endocervical, vaginal, and urethral swab specimens and with urine specimens. They are not approved for rectal or pharyngeal specimens—culture remains the best testing method for detecting gonococcal infection at these sites.[64] Some NAATs can be used for conjunctival specimens.[5]

NAATs and DNA probe tests are adequate for rapid screening in clinical settings, and their results are adequate for making treatment decisions and public health case identifications. Culture remains the definitive test for medicolegal purposes (see the next section). In addition, because of ever-increasing resistance to the available antimicrobial agents, monitoring of gonococcal susceptibility by culture is necessary at the local level, at the very least in patients who do not respond to apparently adequate therapy.[63,336]

MEDICOLEGAL ISSUES RELATED TO DIAGNOSTIC TESTS

N. meningitidis and other members of the Neisseriaceae family are morphologically and often biochemically similar to *N. gonorrhoeae* and may be isolated from sites such as the vagina, blood, and nasopharynx.[108,113,337] Accurate identification of *Neisseria* organisms from any pediatric specimen is essential because misidentification of nongonococcal species as *N. gonorrhoeae* may lead to very serious social consequences for children and their families by precipitating concern regarding sexual abuse. Nonculture methods consistently identify more clinical specimens as positive than standard cultures do.[327] Determining whether such results indicate greater sensitivity, increased false positivity, or a combination of both has been difficult.

Because of this potential for obtaining false-positive results with non-culture NAAT or DNA probe tests, culture remains the medicolegal standard for children who require evaluation for suspected sexual victimization, including prepubertal girls with obvious vaginal discharge. Sequential testing using non-culture tests followed by culture if the former is positive has been proposed as a more sensitive approach than is culture alone.[251] Further study of this approach is required before it can be recommended for adoption.

The CDC also has defined three levels of diagnosis based on clinical and laboratory findings. They are more stringent than are the case definitions used for public health surveillance. A *suggestive diagnosis* is defined by presence of mucopurulent endocervical or urethral exudate and sexual exposure to a person with gonococcal infection. A *presumptive diagnosis* requires two of three criteria: (1) typical gram-negative *intracellular* diplococci on a Gram stain of urethral exudate from males or endocervical secretions; (2) growth of apparent *N. gonorrhoeae* from such specimens on culture medium, defined as typical colonial morphology, positive oxidase reaction, and typical gram-negative morphology; and (3) detection of *N. gonorrhoeae* by a non-culture laboratory test. A *definitive diagnosis* requires (1) isolation of *N. gonorrhoeae* from clinical specimens by culture, as in the second criterion for a presumptive diagnosis, and (2) confirmation of identity by biochemical, enzymatic, serologic, or nucleic acid testing (Table 100–5).[71]

PROPER COLLECTION OF CLINICAL SPECIMENS

Urethral exudate from males may be obtained by passing small swabs or bacteriologic loops 2 to 4 cm into the urethra.[155] Endocervical specimens from postpubertal females are obtained by speculum examination with swabs inserted 1 to 2 cm into the external os after the cervix has been cleansed of external exudate and vaginal secretions.[278] The swab should be rotated one full revolution and withdrawn. Self-obtained vaginal swabs also provide adequate specimens for non-culture methods.[305] This technique has been studied in adolescents. Vaginal specimens collected with tampons also can be used with non-culture methods.[321]

In prepubertal girls, cultures can be obtained from the vaginal introitus by gently swabbing the hymenal opening. Deeper insertion is not necessary. Swabs of exudates emanating from the urethral meatus or vaginal orifice also are sufficient for culture.

In persons with symptomatic anorectal infection, rectal specimens should be obtained by anoscopic means, which increases the sensitivity. In asymptomatic persons, rectal specimens can be procured by blindly inserting a swab 2 to 3 cm into the anal canal and applying lateral pressure to avoid entering any fecal mass. Swabs that are grossly contaminated with fecal matter should be discarded.[101,340]

When urine specimens can be used for non-culture methods, the first 15 to 30 mL of voided urine should be collected.[212,236] Collection of urine should be delayed at least 1 hour after the most recent void to maximize sensitivity. The posterior pharynx, tonsillar areas, and faucial pillars should be swabbed to obtain adequate specimens for the diagnosis of pharyngeal infection.[164]

ANTIMICROBIAL RESISTANCE AMONG GONOCOCCI

Gonococcal strains have been able to acquire resistance to antibiotics since the first agents were introduced. Sulfanilamide became available in 1936 and represented a major improvement over previous therapies that included local genital irrigation with solutions of silver nitrate or potassium permanganate.[255] Widespread resistance to sulfanilamide occurred by 1944. As successive agents have become available, multidrug-resistant strains are being seen with increasing frequency in many parts of the world. Ongoing analysis of gonococcal isolates for antibiotic susceptibility to the available antimicrobial agents remains essential for maintaining effective empiric therapeutic regimens.

In the 1940s, virtually all gonococcal isolates were highly susceptible to penicillin. Despite a gradual increase in the mean minimal inhibitory concentration (MIC) to penicillin from the mid-1950s through the mid-1970s, almost all strains had penicillin MICs of less than 0.5 μg/mL. This low-level resistance is mediated by alterations at a genetic locus called *penA* that result in modification of its product, penicillin-binding protein 2 (PBP-2). Two other loci designated *mtr*, which encodes an efflux pump that reduces concentrations of multiple antibiotics, and *penB*, which is an allele of *por*, the gene of the porin protein, also mediate low-level resistance to penicillins. *penB* encodes a porin with a mutation that decreases permeability to hydrophilic antibiotics.[134]

In 1976, strains of *N. gonorrhoeae* were discovered that had acquired plasmid-conferring resistance to penicillin through the production of penicillinase (a TEM-1 β-lactamase). These strains were found in many parts of the Far East and London, and in the former they constituted approximately 30 percent of the isolates in some cities. The strains caused the expected spectrum of clinical disease, and treatment with penicillin was not effective. Penicillinase-producing gonococci contain one of two closely related 5.3- or 7.2-kb plasmids (Pc^r) that carry a Tn2 transposon

system. This plasmid appears to have been acquired from *Haemophilus ducreyi*.[8,49,77,258] In 1983, an outbreak of chromosomally mediated, penicillin-resistant (MICs of 2 to 4 μg/mL), non–penicillinase-producing gonococci was reported from North Carolina.[124] Such strains have been seen subsequently in other areas of the country.

Resistance to tetracycline antibiotics emerged in the 1980s and subsequently increased. Three chromosomal loci designated *mtr*, *penB*, and *tet* mediate low-level resistance. High-level resistance to tetracycline is conferred by *tetM*, which resides on a 38-kb plasmid (Tc^r) that is a derivative of the 36-kb conjugal plasmid. *tetM* produces a cytoplasmic protein that protects ribosomes from tetracycline. Tc^r gonococci can transfer this plasmid, as well as Pc^r, efficiently to other gonococcal strains.[228,308]

Spectinomycin resistance was described first in 1987 in U.S. military personnel in Korea. This agent had been introduced as the drug of choice there in 1981 because of high rates of penicillin resistance. Treatment failures actually began to occur in 1983. Resistance is chromosomally mediated and results in alteration of the ribosomal target site of the drug.[31,49] The widespread use of spectinomycin was associated with a decline in the rate of penicillin resistance.[31] Many gonococcal strains in some parts of the world also are resistant to streptomycin.[244]

Ciprofloxacin and other fluoroquinolone antibiotics became widely available for the treatment of gonococcal infection in the 1980s. Low-level resistance to fluoroquinolones is associated with mutations in the DNA gyrase gene *gyrA*, and high-level resistance has been linked to mutations in the topoisomerase gene *parC*.[174] Resistance to these agents has been noted since the early 1990s in areas of Southeast Asia.[126] In Hawaii in 1999, 9.5 percent of isolates were resistant to ciprofloxacin, but resistance elsewhere in the United States remained low at 0.2 percent.[61,62]

By the year 2000, fluoroquinolones no longer were recommended for initial treatment of gonococcal infection in Asia, the Pacific Islands, or Hawaii. In 2002 this recommendation was extended to the state of California and in 2004 to MSM throughout the United States. During the first 6 months of 2006, 13.3 percent of 3005 isolates collected through the CDC's Gonococcal Isolate Surveillance Project (GISP) were resistant to ciprofloxacin (and thus all other quinolone antibiotics). Among gonococcal isolates from MSM and heterosexual males from U.S. states other than California and Hawaii, ciprofloxacin-resistant rates were 30.7 and 5.1 percent, respectively. Therefore, as of April 2007, the CDC no longer recommends the use of fluoroquinolones for the treatment of gonococcal infections in the United States.[67]

In 1986, the CDC initiated the GISP to monitor the antimicrobial sensitivities of *N. gonorrhoeae* in STD clinics in 21 cities in the United States.[56] This system has been expanded to 27 sites.[62,68] In 1989, 13 percent of the *N. gonorrhoeae* isolates evaluated were resistant to penicillin, tetracycline, or both.[57] In 1999, such strains accounted for 28 percent of all isolates.[62] Rates of resistance to these two agents have fallen slightly in the United States since that time, with 9 percent being resistant to penicillin and 17 percent resistant to tetracycline in 2005.[68]

Strains resistant to azithromycin and erythromycin have been identified in the United States.[61] The distribution of azithromycin MICs has shifted upward in the last decade, although the proportion of strains that probably were resistant in 2005 was less than 3 percent.[68] Rifampin resistance is also high in some areas of the world.[244]

TREATMENT

Because of ever-changing gonococcal susceptibility patterns and variations in susceptibility in different international regions, practitioners must remain alert for modifications of treatment guidelines for their respective geographic locations. Indeed, based on the current patterns of antimicrobial resistance in prevalent *N. gonorrhoeae* strains in the United States, extended-spectrum, third-generation cephalosporins are the only remaining antibiotics routinely recommended as initial therapy in children and adults as of April 2007.

The recommendations for treatment of childhood gonorrhea in the United States discussed in this section and listed in Tables 100–6 and 100–7 are based on 2006 guidelines from the CDC[64,67,69] and the 2006 Report of the Committee on Infectious Diseases of the American Academy of Pediatrics.[5] The CDC guidelines are based on the stringent clinical efficacy criterion of an expected

TABLE 100–6 Treatment of Gonococcal Infections in the Neonatal Period

Disease Category	Treatment Regimen	Comments
Infants born to mothers with gonococcal infection	Ceftriaxone, 25 to 50 mg/kg IV or IM, not to exceed 125 mg (single dose) *or* Cefotaxime, 100 mg/kg IV or IM (single dose)	Ceftriaxone should be given cautiously to hyperbilirubinemic infants, especially premature ones
Gonococcal ophthalmia neonatorum (GON) or other focal sites of infection (i.e., rectum, pharynx, vagina, urethra)	Ceftriaxone, 25 to 50 mg/kg IV or IM, not to exceed 125 mg (single dose) *or* Cefotaxime, 100 mg/kg IV or IM (single dose)	Infants with GON should receive eye irrigation with saline solution immediately upon recognition and at frequent intervals subsequently until the discharge is eliminated Topical agents alone are inadequate and unnecessary when recommended systemic antibiotics are given Some experts prefer to continue parenteral therapy with one of these agents until blood (with or without cerebrospinal fluid) cultures have been negative for 48 to 72 hours
Disseminated gonococcal infection (septic arthritis, sepsis, meningitis) or scalp abscess	Ceftriaxone, 25 to 50 mg/kg IV or IM once daily for 7 days (10-14 days for meningitis) *or* Cefotaxime, dosed according to neonatal algorithms, IV or IM for 7 days (10-14 days for meningitis)	Cefotaxime is preferred for infants with hyperbilirubinemia who require more than a single dose of therapy If meningitis is present, higher doses in the recommended ranges may be needed

Data largely compiled from Centers for Disease Control and Prevention: Sexually transmitted diseases treatment guidelines 2006. M. M. W. R. Recomm. Rep. 55(RR-11):1-94, 2006; and American Academy of Pediatrics: Gonococcal infections. In Pickering, L. K. (ed.): 2006 Red Book: Report of the Committee on Infectious Diseases. 27th ed. Elk Grove Village, IL, American Academy of Pediatrics, 2006, pp. 301-309.

TABLE 100–7 Treatment of Gonococcal Infections in Children beyond the Neonatal Period*,†

	Prepubertal Children Who Weigh <100 lb (45 kg)	Patients ≥8 Years Old and Who Weigh >100 lb (45 kg)
Uncomplicated Gonococcal Infections‡		
Vulvovaginitis Endocervicitis Urethritis Proctitis Pharyngitis	Ceftriaxone, 125 mg IM in a single dose *Alternative regimen* Spectinomycin,§ 40 mg/kg (maximum, 2 g) IM in a single dose (Cefixime has been used by some experts because it can be administered orally. There are no published data regarding safety or efficacy for this purpose)	Ceftriaxone, 125 mg IM in a single dose¶ *or* Cefixime,¶ 400 mg orally in a single dose *Alternative regimens* Spectinomycin,§ 2 g IM in a single dose *or* Single-dose cephalosporin regimens (see Note)
Conjunctivitis**	Ceftriaxone, 50 mg/kg (maximum, 1 g) IM in a single dose	Ceftriaxone, 1 g IM in a single dose
Disseminated Gonococcal Infection††,‡‡		
Arthritis, sepsis Arthritis-dermatitis syndrome	Ceftriaxone, 50 mg/kg/day (maximum, 1 g/day) IV or IM once a day for 7 days§§	Ceftriaxone, 1 g IV or IM every 24 hours for 24-48 hours after clinical improvement, followed by cefixime, 400 mg twice daily orally, or cefpodoxime, 400 mg twice daily orally to complete at least 7 days of total antimicrobial therapy§§ *Alternative regimens* Cefotaxime, 1 g IV every 8 hours, or ceftizoxime, 1 g IV every 8 hours, with switch to oral therapy and duration as for ceftriaxone§§ *or* Spectinomycin, 2 g IM every 12 hours *or* Fluoroquinolones if antimicrobial susceptibility can be documented by culture¶¶
Meningitis Endocarditis	Ceftriaxone, 50 mg/kg/day (maximum, 2 g/day) IV or IM given every 12 hr; for meningitis, the duration is 10-14 days; for endocarditis, the duration is at least 28 days	Ceftriaxone, 1-2 g IV every 12 hr; for meningitis, the duration is 10-14 days; for endocarditis, the duration is at least 28 days
Epididymitis		Ceftriaxone, 250 mg IM in a single dose
Treatment of potential concurrent *C. trachomatis* infection that has not been ruled out†	Azithromycin, 20 mg/kg (maximum, 1 g) in a single dose *or* Erythromycin base or ethylsuccinate, 50 mg/kg/day (maximum, 2 g/day) in 4 divided doses for 14 days	Doxycycline,¶¶ 100 mg orally twice a day for 7 days *or* Azithromycin, 1 g orally in a single dose

Note: Other single-dose cephalosporin therapies that are considered alternative treatment regimens for uncomplicated urogenital and anorectal gonococcal infections include ceftizoxime, 500 mg IM, or cefoxitin, 2 g IM, administered with probenecid, 1 g orally, or cefotaxime, 500 mg IM. Some evidence indicates that cefpodoxime, 400 mg, and cefuroxime axetil, 1 g, might be adequate oral alternatives. Ceftriaxone and cefixime are preferred.

**See text for discussion of treatment options for patients with allergies to the recommended regimens.*

†In addition to the recommended treatment of gonococcal infection, therapy for Chlamydia trachomatis is recommended because of the common occurrence of co-infections with these microbes.

‡Hospitalization should be considered for children (1) who are unlikely to receive the prescribed treatment because of personal or parent/guardian failure to adhere to the regimen or (2) whose infection has not responded to outpatient therapy.

§Spectinomycin currently is not available in the United States. This agent is not recommended for the treatment of pharyngeal infections. If spectinomycin must be used for pharyngeal infection, follow-up cultures should be performed.

¶Alternative regimens for uncomplicated infections include spectinomycin (2 g IM in a single dose), ceftizoxime, cefotaxime, cefotetan, and cefoxitin. Spectinomycin is not recommended for pharyngitis.

¶Experience in adults suggests that cefixime can be considered for use in children with uncomplicated gonococcal infections, but few data are available to confirm its effectiveness for gonococcal infections in children.

***Eyes should be lavaged with saline initially and at regular intervals until secretions no longer continue to accumulate.*

††Hospitalization is required. For older children and adolescents, parenteral therapy can be discontinued 24 to 48 hours after improvement occurs and the 7-day course completed with an appropriate oral antimicrobial agent. Cefotaxime also can be used for disseminated infections in children.

‡‡Persons with disseminated gonococcal infections also should receive one of the age-appropriate regimens for treatment of possible C. trachomatis co-infection listed in this table as part of treatment for persons with uncomplicated gonococcal infections.

§§Some experts advise a 10- to 14-day course of therapy for gonococcal sepsis or septic arthritis.

¶¶Fluoroquinolones are no longer recommended in the United States because of an increasing prevalence of antibiotic-resistant strains. Ciprofloxacin, ofloxacin, and levofloxacin are acceptable for use in adults and adolescents when gonococcal isolates have documented susceptibility. These agents generally are not used in children but may be considered depending on clinical circumstances and susceptibility of the infecting strain. Quinolones are contraindicated for women who are pregnant or nursing.

¶¶Doxycycline is not recommended for routine use in children younger than 8 years.

Data from Centers for Disease Control and Prevention: Sexually transmitted diseases treatment guidelines 2006. M. M. W. R. Recomm. Rep. 55(RR-11):1-94, 2006; Centers for Disease Control and Prevention: Updated recommended treatment regimens for gonococcal infections and associated conditions—United States, April 2007. Available at http://www.cdc.gov/std/treatment/2006/updated-regimens.htm *(accessed May 2007); and American Academy of Pediatrics: Gonococcal Infections.* In *Pickering, L. K. (ed.): 2006 Red Book: Report of the Committee on Infectious Diseases. 27th ed. Elk Grove Village, IL, American Academy of Pediatrics, 2006, pp. 301-309.*

95 percent efficacy with a lower bound of the 95 percent confidence interval of 95 percent or greater.[241] Children who are postpubertal or who weigh more than 45.4 kg (100 lb) may be treated with dosage regimens as defined for adults (including fluoroquinolones for infecting strains known to be susceptible to these agents).[64] The recommended regimens generally have not been studied in populations of prepubertal children with either uncomplicated or complicated gonococcal infection, but these regimens are likely to be highly effective in most cases, as they are for older adolescents and adults.

As of April 2007, recommendations for treating uncomplicated urogenital and anorectal gonorrhea in adolescents and adults in the United States are limited to a single 125-mg intramuscular dose of ceftriaxone or a single 400-mg oral dose of cefixime. Up-to-date information on treatment regimens for gonorrhea and other STDs can be obtained from the CDC website *http://www.cdc.gov/std/treatment*.[67,69]

In adults with an uncomplicated gonococcal infection at any site, 99 percent of cases are cured by ceftriaxone. As a general rule, children treated with ceftriaxone do not require follow-up cultures, but if other treatment regimens are used, follow-up cultures may be indicated. Cefixime has an antimicrobial spectrum similar to that of ceftriaxone. Experience in adults, including pregnant women,[267] suggests that oral cefixime may be considered for the treatment of uncomplicated gonococcal infections in children, provided that follow-up is ensured. The 400-mg oral dose in adults does not provide as high or as sustained a bactericidal concentration as that provided by a 125-mg parenteral dose of ceftriaxone, but clinical trials in adults with uncomplicated gonococcal infection have shown cure rates of 97 percent with cefixime.

Other parenteral cephalosporins that are safe and highly effective against uncomplicated gonococcal infection in adults—and probably in children as well—include cefotaxime, ceftizoxime, cefotetan, and cefoxitin. Some evidence indicates that cefpodoxime and cefuroxime axetil might be adequate oral alternatives in adults,[69] but no data have been reported regarding their use for gonococcal infections in children.

The fluoroquinolone antibiotics ciprofloxacin, ofloxacin, and levofloxacin have been used widely for treating gonococcal infection in adults. Cure rates for uncomplicated gonococcal infection with both agents exceed 98 percent in adults with susceptible isolates. These agents no longer are recommended for routine treatment of gonococcal infections in the United States and many other parts of the world because of substantial resistance rates.[67,69] They remain an option for adults and potentially for children in selected circumstances when the infecting gonococcal strain is known to be susceptible to them.

Resistance to spectinomycin remains rare in the United States, and this compound still is an effective alternative in most cases when other agents cannot be used.[5] However, spectinomycin remains unavailable in the United States at this time. Azithromycin may be useful in circumstances in which patients are unable to take standard regimens because of allergies, pregnancy, or concerns of age-related toxicity (e.g., dental staining with tetracyclines) or when no other alternatives are available.

PRESUMPTIVE TREATMENT OF CONCURRENT *CHLAMYDIA TRACHOMATIS* INFECTION

Persons with gonococcal infection, including children, are at high risk for acquiring concurrent chlamydial infection. Co-infections frequently occur and were present in 50 of 5877 students attending an urban U.S. high school in 1998 to 1999 who participated in a school-based screening program.[245] Among adolescents in 14 U.S. juvenile detention centers from 1997 through 2002, more than 50 percent of the teens with gonorrhea were co-infected with *C. trachomatis*.[183] In adolescents, treatment of gonococcal cervicitis with drug regimens that are effective against gonococci but not *Chlamydia* has been associated with a high incidence of residual salpingitis in females and urethritis in males because of the ongoing presence of *C. trachomatis*.[254,268,271,294]

Therefore, treatment recommendations for gonococcal infections beyond the neonatal period include agents active against both organisms (Table 100–7). Neonates with gonococcal infections also should be evaluated for *C. trachomatis* co-infection. Penicillin, amoxicillin, ceftriaxone, or spectinomycin alone will fail to eradicate *C. trachomatis*. Trimethoprim-sulfamethoxazole, tetracycline, doxycycline, azithromycin, and erythromycin are effective in vitro and in many clinical forms of chlamydial disease.

TREATMENT OF INFANTS BORN TO MOTHERS WITH GONOCOCCAL INFECTION

Infants born to mothers with untreated gonorrhea are at high risk of acquiring infection (e.g., ophthalmia, disseminated gonococcal infection); consequently, even without overt signs of infection, such infants should be treated with a single injection of ceftriaxone (25 to 50 mg/kg intravenously or intramuscularly, not to exceed 125 mg). Ceftriaxone should be given cautiously to hyperbilirubinemic infants, especially premature ones (see Table 100–6). A single dose of cefotaxime (100 mg/kg intravenously or intramuscularly) is an acceptable alternative. Topical prophylaxis for neonatal ophthalmia is not adequate therapy for documented infections of the eye or other sites.

TREATMENT OF NEONATES WITH GONOCOCCAL INFECTION

Neonates with clinical evidence suggestive of gonococcal infection at any site (including the eye) should be evaluated for disseminated disease. The evaluation should include a thorough physical examination, especially of the joints. Exudate from the eyes or other sites of apparent local infection should be sent for Gram stain and culture on appropriate media. Blood and CSF generally should be cultured, and the infant should be admitted to the hospital for parenteral antibiotics and any needed supportive care. Most but not all experts recommend that CSF studies be performed even in afebrile, otherwise well-appearing infants whose only clinical manifestation is apparent GON.

The presence of typical gram-negative diplococci in Gram-stained specimens is sufficient justification to begin treatment of GON or gonococcal infection in other sites. The absence of gram-negative diplococci in Gram-stained specimens is not sufficient to abrogate presumptive treatment of GON in a neonate with conjunctival exudate.

Tests for concomitant *C. trachomatis* infection, HIV infection, and congenital syphilis should be performed in infants with gonococcal infection at any site. The mother and her partners should be evaluated for gonococcal infection (and other STDs) and treated according to the recommendations for gonococcal infection in adolescents and adults (see the next section).

Infants with GON can be treated with a single dose of ceftriaxone (25 to 50 mg/kg intravenously or intramuscularly, not to exceed 125 mg) (Table 100–6). This regimen also may be used for infants with other sites of nondisseminated gonococcal infection, including the rectum, pharynx, vagina, and urethra. A single dose of cefotaxime (100 mg/kg given intravenously or intramuscularly) is an alternative treatment of GON. Some experts prefer to continue parenteral therapy with one of these agents until blood cultures (with or without CSF cultures) have been negative for 48 to 72 hours. Infants with GON also should receive eye

irrigation with saline solution immediately on recognition and at frequent intervals until the discharge is eliminated. Topical antimicrobial agents alone are inadequate and unnecessary when the recommended systemic antibiotics are given.[5,128,198]

Simultaneous infection with *C. trachomatis* should be considered a potential explanation for neonates who do not respond satisfactorily to the recommended treatment.

DISSEMINATED GONOCOCCAL INFECTION OR SCALP ABSCESS. The recommended therapy for gonococcal arthritis, scalp abscess, and sepsis is ceftriaxone (25 to 50 mg/kg intravenously or intramuscularly given once a day) for 7 days or cefotaxime for 7 days (50 mg/kg/day given intravenously or intramuscularly in two divided doses will be adequate for many infants; dose and interval adjustments may be needed depending on gestational and chronologic age and other clinical considerations). Cefotaxime is preferred for infants with hyperbilirubinemia. For gonococcal meningitis, treatment should be continued for 10 to 14 days, with consideration of the use of higher daily doses of these agents (see Table 100–6).

TREATMENT OF GONOCOCCAL INFECTIONS BEYOND THE NEONATAL PERIOD

Treatment recommendations based on weight for uncomplicated and complicated gonococcal infection are outlined in Table 100–7. Treatment recommendations for adolescents are the same as those for adults. For treatment recommendations for PID, see Tables 100–7 and 100–8. All treatment regimens include agents active against *C. trachomatis* in addition to *N. gonorrhoeae*. Treatment issues in a number of circumstances are discussed in more detail in the following text.

UNCOMPLICATED PHARYNGEAL GONORRHEA. Gonococcal infection of the pharynx is more difficult to eradicate than is infection of urogenital and anorectal sites. Chlamydial infection of the pharynx is an unusual occurrence, but genital co-infection may be present. A single dose of ceftriaxone (125 mg, intramuscularly) is the preferred treatment of uncomplicated pharyngeal gonococcal infection. A single dose of an oral fluoroquinolone may be used if the isolate is known to be susceptible to these agents. Spectinomycin is unreliable against *N. gonorrhoeae* in the pharynx; it eradicates the organism in only approximately 50 percent of cases. If spectinomycin is required because of allergies or contraindications to the other recommended treatments, pharyngeal culture should be performed 3 to 5 days after completion of therapy to verify eradication of the infection.

SEVERE ALLERGIES TO CEPHALOSPORINS. Selection of alternative antibiotic therapies for persons with a history of a reaction to a cephalosporin must be guided by the severity of the reaction and the availability of suitable alternative regimens.[63] Azithromycin is probably the best available choice at this time for persons with documented severe allergies to penicillins or cephalosporins.[67,69] If circumstances permit delay in treatment until antibiotic susceptibility test results can be obtained, other agents such as fluoroquinolones or doxycycline may be used if the isolate is shown to be susceptible.

Azithromycin, 2 g orally, is effective against uncomplicated gonococcal infection in adolescents and adults, but it is expensive and frequently associated with gastrointestinal problems. Because of these issues and concern about rapid emergence of resistance, it is not recommended for routine use.[64] A single dose of 20 mg/kg (maximum, 1 g) is recommended for the treatment of chlamydial infection in children, but no dose recommendations for azithromycin are available for the treatment of gonococcal infection in children.[5]

Patients should be observed for at least 30 minutes after the ingestion of a dose of 2 g of azithromycin to monitor tolerance of the medication.[70] An oral dose of 1 g of azithromycin cures approximately 93 percent of uncomplicated gonococcal infections in adults. Though better tolerated, this dose is not sufficiently effective for routine use.

Spectinomycin (40 mg/kg given intramuscularly, with a maximal dose of 2 g) remains effective but no longer is available in the United States. Updated information regarding its potential availability can be obtained from the CDC website *http://www.cdc.gov/std/gonorrhea/org*.

INFECTION WITH HUMAN IMMUNODEFICIENCY VIRUS. Children and adolescents infected with HIV who acquire a gonococcal infection should receive the same treatment as persons without HIV infection.

CONCURRENT SYPHILIS INFECTION. A single dose of ceftriaxone is not adequate for treating syphilis. Longer courses of therapy are required (see Chapter 156). *Treponema pallidum* is not susceptible to fluoroquinolones or spectinomycin.

PREGNANCY. Pregnant women should not be treated with quinolone or tetracycline agents. Those unable to take one of the recommended cephalosporin regimens can be treated with spectinomycin. Azithromycin may be considered if the recommended cephalosporins or spectinomycin cannot be used.

FOLLOW-UP

The recommended regimens have such high cure rates that routine repeat testing for cure no longer is recommended.[59,64,80] Obtaining follow-up cultures may be prudent if alternative thera-

ND, no data.

pies are used or adherence is uncertain. Children who receive treatment regimens other than ceftriaxone or who remain in at-risk environments for reinfection should have follow-up evaluations.[5]

Treatment failures can occur, and cultures should be repeated for antibiotic susceptibility testing when symptoms persist after treatment. This precaution may lead to recognition of an antibiotic-resistant strain that could have public health implications.

Apparent treatment failure usually is the result of reinfection. Reinfection may be associated with a higher risk for PID and other complications of gonococcal infection. Therefore, retesting in 3 months for reinfection (not test of cure) is advisable for sexually active adolescents and adults, regardless of whether patients think that their sex partners have been treated.[64]

GONOCOCCAL INFECTION AND SEXUAL ABUSE OF CHILDREN

When gonococcal infection or any other STD is identified in a prepubertal child or in adolescents who are not sexually active within their peer groups, sexual abuse must be considered to have occurred unless proved otherwise.[5] Nonsexual transmission never should be assumed without extensive investigation of the social setting of an infected child.[5,239] Isolation of *N. gonorrhoeae* in cultures from children should be reported to local public health authorities and also to child protective services to ensure that the child is not exposed to further abuse. Sexual abuse has been reported in approximately 10 percent of all self-reporting populations of girls during childhood in numerous studies, and rates in boys are around 3 percent.[14,284] Approximately 1 percent of children appear to experience serious forms of sexual abuse yearly.[6]

STDs occur in 3 to 20 percent of sexually abused children.[104,171,172,235,277,300,330,335] Gonococcal infections have been found in 5 to 7 percent of sexually abused children.[104] The absence of STDs does not rule out sexual abuse when other findings suggest that it has occurred. Table 100–8 summarizes the STD diagnoses from eight studies involving children who had been evaluated for suspected sexual abuse.

The prevalence and clinical manifestations of gonococcal infection in sexually abused children are determined by the prevalence of infection in the adults who constitute the population with whom the child resides, the age of the child, and the type and frequency of sexual contact.[251] Gonorrhea was the STD recognized most frequently in abused children when gonococcal infection was highly prevalent in the general population. As a result of improved control of gonorrhea in the 1980s, fewer pediatric cases have been recognized in the United States in recent years. Nonetheless, girls who are exposed to an infected male appear to have a high rate of acquired disease. In an outbreak in an orphanage, 53 of 95 abused girls were found to have contracted infection.[2]

Among prepubertal girls who have a vaginal discharge after being sexually abused, 9 to 11 percent have been found to have gonococcal infection. No cases of genital tract gonorrhea without discharge have been reported in prepubertal girls.[171,297,300] The oropharynx also is a common site of gonococcal infection associated with sexual abuse of children and may be the only site of infection in children forced to perform orogenital sexual acts with an infected abuser. Pharyngeal infection may be asymptomatic. Although few children who suffer sexual abuse subsequently contract an STD, the diagnosis of an STD is a very important indication that the child probably has been abused, and an STD may be the sole finding on physical examination.[169]

Children with suspected gonococcal infection (or suspected to have suffered sexual abuse) should undergo a thorough physical examination by someone familiar with the medicolegal and clinical aspects of sexually abused children. Genital, rectal, and pharyngeal cultures should be obtained. Vaginal cultures are satisfactory in prepubertal girls. Endocervical cultures should be obtained only after puberty. Blood culture should be performed if disseminated disease is a consideration. Other sites (conjunctivae, joint fluid) should be cultured if clinically indicated. Cultures should be handled in a manner that will ensure legal acceptance if needed (see later).

Non-culture methods may be used in conjunction with—but not in lieu of—routine cultures to increase sensitivity in detecting gonococcal infection. These test results, when rapidly available, may permit more rapid initiation of therapy than possible with standard culture results.[251]

Selective criteria based on the observations that most sexually abused children do not have gonococcal infection or other STDs and that the vast majority of prepubertal girls with gonococcal infection will have clinical signs of vulvovaginitis have been developed to determine which children undergoing evaluation for sexual abuse should be tested for the presence of gonococcal infection and other STDs.[170,235,297,299,300] These criteria are (1) the known presence of any STD in the child, a sibling, another household member, a close associate of the child, or the apparent perpetrator or (2) a history or physical findings suggesting that oral, genital, or rectal contact has occurred.[170]

It is highly unlikely that a sexually abused child with gonococcal or chlamydial infection will be missed through the use of these criteria. Meanwhile, the number of potentially sexually abused children who must undergo culture is greatly decreased.[170,173] One caveat is that rectal and pharyngeal gonococcal infections in girls and boys and genital infections in boys often are asymptomatic, so these selective criteria may apply only to the issue of vaginal cultures in girls.[57]

All children with gonococcal infections (including neonates) should be evaluated for other STDs, including chlamydial disease, syphilis, hepatitis B, and HIV infection.[5,148,286]

The following are general issues for evaluation and management of children who may have been sexually abused:

1. Many institutions have a clinical service or clinician with training and skill in interviewing and examining children suspected of having experienced sexual abuse. Direct involvement by or consultation with persons with such expertise should be sought at the time of initial evaluation.[249]

2. If the child is symptomatic, all available and appropriate cultures and examinations should be completed before the child receives therapy. Because asymptomatic gonococcal infections occur commonly, strong consideration should be given to obtaining cultures from the rectum and oropharynx, even in the absence of symptoms, especially for children and adolescents who meet the selective criteria described earlier.[29,123,158]

3. A chain-of-custody policy that ensures proper handling, labeling, and delivery of diagnostic samples to the appropriate laboratory is essential for test results to be used in any court procedures when issues of the child's safety are being considered.

4. If sexual abuse is confirmed or suspected by the social history, physical findings, or laboratory results, the child should not be allowed to leave the evaluation site until the child's safety has been ensured. This determination usually is made by the local department of social services and may require involvement of law enforcement agencies. Temporary hospitalization of the child may be needed to permit sufficient time for any additional investigations to be performed. Reporting of suspected and confirmed cases to the social service of the county in which the child resides is required by child abuse reporting laws.

5. Most children who have been victims of sexual abuse will not have specific physical findings. Oral-genital contact is a common form of abuse, as are fondling and external genital contact. These forms of abuse may occur without physical signs of injury.

6. If the child is identified with an STD, other members of the family may be infected as well. Other female children are especially likely to be infected and should be examined.[123,131]

7. Internal pelvic examination of prepubertal children rarely is necessary unless there has been major trauma or there are concerns regarding foreign bodies. Internal examination of prepubertal girls should be performed by an experienced examiner with appropriate sedation or anesthesia.

8. Children often have compelling reasons to deny abuse and frequently do not disclose sexual abuse, even to skillful forensic interviewers.[202] Denial, therefore, is not compelling disproof of sexual abuse.

9. Sexual abuse of children can be a repeated event if the perpetrator has ongoing access to the child. If the child remains unprotected and the perpetrator has an STD, the child may be subject to recurrent episodes of that STD.[201]

10. Counseling with providers skilled in helping children who have been sexually abused should be part of long-term follow-up care. The likelihood of the child having serious emotional harm is greater when abuse has been more intrusive or violent, occurred repetitively over longer periods, or was committed by someone in a close relationship with the child.[85] Parents of victims also may need treatment and support.

11. Behavioral changes such as developmentally unusual sexual behavior or acting out can be a manifestation of child sexual abuse.[129] New onset of symptoms such as abdominal pain (which may lead to medical attention when it becomes persistent), enuresis, encopresis, sleep disturbances, and phobias can be manifestations of child sexual abuse. These issues also can arise from physical or emotional abuse or from non–abuse-related social stressors and do not indicate sexual abuse per se.[85]

PREVENTION AND CONTROL OF GONOCOCCAL INFECTIONS

All gonococcal infections must be reported to public health officials. Effort should be made to evaluate, counsel, and treat all sexual partners who were exposed to the index case within 60 days before the onset of symptoms or diagnosis in the index case. If a patient's last sexual intercourse occurred more than 60 days before the onset of symptoms, the most recent sexual partner of the patient should be evaluated and treated. Patients should be instructed to avoid engaging in sexual activity until therapy is completed and any symptoms have resolved.[69] Cases in prepubertal children must be investigated to identify the source of infection (and potential perpetrator of abuse).[5]

Condoms provide a high degree of protection against the acquisition and transmission of genital gonococcal infection.[181,324] Other barrier contraceptive measures and topical spermicidal and bactericidal agents likewise can reduce the likelihood of acquiring gonococcal (and chlamydial) infection.[15,54,214,316] Postexposure prophylactic antibiotics also reduce the risk of infection developing but are unlikely to be cost-effective.[156]

When patients, including infants with ophthalmia neonatorum,[5] with gonococcal infection are hospitalized, standard precautions are recommended.

PREVENTION OF NEONATAL INFECTION

Pregnant women should have an endocervical culture for *N. gonorrhoeae* as part of their initial prenatal care visit. A second culture late in the third trimester should be performed for those at high risk of exposure during pregnancy. Pregnant adolescents are at higher risk for contracting gonococcal infection than older women are. Treatment options are listed in Table 100–8. Fluoroquinolone and tetracycline antibiotics should not be used during pregnancy because of potential fetal toxicity.[5]

Infants born to mothers known to have active gonococcal infection are at risk of acquiring local and disseminated infection from colonization during birth. Such infants should be treated as listed in Table 100–7. Standard preventive measures for GON were described earlier.

VACCINE DEVELOPMENT

Research into the development of vaccines for gonococcal infection is ongoing. Although natural infection induces antibody responses directed primarily against pili, Opa, porin protein, and LOS, two factors render efforts to use these gonococcal components for vaccines a difficult challenge: (1) the rapid antigenic variation in gonococcal surface proteins and (2) the reality that natural genital infection does not induce a sufficient immune response to prevent later reinfection by the same strain. The development of a gonococcal vaccine shares the difficulties of similar efforts that are under way to produce nonpolysaccharide vaccines effective against serogroup B strains of *N. meningitidis*.[82,242]

Molecular analysis of gonococcal transferring binding proteins (Tbps) may have potential as vaccine antigens because of their exposure on the microbial surface. These proteins are expressed in all strains and have highly conserved gene sequences. Natural infection, however, generates little systemic or local antibody response to Tbps.[264] An oligosaccharide epitope (2C7 OS) of gonococcal LOS that is expressed on most strains and is widely conserved has been identified. A peptide that mimics the structure of 2C7 OS was able to induce antibodies in mice that possess dose-responsive complement-dependent bactericidal activity against $2C7^+$ strains.[242] This approach, as well as the potential use of combinations of recombinant antigens from multiple porin or Opa proteins, may have promise for future gonococcal vaccine development.

Acknowledgment

The author would like to acknowledge the contribution of Dr. Laura Gutman to this chapter through her authorship of this chapter in the first four editions of this textbook.

SUBSECTION 3

Gram-Positive Bacilli

CHAPTER 101

DIPHTHERIA

Ralph D. Feigin ✪ Barbara W. Stechenberg ✪ Pratip K. Nag

Diphtheria is an acute infectious disease caused by *Corynebacterium diphtheriae* or, less commonly, *Corynebacterium ulcerans*. *Corynebacterium pseudotuberculosis*, which primarily causes infections in sheep and goats, is not discussed here because it only rarely causes a diphtheria-like disease in humans. Infection by toxigenic strains of *C. diphtheriae* causes disease that is mediated by the production of an extracellular protein. Nontoxigenic strains also can cause disease, but it is usually less severe.

Before the discovery of antitoxin at the turn of the 20th century, the "strangling angel of children," as diphtheria once was called, was a significant cause of mortality in children and adults.[104] Apparent reference to diphtheria can be traced to the 5th century B.C. in the works of Hippocrates, *Epidemics III*, case 7.[74] In 1821, it was recognized as a specific entity by Brettoneau, who suggested that the disease was caused by a germ and that it could be transmitted from person to person. Brettoneau coined the origin of the modern term *diphtheria* from the Greek root *diphthera*, which means "skin" or "hide."[46] In 1883, the causative agent was identified by Klebs in stained smears from diphtheritic membranes; in 1884, Löffler grew the organism on artificial media and showed that in guinea pigs it caused a fatal infection closely resembling human disease.

The toxin was purified in 1889 by Roux and Yersin, who found that toxin alone could cause the disease. Shortly thereafter, Behring and Kitasato discovered antitoxins when they immunized animals with toxins rather than bacteria. The use of antitoxin to treat children with diphtheria at the turn of the 20th century resulted in one of the largest decreases in mortality rates by a therapeutic intervention. In Germany alone, an estimated 45,000 lives were saved each year.[57]

ETIOLOGY

Corynebacteria (Klebs-Löffler bacilli) are irregularly staining, gram-positive, nonmotile, nonsporulating, pleomorphic bacilli.[49] The club-shaped appearance of the bacillus is not a true morphologic feature, but results from attempting to grow the bacillus on media that are nutritionally inadequate (Löffler media). The organism can be recovered most readily on media containing selective inhibitors that retard the growth of other microorganisms; a sheep blood agar–based medium containing fosfomycin (for selectivity) and Tindale medium (tellurite medium with cystine) are ideal.[39,40] *C. diphtheriae* and *C. ulcerans* grow on

supplement-free blood agar, chocolate agar, and other standard media.[39]

Colonies of *C. diphtheriae* (with the exception of the lipophilic, gray *intermedius*) and *C. ulcerans* appear grayish white on Löffler medium. On tellurite medium, three diphtheria colony types can be distinguished: *mitis*, *gravis*, and *intermedius*. *Mitis* colonies are smooth, black, and convex; they do not ferment starch or glycogen and are hemolytic. *Gravis* colonies are gray, radially striate, and semirough; they ferment starch and glycogen and usually are not hemolytic. *Intermedius* colonies are small and smooth and have a black center; they do not ferment starch or glycogen and are not hemolytic. *C. ulcerans* colonies resemble *gravis* on Tindale medium but differ in that they are hemolytic. Similar to *gravis*, they ferment starch and glycogen. All diphtheria biotypes and *C. ulcerans* are characterized by cystinase activity and absence of pyrazinamidase activity. *C. ulcerans* may be distinguished from *C. diphtheriae* by its urease activity and ability to liquefy gelatin. Biotype *belfanti*, which does not occur in a toxigenic form, may be distinguished from the three potentially toxigenic diphtheria biotypes by its inability to reduce nitrate on Tindale medium and from *C. ulcerans* by its lack of production of urease.[39] Ribotyping and pulsed-field gel electrophoresis, both of which involve restriction digestion of genomic bacterial DNA followed by gel electrophoresis and Southern blotting, permit more specific typing within each diphtheria biotype and aid in the epidemiologic study of outbreaks.[36,91]

C. diphtheriae biotypes *intermedius*, *gravis*, and *mitis* and *C. ulcerans* all have been observed in a toxigenic form. *Intermedius* was the biotype isolated most commonly in the United States between 1971 and 1981. Of the strains isolated, *intermedius* was found to be toxigenic more often than was either *mitis* or *gravis*.[31] In the United Kingdom between 1993 and 1998, and similarly in other parts of Europe, the biovar *gravis* has represented most nontoxigenic isolates, followed by *mitis* and *belfanti*.[40] Of the four nontoxigenic isolates obtained during a surveillance study of a U.S. Northern Plains Native American Community in 1996, two were of biotype *mitis*, and two were *gravis*.[54] According to a United Kingdom diphtheria reference laboratory, between 1993 and 1998, the toxigenic isolates originating from Asia, Africa, and the Middle East were reported to be of the biotype *mitis* or *gravis*, with the exception of one *intermedius* isolate.[40] Golaz and associates[54] reported similar findings when they surveyed the different biotypes in South Dakota. A significant overall increase in the proportion of nontoxigenic isolates has been observed in Europe and Australia in recent years.[52] The reason for this increase is unclear, but one hypothesis is that increased immunity to toxigenic strains secondary to immunization has altered this epidemiology.

The complete genome sequence of *C. diphtheriae* biotype *gravis* has been elucidated.[28] The genome is approximately 2.48 Mb with a G+C content of 53 percent and has approximately 2320 predicted coding sequences. Metabolic analysis of the genome has revealed that *C. diphtheriae* has a complete set of enzymes for glycolysis, gluconeogenesis, pentose-phosphate pathways, anaerobic and aerobic respiration, amino acid biosynthesis, and purine nucleotide biosynthetic pathway. Most of the enzymes for the tricarboxylic acid cycle are present with the exception of an enzyme succinyl–coenzyme A (CoA) synthetase that catalyzes the conversion of succinate to succinyl-CoA. An alternative enzyme present in *C. diphtheriae* may fulfill this conversion, however. The pyrimidine pathway in *C. diphtheriae* lacks an enzyme that interferes with the production of cytidine; the pathway to the biosynthesis of thymidine is complete. The genome has revealed 13 regions that are unique to *C. diphtheriae* and may serve as pathogenicity islands.[28]

No functional or significant differences have been detected in the exotoxins elaborated by the three strains of *C. diphtheriae* or by *C. ulcerans*. Only strains that are lysogenic for beta-prophage or a closely related phage carrying the gene for toxin production produce diphtheria toxin. One or more *tox* gene sequences may exist in the bacterial genome, and the most highly toxigenic strains contain three or more copies.[77] Phage multiplication is not a prerequisite for the production of toxin. The capacity to synthesize toxin depends on genetic and nutritional factors. Toxin-producing cells apparently are cells in which spontaneous induction of the prophage to the phage occurs.[48] The most important factor controlling the yield of toxin is the concentration of inorganic iron in the culture medium.[34] Growth of *C. diphtheriae* in iron-deficient media prolongs the duration of induction lysis and is associated with a high yield of toxin. High concentrations of iron inhibit the production of toxin. Production of toxin also can be increased by the use of ultraviolet radiation. Conversion to a toxigenic strain occurs in nature, as has been shown by restriction enzyme studies of carriers of toxigenic and nontoxigenic strains in Manchester, England.

The ability of a strain of *C. diphtheriae* to elaborate diphtheria toxin can be shown by using several methods. In vivo studies involving necrosis of tissue in guinea pigs has been replaced by the widely used Elek[42] or modified Elek test.[45] Enzyme immunoassay[44] and polymerase chain reaction (PCR)[90] have been used to detect toxigenicity.

Diphtheria toxin is lethal to humans in an amount of approximately 130 μg/kg body weight. Cytoplasmic internalization of one molecule of toxin has been shown to cause cell death.[11] Toxigenic and nontoxigenic strains of *C. diphtheriae* can cause disease, but only strains that produce toxin cause disease with symptoms of myocarditis and neuritis.

EPIDEMIOLOGY

Asymptomatic human carriers serve as the reservoir for *C. diphtheriae*. Infection by *C. diphtheriae* is acquired by contact with either a carrier or an individual with active disease. The bacteria may be transmitted via droplets during coughing, sneezing, or talking. Rarely, transmission of *C. diphtheriae* occurs from skin lesions or fomites. Some reports suggest that skin carriers of *C. diphtheriae* are more infectious than are either nose or throat carriers and that skin carriers may serve as potential reservoirs for the initiation of epidemic spread.[12,63] In areas in which skin infections are endemic, levels of natural immunization may be high.[21] This phenomenon is illustrated particularly well in a survey of tetanus and diphtheria immunity in a rural Kenyan community, where age was not found to be predictive of immunity and no correlation was found between levels of antibody for tetanus and diphtheria.[72]

Person-to-person transmission of *C. ulcerans* is not known to occur, although *C. ulcerans* was isolated from the siblings of two patients reported in the United Kingdom between 1995 and 1997.[18] Cases of respiratory diphtheria caused by *C. diphtheriae* and by *C. ulcerans* have been documented in association with contaminated unpasteurized milk taken from cows with infected teats.[19,55,101] *C. diphtheriae* has been isolated from horses, dogs, and other domestic animals. *C. ulcerans* has been reported to infect ground squirrels in the United States, but transmission to humans has not been reported.[62,89]

According to World Health Organization reports, diphtheria is distributed worldwide and remains endemic in many developing areas of the world, including Asia, Africa, South America, and the Mediterranean regions.[20] Worldwide, diphtheria epidemics have occurred in a cyclical manner since the 16th century. The most recent epidemic began in 1990 in the Russian Federation, Ukraine, and the other newly independent states of the former Soviet Union.[23,103]

In the United States, the incidence and mortality rates from diphtheria in the 1920s were 140 to 150 cases per 100,000, with

13,000 to 15,000 deaths each year. The number of cases gradually declined to 15 per 100,000 population in 1945 with the extensive use of diphtheria toxoid vaccine. From 1970 through 1979, the average number of cases of diphtheria reported annually in the United States was 196.[8] From 1980 to 2004, only 57 cases of diphtheria were reported in the United States. Approximately 75 percent of the cases were in patients older than 15 years who were unimmunized or inadequately immunized.[8] From 1980 to 1995, only four fatal cases involving diphtheria and unimmunized children were reported.[14,83,92] In 1996, *C. diphtheriae* was isolated from a Native American population in South Dakota.[54] Only five cases of diphtheria have been reported since 2000. Maintenance of immunity in adults requires a booster vaccination every 10 years. The Centers for Disease Control and Prevention estimated in the mid-1990s that less than 50 percent of adults in the United States had received their 10-year boosters and that 40 to 50 percent of adults were susceptible to diphtheria.[81,92] In addition, the toxoid vaccine does not provide any protection against nontoxigenic strains.

The incidence peaks during the cooler autumn, winter, and spring months. Several epidemics, primarily in the southern United States, have occurred in late summer and fall and corresponded to a high prevalence of *C. diphtheriae* skin infections. Between the years 1971 and 1981, the incidence of diphtheria was highest in the western United States. A 100-fold greater incidence of diphtheria occurs in Native Americans than in the general population.[31] This difference may be attributable to socioeconomic factors more than to race.

Evidence that diphtheria is diagnosed more frequently in chronic alcoholics and the indigent than in the general population is significant. In a 1993-1994 outbreak in St. Petersburg, Russia, 69 percent of a total of 42 deaths occurred in individuals classified as chronic alcoholics.[94] Between 1972 and 1982, three outbreaks occurred in the indigent alcoholic population living in Seattle's Skid Road.[61] Cutaneous infections accounted for 86 percent of the 1100 total cases. The first outbreak was caused by a single toxigenic *intermedius* biotype clone, whereas the other two involved nontoxigenic *mitis* and *gravis* strains. The incidence was highest in winter and spring.

Native Americans also represent a disproportionate number of diphtheria cases, the reasons for which are unclear, but apparently infection is endemic in some closely knit communities. During 1974 and 1975, 27 percent of Native Americans in the Skid Road population were affected, compared with 5 percent of the white population. In 1996, a surveillance study was conducted in a Northern Plains American Indian community after *C. diphtheriae* was isolated from the skin of a resident of the community. The woman was a chronic alcoholic admitted to the hospital for detoxification and treatment of severe necrotizing leg ulcers, from which a toxigenic *mitis* biotype was isolated. In the following 4 months, 11 positive cultures were obtained from the community: 6 pharyngeal isolates from patients with pharyngitis, 1 ear isolate from a patient with suppurative otitis media, and 4 positive throat swabs from asymptomatic household contacts of the index cases. Of the 11 total isolates, 6 were biotype *mitis* and 5 were *gravis*; 9 isolates were toxigenic or weakly so. The two nontoxigenic isolates were biotype *gravis*. Ribotyping indicated that the isolates were related closely to each other genetically and to strains obtained from past cases from the same area; they were different from organisms obtained from other parts of the United States and from the former Soviet Union, where an ongoing epidemic was occurring at the time.[54,102]

A similar study was conducted in a Koorie (Aborigine) community in Victoria, Australia, in 1994, after three cases of nontoxigenic *C. diphtheriae* endocarditis were diagnosed in the community. After screening 359 asymptomatic (with the exception of 4 people who had chronic skin ulcers swabbed) contacts of the index cases, 12 produced positive cultures for nontoxigenic *C. diphtheriae*. Five of them were of the same biovar *gravis* clone as the three index cases.[64]

A major epidemic began in 1990 in the new independent states of the former Soviet Union and spread throughout the area. Between 1990 and 1997, approximately 150,000 cases of diphtheria were reported, with approximately 4000 fatalities.[60,91] The epidemic was attributed to decreasing immunization rates and immunity in adults and children and to movement of large numbers of people during the collapse of the former Soviet Union.[23,103] Apparently multiple foci of infection existed across the continent. Most of the epidemic isolates from Ukraine and Russia were biotype *gravis*, but further molecular characterization of the *tox* genes from these areas revealed distinct epidemic strains in each location.[65] Superimposed over the steady increase in the number of cases from 1990 through 1994, a seasonal variation typical of the Northern Hemisphere also was observed, with a significant peak in the number of diagnoses occurring in October and November and a trough from April to July.[60]

A mass immunization program was initiated in Russia in 1993, with a resultant 10 percent decrease in the number of new cases reported between 1994 and 1995 (versus twofold to threefold increases in the number of cases each year for the preceding 3 years).[52] The World Health Organization also held training workshops and assembled laboratory kits to assist in establishing the proper diagnosis of diphtheria. As cases also began to appear in Europe with increasing frequency during this period, the European Working Group on Diphtheria (ELWGD) and reference laboratories were assembled to assist in an effort to increase routine screening for diphtheria. The ELWGD since has expanded and currently includes 20 participating countries, including representatives in Western and Eastern Europe, the United States, Australia, and Southeast Asia.[41]

PATHOGENESIS AND PATHOLOGY

Diphtheria is initiated by entry of *C. diphtheriae* into the nose or mouth, where the bacilli remain localized on the mucosal surfaces of the upper respiratory tract. Occasionally, the ocular or genital mucous membranes serve as the site of localization. The bacilli are unable to invade intact skin but may infect preexisting skin lesions. After a 2- to 4-day period of incubation, lysogenized strains may elaborate toxin.

Diphtheria toxin is secreted as a single polypeptide of 535 amino acids with a molecular weight of 58,342 D.[65] The toxin is composed of two subunits: a large B subunit that is involved in receptor binding and an A subunit that is the enzymatically active portion of the toxin. The toxin initially is absorbed onto the target cell membrane by binding a receptor on the cell surface and then undergoes receptor-mediated endocytosis. When it is in the endolysosomal complex, it undergoes a conformational change with subsequent release of the A subunit into the cytoplasm. The A subunit transfers an adenosine diphosphate (ADP)–ribosyl group from nicotinamide adenine dinucleotide (NAD) to elongation factor 2. This ADP-ribosylation inactivates elongation factor 2 and inhibits protein synthesis in the cell. Cholera and pertussis toxins also mediate target protein ribosylation by this mechanism. In addition to the inhibition of cellular protein synthesis, an independent mechanism of cytolysis has been described. In the presence of calcium and magnesium, diphtheria toxin has a nuclease-like activity that causes DNA fragmentation that results in cytolysis.[29,30,65,73]

Marked toxin-mediated tissue necrosis occurs in the vicinity of *C. diphtheriae* colonization and induces a robust local inflammatory response. The inflammatory response coupled with the necrotic tissue produces a patchy exudate that initially can be removed. As the infection progresses, the increased production of toxin causes a centrifugal widening of the area of infection,

and eventually a fibrinous exudate develops. A tough adherent membrane results from coagulation of the exudate. The color of the pseudomembrane initially is white but over the course of time becomes dirty gray. Late in the course of the infection, green or black spots appear on the membrane, representing areas of necrosis. Histologic analysis of the pseudomembrane differs, based on the site of formation and maturation of the membrane. Analysis of the pharyngeal pseudomembrane shows fibrin; inflammatory cells, primarily composed of neutrophils, red blood cells, and colonies of organisms; and superficial epithelial cells.

With severe infections, significant vascular congestion, interstitial edema, fibrin exudate, and intense neutrophilic infiltration develop.[59] Profuse bleeding can occur when the membrane is torn off. The edematous tissue and the diphtheritic membrane may encroach on the airway. The membrane sloughs spontaneously during the recovery period, although sloughing can occur during the acute phase of the illness, leading to aspiration. Occasionally, secondary bacterial infection (classically caused by *Streptococcus pyogenes*) develops. Respiratory embarrassment or suffocation may occur, with involvement of the larynx or tracheobronchial tree. Bronchopneumonia may develop if the exudate enters the small airways and alveoli. Infection of these sites is an uncommon occurrence, however. Infections of the esophagus and stomach, with pseudomembranous lesions indistinguishable from lesions found in the respiratory tract, have been reported.[67]

Toxin produced at the site of infection is distributed throughout the body via the bloodstream and the lymphatics. This distribution occurs most readily when the pharynx and tonsils are covered by a diphtheritic membrane. Any organ or tissue can be damaged as a result of diphtheria toxin, but lesions of the heart, nervous system, and kidneys are particularly prominent. Clinical manifestations appear after a variable latent period of 10 to 14 days for myocarditis and 3 to 7 weeks for manifestations in the nervous system, such as peripheral neuritis. In a study of 102 patients who died of diphtheria caused by *C. diphtheriae*, the hearts appeared dilated, flabby, and pale, with a characteristic "streaky" appearance in the myocardium. The most prominent pathologic findings are necrosis and hyaline degeneration of the myocardium. The myocardium also appears edematous and is infiltrated with mononuclear cells with eosinophilic cytoplasm. In a significant proportion of cases, fatty accumulation in muscle fibers and the conducting system may be observed.[86] Burch and associates[22] showed mitochondrial damage with depletion of glycogen and accumulation of lipid droplets in the damaged myofibrils. Toxin may be observed within the myocardial cells with fluorescent antibody staining.[59] If the patient survives, muscle regeneration and interstitial fibrosis can be seen.

Peripheral neuropathy occurs secondary to *C. diphtheriae* infections. Histologic studies have shown that affected nerves have significant degeneration of myelin sheaths and axons. A toxic neuritis with fatty degeneration of paranodal myelin can be noted early in the disease course; segmental demyelination occurs later.[9] Axonal damage is secondary to the application of external pressure from the swollen Schwann cell cytoplasm and myelin.[76]

C. diphtheriae infections also can lead to necrosis and hyaline degeneration of the liver, which can lead to hypoglycemia. Adrenal hemorrhage and acute tubular necrosis of the kidney also have been known to occur secondary to *C. diphtheriae* infections.[59]

CLINICAL MANIFESTATIONS

The signs and symptoms of diphtheria depend on the site of infection, the immunization status of the host, and whether toxin has been distributed to the systemic circulation. The incubation period is 1 to 6 days (range, 1 to 10 days). Diphtheria can be classified clinically on the basis of the anatomic location of the initial infection and the diphtheritic membrane (nasal, pharyngeal/tonsillar, laryngeal or laryngotracheal, skin, and others) involved. More than one anatomic site may be involved simultaneously.

Nasal diphtheria initially resembles a common cold and is characterized by mild rhinorrhea and a paucity of systemic symptoms. Gradually, the nasal discharge becomes serosanguineous and then mucopurulent. A foul odor may be noticed, and careful inspection reveals a white membrane on the nasal septum. In severe cases, the infection may excoriate the nares and upper lip. Nasal diphtheria is a mild form of the disease because absorption of toxin usually is slow from this site. Frequently, delays in establishing an accurate diagnosis of nasal diphtheria occur because of the lack of systemic symptoms. The nasal form of the disease occurs most often in infants.

Pharyngeal and tonsillar diphtheria begin insidiously with anorexia, malaise, low-grade fever, and pharyngitis. Within 1 or 2 days, a membrane appears. The extent of membrane formation correlates with the immune status of the host; in some partially immune individuals, a membrane may not develop. The white or gray adherent membrane may cover the tonsils and pharyngeal walls and extend on to the uvula and soft palate or down on to the larynx and trachea. Attempts to remove the membrane are followed by bleeding. Cervical lymphadenitis varies. In some cases, it is associated with edema of the soft tissues of the neck and may be so severe that it gives the appearance of a "bull neck." In a 1970 epidemic, "erasure" edema of the neck was noted in patients with pharyngeal diphtheria.[80] Patients with erasure edema did not have a classic bull neck appearance, but the edema was characterized by obliteration of the sternocleidomastoid muscle border, the mandible, and the median border of the clavicle. The edema was brawny, pitting, warm to the touch, and tender to palpation. Erasure edema was noted in 29 percent of immunized patients and 30 percent of nonimmunized or inadequately immunized patients. It occurred most commonly in children older than 6 years and generally was associated with infection by the *gravis* or *intermedius* strain of *C. diphtheriae*.

The course of pharyngeal diphtheria depends on the degree of elaboration of the toxin and the extent of the membrane. In severe cases, respiratory and circulatory collapse may occur. The pulse rate is increased disproportionately to body temperature, which generally remains normal or slightly elevated. The palate may be paralyzed. This paralysis may be unilateral or bilateral and associated with difficulty swallowing and nasal regurgitation of swallowed fluids.[37] Stupor, coma, and death may occur within 7 to 10 days. In less severe cases, recovery may be slow and may be complicated by the development of myocarditis or neuritis. In mild cases, the membrane sloughs off in 7 to 10 days, and recovery is uneventful.

Laryngeal diphtheria generally reflects a downward extension of the membrane from the pharynx. Rarely, laryngeal diphtheria is primary and does not reflect an extension of disease from the pharynx. In these cases, toxicity and signs of toxemia generally are less prominent. Two cases of isolated diphtheritic tracheitis have been reported in the literature.[13,99] The clinical findings of laryngeal diphtheria are indistinguishable from other types of infectious croup. Noisy breathing, progressive stridor, hoarseness, and a dry barking cough may be noted. Suprasternal, subcostal, and supraclavicular retractions reflect severe laryngeal obstruction, which may be fatal unless alleviated. Occasionally, in a mild case, an acute and fatal obstruction may occur because of a partially detached piece of membrane that occludes the airway. In severe cases of laryngeal diphtheria, the membrane may extend downward and invade the entire tracheobronchial tree.

Cutaneous disease, in contrast to pharyngeal disease, is more common in warmer climates and often is caused by nontoxigenic

strains. In some countries with tropical and subtropical climates, such as Uganda, Tanzania, Sri Lanka, and Samoa, *C. diphtheriae* has been isolated from 60 percent of skin lesions in children.[63] Cutaneous diphtheria is more contagious than is respiratory diphtheria. Cutaneous diphtheria may be an important source of person-to-person transmission of diphtheritic organisms and outbreaks in indigenous populations in which overcrowding and poor hygiene are important risk factors.[12,21,63] The skin lesions begin as vesicles or pustules that progress to typical ulcers with sharply defined borders, membranous bases, and surrounding erythema and edema. They may be covered with a dark pseudomembrane. The lesions occur most commonly on the legs, feet, and hands. For the first 1 to 2 weeks, the lesions are painful. Spontaneous healing generally takes 6 to 12 weeks, but lesions have been reported to persist for 1 year.[63]

Conjunctival, aural, and vulvovaginal diphtheria also may occur. Conjunctival lesions usually are limited to the palpebral conjunctiva, which appears red, edematous, and membranous. Rarely, conjunctival lesions have been associated with corneal erosion.[96] Diphtheria infections of the ear are characterized by the development of otitis externa with a persistent purulent and frequently foul-smelling discharge.

Clinical presentations other than typical diphtheria have been associated with isolation of the organism from patients with meningitis, endocarditis, osteomyelitis, and hepatitis. In most cases, these infections have occurred in patients with underlying problems, such as structural or valvular heart disease or intravenous drug use, or in individuals from poor socioeconomic backgrounds.[35,101]

Several cases of septic arthritis caused by nontoxigenic *C. diphtheriae* have been described.[1,58,101] Afghani and Stutman[1] reported the case of a 27-month-old child who had septic arthritis of the hip and skin lesions on the lower extremities. In this case, the skin lesions were presumed to be the portal of entry for nontoxigenic *C. diphtheriae*. Although the child had received four doses of diphtheria and tetanus toxoids and pertussis vaccines, immunization with toxoid does not provide protection against nontoxigenic strains of *C. diphtheriae*. In this case, the organism was sensitive to penicillin, cefuroxime, cephalothin, and clindamycin but was resistant to oxacillin, an antistaphylococcal antibiotic often used for the treatment of septic arthritis when the causative organism cannot be identified. A similar case was described in an immunocompetent, fully vaccinated 2-year-old child who had skin lesions from which *C. diphtheriae* was isolated. The skin lesions also were assumed to be the portal of entry for the organism because pan-sensitive *C. diphtheriae* were isolated from the skin and the articular aspirate.[58]

Within a 12-month period, in New South Wales, Australia, four cases of septic arthritis complicating endocarditis caused by the nontoxigenic *gravis* variety of *C. diphtheriae* were reported. In addition, the same strain caused three cases of endocarditis without the development of septic arthritis. Demographic distribution of these seven cases included a 12-year-old boy who died, five patients who were in their 20s, and a patient who was 49 years old. Three of the patients had underlying cardiac abnormalities, and one had a history of intravenous drug use.[101] This same clone of nontoxigenic *C. diphtheriae* was isolated from three patients in Koorie, an aborigine community in Victoria, Australia, who had with endocarditis and five asymptomatic contacts.[64] Two of the three patients with endocarditis were members of the same family, and one of them had a history of alcohol abuse. The third patient had a septic sternoclavicular joint, in addition to endocarditis, with isolation of the same organism. Nontoxigenic *C. diphtheriae* sepsis can lead to splenic and hepatic abscesses, as reported in a patient with chronic lymphocytic leukemia in British Columbia, Canada.[66]

Complications secondary to elaborated diphtheria toxin may affect any system, but myocarditis and involvement of the nervous system are most characteristic. Myocarditis may occur after mild and severe cases of diphtheria. Generally, it develops in patients in whom administration of antitoxin is delayed. Myocarditis most commonly appears in the second week of the disease, but it can appear as early as the first or as late as the sixth week of illness. Tachycardia, a muffled S_1, murmurs, and arrhythmias such as atrioventricular dissociation indicate myocardial involvement. Echocardiography may show left ventricular dysfunction.[3,56,75] Although some cases may result in cardiac failure, most myocardial complications are temporary.

Neurologic complications appear after a variable latent period. Approximately 75 percent of all patients with severe diphtheria develop neuropathies. The incidence of neurologic sequelae has been shown to correlate with the severity of respiratory symptoms; 20 percent of all patients with respiratory problems develop polyneuritis. Neurologic complications from diphtheria infections predominantly are bilateral, are motor rather than sensory, and usually resolve completely. Paralysis of the soft palate is the most common occurrence and generally appears in the third week. It is manifested by a nasal quality in the voice, nasal regurgitation, and difficulty swallowing. Ocular paralysis usually occurs around the fifth week of illness and is characterized by blurring of vision and difficulty with accommodation. Internal strabismus also may be noted. Paralysis of the diaphragm, peripheral neuropathy involving the limbs, and loss of deep tendon reflexes likewise are reported as complications of diphtheria. When they occur, along with an elevated cerebrospinal fluid protein, the syndrome is clinically indistinguishable from Guillain-Barré syndrome.

Rarely, 2 or 3 weeks after the onset of illness, involvement of the vasomotor centers results in hypotension and cardiac failure. Gastritis, hepatitis, nephritis, and hemolytic-uremic syndrome also have been reported as complications of diphtheria.[98]

Information on the effects, if any, of diphtheria on the fetus during pregnancy was unavailable until more recently. El Seed and associates[43] reported a case of pharyngeal diphtheria in a pregnant woman that occurred during the first trimester of pregnancy. Apart from vaginal bleeding, no complications of pregnancy were noted. Severe diphtheritic toxemia in the mother was characterized by quadriparesis, from which she fully recovered. A physically normal female infant was delivered at term. In this single case, severe diphtheritic toxemia during pregnancy was not associated with any teratogenic effect in the fetus and did not impair intrauterine fetal growth.

DIAGNOSIS

The diagnosis of diphtheria should be based on clinical findings because any delay in initiating therapy poses a serious risk to the patient. Isolation of the organism is used to confirm the clinical diagnosis. Material obtained from beneath the membrane, where organisms are concentrated most highly, or a portion of the membrane itself should be obtained for culture.[5,33]

C. diphtheriae is relatively resistant to drying. The use of a non-nutritive, moisture-reducing transport medium helps prevent the overgrowth of other microorganisms. The laboratory should be notified about the possibility of diphtheria so that appropriate culture media are inoculated. A Löffler slant, a tellurite plate, and a blood agar plate should be inoculated. Tellurite-containing media inhibit the growth of normal oral flora, allowing *C. diphtheriae* to grow into characteristic black colonies. Other corynebacteria, staphylococci, and yeast also can reduce tellurite and grow into black colonies.[14,33] Although examination of direct smears of colonies or diphtheritic lesions remains an important supplement to clinical examination, it often is inaccurate. Screening the colonies from the tellurite plate for catalase, urea, nitrate, pyrazinamidase, and cystinase is important. Most biotypes of

C. diphtheriae are catalase-positive, urease-negative, nitrate-positive (except biotype *belfanti*), pyrazinamidase-negative, and cystinase-positive.[39]

All diphtheria bacilli that are recovered should be tested for toxigenicity. In 1949, the Elek immunoprecipitation assay replaced in vivo testing for toxigenicity using guinea pigs or rabbits.[42] The Elek test is based on gel diffusion and immunoprecipitation of toxin, from organisms inoculated onto agar adjacent to an antitoxin-containing well. A strain that is positive for toxin is indicated by the formation of a precipitin band between the toxin and antitoxin.[40,42] The Elek test would take 48 hours to yield results on the toxigenic nature of a *C. diphtheriae* strain. A modified Elek test that consists of placement of an antitoxin-impregnated disk onto an agar plate surrounded by inoculates of clinical specimen and positive control has been described. Compared with the conventional Elek test, the modified test has the advantage of using "spot" inoculations of numerous colonies directly from the primary plate. In addition, the modified Elek test has fewer false-positive and false-negative results and yields results more rapidly (16 to 24 hours).[39]

A rapid enzyme immunoassay is another test available for the detection of diphtheria toxin. This method uses equine polyclonal antibody to capture the diphtheria toxin and an alkaline phosphatase-labeled monoclonal antibody to detect fragment A of the toxin. It is a rapid test that takes 3 hours and has a limit of detection of 100 pg/mL.[44]

Rapid testing for diphtheria toxin by PCR specific for the "A" or "B" portion of the toxin gene, *tox*, is sensitive and has produced positive results in specimens stored for 12 months before performance of the assay.[7,69,70,87,88,90] The absence of the *tox* gene by PCR excludes the diagnosis of diphtheria. PCR may give false-positive results, however, because it does not differentiate between partial or nonfunctional *tox* genes and functional *tox* gene products. An increasing number of cases of nontoxigenic diphtheria that are positive for *tox* gene by PCR have been reported from Ukraine and Russia.[53,78]

The immune status of patients can be determined by toxin neutralization in Vero cells.[85] This method is used frequently, although it is difficult to standardize and relies heavily on individual interpretation of results. Enzyme-linked immunosorbent assay is a more rapid and quite sensitive method, but it detects some nonspecific antibodies; when antitoxin levels are in the low range, the assay may generate falsely elevated results.[82] Finally, a delayed fluorescence immune assay method was developed by Aggerbeck and colleagues[2] in 1996 and has been reported to have good sensitivity, specificity, and reproducibility.[17] Levels of diphtheria antitoxin of 0.01 IU/mL or greater generally are accepted as protective. A skin-testing method, the Schick test, also has been used to assess immunity.

The Schick test was used previously to determine the immune status of the patient. It is not helpful in establishing an early diagnosis because it cannot be read for several days, and currently it is not widely used. In the Schick test, a measured amount of purified diphtheria toxin (0.1 mL) is injected subcutaneously. A hypersensitivity reaction indicates an inadequate presence of antitoxin. A toxoid control also is injected, in the opposite arm, to help distinguish between a reaction to toxin and a reaction to other antigens in the toxin preparation.

Other laboratory studies are of little diagnostic value. The white blood cell count may be normal or elevated. Rarely, anemia develops as a result of rapid hemolysis of red blood cells. Examination of cerebrospinal fluid may reveal a minimal elevation of protein and, rarely, a mild pleocytosis in patients with diphtheritic neuritis. Hypoglycemia, glucosuria, or both may occur and reflect hepatic toxicity. An elevation in blood urea nitrogen may develop in patients with acute tubular necrosis. An electrocardiogram should be obtained and may reveal ST-segment and T-wave changes or arrhythmias indicative of myocarditis.

DIFFERENTIAL DIAGNOSIS

Mild forms of nasal diphtheria in a partially immunized host may resemble the common cold. When the nasal discharge is more serosanguineous or purulent, nasal diphtheria must be distinguished from a foreign body in the nose, sinusitis, adenoiditis, or the snuffles of congenital syphilis. Careful examination of the nose with a nasal speculum, sinus radiographs, and appropriate serologic tests for syphilis are helpful in excluding these disorders.

Tonsillar or pharyngeal diphtheria must be differentiated from streptococcal pharyngitis. Generally, streptococcal pharyngitis is associated with more severe pain on swallowing, higher temperature, and a nonadherent membrane limited to the tonsils. In some patients, pharyngeal diphtheria and streptococcal pharyngitis coexist.

Tonsillar and pharyngeal diphtheria also must be differentiated from infectious mononucleosis (lymphadenopathy and splenomegaly are common findings, atypical lymphocytes are generally present, and heterophile antibody may be present), nonbacterial membranous tonsillitis (white blood cell count generally is low, throat cultures reveal normal flora, and the course is unaffected by antibiotics), primary herpetic tonsillitis (presence of gingivitis, stomatitis, and discrete lesions of the tongue and palate may be helpful), Vincent angina (may be indistinguishable), and thrush (constitutional symptoms are absent, and lesions are present on the buccal mucosa and tongue). Tonsillar and pharyngeal diphtheria also must be differentiated from blood dyscrasias such as agranulocytosis and leukemia (complete blood count and bone marrow study are helpful); post-tonsillectomy faucial membranes (membranes are stationary and do not spread); and oropharyngeal involvement by toxoplasmosis, *Arcanobacterium*, cytomegalovirus, tularemia, and salmonellosis (associated signs and symptoms and appropriate cultures and serologic tests may be diagnostic).[50]

Laryngeal diphtheria must be differentiated from spasmodic or nonspasmodic croup; acute epiglottitis; laryngotracheobronchitis; aspirated foreign bodies; peripharyngeal and retropharyngeal abscesses; and laryngeal papillomas, hemangiomas, or lymphangiomas. A careful history, followed by careful visualization in the hospital under controlled conditions, aids in making a correct diagnosis.

PREVENTION

Diphtheria is prevented on a community-wide basis most effectively by active immunization. Diphtheria toxoid is available in combination with tetanus toxoid as pediatric DT or adult Td and in combination with acellular pertussis as DTaP and Tdap. Combination regimens with DTaP and inactivated poliovirus and hepatitis B (Pediatrix) and inactivated poliovirus and *H. influenzae* type B (Pentacel) are also available. Pediatric formulations of diphtheria toxoid vaccines contain three to four times more diphtheria toxoid but the same tetanus toxoid compared with the adult formulations. Children younger than 7 years should be given the pediatric formulations of vaccine, whereas children older than 7 years should receive the adult Td. Two forms of Tdap are available: Boostrix, which is approved for children 10 to 18 years old, and Adacel, which is approved for individuals 11 to 64 years old.[24-27,38]

Primary immunization is carried out conveniently and effectively by giving diphtheria and tetanus toxoids and pertussis vaccine, DTaP, at 2, 4, and 6 months of age, with booster doses given at 15 to 18 months and again when the child is 4 to 6 years of age. Booster doses with adult-type diphtheria and tetanus toxoids adsorbed (Td) should be given at 10-year intervals to all immunized individuals. Current recommendations are to give

Tdap as the first booster dose in patients who are 11 to 12 years old. Td and Tdap contain 2 to 2.5 Lf (flocculation units) diphtheria toxoid per dose compared with 7 to 25 Lf in the pediatric diphtheria, tetanus toxoid, and pertussis vaccine preparations (DTaP, DT). Primary immunization of children older than 7 years may be performed with Td. Two doses are given intramuscularly at least 4 weeks apart, with a booster dose provided 1 year later. Children and adults who are severely immunocompromised or undergoing long-term hemodialysis should use the standard immunization schedule, although response may be suboptimal.[47,51,71]

Most local and systemic reactions to the diphtheria and tetanus toxoids and whole cell pertussis vaccine (DTP), including fever, were related to the pertussis component.[10,32] Administration of tetanus and diphtheria toxoids is not followed by the high incidence of reactions associated with the use of pediatric DTP vaccines. At least one study showed that 7.5 Lf toxoid can be given safely to adults without a higher risk of reactions occurring.[15] Primary immunization against diphtheria for infants with progressive neurologic disorders and completion of the primary immunization series in patients who had experienced an untoward reaction to an earlier DTP vaccine injection may be performed with diphtheria and tetanus toxoids rather than diphtheria and tetanus toxoids and pertussis vaccine.[4]

A report of 97 preterm infants who received diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP) (94 of these infants also received *Haemophilus influenzae* type b vaccine) showed that most infants tolerated the vaccination without side effects, although a subgroup of very-low-birth-weight infants (mean 873 g) had either recurrence or an increase in the number of apneic and bradycardic episodes in the 48 hours after receiving vaccination. The apneic and bradycardic episodes were present before immunization in every case.[97]

Booster doses of tetanus and diphtheria toxoids should be given at 10-year intervals to all immunized individuals. As mentioned earlier, levels of diphtheria antitoxin of 0.01 IU/mL or greater generally are accepted as protective.

Diphtheria immunization is not always followed by complete protection.[79] Immunization is directed against the phage-mediated toxin, not against infection. Fully immunized individuals may be carriers or may have disease caused by nontoxigenic strains. An investigation conducted during an epidemic in Texas showed no statistical difference in the risk of diphtheria infection developing in individuals with full, lapsed, inadequate, or no previous diphtheria immunization; however, a 30-fold increased risk of development of symptomatic diphtheria in individuals with no immunization and an 11.5-fold increase in individuals with inadequate immunization was noted.[84]

The most important health problem in the United States today is inadequate immunization of the population. Immunization rates in adults are poorer than those in infants and children because of failure to maintain adequate immunity through appropriate booster immunization. A 70 to 80 percent immunization level is thought to be required to prevent epidemic spread.[31]

Prevention of diphtheria also depends on management of the contacts of known cases of diphtheria and carriers of the organism and on isolation of patients to minimize the spread of disease. Individuals at risk of contracting the disease from the index case include those who have had close respiratory or physical contact or prolonged close proximity with the infected individual, including members of the index case's household.[18] Specifically, family members who share body towels and cups or eating utensils, share a bed or a bedroom with more than two people, or take a bath less than once a week have a significantly greater risk of contracting the disease from the infected patient. A history of eczema in the contact also has been associated with a significantly increased risk of contracting diphtheria from the index case.[93] The patient is infectious until diphtheria bacilli no longer can be cultured from the site of infection. Two or three consecutive negative cultures at least 24 hours apart are required, and antibiotic therapy must be complete for 24 hours before the patient is released from isolation. If obtaining cultures is impossible, isolation may be ended after the completion of 14 days of appropriate antibiotic treatment.[6]

Cultures should be taken from the nose and throat of all close contacts, who should be kept under surveillance for 7 days (surveillance as an outpatient is acceptable).[5] Regardless of their immunization status, contacts should be treated with a single intramuscular dose of benzathine penicillin G (600,000 U for individuals weighing <30 kg and 1.2 million U for individuals weighing >30 kg) or a 7-day course of erythromycin, 40 to 50 mg/kg/day (maximum 2 g/day) divided into four doses.[5] The immune status of each contact should be determined; individuals for whom immune status is inadequate, including individuals who have had the primary series but more than 5 years has elapsed since they received their last booster dose, should receive an injection of diphtheria toxoid. In addition, patients with diphtheria should be immunized during convalescence because infection may not confer immunity.[6]

Asymptomatic carriers who previously were not immunized against diphtheria should have cultures taken, receive diphtheria toxoid and penicillin or erythromycin (as described earlier), and be seen daily by a physician. Asymptomatic contacts who are found to carry a toxigenic strain should be subjected to the same isolation and treatment measures as the index case.[6] If daily surveillance is impossible, benzathine penicillin is preferred over erythromycin for treatment because failure to adhere to an oral drug regimen is a concern. If a contact is experiencing symptoms when seen, treatment of diphtheria is indicated. It is important to initiate prophylactic therapy in contacts who have not been immunized, before the results of culture are received. Management of carriers is described in the next section. Contacts whose occupations involve close contact with unimmunized children or food handling (especially milk) should refrain from working until cultures are confirmed to be negative.[6]

TREATMENT

Treatment of diphtheria is predicated on neutralization of free toxin and eradication of *C. diphtheriae* or *C. ulcerans* by the use of antibiotics. Disease caused by *C. ulcerans* should be treated in the same manner as is disease caused by *C. diphtheriae*.[3,95] The decision to administer equine antitoxin should be based on the site and size of the membrane, the degree of toxicity, and the duration of illness.[16]

Antitoxin can neutralize circulating toxin or toxin that is absorbed onto cells, but is ineffective when cells have been penetrated. Early treatment is essential to limit tissue damage. An adequate dose of antitoxin must be administered intravenously as early as possible to neutralize all free toxins. A single dose is used to avoid the risk of developing sensitization from repeated doses of horse serum. Tests for sensitivity to horse serum must be performed before antitoxin is administered. For this purpose, 0.02 mL of a 1:1000 dilution of antitoxin in saline can be given intracutaneously. Positive (histamine) and negative (isotonic saline) controls should be applied similarly. A positive reaction consists of a wheal at least 3 mm larger than the negative control, with surrounding erythema at the site of injection, developing within 15 to 20 minutes, and necessitates desensitization. The histamine control must be positive if test results are to be considered valid. Alternatively, the test may be done with a drop of serum diluted 1:100 and applied to the site of a superficial scratch, prick, or puncture on the volar aspect of the forearm.

Controls should be applied and results interpreted as described for intracutaneous administration.[5]

If a patient has been shown to be sensitive to horse serum, the serum should be provided in a slowly increasing dosage given at 15-minute intervals. Several regimens have been used. One recommended regimen is as follows:[5]

- 0.1 mL of a 1:1000 dilution intravenously
- 0.3 mL of a 1:1000 dilution intravenously
- 0.6 mL of a 1:1000 dilution intravenously
- 0.1 mL of a 1:100 dilution intravenously
- 0.3 mL of a 1:100 dilution intravenously
- 0.6 mL of a 1:100 dilution intravenously
- 0.1 mL of a 1:10 dilution intravenously
- 0.3 mL of a 1:10 dilution intravenously
- 0.6 mL of a 1:10 dilution intravenously
- 0.1 mL undiluted intravenously
- 0.3 mL undiluted intravenously
- 0.6 mL undiluted intravenously
- 1 mL undiluted intravenously

The intravenous route for desensitization is considered safest because it offers good control, but protocols involving the intradermal, subcutaneous, and intramuscular routes also have been used frequently.[5]

If no reaction has occurred, the remaining material is given by slow intravenous infusion. Intravenous administration results in more rapid excretion of antitoxin into saliva, rendering it atoxic and preventing further absorption of toxin in the oropharynx, but it does not result in more rapid systemic elimination of antitoxin than intramuscular administration.[100] Reactions should be treated with aqueous epinephrine (1:1000) provided intravenously.

The antitoxin dosage is empiric. Pharyngeal or laryngeal disease of 48 hours' duration or less should be treated with 20,000 to 40,000 U, nasopharyngeal disease with 40,000 to 60,000 U, and severe pharyngeal or laryngeal diphtheria with 80,000 to 120,000 U of antitoxin. The last dose also should be given to patients with mixed clinical symptoms and to patients with brawny edema or disease of longer than 48 hours' duration. The value of antitoxin in the treatment of cutaneous disease is debated, but some experts recommend 20,000 to 40,000 U because toxic effects have been reported.[5]

Although antibiotics are not a substitute for treatment with antitoxin, they should be given when diphtheria is suspected clinically. Penicillin and erythromycin are still effective against most strains of *C. diphtheriae*. Penicillin and erythromycin also are effective in eradicating group A hemolytic streptococci, which may complicate 30 percent of cases of diphtheria. Treatment consists of a 14-day course of penicillin or erythromycin. Penicillin may be given as aqueous penicillin G, 100,000 to 150,000 U/kg/day in four divided doses intravenously, or as procaine penicillin, 25,000 to 50,000 U/kg/day (maximum of 1.2 million U) in two divided doses intramuscularly. Patients who are sensitive to penicillin should be given erythromycin in a daily dosage of 40 to 50 mg/kg (maximum of 2 g/day) in four divided doses for 14 days. When the patient is able to tolerate oral medications, erythromycin or penicillin V may be used in place of the intravenous antibiotics.[5]

Follow-up cultures should be obtained at least 2 weeks after antibiotic therapy is complete; if they are positive, erythromycin should be given for an additional 10 days.[5] Some resistance to erythromycin has been observed, but it is uncommon, and its epidemiologic significance is unknown.[5,6] Penicillin is recommended as first-line treatment in Vietnam, based on sensitivity data.[68] Amoxicillin, rifampin, and clindamycin provided in appropriate dosages also may be effective. Lincomycin and tetracycline have proved to be less effective, and cephalexin, oxacillin, and colistin have been shown to be ineffective against *C. diphtheriae*. The end-point of therapy is two to three consecutive negative cultures at least 24 hours apart. In addition to receiving antibiotic therapy, patients with diphtheria should be immunized during convalescence because infection may not confer immunity.[5]

The carrier state has been treated effectively with a single intramuscular dose of benzathine penicillin G (600,000 U for children weighing <30 kg or 1.2 million U for individuals weighing ≥30 kg) or oral erythromycin (40 to 50 mg/kg/day for children and 1 g/day for adults) for 7 to 10 days.[5] Carriers should have repeat pharyngeal cultures performed a minimum of 2 weeks after antibiotic therapy is complete; if the repeat cultures are positive, carriers should receive an additional course of antibiotics.

SUPPORTIVE TREATMENT

Bed rest is extremely important and should be required for 2 to 3 weeks. Serial electrocardiograms should be obtained two or three times each week for 4 to 6 weeks to detect myocarditis as early as possible. Absolute bed rest must be enforced if myocarditis is detected because sudden death has been precipitated by excessive activity. A patient with myocarditis may receive digitalization if congestive heart failure develops. Digitalization for arrhythmias caused by diphtheria may be contraindicated, however. In severe disease, prednisone, 1 to 1.5 mg/kg/day for 2 weeks, has been shown to lessen the incidence of myocarditis.

Hydration should be maintained, and a high-calorie liquid or soft diet should be provided. Secretions should be suctioned as needed to prevent aspiration. Palatal and pharyngeal paralysis increases the risk of aspiration occurring, so gavage via a nasogastric tube is indicated in these patients.

The quality of the voice and the gag reflex should be checked regularly for assessment of progression of the disease. Laryngeal diphtheria may require relief of obstruction with a tracheostomy. This procedure should be performed before the patient has become exhausted.

Adequate immunity does not develop in at least half of patients who recover from diphtheria, and they remain subject to reinfection. Immunization is indicated after the patient recovers.

PROGNOSIS

Many factors affect the prognosis in cases of diphtheria, the most important being the immunization status of the host. Morbidity and mortality rates are increased significantly in patients who are unimmunized or inadequately immunized. The rapidity with which medical care is sought and the diagnosis of diphtheria is suggested has a great impact on outcome. If specific treatment is provided on the first day of disease, the mortality rate may be reduced to less than 1 percent; delay in providing treatment until day 4 may be associated with a 20-fold increase in the mortality rate.

The virulence of the infecting organism and the location of infection are important prognostic factors. Infection with a nontoxigenic *C. diphtheriae* strain may cause disease but does not lead to myocarditis, neuritis, and other toxin-related phenomena. Toxigenic disease may vary from mild to severe. In cases of mild diphtheria, membrane sloughing and full recovery generally occur within 7 days. Disease caused by toxigenic *gravis* strains tends to be more severe and carries a poorer prognosis. Although diphtheria may affect the skin, nasopharynx, and other mucous membranes, involvement of the larynx heralds a more complicated course. Laryngeal diphtheria increases the risk of development of airway obstruction and promotes systemic absorption of

the toxin. These patients require close monitoring of respiratory function and for involvement of other organ systems. Laryngeal diphtheria is more likely to be fatal in infants.

Few laboratory parameters indicate the severity of diphtheria. The development of amegakaryocytic thrombocytopenia and leukocytosis with counts of greater than 25,000 cells/mm^3 has been associated with a poor outcome.

The prognosis in a patient with diphtheria remains guarded until recovery is complete. At any time during the course of the illness, complications such as laryngeal obstruction, shock, and ventricular fibrillation may occur suddenly and unexpectedly. In patients with myocardial involvement, permanent damage to the heart, specifically fibrosis, may occur and lead to later complications. In addition, potentially severe neurologic manifestations, such as phrenic nerve paralysis, may appear late in the course of the disease.

Persistence of *C. diphtheriae* may be noted in the nasopharynx of 5 to 10 percent of convalescing patients. Recovery from diphtheria is followed by immunity that is demonstrable for at least 1 year after illness in 50 percent of patients. Second attacks are rare; nonetheless, immunization should be performed after the patient recovers.

Before the use of antitoxin and the availability of antibiotics, the mortality rate from diphtheria was 30 to 50 percent. Death was most common in children younger than 4 years old and was the result of suffocation. At present, the worldwide mortality rate is 5 to 10 percent, with no clear association with age.

CHAPTER 102

Anthrax

Morven S. Edwards

Anthrax is a toxigenic disease of herbivores for which humans are an incidental host. The term *anthrax*, derived from the Greek *anthrakos*, which means "coal," refers to the black eschar characteristic of cutaneous anthrax. The three clinical manifestations of anthrax are cutaneous, which accounts for 95 percent of infections in the United States; inhalational; and gastrointestinal. Each manifestation can occur in children,[22,30,42,48] and all can be complicated by meningitis.

HISTORICAL ASPECTS

Anthrax has been recognized since antiquity. The earliest reference to a disease thought to be anthrax is a description in *Exodus* of the plague that caused the death of all of the Egyptians' cattle.[7] Hippocrates described carbuncles that are thought to represent the cutaneous form of anthrax. An account of anthrax in animals is detailed in the third of the Roman poet Virgil's four *Georgics*.[39] In the early 17th century, an anthrax pandemic referred to as the "Black Bane" caused 60,000 human deaths in Europe.[7] By the 18th century, several excellent descriptions of the clinical disease in humans had been published.

Bacillus anthracis has a unique niche in the history of infectious diseases. The organism, seen microscopically by Delafond in 1838, was isolated and cultivated in 1877 by Koch, who showed its proliferation in vivo, establishing a model for the causation of infectious disease. In 1881, both Pasteur and Greenfield[45] showed that a live-attenuated anthrax bacillus vaccine protected against subsequent challenge in animals, demonstrating the efficacy of immunization for the prevention of an infectious disease. In the late 1800s, anthrax was proved to be the cause of woolsorter's disease, or inhalation anthrax, contracted by factory workers handling anthrax-contaminated animal hides.

During World War I, *B. anthracis* was manufactured as an agent for biologic warfare. Because anthrax is transmissible by the respiratory route, inhalational anthrax usually is fatal, and because *B. anthracis* spores are stable in the environment, anthrax continues to be a focus of biologic warfare research programs.[12] The accidental release of anthrax spores from a military research facility in Sverdlovsk in the former Soviet Union in 1979 resulted in at least 68 deaths from inhalational anthrax.[32] One estimate is that the aerosolized release of 100 kg of anthrax spores upwind of Washington, D.C., would result in 130,000 to 3 million deaths.[23]

The first confirmed outbreak associated with intentional anthrax release in the United States occurred in October and November 2001.[24] Anthrax spores were disseminated by mail, resulting in 5 deaths from inhalation and 22 total cases of cutaneous and inhalational anthrax. Envelopes containing anthrax spores were sent through the U.S. Postal Service to offices of newspaper and broadcast media and U.S. senators. The spores were "weaponized," or finely milled, and treated with chemicals to prevent clumping so that they dispersed when the envelopes were opened and leaked from sealed envelopes as they passed through mail sorting machines. A single anthrax strain was implicated. This outbreak has had a substantial impact on the health care system and has revealed the potential impact of a bioterrorism event on society.[5]

BACTERIOLOGY

B. anthracis is an aerobic, nonmotile, spore-forming rod in the family Bacillaceae. Optimal growth occurs at 36° C in nonselective media. Colonies are gray-white, rough, and flat and may have comma-shaped projections caused by the outgrowth of chains of bacilli from the edges of the colony, giving it a "Medusa head" appearance. Individual colonies are 4 to 5 mm in diameter with a ground-glass appearance and exhibit tenacity or a "beaten egg white" appearance when lifted with an inoculating loop.[16] A capsule, which is associated with virulence, can be delineated by electron microscopy. Encapsulation occurs with growth on enriched media. Gram stain of clinical material reveals large, square-ended, gram-positive rods singly or in short chains without a visible capsule. The equatorial or paracentral spores are invisible in smears fixed promptly after collection. After 24 to 48 hours of aerobic incubation, strands of rods are arranged in "boxcar" or "bamboo" fashion, and sporulation occurs. Small numbers of bacteria are pathogenic for mice, guinea pigs, and rabbits, and death usually occurs 2 to 5 days after inoculation. Currently, no method exists for serologically classifying strains of *B. anthracis*.

EPIDEMIOLOGY AND TRANSMISSION

Domestic herbivores—cattle, sheep, horses, goats, and swine—are the most important agricultural sources of anthrax, but all domestic and many wild animals can serve as hosts. Animals are infected by ingestion of spores from infected pastures. Spores germinate in vivo, and death, associated with massive septicemia, usually occurs in 1 or 2 days. Anthrax is endemic in areas where an animal-soil-animal cycle is established because the spores can survive indefinitely in a dry environment. Uncultivated soil with a pH greater than 6.0 and ambient temperature greater than 15.5° C provides an environment favorable for persistence of spores.[47]

An estimated 20,000 to 100,000 human cases of anthrax occur yearly worldwide.[40] Regions of high endemicity include South and Central America, southern Europe, eastern Europe, Asia, Africa, the Caribbean, and the Middle East. The number of human cases probably correlates with the enzootic status of the disease in livestock in these countries. Familial clustering can occur in association with exposure to diseased animals.[1,35] Children who live in endemic areas often contract cutaneous anthrax from direct animal contact.[34] More than half of 448 patients from the Gambia with cutaneous anthrax were younger than 15 years of age, and 11 percent were younger than 2 years.[20] In the United States, epizootics of anthrax occur in the lower Mississippi valley and in parts of California, Texas, Missouri, Nebraska, and South Dakota[49]; sporadic cases have been reported from almost every state. Cases of illness were identified in four states and in Washington, D.C., during the 2001 bioterrorism-related outbreak.

The incidence of human anthrax in the United States has decreased markedly since the early 1900s, when more than 100 cases were reported annually. Cutaneous infections are reported sporadically.[9] Cases often are associated with exposure to contaminated animal products in commercial preparations, but exposure to indigenous animal anthrax does occur in the United

States.[43] Two members of a farmer's family ate hamburgers made from an anthrax-infected steer in Minnesota in 2000. The family members received antibiotic prophylaxis and anthrax vaccine and remained well.[9]

Direct contact with contaminated animal meat or carcasses or with contaminated animal products, such as hides, hair, wool, bone meal, and animal feed, are sources of transmission of anthrax spores to humans. Children of industrial workers have acquired infection, presumably from contact with their parents' contaminated clothing.[7] Processed products, such as shaving brushes and saddle blankets, have been implicated as sources of infection. Cutaneous anthrax is transmitted by deposition of spores or bacilli into abrasions or cuts in the skin. Blood-sucking insects, including mosquitoes and stable flies, can be vectors.[31,46,47]

The specific mode of acquisition may be difficult to determine in children; in one child with cutaneous anthrax, the only potential exposure was proximity to a bone meal factory that he walked past on his way to school.[27] Tying the umbilicus with a dirty thread was the presumed portal of entry for a neonate with *B. anthracis* sepsis.[34] Rubbing with contaminated fingers or deposition by an insect vector can lead to cutaneous involvement of the eyelids.[51] Discharge from cutaneous lesions theoretically is infectious, but person-to-person transmission has not been confirmed. Skin-to-skin contact through his mother's exposure at her workplace was proposed as the route of transmission to an infant in the bioterrorism-related outbreak in the United States in 2001.[19] Maternal anthrax has been associated with preterm delivery.[25]

Inhalational anthrax results from inhalation of spores. The estimated infectious dose in humans is 8000 to 50,000 spores. Cases of inhalational anthrax in the United States have occurred in a weaver whose imported yarn was contaminated and in a drum maker whose imported hand-dried animal hide was contaminated with *B. anthracis*.[8,13] Eleven adults acquired inhalational anthrax during the 2001 bioterrorism outbreak of anthrax in the United States. Gastrointestinal anthrax is caused by ingestion of contaminated meat. A newborn was reported to have contracted anthrax meningitis from his mother, who was septicemic at the time of delivery.[20]

PATHOGENESIS AND PATHOLOGY

Anthrax toxicity results from the activity of three polypeptides—protective antigen, edema factor, and lethal factor—that combine to form two toxins, lethal toxin and edema toxin. Protective antigen is integral to the action of both toxins. Toxin entry into cells is initiated when protective antigen binds to membrane receptors of susceptible cells. Two related proteins, tumor endothelial marker 8 and capillary morphogenesis protein 2, function as receptors. Cleaved protective antigen oligomerizes, and a heptamer of protective antigen provides binding sites for edema factor or lethal factor. The complex is endocytosed as edema toxin or lethal toxin.

Edema factor is a calmodulin-dependent adenylate cyclase that increases intracellular cyclic adenosine monophosphate levels and is responsible for the massive edema that occurs in cutaneous anthrax.[28] Lethal factor is a zinc metalloproteinase that cleaves mitogen-activated protein kinase kinases so that they are unable to activate their downstream substrates, the mitogen-activated kinases.[18] Lethal factor stimulates production of tumor necrosis factor-α and interleukin-1β. The capsule of *B. anthracis* also contributes to virulence by inhibiting phagocytosis, and the toxins inhibit neutrophil priming by lipopolysaccharide, modulating the inflammatory response.[24,50]

Cutaneous infection is initiated when anthrax spores are ingested at the site of entry by macrophages, and germination occurs in skin tissues. Production of toxin results in local edema. Regional lymphangiitis and lymphadenopathy can occur.[15] Interstitial edema, lymphatic dilation, and thrombosis and necrosis of blood vessels are characteristic microscopic features of cutaneous anthrax lesions. Erythrocytes extravasate freely into interstitial fluid. Few neutrophils or other inflammatory cells are present unless a lesion is infected secondarily. Hemorrhagic lymphadenitis involving regional lymph nodes occurs in all forms of anthrax.

In inhalation anthrax, spores entering the alveoli are phagocytosed by alveolar macrophages and dendritic cells and carried to hilar lymph nodes, where they germinate. Primary focal hemorrhagic necrotizing pneumonia can occur at the pulmonary portal of entry.[2] Massive hemorrhagic mediastinal lymphadenitis can block lymphatic drainage routes and can be causally related to the pulmonary edema and respiratory distress observed clinically.[48]

Gastrointestinal anthrax results from ingestion of spores or vegetative bacilli in contaminated meat. The primary sites of infection are the epithelium of the stomach or bowel wall.[6] Edema and small necrotic ulcers of the mucosa of the gastrointestinal tract, especially the ileum or cecum, are characteristic findings. Dissemination to the central nervous system can occur by hematogenous or lymphatic routes from any site of primary involvement. Hemorrhage involving the meninges and intense arteritis are uniform findings in patients who die of anthrax meningitis.

CLINICAL MANIFESTATIONS

CUTANEOUS ANTHRAX

The lesions of cutaneous anthrax occur mainly on exposed areas of the body. In one report, the distribution in young children was 52 percent of lesions on the head and neck, 28 percent on the trunk, and 20 percent on the extremities, whereas in older children, the distribution was 70 percent on the head and neck, 16 percent on the trunk, and 14 percent on the extremities.[22] Spores are introduced through abraded or injured skin. Children can have one or several lesions, and they are associated with regional adenitis.[29] After an incubation period of 2 to 5 days, a small, nontender, but frequently pruritic, papule develops at the site of inoculation. The lesion progresses to a serous or serosanguineous vesicle with surrounding nonpitting edema within 36 hours. Satellite vesicles, sometimes referred to as a "pearly wreath,"[51] may be seen occasionally.

The lesion undergoes central necrosis, with a black eschar left behind (Fig. 102–1).[38] The term *malignant edema* is used to describe severe lesions, particularly lesions involving the head and neck, which can be associated with systemic toxicity and occlusion of the airway. Small children can appear acutely ill with a temperature of 39° C to 40° C and leukocytosis with counts of 20,000 to 30,000 cells/mm^3.[19] Approximately 5 percent of patients are bacteremic. With appropriate therapy, the edema usually resolves within 2 to 3 days, but the central lesion continues its evolution unaffected. The eschar usually is 1 to 3 cm in diameter, with sharply defined margins seen 1 week to 10 days after onset. Separation of the eschar may take several weeks, and healing occurs with variable central scarring.[27]

INHALATIONAL ANTHRAX

Inhalational anthrax is a biphasic illness. Symptoms in the initial stage—malaise, low-grade fever, myalgia, and nonproductive cough—are nonspecific and resemble the symptoms of a respiratory viral illness or bronchitis. Adults who have inhalational anthrax are more likely to present with tachycardia, high hematocrit, low albumin, and sodium levels, and are less likely to present with myalgias, headache, and nasal symptoms than are

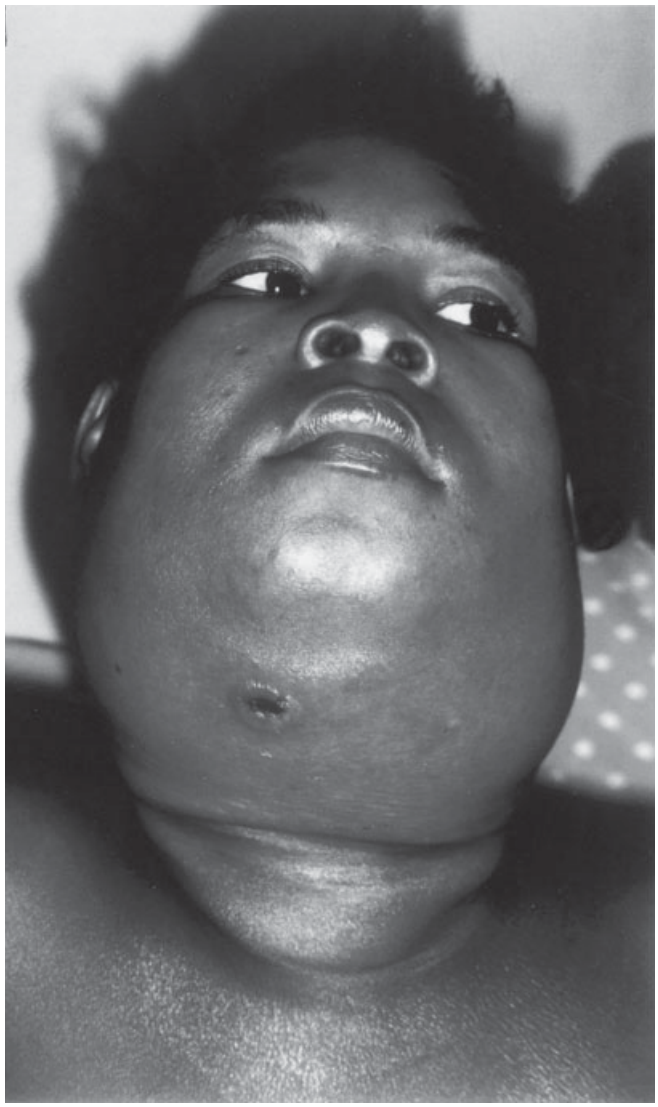

Figure 102–1 Cutaneous anthrax with associated massive submental edema. The lesion is located at the site of a small, initially trivial laceration that served as the portal of entry for the anthrax endospores. The patient received ampicillin and recovered completely. *(Courtesy of M. Thomas Casey, M.D.)*

adults who have influenza-like illnesses.[26] After several days of illness, dyspnea and stridor initiate onset of the second stage, which usually terminates fatally within 24 hours. Chest radiographs show a widened mediastinum with smooth borders and evidence of hemorrhagic mediastinitis and pleural effusions.[48] The pleural effusions often are large and usually contain bloody fluid. Pulmonary infiltrates usually are the result of superimposed bacterial infection. In the more recent cases from the United States, computed tomography scans of the chest showed the characteristic findings of hemorrhagic mediastinal and hilar lymph nodes and mediastinal edema and pleural effusions.[5]

GASTROINTESTINAL ANTHRAX

Gastrointestinal anthrax can manifest with oropharyngeal or intestinal manifestations. Each has an incubation period of 2 to 5 days after the ingestion of contaminated meat. The oropharyngeal form results in an oral or esophageal ulcer.[6,24,37] Presenting features include fever, severe sore throat, neck swelling caused by edema and enlargement of the cervical lymph nodes, dysphagia, and respiratory difficulty. Lesions on the tonsils or posterior oropharynx progress over 1 to 2 weeks from an area of edema to a pseudomembrane-covered ulcer. The oropharyngeal form of anthrax, although uncommon, has a more favorable prognosis than does intestinal anthrax.

Initial features of intestinal anthrax are fever, nausea, anorexia, vomiting, and diffuse abdominal pain that progresses rapidly to severe abdominal pain with rebound tenderness. Vomiting of blood-tinged or coffee ground-like material and melena are common symptoms and are secondary to ulceration of the intestinal mucosa.[6,24,33] The pain decreases, and massive ascites develops 24 to 48 hours after the onset of symptoms. Abdominal radiographs at this time show edematous loops of bowel and decreased air. If the abdomen is explored, findings include enlarged, erythematous mesenteric lymph nodes and straw-colored to purulent ascitic fluid in which organisms are readily visible.[3] Death usually occurs in association with significant blood loss, fluid and electrolyte imbalances, and subsequent shock. If the patient survives the acute illness, the edema and melena subside in 10 to 14 days.

MENINGITIS

Most reports of anthrax meningitis are associated with cutaneous disease, likely due to the higher frequency of cutaneous disease. Anthrax can disseminate to the meninges from any site of primary involvement. In the 2001 bioterrorism event, one adult with inhalation anthrax presented with meningitis, and several others had features suggestive of central nervous system involvement.[36] In a report of 70 patients with anthrax meningitis who ranged in age from newborn to 71 years, no primary focus could be found in 12 percent of patients.[21] Young and middle-aged men are affected most often as a consequence of occupational exposure.

Anthrax meningitis is characterized by a sudden onset and fulminant course. Initial symptoms include intense headache, nausea and vomiting, myalgia, chills, dizziness, and, occasionally, a petechial rash. Meningismus is usually, but not invariably, present because of the acuity of the course. Progressive neurologic deterioration with delirium, convulsions, and coma can occur in hours or over the course of 2 to 4 days. Overall survival has been only approximately 5 percent, but survival without apparent neurologic sequelae has been reported in at least three children, two of whom had cutaneous lesions at the time of diagnosis.[36,41,42,44]

Examination of cerebrospinal fluid reveals (1) gross or microscopic hemorrhage, (2) leukocytosis consisting predominantly of polymorphonuclear leukocytes, (3) elevated protein, and (4) depressed glucose levels. Gram-positive rods can be seen easily on smears of cerebrospinal fluid. Peripheral leukocytosis is a common finding, and the white blood cell count may be 60,000 to 80,000 cells/mm^3. Blood cultures yield the organism in 70 percent, and cerebrospinal fluid cultures yield the organism in virtually 100 percent of patients.[20] Neuroimaging findings are notable for multiple hemorrhages in the ventricles, subarachnoid space, and deep gray matter.[36]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

B. anthracis can be visualized by direct smear and cultured from vesicular fluid or exudate from cutaneous lesions and from pleural fluid, blood, and cerebrospinal fluid in systemic infections. The commercially available QuickELISA Anthrax-PA Kit (Immunetics Inc., Boston, MA) can be used as a screening test.[4] Definitive diagnosis can be obtained through the Laboratory Response

Network for Bioterrorism in each state. Time-resolved fluorescent assay, real-time polymerase chain reaction, serologic tests to detect antibodies against protective antigen, and tissue immunochemistry also are available through state health laboratories. The enzyme-linked immunosorbent assay used to detect IgG to *B. anthracis* protective antigen is highly sensitive, has good specificity, and yields a positive result 10 days after the onset of symptoms.[5]

The lesion of cutaneous anthrax must be differentiated from ecthyma gangrenosum and from ulcerative skin lesions with regional lymphadenopathy, including rat-bite fever, ulceroglandular tularemia, plague, glanders, scrub typhus, rickettsialpox, cowpox, and orf. Staphylococcal lymphangitis can be distinguished from anthrax by the discharge of purulent material and by the inflammatory response observed microscopically. Noninfectious causes of eschars include arachnoid bites and vasculitides.[24] The first stage of inhalational anthrax and the clinical features of the intestinal form are nonspecific, so a history of exposure is crucial for establishing the diagnosis. The mediastinal widening that occurs early in the course of inhalational anthrax can cause confusion with that seen in acute bacterial mediastinitis and in fibrous mediastinitis caused by *Histoplasma capsulatum*.[15] Gastrointestinal anthrax must be differentiated from other causes of acute abdominal illness and, if bleeding is present, from duodenal ulcer, typhoid, and intestinal tularemia. Anthrax meningitis must be differentiated from subarachnoid hemorrhage.[20]

TREATMENT

Most, but not all, strains of *B. anthracis* are susceptible to penicillin and tetracycline, but naturally resistant strains occur, and penicillin resistance can be induced. Resistance occurs sufficiently uncommonly in naturally occurring cutaneous disease that penicillin or tetracycline for 7 to 10 days is adequate treatment. Treatment for bioterrorism-associated cutaneous anthrax should be initiated with ciprofloxacin, 10 to 15 mg/kg every 12 hours (not to exceed 1 g/day) orally until susceptibility data are available. Doxycycline is an alternative antimicrobial for initial therapy. The dosage is 100 mg orally every 12 hours (children >8 years old) or 5 mg/kg/day in divided doses given every 12 hours (children ≤8 years old). Treatment should continue for 60 days in the context of bioterrorism-associated cutaneous anthrax.[4]

The initial regimen for treatment of inhalational anthrax, gastrointestinal anthrax, anthrax meningitis, or cutaneous anthrax if (1) systemic signs are present, (2) lesions are located on the head and neck, and (3) extensive edema is present should be ciprofloxacin intravenously (400 mg every 8-12 hours) or doxycycline intravenously (200 mg every 8-12 hours).[4,10,11] One or two additional antimicrobials should be administered intravenously with either ciprofloxacin or doxycycline as initial therapy until susceptibility testing is available. Other agents with in vitro activity include levofloxacin, gatifloxacin, penicillin, ampicillin, clindamycin, vancomycin, rifampin, imipenem, meropenem, clarithromycin, and chloramphenicol.[17] If the organism is determined to be susceptible to penicillin, penicillin may be administered at a dosage of 300,000 to 400,000 U/kg/day intravenously or 50,000 U/kg/day orally. Therapy should be continued for at least 60 days.

Supportive therapy includes attention to details of fluid and electrolyte balances, endotracheal intubation if indicated to maintain a patent airway, and local care for cutaneous lesions. Systemic steroids may reduce the severity of infections in patients with massive edema or meningitis.[42] A specific anthrax antitoxin is not available.

PROGNOSIS

Before penicillin was introduced, cutaneous anthrax was fatal in approximately 20 percent of patients. With effective treatment, the mortality rate is less than 1 percent. Cutaneous anthrax of the eyelid may be complicated by ectropion of the upper lid and corneal scarring with blindness.[51] Immunity probably is lifelong in most patients. Although second attacks of cutaneous anthrax have been recorded, they have not been confirmed serologically and usually are mild.[14,22] Fatality rates are high for systemic anthrax and range from 50 to 100 percent for gastrointestinal anthrax to virtually 100 percent for inhalation anthrax, but children who have survived these infections have no apparent sequelae.

PREVENTION

The only human anthrax vaccine licensed in the United States is BioThrax (BioPort Corporation, Lansing, MI), formerly known as *anthrax vaccine adsorbed*, which is prepared from a cell-free filtrate of *B. anthracis* that contains no dead or live bacteria.[12] It is an aluminum hydroxide–precipitated preparation of protective antigen from an attenuated, nonencapsulated anthrax strain. Routine vaccination is indicated for individuals engaged in work involving the production of quantities or concentrations of *B. anthracis* in culture and in activities involving a high potential for aerosol production. The primary immunization series consists of three subcutaneous injections at 0, 2, and 4 weeks and three booster vaccinations at 6, 12, and 18 months. To maintain immunity, an annual booster dose is recommended.[12]

The limited data available suggest that the best means of preventing inhalational anthrax after exposure to spores is administration of ciprofloxacin (10 to 15 mg/kg orally every 12 hours to a maximum of 500 mg orally every 12 hours) or doxycycline (100 mg orally every 12 hours for children >8 years old or 5 mg/kg/day in divided doses given every 12 hours for children ≤8 years old) in conjunction with a three-dose regimen of vaccine (given at 0, 2, and 4 weeks after exposure).[4] In the event of a biologic anthrax attack, children exposed to spores should receive ciprofloxacin as postexposure prophylaxis for 60 days. If penicillin sensitivity is established, prophylactic therapy can be changed to amoxicillin, 80 mg/kg divided into three doses taken every 8 hours (maximum dose 500 mg orally every 8 hours). Although no data in children are available, the vaccine probably would be safe and effective.[23]

Worldwide, anthrax is controlled through livestock immunization programs. Procedures to prevent the spread of anthrax in animals include disposal of contaminated carcasses by burning and annual vaccination of livestock in known enzootic areas. All suspected or proven cases of anthrax should be reported to public health officials. Hospitalized patients should be kept under isolation until the lesions are bacteriologically sterile. Contaminated dressings and clothing must be burned or sterilized, and the patient's room must be disinfected to destroy spores.

CHAPTER 103

BACILLUS CEREUS

Richard A. Oberhelman ✪ Thomas G. Cleary

Recognition of *Bacillus cereus* pathogenicity was delayed until clarification of the taxonomy of the genus *Bacillus* in the early 1950s. Multiple early reports of food poisoning and other infections including gastroenteritis, bacteremia-septicemia, cellulitis, ear and eye infections, endocarditis, and urinary tract infections that were attributed to *Bacillus subtilis* or to other *Bacillus* spp. probably were caused by *B. cereus.*[91] *B. cereus* can give rise to two distinct forms of food-borne diseases related to different toxins, the emetic and the diarrheal syndromes, and occasionally to localized and systemic disease.[36,53]

The diarrheal syndrome was recognized first by Hauge[43] in 1955 after four clinically similar outbreaks in Norway occurred. This common form of disease was related to a great variety of foods, such as meat and vegetable soup, poultry, pudding, sauce, pasta, cake, and milk. In 1974, Mortimer and McCann[69] described a vomiting syndrome associated with the consumption of fried rice in Chinese restaurants. Despite widespread recognition in Europe, *B. cereus* outbreaks have been reported infrequently in the United States. The first documented outbreak in the United States occurred in 1970.[66]

BACTERIOLOGY

Members of the genus *Bacillus* are aerobic or facultative anaerobic, gram-positive or gram-variable, spore-forming rods. They are distributed widely in the environment because of the high resistance of their endospores to extreme conditions, including heat, cold, desiccation, salinity, and radiation.[28,79] Based on the high variability in guanine and cytosine content (32 to 69%), the debate ensues regarding the classification of *Bacillus* spp.[96]

B. cereus belongs to the group of gram-positive rods that produce central or terminal ellipsoid or cylindric spores that do not distend the sporangia.[96] Studies of DNA-DNA hybridization and 16S and 23S rRNA sequencing and enzyme electrophoretic patterns have shown a close relationship among *B. cereus*, *Bacillus anthracis*, *Bacillus mycoides*, and *Bacillus thuringiensis*; these organisms are so closely related that they all may be considered variants of *B. cereus*. Differentiating, particularly between *B. cereus* and the insect pathogen *B. thuringiensis*, sometimes is difficult in the diagnostic laboratory. Polymerase chain reaction technology has been used for identifying species.[16]

B. cereus is a flagellated, motile, gram-positive rod, typically 1 to 1.2 µm in diameter by 3 to 5 µm in length. The organism sporulates freely on many media under well-aerated conditions, but vegetative cells also can grow anaerobically. It is able to metabolize glucose, fructose, and sucrose but not pentose and other sugar alcohols. It produces acid from glucose but not from arabinose, xylose, or mannitol. Starch hydrolysis and catalase production are similar to those of the other members of the genus. The presence of lipid globules or protoplasts is a characteristic that it shares with *Bacillus megaterium*.[54] Colonies on blood agar are large, flat, granular, and slightly green-tinged. *B. cereus* is differentiated from *B. anthracis* by motility, hemolysis, lack of lysis by gamma-phage, penicillin resistance, and absence of a capsule in *B. cereus*.[28] Identifying morphologic differentiation with nonmotile *B. cereus* strains and *B. anthracis* strains that are occasionally weakly hemolytic may be difficult.

Growth and multiplication of vegetative cells occur in a temperature range of 10° C to 50° C, with an optimum of 28° C to 35° C. Variations in toxin levels found in certain foods also can be related to pH levels, sugar content, the presence of other lactic acid bacteria, and aeration.[85,86] Some strains responsible for milk spoilage can grow at temperatures of 5° C,[54,79] but few strains are able to produce toxin at temperatures less than 7° C.[79] Ribosomal DNA characterization and genotyping based on the major cold shock protein homologue cspA have defined a novel species, *Bacillus weichenstephanensis*, which can grow at 4° C to 7° C, but not at 43° C.[56] These strains form a new fifth subgroup of *B. cereus* organisms described as psychrotolerant or psychrotropic, meaning they are able to grow at temperatures of 7° C and less.[55,75,87] Spore formation allows some *B. cereus* strains to survive pasteurization and heating.[55] More recently, a crystalline cell surface protein layer or "S-layer" has been described as a determinant of cell hydrophobicity. S-layer–producing cells are hydrophilic and able to bind to human matrix proteins, and presence of the S-layer in some *B. cereus* strains is associated with resistance to phagocytosis and increased radiation resistance against gamma irradiation.[53]

Serologic differentiation of *Bacillus* spp. is hampered by cross-reactive antigens and autoagglutination of spores caused by hydrophobic surface properties. Serologic typing based on the flagellar (H) antigen can be used during an outbreak to distinguish among strains and to determine the similarity of isolates obtained from humans with the strains isolated from suspect foods.[28] The serotype scheme is based on 42 H antisera raised against prototype strains. A common flagellar antigenic epitope has been suggested. Detection of the flagellar antigen by enzyme-linked immunosorbent assay is perhaps more sensitive than is detection by the agglutination method.[70] In addition to serology and biotyping (based on biochemical typing), plasmid analysis and phage typing have proved useful epidemiologically.[2,54,83,100] Techniques such as pyrolysis mass spectrometry and gas-liquid chromatography of whole-cell fatty acids are showing promise.[28]

Diagnosis of the rare extraintestinal infection is made by isolation from normally sterile sites (blood or tissue) after overnight incubation on nutrient or blood agar; clinical specimens from normally nonsterile sites (feces, vomitus) and food or environmental samples require selective techniques. Polymyxin B is used as a selective agent, and the lecithinase reaction of the organism on egg yolk and its inability to catabolize mannitol permit presumptive identification to be made with a variety of media: mannitol–egg yolk–polymyxin B, Kim and Goepfert medium, and polymyxin B–pyruvate–egg yolk–mannitol with bromothymol blue or bromocresol purple.[28]

EPIDEMIOLOGY

B. cereus in the spore and vegetative form is a ubiquitous organism found in soil, water, vegetation, and food products, especially cereals, dairy products, dried foods, spices, meat products, and vegetables.[54] The emetic syndrome typically is associated with cooked rice, usually fried, from Chinese restaurants.[52,69] Saving portions of boiled rice at room temperature overnight until required for frying previously was a common practice. Refrigerating boiled rice makes the grains stick together, which is less convenient for frying. The spores of *B. cereus* survive cooking and are capable of germination and outgrowth.[37,39] The optimal temperature for growth in boiled rice is 30° C to 37° C, although growth does occur during storage at 15° C to 43° C.[37] Most samples of uncooked rice contain multiple serotypes of *B. cereus*, and little difference occurs in the growth rate of the various serotypes in boiled rice at 22° C, but spores of serotype 1 strains are more resistant to heating at 95° C, which probably is the reason that this serotype usually is implicated in outbreaks.[72]

Starchy dried foods other than rice, such as cereals, frequently are contaminated.[15] Tortillas can be contaminated with the water used in preparation and from the hands of producers.[19] Specific foods incriminated in outbreaks in the United States include Chinese food (accounting for 50% of reported outbreaks between 1973 and 1987), followed by Mexican food, beef, fruits, and vegetables. Other foods implicated, particularly in the enterotoxin syndrome, include beef stew, turkey loaf, barbecued pork, macaroni and cheese, potatoes, spaghetti and other pastas, dairy and dried milk products, and seafoods.[27,35,46,50,53,59] In a study of 96 milk and milk product samples collected from retail shops in Nairobi, Kenya, 57 percent of samples were contaminated with *B. cereus* and 81 percent of the bacterial isolates (38 of 47) produced non-hemolytic enterotoxins, including 6 of 43 pasteurized milk products (43%).[71] Among the factors thought to contribute to the outbreaks, the most frequent were improper storage or holding temperature (94%), contaminated equipment (53%), inadequate cooking (32%), and poor personal hygiene (24%).[7]

Outbreaks of *B. cereus* have been recognized widely in Europe but rarely in the United States. In the Netherlands, *B. cereus* reportedly was the cause of 22.4 percent of food-borne disease outbreaks of known bacterial cause. Similarly, in Finland, it accounted for 11.9 percent of outbreaks. In most places, *B. cereus* is incriminated in 0.9 to 7 percent of outbreaks of food-related disease and 0.7 to 3 percent of cases.[54] In the United States between 1998 and 2002, *B. cereus* was identified as the cause of 37 of 6647 (0.6%) foodborne outbreaks reported to the Centers for Disease Control and Prevention, with a total of 571 cases and no deaths recorded.[62] The location of the outbreak is known for 24 of these outbreaks, and most of these (15 of 24 [62.5%]) occurred in commercial food outlets, such as restaurants, delicatessens, or workplace cafeterias. In outbreaks for which the impli-

cated source was known, cereal products were the most common vehicle.[62] The susceptibility of children to this pathogen is evident from the report of an outbreak involving two daycare centers[52] and other reports that included neonates, children, and adolescents.[31,45,49,73,78,92,104] Only a small fraction of outbreaks are reported to the Centers for Disease Control and Prevention; small outbreaks of mild, brief illness are less likely to be reported. It is thought that 10^5 to 10^8 organisms per gram need to be ingested to cause the emetic syndrome and 10^5 to 10^7 cells or spores (total dose) ingested to cause the enterotoxin syndrome.[40]

For infections not related to food, groups at risk include neonates,[31,73] immunocompromised hosts,[4,20,30,39,45,49,83,89] intravenous drug abusers,[23,89] and patients with intravascular devices or artificial prostheses.[4,6,30,31,83,84] Studies in three different populations in South Africa and London, including school-aged children, found the organism in 18 to 43 percent of fecal samples.[95] The organism can be part of the normal intestinal flora. *B. cereus* does not persist in the intestine after ingestion.[34]

PATHOGENESIS

B. cereus produces an enormous range of extracellular metabolites, including peptides with antibiotic properties (biocerin, cerein, thiocillins), β-lactamases, hydrolases, nuclease, urease, and proteases.[91] Two different groups of toxins, known as diarrheal enterotoxins and emetic toxin, are responsible for the clinical syndromes of food poisoning.[64,97] Some strains may be able to produce both toxins based on the evidence that culture filtrates derived from strains isolated from emetic poisoning occasionally are able to produce a positive rabbit ileal loop assay.[79]

Biologic activities of diarrheal enterotoxins can be shown in multiple different assay systems. Three enterotoxins are produced. Purification plus isolation of multiple toxic fractions with some, but not all, of these activities has caused confusion.[28,90] Evaluation of the toxic activity of whole-cell suspension, cell-free culture filtrates, and the purified enterotoxin complex classically has included the rabbit ileal loop fluid accumulation assay, vascular permeability in rabbit skin, dermonecrosis and intestinonecrosis, mouse lethality, cytotoxicity, and hemolysis.[12,18,58,88,93,98] Hemolytic *B. cereus* enterotoxin has been characterized as a complex called *hemolysin BL* or *HBL*, composed of a binding component B (35 kd) and two lytic components, L1 and L2 (36 kd and 45 kd)[8]; all three are needed for fluid accumulation in the rabbit ileal loop.[10] Another *B. cereus* enterotoxin complex that is non-hemolytic and is composed of three distinct proteins has been described.[61] Several other single proteins with enterotoxic diarrhea–producing activity also have been described.[53]

The emetic toxin cereulide is a heat-stable (126° C for 90 minutes), ring-shaped peptide with a molecular weight of 1.2 kd[65]; it is stable between pH 2 and 11 and is protease-resistant. In contrast to the diarrheal toxins, it is preformed in foods, so the presence of living organisms at the time of ingestion is not necessary to cause symptoms.[36,91] Rice culture filtrates derived from emetic syndrome–associated strains cause cytoplasmic vacuolation and swollen mitochondria in HEp-2 cells, characteristics suggestive of uncoupling of oxidative phosphorylation.[76] Emetic activity occurs through the serotonin 5-HT_3 receptor and stimulation of the vagus afferent nerve.[1]

Among the multiple other substances with relevant activity, two groups are associated with local infection.[93,94] Cereolysin, or hemolysin I, is a thiol-activated cytolysin. Phospholipase C–like or lecithinase-like substances, including a sphingomyelinase and two hydrolases with preference for phosphatidylcholine and phosphatidylinositol, also exist. These enzymes induce the release of lysosomal enzymes from neutrophils that probably are involved in tissue damage, especially in wound and ocular infections.[28,106]

CLINICAL MANIFESTATIONS

FOOD POISONING

Diarrheal Syndrome

The enterotoxins preformed in food or produced in vivo in the intestine after the ingestion of bacilli cause profuse, watery, nonbloody diarrhea accompanied by abdominal pain and cramps, nausea, and, occasionally, vomiting or low-grade fever.[3,27,35,50,54,60,82] The typical incubation period is 8 to 16 hours, and the clinical characteristics resemble the food poisoning of *Clostridium perfringens*. The interval between ingestion and the onset of symptoms reflects the time required for production of toxin in the gut. The symptoms resolve within approximately 12 to 24 hours but occasionally can last 2 days to 2 weeks.[35] The diarrhea (3 to 10 bowel movements per day) rarely leads to dehydration in healthy individuals. In the elderly, bloody stools can occur.[35] The most prevalent flagellar H serotypes are 1, 2, 6, 8, 10, 12, and 19. Serotyping is available at research laboratories.[15,27,59,95]

Emetic Syndrome

The usual illness is characterized by a rapid onset (within 1 to 5 hours after the ingestion of contaminated food) of nausea, vomiting, and malaise, occasionally followed by diarrhea hours later.[69] Infrequently, the diarrhea is reported to last several days.[101] The short incubation reflects the ingestion of preformed emetic toxin.

EXTRAINTESTINAL INFECTIONS

Eye Infection

Keratitis, conjunctivitis, endophthalmitis, and panophthalmitis can be produced by *B. cereus*. Endophthalmitis that develops after the occurrence of penetrating wounds is caused by this organism in 27 to 46 percent of cases.[25,99] A history of soil contamination or the presence of a metal foreign body should raise clinical suspicion. Less frequently, corneal ulcers and surgical procedures are predisposing factors.[44,99] Exogenous endophthalmitis usually progresses rapidly, with deterioration of vision occurring in less than 48 hours. Severe pain is accompanied by chemosis, periorbital swelling, proptosis, and pus in the anterior chamber. The classic lesion is a corneal ring abscess, similar to that produced by *Pseudomonas* and *Proteus* spp. Endogenous cases may have subretinal exudation, retinal hemorrhage, and perivasculitis. Associated systemic symptoms are not unusual manifestations.[23] The outcome is poor, with almost half of patients left with visual acuity no better than simple light perception.[99] Many patients require enucleation. Endogenous ophthalmitis is associated with the use of illicit intravenous drugs or transfusion of contaminated blood products and subsequent bacteremic seeding of one eye.[23,83,89,99]

The pathogenesis of *B. cereus* on ocular tissue has been linked to the lecithinase activity of phospholipase C. A toxin fraction, hemolysin BL, which is formed by three separate components, produces similar destruction of retinal tissue in vitro and in animal experiments.[9] Its relationship with the diarrheal enterotoxin is unclear.[12]

Wound and Soft Tissue Infections

Wound infections of variable severity related to trauma, burns, or postsurgical complications occasionally are reported.[92-94,104] Because *Bacillus* is a common environmental contaminant, proof of the relevance of a *B. cereus* isolate is clearer if the organism is obtained from deep tissue in heavy pure growth. Severe infec-

tions in individuals involved in motor vehicle accidents can be complicated by necrotizing fasciitis and require extensive débridement.[104] Superficial, benignly infected wounds are common findings in the tropics.[29] Immunosuppressed patients may contract a severe gas gangrene–like infection with myonecrosis similar to disease caused by *Clostridium* spp.,[65] requiring amputation,[42] or a less severe primary cutaneous infection manifested by vesicles, pustules, or cellulitis.[45]

Skeletal Infections

Cases of chronic osteomyelitis occur rarely and result from accidental or surgical trauma. Radical débridement and antibiotic treatment are required.[83] Because *B. cereus* can be found as a copathogen with other more frequent pathogenic bacteria, resolution of symptoms is delayed until eradication of the organism.[78] Acute osteomyelitis may occur in drug abusers.[83,89]

Bacteremia and Septicemia

Bacteremia occurs with indwelling catheters and other foreign bodies, contaminated intravenous drugs (e.g., heroin), and blood products, particularly platelets.[17,30,107] Immunosuppression and impaired neutrophil killing, such as occur in individuals with neutropenia secondary to malignancy or chemotherapy and in neonates with immaturity of the immune system, are major contributors to morbidity in systemic *B. cereus* infection.[4,18,47,73,74] Disseminated intravascular coagulation, multiorgan failure, and a fulminant course may occur in neonates and compromised hosts. Intestinal perforation with abdominal infection in neonates also has been described.[38] Outbreaks of sepsis in newborn nurseries have been linked to contaminated ventilation balloon devices.[102] Endocarditis is an infrequent complication of bacteremia that usually occurs in intravenous drug abusers or individuals with a long-term intravascular device.[83,89] Vegetations can form over mechanical prosthetic valves or pacemaker wires, requiring their replacement.[83,84] Morbidity and mortality rates are high in patients with valvular heart disease. Fatal serosanguineous pericarditis in a patient undergoing hemodialysis has been reported.[32]

Pneumonia

Primary pulmonary disease rarely has been recorded. The manifestation can be subacute and consist of cough, fever, dyspnea, chest pain, and hemoptysis, with progression to necrotizing pneumonia, cavitation, and empyema. Pleural fluid may appear serosanguineous or sanguinopurulent.[13,47] Underlying predisposing conditions include leukemia, alcohol abuse, chronic hepatitis, and steroid use.[13,30,47,83] Multiorgan disease in premature neonates with necrotizing pneumonia usually is fatal.[51] Outbreaks of *B. cereus* pneumonia in neonates have been linked to contaminated ventilators.[41] Blood culture is positive in 75 percent of cases, followed by pleural fluid and sputum culture in 40 to 60 percent.[13] The pleural space may become contaminated with *B. cereus* by mishandling of the thoracic drainage system in patients with other causes of pleuritis.[48]

Infection of the Central Nervous System

Intracranial shunts and penetrating surgical or traumatic cranial wounds expose the central nervous system to environmental *B. cereus*.[31,81] Spinal anesthesia[30] was associated with *Bacillus* infection in the past. Contamination in the operating room through the linen is a potential source.[5,6] Premature neonates are susceptible to meningeal seeding by dissemination of intravascular infection related to catheters.[73] As in patients with other serious infections, patients who are immunosuppressed are at higher risk.[47] The cerebrospinal fluid in *B. cereus* meningitis is purulent, with white blood cell counts of more than 1000/mm^3, a predominance of polymorphonuclear leukocytes, and moderate increments in protein content. Gram stain is positive in 70 percent of cases. Multiple brain abscesses may result from hematogenous spread in patients with leukemia.[47,49] Sequelae include hydrocephalus and brain damage. Often, the infection is fatal unless caused by a contaminated spinal anesthetic, in which case the course is usually more benign.

Liver Failure

Fulminant hepatitis and rhabdomyolysis have been associated with the emetic toxin. The toxin inhibits hepatic mitochondrial fatty-acid oxidation. Liver changes include fatty infiltrates and midzonal necrosis.[63]

Pseudoinfections

Pseudoepidemics with *B. cereus* are a challenge for the clinical microbiologist.[67] Because these spore formers are so hardy, they are common laboratory contaminants. *Bacillus* spp. isolated from clinical specimens usually should be considered a contaminant, although their pathogenic potential is well known.[24,30,47,74,83,89,93,94] Pseudoinfections have been associated with contaminated blood culture media, syringes, blood culture analyzers, and fiberoptic bronchoscopes.[24] Colonization of umbilical cord stumps and eye surfaces by contaminated diapers may cause pseudo-outbreaks in nurseries.[105]

COMPLICATIONS

Death rarely ever results from the food-poisoning syndromes. Rapidly spreading wound infections may require amputation of extremities,[39] and ocular infections can lead to loss of vision with or without enucleation.[44,99,106] The risk of death in patients with septicemia, endocarditis, and meningitis is related to the underlying condition and severity of the disease.[4,45,68,73,84]

DIAGNOSIS

The laboratory finding of *B. cereus* in a foodstuff without quantitative cultures and without epidemiologic data is insufficient to establish its role in an outbreak.[101] In practice, appropriate specimens often either are unavailable or are submitted long after the incident, rendering their microbiologic significance questionable. During analysis of foods not involved in food-borne illness, the bacteria may be found in counts of 10^1 to 10^6 organisms per gram.[14,15,19,37,72,85] Diagnosis of the diarrheal form of *B. cereus* food poisoning is supported by the isolation of 10^5 or more organisms per gram from epidemiologically incriminated food.[68] The levels of *B. cereus* found in the implicated foods usually are in the range of 5×10^5 to 9.5×10^8 colony-forming units per gram. With the exception of milk, the products rarely appear to be spoiled, despite the bacteria's high density. Isolation of more than 10^5 organisms per gram in feces during an acute attack provides supportive evidence for the presumed diagnosis and confirms the association if the same serotype is isolated from incriminated food.

The organisms that produce emetic toxin are present in concentrations of 1×10^3 to 5×10^{10} colony-forming units per gram. Reheating may decrease or eliminate the organisms and leave the toxin intact, but render isolation of the organism difficult to accomplish.[28,101]

Commercial immunoassay kits (reversed passive latex agglutination test, enzyme-linked immunosorbent assay, and microslide

TABLE 103–1 Management and Complications Associated with *Bacillus cereus* Infections

Condition	Management	Complications
Food poisoning	Supportive measures; hydration	Usually none; liver failure rarely reported
Ocular	Systemic, topical, intravitreal antibiotics—vancomycin or clindamycin ± aminoglycosides; surgical—early vitrectomy	Severe decreased visual acuity, blindness, enucleation
Septicemia	Removal of IV device, foreign body; IV antibiotics (according to sensitivity)—vancomycin	Localization of infection—endophthalmitis, endocarditis, meningitis; death
Pneumonia/pleuritis	IV antibiotics; drainage of pleural space; resection of necrotic tissue	Death
Meningitis	IV antibiotics; removal of infected intracranial shunts or cerebrospinal fluid reservoirs	Hydrocephalus, brain damage, death
Wound/subcutaneous infection	IV antibiotics; surgical débridement	Amputation, death

IV, intravenous.

immunodiffusion assay) are available for the detection of *B. cereus* diarrheal toxin. The kits may detect a variety of proteins, however.[11,26] Experimental techniques based on the detection of genes for phospholipase C and sphingomyelinase by polymerase chain reaction have been developed for the identification of *B. cereus* in food products.[65]

The relevance of clinical isolates in extraintestinal syndromes can be assessed by the degree of growth (heavy versus scanty), the number of occasions that growth was obtained, the source of the material cultured, and predisposing or underlying conditions.[94] For suspected endophthalmitis, aqueous and vitreous samples should be obtained if possible before the initiation of antibiotics.[25]

TREATMENT

During a mild, self-limited attack of food poisoning, patients require only supportive therapy. Usually, oral fluid and electrolyte replacement is adequate (Table 103–1).[35]

No antibiotic therapy is required except in cases of nongastrointestinal infection. The production of three different β-lactamases by most of the organisms renders penicillin derivatives, including third-generation cephalosporins, ineffective against *B. cereus*. Most strains are susceptible to chloramphenicol, vancomycin, clindamycin, aminoglycosides, erythromycin, tetracycline, imipenem, and ciprofloxacin.[4,21,93,94,103] Definitive antibiotic therapy should be based on the antibiogram susceptibility, but initial empiric therapy with clindamycin or vancomycin, with or without an aminoglycoside, is appropriate, pending susceptibility data.[4,13,24,49,78,104] Ciprofloxacin has been reported to be useful in the treatment of recurrent pneumonia and bacteremia[33] and may have advantages in the penetration of respiratory and eye secretions,[57] but other options for children younger than 18 years are preferred.

Immediate empiric coverage for *B. cereus* is indicated for endophthalmitis in groups at risk. Selection of the antibiotic and the appropriate means of administration are controversial.[25] Clindamycin and an aminoglycoside[106] or vancomycin[99] are the best options. Together with antibiotics administered parenterally, topical and periocular antibiotics are considered adjunctive therapy. In cases of penetrating trauma, early vitrectomy and intravitreal antibiotics (vancomycin in combination with amikacin) should be considered.[25,99]

Surgical débridement of necrotic tissue, drainage of closed-space infections, and prompt removal of foreign bodies and indwelling catheters are important aspects of successful therapy.[13,22,78] Some bacteremic patients may be cured by removal of the intravenous catheter only.[83]

PREVENTION AND CONTROL

Low-level contamination in food products is difficult to avoid, but proper food handling should diminish the proliferation of bacilli.[79] Practical precautions for handling cereals and rice include not preparing large quantities at a single time and maintaining the food at a hot temperature (>63° C) or cooling it quickly. The food must not be stored under warm conditions, especially in the range of 15° C to 50° C.[15,37]

CHAPTER 104

ARCANOBACTERIUM HAEMOLYTICUM

Natascha Ching

Arcanobacterium haemolyticum is a pleomorphic gram-positive coryneform rod that causes pharyngitis and exanthem in children and young adults.[18,37,41,46]

HISTORY

This diphtheroid was noted first by MacLean and colleagues[41] in association with exudative pharyngitis in American servicemen in the South Pacific during World War II. The organism originally was named *Corynebacterium haemolyticum* but was reclassified in 1986 as *A. haemolyticum* on the basis of phenetic, peptidoglycan, fatty acid, menaquinone, and DNA data.[16-18] The association between infection with *A. haemolyticum* and pharyngitis was observed repeatedly over the years, but a cause-and-effect relationship between the organism and illness has been established only more recently.[10,40,46]

ORGANISM

MICROBIOLOGY

A. haemolyticum is a gram-positive to gram-variable pleomorphic rod.[18,20,25,64,67] The laboratory characteristics are presented in Table 104–1. *A. haemolyticum* grows best at 37° C on a blood-enriched or serum-enriched medium with the addition of 5 percent carbon dioxide. Alternatively, it grows well anaerobically. On rabbit or human blood agar, colonies are pinpoint (0.5 mm) at 24 hours; they increase to 1 to 1.5 mm after 48 hours. At this time, a unique black opaque dot is noted in the center of the colony, and this dot remains on the agar when the colony is scraped away.

TABLE 104–1 Identification Characteristics of *Arcanobacterium haemolyticum*

Test or Characteristic	Finding
Catalase	Negative
Beta-hemolysis	Positive (narrow zone of slight hemolysis after 48 hr on sheep blood)
Nitrate reduction	Negative
Pigment production	White or gray
Urease	Negative
Gelatin hydrolysis	Negative
Motility	Negative
Esculin hydrolysis	Negative
Carbohydrate use	
Glucose	Positive
Maltose	Positive
Sucrose	Positive (requires rabbit serum for growth in peptone water)
Mannitol	Negative
Xylose	Negative

Data from Collins, M. D., and Cummins, C. S.: Genus Corynebacterium. In *Sneath, P. H. A., Main, N. S., Sharpe, M. E., et al. (eds.): Bergey's Manual of Systemic Bacteriology. Vol. 2. Baltimore, Williams & Wilkins, 1986, pp. 266-276.*

At 24 hours, a 1-mm zone of hemolysis develops around colonies grown on human or rabbit blood agar. The hemolytic zone increases to 3 to 5 mm by 48 hours. Growth and red blood cell hemolysis are minimal on horse and sheep blood agar. Because throat cultures usually are performed on sheep blood agar plates, the hemolytic activity of *A. haemolyticum* may be missed.

Colonies of *A. haemolyticum* can be of either the smooth or the rough biotypes on horse blood agar.[12] These biotypes also

differ in their hemolysis and biochemical properties. Smooth colonies predominate in wound infections and frequently use sucrose and trehalose, are beta-hemolytic, and lack β-glucuronidase. Rough colonies are found almost exclusively in the respiratory tract and do not use sucrose and trehalose, are non-hemolytic, and are β-glucuronidase-positive.

A. haemolyticum resembles *Actinomyces pyogenes* (formerly *Corynebacterium pyogenes*), a common cause of bovine mastitis and a rare cause of skin ulcers in children.[33] These organisms can be differentiated by several means. *A. pyogenes* is able to hydrolyze gelatin and ferment xylose. In addition, *A. haemolyticum* has a positive reverse CAMP (Christie, Atkins, and Munch-Petersen) test in that it inhibits the beta-hemolysis of *Staphylococcus aureus*, whereas *A. pyogenes* shows slight enhancement of beta-hemolysis.[24] *A. haemolyticum*'s poor growth on tellurite medium and lack of catalase help distinguish it from *Corynebacterium diphtheriae*, which also causes pharyngitis.[29,35,37]

TOXIN PRODUCTION

A. haemolyticum liberates three toxins: phospholipase D (PLD), a hemolysin, and neuraminidase.[18] PLD is a dermonecrotic toxin that causes local hemorrhagic necrosis after intradermal inoculation in rabbits and guinea pigs; injection of PLD also is lethal in rabbits.[54] The PLD gene of *A. haemolyticum* has a high degree of homology to that of *Corynebacterium pseudotuberculosis*.[19,43] PLD has been shown to be involved in the virulence of *C. pseudotuberculosis*; PLD mutants are less pathogenic in experimental infections in goats.[42] The PLD of *C. pseudotuberculosis* is similar biochemically and shares some biologic activity with the PLD that is found in brown recluse spider venom and that plays a role in the venom's toxicity.[6,37] *A. haemolyticum* carries a gene similar to the gene encoding the erythrogenic toxin of *Streptococcus pyogenes*.[18]

ANTIMICROBIAL SUSCEPTIBILITY

Almost all *A. haemolyticum* strains are highly susceptible to erythromycin (minimal inhibitory concentration <0.06 μg/mL). Erythromycin is not bactericidal, however.[9,41,64] Carlson and colleagues[11] reported an *A. haemolyticum* isolate from a diabetic foot ulcer that was exceptionally resistant to macrolides, clindamycin, tetracycline, and ofloxacin. Waagner[64] noted that of 100 pharyngeal isolates, all were inhibited by concentrations of 0.25 μg/mL or less of penicillin G and by 1 μg/mL of penicillin V. Tolerance to penicillin has been observed, however.[41,51] In one study, the minimal bactericidal concentration-to-minimal inhibitory concentration ratio varied from 1:1 to 1:8.[41] In addition to being sensitive to penicillin and erythromycin, *A. haemolyticum* is sensitive to other β-lactams, clindamycin, chloramphenicol, azithromycin, vancomycin, ciprofloxacin, tetracyclines, and rifampin; most strains are resistant to sulfonamides and trimethoprim-sulfamethoxazole.[9,11,64]

Carlson[8] compared E Test (AB Biodisk, Sweden) and agar dilution methods for susceptibility testing of 12 antimicrobial agents in 70 *A. haemolyticum* isolates. E test and agar dilution method results for benzylpenicillin, clindamycin, erythromycin, imipenem, levofloxacin, rifampin, and vancomycin were in 100 percent agreement. Tetracycline, ciprofloxacin, and ofloxacin were in 97 to 99 percent agreement, but a lower percentage of agreement was found for cefotaxime and cefuroxime, 93 percent and 84 percent, respectively. Because there are no universal standards for the organism with regard to susceptible, intermediate, or resistant categories, results should be interpreted with caution for clinical care. Almuzara and colleagues[1] also evaluated the susceptibility of 19 strains of *A. haemolyticum* according to National Committee for Clinical Laboratory Standards interpretative standards for aerobic organisms. Most isolates were susceptible to penicillin, cephalosporins, clindamycin, ciprofloxacin, vancomycin, and macrolides (erythromycin and azithromycin). Only 68 percent of isolates were found to be sensitive to tetracycline.

Although the Clinical and Laboratory Standards Institute has no standardized susceptibility testing method for *Arcanobacterium* spp., it has been suggested that the broth microdilution method used for testing *Corynebacterium* spp.[15] is appropriate for *Arcanobacterium* spp. (Janet Hindler, MCLS, UCLA Medical Center, Clinical Microbiology Laboratory, Los Angeles, CA, and Guido Funke, MD, Gartner & Colleagues Laboratories, Ravensburg, Germany, personal communication). This method involves testing in cation-adjusted Mueller-Hinton broth supplemented with lysed horse blood (2.5 to 5% v/v). Some investigators have used agar dilution or E test satisfactorily.[8]

A vancomycin-resistant *A. haemolyticum* isolated from stool during an outbreak of vancomycin-resistant enterococci has been described. It contained the *vanA* gene primarily found in *Enterococcus faecium*.[47] Two other case reports have described organisms resistant to ciprofloxacin[63] and tetracycline.[36]

EPIDEMIOLOGY

Although similar organisms are common causes of infection in animals, humans seem to be the primary host of *A. haemolyticum*.[56,64] The organism is isolated primarily from throat specimens in patients with pharyngitis,[41,46,64] although it also may be a commensal of human skin.[40] It likewise may be a commensal in the throat, but it often is overlooked because laboratories frequently do not differentiate diphtheroids, which are considered "normal flora." In addition, because *A. haemolyticum* often is found in polymicrobial respiratory infections with classic respiratory pathogens, including *S. pyogenes*, it sometimes is missed when these more classic pathogens are identified.[37]

Although no definitive data are available, person-to-person spread is assumed to be from the throat discharge of an infected individual to the throat of a susceptible host. Transmission could occur directly or indirectly by fomites. Secondary cases in families indicate that spread is from person to person rather than from an environmental source.[23,46]

In an 8-year study, the organism was found to be isolated from throat specimens in each year, with isolation rates varying from 0.2 to 0.7 percent.[46] The peak age for contracting illness caused by *A. haemolyticum* is during the second decade of life; in contrast, the peak age for developing pharyngitis caused by *S. pyogenes* is during the first decade of life.[23,41,46] In two studies, illnesses occurred more commonly in young women than in young men.[23,46] In a review of *A. haemolyticum* systemic and deep-seated infections, a preponderance of boys over girls was found among adolescents with no risk factors for development of invasive disease.[60] No seasonal prevalence has been reported.

Screening throat cultures for pharyngotonsillitis in northern Israel were performed in 518 patients aged 1 to 90 years old.[14] Only one culture was positive (0.2%) for *A. haemolyticum* compared with 26 percent recovery of group A streptococcus. The one case was in a 9-year-old patient, however, and only 58.7 percent of patients were aged 1 to 18 years old, the more common age of isolation for this organism.

PATHOGENESIS AND PATHOLOGY

Few data are available regarding pathogenesis and pathology. The dermonecrotic toxin probably plays a role in pharyngitis. Skin biopsy specimens were taken from the exanthem in two

TABLE 104–2 Signs and Symptoms in Children, Adolescents, and Young Adults with *Arcanobacterium haemolyticum* Infection

	Frequency (%)
Symptoms	
Sore throat	100
Rash	40-70
Pruritus	50
Fever	40-75
Hoarseness	60
Cough (nonproductive)	40-60
Vomiting	30
Signs	
Pharyngitis or tonsillitis	100
Exudative	50-70
Palatal petechiae	30
Glossitis	25
Cervical lymphadenitis	40-75
Rash	40-70
Scarlatiniform	50
Urticarial	5
Maculopapular	25

Data from references 23, 32, 41, 46, and 64.

patients, and both showed only a mild lymphohistiocytic perivascular infiltrate.[46] Cultures of both samples were negative, and no IgG, IgA, or IgM deposition was noted. These findings suggest that the rash may be toxin-mediated, similar to the rash in group A streptococcal infections.

A. haemolyticum has been found to persist intracellularly,[52] which might account for failure of penicillin treatment in some cases. In one study, 5 of 42 patients were found to have apparent dual infections with Epstein-Barr virus (EBV) and *A. haemolyticum*.[41] The authors of this study suggested that immunosuppression by the virus contributes to a more marked effect of the bacterial infection in the throat. With regard to the immune response to *A. haemolyticum*, paired acute and convalescent sera showed the development of a humoral response to four distinct cell wall–associated proteins on Western blot analysis in seven of eight patients with culture-confirmed infection.[49]

CLINICAL MANIFESTATIONS

PHARYNGITIS

Pharyngitis* is the most common finding in *A. haemolyticum* infection. Signs and symptoms associated with pharyngitis are listed in Table 104–2. The illness is indistinguishable from that caused by group A streptococci; frequently, it resembles EBV infectious mononucleosis. Several patients with typical infectious mononucleosis had laboratory evidence of infection with EBV and *A. haemolyticum*.[27,28,41] Peritonsillar abscess caused by *A. haemolyticum* has been reported on several occasions.[4,35,38,45] The most common exanthem is scarlatiniform, the onset of which occurs 1 to 4 days after the beginning of pharyngeal symptoms. The rash is most prominent on the extensor surfaces of the arms and legs (see Fig. 64–19). Circumoral pallor, which is seen with group A streptococcal scarlet fever, does not seem to occur with *A. haemolyticum* infection. The rash may progress to involve the chest and back; it usually spares the palms, soles, and face, and it rarely involves the abdomen and buttocks.

The rash frequently is pruritic and may be urticarial. Erythema multiforme has been described.[3] Gaston and Zurowski[26] reported a 20-year-old man who had, in addition to pharyngitis, a rash involving mainly his hands and feet. His feet were swollen, and on the soles were erythematous macules, petechiae, and vesicles. His palms were tender, and 2- to 4-mm erythematous macular lesions that contained small central vesicles were present. Mehta[44] reported a 19-year-old woman who presented with pharyngitis and a pruritic rash on her arms and legs 4 days before evaluation. Physical examination revealed an erythematous, urticarial rash with large and small annular rings over the whole body with confluence on the upper thighs and smaller lesions in groups on distal dorsal parts of the hands and feet.

Carlson and colleagues[13] also reported a 19-year-old man who presented with a 2-day history of a pruritic exanthem on the upper back and chest, which spread centrifugally. The patient had pharyngitis that worsened to exudative tonsillitis, and a throat culture was positive for *A. haemolyticum*. He also had swollen fingers and worsening erythematous maculopapular exanthem over his trunk and proximal extremities. Pastia lines were observed on the third day. Two weeks after initiation of antimicrobial treatment and discharge, a mild late desquamation was noted on his palms and around his fingernails. The duration of the exanthem has not been described adequately in the literature. In one study, exanthem was noted to persist for longer than 2 days in 69 percent of patients.[46]

Occasionally, *A. haemolyticum* infection has been manifested as a grayish white pharyngeal pseudomembrane that has been confused with diphtheria.[3,29,31,35] *C. diphtheriae* and *A. haemolyticum* are diphtheroids that cannot be distinguished on Gram stain but can be differentiated by their biochemical properties.

SKIN INFECTIONS

In the initial report of infections with *A. haemolyticum* in 1946, MacLean and associates[41] noted pharyngitis in U.S. servicemen and skin infections in the native populations of the South Pacific Islands. Cutaneous infections have been observed mainly in tropical countries.[64] The most common manifestations are ulcerative lesions that resemble ecthyma. Cellulitis, wound infections, and paronychia all have been noted.[7,22,23,34,45,47,64,68] In wound infections, mixed infections with *A. haemolyticum* and other organisms are common.

Tan and colleagues[62] reported five cases of *A. haemolyticum* bacteremia associated with soft tissue infections in adults. These patients, two elderly bedridden patients with decubitus ulcers and three diabetic patients with foot ulcers with extensive involvement that required surgical débridement, had a history of soft tissue infections. Four patients also had *A. haemolyticum* isolated from the suspected soft tissue focus of infection. A 3-year retrospective review of clinical samples over the same period as the five reported cases revealed 25 isolates of *A. haemolyticum*. Isolates from wound infections or cellulitis or both were found in 96 percent of cases; 20 percent of those patients also had bacteremia. Cultures from nonsterile sites often were polymicrobial, but the authors reported that *A. haemolyticum* usually was the predominant isolate.

OTHER MANIFESTATIONS

Isolated instances of septicemia, brain abscess, meningitis, meningoencephalitis, orbital cellulitis, endocarditis, osteomyelitis, deep soft tissue infections, pleural empyema, cavitary pneumonia, pyothorax, Lemierre syndrome, and sinusitis have been attributed to *A. haemolyticum* infection.* Most of these serious infections

*See references 3, 10, 23, 26, 28, 29, 32, 40, 41, 46, 48, 50, 57-59, 64.

*See references 2, 5, 21, 24, 27, 28, 30, 36, 39, 53, 60, 62, 64-66, 69, 70.

occurred in adults and frequently were associated with underlying conditions, such as diabetes, a malignancy, or intravenous drug use. In a 1998 review of systemic and deep-seated infections caused by *A. haemolyticum*, Skov and associates[60] identified two groups of patients. The first group comprised middle-aged to elderly adults who were immunocompromised or had other known risk factors for development of serious infectious disease. The second group consisted of preteens to young adults with no known risk factors except for one individual receiving steroid treatment for EBV infection.

A pyothorax with multiloculated hydropneumothorax was reported in a 19-year-old man in India with no history of pharyngitis.[53] Pure growth of *A. haemolyticum* was obtained from the thoracentesis. Treatment consisted of a therapeutic thoracentesis and continued chest tube drainage for 1 month. Ceftriaxone and metronidazole were given for 1 month, and the patient had clinical and radiologic resolution.

A brain abscess was documented in an 18-year-old man in Venezuela with a history of multiple periodontal problems, including periodontitis, dental caries, and multiple teeth extractions.[63] The patient presented with headache, vomiting, and neurologic deficits in the left extremities. Computed tomography of the chest revealed a left-sided hypodense frontoparietal lesion with cystic, contrast ring enhancement; edema; and midline mass effect. When his neurologic status worsened, a craniotomy was performed, and aspiration of purulent material from the encapsulated mass revealed positive cultures with pure *A. haemolyticum* growth. Therapy consisted of ceftriaxone and metronidazole for 1 week, and he was switched after susceptibility testing to penicillin for 3 weeks. Limjoco-Antonio and colleagues[36] reported a 9-year-old girl who presented with a swollen right eye after incuring a blunt trauma. She had ethmoid and maxillary sinusitis and orbital cellulitis that required surgical drainage, débridement of a subperiosteal abscess, and a second procedure with external ethmoidectomy and endoscopic sinus surgery. Cultures from the ethmoid sinus grew *A. haemolyticum.* She was treated with ceftriaxone and clindamycin.

Younus and colleagues[70] reported Lemierre syndrome with co-infection of *A. haemolyticum* and *Fusobacterium necrophorum* bacteremia. A 21-year-old man presented with fever, sore throat, tenderness along the border of the left sternocleidomastoid muscle, crackles, a blanching maculopapular rash, sepsis, and worsening pulmonary symptoms. The initial blood culture had *F. necrophorum*, and repeat blood cultures from day of admission had *A. haemolyticum* before initiation of antimicrobial therapy. Computed tomography of the chest revealed multiple nodular densities in the lungs with evidence of central necrosis in one area. Therapy consisted of anticoagulation with heparin and initial antimicrobial therapy of gatifloxacin and metronidazole, which was switched to vancomycin and piperacillin-tazobactam for 2 weeks followed by an oral course of amoxicillin-clavulanic acid for 3 months; no surgical intervention was needed.

DIFFERENTIAL DIAGNOSIS

Pharyngitis caused by *A. haemolyticum* must be differentiated from all other causes of pharyngitis (see Chapter 10). Of particular importance is distinguishing *A. haemolyticum* pharyngitis from *S. pyogenes* pharyngitis. Such differentiation can be achieved with certainty only by specific culture. In *A. haemolyticum* infection, the rapid group A streptococcal antigen tests would be negative, as would the usual group A streptococcal culture. These negative tests in specimens from adolescents should suggest strongly the possibility of *A. haemolyticum* pharyngitis.

When exanthem occurs, the confusion with illness caused by *S. pyogenes* is more pronounced. In many cases, the rash in patients infected with *A. haemolyticum* is scarlatiniform. The lack of typical circumoral pallor and a tendency for more discrete lesions in *A. haemolyticum* infection occasionally may help in establishing the clinical diagnosis. Other common causes of pharyngitis and exanthem in adolescents and young adults are *Mycoplasma pneumoniae* and EBV infections. As noted by Mackenzie and colleagues,[40] *A. haemolyticum* and EBV co-infections are common findings. Concurrent *M. pneumoniae* pneumonia and *A. haemolyticum* empyema and bacteremia have been reported in a previously healthy 20-year-old man.[61] Cutaneous infections, including subacute ulcerations, wound infections, cellulitis, and paronychia caused by *A. haemolyticum*, must be differentiated from cutaneous infections caused by other organisms, such as staphylococci and streptococci.

SPECIFIC DIAGNOSIS

A specific diagnosis is made by culturing *A. haemolyticum* from the pharynx, a skin lesion, or a sterile body site in invasive infections. Culturing is done best with rabbit or human blood agar and the addition of 5 percent carbon dioxide.[18,20,64,67] Horse or sheep blood agar, which generally is used for culture of *S. pyogenes*, is not satisfactory for the growth and identification of *A. haemolyticum*. Using biochemical identification systems such as the API (RAPID) Coryne strip (API bioMérieux, La-Balme-les-Grottes, France) or the Biolog system (Biolog, Hazelwood, CA) can help differentiate *A. haemolyticum* from other coryneform bacteria. The Biolog system can make the identification in 4 hours.[25]

TREATMENT

A. haemolyticum is highly sensitive to numerous antibiotics.[9,12,41,50,64] Although no specific treatment studies have been done, the experience in several large studies suggests that penicillin and erythromycin are effective.[9,32,41,46] Clinical failure with penicillin has been noted.[3,52,64] Erythromycin has been suggested for first-line therapy for certain indications, such as *A. haemolyticum* tonsillitis.[11] Carlson and coworkers[11] suggest using either a broad-spectrum β-lactam antibiotic or clindamycin or macrolides for serious systemic *A. haemolyticum* infection, although these authors acknowledge that macrolides do not provide anaerobic coverage. An alternative approach would be to use high-dose penicillin plus an aminoglycoside.[60,64]

PROGNOSIS

The prognosis in cases of *A. haemolyticum* pharyngitis is good, even in untreated patients. Invasive disease can be fatal, however, and peritonsillar abscess requires prompt surgical intervention and appropriate antimicrobial therapy.

CHAPTER 105

ERYSIPELOTHRIX RHUSIOPATHIAE

Randall G. Fisher

Erysipelothrix rhusiopathiae (insidiosa) was identified definitively first by Rosenbach[29] in 1884 as a cause of the cutaneous disease erysipeloid. Although most commonly associated with localized skin infection in humans, this organism has been associated with sepsis,[13,27,37] chronic skin eruption,[9,16] and endocarditis.[3,13,21,22,28,37]

BACTERIOLOGY

E. rhusiopathiae is a slender, pleomorphic, gram-positive, unencapsulated rod that produces 0.1-mm bluish colonies on blood agar. On Gram staining, they may appear singly, in short chains, or, rarely, in long, branching filaments. Although they are gram-positive, they decolorize readily, sometimes producing a spotted appearance. Some strains produce alpha-hemolysis in 48 to 72 hours. Gelatin inoculated by stab inconsistently forms a "test-tube brush" or "pipe-cleaner pattern" appearance diagnostic for this organism.[13] *Erysipelothrix* is differentiated from morphologically similar *Listeria monocytogenes* and diphtheroids by the absence of motility and catalase production, and the presence of hydrogen sulfide production in triple-sugar iron medium.[13,37]

EPIDEMIOLOGY

First isolated from mice in 1880 by Koch, *Erysipelothrix* is a common commensal of wild and domestic mammals, birds, and fish.[13,37] The *Erysipelothrix* organism may lead a saphrophytic existence in soil. First identified by Loeffler in 1882 as the causative agent of swine erysipelas, it remains an important epidemic cause of disease in these animals, with losses greater than $25 million annually to this industry.[13] Sheep, rabbits, cattle, turkeys, and rats are subject to infection with this organism. *Erysipelothrix* has been recovered from wild moose and domestic emus.[5,20] *E. rhusiopathiae* survives salting and smoking procedures. Pieces of meat may contain the organism for 170 days after pickling, but exposure to moist heat for 15 minutes at 55° C[35] kills most strains.[13] Fish handlers, meat processors, poultry workers, veterinarians, abattoir workers, and food handlers are at risk for exposure to *Erysipelothrix*.[25] Isolates of the same serotype may show genetic diversity, so serotyping may not be completely reliable as an epidemiologic tool for tracking outbreaks.[6]

PATHOPHYSIOLOGY

Human infection is largely accidental and results from contamination of skin abrasions during handling of infected material. Males are infected more commonly than are females, perhaps because of an increased risk of exposure. The presence of an antiphagocytic capsule may be a virulence factor for *E. rhusiopathiae*.[32] In vitro study shows that encapsulated strains are poorly phagocytized by macrophages, unless immune serum is provided; ingested bacteria are able to replicate within the macrophage. The ability to survive and replicate within macrophages probably is due to failure of the encapsulated strains to induce the oxidative burst.[31] Disease usually is self-limited, most often involving the hands. Biopsy of skin lesions shows a marked inflammatory response. Difficulty of establishing bacteriologic confirmation has been attributed to the organism's location in the deep part of the pars reticularis of the corium.[7]

CLINICAL MANIFESTATIONS

Human disease typically manifests as a mild, localized cutaneous eruption; a more severe, generalized cutaneous form; or a septicemia often associated with endocarditis. Localized cutaneous infection, the erysipeloid of Rosenbach,[29] is the most common manifestation of *Erysipelothrix* disease.[25] After a 1- to 4-day incubation period, an acute localized lesion appears at the site of an abrasion contaminated with *E. rhusiopathiae*–colonized material. Slowly progressive, purplish red, painful induration is typical. Absence of suppuration and involution without desquamation help to distinguish this lesion from streptococcal or staphylococcal infection. Occasionally, the skin may show sharply circumscribed bluish red lesions, which are similar to the cutaneous manifestations in swine.[13,37] Fever and other constitutional symptoms are uncommon manifestations, occurring in less than 10 percent of cases, unless bacteremia supervenes.[9,25] Untreated infection usually is self-limited, with an average duration of 3 weeks.

Lymphangitis and adenitis occur in 10 percent of cases; in 20 percent of cases, progression of disease extends from lesions on the hand to the wrist and forearm.[17] In one case, a patient with type 2 diabetes was discovered at the time of surgery to have necrotizing fasciitis; *E. rhusiopathiae* was the predominant but not only organism isolated from surgical specimens.[33] A 7-week-old infant with localized *E. rhusiopathiae* infection of the knee without a known source of exposure has been reported,[19] and a 6-year-old girl with *Erysipelothrix* pyopneumothorax has been described.[26] Septic arthritis has been described in a healthy 18-year-old man in whom disease developed after he underwent arthroscopic knee surgery,[2] in association with infective endocarditis,[30] and in a patient with systemic lupus erythematosus and chronic monarthritis without associated systemic symptoms.[36]

Cutaneous eruptions rarely may occur in areas distant from the site of inoculation,[18] appearing as violaceous lesions with advancing pink borders. Bullous vesiculation has been described.[9] In 1921, Prausnitz[27] reported the first case of apparent septicemia in childhood, isolating the organism from the blood of a 10-year-old boy.

E. rhusiopathiae rarely is associated with the bite of a domestic dog or cat.[1] In one prospective study of infected domesticated animal–bite wounds, two patients who had cat-bite wounds infected with *E. rhusiopathiae* were identified.[34] Cultures were carefully processed and were performed in reference laboratories.

An uncommon but important complication of *Erysipelothrix* infection is endocarditis. Presumed or proven endocarditis accounts for 90 percent of serious *E. rhusiopathiae* infection.[12] Patients with congenital heart disease or heart valve damage secondary to acute rheumatic fever are at the greatest risk for development of endocarditis. However, previously normal heart valves can be infected.[13,21] Valvular and myocardial abscesses have

been described.[24] In contrast to diphtheroid endocarditis, *E. rhusiopathiae* endocarditis usually does not involve prosthetic valves, and in contrast to *Bacillus* spp. endocarditis, it is not associated with intravenous drug abuse.[12] In a review of 1989 cases of endocarditis from 13 series,[3] *Erysipelothrix* was documented in two patients. *Erysipelothrix* endocarditis commonly involves the aortic or mitral valves or both. Overall mortality in reported cases is 38 percent, which is considerably higher than that associated with other pathogens of endocarditis.[11] Many patients with endocarditis are treated empirically with vancomycin, a drug to which all *Erysipelothrix* isolates are constitutively resistant.[15] No history or physical evidence of cutaneous lesions is found in 50 percent of cases of endocarditis, and history of exposure to contaminated material often is lacking. Although immunocompromised individuals[22] may be at increased risk, serious infection also occurs in otherwise normal hosts,[4,13,21] particularly in association with occupational exposure.

DIAGNOSIS

For localized disease, diagnosis depends largely on clinical appearance of the lesion in association with an appropriate history of exposure. Attempts to culture the organism from material collected by swab or aspirate of a local lesion almost always are unsuccessful, presumably because of the bacteria's location deep within the skin.[7,37] Biopsy specimens of affected skin cultured in broth generally yield the offending bacteria. Amplification and detection of *Erysipelothrix* DNA by polymerase chain reaction show promise in animal models of infection.[20] *Erysipelothrix* is isolated commonly from the blood of patients with septicemia or endocarditis and can be found in affected heart valves at autopsy or at the time of valve replacement.[9] A high index of suspicion is important for establishing the diagnosis of endocarditis. The organism has been misidentified as a viridans group streptococcus because of its pleomorphic coccoid appearance, alpha-hemolysis, and catalase-negative character. Abbreviated identification schema that do not include testing for hydrogen sulfide production sometimes lead to misidentification as *Lactobacillus* spp. or enterococci.[8]

TREATMENT

E. rhusiopathiae is exquisitely sensitive to penicillin. Most isolates also are sensitive to ceftriaxone.[10] Clindamycin or ciprofloxacin may be used for patients who are allergic to penicillin.[10] Localized disease usually can be treated with oral medication, but high parenteral doses occasionally are necessary, particularly for disseminated disease.[13] Treatment of endocarditis is similar to treatment of endocarditis caused by viridans streptococci. At least 12 million U of penicillin administered for 4 weeks has been curative in adult patients, but many cases have been treated for 6 weeks or longer. Concomitant administration of an aminoglycoside has been used in some cases. *Erysipelothrix* is resistant to vancomycin.[15] Prompt microbiologic differentiation of *E. rhusiopathiae* from other gram-positive organisms is important in guiding antimicrobial choice because vancomycin often is employed in empiric therapy for endocarditis. Hyperimmune serum, which at one time was advocated for therapy, is of little value. Risk of acquiring disease is minimized by protecting individuals exposed to potentially contaminated materials.

Acknowledgments

The author would like to thank Dr. William Gruber and Dr. Thomas Boyce for their invaluable assistance with earlier versions of this chapter.

CHAPTER 106

LISTERIOSIS

Robert Bortolussi ✪ Timothy Mailman

Listeria monocytogenes was described first by Murray and associates[105] in 1926 while they were investigating an epidemic of perinatal infection in laboratory rabbits. Human disease caused by *Listeria* was first published 3 years later, in 1929.[111] Neonatal infection was not described until 1936.[22] Since then, the organism has been isolated with increasing frequency from elderly individuals, pregnant women, immunocompromised individuals, and neonates. A large body of information has accumulated, and several comprehensive reviews have been published.[16,45,118,128] More recently, food-borne outbreaks of *Listeria* causing gastroenteritis have refocused attention on this organism.[6,112,124]

ORGANISM

Listeria is a regular, short, facultatively anaerobic, non–spore-forming, gram-positive rod that is motile and forms bluish gray colonies on nutrient agar. The genus is thought to be named in honor of Lister, the father of antiseptic technique. Of the six *Listeria* spp. (*L. monocytogenes*, *Listeria innocua*, *Listeria grayi*, *Listeria welshimeri*, *Listeria seeligeri*, and *Listeria ivanovii*), only *L. monocytogenes* and *L. ivanovii* have been reported to infect humans.[59,85] Various features of *L. monocytogenes* have been used to separate it from nonpathogenic *Listeria* spp. and other gram-positive rods.[130] The following four characteristics are used commonly for differentiation: (1) *Listeria* exhibits a characteristic tumbling motility at 25° C (77° F), with reduced motility at 37° C (98.6° F); (2) it grows with a narrow zone of beta-hemolysis (nonhemolytic strains exist but rarely appear in clinical material) and exhibits a rectangular area of increased hemolysis when streaked on blood agar in proximity to *Staphylococcus aureus* (Christie, Atkins, Munch-Peterson [CAMP] test); (3) it is catalase-positive; and (4) it ferments α-methyl-D-mannoside and L-rhamnose but not D-mylose.

Listeria organisms tolerate low temperatures, high salt concentrations, and high pH, which allows replication to occur in soil, water, sewage, manure, animal feed, and, more importantly, refrigerated foods. Cold enrichment procedures have been used to improve the isolation rate from clinical material, but generally they are not recommended.[12,45,128]

After the early work of Paterson,[113] Seeliger and Finger[131] performed an extensive serologic characterization of *L. monocytogenes*. At least 17 serotypes have been identified on the basis of somatic and flagellar antigens, but three (1/2a, 1/2b, 4b) account for most clinical isolates and are the serotypes most commonly found in food.[97,114]

TRANSMISSION

The factors involved in transmission are not well understood. Although contamination of food and human exposure to *Listeria* are common occurrences,[51] most infections are sporadic and have no epidemiologic explanation.[21,104,146] In investigations of outbreaks, a source that is linked to food often is discovered. An outbreak described by Schlech and colleagues[125] involving the consumption of *Listeria*-contaminated cabbage was the first investigation to prove that food-borne transmission can occur. Since then, numerous outbreaks have been linked to food, particularly contaminated dairy products.[45,66,86,124,145,146] Pate, pork, ready-cooked chicken, and hot dogs also have been implicated.[6,66,69,98,124,129] The incubation period for food-borne listeriosis is approximately 3 weeks. Molecular techniques involving polymerase chain reaction and multilocus enzyme electrophoresis are being used to track epidemic and sporadic strains found in food.[4,66,92,107,114,120]

EPIDEMIOLOGY

L. monocytogenes colonizes humans and a variety of mammals worldwide.[130] In the developed world, approximately 1 to 5 percent of the population carry the organism in their feces.[51,77] Nonetheless, listeriosis remains an uncommon infection. In the United States, estimates of its incidence range from 0.4 to 0.7 case per 100,000 population.[138] Listeriosis reported in the United States has a nonuniform age distribution, with most cases occurring in newborns and elderly individuals (Fig. 106–1). Although cases can occur in otherwise healthy subjects,[128,148] immunocompromised individuals with acquired immunodeficiency syndrome (AIDS), individuals with cancer (related to chemotherapy, particularly fludarabine), or organ transplant recipients are at significantly increased risk.[30,104,110,135] Other host factors associated with listeriosis include diabetes mellitus, renal failure requiring dialysis, hemochromatosis, and cirrhosis.

Perinatal attack rates during outbreaks are extremely high, reaching 1 to 2 percent of all deliveries.[125] Vertical transmission from mother to infant through the placenta is the mode of transmission for early-onset newborn infection; the epidemiologic factors contributing to late-onset infection are unknown. Nosocomial spread rarely has been reported in nursery outbreaks.[40,50,81,98,127]

PATHOGENESIS AND PATHOLOGY

The gross and microscopic findings in listeriosis are well documented. Although multiple granulomata are characteristic of disseminated disease, the basic pathologic change of suppurative inflammation is nonspecific.[75] Examination of the placenta of infants with early-onset infection reveals macroabscesses, funisitis, and villitis in most cases.[140]

L. monocytogenes is a facultative intracellular pathogen that has been used extensively to study cell-mediated immunity and the biochemical and pharmacologic abnormalities associated with

Figure 106–1 Human listeriosis cases by age group for the United States, 1970-1971 and 1980-1981. *(From Albritton, W. L., Cochi, S. L., and Feeley, J. C.: Overview of neonatal listeriosis. Clin. Invest. Med. 7:311-314, 1984.)*

infection.[7,13,64,78,93,96,137,151] Factors involved in mucosal colonization are crucial for invasion of the host to occur.[112] The cycle begins with adhesion to a eukaryotic cell and subsequent internalization. This process is mediated partly by an *L. monocytogenes* surface protein known as internalin[8,54,82] and its mammalian cell receptor, E-cadherin.[82] The internalin–E-cadherin interaction is necessary for the organism to cross the intestinal epithelium barrier. The intestinal mucosa is a depot for *Listeria*-specific effector $CD8^+$ T cells, which accumulate during and after infection.[63] Spread of the organism to the liver and bloodstream is the usual mode of infection. Resident hepatocytes, enterocytes, and fibroblasts are invaded by the organism. Intracellular bacteria are shielded from macrophage and polymorphonuclear phagocytic cells, permitting intracellular proliferation to occur.[27,43,56,70,79,117] Numerous virulence genes and their roles in the pathogenesis (internalization, vacuole escape, intracellular proliferation, and intercellular spread) are known to exist.[57,115] When inside the host cell, *Listeria* uses a hemolysin to escape into the cytoplasm.[116] The hemolysin secreted by *L. monocytogenes*, termed *listerolysin O*, has been purified, and its gene, *hly*, has been sequenced.[24,115] It is a pore-forming protein (antigenically similar to streptolysin O produced by group A streptococci) that causes lysis of host-cell vacuoles with the subsequent release of *Listeria* into the host cytoplasm. Monoclonal antibody to listerolysin O provides resistance to *Listeria* infection in a murine model of infection.[17,32,33] When in the cell, *Listeria* uses its ActA protein to promote actin polymerization for intracellular movement. The intracellular cycle is complete after escape from the host cell.[71,146]

The mechanism for passage through the placenta has provided new insights into pathogenic mechanisms in utero. In a transgenic mouse model that expresses human E-cadherin, the internalin–E-cadherin interaction was found to mediate crossing of the placental barrier by *L. monocytogenes*. The crucial role of internalin for placental passage was not present in a guinea pig model of perinatal infection model.[8] ActA-mediated, cell-to-cell spreading also plays a role in the vertical transmission of *Listeria* to the fetus in the murine model.[83]

For many years, immunity to *L. monocytogenes* and other facultative intracellular bacteria has been attributed almost exclusively to a repertoire of T cells and cytokines.[93,99] We now realize that phagocytic cells also play a role in resistance to *Listeria* infection.[31,88,152] Peak immunity to *Listeria* in adults is expressed after 5 to 6 days of infection, coinciding with the maximal T-cell responses.[15,76,99,33] Cytokines such as granulocyte colony-stimulating factor, tumor necrosis factor-α, and interleukin-6 (IL-6), IL-10, IL-12, IL-15, and IL-18 are induced and mediate clearance of *Listeria*.*

In newborn animals, susceptibility to *L. monocytogenes* is associated with delayed production of cytokines and activation of T cells and natural killer cells.[14,36,90] In particular, monocyte,[152] T-cell,[91] and natural killer cell activity[36,91] is immature in animal models. Delayed cytokine and cell activation processes seem to operate in humans.[65,152] Synthesis of tumor necrosis factor-α, interferon-γ, interferon-α, and IL-2, all of which modulate the immune response and macrophage activation, is deficient in newborns.[132,152] Pretreatment of newborn animals with interferon or inducers of interferon seems to enhance immune responsiveness and protects against *L. monocytogenes* infection.[16,20,24]

In older children and young adults, *Listeria* infection is rare; however, underlying diseases or medications that interfere with cell-mediated immunity may increase susceptibility.[30,133] Cyclosporine, which blocks production of cytokine, is associated with increased susceptibility.[62]

CLINICAL MANIFESTATIONS

Although a variety of clinical manifestations are described in *L. monocytogenes* infections, most pediatric infections occur in the first months of life. The initial clinical features are similar to those of the more prevalent group B streptococcal infection.[9] The serotype distribution of *L. monocytogenes* seems to depend on the age at onset. Serotypes 1a and 1b occur more commonly in the early-onset form of disease (<7 days of age), and serotype 4b occurs in the late-onset form (>7 days of age).[3]

The early-onset form of neonatal listeriosis usually is diagnosed within the first 24 hours of life, and affected infants have respiratory distress or pneumonia, septicemia, and, occasionally, meningitis (Table 106–1).[2,3,39,86,139,148] Mothers of these infants frequently have an influenza-like illness with fever, malaise, headache, gastrointestinal symptoms, or pharyngitis in the few days

TABLE 106–1 Features of Early-Onset and Late-Onset Neonatal Listeriosis*

	Early Onset[2,3,39,86,140]	Late Onset[3,41,74,128,148]
Age at onset (median in days)	<0.1 (<0.1-1.3)	28 (7-140)
Birth weight (median in g)	2250 (1800-2540)	3100 (3000-3150)
Percentage of isolates from		
Cerebrospinal fluid	5 (2-7)	63 (30-87)
Blood and cerebrospinal fluid	10 (6-26)	25 (13-40)
Blood alone	74 (45-88)	12 (0-30)
Other only†	5 (0-24)	0
Newborn and maternal	72 (54-93)	4 (0-8)
Percent mortality	38 (22-63)	3 (0-10)
Percentage with obstetric complications	63 (38-87)	3 (0-7)

**This table shows the median values and ranges of results from various publications.*
†Sources other than blood and cerebrospinal fluid included cutaneous, gastric, throat, urine, and rectal sources.

preceding delivery.[60,86] During labor, maternal fever and green-stained or brown-stained amniotic fluid may be seen.[2,84] More severely affected infants are infected in utero, born prematurely, and often critically ill at birth. Widespread microabscesses and macroabscesses may occur and are demonstrable externally as discrete roseolar or pustular lesions on the skin and pharynx. The rash has been termed *granulomatosis infantisepticum* (Fig. 106–2). Depression at birth, respiratory distress, apnea, lethargy, and fever are common manifestations; diarrhea, conjunctivitis, and myocarditis also have been described.[84] The respiratory symptoms may mimic symptoms of respiratory distress syndrome. Patchy bronchopneumonic infiltrates, probably caused by aspiration of infected amniotic fluid, may be seen on chest radiographs. In addition, intrauterine infection may result in spontaneous abortion or stillbirth.[60] Colonized asymptomatic adults and neonates have been reported, however.[126]

The late-onset form of neonatal listeriosis occurs less commonly than does the early-onset form and usually affects term infants, who appear healthy until the onset of meningitis or, less commonly, septicemia and colitis 1 to 8 weeks after birth.[3,41,60,74,81,127] Clinical manifestations of late-onset meningitis may be subtle and include fever, irritability, lethargy, and poor feeding.[74,127] Cerebrospinal fluid findings vary. Although pleocytosis usually is significant, not all infections have a polymorphonuclear cell predominance. The maternal history in these cases usually is negative. An outbreak of late-onset neonatal listeriosis associated with mineral oil, reported by Schuchat and associates,[127] provides insight into the pathophysiology of this disease. During the outbreak, infants were bathed at birth with mineral oil. A strain of *L. monocytogenes* identical to the one causing the outbreak was isolated from a mineral oil container in the delivery room. Despite intensive investigation, no other source of infection was identified. The incubation period before the development of symptoms was 5 days, and the median age at first positive culture was 7 days. The symptoms and signs in infants were those of the late-onset form of *Listeria* infection, including fever and meningitis, and, in 7 of 10 infants, a positive cerebrospinal fluid culture.

Immunocompromised patients can have a variety of clinical findings, most commonly meningitis or septicemia. Although patients receiving immunosuppressive therapy have a high incidence of infection, the clinical features are similar to those of non-immunosuppressed patients with *Listeria* infection.[133] Rhombencephalitis, brain abscess, arthritis, osteomyelitis, endocarditis, endophthalmitis, liver abscess, and peritonitis also have been reported in adult patients.* Rarely, invasive listeriosis has been seen in children who are otherwise well.[94,97,128,148] *Listeria* also is recognized as a cause of febrile gastroenteritis.

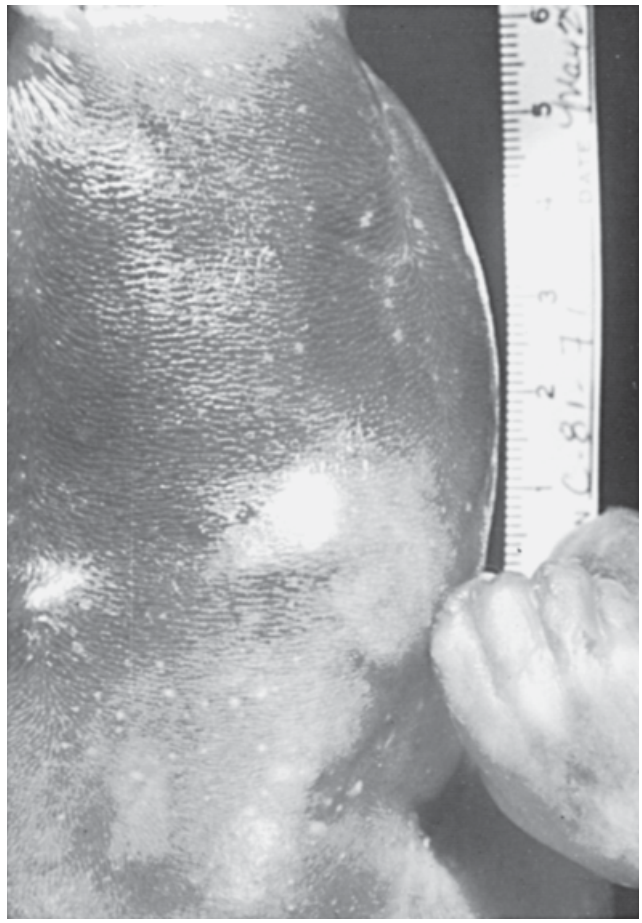

Figure 106–2 Typical pustular rash on the abdomen of a stillborn infant with listeriosis. Note the small pale granuloma measuring 1 to 3 mm and the dark erythema surrounding these lesions.

DIAGNOSIS

Appropriate specimens for staining and culture vary with the clinical syndrome, but investigation of the usual sources, such as blood, cerebrospinal fluid, amniotic fluid, and genital tract secretions, is most productive. Because prompt recognition is essential, examination of Gram-stained material (ear, meconium, and placenta) from newborns is recommended in suspected, early-onset sepsis.[83] Pathologic specimens (e.g., biopsy material, placental or fetal tissue) may reveal the characteristic Gram-stain morphology and pathologic features, such as microabscesses and granulomata. Selective culture media, such as PALCAM (polymyxin B–acriflavine–lithium chloride–ceftazidime–esculin–mannitol agar) or modified Oxford agar, may be helpful for isolating from contaminated material, such as stool or vaginal secretions.[95,114] Laboratories undertaking primary isolation must be aware of the similarities between *L. monocytogenes* and frequently discarded "commensals."[97]

After 48 hours of incubation at 37° C on 5 percent sheep blood agar, colonies are gray with a narrow zone of beta-hemolysis. The appearance on Gram stain of short rods has been confused with lancet-shaped pneumococci. Traditionally,

*See references 1, 5, 19, 23, 35, 44, 52, 89, 94, 103, 106, 135.

identification is based on morphology; tumbling motility; beta-hemolysis; positive catalase, esculin, and CAMP tests; and carbohydrate use pattern. Commercial kits are available for the rapid identification of *Listeria* from culture. These kits include DNA probes, latex agglutination, and enzyme immunoassay methods.

Despite extensive attempts to develop serologic techniques for the diagnosis of listeriosis, none has proved satisfactory, and few centers attempt serodiagnosis.[10,61] At present, a confirmed diagnosis requires isolation of the organism.

Histologic diagnosis from pathologic material should be attempted if the organism is not cultured. Specific fluorescent antibody staining,[25] nucleic acid hybridization,[136] and polymerase chain reaction[4,67] generally are not available in the routine diagnostic laboratory, but they offer the potential for development in the future, especially in patients pretreated with antibiotics and for rapid food surveillance.

TREATMENT

Prompt administration of antibiotic therapy is needed to prevent death or severe sequelae caused by *Listeria* infection. Antibiotic resistance in *L. monocytogenes* is low.[53,150] The bactericidal activity of the antibiotics commonly used is influenced in vitro by such factors as size of inoculum, type of medium, and definition of end-points.[37,89] Similar to a few other bacteria, *L. monocytogenes* shows tolerance to some antibiotics in vitro; the minimal bactericidal concentration is more than fourfold the minimal inhibitory concentration.[37,102] The antibiotics commonly recommended for treatment—ampicillin, penicillin, erythromycin, and tetracycline—are bacteriostatic only at concentrations usually achieved in blood.[37,46,47,142,147] Relapse of *L. monocytogenes* infection after apparent therapeutic success has been documented in immunocompromised patients, suggesting that bactericidal regimens may be needed in such patients.[42,122]

Other antibiotics have been considered for possible therapy. Some studies have shown trimethoprim-sulfamethoxazole and rifampin to be effective in eradicating *Listeria* in vivo.[42,55,58,100,123] These drugs seem to be bactericidal and have been used successfully in a few cases of human listeriosis.[51,135] Rifampin and trimethoprim-sulfamethoxazole offer a theoretical advantage over other drugs because of their better intracellular penetration.[42] Many newer antibiotics, such as the quinolones, macrolides, and imipenem, have only moderate activity in vitro against *Listeria*. Most quinolone and macrolide antibiotics are bacteriostatic only, and in vivo studies with these agents are not promising.[101,121] In addition, *L. monocytogenes* is resistant to cephalosporin antibiotics.[37] Vancomycin has been used in a few penicillin-allergic and sulfa-allergic patients with some success, but experience with this drug is limited.[119]

Combinations of antibiotics for therapy and in vitro testing also have shown variable results. Ampicillin plus gentamicin has a synergistic effect on most *Listeria* strains.[34,100,141] Partial synergy seems to occur with combinations of ampicillin or vancomycin and rifampin, but combinations of penicillin G and rifampin have shown activity ranging from synergy to antagonism.[100] In an in vivo model of *L. monocytogenes* encephalitis, the combinations ampicillin/gentamicin and co-trimoxazole/rifampin were highly active against intracerebral bacteria.[11] Antagonism also seems to occur between some antibiotic combinations (erythromycin and penicillins, erythromycin and aminoglycosides, penicillin and chloramphenicol, and penicillin and tetracycline).[37,46,100] On the basis of results of in vitro susceptibility testing and in vivo models, ampicillin plus gentamicin has proved to be the most reliable synergistic combination and remains the recommended initial therapy for patients suspected to have listeriosis. Trimethoprim-sulfamethoxazole may be considered for use in non-perinatal listeriosis, particularly in the presence of penicillin allergy, but it cannot be recommended for use in perinatal infections because of the concern of bilirubin toxicity developing with sulfonamides.[42] The duration of therapy depends on the clinical syndrome, the presence of underlying disease, and the response to treatment. In newborns, 2 weeks of antibiotic therapy usually seems to be adequate. Liposomal encapsulation also results in marked enhancement of the therapeutic activity of ampicillin.[8]

PROGNOSIS

Precise morbidity and mortality data for *L. monocytogenes* infection are unavailable. Maternal listeriosis may result in abortion or stillbirth. Fetal mortality rates probably are high with gestational listeriosis, although the relative risk of intrauterine death occurring is unknown. Convincing evidence that *L. monocytogenes* is associated with repeated abortions is lacking.[49]

Among reported cases of early-onset sepsis, the more recent mortality rate in North America is approximately 40 percent (see Table 106–1).[2,39] Most survivors seem to be normal.[38,39,139] Sequelae are related to the associated complications of prematurity, pneumonia, and sepsis; hydrocephalus and cerebral palsy also have been reported.[38,72] Early treatment of maternal disease would seem to affect fetal and neonatal outcome favorably.[39,72]

Late-onset *Listeria* meningitis has a mortality rate of less than 10 percent. The outcome after *Listeria* meningitis may be more favorable than the outcome associated with other types of bacterial meningitis.[74,148] Major sequelae are hydrocephalus and mental retardation. Beyond the newborn period, the outcome of listeriosis depends on the nature of any underlying disease and the availability of intensive medical care.

PREVENTION

The sporadic nature of the disease in North America emphasized the need for collaborative investigation and reporting of infections by physicians and veterinarians to public health authorities.[12,45] In the early 1990s, epidemiologists in the United States and Canada endorsed making listeriosis a notifiable disease.[114,138] Since then, the important role of food in the transmission of sporadic cases has been linked firmly.[128] Aggressive investigation of cases and close inspection and testing of food and food-handling facilities in the United States have been under way since the early 1990s.[92,138] By tracking strains of *L. monocytogenes* from patients' refrigerators to retail sources, specific foods have been identified. Strict adherence to regulations for pasteurization of raw milk is important to inactivate the organism and prevent listeriosis.[143] Contamination of food can occur during the preparation and processing of pasteurized milk products and ready-to-eat meat or poultry products. Recommendations for individuals at high risk, such as pregnant women and immunocompromised patients, include avoiding soft cheeses and delicatessen meats and avoiding reheating leftover foods or ready-to-eat foods (e.g., hot dogs).[114,138] Preventive strategies involving inspection of food and facilities and dissemination of recommendations and educational materials seem to have reduced the incidence of listeriosis in the developed nations.[4,48,138]

During an outbreak of *Listeria*, prompt investigation and treatment of pregnant women with a febrile "influenza-like" illness have been advocated.[12,72] The attack rate for late-onset disease in colonized infants is unknown, and no data show that treatment of colonized infants can either eradicate asymptomatic carriage or prevent infection. Careful attention given to the handling of infected infants in a neonatal unit in an attempt to prevent transmission is of the utmost importance for preventing nosocomial infection.[40,127]

CHAPTER 107

TUBERCULOSIS

Jeffrey R. Starke

Tuberculosis still ranks as one of the three most important infectious diseases in the world in terms of morbidity and mortality. Recognizable in skeletons from the Stone Age and in mummified corpses from the Egyptian Old Kingdom, tuberculosis became more widespread in western Europe after the plague years of the Middle Ages and the epidemic during the era of urbanization and industrialization in the 18th and 19th centuries.[153] At that time, scrofula affected more than half the young inhabitants of workhouses and orphanages.

As similar social trends developed outside Europe, tuberculosis followed. In the eastern cities of the United States (Boston, New York, and Philadelphia), the mortality rate from tuberculosis was about 400 per 100,000 population. With improving socioeconomic conditions, the mortality rate fell to 200 per 100,000 around 1900 and to 26 per 100,000 by 1950. Stress in all its forms—famine, war, rationing, long working hours, child labor, population displacement, crowded living and working conditions—favors the spread of tuberculosis in human beings, whereas years of peace and plenty favor its rapid decline.[152,463] The decrease in the Western world in the incidence of tuberculosis was accentuated by the discovery, development, and widespread use of antituberculosis drugs beginning in the late 1940s.

Another important factor leading to the decline of tuberculosis in Western countries was the recognition in the 1920s of the importance of bovine tuberculosis and its successful eradication as a public health problem in the United States by gradual slaughter of infected cattle and almost universal pasteurization of milk.

Tuberculosis was recognized as a clinical entity in the early 19th century by Schönlein, who first used the term *tuberculosis* in 1830, and by Laennec in Paris, among others. Credit for extensively detailed descriptions of the primary focus goes to Anton Ghon (1866-1936), professor of pathology in Prague. In 1882, Koch identified *Mycobacterium tuberculosis*. The special diagnostic tools essential to understanding the disease in children were provided by Escherich, who in 1898 set up the first diagnostic radiography for children; by von Pirquet, Mantoux, Mandel, and Moro, who developed tuberculin testing between 1907 and 1910; and by Meunier and DeLille, who in 1898 taught the usefulness of gastric lavage in children. Revealing, long-term studies on the natural history of tuberculosis in children and on chemotherapy and prevention came principally from Scandinavia (Wallgren, Ustvedt, Holm, Hyge) and the United States (Brailey, Hardy, Lincoln, Hsu, Ferrebee).

TERMINOLOGY: EXPOSURE, INFECTION, DISEASE[12]

The pathophysiologic process of tuberculosis is complicated, and the delay between acquisition of infection and manifestation of disease renders certain pathophysiologic events less distinct. This chapter considers three major stages of tuberculosis: exposure, infection, and disease.[561]

Exposure means that the child has had significant contact with an adult or adolescent with infectious pulmonary tuberculosis. The contact investigation—examination of individuals close to a person suspected of having tuberculosis by performing a tuberculin skin test, chest radiograph, and physical examination—is the most important activity in a community to prevent cases of

tuberculosis in children.[10,50,234] The most frequent setting for exposure of a child is the household, but it can occur in a school, daycare center, or other closed setting.[136,227] In this stage, the tuberculin skin test result is negative, the chest radiograph is normal, and the child lacks signs or symptoms of disease. Some exposed children may have inhaled droplet nuclei infected with *M. tuberculosis* and have early infection, but the clinician cannot know it because delayed hypersensitivity to tuberculin—a positive skin test response—takes up to 3 months to develop. Children younger than 5 years old who are in the exposure stage should be treated to prevent the rapid development of disseminated or meningeal tuberculosis, which can occur before the skin test becomes reactive.[160,338,416,444,576]

Infection occurs when the individual inhales droplet nuclei containing *M. tuberculosis*, which becomes established intracellularly within the lung and associated lymphoid tissue. The hallmark of latent tuberculosis infection is a reactive tuberculin skin test. In this stage, the child has no signs or symptoms and the chest radiograph is either normal or reveals only granuloma or calcifications in the lung parenchyma or regional lymph nodes or in both tissues. In developed countries, virtually all children with tuberculosis infection should receive treatment, usually with isoniazid, to prevent the development of disease in the near or distant future.

Disease occurs when signs or symptoms or radiographic manifestations caused by *M. tuberculosis* become apparent. The word *tuberculosis* refers to disease. Not all infected individuals have the same risk of contracting disease. An immunocompetent adult with untreated tuberculosis infection has approximately a 5 to 10 percent lifetime risk for development of disease; half the risk exists in the first 2 to 3 years after infection occurs. Adults with tuberculosis infection who then become infected with human immunodeficiency virus (HIV) have a 5 to 10 percent annual risk for development of tuberculosis disease.[508] Historical studies have shown that disease, often serious, life-threatening forms, will develop within 1 to 2 years in as many as 40 percent of immunocompetent infants with untreated tuberculosis infection.

EPIDEMIOLOGY

INCIDENCE AND PREVALENCE

Between 20 and 45 percent of the world's population (approximately 2 billion people) are infected with *M. tuberculosis*, and more than 90 percent of new cases occur in the developing world, where resources are very limited. According to the World Health Organization (WHO), in 1997, only 32 percent of the world's population lived in areas where effective tuberculosis control programs were fully operational.[412] The WHO estimates that 8 million new cases and 2 million deaths from tuberculosis occur annually worldwide.[464,644] Approximately 11 percent (884,000) of new cases and about 5 percent of deaths are predicted to occur in children younger than 15 years.[295,405] Approximately 75 percent of childhood cases occur in the 22 highest burden countries. The inability to control tuberculosis despite the availability of effective, relatively inexpensive therapy is one of the greatest medical failures of our time.[210,560]

Between 1953, when reporting began, and 1985, the number of annually reported tuberculosis cases in the United States fell by 74 percent from 84,304 to 22,201.[92,93] In 1985, the overall case rate was approximately 10 per 100,000 population. At that time, the incidence curve flattened out, and for the first time since 1953, case numbers and rates increased to a peak of 26,673 cases in 1992. Between 1985 and 1992 in the United States, the total tuberculosis case numbers rose 20 percent.[92] During that same time, the number of pediatric tuberculosis cases rose 40 percent[264,612] (Fig. 107–1). Most experts cite four probable causes

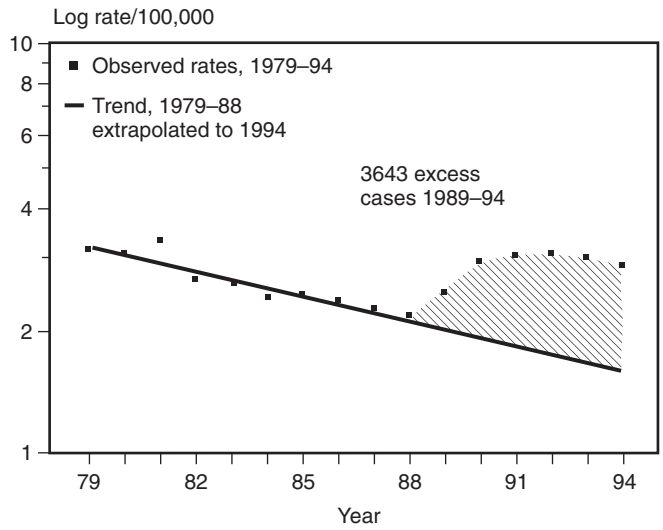

Figure 107–1 Observed and expected tuberculosis cases in children younger than 15 years old in the United States, 1979 to 1994.

for the increases: (1) the co-epidemic of HIV infection; (2) the increasing rates of tuberculosis in foreign-born individuals in the United States[71]; (3) the increased transmission among adults in congregate settings, including jails and prisons, nursing homes, homeless shelters, HIV treatment facilities, hospitals, and, rarely, schools;[35,38,52,376,442] and (4) a decline in the public health infrastructure in many areas of the country.[66,112,465,562] After several years of intense and expensive effort were expended, the number of tuberculosis cases in the United States declined again. In 2006, a total of 13,779 tuberculosis cases (4.6 cases per 100,000 population) were reported in the United States, a 21 percent decrease from 1999 and 48 percent decrease from 1992.[92] Rates have decreased consistently in the United States in all groups except immigrants from high-risk countries. However, the annual cost of tuberculosis in the United States still exceeds $1 billion.[65] An estimated 4 to 6 percent of the U.S. population, or approximately 11 million people, are infected with *M. tuberculosis*. This group represents a large reservoir from which cases of tuberculosis disease will emerge in the future if these individuals are not treated.[6] The resurgence of tuberculosis in the United States between 1985 and 1992 was associated with the emergence of multidrug-resistant tuberculosis (MDR-TB), strains that are resistant to at least isoniazid and rifampin and may be resistant to other antituberculosis medications as well.[654] MDR-TB is difficult and expensive to treat, and the mortality rates may be as high as 50 percent in complicated cases.[193,253] Since 1993, the incidence of resistance to isoniazid has remained stable, and the incidence of MDR-TB has decreased. In 2006, 8 percent of isolates were resistant to at least isoniazid, and 1 percent were resistant to at least isoniazid and rifampin (MDR-TB) in the United States.[92]

MDR-TB has become an important problem in many areas of the world.[159,654] Global surveys conducted between 1996 and 1998 in 58 geographic areas showed a median prevalence of MDR-TB of 1 percent, but the rates in some regions were alarming: 14 percent in Estonia, 10 percent in the Henan Province in China, and 9 percent in Latvia and parts of Russia.[171,654] There has been an emergence recently of extremely drug-resistant tuberculosis, isolates resistant to isoniazid, rifampin, fluoroquinolones, and at least one injectable drug.[514] In adults, drug resistance in *M. tuberculosis* often is secondary, the resistance emerging during therapy because treatment is inadequate or interrupted.[180] In children, drug resistance usually is primary in that the child is infected with a strain that already has become resistant.[413,494,496,591]

Rates of drug resistance in children tend to mirror those in adults in the same population.[567-569] Rates of drug resistance may be higher in developing countries because of difficulty in completing therapy, inadequate supply of medications, and use of over-the-counter cough medications that often contain isoniazid or rifampin.

Since treatment became available in the late 1940s, tuberculosis has been concentrated in certain high-risk groups in the United States[94] (Table 107–1). Tuberculosis occurs most commonly in areas with ethnically diverse populations, including large urban areas, coastal states, and states bordering Mexico[85,95] (Fig. 107–2). Tuberculosis disproportionately affects ethnic and minority populations in the United States. In 2006, the Centers for Disease Control and Prevention (CDC) reported the highest overall number of cases in Latinos, 4066 cases, but the case rate was highest among Asians, with 25.6 cases per 100,000 population.[92,414]

During the 1990s, immigration from a high-prevalence country was the single largest risk factor for tuberculosis, with rates among foreign-born persons being four to six times higher than those for U.S.-born persons.[108] In 2006, the CDC reported that 50 percent of all cases occurred in foreign-born individuals.[92] Tuberculosis is endemic in most developing countries, and between 30 and 50 percent of recent immigrants to the United States have latent tuberculosis infection on entry into the country.[108,588] During the immigration process, adults are screened for tuberculosis disease with a chest radiograph, but skin testing to detect tuberculosis infection is not required. Children younger than 15 years receive neither a chest radiograph nor a tuberculin skin test.[506] Among children in the United States, being born in a country with a high rate of tuberculosis is the most important risk factor for having tuberculosis infection. Foreign-born adopted children also are at risk for having tuberculosis infection and disease.[179,309,482] People who enter the United States illegally may be unable or afraid to seek medical treatment, even when they are ill. Studies have shown that in most immigrants in whom tuberculosis develops, it does so within 5 years of immigration, thus indicating that many cases could be prevented if appropriate screening and treatment programs were conducted.

Other important risk factors for tuberculosis in adults include lower socioeconomic status, migrant work,[87] HIV infection, drug use, homelessness, travel to high-prevalence countries, history of incarceration, and occupations with exposure to high-risk populations (see Table 107–1). Children from high-risk population groups or children who have contact with adults in these groups may be at increased risk for development of tuberculosis infection.[359] Age has an important influence on tuberculosis case rates.[404] During 2006, 6 percent of cases in the United States occurred in children younger than 15 years, 11 percent in persons 15 to 24 years old, 34 percent in persons 25 to 44 years old, 29 percent in persons 45 to 64 years old, and 19 percent in persons older than 64 years.[92] The highest case rates among children are in those younger than 5 years. Children aged 5 to 14 years, the so-called favored age, have a consistently lower case rate than that of any other segment of the population.[353,404] In early childhood, the incidence is not significantly different in girls and boys, although adolescent girls generally experience higher rates of disease than adolescent boys do.[59]

The age at which tuberculosis disease initially develops currently varies among ethnic groups in the United States.[92] White persons develop tuberculosis more commonly as older adults, whereas African Americans and Hispanics have a higher incidence of disease as young adults or children (Fig. 107–3).[577] Many of the risk factors for development of tuberculosis, such as HIV

TABLE 107–1 High-Risk Groups for Tuberculosis Infection and Disease

Groups at High Risk of Exposure or Infection
Close contacts of person with tuberculosis
Foreign-born persons from high-risk countries (Asia, Africa, Latin America, Russia, eastern Europe)
Residents and employees of high-risk congregate settings (correctional institutions, nursing homes, homeless shelters, hospitals serving high-risk populations, drug treatment centers)
Medically underserved, low-income populations
High-risk racial or ethnic minority populations
Injection drug users
Children exposed to adults in high-risk categories
Groups at Higher Risk for Disease Once Infected
Immunosuppressed patients, including HIV infected
Recent tuberculosis infection (within past 2 years)
Persons with certain medical conditions (diabetes mellitus, silicosis, cancer, end-stage renal disease, gastrectomy, body weight ≤90% of ideal)
Injection drug users
History of inadequately treated tuberculosis
Children ≤4 years, especially infants

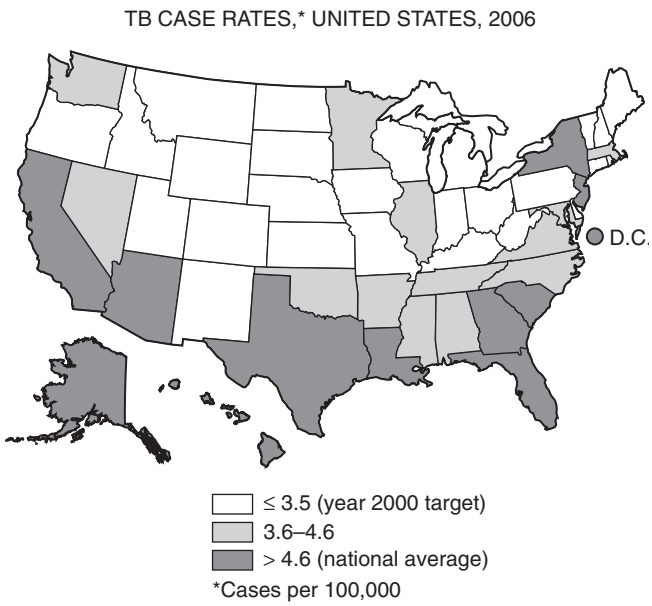

Figure 107–2 Tuberculosis case rates (cases per 100,000) by state, 2006. *(From Centers for Disease Control and Prevention: Reported Tuberculosis in the United States, 2006. Atlanta, GA, U.S. Department of Health and Human Services, CDC, October 2007.)*

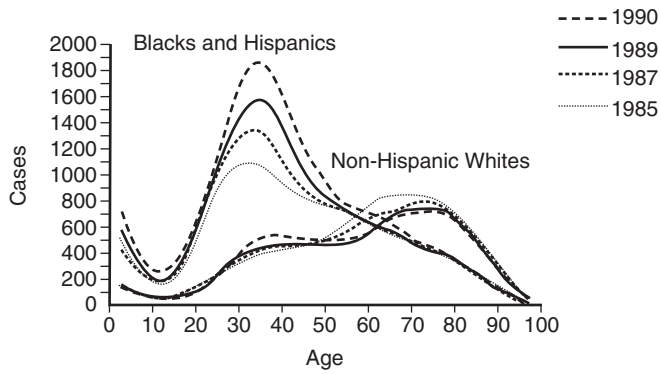

Figure 107–3 Tuberculosis cases in Hispanics and blacks versus non-Hispanic whites in the United States, 1985 to 1990.

infection, drug use, history of incarceration, and recent immigration, occur more commonly in young adults in their 20s, 30s, and 40s, a time when contact with children is more likely. Other factors, including recent immigration, socioeconomic status, high-risk behavior, and possibly genetic susceptibility, may influence the peak age distribution of tuberculosis among different groups.[349] Inherited susceptibility to tuberculosis may contribute to differences among various ethnic groups.[349] Laboratory animals and humans have been shown to differ in genetic susceptibility to tuberculosis.[343,511] In the United States, highly urbanized immigrants, such as Jews from European ghettos, fared much better than did their rural Irish and African counterparts, presumably because generations of exposure to tuberculosis in previous European epidemics had selected in favor of more resistant individuals.[454] As the disease spread to other continents, previously unexposed populations may have been more susceptible to tuberculosis and experienced higher rates of disease.

In some U.S. locales that have had recent increases in tuberculosis, the demographic groups with the greatest tuberculosis morbidity also have large numbers of HIV-infected persons.[104,226,401] The HIV epidemic has had a profound effect on the epidemiology of tuberculosis in children by two mechanisms[490]: (1) most important, in the United States, HIV-infected adults with tuberculosis may transmit *M. tuberculosis* to children in their environment, and tuberculosis disease will develop in some of them; and (2) important in many developing countries, children with HIV infection are at increased risk of progressing from asymptomatic tuberculosis infection to disease.[244,342] Several studies have demonstrated increased rates of childhood tuberculosis associated with increased rates of disease among HIV-infected adults in the community.[209,270] Tuberculosis probably is underdiagnosed in HIV-infected children, especially in the developing world, because of the similarity of its clinical manifestations with other opportunistic pulmonary diseases and the difficulty of confirming the diagnosis with the skin test or culture. All children with suspected tuberculosis disease should have HIV serotesting because the two infections are linked epidemiologically and many experts prolong treatment in HIV-infected children with tuberculosis.[204,640]

The site of manifestation of tuberculosis disease differs between adults and children. Although pulmonary disease is most common for all ages, extrapulmonary tuberculosis occurs more often in children.[404] Because HIV co-infection increases the risk for development of extrapulmonary disease, rates have increased in adults during the past 15 years. In general, 25 percent of pediatric cases are extrapulmonary, with 75 percent being pulmonary. In 1985, before widespread HIV infection occurred, 85 percent of adults had pulmonary disease and 15 percent had extrapulmonary disease. With the spread of HIV infection, these numbers have shifted, and in 2006, the CDC reported that 79 percent of all new cases, including those in adults and children, were pulmonary and 21 percent were extrapulmonary.[92] Comparison of the site of extrapulmonary disease in children and adults in 1985, before the acquired immunodeficiency syndrome (AIDS) epidemic, shows some important differences. First, approximately 70 percent of extrapulmonary tuberculosis in children involved the lymph nodes, as opposed to 25 percent in adults (Fig. 107–4). Second, tuberculous meningitis accounted for 13 percent of extrapulmonary disease in children versus 4 percent in adults. Genitourinary involvement occurred in 16 percent of adults, but it was a rare finding in children. Although the proportion of extrapulmonary cases in adults has increased as a result of the HIV-AIDS epidemic, extrapulmonary disease still occurs more commonly in children.

The global epidemiology of childhood tuberculosis is not well described.[405] In developing countries where the burden of disease is greatest, the only available diagnostic test often is an acid-fast smear of sputum, the result of which rarely is positive from

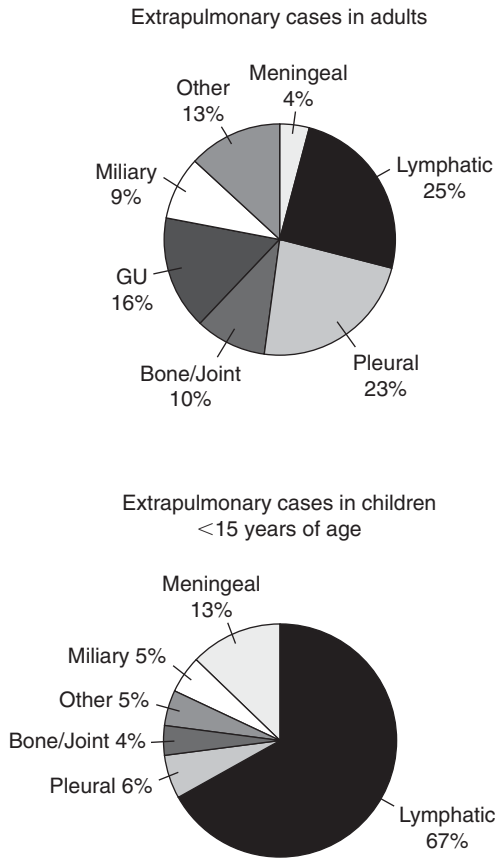

Figure 107–4 Extrapulmonary disease by site in adults and children in the United States. *(From the Centers for Disease Control and Prevention.)*

infants and children with pulmonary tuberculosis. In many developing countries, more than 50 percent of the population is younger than 18 years, so the true burden of childhood tuberculosis has been underestimated.

TRANSMISSION

Transmission of tuberculosis is from one human to another, usually through infected droplets of mucus that become airborne when an individual coughs, sneezes, or laughs.[103] The droplets dry and become droplet nuclei, which may remain suspended in air for hours. Only particles less than 10 μm in diameter are small enough to reach the alveoli.[476] Transmission sometimes occurs by direct contact with infected discharges (sputum, saliva, urine, or drainage from an open sinus or abscess); it occasionally occurs by means of heavily contaminated fomites, such as shoes, gastric lavage tubes, bronchoscopes, or syringes prepared by someone with positive sputum.[223] Rare cases of tuberculosis transmitted by a lung or kidney transplant have been reported.[381,400,473] Dogs may be a source of infection for children because dogs are susceptible to the human type of tubercle bacillus.[470]

The collective experience of many clinicians is that children usually are infected by an adult or adolescent in the immediate household, most often a parent, grandparent, older sibling, boarder, or household employee.[37] Casual extrafamilial contact is the source of infection much less often, but physicians, babysitters, schoolteachers, music teachers, school bus drivers, parishioners, nurses, gardeners, and candy store keepers have been implicated in individual cases and in hundreds of mini-epidemics.[23,57,155,320,326,635] Attention has been drawn to the preva-

lence of active tuberculosis among residents of nursing homes for the elderly. Children visiting their grandparents have contracted tuberculosis in this setting. Within the household of an infectious adult, infants and toddlers most often become infected. Adults with pulmonary disease who are receiving regular, appropriate chemotherapy probably rarely infect children; much more dangerous are those with chronic tuberculous disease that is unrecognized, inadequately treated, or in relapse because of the development of resistance.

Wallgren[631] was the first to point out that children with tuberculosis rarely if ever infect other children. Many children with the disease have tuberculin-negative siblings and parents. Children with tuberculosis often have been cared for by their families or in hospitals and institutions without infecting their contacts.[399] When transmission of *M. tuberculosis* has been documented in children's hospitals, it almost invariably has come from an adult with undiagnosed pulmonary tuberculosis.[24,187,277,278,391,636] Adults accompanying a child with suspected tuberculosis disease should be screened as soon as possible for pulmonary tuberculosis.[61,82,107,279,280,559] In tuberculous children, tubercle bacilli in endobronchial secretions are relatively sparse, and cough is not characteristic of endothoracic tuberculosis or miliary disease. When young children cough, they lack the tussive force of adults. Specimens collected by bronchoalveolar lavage or early-morning gastric aspiration from children with clinically suspected tuberculosis seldom if ever have acid-fast bacilli seen on smears. Only approximately 40 percent eventually will grow *M. tuberculosis* by culture.[546] Young infants with congenital tuberculosis or advanced, postnatally acquired pulmonary disease are more likely to have smear- or culture-positive specimens (80%) than older children are.[493,613] Therefore, specimens and secretions from infants, children with cavitary lesions, and intubated patients should be handled as potentially infectious.[82,366] Most preadolescent children with tuberculosis, however, are not contagious and do not require isolation. Tuberculosis in adolescents may be more typical of adult-type reactivation disease, including the presence of cavitary lesions with smear- and culture-positive sputum. Children or adolescents who have symptomatic pulmonary tuberculosis with features of adult-type tuberculosis should be treated as potentially contagious until mycobacterial smears and cultures are negative.[74,120,175]

Children, nonetheless, play an extremely important role in the transmission of tuberculosis, not so much because they are likely to contaminate their immediate environment but rather because they may harbor a partially healed infection that lies dormant, only to be reactivated as infectious pulmonary tuberculosis many years later under the social, emotional, and physiologic stresses arising during adolescence, pregnancy, or old age. Thus, children infected with *M. tuberculosis* constitute a long-lasting reservoir of tuberculosis in the population.

The risk of infection developing in child contacts of adults receiving antituberculosis chemotherapy often is a matter of practical concern. Several studies reveal that most contacts are infected by the index case before the diagnosis is made and treatment is initiated. Although it is not possible to carry out a definitive clinical study, evidence indicates that patients receiving effective chemotherapy rarely transmit *M. tuberculosis*. Nonetheless, it seems prudent to avoid exposure of children to adults with positive sputum smears or positive cultures and to assume that adults positive by smear or culture remain infectious for at least several weeks after the start of therapy.

MYCOBACTERIOLOGY

The genus *Mycobacterium*, closely related by its cell wall antigens to the genera *Corynebacterium* and *Nocardia*, presently is classified in the order Actinomycetales and the family Mycobacteriaceae. Mycobacteria are nonmotile, non-spore-forming, pleomorphic, weakly gram-positive rods measuring 1 to 5 μm long, typically slender and slightly "bent." Some appear beaded, and some are clumped. In general, species pathogenic for humans are more acid fast, have more exacting nutritional requirements, grow more slowly, form less pigment, and are more sensitive to chemotherapeutic agents than are the saprophytic species.

The cell wall constituents of mycobacteria determine their most striking biologic properties. The cell walls contain 20 to 60 percent lipids by dry weight, largely bound to proteins and carbohydrates. These organisms are more resistant than are most others to light, alkali, acid, and the bactericidal action of antibodies. Their growth is slow, with a generation time of 14 to 24 hours, perhaps because of the slow metabolic exchange through the waxy "capsule." Their hydrophobic properties render them difficult to study.

Acid-fastness, that is, the capacity to form stable mycolate complexes with certain aryl methane dyes (specifically, carbolfuchsin, crystal violet, auramine, and rhodamine, which then are not removed readily even by rinsing with 95 percent ethanol plus hydrochloric acid), is the hallmark of mycobacteria. The cells appear red when stained with fuchsin (as with the Ziehl-Neelsen or Kinyoun stains), appear purple with crystal violet, or exhibit yellow-green fluorescence under ultraviolet light (when stained with auramine and rhodamine, as in Truant stain). Truant stain, in experienced hands, is considered the best stain for specimens expected to contain small numbers of organisms.

Identification of mycobacteria depends on their staining properties and on their biochemical and metabolic characteristics. Mycobacteria are obligate aerobes. On the whole, their growth requirements are simple. *M. tuberculosis* can grow in "classic" media, whose essential ingredients are egg yolk and glycerin (Löwenstein-Jensen, Petragnani, Dorset); often, a dye such as malachite green to inhibit contaminants; and, sometimes, potatoes, charcoal, and so on, which probably neutralize growth inhibitors. They also can grow in simple synthetic media, frequently with an admixture of asparagine, glutamate, or amino acid mixtures (Middlebrook 7H9, Tween-albumin). Once grown, they can be replated on media also containing antituberculosis drugs to determine drug susceptibility patterns. Isolation on solid media often takes 3 to 6 weeks, followed by another 2 to 4 weeks for drug susceptibility results. Improvements in laboratory methods have permitted more rapid culture, identification, and drug susceptibility testing of mycobacteria, such as by an automatic radiometric method known as the BACTEC (Becton-Dickinson, Towson, MD) method, in which a decontaminated, concentrated specimen is inoculated into a bottle of medium containing carbon 14–labeled palmitic acid as the substrate.[524] As mycobacteria metabolize the carbon 14–labeled palmitic acid, carbon dioxide 14 accumulates in the head space of the bottle, where radioactivity can be measured. Unfortunately, cross-contamination of bottles has been reported and has resulted in false-positive culture results.[154] The addition of appropriate dilutions of antituberculosis drugs permits an evaluation of drug susceptibility to be made. The time for identification and drug susceptibility testing can be reduced to 1 to 3 weeks, depending on the size of the inoculum.

Bacteriophage typing to determine the relatedness of isolates has advanced slowly. Progress is being made, however, in standardization of techniques, and phage typing already is of use in strain identification for epidemiologic purposes. However, a newer technique, restriction fragment length polymorphism analysis of mycobacterial DNA, has become a powerful tool for determining strain relatedness in both outbreaks and routine epidemiology of tuberculosis in a community.[8,529]

RESISTANCE AND IMMUNITY

Natural resistance to tuberculosis infection varies greatly among animal species; humans, guinea pigs, and rabbits are highly susceptible. However, Lurie[343] experimentally bred resistant rabbits and showed that although the virulent tubercle bacilli disseminated just as well in the resistant rabbits, multiplication within tissues was inhibited. Thus, the differences between resistant and susceptible rabbits appeared to lie in the ability of the resistant rabbits to produce an effective immune response, and this ability seemed to be controlled genetically.

Additional evidence that genetic factors influence susceptibility comes from data involving twins. Kallmann and Reisner[273] noted that when one homozygous twin suffered from tuberculosis, the other twin had a higher chance of being affected than was the case with heterozygous twins. Gender affects resistance, and females appear to be especially susceptible during adolescence. The negative nitrogen and calcium balance that can arise during adolescence may account in part for susceptibility at this age.[268]

Likewise, young age appears to predispose one to tuberculosis.[404,492,613] However, one cannot be sure that the apparent susceptibility is not due to a larger dose of bacteria because of more intimate contact between very young children and their infectors. Although diabetes mellitus affects the resistance of adults, whether it affects that of children is not clear. Many viral infections depress tuberculin reactivity, but only measles and perhaps influenza have been incriminated in lowering resistance to tuberculosis.[39,64,215,564,657] Unfortunately, natural resistance is ill-defined and poorly understood.

Cell-mediated immunity is regarded as most important in host defense against *M. tuberculosis*.[126,323,418] The T cell–mediated immune response involves a variety of cell subsets that are involved in numerous functions, including protection, delayed hypersensitivity, cytolysis, and establishment of memory immunity.[428] The functions also involve an array of cytokines, several of which direct cells of the monocyte-macrophage axis to contain and destroy the invading bacilli.[14,582] The exact role of individual cytokines is not yet clear, but an emerging concept is that much of the clinical response to the presence of *M. tuberculosis* is determined by the balance of the cellular-cytokine response, which to some degree is under genetic influence.[428] In general, T-helper 1 (T_H1) responses are more beneficial to the host than are T_H2 responses, but unfortunately, infants and young children have increased propensity to develop T_H2 responses to mycobacterial immunogens.[323] More details about the immune response to *M. tuberculosis* are emerging as new immunotherapies are developed. During the past decade, several monoclonal antibodies directed against tumor necrosis factor–α have been used to manage inflammatory bowel disease and rheumatologic disorders. Unfortunately, use of these agents, particularly infliximab, has been associated with a high incidence of serious tuberculosis in patients who had existing tuberculosis infection or who acquire it during treatment.[60,275,458] All immunocompromised patients, including those who will undergo any form of immunotherapy, should be evaluated carefully for tuberculosis infection or disease.

PATHOGENESIS

PORTAL OF ENTRY

The tubercle bacillus usually is inhaled. The observations of Riley[476] suggest that a single tubercle bacillus can initiate infection. Ghon, Kuedlich, and their associates (Table 107–2) reported that the primary focus found in 2114 autopsies on children was the lung in 95.93 percent of cases. Especially significant is that their study was done at a time when bovine tuberculosis, which might have produced many primary gastrointestinal foci, was much more common than it is today. Ingestion probably accounts for a small percentage of primary pulmonary foci and for some gastrointestinal foci, particularly in infants who have consumed milk containing bovine tubercle bacilli. Contamination of a superficial skin or mucous membrane lesion, such as an abrasion of the sole of the foot or the elbow, insect bite, ritual circumcision, or infection of the vulva, may lead to infection. Infection by inoculation with a sputum-contaminated syringe has been reported in more recent years.[223] True congenital infection, although rare, may be a result of either lymphohematogenous spread in the mother during pregnancy or smoldering endometritis.[615]

INCUBATION PERIOD

The incubation period from the time that the tubercle bacillus enters the body until cutaneous sensitivity develops has been found to be 3 weeks to 3 months.[355] With both bacille Calmette-Guérin (BCG) and experimental infections, the incubation period is shorter when the inoculum is large, and clinical experience suggests that the same is true in humans. Debré, for example, noted long ago that tuberculosis acquired by an infant from its mother was likely to be much more severe than was an infection acquired from a visitor to the home. Animal experiments support this concept. The end of the incubation period coincides with the onset of tuberculin hypersensitivity and may be accompanied by a period lasting 1 to 3 weeks that Wallgren called fever of onset or fever of invasion. At this time, the tissue reaction intensifies throughout the primary complex and may permit the complex to be visible on x-ray films.

THE "TIMETABLE" OF TUBERCULOSIS

Wallgren's tremendous experience with tuberculous children in institutions permitted him to recognize and to describe the usual early course and timing of the initial infection and each of its best-known complications.[634] His timetable concept is an extremely useful one for clinicians because it permits a realistic prognosis, an understanding of what complications to look for and when, and a more productive approach to finding the infectious source case (Fig. 107–5).[355]

Symptomatic, massive lymphohematogenous spread (i.e., miliary or acute meningeal tuberculosis) is seen in only 0.5 to 3 percent of infected children. When it does occur, the usual onset is 2 to 6 months after initial infection. Endobronchial tuberculosis, possibly with segmental pulmonary lesions, develops slightly later on average. The metastatic lesions of bones and joints, which can be expected in 5 percent of untreated infected children, usually do not appear until approximately 1 year after infection

occurs, at the earliest. Renal lesions come later still, 5 to 25 years after initial infection. The relationship between the anatomic site of tuberculosis and the median age at onset in children is shown in Table 107–3. The interval between the acquisition of initial infection and the appearance of chronic pulmonary tuberculosis is extremely variable but can be months to decades, depending mainly on the age of the child at the time of infection. The interval is likely to be short in adolescents but much longer in infants.

In summary, the first 5 years after initial acquisition of tuberculosis infection in childhood, especially the first year, is when complications usually occur. Later in life, during times of stress, a previously silent or arrested lesion may reactivate and become dangerous to the patient as well as highly infectious to others.

CLINICAL FORMS OF TUBERCULOSIS IN CHILDREN

ENDOTHORACIC

Asymptomatic Tuberculosis Infection

Asymptomatic (or latent) infection can be defined as infection associated with tuberculin hypersensitivity and a positive tuberculin test result but with no striking clinical or radiographic manifestations. Computed tomography may reveal enlarged lymph nodes in the chest, even though the plain radiograph is normal.[19,132] On occasion, low-grade fever is found at the onset, usually by chance. If the child has been in recent contact with a person who has contagious tuberculosis and the tuberculin test result is positive, disease should be ruled out immediately with a chest radiograph and a thorough physical examination. Asymptomatic tuberculosis infection occurs more frequently in children of elementary school age than in adolescents or infants. Some 40 to 50 percent of infections in infants younger than 1 year and 80 to 95 percent in older children can be expected to cause no specific recognizable symptom or radiographic findings.[441] Gastric washings in these patients, even when performed with great care, yield a very low percentage of positive results.

A clinician making a diagnosis of tuberculosis infection in a child must assume, however, that the patient might be in the earliest stage of infection and at risk for the development of symptomatic disease in the near future.[355] A careful history and investigation of contacts should be undertaken immediately for determination, if possible, of the date of exposure. Chemotherapy must be started, and the patient closely monitored not only to detect any toxic effect of chemotherapy and to monitor adher-

ence with treatment but also to be sure that disease does not develop.

The Endothoracic Primary Complex and Its Complications

The primary complex, described by Ghon,[188] includes three elements: the primary focus, lymphangitis, and regional lymphadenitis. This complex holds true for every primary infection, regardless of the portal of entry. Ghon noted that at least 70 percent of primary pulmonary foci are subpleural. Thus, pleurisy is almost a regular feature of the primary complex.

Evolution of the primary pulmonary focus begins with an acute inflammatory reaction around tubercle bacilli inhaled into an alveolus, with the localized alveolar consolidation varying from the size of a pea to the size of a walnut. Macrophages appear within hours in the inflammatory exudate and change into clusters of epithelioid cells to form tubercles. In turn, these tubercles may resolve and disappear, or central caseation consisting of incomplete cell autolysis may develop. The caseous lesion contains large numbers of multiplying tubercle bacilli that spread rapidly from the primary focus through the regional lymphatic vessels to the regional lymph nodes, with areas of inflammation being set up along the way that later may caseate and calcify.[452]

The primary pulmonary focus has been studied carefully by numerous investigators (Table 107–4). Plotting their locations on a normal chest radiograph creates a pattern resembling the scatter of birdshot on a paper target. Thus, all parts of the lung apparently are at equal risk of being seeded. The thought that the primary focus has a predilection for the lower fields of the lung probably arises from the fact that the lung is pyramid shaped, with more basilar than apical lung tissue.

Many investigators concur that 70 to 85 percent of primary infections are initiated by one focus.[188,585] In a study of 170 cases, Ghon[188] found two foci in 15 percent, three in 7 percent, four in 3 percent, and five in 2 percent. Multiple lung foci can result, although rarely, from the ingestion and inhalation of tubercle bacilli. This pattern of disease was shown clearly in the results of pathologic studies of the 71 infants who died in the Lübeck disaster of the 1930s, an incident in which 251 newborn infants mistakenly had been given live tubercle bacilli by mouth instead of BCG vaccine. Fifteen of the infants were found to have primary lung lesions at autopsy, and all 251 had primary intestinal lesions.

Although the lymphadenitis cannot be detected clinically and rarely is apparent even on radiographs, the hallmark of initial tuberculosis infection is the relatively large size and importance of the adenitis as opposed to the relatively insignificant size of the initial focus in the lung, skin, or elsewhere. The development of tuberculin hypersensitivity within 3 to 12 weeks after initial acquisition of infection enhances the cellular reaction throughout the primary complex, but with a particularly prominent effect on the primary focus and the regional lymph nodes. At this time, the infection may spread along nearby lymphatic chains to involve more distant nodes. The lymphatic drainage of the lungs is outlined in Table 107–5; it occurs predominantly from left to right. One is not surprised, therefore, that the nodes in the right upper paratracheal area appear to be the ones most often affected. Many primary lesions are subpleural, and the lymphatic drainage of the apical pleura is to the cervical nodes. Moreover, the paratracheal chains have communications with both the deep cervical nodes and the abdominal nodes, as shown in Figure 107–6. Among 54 patients with the primary lesion in the right upper lobe, Blacklock found that 14 had involvement of the deep cervical nodes on the same side and three had involvement of the abdominal nodes.

Bronchial obstruction as a result of enlargement of the peribronchial lymph nodes was reported by Ghon[188] and others. Not until the 1920s did Wallgren[632] and others elucidate the role of these large nodes in producing the radiographic shadows variously called epituberculosis, collapse-consolidation, and segmental lesions that so often are seen in cases of childhood tuberculosis.[329,354,632] At the end of the incubation period, as tuberculin sensitivity develops, the hilar lymph nodes enlarge greatly, and in many cases, caseous foci appear within them. Acid-fast studies of smears and sections have confirmed that this caseum has few tubercle bacilli. As the nodes enlarge, they fre-

quently impinge on the neighboring regional bronchus and compress it and cause diffuse inflammation of its wall, even to the point of obstructing the lumen.[329,505,553] Daly and colleagues,[123] in their study of endobronchial tuberculosis in children at Bellevue, found this mechanism to be the cause of obstruction in half their patients. Other mechanisms of obstruction include damage to the bronchial cartilage leading to gradual (or, rarely, abrupt) perforation of the bronchus and the formation of plugs of semiliquid toothpaste-like caseum that partially or completely occludes the bronchus. In some cases, endobronchial granulomatous tissue forms around the stoma of the fistula and obstructs the lumen.

Three immediate results of bronchial obstruction are possible.

The first is sudden death by asphyxia, fortunately an extremely rare event.[311]

The second is obstructive hyperaeration (also called *obstructive emphysema*) of a lobar segment, a lobe, or even an entire lung. This unusual result usually affects children younger than 2 years old, and it may be accompanied by wheezing. Physical examination generally is of little help; radiographs, best taken on expiration, show hyperaeration, which usually is not accompanied by mediastinal displacement, probably because of fixation by the tuberculous mediastinal nodes (Fig. 107–7). Aspiration of a foreign body always must be considered in the differential diagnosis. The obstruction ultimately resolves by itself; however, corticosteroids may be added to the chemotherapeutic regimen to hasten recovery.[406,407,602] Surgical removal of the obstructing nodes has been successful but rarely is performed.[129]

The third possible result of bronchial obstruction is the appearance of a segmental lesion, fan-shaped on a radiograph, representing mainly atelectasis and almost always involving the very segment occupied by the primary pulmonary focus[307,354,393] (Fig. 107–8). Actually, the radiographic opacity results from a combination of several elements: the primary pulmonary focus,

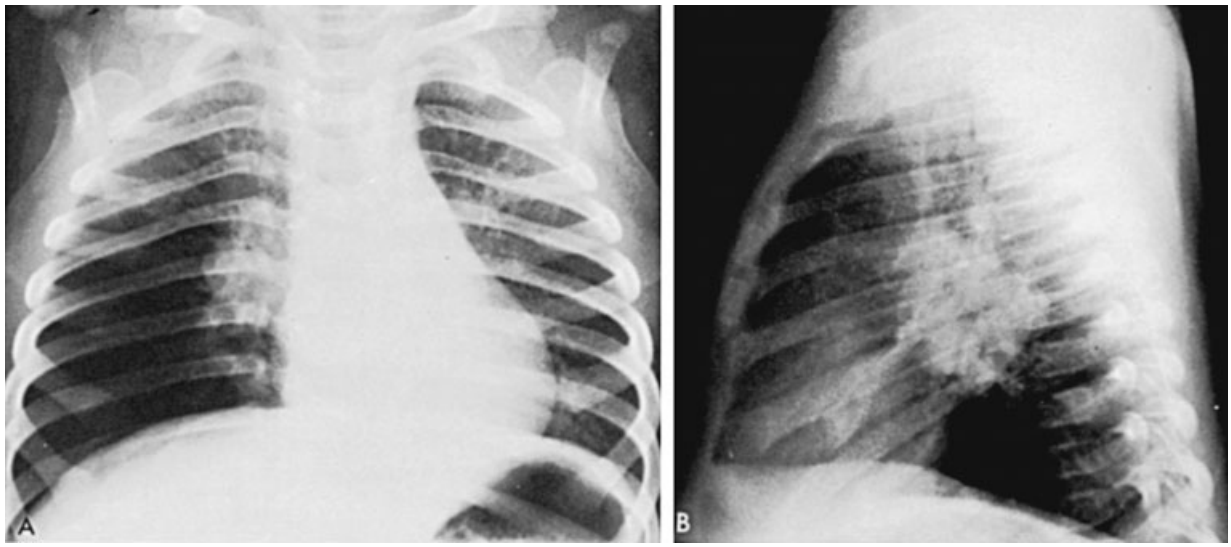

Figure 107–7 X-ray film of an 8-month-old girl with obstructive hyperaeration of the right lower lobe as a result of tuberculosis. **A,** Note the hyperlucent right lower lobe and shift of the heart and mediastinum away from the ball-valve obstruction to the left. **B,** Note the large hilar lymph nodes, which are compressing the right lower lobe bronchi. Tuberculosis should be considered in patients with hyperaeration of unknown etiology.

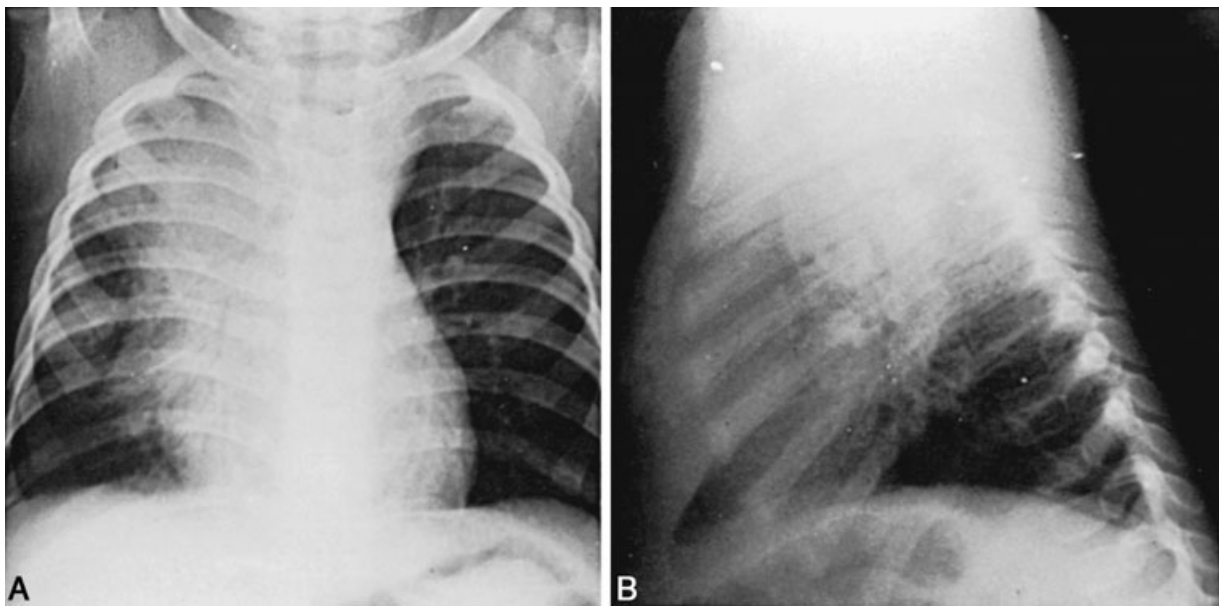

Figure 107–8 **A** and **B,** Radiographs of an 8-month-old boy with primary tuberculosis infection. The posteroanterior film shows collapse-consolidation of the right upper lobe, hilar and paratracheal adenopathy, and pleural reaction. Note the narrowed right bronchi.

the caseous material from an eroded bronchus, the inflammatory response elicited by the caseum, and atelectasis. In some instances, acute secondary infection plays a role. Children with secondary bacterial pneumonia often initially have high fever, cough, and rales; the signs and symptoms respond to conventional antibiotics, but the chest radiographic findings usually do not clear because of the underlying tuberculosis. The relative roles of these various elements often cannot be assessed; sometimes atelectasis is conspicuous, and, at other times, consolidation is the salient pathologic process, with the volume of the segment undiminished or even increased (hence the descriptive term *collapse-consolidation lesion*, preferred by some clinicians to the less accurate term *atelectasis*).

The percentage of infected children in whom segmental lesions develop has been estimated by several investigators. All agree that the younger the child, the more frequently collapse-consolidation lesions occur (Table 107–6). The segmental lesion is likely to form during the first 3 to 6 months after acquisition of infection (50 of 65 in Payne's series[441]). Multiple segmental lesions can occur simultaneously (18 of 160 children in Payne's experience). When multiple lesions develop, the segmental lesions usually form in one lung, but occasionally, the lobes or segments of both lungs are affected. Sometimes, segmental lesions and obstructive hyperaeration occur simultaneously. The physical signs and symptoms of segmental lesions—cough, rales, localized wheezing, egophony—are surprisingly meager but are seen more frequently in infants because of the smaller size of their airways.

Although segmental lesions and hyperaeration are the most common findings produced by enlarging thoracic lymph nodes, others occur. Enlarged peritracheal nodes may cause stridor and respiratory distress.[358] Subcarinal nodes may impinge on the esophagus and cause difficulty swallowing, followed occasionally by the formation of an esophageal diverticulum, or the nodes may rupture directly into the esophagus and produce a bronchoesophageal fistula. Enlarged lymph nodes may compress the subclavian vein and produce edema of the hand and arm, or they may erode major blood vessels, including the aorta. They also may rupture into the mediastinum and point in the left or more often the right supraclavicular fossa. Compression of the left recurrent laryngeal nerve has been reported. Compression of the left phrenic nerve leads to paralysis of the left leaf of the diaphragm in an estimated 0.1 to 0.3 percent of tuberculous children. Rupture into the pericardial sac is described later.

The late results of bronchial obstruction include the following possibilities: complete re-expansion of the lung and resolution of the radiographic findings; disappearance of the segmental lesion, with residual calcification of the primary focus or the regional lymph nodes; or scarring and progressive contraction of the lobe or segment, usually associated with bronchiectasis.[329,355] Permanent anatomic sequelae result from segmental lesions in approximately 60 percent of all cases, even though the abnormality usually is not apparent on plain radiographs. Cylindrical (rarely saccular) bronchiectasis, sometimes stenoses, and elongation or shortening can be demonstrated on bronchography. Fortunately, most of these abnormalities are asymptomatic in the upper lobes. However, secondary infection may occur in the middle and lower lobes and cause the middle lobe syndrome.[63] On occasion, the chronic vascularity that accompanies bronchiectasis leads to poor oxygen saturation during exercise and to restricted body growth. In addition, bronchogenic carcinoma may arise years later in the old scarred lesions remaining in the bronchus.

Calcification of the primary complex, when it appears, always results from caseation. In calcified caseum, as in bone, the predominant calcium salt is tribasic calcium phosphate. Calcification of caseous lesions occurs much more readily in children than in adults, probably because children's calcium and phosphorus plasma levels are higher. In the infants who were victims of the Lübeck disaster, autopsy showed calcification to be present as early as 58 days after the onset of massive infection. Payne,[441] in a study of calcification in 299 children from Newcastle-on-Tyne, reported calcification visible on the chest radiographs of one child within 6 months of infection, 38 within 12 months, 104 within 18 months, 165 within 24 months, 252 within 3 years, and 299 within 4 years.

Calcium usually is deposited as fine particles and creates a stippled effect (Fig. 107–9), but it may be deposited in large, even enormous masses. Calcification may persist without much change, or it may start resorbing within 5 years and eventually disappear completely. It occasionally progresses to ossification with the formation of true bone and functional bone marrow. Calcification, if it is visible at all on radiographs, most often involves the regional lymph nodes.[58] Sometimes, however, the primary pulmonary focus or the entire primary complex, including the lymphangitis, calcifies (Fig. 107–10).

Calcification took place in 75 to 80 percent of the 525 children with pulmonary tuberculosis monitored by Payne.[441] Currently, extensive calcification occurs uncommonly in the Western world, probably because tuberculous lesions treated early with isoniazid rarely caseate, and caseation is a prerequisite for calcification.

TABLE 107–6 Percentage of Tuberculin Converters and Age at Which Segmental Lesions Develop

Pleural Effusion

Pleural effusion can be localized or generalized, unilateral or bilateral.[327] Localized pleural effusion so frequently accompanies the primary pulmonary focus that it is practically a component of the primary complex. All tuberculous serous effusions probably originate in the discharge of bacilli into the cavity from an adjacent lesion—in the case of the pleura, from a subpleural pulmonary focus or from subpleural caseous lymph nodes. The breakthrough may be small and the pleuritis localized and asymptomatic, or it may occur in the form of a generalized effusion, usually 3 to 6 months after infection occurs (Fig. 107–11). In 75 percent of Wallgren's[632] cases, later calcification of the pulmonary focus or regional lymph nodes proved the effusion to be on the same side as the original primary focus. Seemingly without logical explanation are the following clinical observations: tuberculous pleural effusion is a rare occurrence in children younger than 2 years and an uncommon one in children younger than 5 years (perhaps because sensitivity to tuberculin is lower in the very young), occurs more frequently in boys than in girls, almost never is associated with a segmental lesion, and rarely is associated with miliary tuberculosis.

The onset of pleurisy usually is abrupt and resembles bacterial pneumonia, with fever, chest pain, shortness of breath, and, on physical examination, dullness to percussion and diminished breath sounds. Fever may be high and, in untreated cases, last for several weeks. On occasion, differentiation of an effusion from an extensive pneumonic lesion is difficult; lateral decubitus radio-

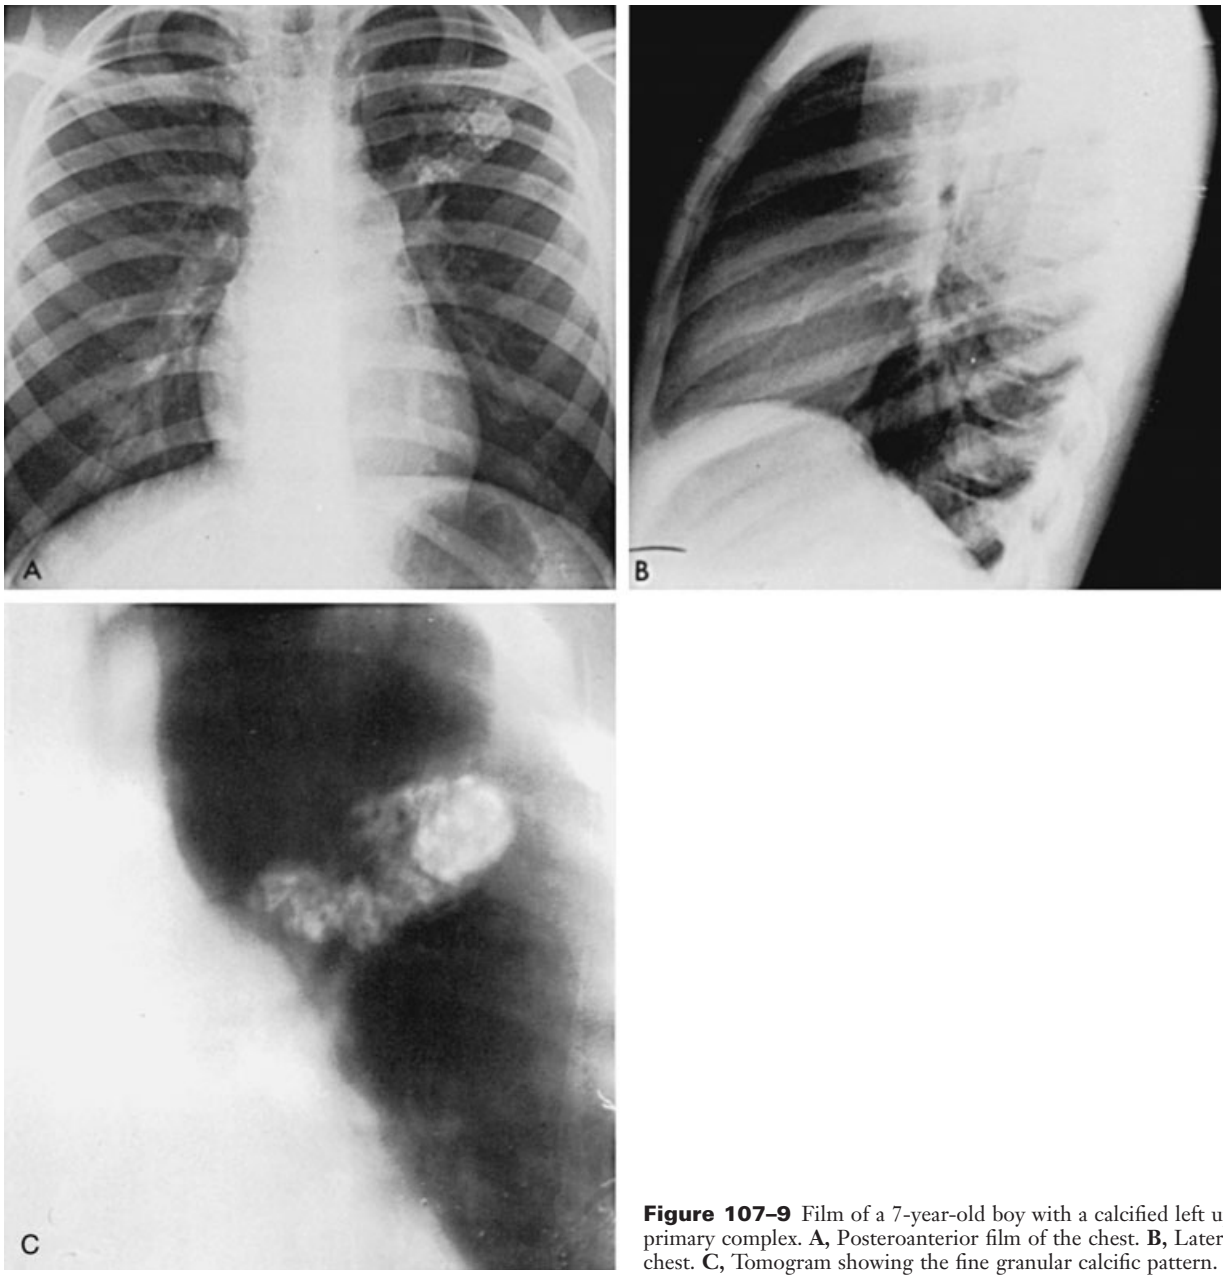

Figure 107–9 Film of a 7-year-old boy with a calcified left upper lobe, primary complex. **A,** Posteroanterior film of the chest. **B,** Lateral film of the chest. **C,** Tomogram showing the fine granular calcific pattern.

graphic views are helpful in confirming the presence of pleural fluid.

Thoracentesis is, of course, the essential diagnostic procedure. The puncture should be made in the area shown on the radiograph to have the greatest accumulation of fluid. No more than 30 mL of pleural fluid should be withdrawn; otherwise, the protein loss from this usually protein-rich fluid may be considerable. The fluid generally is greenish yellow, occasionally tinged with blood, with a specific gravity of 1.012 to 1.022, a high protein content, and often a low glucose level (<30 mg/dL), and it has several hundred white cells per cubic millimeter with a predominance of neutrophils or lymphocytes, depending on the age of the effusion. The cells in tuberculous pleural effusion are predominantly T lymphocytes, which are present in a higher proportion than in blood.[167,520] Tubercle bacilli generally are present in such small numbers that results from direct smears and cultures are likely to be disappointing; smears almost always are negative, and pleural fluid cultures are positive in less than 30 percent of cases. Pleural biopsy is a useful diagnostic procedure because both the finding of typical tubercles on histologic study and culture of the tissue are much more likely to establish the diagnosis than is culture of pleural fluid.[322]

The prognosis for children with tuberculous effusion always has been relatively good compared with that for other overt forms of tuberculosis, even in the days before chemotherapy.[331] Permanent impairment of pulmonary function is a surprisingly uncommon event after pleural effusion.[178] The development of scoliosis is a remote possibility and should be guarded against while the patient recovers.

Progressive Pulmonary Tuberculosis

In this serious complication of the primary complex, the primary pulmonary focus, instead of resolving or calcifying, enlarges steadily and develops a large caseous center. This center then

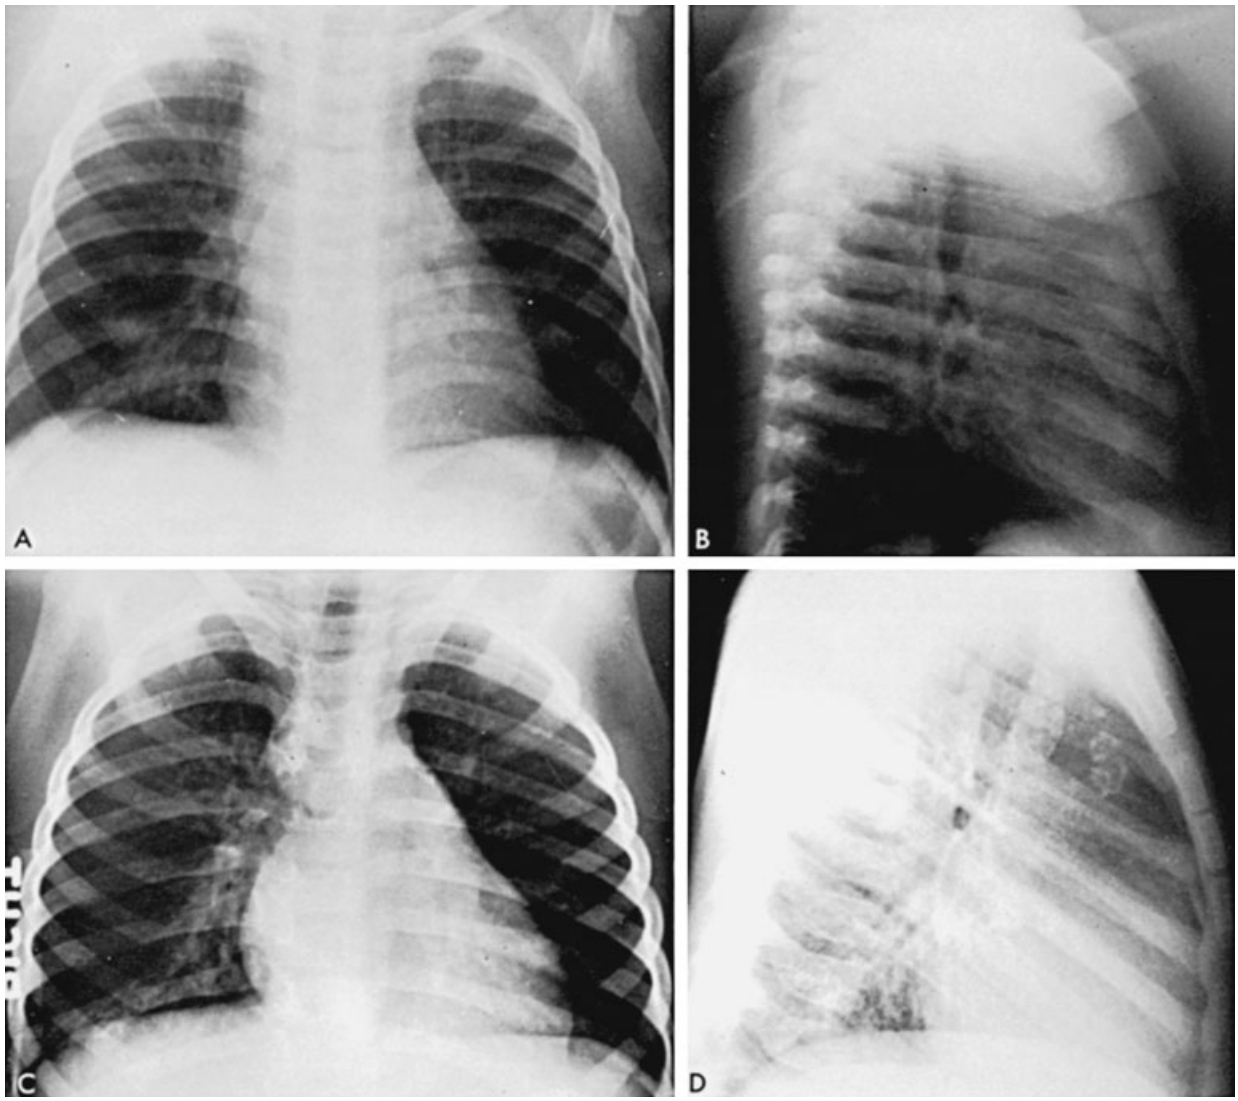

Figure 107–10 **A** and **B,** Radiographs of a 7-month-old girl with mild fullness of the right upper mediastinum and a hazy infiltrate in the right lower lobe. The result of a skin test for tuberculosis was positive. She was treated for tuberculosis and clinically improved. **C,** The same patient 3.5 years later has a calcified primary complex in the right upper and lower lobes over the diaphragm. **D,** The anterior location of the upper lobe complex is seen clearly on the lateral chest film.

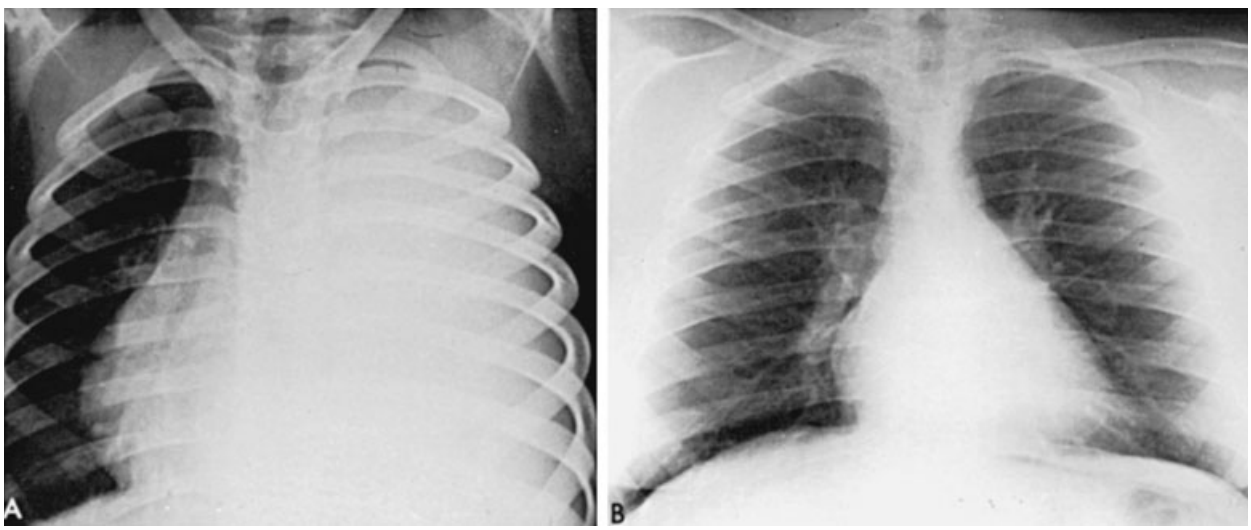

Figure 107–11 Radiographs of a 5-year-old boy with massive left pleural effusion caused by tuberculosis. **A,** Posteroanterior film of the chest. **B,** The same patient 6 years later with a normal chest film and no physical complaint.

liquefies and empties into an adjacent bronchus to create a "primary cavity"[590,619] (Fig. 107–12); the liquefaction is associated with particularly large numbers of tubercle bacilli. The tubercle bacilli further disseminate to other parts of the lobe and to the entire lung, where other foci of infection form. On rare occasion, an enlarging primary focus ruptures into the pleural cavity and creates a pneumothorax, bronchopleural fistula, or caseous pyopneumothorax or into the pericardial sac or the mediastinum.

Whereas clinical symptoms often are minimal when the primary focus is uncomplicated, a progressive lesion often is accompanied by more severe fever, cough, malaise, and weight loss as well as classic signs of cavitation, such as egophony.[202,493] Before chemotherapy was available, the inability to contain the primary focus was associated with a grave outlook; 25 to 65 percent of patients thus affected died. Now, with appropriate treatment, the prognosis is good.

Distinguishing between progressive pulmonary tuberculosis and a simple tuberculous focus with a superimposed acute bacterial pneumonia caused by *Staphylococcus*, *Klebsiella*, or anaerobes may be difficult. Antimicrobial agents effective against these pathogens may be indicated, in addition to appropriate antituberculosis drugs. Sometimes, especially during convalescence from pulmonary parenchymal lesions, bullous lesions appear and persist for several months. They seem to be associated, in children as in adults, either with "tears" in damaged alveolar walls or with the emptying of caseum out of cavities.[567]

Chronic Pulmonary Tuberculosis

Chronic pulmonary tuberculosis, sometimes referred to as adult or reactivation tuberculosis, is the type of disease seen in pulmonary tissue sensitized and immunized by an earlier tuberculosis infection. For many years, ongoing debate centered around whether the lesions of chronic pulmonary tuberculosis, more localized than those of the initial tuberculous lesion and less likely to spread to lymph nodes and the bloodstream, were due to "endogenous reinfection." Evidence that has accumulated during subsequent decades indicates that endogenous reinfection is the

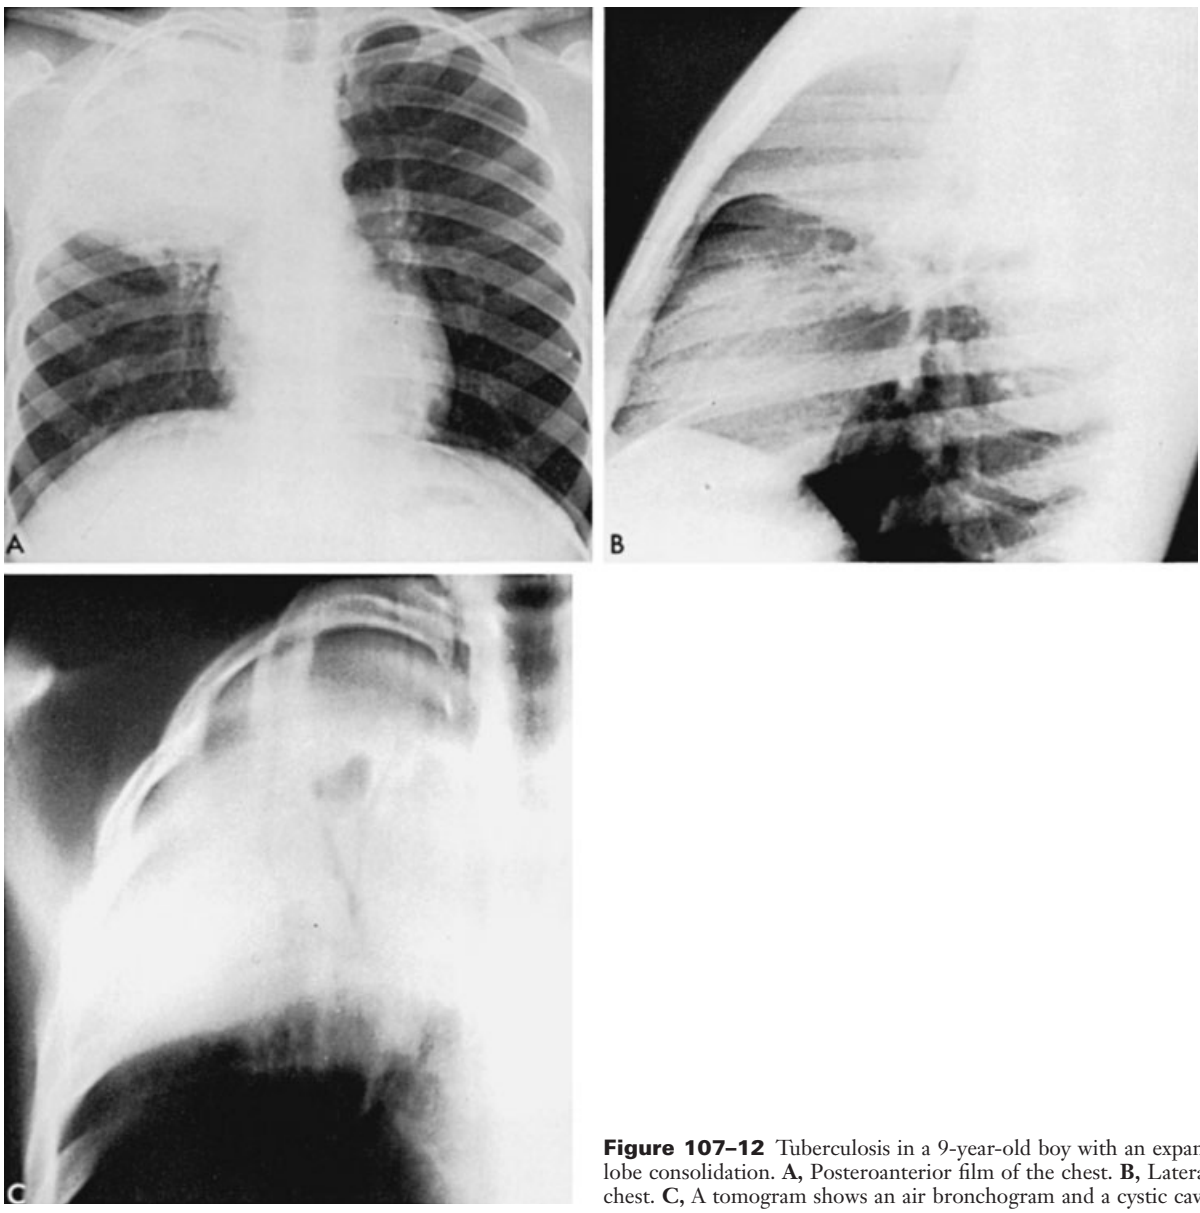

Figure 107–12 Tuberculosis in a 9-year-old boy with an expanding right upper lobe consolidation. **A,** Posteroanterior film of the chest. **B,** Lateral film of the chest. **C,** A tomogram shows an air bronchogram and a cystic cavitary lesion.

usual event.[565] However, reinfection with a different strain of *M. tuberculosis* has been documented and may be more common in areas where tuberculosis is prevalent.[530]

Careful long-term studies of children have revealed a continuum of involvement in many cases: first the primary focus, followed within a few years in some patients by infraclavicular small round foci in the lung apices that often were calcified (Assmann foci, Simon foci) and thought to result from hematogenous spread at the time of initial infection. Later, these foci disappear spontaneously or remain visible as tiny calcifications or as larger "round foci," which may, if untreated, progress to the typical lesions of chronic pulmonary tuberculosis.

Even before antituberculosis drugs were discovered, chronic pulmonary tuberculosis was a rare occurrence in children (6-7% in the series of Lincoln and colleagues[328] of closely monitored patients at Bellevue Hospital). It appears more frequently in children in the lower socioeconomic strata of society and more frequently in girls than in boys. Chronic pulmonary tuberculosis rarely develops in children who survive with a healed, untreated tuberculosis infection acquired before they have reached 2 years of age, but it is much more frequent in children who acquire their initial infection after reaching 7 years of age and particularly if they become infected close to the onset of puberty. In that case, the "adult" type of lesion often develops in the very lobe where the primary lesion occurred. In this situation, progressive pulmonary tuberculosis cannot be differentiated from chronic pulmonary tuberculosis. Now, with effective treatment, such differentiation is unimportant.[211]

Cough, fever of unknown origin, chest pain, hemoptysis, and supraclavicular adenitis are the most common clinical manifestations. Essential diagnostic procedures are the tuberculin skin test and appropriate chest radiographs, often including such special procedures as tomograms and lordotic views. An intense search for tubercle bacilli must be made in sputum, gastric washings, and, if necessary, secretions obtained by bronchoscopy.

Myocardial and Pericardial Tuberculosis

Tubercles often are found in the heart in miliary tuberculosis. Although it is exceedingly rare, myocardial caseation has been described, usually secondary to direct spread from mediastinal glands and accompanied by paroxysmal tachycardia or arrhythmias.[633]

Tuberculous pericarditis, although more common than symptomatic tuberculous myocarditis, occurred in only 0.4 percent of 2500 children monitored by Lincoln and Sewell[331] at Bellevue and in 4 percent of 200 children in Boyd's series.[56] It occurs more commonly in males than in females. In most cases, tuberculous pericarditis probably arises by direct invasion or by lymphatic drainage from caseous lymph nodes in the subcarinal area or from nodes close to the ductus arteriosus, with resulting exudation of hemorrhagic fluid and the development of granulation tissue on both the parietal and visceral surfaces of the pericardium.[477] Pericardial fluid may be serofibrinous or hemorrhagic; tubercle bacilli rarely are found on smears.[242] Sometimes, extensive fibrosis leads to obliteration of the pericardial sac, with the development, usually years later, of constrictive pericarditis.

The initial symptoms generally are nonspecific: low-grade fever, poor appetite, failure to gain weight, and, rarely, chest pain. On examination, a pericardial friction rub may be heard, or if a large effusion already is present, distant heart sounds, tachycardia, and a narrow pulse pressure may suggest the diagnosis. The diagnosis then is confirmed by radiography, echocardiography, electrocardiography, tuberculin skin test, and aspiration of fluid for culture. Before the advent of chemotherapy, approximately half the patients succumbed. Now, with appropriate drugs and possibly corticosteroids to diminish the size of the effusion[578] and also occasional partial pericardiectomy, the outlook is excellent.

Lymphohematogenous Spread

Tubercle bacilli from the lymphadenitis of the primary complex are disseminated during the incubation period in all cases of tuberculosis infection. The results of liver biopsy of young asymptomatic tuberculin converters (indicating recent infection) show that the liver always is involved.[106] Tubercle bacilli can reach deep, distant organs through the bloodstream or lymphatic channels. Autopsies on individuals who have died soon after development of initial infection show that bacilli often are deposited in the liver, spleen, skin, and apical pulmonary tissue.

The clinical picture produced by lymphohematogenous spread probably is determined by host susceptibility at the time of spread and by the quantity of tubercle bacilli released.[516,621] Three clinical forms can be recognized:

1. The lymphohematogenous spread may be occult, in which case it usually remains so, or it may be occult initially with metastatic, extrapulmonary lesions appearing months or years later (e.g., renal tuberculosis).[470]
2. So-called protracted hematogenous tuberculosis, rarely seen today, is characterized by high, spiking fever, marked leukocytosis, hepatomegaly and splenomegaly, and general glandular enlargement, sometimes with repeated evidence of metastatic seeding in the choroid, kidneys, and skin. Calcifications may appear subsequently, often in large numbers, in the pulmonary apices (Simon foci) and in the spleen, thus attesting to the earlier dissemination of tubercle bacilli through blood. The tuberculin skin test result usually is strongly positive. Bone marrow biopsy may confirm the clinical impression, but treatment often must be started on a presumptive basis. Although this type of tuberculosis in past years often ended tragically in tuberculous meningitis, today it is completely treatable if it is diagnosed in time.
3. The third form of lymphohematogenous spread, analogous to sepsis with pyogenic bacteria, is miliary tuberculosis.[244,516] It usually arises from discharge of a caseous focus, often a lymph node, into a blood vessel such as a pulmonary vein; it may be self-propagating, with repeated discharge arising at various sites. Most common during the first 2 to 6 months after infection in infancy, it can arise even in adults who have apparently well-healed, calcified lesions.[290,503]

Miliary disease provides a striking illustration of the difference in susceptibility of tissue to tubercle bacilli; tubercles tend to be larger and more numerous in the lung, spleen, liver, and bone marrow than in the heart, pancreas, and brain. The number of fixed intravascular phagocytes, as well as the relative tortuosity of the smaller blood vessels themselves, must play an important role in determining tissue susceptibility. In acute caseating miliary tuberculosis, the lesions are likely to be numerous and sometimes almost coalescent.

The clinical picture of miliary tuberculosis varies greatly, probably depending on the number of bacilli in the bloodstream. Sometimes, the patient is afebrile and appears to be well, and the condition is diagnosed by chance during contact investigation of another individual with infectious tuberculosis. The onset can be insidious, often occurring after the patient has had another precipitating infection. In rare cases, the onset is abrupt. Drowsiness, loss of weight and appetite, persistent fever, weakness, rapid breathing with a rustling sound on auscultation of the lungs, occasionally cyanosis, and almost always a palpable spleen are the clinical manifestations that lead the clinician to obtain a chest radiograph.

Usually within no more than 3 weeks after the onset of symptoms, tubercles, sometimes tiny and at times large, can be seen evenly distributed throughout both lung fields[427]; in the early stages, they often are detected best on a lateral view of the retrocardiac space (Fig. 107–13). The incidence of choroidal tuber-

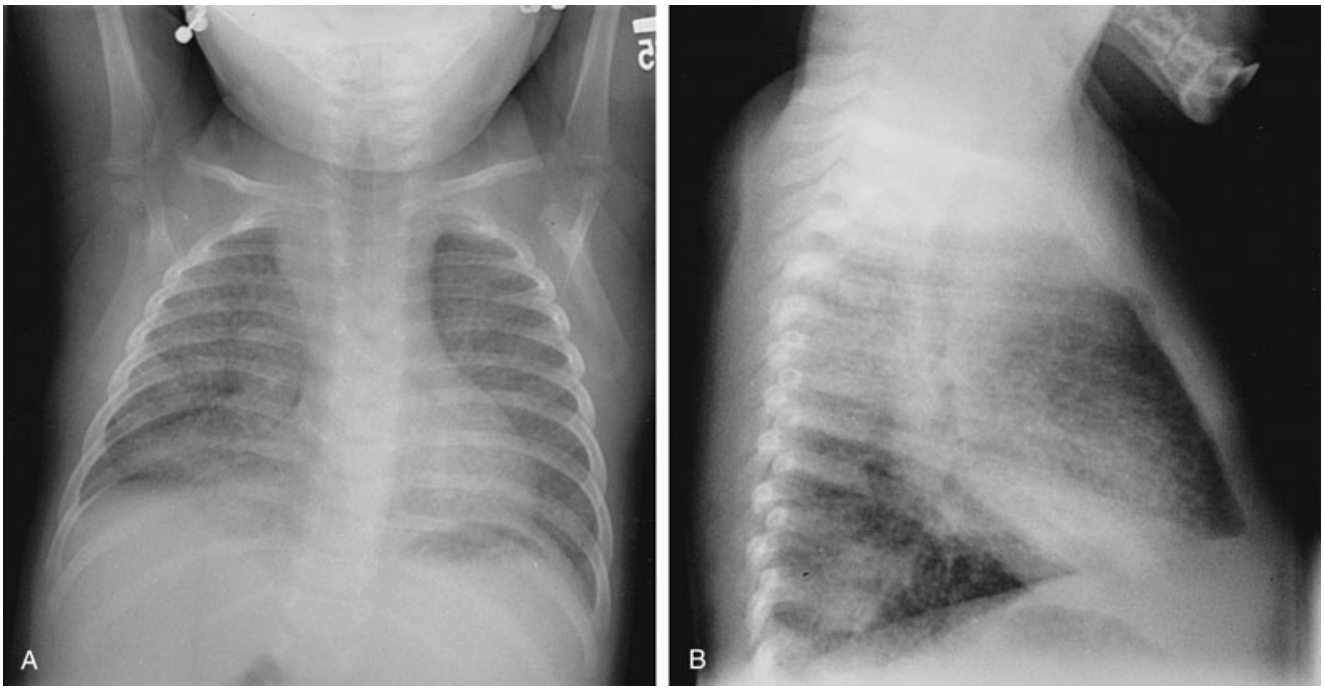

Figure 107–13 Miliary tuberculosis in an infant. The numerous tubercles can be seen on both the posteroanterior (**A**) and lateral (**B**) views.

cles varies greatly; it has been reported variously as 13 and 87 percent. Recurrent pneumothorax, subcutaneous emphysema, pneumomediastinum, and pleural effusion are less serious but well-recognized complications of miliary tuberculosis. Second attacks have been reported.[647] Cutaneous lesions, including painful nodules, papulonecrotic tuberculids, and purpuric lesions, may appear in crops.[286]

The diagnosis usually is established by means of the clinical picture and a chest radiograph. Sometimes it is confirmed by a liver or skin biopsy; by culture of *M. tuberculosis* from the gastric aspirate, urine, or bone marrow[106,214]; or by fiberoptic bronchoscopy and transbronchial biopsy.[67] Treatment usually is successful.

EXTRATHORACIC SPREAD

Central Nervous System Tuberculosis[558]

Tubercle bacilli are distributed by the bloodstream into all parts of the central nervous system (CNS) during lymphohematogenous spread.[330] Surprisingly, they do not multiply as well in nervous tissue as in other areas such as the lung. Thus, CNS tuberculosis, although an early manifestation of infection, usually does not appear simultaneously with miliary spread, but days later. The tubercle bacilli can affect the CNS in various ways[611,628] and produce tuberculous meningitis,[248,581] serous meningitis,[325,611] tuberculoma,[603,611] or tuberculous brain abscess, or it can affect mainly the spinal cord and cause spinal tuberculous leptomeningitis.[420]

Tuberculous meningitis arises from caseous foci, often very small ones, situated in the brain or meninges.[471] These lesions arise from hematogenous spread early in the infection.[143,260] In time, the caseous foci discharge tubercle bacilli directly into the subarachnoid space. The thick, gelatinous exudate lies in the meshes of the pia-arachnoid in the brain, where it infiltrates the walls of meningeal arteries and veins and produces inflammation, caseation, and obstruction; the exudate can extend along small vessels into the cortex, where it causes occlusion and produces infarcts. This same exudate interferes with normal flow of cerebrospinal fluid in and out of the ventricular system and with absorption of the fluid by the pacchionian bodies. The predilection of the exudate for the base of the brain accounts for the frequent involvement of the third, sixth, and seventh nerves and the optic chiasm. The combination of vascular lesions producing infarcts,[321] interference with flow of cerebrospinal fluid resulting in hydrocephalus, and direct cranial nerve involvement, especially of the eye, causes the devastating damage that all too often results from tuberculous meningitis.[20]

Tuberculous meningitis has been estimated to develop in one of every 300 untreated infections.[258] Virtually never seen in infants younger than 4 months, it occurs most frequently in children younger than 6 years, usually appears within 2 to 6 months after initial infection, and accompanies miliary tuberculosis in approximately 50 percent of cases. Tuberculosis should be suspected as the cause of meningitis that is accompanied by cranial nerve involvement, hydrocephalus, or evidence of inflammation at the base of the brain.[616]

The onset of tuberculous meningitis usually is gradual and occurs during a period of approximately 3 weeks; in some cases, it seems to be precipitated by a viral infection, a fall, or a blow on the head. On occasion, the onset is abrupt and marked by a convulsion. A convenient approach is for the clinician to divide the course into three stages. The first stage is characterized by personality change, irritability, anorexia, listlessness, and some fever. After 1 or 2 weeks, the disease passes into the second stage, when signs of increased intracranial pressure and cerebral damage appear: drowsiness, stiff neck, cranial nerve palsies, inequality of the pupils, vomiting, tache cérébrale, absence of the abdominal reflexes, and convulsions that may be tonic or clonic, focal or generalized. The third stage is characterized by coma, irregular pulse and respirations, and rising fever. Papilledema occasionally is noted.

Aids in establishing the diagnosis are a history of contact with an adult who has tuberculosis (however, the family history of tuberculosis often is "negative" because the incubation period of

meningitis is short and the contagious adult has not been discovered yet)[139]; a tuberculin skin test (positive result in only 50% of cases); positive tuberculin skin test results in siblings; a chest radiograph, which often reveals pulmonary disease; and changes in and the characteristic findings from spinal fluid. However, ventricular cerebrospinal fluid may be relatively normal because it is obtained proximal to the site of inflammation. The lumbar spinal fluid usually is clear and under substantially increased pressure. It will contain 50 to 500 white blood cells/mm^3, with polymorphonuclear leukocytes predominant early and lymphocytes predominant later. The spinal fluid glucose level may be at the lower limits of normal if the patient is examined early in the second stage, and it falls by 5 mg or so each day; by the third stage, it usually is very low. The protein content may be normal at the time of the first spinal tap, but it rises steadily to very high concentrations, at which time a pellicle will develop on the fluid on standing. Tubercle bacilli may be found in the pellicle but are scarce at best. Only approximately 50 percent of cases of tuberculous meningitis in children can be confirmed by culture of spinal fluid. Gastric washings should be cultured, not only to confirm the diagnosis in retrospect but also to permit drug susceptibility testing of the organisms.[651]

Computed tomography or magnetic resonance imaging[17,20,203,423] is recommended for the evaluation of all patients with tuberculous meningitis. Both permit recognition and follow-up of tuberculomas,[610,646] infarction or vasculitis, and hydrocephalus that might require shunting.[20,119,265,572] Involvement of the basal ganglia often is a diagnostic clue for the presence of tuberculosis.[17] Profound abnormalities in the electrolyte pattern of intracellular and extracellular fluid and spinal fluid have been reported in patients with tuberculous meningitis. These abnormalities consist mainly of low sodium and chloride levels, with low or normal plasma potassium levels, accompanied by high sodium levels in red cells and skeletal muscle.[212] High levels of antidiuretic hormone (syndrome of "inappropriate" antidiuretic hormone secretion) may cause hypotonic expansion of the extracellular fluid. Because intense vomiting and dehydration usually accompany tuberculous meningitis, the electrolyte disturbances usually include severe hypochloremia. Salt wasting in the urine occurs in rare cases. Determination of the spinal fluid chloride concentration is useless because it merely reflects the plasma level.

A good prognosis depends on immediate initiation of treatment without awaiting epidemiologic and bacteriologic confirmation of the diagnosis.[243,484] Before chemotherapy was used, every case of true tuberculous meningitis was fatal within 3 to 4 weeks, whereas today, appropriate treatment during the first stage allows survival in nearly every case, although the patient's intelligence may never return to its previous level. When it is initiated during the second stage, treatment results in survival in 75 percent or more of patients. If patients are in coma when treatment is begun, they rarely recover unscathed. Very young age and the occurrence of convulsions generally are poor prognostic factors.[484,501] Hydrocephalus, usually of the communicating type, occurs frequently (38% in one series) and is largely responsible for poor outcomes. Relieving the hydrocephalus surgically appears to improve the sensorium, vision, and neurologic deficits. Studies support the early use of ventriculoperitoneal shunting in patients severely ill at the time of admission.[308,435] Infarcts caused by vasculitis also can leave catastrophic residua. The presence of drug-resistant tuberculous meningitis greatly worsens the prognosis,[431] as does co-infection with HIV.[618] The role of corticosteroids in the treatment of intracranial tuberculosis is discussed later in this chapter.

The long-term sequelae of tuberculous meningitis are numerous and include blindness, deafness, intracranial calcification, diabetes insipidus, obesity, paraplegia, and mental retardation.[501]

Serous tuberculous meningitis is an uncommon occurrence (13% of 500 cases in the experience of Udani and associates[611]). Apparently, it develops when a tuberculous focus close to the subarachnoid space causes a lymphocytic reaction in the subarachnoid space without the actual presence of tubercle bacilli.[655] In the days before the advent of chemotherapy, "serous" meningitis was differentiated readily from "true" tuberculous meningitis because the serous type was the only nonfatal form of tuberculous meningitis. Today, such differentiation no longer is possible because treatment is begun immediately, so true tuberculous meningitis does not develop.

Isolated tuberculoma is manifested clinically as a brain tumor.[26,128,140] As many as 30 percent of brain tumors are tuberculomas, depending on the incidence of tuberculosis in the particular population under study (in India, for instance). Tuberculomas occur most often in children younger than 10 years old and often are located at the base of the brain around the cerebellum.[630] In contrast, tuberculomas in adults more often are supratentorial. Headache, convulsions, fever, and other symptoms and signs usually associated with brain abscess or tumor also characterize tuberculoma. Only careful evaluation, including inquiry about exposure to tuberculosis, a tuberculin skin test, chest radiography, and computed tomography, will permit these cases to be recognized in time to begin appropriate chemotherapy before neurosurgical intervention is needed. The widespread use of neuroimaging has revealed that small, multiple tuberculomas are a frequent feature of tuberculous meningitis in infants and young children.[17,20] A phenomenon recognized fairly recently is a symptomatic intracranial tuberculoma appearing and enlarging during treatment of meningeal, miliary, and even pulmonary tuberculosis.[4,319,462,518,595] This phenomenon appears to be mediated immunologically; it usually responds to corticosteroids and does not necessitate a change in antituberculosis chemotherapy. In addition, some small children with severe pulmonary or disseminated tuberculosis have one or several tuberculomas but normal findings on spinal fluid evaluation.[139,261] Computed tomography or magnetic resonance imaging of the head should be performed whenever neurologic signs or symptoms accompany tuberculosis.

Tuberculous brain abscess is a rarely reported form of CNS tuberculosis that tends to occur at an older age than tuberculoma does.[303,641] On pathologic examination, the lesion lacks the giant-cell and granulomatous reaction associated with tuberculoma. Focal neurologic signs occur commonly. Computed tomography and magnetic resonance imaging, if used routinely in cases of tuberculous meningitis, may permit this type of abscess, which requires surgical intervention as well as chemotherapy, to be recognized more frequently. Intramedullary tuberculoma of the spinal cord is exceedingly rare.[266,345] It can be manifested as recurrent abdominal pain.[45,420]

Spinal tuberculous leptomeningitis occurs more often in older children and adults than in infants[340]; in the series of 500 cases studied by Udani and coworkers,[611] only 2 percent fell into this last age group. Protein levels in the spinal fluid are elevated substantially, and sometimes partial or total block may be noted on myelography. Exudate may completely surround the spinal cord.

Cutaneous Tuberculosis

The manifestations of cutaneous tuberculosis can be classified in children according to a modification of the earlier classifications designed for adults[301]: (1) lesions produced by inoculation from an exogenous source[448,517] in a previously uninfected child, in a previously infected child, or after inoculation with BCG vaccine; (2) lesions resulting from hematogenous dissemination[286]; (3) lesions arising from an endogenous source; and

(4) erythema nodosum. A newer classification has been proposed and perhaps is more useful for adults than for children.[44]

Skin lesions associated with the primary complex may be caused by direct inoculation of tubercle bacilli into a traumatized area, such as a lesion on the sole of a child's bare foot, a mosquito bite on the face, an abraded elbow, or the foreskin at the time of ritual circumcision. The initial skin focus usually is a small, painless nodule, sometimes with tiny satellite lesions that soon turn into indolent ulcers without surrounding inflammation. The most striking feature is regional lymphadenitis, which often is what convinces the patient to see a physician. Fever and systemic reactions generally are minimal; low-grade pyogenic infection and cat-scratch fever (*Bartonella* infection) always must be considered in the differential diagnosis. A strongly positive tuberculin skin test result usually is obtained. Needle aspiration and culture may differentiate disease caused by *M. tuberculosis* from that caused by environmental mycobacteria.

Scrofuloderma indicates tuberculosis of the skin overlying a caseous lymph node (most often in the cervical area) that has ruptured to the outside and left either a shallow ulcer or a deep sinus, sometimes surrounded by a cluster of nodules. In the past, scrofuloderma was a frequent manifestation of tuberculosis in children and usually left extensive scars. Today, it is a rare occurrence because the diagnosis generally is made before the node ruptures. Administration of chemotherapy often forestalls the need for surgical excision.

Manifestations that result from hematogenous dissemination are papulonecrotic tuberculids and tuberculosis verrucosa cutis. Papulonecrotic tuberculids[527] are miliary tubercles in the skin that usually appear as tiny papules with "apple-jelly" centers, most often on the trunk, thighs, and face. They frequently are similar to papular urticaria or early varicella lesions, or they may be confused with the skin lesions of Letterer-Siwe disease. Skin biopsy provides a reliable diagnosis. Lupus vulgaris is a rare form of chronic, indolent tuberculosis, usually on the face, that often seems to evolve from tuberculids, very rarely at the site of BCG inoculation.

Tuberculosis verrucosa cutis is a condition characterized by large (several centimeters in diameter) papulonecrotic tuberculids. The lesions usually appear on the arms, legs, or buttocks, suggesting that trauma may play some part in their causation. Fungal infection is the main consideration in the differential diagnosis.

Erythema nodosum formerly was a common manifestation of hypersensitivity to tuberculin. It occurs mostly in young teenage girls. Usually beginning with fever and systemic toxicity manifesting soon after initial infection develops, erythema nodosum is characterized by large, deep, painful, indurated nodules on the shins and sometimes on the thighs, elbows, and forearms. The nodules gradually change from light pink to a bruise-like color. Erythema nodosum is not specific for tuberculosis but also occurs with streptococcal and meningococcal infections, histoplasmosis, coccidioidomycosis, sarcoidosis, drug sensitivity reactions, and perhaps cat-scratch disease. Tuberculin hypersensitivity is pronounced in children with tuberculosis underlying erythema nodosum, and tuberculin skin testing should be performed with caution. These patients may or may not have associated tuberculous lesions, but some clinicians hold that these patients have a greater chance of suffering complications. Skin biopsy reveals only nonspecific changes regardless of cause and, therefore, is useless in establishing the diagnosis. Both fever and nodules clear within 2 or 3 weeks.

Skeletal Tuberculosis

Bone and joint tuberculosis can be expected in 1 to 5 percent of children whose initial infection with tubercle bacilli is untreated. Usually, the tubercle bacilli are disseminated to skeletal structures during lymphohematogenous spread of the initial infection.[31] The disease becomes symptomatic during the first 1 to 3 years after infection occurs. Each of the most frequently involved bones and joints has a characteristic "incubation period" (e.g., 1 month for dactylitis but about 30 months for tuberculosis of the hip). In very young children, blood flow through growing bone is intense; consequently, they suffer from skeletal tuberculosis more often than older children do. The lesion usually starts as an area of endarteritis in the metaphysis of the long bone, where the blood supply is particularly abundant; lesions can be single or multiple.[460,515] Bone infection can be initiated by two other mechanisms, particularly in the vertebrae: (1) direct extension through the lymphatics from a caseous paravertebral lymph node[68] and (2) direct local hematogenous or lymphatic extension from a neighboring bone. As bone is destroyed progressively by pressure necrosis and formation of a cold abscess, a nearby joint may become involved.[461,614,629]

The bones most often affected are the vertebrae.[426] In one study of 1074 patients with the disease, 440 had involvement of the vertebrae; 89, the knee; 81, the hip; and 51, the elbow.[608] The upper extremities and non–weight-bearing bones, such as the skull, clavicle, and mandible, rarely are involved.[213,216] Often a history of trauma is present and may play some part in activation of an underlying lesion or may serve simply to draw attention to the process.

Tuberculous spondylitis, or tuberculosis of the vertebrae, frequently affects the thoracic vertebrae, particularly the 12th one.[225] In one series of 64 cases of spinal tuberculosis in children, the lesions were in the thoracic area in 24 children, in the lumbar area in 19, and in both areas in 13. Cervical involvement is a rare finding.[238] Usually, two vertebrae are involved, but sometimes three, four, or even as many as 11 (usually contiguous, but at times with "skips") are affected. The body of the vertebra is affected far more often than the spinous processes or the arch.

The progression of tuberculous spondylitis, as seen on radiographs, is from slight narrowing of the disk space with only minimal disk involvement and slight collapse and "wedging" of the vertebral body; to marked narrowing of the disk space with collapse, wedging of the bodies, and resulting angulation of the spine (gibbus); to extensive destruction of the bodies with severe kyphosis (Pott disease).

Paravertebral abscess (Pott abscess), retropharyngeal abscess, psoas abscess, and neurologic lesions are serious complications to be expected in 10 to 30 percent of cases of spondylitis. Neurologic complications most often arise from cervical and lumbar vertebral lesions and consist of various degrees of neuroplegia, paraplegia, or even quadriplegia. The complications are caused by inflammation of the spinal cord secondary to a neighboring cold abscess, by caseum or granuloma in the extradural space, or by spinal vessel thrombosis.

The signs and symptoms of spondylitis include "night cries" and restless sleep, a low-grade daily fever, and a peculiar position (such as torticollis with cervical lesions) or gait. Findings on physical examination may include marked "guarding" because of dorsal muscle spasm, pain when the back is "pounded," a deformity (such as gibbus), or reflex changes (including clonus). On occasion, the presence of referred chest pain leads to discovery of a paravertebral abscess on the chest radiograph. With chemotherapy and, when necessary, surgery, the outlook for both eventual clinical healing and neural recovery is in the range of 80 to 90 percent, although patients may not gain their full expected height.

Tuberculosis of the knee can be divided into several clinical types[224]: effusion into the joint without bone erosion and with little restriction of motion; thickening and fibrosis of the synovial membrane without bone erosion but often with considerable restriction of motion; synovial disease and a bone focus but an intact joint space; and synovial disease with diminished range of

motion.[629] Some degree of pain, stiffness, and limping, usually intermittent in milder cases, first calls attention to the problem.

Tuberculosis of the hip, in some series of patients more common than tuberculosis of the knee, should be considered in the differential diagnosis when a child refuses to walk or a limp develops. Today, when the disease still is limited at the time of discovery to the acetabulum or to the head of the femur and no intra-articular disease is present, good mobility of the joint usually can be preserved.

Tuberculous dactylitis (spina ventosa)[208] is the most common form of skeletal tuberculosis in infants. Endarteritis is followed by swelling (often painless), and cystic bone lesions are seen on radiographs. A cold abscess may form and drain spontaneously. The prognosis for recovery without deformity is surprisingly good and was so even before chemotherapy was available.

Tuberculous arthritis is a rare finding in children. Usually monarticular, it involves primarily the weight-bearing joints and only exceptionally the joints of the upper extremities. Bacterial cultures and histologic examination of the synovium establish the diagnosis.[629] Poncet disease is a rare form of rheumatic joint disease associated with tuberculosis; it is an exceedingly rare finding in children.[122] The diagnosis of skeletal tuberculosis should be considered immediately in any child who is known to have been infected with tubercle bacilli and in whom a bone or joint lesion develops and in any child with a persistent, not otherwise explained bone or joint lesion.[625] The differential diagnosis must include low-grade infections caused by *Staphylococcus*, *Haemophilus influenzae*, *Salmonella*, and *Brucella*; fungal infections; rheumatoid arthritis; malignant disease of bone; eosinophilic granuloma, particularly with skull or pelvic lesions; and osteochondrosis resulting from aseptic necrosis of bone, particularly Legg-Calvé-Perthes disease and tuberculosis of the hip.

Children with bone and joint tuberculosis usually react strongly to tuberculin. Although the number of tubercle bacilli in an active bone lesion is much lower than in a lung lesion, the organisms almost invariably can be recovered on culture, and a great effort to do so should be made by means of aspiration or open biopsy.[201]

Treatment of skeletal tuberculosis includes both chemotherapeutic and orthopedic interventions, the chemotherapeutic interventions by far the more important.[457] Orthopedic procedures can be used for several purposes: establishment of the diagnosis, evacuation of caseum and necrotic bone, immobilization of a joint, and reconstruction or strengthening of damaged bone. Since the advent of chemotherapy, any indicated surgical procedure can be performed without fear of subsequent development of sinus formation. However, the trend has been toward reliance on drug therapy with increasingly conservative surgical management. Controlled trials of treatment undertaken in different parts of the world (Southeast Asia) by the Medical Research Council Working Party on Tuberculosis of the Spine and others have demonstrated the remarkable effectiveness of ambulatory treatment with different regimens of chemotherapy in children and adults,[250,371-373] including short-course chemotherapy.[206]

Tuberculosis of the Superficial Lymph Nodes (Scrofula)

Striking enlargement of the superficial regional lymph nodes is an integral component of the primary tuberculous complex. The tonsillar and submandibular nodes are involved most often and probably represent extension from the paratracheal lymph nodes (and not from a primary lesion in the tonsil, as once was thought); occasionally, these nodes are involved when the primary lesion occurs in the mucous membranes of the mouth, a rare event. Enlarged supraclavicular nodes may accompany a primary pulmonary lesion in the upper lung fields. Enlarged axillary and epitrochlear nodes can result from a primary skin lesion of the elbow or hand, often a small, insignificant-looking area that has, however, been present for some time. Preauricular adenitis suggests a focus on the scalp or forehead or in the lacrimal sac, sometimes attributed to an insect bite. With inguinal adenitis, careful examination of the sole of the foot may reveal a small ulcer, often at the base of the toes.

When the superficial lymph nodes are involved early in the course of infection—the normal event—the enlargement usually is painless, and the node or nodes are rubbery and discrete.[360] Low-grade fever generally is present, sometimes unnoticed by the parents. On occasion, acute respiratory infections seem to precipitate or to aggravate superficial tuberculous lymphadenitis, and the patient has high fever, some local pain, and perilymphadenitis. Rarely, the patient is seen first with a fluctuant mass, and the overlying skin is shiny and erythematous.[124,550]

The diagnosis usually is not obvious, so it is wise in all cases of superficial cervical and supraclavicular lymphadenitis to perform a throat culture, radiography of the chest, and a Mantoux tuberculin test. If the node is fluctuant, it should be aspirated and cultured for mycobacteria as well as for pyogenic bacteria.[312] In preauricular, axillary, and inguinal adenitis, a possible primary skin lesion should be sought diligently. If a lesion is found, a biopsy should be performed, in addition to a tuberculin skin test, chest radiography, and a careful history.

Currently, in addition to pyogenic infection, cat-scratch disease, tularemia, malignant tumors, sarcoid, and infection caused by mycobacteria other than *M. tuberculosis* also must be considered as a possible cause.[30,306] If the adenitis is caused by infection with *M. tuberculosis*, the induration from a Mantoux tuberculin skin test usually is greater than 15 mm, whereas mycobacteria other than *M. tuberculosis* produce a less intense reaction. The key to distinguishing tuberculosis from infection by another mycobacterium generally is epidemiologic—has the child been exposed to tuberculosis?

Because infection with pyogenic bacteria often enhances mycobacterial adenitis, frequently a wise approach is to institute therapy with a conventional antibacterial agent while awaiting the results of the skin test, chest radiography, and cultures. If the adenitis persists and evidence of mycobacterial infection is elicited, antituberculosis drug therapy should be initiated and surgical excision seriously considered.[306,504] Surgical excision currently is the treatment of choice for adenitis caused by mycobacteria other than *M. tuberculosis*. In the case of lymphadenitis caused by *M. tuberculosis*, the response to antituberculosis drugs is likely to be good. On the other hand, the adenitis is more likely to extend down into the mediastinum and to be difficult to remove. Under these circumstances, surgical excision probably is unwise, whereas a few weeks of corticosteroid and antituberculosis therapy may be effective.[263,306]

Superficial tuberculous lymphadenitis sometimes occurs early in the course of lymphohematogenous spread, in which case it often is manifested as "general glandular enlargement" accompanied by swinging fever, malaise, and weight loss. The tuberculin test result almost always is positive in immunocompetent patients, and the tuberculin test should be included in the investigation of every patient with general glandular enlargement.

Finally, tuberculous adenitis, either localized or generalized, can occur in adolescents or young adults who were infected months or even years earlier, whose infection has been quiescent, and in whom the appearance of lymphadenitis heralds reactivation of the tuberculosis infection.[305]

Ocular Tuberculosis

Ocular tuberculosis is an uncommon finding in children.[136] When it does occur, the conjunctiva and the cornea are the areas most often involved.

The conjunctiva can serve as the initial portal of entry for tubercle bacilli, especially after trauma. Unilateral lacrimation and reddening may lead to the discovery of yellowish gray nodules, usually on the palpebral conjunctiva. Preauricular adenitis appears early; the submandibular and cervical nodes also may enlarge. A tuberculin skin test and biopsy with culture can be performed to confirm the diagnosis.

Phlyctenular conjunctivitis probably is one of the hypersensitivity phenomena of childhood tuberculosis. Tubercle bacilli have, on rare occasion, been isolated from the small, grayish, jelly-like nodules usually clustered on the limbus and surrounded by dilated conjunctival vessels. Pain and photophobia are intense, and the lesions may recur in crops for weeks and affect one or both eyes. In the differential diagnosis, foreign body, herpes simplex virus conjunctivitis, vernal conjunctivitis, and trachoma should be considered. Tuberculin sensitivity is likely to be pronounced, and 1 tuberculin unit of purified protein derivative (PPD) should be used in the initial tuberculin skin test. Fortunately, hydrocortisone drops are effective in controlling both a strong local reaction to the diagnostic tuberculin test and the discomfort from the underlying disease. The prognosis for complete recovery is excellent, provided the phlyctenules do not ulcerate and leave corneal scars. Systemic chemotherapy should be started immediately after the diagnostic procedures are completed.

Although tuberculosis of the ciliary body and iris has been reported rarely in children, tubercles of the choroid often have been found in patients with miliary tuberculosis (up to 70% of patients in some series) and occasionally in children with a seemingly uncomplicated infection.[394,424] Frequently multiple, the tubercles heal slowly with deposition of retinal pigment; residual scarring apparently can be prevented with steroid therapy. Tuberculous uveitis and tuberculosis manifested as an orbital mass are rare clinical entities.[519]

Tuberculosis of the Middle Ear

Tuberculosis of the middle ear is a relatively rare manifestation of the disease.[168,341,344,398,488] It occurs as a primary focus in the area of the eustachian tube (because of reflux up the tube) in neonates who have aspirated infected amniotic fluid or in older infants who have ingested tuberculous material. It can occur as a metastatic lesion in older children who have a primary focus elsewhere. If it is a primary focus, regional lymphadenitis involves the preauricular lymph node or the anterior cervical chain, and facial paralysis occurs frequently. The primary focus always is unilateral. Otorrhea is a common occurrence and painless but may become foul smelling because of bacterial contamination with enteric organisms. Older patients may complain of tinnitus and "funny noises." The eardrum often is damaged extensively. A large central perforation or several perforations are characteristic findings. A tuberculin skin test, biopsy, and careful cultures for tubercle bacilli are essential. Once greatly feared for the almost inevitable loss of hearing and the frequent occurrence of tuberculous meningitis, tuberculous otitis media now heals well with appropriate chemotherapy.[398]

Gastrointestinal and Abdominal Tuberculosis

Tuberculosis of the mouth occurred more commonly in the days of bovine tuberculosis than it does today; at that time, scrofula often represented a primary complex in the mouth or tonsils, with associated submandibular or cervical lymphadenitis.[380] A primary focus in the mouth generally consists of a painless ulcer or mass of granulation tissue around a tooth socket or in the gingivolabial sulcus, with enlarged submental or submandibular nodes. Primary tuberculosis of the tonsils begins as a painless swelling of one tonsil, sometimes with an ulcer or yellowish node and, of course, enlargement of the regional lymph nodes. If tubercles found on histologic examination of a tonsil removed at tonsillectomy are unaccompanied by lymphadenitis, the lesion is considered a metastatic rather than a primary lesion. Tuberculosis of the esophagus occurs rarely if ever in children; sometimes, dysphagia is produced by a mass of mediastinal nodes, which may rupture into the lumen and later heal, possibly leaving an esophageal diverticulum.

Abdominal tuberculosis may occur after the ingestion of tubercle bacilli or as a part of generalized lymphohematogenous spread, but tuberculous enteritis always has been uncommon.[18,46,480,586,589] When tubercle bacilli penetrate the gut wall, they usually do so through the Peyer patches or the appendix, where they give rise to local ulcers followed by mesenteric lymphadenitis and sometimes peritonitis.[16] On occasion, especially in older children, tuberculous enteritis accompanies extensive pulmonary cavitation. Symptoms and signs include vague abdominal pain, intussusception, blood in the stool, and sinus formation after a seemingly routine appendectomy.

The spleen is seeded during the initial lymphohematogenous spread. Only rarely are the tubercles numerous and large enough to undergo caseation and to calcify.[296] The reticuloendothelial system of the liver is involved also. Symptoms rarely are manifested except in miliary tuberculosis, in which the liver may be enlarged markedly, or in congenital tuberculosis, in which both the liver and spleen usually are enlarged.[347]

Mesenteric lymphadenitis can arise as part of an intra-abdominal primary complex or by extension from tuberculous thoracic or pelvic lymph nodes; often asymptomatic, it may be discovered later when calcified. It can cause ascites and dilatation of the superficial abdominal veins, but the symptom most frequently attributed to mesenteric lymphadenitis is colicky abdominal pain after exercise, probably because adhesions are stretched.

Tuberculous peritonitis can be a result of direct extension from a primary intestinal focus, adjacent mesenteric lymph nodes, or tuberculous salpingitis.[100,137,186] It may be "plastic" or accompanied by a serous effusion. On palpation, a mass of lymph nodes often can be felt, and the abdomen may have a characteristic "doughy" feeling. Paracentesis should be performed with care because the intestine may be immobilized by adhesions. Even with a large effusion, absorption usually occurs within a month. Malignant disease must, of course, be considered strongly in the differential diagnosis, and it may be necessary to obtain a biopsy specimen even if the tuberculin skin test result is positive. Laparoscopy frequently is useful, as is fine-needle aspiration[335] and ultrasonography.[276] The ascitic fluid–blood glucose ratio of the aspirated peritoneal fluid can be helpful in differentiating tuberculous peritonitis from ascites of other causes.[645]

Renal Tuberculosis

Renal tuberculosis is a late and uncommon complication of pulmonary disease; it rarely occurs less than 4 or 5 years after primary infection and is therefore likely to be diagnosed during adolescence.[162,531] However, tubercle bacilli can be recovered from the urine in many cases of miliary tuberculosis and some cases of pulmonary tuberculosis in young children. Hematogenous dissemination can give rise to tubercles in the glomeruli, with resultant caseating and sloughing but tiny lesions, which then discharge tubercle bacilli into the tubules. An encapsulated caseous mass occasionally develops in the zone between the renal pyramid and cortex; it may calcify in situ or discharge into the pelvis of the kidney and form a cavity analogous to a pulmonary cavity. Infection can be unilateral or bilateral and can spread downward to involve the bladder. Frequently, dysuria, hematuria, and "sterile" pyuria are the initial findings in the urine; they may occur grossly but often not until late in the course of a disease that causes strikingly few symptoms. Appropriate examination and culture of

single early-morning urine specimens rarely fail to reveal tubercle bacilli. Intensive chemotherapy renders surgical intervention a rare necessity.[531] Urine from patients with renal tuberculosis is highly infectious, and such children should be isolated until their urine is sterile.

Dialysis- and Renal Transplant–Associated Tuberculosis

Infections are a common cause of morbidity and mortality in patients with end-stage renal disease. Depressed cellular immunity, as manifested by cutaneous anergy, delayed homograft rejection, and depressed lymphocyte count, has been demonstrated in uremic patients, whereas cell-mediated immunity appears to recover in stable patients treated by long-term hemodialysis. Thus, it is not surprising that tuberculosis occurs more frequently in patients maintained on dialysis than in the general population and that when it does become active, it does so before or early in the course of dialysis. Extrapulmonary involvement (mediastinal, meningeal, pleural, osseous, and renal) and miliary tuberculosis appear relatively frequently in this group. In these patients, fever of unknown origin should lead to suspicion of active tuberculosis.[15] Tuberculosis also can originate in the transplanted organ.[400,624]

Genital Tuberculosis

Tuberculosis of the genital tract is an uncommon finding in both sexes before puberty.[531] It usually arises as a metastatic lesion during lymphohematogenous spread and occasionally by direct extension from an adjacent lesion of bone, gut, or the urinary tract. Genital tuberculosis is a particular hazard for adolescent girls with tuberculosis infection. Frequently, other forms of tuberculosis associated with initial infection, such as a pleural effusion, also are present. The fallopian tubes are involved in 90 to 100 percent of cases, the endometrium in 50 percent, the ovaries in 20 to 30 percent, and the cervix in 2 to 4 percent.[498] With tubal involvement, peritoneal tuberculosis occurs frequently.

Lower abdominal pain and amenorrhea usually prompt the patient to seek medical care. A lower abdominal mass, free peritoneal fluid, and constitutional symptoms may or may not be present. Chemotherapy is effective, but infertility remains a potential sequela of the disease.

Tuberculosis of the external genitalia has been seen as a manifestation of child abuse.

Genital tuberculosis can occur in males as primary tuberculosis of the penis after ritual circumcision; many such instances were reported in the past.[228] Massive inguinal lymphadenopathy in a circumcised infant should arouse suspicion of a possible tuberculous etiology. Epididymitis or epididymo-orchitis can occur in early childhood.[196] These disorders are characterized by nodular, painless swelling of the scrotum and a dragging pain in the groin and have a gradual onset rather than the acute onset that results after trauma, torsion of the testis, mumps orchitis, or epididymitis associated with bacterial infection.

Inoculation Tuberculosis

More than 200 cases of syringe-transmitted tuberculosis have been described in the world literature.[223] It has become more common since the widespread use of injectable penicillin and routine childhood immunization and usually has been a result of contamination of the syringe or the solution by an individual with infectious sputum. If the recipient has not been infected previously, the lesion in the muscle or subcutaneous tissue will be the primary focus, and the regional lymph nodes will enlarge, caseate, and, under favorable circumstances, calcify. However, at least 10 infants thus infected have died as a result of generalized tuberculosis, and in others, bone tuberculosis has developed. If the recipient already is tuberculin positive, a tuberculous abscess will form without regional lymphadenitis. In this case, an injection abscess must be differentiated from a deep tuberculous abscess arising in the stage of hematogenous dissemination.

Perinatal Tuberculosis (Congenital and Postnatal)

Transmission of *M. tuberculosis* from mother to infant through the placenta or amniotic fluid has been reported in approximately 300 patients.[73] Infection of the placenta has been demonstrated, and tubercle bacilli have been grown from the tissues of stillborn infants and from living infants within a few days of birth. Perinatal tuberculosis can be acquired by the infant through one of several routes:

1. By transplacental spread through the umbilical vein from a mother with primary hematogenous tuberculosis occurring during pregnancy (i.e., true congenital tuberculosis). The liver is enlarged, enlarged lymph nodes may be present at the porta hepatis, and evidence of widespread miliary disease may be seen in the infant (i.e., the infant may have a primary liver complex or primary lung complexes).
2. By in utero aspiration of amniotic fluid infected from endometritis in the mother or from the placenta. This route of infection also constitutes true congenital tuberculosis. In both these situations, clinical onset of signs and symptoms is likely to be rapid (by 2 to 3 weeks of age) and to include failure to thrive, fever, respiratory distress, and hepatosplenomegaly.
3. By ingestion of infected amniotic fluid or secretions during delivery. This mechanism would seem to be less well documented than the first two routes, but it certainly is a possibility.
4. By inhalation of tubercle bacilli at or soon after birth from the mother, other relatives, or attendants with infectious pulmonary tuberculosis. This route is the most common mode of transmission to newborns.
5. By ingestion of infected breast milk or cow's milk.

One cannot always be sure of the type of infection in a particular neonate; only clear-cut evidence of a primary complex in the liver establishes a definite diagnosis of congenital tuberculosis. However, the presence of early forms of tuberculosis (such as pleural, miliary, or meningeal) in the mother during pregnancy or the puerperium also is strong evidence of true congenital tuberculosis in the infant.

Routes 4 and 5 are really "postnatally" acquired tuberculosis and need, for epidemiologic purposes, to be distinguished from routes 1, 2, and 3. Neonates with these types of tuberculosis usually lack striking clinical features until they are 1 or 2 months of age.

The diagnosis of perinatal tuberculosis is likely to be difficult to establish and often delayed.[318] Disease in the mother often is overlooked; the mother may have pleural effusion, fever of unknown origin, cough, endometritis, and other symptoms without the tuberculous etiology being recognized. The early symptoms and signs in the neonate likewise are overlooked frequently and may be similar to those caused by other congenital infections. Once the diagnosis is suspected, treatment should be started immediately, and diagnostic procedures should be carried out rapidly and aggressively.

The clinical manifestations vary, probably depending on the size of the infecting dose of bacilli and the site and size of the caseous lesions.[368,409] In many of the reported cases, tuberculosis disease was discovered only at autopsy.[241] Symptoms usually appeared during the second week of life and included loss of appetite and failure to gain weight, fever, nasal or ear discharge, cough, bronchopneumonia, jaundice, hepatomegaly, and spleno-

megaly occurring later.[73] Wasting has been noted frequently and, in one case, clearly was shown to be caused by hypoadrenocorticism.[392]

Because the result of the tuberculin skin test very rarely is positive in infants, demonstration of tubercle bacilli in gastric washings, middle ear fluid, lymph node biopsy specimens, skin biopsy specimens, bone marrow aspirate, endotracheal aspirate, or lung biopsy specimens is essential.[205] Examination of the placenta for organisms or characteristic histopathologic changes can be extremely helpful and should be done when tuberculosis is diagnosed in the mother around the time of delivery. Successful treatment of congenital tuberculosis has been reported by several investigators, although clinical response may be very slow, and extensive calcification of the lungs, liver, spleen, and muscles may result.[281,284,409,538,552]

Tuberculosis in Adolescents

Tuberculosis in adolescents has become relatively more important as the incidence of infection in childhood has lessened.[134,357,408,536] Logically, it should be considered in two ways: first, tuberculosis acquired as an initial infection during the adolescent years and, second, tuberculosis infection acquired in early life and reactivated during adolescence.[353,411] In actual practice, separating the two often is difficult or impossible, and most clinical reports and studies do not.

Tuberculosis in adolescents may occur exactly as it does in young children, or a classic primary complex may progress rapidly to chronic pulmonary tuberculosis while the hilar lymph node involvement characteristic of childhood tuberculosis remains present. The Medical Research Council in 1963 published a report of 504 cases of tuberculosis in adolescents, including 316 cases of pulmonary tuberculosis, 44 cases of pleural effusion, 44 with hilar lymph node enlargement, 6 cases of miliary and 5 of meningeal tuberculosis, 13 with bone and joint disease, and 8 with genitourinary tuberculosis. In a series of cases of primary tuberculosis in adults, Stead[565] included 11 adolescents, 5 with simple primary tuberculosis, 5 with pleurisy and effusion, and 1 with progressive pulmonary tuberculosis.

From the extensive clinical experience of Lincoln and Sewell[331] and others, several observations emerge. Tuberculosis infection in early infancy rarely leads to pulmonary tuberculosis in adolescence, perhaps because it has several years in which to heal, whereas tuberculosis infection acquired after 7 years of age and, in particular, acquired after 10 years of age is likely to progress. When *M. tuberculosis* is acquired during adolescence, chronic pulmonary tuberculosis may develop within 1 to 3 years. Moreover, the risk of acquiring pulmonary tuberculosis is two to six times greater for adolescent girls than for adolescent boys. In both sexes, the adolescent growth spurt is the time of greatest risk. The work of Johnston[268] suggests that the depressant effect of puberty on calcium and nitrogen retention, at least in girls, may be correlated with the failure of tuberculosis infection to heal.

Tuberculosis and Pregnancy

In the era before chemotherapy, whether pregnancy and tuberculosis affected each other adversely was an ongoing controversy. Since the advent of chemotherapy, however, the prognosis has improved greatly.[177] The main problems now are serious unrecognized tuberculosis in a pregnant woman, sometimes with a fatal outcome, and serious unrecognized disease in her infant. Another problem is whether pregnancy influences the risk of progression of tuberculosis infection to disease; the data are conflicting in this regard. Tuberculin skin testing probably is valid during pregnancy; chest radiographs (with shielding) should be obtained for all tuberculin-positive pregnant patients. Therapy, when indicated, can safely include isoniazid (which crosses the placenta but apparently without ill effects), rifampin, and ethambutol. The safety of pyrazinamide in pregnancy has not been established, but a growing number of experts recommend it because anecdotal data have not shown it to be harmful to the mother or fetus. Streptomycin, because of fetal ototoxicity, is not recommended.[544] However, one study of seven pregnant women with multidrug-resistant tuberculosis showed no adverse effects on their newborns when mothers were treated with second-line drugs, including aminoglycosides.[150,521] Should a mother receiving antituberculosis therapy breast-feed?[545] It is probably safe for her to do so because the drugs, although found in milk, are present only in small amounts.

Tuberculosis and Human Immunodeficiency Virus Infection

In adults infected with both HIV and *M. tuberculosis*, the rate of progression from asymptomatic infection to disease is increased greatly.[491] The clinical manifestations of tuberculosis in HIV-infected adults are typical when the $CD4^+$ cell count is higher than 500/mm^3. As the $CD4^+$ cell count falls, manifestations become "atypical." Extrapulmonary foci occur in as many as 60 percent of profoundly immunocompromised patients.[27] Pulmonary cavities are rare findings; lower lobe infiltrates or nodules often accompanied by thoracic adenopathy are common occurrences, especially if the patient's tuberculosis infection is recent. Of course, many patients have a nonreactive tuberculin skin test. Sputum is less likely to be produced or to contain visible acid-fast organisms on stained smears; more invasive procedures, such as bronchoscopy, often are required to isolate *M. tuberculosis* and to rule out other causes of opportunistic lung disease.[361] Malabsorption of antituberculosis drugs in HIV-infected patients can lead to prolonged symptoms and disease.[446]

When tuberculosis develops in HIV-infected children, the clinical features tend to be fairly typical of childhood tuberculosis in immunocompetent children, although the disease often progresses more rapidly and the clinical manifestations are more severe.[53,97,105,164,289,395,434,598] Many children have sizeable pulmonary radiographic findings with minimal respiratory signs or symptoms. An increased tendency for extrapulmonary disease may be noted. Recurrent disease occurs more frequently in HIV-infected children.[497] Establishing the diagnosis can be very difficult; a diligent search for an infectious adult in the child's environment may yield the best clues to the correct diagnosis.[293] The prognosis generally is good if tuberculosis disease is not far advanced when the patient is diagnosed and appropriate antituberculosis drugs are available.[218]

The introduction of highly active antiretroviral therapy (HAART) into regions where tuberculosis is prevalent has had a profound effect on the epidemiology and clinical expression of both diseases. During the initial months of HAART, immune reconstitution can be complicated by adverse clinical phenomena in which either previously subclinical infections are "unmasked" or preexisting, partly treated opportunistic infections clinically deteriorate. These phenomena are referred to as the immune reconstitution inflammatory syndrome (IRIS).[555] Sometimes it is difficult to tell if a deterioration in the clinical course of a patient with an opportunistic infection who is started on HAART is due to IRIS, poor compliance with treatment for the opportunistic infection, or drug resistance.[314-316] Factors to be considered that suggest IRIS are temporal association (within 3 months of starting HAART), unusual clinical manifestations, unexpected clinical course, exclusion of alternative explanations, evidence of preceding immune restoration (rise in CD4 lymphocyte count), and fall in HIV viral load. In adults, the risk of developing IRIS in patients with tuberculosis who are started on HAART is greatest if they have extrapulmonary tuberculosis, high initial HIV viral loads

and low CD4 lymphocyte counts, and rapid response to HAART.[54] Published reports of IRIS in children have been rare,[274,403,456,649] although anecdotal evidence from pediatric acquired immune deficiency clinics in Africa suggest it is becoming common as HAART is introduced to more children with HIV infection. IRIS in children has been associated with nontuberculous mycobacteria[456] and previous BCG vaccination.[299,455,523] The finding that IRIS occurs in children with tuberculosis and HIV infection who receive HAART is not surprising. For decades, so-called paradoxical reactions have been described in HIV-uninfected children with tuberculosis after antituberculosis therapy is started. The most common manifestations are fever, enlarging lymph nodes in the thorax or neck, and appearance or enlargement of tuberculomas in the brain, with or without accompanying meningitis.

The best management of IRIS is unknown. As with paradoxical reactions that cause tissue damage or obstruction, corticosteroids may be beneficial to "quiet" the local immune response, although no randomized clinical trials have been reported. The high frequency of IRIS associated with tuberculosis has led some experts to recommend delay of HAART until appropriate (for drug susceptibility pattern) antituberculosis chemotherapy has been given for at least 2 months.[324] No consensus on this approach has been reached, however, and data from children may indicate that they are more likely to die of complications of HIV than of tuberculosis when they are dually infected.[218]

DIAGNOSIS

HOW CHILDREN WITH TUBERCULOSIS ARE DISCOVERED

In the developing world, the only way that children with tuberculosis disease are discovered is passively, when they have a profound illness that is consistent with one manifestation of tuberculosis. Having an ill adult contact is an obvious clue to establishment of the correct diagnosis. The only available laboratory test usually is an acid-fast smear of sputum, which the child rarely produces. In many regions, chest radiography is not available. To aid in establishing the diagnosis, a variety of scoring systems based on available tests, clinical signs and symptoms, and known exposures have been devised.[379,638] However, no single clinical scoring system has been validated, and the sensitivity and specificity of these systems can be very low and lead to both overdiagnosis and underdiagnosis of tuberculosis.[288,379]

In industrial countries, children with tuberculosis usually are discovered in one of two ways.[148,291,492] Obviously, one way is to consider tuberculosis as the cause of a symptomatic illness.[485] Discovering an adult contact with infectious tuberculosis is an invaluable aid to establishing the diagnosis; the "yield" from a contact investigation usually is higher than that from cultures from the child.[56] Culture from the infectious adult case may yield the only drug susceptibility results for the child because cultures from children with tuberculosis frequently are negative. The second way is to discover a child with pulmonary tuberculosis during the contact investigation of an adult with tuberculosis.[362,388,547,576,579] Typically, the affected child has few or no symptoms, but investigation reveals a positive tuberculin skin test result and an abnormal chest radiograph. In some areas of the United States, as many as 50 percent of children with pulmonary tuberculosis are discovered in this manner, before significant symptoms have begun. The recent use of molecular epidemiology techniques has shown, however, occasional discordance between the isolate from the child and that from the presumed source, meaning that the real source of transmission to the child is undiscovered.[642,648] It is less common to find tuberculosis disease in a U.S.-born child as the result of a community-or school-based tuberculin skin testing program, although foreign-born children with tuberculosis may be found in this manner.[149,444]

TUBERCULIN SENSITIVITY AND THE SKIN TEST

Sensitization to tuberculin is induced by infection with living tubercle bacilli. Specific tuberculin sensitivity to either *M. tuberculosis* or other mycobacteria can be transferred in humans by injection of lymphocytes from sensitized donors and also by injection of certain purified mycobacterial protein antigens.

The time of appearance of sensitivity in animals after infection has occurred with tubercle bacilli depends on the number of tubercle bacilli in the infective dose and on the virulence (i.e., the rate of multiplication of the organisms), and such is also likely to be the case in humans.[28] For all practical purposes in humans, tuberculin reactivity seems to appear in 3 to 6 weeks, rarely a few days earlier, and occasionally as long as 3 months after initial infection.

The tuberculin sensitivity reaction has been studied best in the skin, although it can be elicited in any tissue of a sensitive subject (conjunctiva, lung, meninges, kidney, and so on) after tuberculoprotein has been injected. At first, an inflammatory reaction appears at the site of injection, with predominance of segmented neutrophils, followed by immigration of macrophages and T lymphocytes, until the entire area of induration consists of mononuclear cells.

The size of the induration depends on the amount of tuberculoprotein injected and the availability of sensitized T lymphocytes in sufficient number. Multiple tuberculin skin tests given simultaneously result in smaller individual reactions, probably because of a finite number of sensitized cells in the body. Corticosteroids,[55,346,499] adrenocorticotropic hormone, nitrogen mustard, irradiation, and viral infections such as measles, influenza, and mumps diminish tuberculin reactivity, perhaps simply by inducing lymphopenia.[561] The size of the induration seems to depend on at least two additional factors: the local behavior of the skin (the disappearance time for wheals of normal saline solution, the so-called Aldrich-McClure test, is accelerated during fever, pregnancy, cachexia, and extreme malnutrition) and the number of actively multiplying tubercle bacilli in the body, which can be demonstrated in animals and probably in humans as well. That still other factors must be involved is clear because 10 to 20 percent of immunocompetent patients with proven tuberculosis are tuberculin-negative during initial disease, with tuberculin sensitivity often regained during treatment.[450] Decreased T-lymphocyte blastogenesis has been demonstrated in some cases, and inhibition by B lymphocytes may play a role.

Temporary desensitization to tuberculin occurs most strikingly during measles and has been studied carefully. Full reactivity diminished during the incubation period and returned within approximately 1 month after appearance of the exanthem.[215] Influenza and administration of influenza and measles vaccines tend to depress sensitivity but rarely suppress it entirely.[64,657] Whether other viral diseases and vaccines regularly are less active in this regard and what the important factors may be are not known.[39] If a temporary desensitizing effect occurs in bacterial infections such as scarlet fever, it probably depends on factors such as hyperthermia and dehydration.

Sensitization to tuberculin as a result of infection with *M. tuberculosis* tends to persist undiminished for life.[161,207,235] The likelihood of disappearance of tuberculin sensitivity seems to be greater when the lesion is negligible. That low degrees of sensitivity to *M. tuberculosis* are induced by mycobacteria other than *M. tuberculosis* also is clear. Previous receipt of BCG vaccine can cause increased reactivity to tuberculin, but the association is weaker than many clinicians suspect.[9,78,339,396,510] Less than 50 percent of infants given BCG vaccination have a reactive tuberculin skin test at 9 to 12 months of age, and the great majority will have a nonreactive skin test by the time they are 5 years of age. Older children and adults who receive BCG vaccination have a reactive skin test and keep it longer, but by 10 to 15 years after

vaccination, most individuals have lost tuberculin skin test reactivity.[114,378] Repeated administration of BCG vaccine can maintain tuberculin reactivity.[249] Repeated tuberculin skin tests in a person sensitized previously by BCG vaccination, infection with *M. tuberculosis*, or probably infection by an environmental mycobacterium may increase the reaction to subsequent tuberculin skin tests (called the booster phenomenon).[41,182,309,599]

The antigens currently used in tuberculin testing are crude extracts consisting of a mixture of many antigens, some species-specific, some shared among many species. Standardized, isolated, purified mycobacterial antigens are needed in clinical practice. The major antigen used in tuberculin testing is PPD, obtained from filtrates of heat-killed tubercle bacilli. Batch 49608, prepared by Dr. Florence Seibert in 1939, was designated by the WHO as the international standard tuberculin, the only one to be called PPD-S. All other PPD preparations are referred to simply as PPD or as PPD-T. However, each batch now must be stabilized with Tween 80 at 5 ppm to minimize adherence to glass and plastic and must be identified by manufacturer and lot number.

A tuberculin unit is the activity contained in a specified weight of PPD-S. The standard test dose, 5 tuberculin units, refers to the equivalence in biologic activity, determined in the guinea pig, of a commercial PPD preparation with that contained in 5 tuberculin units of PPD-S. Products labeled 1 tuberculin unit and 250 tuberculin units are calculated dilutions based on 5 tuberculin units. However, the potency of PPD doses varies from batch to batch.

The Mantoux test is the reference test. A graduated syringe and a 26- or 27-gauge needle are used to inject 0.1 mL of PPD into the most superficial layer of the epidermis of the forearm, which raises an immediate wheal (Fig. 107–14). Under optimal circumstances, the needle should not be withdrawn for a few seconds to minimize leakage. The reference test uses a dose of 5 tuberculin units. One tuberculin unit very rarely should be used, for example, if extreme hypersensitivity is suspected, as when a tuberculous eye lesion or erythema nodosum is present. The reading should be made at 48 to 72 hours, with the forearm slightly flexed. Any induration (not erythema) should be measured, preferably with calipers, and the diameter at right angles to the axis of administration recorded in millimeters. Use of the words "negative" and "positive" should be avoided because interpretation can change as more epidemiologic information becomes known. The previous widespread use of multiple-puncture tests led to the practice of allowing parents to interpret the results and to report them to the clinician. This practice assumes parental knowledge of and adherence to a broad range of motivational behavior and skills. No study has demonstrated that parents can read positive skin test results accurately, but that they may not correctly interpret or report positive results has been well documented.[101,102,199,233] Two studies have demonstrated that pediatric care providers tend to under-read Mantoux tuberculin skin tests.[77,285]

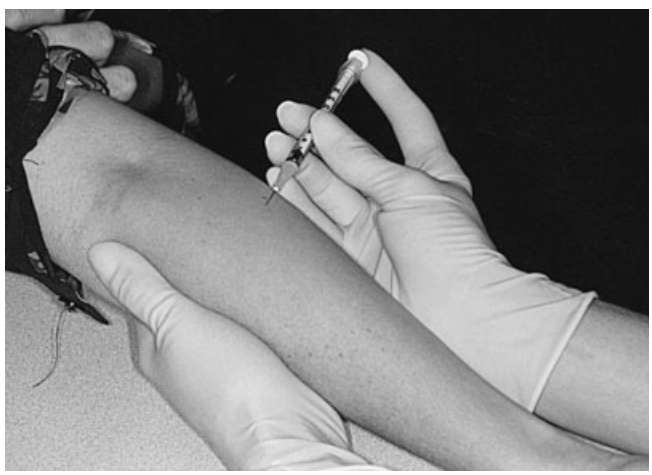

Figure 107–14 A useful technique for performing a Mantoux tuberculin skin test on a child. The needle is applied perpendicular to the long axis of the arm to attain better control.

Several studies have shown great variability in readings of Mantoux tests.[33] Such variability can be minimized only by ongoing training of both testers and readers and by concentrating the responsibility of testing and reading to a small number of trained individuals.

The importance of the tuberculin test cannot be overemphasized as the main criterion for diagnosis of tuberculosis infection in an individual child. Only rarely is the tuberculin test response negative in an infected child, usually as a result of anergy from overwhelming infection, from viral infection, from HIV infection, from the use of immunosuppressive drugs, or because of factors not yet understood.[571] Anergy in tuberculosis can be selective for tuberculin; results of "control" skin tests may be positive but the Mantoux test result negative in a child with tuberculosis disease.[563]

The Mantoux test has a sensitivity and specificity of only approximately 95 percent.[239] When a test with these characteristics is applied to a population with a 90 percent prevalence of tuberculosis infection, the positive predictive value of the skin test is 99 percent, an excellent result. However, if the same test is applied to a population with only a 1 percent prevalence of infection, the positive predictive value drops to 15 percent; 85 percent of the "positive" results are false-positives created by biologic variability, nonspecific reactions, and infection with environmental mycobacteria. These false-positive results lead to unnecessary treatment, cost, and anxiety for the patient, family, and clinician. In short, the low sensitivity and specificity of the tuberculin skin test render the test undesirable for use in persons from low-prevalence groups. The trend in the United States is to reduce or to eliminate routine testing of low-risk children but to target children with specific risk factors for one-time or periodic tuberculosis skin testing.[10,90,389]

Several recently published studies have shown that a questionnaire can be used in the United States to identify children with significant risk factors for tuberculosis infection, who then can receive a tuberculin skin test.[183,337,430,483] Factors that consistently correlate with having a positive tuberculin skin test result include contact with a case of tuberculosis, other family members with a positive tuberculin skin test result, and foreign birth in or extensive travel to a high-prevalence country.[502]

The CDC and the American Academy of Pediatrics (AAP) have recommended varying the size of induration considered positive in various groups, according to their risk factors (Table 107–7), in an attempt to minimize the incidence of false-negative results in children most likely to have rapid progression of asymptomatic tuberculosis infection to disease and the false-positive results in persons with no known risk factors for tuberculosis. In general in the United States, previous receipt of BCG vaccine should not influence interpretation of the initial tuberculin skin test of a child.[267]

INTERFERON RELEASE ASSAYS

Advances in molecular biology and genomics have led to use of alternatives to the tuberculin skin test.[432,472,554] Two new in vitro formats have been developed that measure interferon-γ release by sensitized lymphocytes after stimulation by *M. tuberculosis*

TABLE 107–7 Amount of Induration in Reaction to a Mantoux Tuberculin Skin Test Considered Positive (Indicating Probable Infection with *Mycobacterium tuberculosis*)

Reaction Size	Risk Factors
≥5 mm	Contact with infectious cases
	Abnormal chest radiograph
	HIV infection or other immunocompromise
≥10 mm	Birth or previous residence in a high-prevalence country
	Residence in long-term care or corrections facility
	Certain medical risk factors: diabetes mellitus, silicosis, renal disease
	Occupation in health care field, exposure to patients with tuberculosis
	Member of a local high-risk group
	Close contact with a high-risk adult (except health care workers)
	Age <4 years
≥15 mm	No risk factors

antigens. Both formats use two proteins—early secreted antigen target 6 and culture filtrate protein—that are found on *M. tuberculosis* and only a few fairly rare species of nontuberculous mycobacteria but not on the bacilli BCG or the *Mycobacterium avium* complex. The first test licensed in the United States was QuantiFERON-TB (Cellestis, Carnegie, Australia). The test measures whole-blood interferon production.

The second format licensed in the United States is the enzyme-linked immunospot (ELISPOT, T-SPOT.TB; Oxford Immunotec, Oxford, UK). This technique measures the number of mononuclear cells that produce interferon.

Both formats of interferon release assays have been studied primarily in adults.[432,472] In many clinical situations, these tests have a higher specificity than that of the tuberculin skin test, better correlation with surrogate measures of recent exposure to *M. tuberculosis* in low-incidence settings, and less cross-reactivity than does the tuberculin skin test because of previous BCG vaccination. Like the tuberculin skin test, interferon release assays cannot differentiate between tuberculosis infection and disease. Two clear advantages of the interferon release assays are the need for only one patient encounter (versus two with the tuberculin skin test) and the lack of possible boosting of the result, as the patient is not exposed to any biologic material.

Studies of interferon release assays in children are fewer for both ELISPOT[221,222,548] and QuantiFERON-TB.[22,117,173,606] Studies of child household contacts of adults with pulmonary tuberculosis have shown that children who previously received a BCG vaccination were more likely to have a positive tuberculin skin test result but a negative ELISPOT result.[173] A study from the Gambia showed an 83 percent agreement between tuberculin skin test and ELISPOT results in child household contacts, with a nonsignificant trend toward the ELISPOT being less sensitive than the tuberculin skin test.[25] In this study, previous BCG vaccination did not significantly affect the results of either test.

Although interferon release assays are becoming widely used[433] and are recommended by the CDC,[83] studies in adults have questioned their sensitivity even in patients with tuberculosis disease. At present, although the interferon release assays show great promise for improving the diagnosis of tuberculosis infection, too little is known about their characteristics in young children and immunocompromised hosts for their routine use to be recommended in these groups.

DIAGNOSTIC MYCOBACTERIOLOGY IN CHILDREN[487]

The demonstration of acid-fast bacilli in stained smears of sputum is presumptive evidence of pulmonary tuberculosis in most patients. However, in children, tubercle bacilli usually are relatively few in number. Gastric washings, which often are used in lieu of sputum, can be contaminated with acid-fast organisms from the mouth. However, fluorescence microscopy of gastric washings has been found to be useful, particularly in a setting where malnutrition and tuberculin-negative tuberculosis are rampant.[313] Tubercle bacilli in cerebrospinal fluid, pleural fluid, lymph node aspirate, and urine are sparse; thus, only rarely are direct-stained smears for tubercle bacilli of any use in pediatric practice.[573] Cultures for tubercle bacilli are of great importance, not only to confirm the diagnosis but increasingly to permit testing for drug susceptibility. If culture and drug susceptibility data are available from the associated adult case and the child has classic features of tuberculosis (positive skin test result, consistent abnormal chest radiograph), obtaining cultures from the child adds little to management.

Painstaking collection of specimens is essential for diagnosis of children because fewer organisms usually are present than in adults.[522] Gastric lavage should be performed in the very early morning, when the patient has had nothing to eat or drink for 8 hours and before the patient has a chance to wake up and start swallowing saliva, which could dilute the bronchial secretions that were brought up during the night and made their way into the stomach. The stomach contents should be aspirated first. Then, no more than 50 to 75 mL of sterile distilled water (not saline) should be injected through the stomach tube and the aspirate added to the first collection. The gastric acidity (poorly tolerated by tubercle bacilli) should be neutralized immediately. Concentration and culture should be performed as soon as possible after collection. However, even with optimal, in-hospital collection of three early-morning gastric aspirate samples, *M. tuberculosis* can be isolated from only 30 to 40 percent of children and 70 percent of infants with pulmonary tuberculosis.[69,563,613]

Bronchial secretions (sputum) produced by stimulation of a cough with an aerosol solution can be obtained commonly from older children.[76] The aerosol is heated in a nebulizer at 46° C to 52° C (114.8° F to 125.6° F) and administered to the patient for 15 to 30 minutes. This method gives good results and may be superior to gastric lavage both in yield of positive cultures and in acceptance by the patient.[76,517] Recent improvements in technique have led to improved induction of sputum in even young children, with culture yields as high as from inpatient gastric aspirates.[252,650] Nasopharyngeal aspiration also has been used.[429] The bronchial aspirate obtained at bronchoscopy often is thick, and the laboratory will process it with a mucolytic agent such as *N*-acetyl-L-cysteine. In most studies, the yield of *M. tuberculosis* from bronchoscopy specimens has been lower than from properly obtained gastric aspirates.[1,96]

Cerebrospinal fluid, pleural fluid, and synovial fluid (as much fluid as possible should be collected) usually are centrifuged, and the sediment is used for stained smear and culture. An overnight urine specimen should be obtained in the early morning and taken immediately to the laboratory for processing because the organisms tolerate the low pH of urine poorly. Lymph node aspirates and bits of biopsy tissue can be inoculated directly into a fluid medium such as Middlebrook 7H9.

Staining and examination of smears as well as inoculation of special media, incubation in a carbon dioxide environment, strain differentiation based on many cultural characteristics, and drug susceptibility testing require equipment, skills, and experience beyond those available in the usual clinic or hospital laboratory.[217] Thus, most laboratories depend on regional or reference laboratories for procedures beyond their scope.

Despite an enormous amount of research and thousands of publications on the subject, the only definite way to diagnose active tuberculosis is to demonstrate tubercle bacilli in tissues or secretions. No single species–specific antigen of *M. tuberculosis* ever has been identified. The search for quick, simple, inexpensive, specific, sensitive immunologic and chemical detection techniques is ongoing.

NUCLEIC ACID AMPLIFICATION

The main form of nucleic acid amplification studied in children with tuberculosis is polymerase chain reaction (PCR), which uses specific DNA sequences as markers for microorganisms.[163,352,390] Various PCR techniques, most using the mycobacterial insertion element IS6110 as the DNA marker for *M. tuberculosis* complex organisms,[11,81] have a sensitivity and specificity of more than 90 percent in comparison to sputum culture for detecting pulmonary tuberculosis in adults. However, test performance varies even among reference laboratories.[417,501] The test is relatively expensive, calls for fairly sophisticated equipment, and requires scrupulous technique to avoid cross-contamination of specimens. In the United States, it is approved for use only on acid-fast stain–positive specimens.

Evaluation of PCR in childhood tuberculosis has been limited. Compared with a clinical diagnosis of pulmonary tuberculosis in children, the sensitivity of PCR has varied from 25 to 83 percent, and specificity has varied from 80 to 100 percent.[133,390,440,451,533] PCR of gastric aspirates may be positive in a recently infected child even when the chest radiograph is normal, thus demonstrating the occasional arbitrariness of the distinction between tuberculosis infection and disease in children. PCR may have a useful but limited role in evaluating children for tuberculosis. A negative PCR analysis never eliminates tuberculosis as a diagnostic possibility, and a positive result does not confirm it. The major use of PCR will be in evaluating children with significant pulmonary disease when the diagnosis is not established readily by clinical or epidemiologic grounds. PCR may be particularly helpful in evaluating immunocompromised children with pulmonary disease, especially those with HIV infection, although published reports of its performance in such children are lacking. PCR also may aid in confirming the diagnosis of extrapulmonary tuberculosis, but only a few reports have been published.[194,351,383]

SEROLOGY AND ANTIGEN DETECTION

Despite hundreds of studies published during the past century, serology has found little place in the routine diagnosis of tuberculosis in adults or children.[125] Some studies have used enzyme-linked immunosorbent assay to detect antibodies to whole bacterial cells or to various purified or complex antigens of *M. tuberculosis* in children.[125,271,272] In general, both the sensitivity and specificity of the various tests have been unacceptably low.[42,245] Tests using the mycobacterial antigen A60 have shown both good and poor results in children.[131] No available serodiagnostic test for tuberculosis is adequate under various clinical conditions to be useful for children.

Detection of mycobacterial antigen has been evaluated in clinical samples from adults but rarely from children.[481] Most of these techniques require technically advanced equipment (such as high-pressure liquid chromatography apparatus) and expertise that are not available where tuberculosis in children is common.

TREATMENT

MANAGEMENT OF TUBERCULOUS CHILDREN

Treatment of cavitary tuberculosis in adults is one of the most scientifically accurate areas in all of medicine and one of the finest examples of international professional cooperation in all of history. Because tubercle bacilli in adult patients with tuberculosis can be seen and cultured, their numbers quantified, and the size of the cavities that they produce measured and because so many cases of tuberculosis exist in the world, researchers have been able to ask precise questions about treatment and to design prospective cooperative studies that yield accurate answers about the effect of individual drugs, multiple drug regimens, drug dosage, duration of chemotherapy, rest, and surgical procedures on the course of the disease. Although chemotherapy, without doubt, has been extremely effective in treating childhood tuberculosis, recommendations for treatment historically have been based to a great extent on analogy with adults, on "custom," and on "experience" because in children the tubercle bacilli are fewer in number and not readily accessible and the lesions are not as easy to evaluate as are cavities. However, during the past 3 decades, a large number of treatment trials for children have been reported, which has led to dramatic changes in the therapeutic approach to childhood tuberculosis.

As recently as the early 1980s, the recommended treatment duration for children with tuberculosis disease was 12 to 18 months. Although these regimens are effective when they are used properly, actual failure rates are high because of poor adherence during the long period of treatment. Newer regimens often are called short-course chemotherapy because treatment durations as short as 6 months are routinely successful. However, the key to the new approach is not the short duration but the intensive initial therapy with three or more antituberculosis drugs.

Antituberculosis Drugs (Tables 107–8 and 107–9)

Isoniazid (INH) is the mainstay of therapy for tuberculosis in children. Inexpensive, highly effective in preventing the multiplication of tubercle bacilli, of low molecular weight and therefore readily diffusible to all tissues in the body,[141] and relatively nontoxic to children, INH is one of the most nearly perfect drugs in the pediatrician's armamentarium. It can be administered orally, intramuscularly, or intravenously. When INH is taken orally, high plasma, sputum, and spinal fluid levels are reached within a few hours and persist for at least 6 to 8 hours.[310,425] Because of the slow multiplication of *M. tuberculosis*, the total daily dose can be given at one time. The usual level necessary to inhibit multiplication of tubercle bacilli is 0.02 to 0.05 μg/mL.

Human variation in the acetylation rate of INH to an inactive compound is known to be determined genetically.[365] Rapid acetylation occurs more frequently in black people and Asians than in whites. Although a simple method, specifically the use of a urine sample, now is available for classifying patients as slow or rapid inactivators of INH, the normal way of coping with the problem in children has been to give a sufficiently large dose of INH to ensure an adequate level even in rapid inactivators.[364,623]

The principal toxic effects of INH are peripheral neuritis and hepatitis. Peripheral neuritis resulting from competitive inhibition of pyridoxine utilization is a rare event in North American children because both milk and meat are the main dietary sources of pyridoxine.[48] In some well-nourished children, serum pyridoxine concentrations are depressed by INH, but clinical signs are not apparent.[445] In the case of most children, therefore, the use of supplementary pyridoxine is not necessary. However, in teenagers whose diets may be inadequate, in children from ethnic groups with low milk and meat intake, and in breast-fed babies,

TABLE 107–8 Commonly Used Drugs for the Treatment of Tuberculosis in Children

Drug	Dosage Forms	Daily Dose (mg/kg/day)	Twice-Weekly Dose (mg/kg/dose)	Maximal Daily Dose
Ethambutol	Tablets 100 mg 400 mg	20-25	50	2.5 g
Isoniazid*†	Scored tablets 100 mg 300 mg Syrup‡ 10 mg/mL	10-15†	20-30	Daily: 300 mg Twice weekly: 900 mg
Pyrazinamide	Scored tablets 500 mg	20-40	50	2 g
Rifampin*	Capsules 150 mg 300 mg Syrup Formulated in syrup from capsules	10-20	10-20	Daily: 600 mg Twice weekly: 900 mg
Streptomycin (IM administration)	Vials 1 g 4 g	20-40	20-40	

**Rifamate is a capsule containing 150 mg of isoniazid and 300 mg of rifampin. Two capsules provide the usual adult (>50 kg body weight) daily doses of each drug.*
†When isoniazid is used in combination with rifampin, the incidence of hepatotoxicity increases if the isoniazid dose exceeds 10 mg/kg/day.
‡Most experts advise against the use of isoniazid syrup because of instability and a high rate of gastrointestinal adverse reaction (diarrhea, cramps).

TABLE 107–9 Drugs for Treatment of Drug-Resistant Tuberculosis in Children

Drugs	Dosage Forms	Daily Dosage (mg/kg/day)	Maximum Daily Dose
Capreomycin	Vials: 1 g	15-30 (IM)	1 g
Ciprofloxacin	Tablets 250 mg 500 mg 750 mg	Adults: 500-1500 mg in 2 divided doses	1.5 g
Clofazimine	Capsules 50 mg 100 mg	50-100 mg/day	200 mg
Cycloserine	Capsules 250 mg	10-20	1 g
Ethionamide	Tablets 250 mg	15-20 given in 2 or 3 divided doses	1 g
Kanamycin	Vials 75 mg/2 mL 500 mg/2 mL 1 g/3 mL	15-30 (IM)	1 g
Levofloxacin	Tablets 250 mg 500 mg 750 mg	Adults: 500-750 mg total/day	750 mg
p-Aminosalicylic acid	Packets: 4 g	200-300 given in 2 to 4 divided doses	12 g

pyridoxine supplementation (25 to 50 mg/day) is important. Peripheral neuritis, when it does occur, usually is manifested by "pins and needles" sensations in the hands and feet.

The risk for development of hepatotoxicity from INH, rare in children, increases in frequency with age.[34,80,298,333,402,422,459,551,566] Its cause is unclear.[300] Rapid acetylators are no more susceptible than are slow acetylators.[165,364] Simultaneous use of alcohol, phenytoin, piperazine, and especially rifampin (RIF) seems to increase the likelihood of hepatotoxicity.[80,304] Monitoring of aspartate aminotransferase and alanine aminotransferase activity sometimes reveals transient increases during treatment with INH, but the levels usually return spontaneously to normal without interruption of treatment. Liver enzyme abnormalities in adolescents receiving INH are common occurrences and usually disappear spontaneously, but severe hepatitis can occur.[184,334,436,539,617]

The possible occurrence of hepatitis raises the question of routine monitoring of liver enzyme levels once a month in all children receiving INH. The advantage of doing so has to be weighed not only against the expense but particularly against the difficulty of ensuring regular monthly visits if the patient and parents know that every clinic visit entails a venipuncture. Most experts prefer to substitute routine questions about appetite and well-being, determination of weight, and a check of the appearance of the sclera and the size of the liver.[70,444] Patients should be counseled to stop taking INH and to contact the clinician immediately if significant nausea, vomiting, abdominal pain, or jaundice occurs during the use of INH.

Allergic manifestations of INH hypersensitivity are extraordinarily rare. Convulsions have been reported after doses of 100 mg/kg or more, as in suicide attempts.[369,415,437,513]

The usual dosage in children is 10 to 20 mg/kg/day, to a maximum of 300 mg/day. INH is available in tablets of 100 and 300 mg. The original liquid preparation of INH in syrup was abandoned when investigators found that the drug was unstable in sucrose. A syrup of INH in sorbitol (10 mg/mL) is now on the market and appears to be satisfactory; however, it is unstable at 37° C (98.6° F) and should be kept cool. Significant gastrointestinal intolerance (nausea, diarrhea) develops in many children while they are taking the INH suspension. If tablets are used, they are crushed easily in a dessert spoon, to which then is added in the same spoon a vehicle such as applesauce, mashed banana, thawed undil frozen orange juice, or another palatable medium. The crushed tablets must never be added to the nursing bottle or offered in milk or water because they will be ingested only partially. If INH is given concurrently with RIF, the dose should not exceed 10 mg/kg/day.[422] If the intramuscular form is used, for example, in a child with meningitis who is vomiting, the daily dose is the same as the daily oral dose but usually is divided and given every 8 to 12 hours. INH can interact with several other drugs, particularly theophylline, and the dosage of each may need to be modified in a patient taking several drugs.[25] INH also can increase serum phenytoin levels by blocking its metabolism in the liver, thereby leading to toxicity.[382]

RIF is a semisynthetic drug derived from *Streptomyces mediterranei*. Active against a wide variety of both intracellular and extracellular organisms, it is more effective against mycobacteria than is any other drug except INH. Most clinical isolates are susceptible to 5 μg/mL or less. The drug is absorbed readily from the gastrointestinal tract in the fasting state; peak serum levels of 6 to 10 μg/mL are achieved within 2 hours, and the drug is distributed widely in body fluids and tissues, including spinal fluid. Excretion is mainly through the biliary tract; however, effective levels are achieved in the kidneys and urine. In many patients receiving RIF treatment, tears, saliva, urine, and stool turn orange as the result of a harmless metabolite, but patients always must be warned in advance. Drawbacks include the relatively high cost of treatment; the rare occurrence of explosive hypersensitivity reactions with hemolytic anemia, which, however, usually accompany intermittent (separated by weeks or months) rather than daily RIF therapy[190]; the occasional occurrence of leukopenia or thrombocytopenia while the patient is taking daily RIF[200]; the fact that RIF can render birth control pills inactive when both are used (an alternative method of birth control must be used); and finally—most serious of all for children—a "therapeutic orphan" clause in the United States for children younger than 5 years, which also means that no formulation is commercially available for young children. However, RIF easily can be made into a suspension for use in children.

RIF should be used alone only in treating tuberculosis infection with an INH-resistant organism. If one uses INH, 20 mg/kg, and RIF, 15 to 20 mg/kg, the incidence of hepatotoxicity is appreciable. Therefore, when the two are used together, one would be wise to approximate INH, 10 mg/kg, and RIF, 15 to 20 mg/kg. Rifamate is a capsule containing both INH (150 mg) and RIF (300 mg). Two capsules supply the usual adult (more than 50 kg) daily dose of each drug. Rifamate may be appropriate for older children and adolescents.[3] Rifater contains INH, RIF, and pyrazinamide (PZA) together in one pill in varying concentrations. Rifapentine is a new rifamycin with a very long half-life. Pharmacokinetic studies have been performed in adolescents, but no data on its effectiveness in adolescents or children have been published.[363]

PZA contributes to the killing of *M. tuberculosis*, particularly at a low pH, such as within macrophages.[486] The exact mechanism of action of PZA is a subject of controversy. PZA has no effect on extracellular tubercle bacilli in vitro but clearly contributes to the killing of intracellular bacilli. Primary resistance is very rare, except that *Mycobacterium bovis* is resistant. The drug diffuses readily into all areas, including spinal fluid.[166] The usual adult daily dose is 30 to 40 mg/kg. The adult dose is tolerated well by children, results in high cerebrospinal fluid concentrations, and clearly is effective in therapy trials for tuberculosis in children.[144,478,489,556] However, serum concentrations are lower in children than in adults taking a weight equivalent dose.[197] PZA appears to exert its maximal effect during the first 2 months of therapy. Hepatotoxicity can occur at high doses but rarely does at the usual dose. PZA routinely causes an increase in serum uric acid concentration by inhibiting its excretion through the kidneys. Toxic reactions in adults include flushing, cutaneous hypersensitivity, arthralgia, and overt gout; however, the considerable experience with this drug in children in Latin American countries, Hong Kong, and the United States has revealed few problems. It plays a major role in intensive, short-course treatment regimens.[191,556]

Ethambutol (EMB) has been used for many years as a companion drug for INH in adults. The usual oral dose is 20 mg/kg/day.[142] At this dose, the drug primarily is bacteriostatic, its major role being to prevent the emergence of resistance to other drugs. However, at doses of 25 mg/kg/day or 50 mg/kg given twice a week, EMB has some bactericidal action.[118,185] Unfortunately, at these higher doses, optic neuritis or red-green color blindness has occurred in some adults. Regular visual field and color chart testing should detect these reversible effects early. The incidence of ophthalmologic toxicity in children is extremely low, if it occurs at all.[142] It is used frequently and safely in children with life-threatening forms of tuberculosis or who are at risk for drug-resistant tuberculosis.

Ethionamide is an effective and well-tolerated drug in children at a dose of 15 to 20 mg/kg/day divided into two or three doses given after meals. Children rarely complain about its sulfurous taste, which is repulsive to adults. Related to INH, it likewise diffuses readily into spinal fluid.[145,146,240] Ethionamide is used in cases of drug-resistant tuberculosis and tuberculous meningitis. Unfortunately, no convenient pediatric dosage form is available.

Streptomycin (STM) is used in conjunction with INH and RIF in life-threatening forms of tuberculosis. It is bactericidal and tolerated well in children in the usual dose of 20 to 40 mg/kg/day intramuscularly up to 1 g. Usually, STM can be discontinued within 1 to 3 months if clinical improvement is definite, whereas the other two or three drugs are continued by mouth.

p-Aminosalicylic acid, either the sodium or the potassium salt, formerly was part of the standard treatment of tuberculosis. However, it is a purely bacteriostatic drug that has been superseded by more powerful drugs (RIF, PZA). It is used only for the treatment of drug-resistant tuberculosis.

Other antituberculosis drugs that may be needed for patients whose mycobacteria are resistant to INH or RIF are the aminoglycosides kanamycin, amikacin, and capreomycin, each of which has a spectrum of activity that differs from that of STM with respect to individual mycobacterial strains. Cycloserine and viomycin are other drugs sometimes used in patients with multidrug resistance. Clofazimine[259] and rifabutin (related to RIF) are newer drugs that have antimycobacterial activity but have been used mainly in children who have AIDS and are suffering from *M. avium-intracellulare* infection. Clofazimine also is used for infection with *Mycobacterium leprae*.

Several of the fluoroquinolones, especially levofloxacin and ciprofloxacin, have significant antituberculosis activity,[287,387] but they cannot be used routinely in children because of the possible destruction of growing cartilage seen in animal models. However, the dire consequences of drug-resistant tuberculosis lead many experts to use them successfully and with little apparent toxicity in children with MDR-TB disease.[246]

TABLE 107–10 In Vivo Location of *Mycobacterium tuberculosis*: A Model

	Population Size	Metabolism and Replication	pH	Most Effective Drugs
Cavity	10^7-10^9	Active and rapid	Neutral or alkaline	INH, RIF, STM
Closed caseous lesions	10^5-10^7	Slow and intermittent	Neutral	RIF, INH
Within macrophages	10^4-10^6	Very slow	Acid	PZA, RIF, INH

INH, isoniazid; PZA, pyrazinamide; RIF, rifampin; STM, streptomycin.

Microbiologic Basis for Treatment[384,537]

Laboratory observations of *M. tuberculosis* and the results of clinical therapy trials have led to a hypothesis concerning the actions of various drugs and drug combinations.[157,200,384,385] The tubercle bacillus can be killed only during replication, which occurs in organisms that are active metabolically. In one model, bacilli in a host exist in different populations (Table 107–10). They are active metabolically and replicate freely where oxygen tension is high and the pH is neutral or alkaline. Environmental conditions for growth are best within cavities, and such conditions can lead to a large bacterial population. Adults with reactivation-type pulmonary tuberculosis usually have all three populations of tubercle bacilli. Children with pulmonary tuberculosis and patients of all ages with only extrapulmonary tuberculosis are infected with a much smaller number of tubercle bacilli because the cavitary population is not present.

Naturally occurring drug-resistant mutant organisms occur within large populations of tubercle bacilli even before chemotherapy is started. All known genetic loci for drug resistance in *M. tuberculosis* are located on the chromosome; no plasmid-mediated resistance is known. The rate of resistance within populations of organisms is related to the rate of mutations at these loci.[375,584,587,592,652,653] Although a large population of bacilli as a whole may be considered drug susceptible, a subpopulation of drug-resistant organisms occurs at a fairly predictable rate. The mean frequency of these drug-resistant mutants is about 10^{-6} but varies among drugs: STM, 10^{-5}; INH, 10^{-6}; and RIF, 10^{-7}.[124] A cavity containing 10^9 tubercle bacilli has thousands of single drug–resistant mutant organisms, whereas a closed caseous lesion contains few if any resistant mutants.

The two microbiologic properties of population size and drug resistance mutation explain why single antituberculosis drugs cannot cure cavitary tuberculosis.[370] In the mid-1940s, STM alone was given to adults with cavitary pulmonary tuberculosis.[338] Within 3 months, 80 percent of patients had significant numbers of STM-resistant organisms. This phenomenon has been observed for every antituberculosis drug developed subsequently. However, the natural occurrence of resistance to one drug is independent of resistance to any other drug because the resistance loci are not linked. The chance of having even one organism "naturally" resistant to two drugs is on the order of 10^{-11} to 10^{-13}. Populations of this size in patients are extremely rare, and mutants naturally resistant to two drugs are nonexistent.

The population size of tubercle bacilli within a patient determines the appropriate therapy. For patients with large bacterial populations (adults with cavities or extensive infiltrates), many single drug–resistant mutants are present, and at least two antituberculosis drugs must be used.[127] Conversely, for patients with tuberculosis infection but no disease, the bacterial population is small (about 10^3 to 10^4 organisms), drug-resistant mutants are rare findings, and a single drug can be used. Children with pulmonary tuberculosis and patients of all ages with extrapulmonary tuberculosis have medium-sized populations in which drug-resistant mutants may or may not be present. In general, these patients should be treated with at least two drugs.

Some antituberculosis drugs, such as INH, RIF, and STM, are bactericidal against *M. tuberculosis*. Other drugs, including ethionamide, *p*-aminosalicylic acid, and low-dose EMB, are bacteriostatic. The earliest treatment regimens for tuberculosis combined the killing action of a bactericidal drug with a bacteriostatic drug that would suppress replication of drug-resistant mutant organisms. A small number of organisms survived despite administration of chemotherapy, and 18 to 24 months of treatment was necessary to permit host defenses to eliminate persisting organisms. Despite the prolonged treatment period, relapse rates were 5 to 15 percent, mostly a result of poor adherence to treatment.

The availability of RIF and the rediscovery of PZA in the early 1970s effected radical change in antituberculosis chemotherapy. These two drugs have the most potent sterilizing action, the ability to kill tubercle bacilli within lesions as quickly as possible. The addition of RIF to INH for the treatment of pulmonary tuberculosis leads to cure rates approaching 100 percent with only 9 months of treatment. The further addition of PZA shortens the necessary treatment duration to only 6 months.

TREATMENT OF THE STAGES OF TUBERCULOSIS

EXPOSURE

Children exposed to potentially infectious adults with pulmonary tuberculosis should begin treatment, usually with INH only, if the child is younger than 5 years or has other risk factors for the rapid development of tuberculosis disease, such as immunocompromise of some kind.[576,643] Failure to do so may result in the development of severe tuberculosis disease even before the tuberculin skin test becomes reactive; the "incubation period" of disease may be shorter than that for the skin test. The child is treated for a minimum of 3 months after contact with the infectious case is broken (by physical separation or by effective treatment of the case). After 3 months, the tuberculin skin test is repeated. If the second test result is positive, infection is documented and INH should be continued for a total duration of 9 months; if the second skin test result is negative, treatment can be discontinued. If the exposure was to a person with an INH-resistant but RIF-susceptible isolate, RIF is the recommended treatment.

Two special circumstances of exposure deserve attention. A difficult situation arises when exposed children are anergic because of HIV infection. These children are particularly vulnerable to rapid progression of tuberculosis, and it will not be possible to determine whether infection has occurred. In general, these children should be treated as though they have tuberculosis infection.

The second situation is potential exposure of a newborn to a mother (or other adult) with a positive tuberculin skin test result or, rarely, a nursery worker with contagious tuberculosis.[324,570] Management is based on further evaluation of the mother:

1. *The mother has a normal chest radiograph:* no separation of the infant and mother is required. Although the mother should receive treatment of tuberculosis infection and other household members should be evaluated for tuberculosis infection or disease, the infant needs no further work-up or treatment unless a case of disease is found.

2. *The mother has an abnormal chest radiograph:* the mother and child should be separated until the mother has been evaluated thoroughly. If the radiograph, history, physical examination, and analysis of sputum reveal no evidence of pulmonary tuberculosis in the mother, a reasonable assumption is that the infant is at low risk of acquiring infection. The radiographic abnormality is due to another cause or a quiescent focus of previous tuberculosis infection. However, if the mother remains untreated, contagious tuberculosis may develop later, and the infant will be exposed. Both the mother and infant should receive appropriate follow-up care, but the infant does not need treatment. If the radiograph and clinical history are suggestive of pulmonary tuberculosis, the child and mother should remain separated until both have begun appropriate chemotherapy. The infant should be evaluated for congenital tuberculosis. The placenta should be examined. If the mother has no risk factors for drug-resistant tuberculosis, the infant should receive INH and close follow-up care. The infant should have a tuberculin skin test at 3 or 4 months after the mother is judged to be contagious no longer; evaluation of the infant at this time follows the guidelines for other exposure of children. If no infection is documented at this time, repeating the tuberculin skin test in 6 to 12 months would be prudent. If the mother has tuberculosis caused by a multidrug-resistant isolate of *M. tuberculosis* or she has poor adherence to therapy, the child should remain separated from her until she is no longer contagious or the infant can be given BCG vaccine and be kept separated until the vaccine "takes" (marked by a reactive tuberculin skin test).

INFECTION

The recommendation for treatment of asymptomatic tuberculin-positive individuals is based on data from several well-controlled studies; it applies particularly to children and adolescents who are at high risk for the development of overt disease but at very low risk for development of the main toxic manifestation of INH therapy, which is hepatitis.[147,176,410,422,541] The large, carefully controlled U.S. Public Health Study of 1955, followed by others both in this country and abroad, demonstrated the favorable effect of 12 months of INH on the incidence of complications as a result of both lymphohematogenous and pulmonary spread.[237] The younger the tuberculin reactor, the greater the benefit.[116]

The American Thoracic Society and CDC,[13] recommend that INH treatment of tuberculosis infection be given to the following groups:

1. Household members and other close associates of potentially infectious tuberculosis cases. All contacts of any age with a Mantoux tuberculin skin test reading of 5 mm or greater and without a documented history of reaction in the past should be considered recently infected and receive therapy.

2. Newly infected people, regardless of age, who have had a tuberculin skin test conversion within the past 2 years.

3. People with HIV infection or at risk for development of HIV infection who have a reaction of 5 mm or greater to a Mantoux test.

4. People of any age with tuberculosis in the past who received inadequate treatment.

5. People of any age with a significant tuberculin reaction and an abnormal but stable chest radiograph.

6. People with significant tuberculin reactions who have special clinical situations, including silicosis, diabetes mellitus, prolonged corticosteroid therapy, immunosuppressive therapy, hematologic malignant disease, and end-stage renal disease.

7. All children and adolescents with a "positive" tuberculin skin test reaction or interferon release assay result.

The question arises regarding how long the protective effect can be expected to last. Comstock and associates,[113] in their final report on INH prophylaxis in Alaska, demonstrated the protective effect of 1 year of chemoprophylaxis to be 19 years at least. Hsu[236] described 2494 patients monitored for up to 30 years and showed that adequate drug prophylaxis prevented reactivation of tuberculosis infection during adolescence and into young adulthood. It seems reasonable to hope that the decreased risk of active tuberculosis after INH prophylaxis may in fact be lifelong in individuals infected with INH-susceptible tubercle bacilli. Failure of INH after exposure to INH-resistant *M. tuberculosis* has been documented. No controlled study of an alternative regimen has been reported. RIF alone is recommended and widely used, although failures have been reported.[336]

The dosage of INH to be used has had little study. Most investigators have used a regimen based on 4 to 8 mg/kg of body weight per day, usually taken all at once, for a period of 6 to 12 months. A dose of 5 mg/kg/day was found satisfactory in one study.[115] Most clinicians prescribe a dose of 10 to 15 mg/kg/day to a total of 300 mg/day for treatment of infection to be sure of achieving therapeutic levels even in patients who inactivate the drug rapidly by acetylation.

The duration of INH treatment initially was set arbitrarily at 12 months.[251] A large trial comparing regimens of daily INH taken for 12, 24, and 52 weeks with placebo for their ability to prevent tuberculosis disease was conducted in eastern Europe with adults who had old fibrotic lesions caused by tuberculosis. Therapy for 1 year was most effective, especially if the patients were adherent. However, therapy for 24 weeks afforded a fairly high level of protection. A subsequent analysis concluded that the 24-week duration of preventive therapy was more cost-effective for adults than was the 52-week duration.[540] Subsequently, many health departments have accepted 6 months of INH preventive therapy as their standard regimen for adults. However, the cost-effectiveness analysis does not apply to children. A recent review of all published studies concluded that the effectiveness of INH therapy increased up to 9 months' duration, but no additional benefit was achieved with a longer duration.[13] A duration of 9 months is recommended for children and adults by the AAP and CDC.[13] INH is taken daily under self-supervision or can be taken twice weekly under directly observed therapy. When the child is infected with an INH-resistant but RIF-susceptible strain of *M. tuberculosis*, RIF should be substituted for INH and given for 6 months' duration. If the infecting strain is resistant to both INH and RIF, usually two other drugs are used; an expert in tuberculosis should be consulted in this situation.

A shorter duration of effective treatment for tuberculosis infection is highly desirable to improve compliance and effectiveness.[359] In England, a 3- to 4-month course of INH plus RIF is used frequently. There have been published case-control series, and a recent meta-analysis of available data suggests that especially when compliance is considered, a 3- to 4-month course of INH plus RIF may be as effective as is a 9-month course of INH.[169] One small, randomized study also yielded favorable results with this regimen.[549] However, this regimen is not yet recommended by the CDC, AAP, or WHO.

DISEASE IN ADULTS

A shorter duration of antituberculosis chemotherapy is desirable for several reasons: it may be significantly less expensive than

traditional therapy; the patient is exposed to potentially toxic drugs for shorter periods of time; more time and resources can be allotted to ensure adherence with treatment; and if a patient absconds from treatment, a greater likelihood will exist that bacteriologic cure already has been achieved as a result of the early and rapid sterilizing activity of the newer regimens.

A 9-month regimen of INH and RIF cures more than 98 percent of cases of drug-susceptible pulmonary tuberculosis in adults.[528] Both drugs are given daily for the first 2 weeks to 2 months and then can be given daily or twice weekly under directly observed therapy for the remaining 7 to 8 months with equivalent results and rates of adverse reactions. When it is given twice weekly, the RIF dose is the same as the daily dose, but the INH dose is increased to 900 mg in adults. Twice-weekly administration is supported by pharmacologic and animal model data determining the area-under-the-curve characteristics for these antituberculosis drugs. Unfortunately, durations of therapy with only INH and RIF for less than 9 months are unacceptable because failure and relapse rates exceed 10 percent.

When three or more antituberculosis drugs are used initially, treatment durations of 6 months are routinely successful.[109] Regimens using INH, RIF, PZA, and STM during the initial phase (2 months), followed by INH and RIF in the continuation phase (4 months), routinely yield cure rates greater than 98 percent and relapse rates below 4 percent.[21,525] If PZA is excluded from the initial phase, the rate of bacteriologic failure rises to 7 to 10 percent.[229] However, exclusion of STM does not affect cure or relapse rates appreciably.[229,542] Use of PZA beyond the first 2 months of therapy does not add any benefit.[230] Regimens of 4 months' total duration have unacceptably high relapse rates of 10 percent or greater.[262] On the basis of all reported studies, the American Thoracic Society and CDC currently recommend for the treatment of pulmonary tuberculosis in adults a 6-month regimen using INH, RIF, PZA, and EMB for 2 months, followed by 4 months of daily or twice-weekly doses of INH and RIF.[51,88]

CHEMOTHERAPY FOR CHILDREN

Clinical trials of antituberculosis drugs in children are difficult to perform, mostly because of the difficulty in obtaining positive cultures at diagnosis or relapse and the need for long-term follow-up.[556] Historically, recommendations for treating children with tuberculosis have been extrapolated from clinical trials of adults with pulmonary tuberculosis.[535] However, during the past 2 decades, a large number of clinical trials involving only children have been reported. In 1983, Abernathy and colleagues[2] reported successful treatment of 50 children with tuberculosis in Arkansas using INH and RIF daily for 1 month, then twice weekly for 8 months. The success rate virtually was 100 percent. Most pulmonary infiltrates cleared by the end of therapy, but hilar adenopathy usually was still present radiographically and then gradually cleared during a period of 2 to 3 years. Patients with only hilar adenopathy can be treated successfully with INH and RIF for 6 months.[256,467]

Several major studies of 6-month therapy in children with at least three drugs in the initial phase have been reported.[7,47,247,302,583,596,605] The regimen used most commonly was 6 months of INH and RIF supplemented during the first 2 months with PZA. The overall success rate has been greater than 98 percent and the incidence of clinically significant adverse reactions less than 2 percent. Regimens not using STM were as successful as those that included it. Use of twice-weekly medications (under directly observed therapy) during the continuation phase was as effective and safe as was daily administration. Three studies used twice-weekly therapy throughout the treatment regimen with excellent success.[302,596,622] The 6-month, three-drug regimen is successful, tolerated well, and less expensive.[574,607] It also effects a cure faster, so the likelihood of successful treatment is greater if the child becomes nonadherent later in therapy.

EXTRAPULMONARY TUBERCULOSIS

Controlled treatment trials for various forms of extrapulmonary tuberculosis are rare. In most reports, extrapulmonary cases have been combined with pulmonary cases and often are not analyzed separately. Several of the 6-month, three-drug trials in children included extrapulmonary cases.[47,302] Most non–life-threatening forms of extrapulmonary tuberculosis respond well to a 9-month course of INH and RIF[156,158] or to a 6-month regimen including INH, RIF, and PZA.[254] One exception may be bone and joint tuberculosis, which may have a high failure rate when 6-month chemotherapy is used, especially if surgical intervention has not occurred.[156] Tuberculous meningitis usually is not included in trials of extrapulmonary tuberculosis therapy because of its serious nature and low incidence. Treatment with INH and RIF for 12 months generally is effective.[626] In the 1950s, Lorber[340] treated children with tuberculous meningitis for only 6 months with good results. A more recent study from Thailand showed that a 6-month regimen that included PZA for serious tuberculous meningitis led to fewer deaths and better outcomes than did longer regimens that did not contain PZA.[257] Most children are treated initially with four drugs (INH, RIF, PZA, and ethionamide or STM). Treatment with PZA and the fourth drug is stopped after 2 months, and INH and RIF are continued for a total of 6 to 9 months.[146]

DRUG-RESISTANT TUBERCULOSIS IN CHILDREN

The incidence of drug-resistant tuberculosis is increasing in the United States and the world because of poor adherence by the patient, the availability of some antituberculosis drugs in noncontrolled over-the-counter formulations, and poor management by physicians.[49,181,348,419] In the United States, approximately 10 percent of *M. tuberculosis* isolates are resistant to at least one drug.[86,92] Initial drug resistance rates of up to 80 percent have been noted in adults with pulmonary tuberculosis in some countries,[350] and rates of 20 to 30 percent are common findings. Resistance is most common to STM and INH and still is relatively rare to RIF.[130,231,386,656] Certain epidemiologic factors—disease in an Asian or Hispanic immigrant to the United States, homelessness in some communities, and history of previous antituberculosis therapy—correlate with drug resistance in adult patients.[5,29,439] Patterns of drug resistance in children tend to mirror those found in adult patients in the population.[84,475,495,512,543,567,569] Outbreaks of drug-resistant tuberculosis in children occurring at schools have been reported.[84,474] Individual cases also have been recognized. The key to determining drug resistance in childhood tuberculosis usually comes from the drug susceptibility results of the infectious adult contact case's isolate.

Therapy for drug-resistant tuberculosis is successful only when at least two bactericidal drugs are given to which the infecting strain of *M. tuberculosis* is susceptible.[72,193,438,494,593] If only one effective drug is given, secondary resistance will develop. When INH resistance is considered a possibility on the basis of epidemiologic risk factors or the identification of an INH-resistant source case isolate, an additional drug—usually EMB or STM—should be given initially to the child until the exact susceptibility pattern is determined and a more specific regimen can be designed.[584] Exact treatment regimens must be tailored to the specific pattern of drug resistance. The duration of therapy

usually is extended to at least 9 to 12 months if either INH or RIF can be used and to at least 18 to 24 months if resistance to both drugs is present.[253] Children tend to tolerate second-line antituberculosis drugs well, and community-based treatment usually is successful.[151,397] On occasion, surgical resection of a diseased lung or lobe is required.[255,453] An expert in tuberculosis always should be involved in the management of children with drug-resistant tuberculosis infection or disease.

ADHERENCE AND DIRECTLY OBSERVED THERAPY

Nonadherence with drug treatment by patients is a major problem in control of tuberculosis because of the long-term nature of its treatment.[377,580,620,627] As treatment regimens become shorter in duration, adherence assumes an even greater importance.[43] Suspected cases of tuberculosis must be reported to the local health department so that it can perform the necessary contact investigations and assist both patients and health care providers in overcoming barriers to adherence. To comply, the patient and family must know what is expected of them through verbal and written instructions in the patient's first language. An assessment of potential nonadherence should be made at the beginning of therapy.[32] Missed appointments should be brought quickly to the attention of the responsible public health officials, who may be able to use incentives or enablers, behavior modification, or, rarely, confinement to ensure adherence. The success of twice-weekly therapy, especially after a period of daily administration of medications, allows directly observed therapy to be given by a health care professional in cases of proven or suspected nonadherence.[99,254] Most experts hold that twice-weekly medication should be administered only under the direct observation of a health care worker.[297,637] Direct observation means that a health care worker or other nonrelated third party (e.g., teacher, school nurse, social worker) is physically present while the patient ingests the medication. As many as 50 percent of patients taking long-term antituberculosis medications will have significant nonadherence, and its occurrence is not predictable by the physician. In most communities in the United States and in an increasing number of other nations, directly observed therapy is the standard of care for all patients with tuberculosis disease.[90,170] However, when directly observed therapy cannot be used, structured behavior interactions can increase compliance with treatment.[79,597]

SUMMARY OF TREATMENT RECOMMENDATIONS

1. A regimen of INH and RIF for 6 months, supplemented with PZA during the first 2 months, is standard therapy for children with drug-susceptible intrathoracic tuberculosis in the United States and Canada.

2. An alternative regimen is INH and RIF for 9 months. The disadvantages of this regimen include a longer duration, the potential for increased drug resistance during therapy, and less effectiveness if the patient absconds from treatment. This regimen should be used only if PZA cannot be tolerated.

3. After an initial 2 weeks to 2 months of daily drug administration, drugs can be given twice weekly under directly observed therapy with excellent effectiveness.[449] With patients for whom social or other restraints prevent reliable daily self-administration even during the initial phase of therapy, drugs can be given two or three times per week from the beginning under directly observed therapy.

4. In most cases, extrapulmonary tuberculosis can be treated with the same regimens as used for pulmonary tuberculosis, although data for tuberculous meningitis and bone or joint disease are relatively lacking.

5. In cases of possible initial INH resistance, EMB or STM should be added to the initial phase of all regimens until drug susceptibilities are known.[87]

6. Optimal therapy for tuberculosis in children with HIV infection has not been established.[575] Most HIV-infected adults with tuberculosis respond well to antituberculosis drugs but may require longer durations of treatment.[269] Immunosuppressed children with tuberculosis, including those with HIV infection, should be treated with at least three drugs initially, and treatment should be continued for a minimum of 9 months. HIV testing is recommended for all infants and children with tuberculosis disease.

7. Tuberculosis disease occurring during pregnancy should be treated with a 9-month regimen of INH and RIF supplemented during the initial phase with EMB (STM should not be used). The use of PZA in pregnant patients is controversial although probably safe.

CORTICOSTEROIDS

Corticosteroids have a place in the treatment of patients with tuberculosis. They should never be used except under cover of effective antituberculosis drugs. Corticosteroids would be expected to be beneficial in situations in which the host inflammatory reaction is contributing to tissue damage or is impairing function.

Corticosteroids often are a useful addition to antituberculosis drugs if suppression of inflammatory reaction is desired, such as in the following situations[534]:

1. In patients with tuberculous meningitis in whom increased intracranial pressure is present.[600] The major actions are to reduce vasculitis, inflammation, and, ultimately, intracranial pressure. Not only is reduction of pressure desirable, but lowering of the pressure also probably favors the circulation of chemotherapeutic drugs through the brain and meninges.[174,189] One study demonstrated lower rates of mortality and long-term neurologic sequelae in patients with tuberculous meningitis treated with corticosteroids than in control patients not treated with steroids.[189]

2. In patients with acute pericardial effusion in whom tamponade is occurring. Relief of symptoms takes place within hours.[477,578]

3. In patients with pleural effusion, a shift of the mediastinum, and acute respiratory embarrassment.[317,537] The long-term course probably is the same with or without steroids, but symptomatic improvement usually is dramatic.

4. In patients with miliary tuberculosis if the inflammatory reaction is so severe that it produces alveolocapillary block with cyanosis.

5. In patients with enlarged mediastinal lymph nodes that are causing respiratory difficulty or a severe collapse-consolidation lesion, particularly in the middle or lower lobes, when bronchiectasis is likely to be a troublesome sequela.[407,408] Under either of these circumstances, a course of corticosteroids is warranted, with the realization that it will be more successful in a younger infection because inflammation characterizes the early stages of tuberculosis. If caseation already is advanced, steroids will be of little benefit.

The dosage of corticosteroids should be in the anti-inflammatory range, that is, prednisone, 1 to 2 mg/kg/day for 4 to 6 weeks with gradual withdrawal. Some experts prefer dexamethasone, but no comparative trials have been published.

ACTIVITY

Activity need not be restricted in children with tuberculosis, except when a particular complication is inevitable (shortness of breath in pleural effusion, immobilization for a vertebral lesion). During the early months of treatment, patients probably should avoid engaging in competitive sports, excessive study, fatigue, and sunburn.

ISOLATION

Isolation should be maintained for children with cavitary lesions, productive cough with acid-fast, stain–positive sputum, draining sinuses, or renal tuberculosis until their secretions are negative on smear and preferably on culture. Young children are virtually noninfectious because they rarely cough and because their bronchial secretions contain few bacilli compared with those of adults with tuberculosis. Guidelines issued by the CDC state that most children with typical tuberculosis do not require isolation in the hospital.[82,399] Children with possible pulmonary tuberculosis should be treated as potentially infectious if they have a cavity or extensive upper lobe infiltrate, if they have a productive cough (especially if the sputum is acid-fast smear positive), or during high-risk procedures such as bronchoscopy.

FOLLOW-UP

Follow-up of children treated with antituberculosis drugs has become somewhat more streamlined in recent years. While receiving chemotherapy, the patient should be seen monthly, both to encourage regular intake of the prescribed drugs and to check, by a few simple questions (concerning appetite, well-being) and a few observations (weight gain; appearance of the skin and sclerae; palpation of the liver, spleen, and lymph nodes), that the disease is not spreading and that toxic effects of the drugs are not appearing.[639] Repeated chest radiographs should be obtained 1 to 2 months after the onset of chemotherapy to ascertain the maximal extent of disease before chemotherapy takes effect; thereafter, radiographs rarely are necessary.[292] Chemotherapy has been so successful that follow-up beyond its termination is not necessary, except for children with serious disease, such as tuberculous meningitis, or those with extensive residual chest radiographic findings at the end of chemotherapy.

CASE REPORTING

Every case of definite or suspected tuberculosis, by law,[89] must be reported immediately by telephone to the health authority[192] to ensure prompt contact investigation[234] and free antituberculosis drugs, which are available for diagnosed cases and for intimate contacts in almost every state of the United States and in many countries.

PREVENTION

Prevention of tuberculosis can be subdivided logically to consider the following circumstances:

1. Protection against exposure to the disease.
2. Use of antituberculosis drugs in tuberculin-negative individuals at high risk for development of infection.
3. Immunization of tuberculin-negative individuals.

Protection against exposure to disease is the ideal form of prevention.[356] It presupposes thorough pre-employment and ongoing case-finding programs among all who come in contact with children, including daycare center and school personnel, Sunday school personnel, music and art teachers, hospital nurses, babysitters, household servants, food handlers, beauticians, and barbers. Numerous epidemics, mini-epidemics, and mass exposures in newborn nurseries have been traced to such infected individuals.

IMMUNIZATION

Immunization against tuberculosis theoretically would be a tremendous boon to humanity, but in practice, it has been fraught with very great difficulty. Various strains of mycobacteria and diverse nonliving immunogenic fractions have been studied. The impossibility of standardizing vaccines in the early days, the lack of any clinically useful test reflecting the immune status of the individual, and the relatively slow course of the disease have handicapped epidemiologic studies considerably. Furthermore, the very lack of adequate scientific data has intensified national and individual emotional responses to the point that rational approaches to data gathering and interpretation are often impossible. Although the use of tuberculosis vaccines for control of tuberculosis has waned in recent years in industrialized countries because of the falling incidence of the disease, new interest in them has cropped up because of their beneficial effect in certain types of malignant disease. New insights into their mode of action may prove fruitful in the long run in understanding immunity to tuberculosis, as well as to neoplasia, and might lead to a greatly improved and clinically useful vaccine.

BCG was developed at the Institut Pasteur in Paris by Calmette and Guérin, who, starting in 1908, made 231 passages of a strain of *M. bovis* on a beef bile medium, thereby producing marked attenuation. Injected into laboratory animals, this strain was shown to increase resistance to challenge with virulent *M. tuberculosis*. In 1921, it first was administered orally to newborn infants and since then has been given to more than 4 billion people.

BCG vaccine attempts to replace the potentially dangerous primary infection with *M. tuberculosis* with an innocuous primary infection with the bacillus of Calmette and Guérin, thus activating host cell-mediated immunity with minimal chance of causing progressive disease so that an infection with *M. tuberculosis* will be of the "reinfection" type.[332]

Variations in strains and lack of standardization are basic problems in evaluating the results of immunization.[198,594] BCG was maintained for many years by serial passage at the Institut Pasteur and distributed to hundreds of laboratories all over the world. Not until 1966 did the WHO Expert Committee on Biological Standardization adopt formal requirements for the maintenance of frozen "seed lots" to minimize the inevitable mutations that have produced BCG vaccines with widely varying characteristics. Routine quality control measures carried out by the production laboratory include an identity test, a test for contamination, a safety test in guinea pigs, an estimate of the total bacillary mass, viability, and a test of heat stability. Periodic assessment of the allergenic capacity in humans is part of quality control testing. The WHO, through its International Reference Preparation for BCG vaccine and through quality control testing on request carried out in its several cooperating laboratories, has helped decrease the gross variations in BCG vaccine found until recent years.

Vaccination techniques and dosages are variable. Intradermal injection is the most precise technique. Multiple-puncture techniques are popular because they are easy, but reported results consistently are inferior to those obtained with intradermal injection. Oral vaccination, the original method of administration,

largely has been abandoned because of poor results. The actual dose of BCG at present usually is approximately 10^6 culturable particles. Because in animals large doses produce better resistance to challenge than small ones do, the largest convenient dose is used. However, in neonates, who have a higher incidence of untoward reactions, the customary approach is to halve the dose generally used in older infants and children to prevent local complications.

The usual local reaction to intradermal BCG vaccine is the development of a papule at the site of vaccination, and this papule reaches its maximal diameter (10 to 20 mm) in the sixth week. A small crust that may form on the papule detaches at about this time, with only a small ulcer remaining that may discharge a surprising amount of pus. Most ulcers are healed by the 10th week. A small scar is visible in almost all BCG-vaccinated individuals. Enlargement of the regional lymph nodes occurs regularly and is painless, sometimes ending in calcification. Formation of an abscess with breakdown is a rare event, but it occurs more often in infants.

Untoward reactions to BCG rarely have been a problem.[609] Fatalities caused by progressive disease have been reported in no more than 60 vaccine recipients (of an estimated 3+ billion), usually (but not always) children with well-documented immunodeficiency.[75,135,172,195,443,447] No return of the attenuated strain to virulence has ever been noted. In countries where BCG is used routinely for immunization of neonates, osteomyelitis has been diagnosed in some 5 per 100,000 neonates. It usually becomes manifested when the child is between 5 and 33 months of age, when a tender swelling is noted near a joint; bone destruction is well localized and responds to conservative treatment. On the whole, BCG is one of the safest vaccines in use.

In many countries where BCG is given routinely, the incidence of HIV infection in adults and children is high.[62,479] Reports of local and systemic complications from BCG vaccine in HIV-infected people are increasing, but the true magnitude of the interaction is not known yet.[40,219,220,232,421,466] However, in more recent studies, the rate of adverse BCG reactions in HIV-infected children appears to be higher than thought previously.[219,220] In most cases, BCG complications occur shortly after vaccination, but in one man with AIDS, adenitis as a result of BCG occurred 30 years after inoculation.[469] Routine treatment of patients with previous BCG vaccination who subsequently become immunocompromised is not recommended, but the clinician should be aware of previous BCG vaccination if signs or symptoms of mycobacterial infection occur.

The effectiveness of revaccination has never been evaluated scientifically and is not recommended.

The efficacy of BCG vaccines in humans has been evaluated in several large, well-controlled studies (Table 107–11). Three of these trials showed excellent protection, two showed mediocre protection, and two showed little or no effect of BCG. Another study, not tabulated because its numbers are relatively small, is the "experiment of nature" reported by Hyge[246a] in 1957. Hyge[246a] observed an epidemic of tuberculosis in a school for girls, where 105 girls initially were tuberculin negative, 130 were tuberculin positive, and 133 were BCG immunized. In this group, the total incidence of tuberculosis was 23 times as high in the tuberculin-negative as in the BCG-immunized girls. Explanations for these differences in outcomes among trials must be sought in the quality and characteristics of the BCG vaccine used in the particular trial, the possible immunizing effect (in Georgia and Alabama) of infections with other mycobacteria,[532] the possibly greater effectiveness of BCG vaccine in areas of high tuberculosis prevalence, and methodologic variations among the trials.

The most recent large study of BCG effectiveness is the Chingleput study, started in 1968 in Chingleput District near Madras, South India, an area where sensitization with environmental mycobacteria is prevalent. People of all ages were vaccinated with one of two BCG vaccines or a placebo; only the incidence of adult-type pulmonary tuberculosis in the three groups was compared (i.e., not the forms usually found in children). During the ensuing years, no difference in incidence was noted among the three groups.[20a] This disturbing result has been the subject of several WHO investigations because BCG is one of the vaccines recommended for all children in the Expanded Program of Immunization sponsored by the WHO itself.[468] Another study of neonatal vaccination with BCG in England reported very favorable results with BCG.[121]

A group at the Harvard School of Public Health reviewed all published studies of BCG efficacy in a meta-analysis.[111] Most published trials were not analyzed because of serious flaws in their experimental design or reporting. Among all trials and case-control studies included, the average protection against tuberculosis disease by various BCG preparations was 50 percent. The protective levels were higher for disease in children, particularly for meningitis and tuberculosis-associated death.[110,604] However, ascertainment bias and lack of standardized case definitions render the results of these analyses very difficult to interpret. The BCG vaccines prevent many cases of tuberculosis in children, but the effect is quite variable. That BCG vaccines are not an instrument of tuberculosis control also has become apparent because they do not prevent infection with *M. tuberculosis*, their protective effect is short-lived, and vaccination of infants does little to prevent future cases of contagious tuberculosis among adults in a community.

The role of BCG vaccine in the United States today is very limited. The Advisory Committee on Immunization Practices of the U.S. Public Health Service and the Advisory Council for the Elimination of Tuberculosis recommend BCG only for tuberculin-negative infants and children in the United States who (1) are at high risk for having intimate and prolonged exposure to persistently untreated or ineffectively treated adults with infectious pulmonary tuberculosis, cannot be removed from the source of infection, and cannot be prescribed long-term preventive

TABLE 107–11 Summary of Seven Large Controlled Trials of Bacillus Calmette-Guérin (BCG) Immunization Against Tuberculosis

Trial	Investigators	Intake Period	Vaccine Laboratory	Duration of Observation (yr)	% Protection from BCG
North America: Native Americans	Stein and Aronson, 1953	1935-1938	Phipps	9-11	80
Chicago: infants	Rosenthal et al., 1961	1937-1948	Tice	12-23	75
Britain: schoolchildren	Medical Research Council, 1971	1950-1952	Copenhagen	15	78
South India: rural population	Frimodt-Moller et al., 1964	1950-1955	Madras	2.5-7	60/31*
Puerto Rico: children	Palmer et al., 1958	1949-1951	New York State	5.5-7.5	31
Georgia, Alabama: population	Comstock and Palmer, 1966	1950	Tice	14	14
Georgia: schoolchildren	Comstock and Webster, 1969	1947	Tice	20	0

**The initial estimate of efficacy was 60 percent. Subsequently, when follow-up was extended to 9 to 14 years, the efficacy figure declined to 31 percent.*
Modified from Sutherland, quoted by Eickhoff, T. C.: The current status of BCG immunization against tuberculosis. Annu. Rev. Med. 28:411-423, 1977.

therapy or (2) continuously are exposed to people with tuberculosis resistant to INH and RIF.[91] A few experts, however, are more inclined toward the use of BCG in neonates who are at any risk of exposure to tuberculosis whatsoever.[282,283,526,601]

Contraindications to the use of BCG for prevention of tuberculosis include congenital immunodeficiency, known HIV infection (in the United States; the WHO recommends giving BCG to asymptomatic HIV-infected infants who reside in areas with high tuberculosis rates), leukemia, lymphoma, and generalized malignant disease as well as treatment with corticosteroids, alkylating agents, antimetabolites, and radiation.

CHAPTER 108

Other Mycobacteria

J. Thomas Cross, Jr. ❂ Richard F. Jacobs

The definition of mycobacteria other than tubercle bacilli is quite confusing. Runyon,[135] in his address to the International Conference on Atypical Mycobacteria, probably defined them best: "Tubercle bacilli include *Mycobacterium tuberculosis*, *Mycobacterium bovis*, and *Mycobacterium africanum*. Together with *Mycobacterium microti* (not pathogenic for humans), these organisms constitute the tubercle bacillus complex." Any mycobacterium not listed in this group is considered to be in the "other" grouping. Mycobacteria other than those causing tuberculosis and leprosy were not recognized as causes of disease in humans until the 1950s.[165] The incidence of disease caused by these organisms remained stable until the acquired immunodeficiency syndrome (AIDS) epidemic began in the 1980s. The most common forms of the disease are chronic pulmonary disease resembling tuberculosis (occurring mainly in adults), cervical adenopathy in children, skin and soft tissue infection, and disseminated disease in immunocompromised individuals.[120] In the mid-1980s, the incidence of infections with atypical mycobacteria increased markedly, probably because of the increased number of immunocompromised patients (e.g., because of AIDS and organ transplantation) and the significant improvement in microbiologic methods for cultivating these organisms.[186,191]

EPIDEMIOLOGY

The atypical mycobacteria are ubiquitous in nature. They are found in soil, animals, milk,[42] and food. Of importance in some hospital-acquired infections or infections in immunocompromised hosts is the presence of the organisms in common tap water.[16,59,109,157] Exposure to environments (especially soil) colonized by these organisms seems to be important for acquisition of disease in children. Organisms commonly found in soil include *Mycobacterium scrofulaceum*, *Mycobacterium flavescens*, *Mycobacterium avium–intracellulare* (MAI), *Mycobacterium gastri*, *Mycobacterium terrae*, *Mycobacterium fortuitum*, and *Mycobacterium chelonae*. Water is an important source for all of the previously named organisms and for *Mycobacterium kansasii*, *Mycobacterium marinum*, *Mycobacterium gordonae*, and *Mycobacterium xenopi*.

In contrast, humans are the only known reservoirs for *M. tuberculosis*. In a survey from the Centers for Disease Control and Prevention (CDC), 35 percent of mycobacteria isolated in laboratories were nontuberculous.[53] MAI accounted for 66 percent of the nontuberculous isolates, followed by *M. fortuitum* (19%), *M. kansasii* (9%), and *M. scrofulaceum* (6%). These data were collected in 1980 before the present AIDS epidemic and before the rapid increase in the number and types of immunocompromised patients; therefore, current rates probably are much higher.

Geography also apparently has some bearing on the prevalence of these infections. The southeastern part of the United States has much higher rates in children than does the Northeast or the Northwest. *M. avium* complex (MAC) was seen most commonly along the coastal borders of the United States and in the states bordering Canada. The highest rates were seen in Hawaii (10.9 cases per 100,000 population), Connecticut (8.9 cases per 100,000 population), and Florida (8.4 cases per 100,000 population). High rates also were seen in Kansas and the desert

Southwest, however, showing the widespread nature of this organism in causing disease. In contrast, *M. kansasii* was seen most commonly in the Midwest of the United States and almost never was seen in the Southeast.[53] States with rates of *M. kansasii* greater than 0.75 case per 100,000 included Missouri, Illinois, Kentucky, Indiana, Kansas, Nebraska, Louisiana, Texas, Arizona, and Florida. North Carolina, a state with one of the highest rates of MAC (>4.8 cases per 100,000 population), had very few cases of *M. kansasii* (0 to 0.25 case per 100,000 population). *M. marinum* frequently was isolated from coastal areas, whereas *M. xenopi* was scattered across the United States, with 50 percent of cases being found in just three states (Connecticut, Wisconsin, and California).

For all the nontuberculous species, males and rural residents had a much higher incidence of infection.[141] Extrapolation of these rates to determine disease patterns is not without problems, however. The number of mycobacterial isolates could be skewed easily by the presence of multiple isolates from a single patient, or it may just represent colonization. Nonetheless, these rates can help predict which species of nontuberculous mycobacteria are most likely to be encountered in a particular geographic region while the physician awaits final identification and sensitivity testing on an isolated nontuberculous organism.

The site of isolation from the human source can be helpful in determining the type of mycobacteria that may be involved in the disease process. *M. avium* and *Mycobacterium intracellulare* are responsible for lymphadenitis, particularly in children. These two organisms also are responsible for pulmonary disease and disseminated disease to bones and occasionally to the meninges. *M. kansasii* is associated most commonly with infections of pulmonary origin and disseminated lesions in adults; rarely, it is associated with adenitis and skin granuloma in children. *M. scrofulaceum* also causes lymphadenitis in children, and *M. marinum* is responsible for skin granuloma and ulcers after exposure to certain salt-water beaches, swimming pools, and tropical fish tanks. The rapid growers (*M. fortuitum* and *M. chelonae*) rarely are responsible for pulmonary and disseminated disease in adults and children.

A familial immune defect predisposing to disseminated atypical mycobacterial infection in childhood has been reported.[96] The six children studied had disseminated infection with atypical mycobacteria and no obvious evidence of immunodeficiency. Clinical and immunologic features seem to indicate that these children acquire infections similar to Lsh/Ity/Bcg-susceptible mice. Ongoing studies to determine the defect may provide insight into the mechanisms by which certain children are susceptible to mycobacterial infections, whereas others exposed to the same environmental factors do not develop disseminated disease.

MICROBIOLOGY

Runyon and Timpe[133,134,165] in their monumental work on atypical mycobacteria suggested a useful classification system based on three characteristics of the organisms: production of pigment, rate of growth, and colonial characteristics. The four groups are as follows: group I—photochromogens, which produce bright yellow to red pigment in the presence of light; group II—scotochromogens, which produce yellow to orange pigment in the dark; group III—nonphotochromogens, which are nonpigment producers; and group IV—rapid growers, which generally grow in less than 1 week. Kubica[89] published an updated version of Runyon's classification in 1978, and it was useful for many years. Subsequently, a more "simplified" classification based on the growth rates of the organisms alone was proposed.[186]

The atypical mycobacteria still are differentiated by most clinical laboratories on the basis of various morphologic, physiologic, and biochemical characteristics (Tables 108–1 and 108–2). The difficulty with identifying many of these organisms is their slow growth rates with standard techniques. Beginning sensitivity testing as soon as an organism is cultivated and thought to be the responsible pathogen is useful because several months may be required for proper identification and susceptibility testing. Serologic tests can be helpful in identifying some of the

TABLE 108–1 Characteristics of Slow-Growing Pathogenic Mycobacteria

Organism	Growth Present (° C)			Growth Rate (Days)	Niacin	Nitrate Reduction	Pigment Dark	Pigment Light	Growth in 5% NaCl

Mycobacterium chelonae	37° C	3-7 days	–	–	–

organisms.[35,90,133,168,176,186,187,191] In clinical medicine, they rarely are valuable, however, for establishing a diagnosis in an individual patient. A study using humoral immunoglobulins against mycobacterial antigens failed to diagnose tuberculosis or nontuberculous adenitis in children.[169]

Blood cultures for mycobacteria are best performed with the Isolator lysis-centrifugation system (Wampole Laboratories, Cranbury, NJ) or the radiometric BACTEC 13A blood culture bottle (Becton-Dickinson Diagnostic Instrument Systems, Cockeysville, MD).[1,81,82] Blood collected in ethylenediaminetetraacetic acid or coagulated blood is unacceptable. Body fluids such as cerebrospinal fluid, pleural fluid, and peritoneal fluid can be inoculated directly into BACTEC or Septi-Chek (Becton-Dickinson) broth, particularly if only small volumes are available. Gene probes became commercially available in the late 1980s. They involve DNA probes complementary to species-specific sequences of rRNA for the identification of *M. tuberculosis*, MAC, *Mycobacterium gordonae*, and *M. kansasii* (AccuProbe; Gen-Probe, San Diego, CA).[55]

Polymerase chain reaction (PCR) assay has been evaluated for the routine detection of *M. tuberculosis* in the clinical laboratory and compared with fluorochrome smear and culture. Two large studies compared PCR with the standard technique and found that the sensitivity of PCR assay was 84 percent in both studies.[28,50] In another study, a multiplex PCR assay for immediate identification of various *Mycobacterium* spp. was shown to be 97.9 percent sensitive and 96.9 percent specific.[87] The PCR testing offered by commercial laboratories at present is not approved by the U.S. Food and Drug Administration for in vitro diagnosis. The sensitivity and specificity of this test vary widely among laboratories.[118]

MANIFESTATIONS OF NONTUBERCULOUS MYCOBACTERIAL INFECTION IN CHILDREN

LYMPHADENITIS

Lymphadenitis is the most common manifestation of atypical mycobacterial infection in children. It also can occur rarely in adults.[37,94,101] All nodes in the cervical chain can be affected, but the nodes of the submandibular region seem to be the ones most commonly involved.[39] The parotid gland also can be affected.[32] The differential diagnosis frequently centers on deciding whether a malignant process versus a nonmalignant process is present. Nonmalignant processes to consider include mononucleosis, bacterial adenitis, cat-scratch disease, toxoplasmosis, and *M. tuberculosis* infection.

Most mycobacterial cases of lymphadenitis are caused by the nontuberculous organisms. The clinician also must consider the possibility of *M. tuberculosis*, however.[30] No clinical features help the clinician discern between nontuberculous mycobacterial infection and tuberculosis. The use of histopathology has been postulated to help differentiate between atypical and tuberculous infections.[124] In this retrospective study, the findings of ill-defined (nonpalisading) granulomas, irregular or serpiginous granulomas, a predominantly nonspecific granulomatous response, predominantly sarcoid-like granulomas, or lack of significant caseation were seen more commonly with nontuberculous lymphadenitis. Additionally, nontuberculous infections had neutrophils predominantly in the center of the necrosis, whereas in tuberculous infections, neutrophils were scattered throughout the specimen. A prospective study investigating these findings has not been published to date, and other authors have not noted similar patterns.[11]

In a Canadian study, the rate of atypical mycobacteria as a cause of lymphadenitis was 1.21 cases per 100,000 children, whereas the rate for tuberculosis was 0.3 case per 100,000 children.[147] Investigators from San Diego reported a marked increase in the number of infections in children.[125] Other authors around the world have reported a markedly increased incidence of infection with these organisms in immunocompetent children.[52] In one study, the incidence increased from one case between 1987 and 1990 to 85 cases between 1991 and 1993.[93] In a large study compiled by Lincoln and Gilbert[100] involving 243 children, more than 50 percent were younger than 3 years of age, and 80 percent were younger than 5 years. In contrast, one study showed that the mean age had increased to 5.2 years.[183]

Most patients have no systemic symptoms and normal chest radiographs; other laboratory studies generally are not helpful. The mean duration of swelling is approximately 6 weeks. Historically, the cervical nodes are affected most commonly in children, although a more recent study from Greece reported submandibular prominence.[107]

Infections are caused mainly by MAI and *M. scrofulaceum*. A large prospective study spanning 32 years from 1958 to 1990 showed that MAC has become the predominant etiologic agent and has surpassed *M. scrofulaceum* from earlier in the study.[189] A series of 190 patients from India showed, however, that 60 percent of the nontuberculous adenitis cases were caused by *M. scrofulaceum* followed by 40 percent by *M. avium* intracellulare.[77] Case reports involving *M. fortuitum* also have been published.[131] Lymphadenitis caused by *Mycobacterium haemophilum* is being diagnosed in immunocompetent children in increasing numbers.[7,138]

Samra and colleagues[138] showed that the BACTEC radiometric system or MB Redox broth (Heipha Diagnostika Biotest, Heidelberg, Germany) is superior to Löwenstein-Jensen (Heipha Diagnostika Biotest) media for isolation of *M. haemophilum*. This organism is thought to have been underdiagnosed previously because of the widespread use of Löwenstein-Jensen media. *Mycobacterium malmoense* also has been described as an etiologic agent of cervical lymphadenitis in children.[167] Haas and associates[62] have described *Mycobacterium heidelbergense*, a new agent of mycobacterial lymphadenitis in children.

The usefulness of mycobacterial antigens in skin testing for the diagnosis of atypical mycobacterial infection versus tuberculous lymphadenitis is controversial. The use of purified protein derivative type B (PPD-B) (*M. intracellulare*), PPD-Y (*M. kansasii*), PPD-G (*M. scrofulaceum*), and PPD-T (*M. tuberculosis*) was compared to discern whether children with active lymphadenitis caused by the atypical mycobacteria could be distinguished from children with tuberculosis.[74] Children with confirmed nontuberculous adenitis were six times more likely to have greater than 10-mm induration to PPD-B than were children with negative culture or biopsy results. In all groups except those with confirmed *M. tuberculosis*, responses to PPD-T were significantly smaller than responses to the nontuberculous mycobacterial antigens. The results of the study seem to indicate that the use of nontuberculous mycobacterial antigens could be helpful in diagnosing mycobacterial cervical adenopathy. The specificity for nontuberculous organisms is unknown, however.

Needle aspiration of an affected node can be a valuable diagnostic tool. Cultures for bacterial and mycobacterial etiologies should be performed, and recovery rates in children with cervical lymphadenitis range from 60 to 88 percent.[9,14,80,193] The aspirate should be inoculated onto aerobic and anaerobic media and Sabouraud agar and mycobacterial media (Löwenstein-Jensen slants or Middlebrook media). Use of the BACTEC system can be very helpful; mycobacteria can be isolated 12 to 17 days after inoculation.[152]

More recently, preoperative diagnosis of *M. avium* lymphadenitis was accomplished with the use of PCR of gastric aspirates in two children.[61] Further studies are needed to conclude whether PCR could be a noninvasive method of diagnosing this infection.

The best treatment of lymphadenitis caused by atypical mycobacteria is complete excision of the involved lymph node.[108,172] Incision and drainage without excision result in a high rate of secondary drainage, and subsequent excision of the remaining tissue is required for cure.[4,137,144] Small uncontrolled trials have attempted to use antimicrobials alone for lymphadenitis caused by nontuberculous mycobacteria.[102] Preliminary results have been successful, but use of toxic agents for prolonged periods was required. Controlled trials have not been published.

ACQUIRED IMMUNODEFICIENCY SYNDROME AND ATYPICAL MYCOBACTERIA

Surveys have noted an increasing rate of nontuberculous infection in children with AIDS.[73] Approximately 6 percent of adults and 4 percent of children with AIDS reported to the CDC had disseminated MAC infection as AIDS-defining disease.[20] Autopsy studies show that MAC infection is present in 20 to 50 percent of adult human immunodeficiency virus (HIV)–infected patients.[129,182,185] In a retrospective study from 1990 to 1996 in New York City, 26 percent of children had evidence of MAC infection at the time of their deaths.[78] MAC infection was thought to be the cause of death in 13 percent of the 54 children with HIV infection, and the mean age at death was 7.8 years. In two autopsy studies of opportunistic infection in HIV-infected children in Latin America and Argentina, only 2.7 percent and 3.4 percent had evidence of disseminated disease.[41,127] In these studies, 62 percent (Argentina) and 72 percent (Latin America) of the children studied were younger than 1 year of age. These data indicate that MAI infection is seen less commonly in younger children with HIV.

In the CDC study, MAC was the nontuberculous mycobacterium most commonly isolated. *M. kansasii* and *M. scrofulaceum* were found in one case each. In adult studies, the incidence of infection with *M. kansasii* and *M. scrofulaceum* also is quite low.[38,72] More than 70 percent of children with MAC and AIDS had evidence of disseminated disease. Almost all had $CD4^+$ counts less than 100 cells/mm^3. Clinical findings included failure to maintain growth curves, anorexia, fever, abdominal pain, and anemia. The median age at diagnosis was 46 months, with a median of 9 months elapsing between the onset of symptoms and positive cultures. When nontuberculous mycobacterial infection was diagnosed in these patients, they survived less than 10 months. Blood cultures have 90 to 95 percent sensitivity in detecting disseminated MAC infection in adult patients with AIDS.[65]

MAI has been shown to infect the esophagus, stomach, and intestine of pediatric patients with AIDS.[79] Patients with extensive MAI infection of the small and large intestines have severe, persistent diarrhea.

Mycobacterium genavense has been shown to cause infection in children with HIV infection.[117] The children were febrile and had abdominal cramps and diarrhea. $CD4^+$ lymphocyte counts were less than 400/mm^3. The organism was found in numerous stool samples and lymph node specimens. Multiple-drug regimens that include amikacin, ethambutol, rifampin, and clarithromycin may be useful in treating this infection.

For treatment of MAC infection in HIV-infected children, combination therapy is recommended.[6] Clarithromycin (15 mg/kg/day divided into two oral doses, maximum of 500 mg) and ethambutol (15 to 20 mg/kg/day in a single dose, maximum of 1600 mg) should be included. Additionally, the use of rifabutin (5 to 10 mg/kg/day once daily, maximum of 300 mg), ciprofloxacin (20 to 30 mg/kg/day intravenously or orally once daily, maximum of 1.5 g), or azithromycin (10 mg/kg once daily) can be considered. Because of their liquid form, clarithromycin and azithromycin have become available therapy for many infections in pediatric patients, including otitis media, pharyngitis, and skin infections.[85] The use of granulocyte colony-stimulating factor as an adjunct to antimicrobial therapy for disseminated MAC infection has been reported,[121] but additional data are needed to determine the usefulness of this agent.

For secondary prevention of recurrent disease, lifelong prophylaxis with clarithromycin is recommended (15 mg/kg/day in two divided doses, maximum of 500 mg), in combination with at least one of the following: ethambutol (15 to 20 mg/kg/day once daily), rifabutin (5 mg/kg/day once daily, maximum of 300 mg), or ciprofloxacin (20 to 30 mg/kg/day in two divided doses, maximum of 1.5 g).

The use of rifabutin or azithromycin (5 mg/kg/day once daily, maximum of 250 mg, or 20 mg/kg once weekly) for prophylaxis has been recommended based on adult studies in an attempt to delay and prevent MAC bacteremia in adults with $CD4^+$ cell counts less than 100 cells/mm^3. The U.S. Public Health Service and the Infectious Disease Society of America have published guidelines for the prevention of opportunistic infections, including disseminated MAC.[170] These guidelines incorporate age-specific $CD4^+$ counts at which prophylaxis should be used: children 6 years or older, less than 50 cells/μL; children 2 to 6 years old, less than 75 cells/μL; children 1 to 2 years old, less than 500 cells/μL; and children younger than 12 months, less than 750 cells/μL. Azithromycin (20 mg/kg once weekly) seems to be effective. A phase I/II study of prophylactic rifabutin for prevention of disseminated MAC infection in children showed a side effect of bilateral, stellate, corneal deposits without associated uveitis in 6 of 25 children.[149]

The emergence of resistance is a concern with the MAC prophylactic regimens in patients with AIDS. In some trials, 9 percent of adults receiving azithromycin prophylaxis and 5 percent of adults receiving clarithromycin prophylaxis had breakthrough MAC bacteremia. Of these cases, 11 percent and 58 percent of the azithromycin and clarithromycin, respectively, breakthrough isolates were macrolide-resistant.[5,64]

PULMONARY INFECTIONS

Reviews from the late 1970s showed that pulmonary disease caused by atypical mycobacteria usually was caused by *M. kansasii* and MAC.[26,54,132] MAC infection most commonly occurred during the sixth decade, whereas *M. kansasii* infection occurred in individuals a decade younger. Men were affected most commonly, in ratios as high as 4:1. Chronic obstructive pulmonary disease as noted by radiographic findings was found in 50 to 60 percent of patients with atypical mycobacterial pulmonary infections. Bullous lung disease was seen in 24 to 39 percent. The lobar distribution and severity of disease were similar for atypical mycobacterial agents and *M. tuberculosis*, with one exception: *M. kansasii* was much more prone to produce unilateral disease, which occurred nearly 60 percent of the time compared with 35 percent of the time in MAC or *M. tuberculosis* infection. Typically, disease begins in the posterior portions of the upper lobes. Progression to cavitary disease occurred in 87 percent of patients with *M. tuberculosis* and MAC infections and in 96 percent of patients with *M. kansasii* infection. Rare case reports of mediastinal mass lesions in children caused by nontuberculous mycobacteria have been published.[48]

Hilar and mediastinal adenopathy was an uncommon finding, particularly with MAC (4%) and *M. kansasii* (0.5%). Pleural effusions were rare, occurring in 6 percent of patients with MAC and 4 percent with *M. kansasii*. Treatment at that time generally

involved three to four courses of drug therapy, including regimens of isonicotinic acid hydrazide, *p*-aminosalicylic acid, streptomycin, and rifampin. The American Thoracic Society recommends a four-drug regimen for MAC pulmonary infection in adults: isoniazid (300 mg), rifampin (600 mg), ethambutol (25 mg/kg for 2 months, then 15 mg/kg), and streptomycin (0.5 to 1 g five times each week for 8 to 12 weeks, then 0.5 to 1 g two or three times each week for 3 months, as tolerated).[177] Drugs are administered for 18 to 24 months, with a minimum of 12 months of culture negativity required while receiving therapy. A previous clinical investigation revealed success rates of 25 to 80 percent, and the best response rate was noted with a three-drug regimen of ethambutol, ethionamide, and cycloserine.[44] Resectional surgery seemed to have poor outcomes. For *M. kansasii* pulmonary infection, the American Thoracic Society recommendations include isoniazid (300 mg/day), ethambutol (15 mg/kg/day), and rifampin (600 mg/day) for 18 months in adults.

Patients with cystic fibrosis have been noted to have an increased incidence of infection with nontuberculous mycobacteria. Prevalence rates of 2 to 20 percent have been reported.[3,67,68,84] A study from France involving children aged 1 to 18 years old indicated that mycobacterial species were isolated from 6.6 percent of routine sputum samples, and that 1.9 percent had documented mycobacterial lung infection.[47] Mycobacterial infections are seen more commonly in older patients with cystic fibrosis. Frequent intravenous antibiotic use is a possible risk factor for colonization with nontuberculous mycobacteria.[166] Organisms most commonly found are MAC, *M. kansasii*, *M. fortuitum*, and *M. chelonae*. *Mycobacterium abscessus* has emerged as a clinically persistent pathogen in patients with cystic fibrosis, especially patients on steroid therapy for allergic bronchopulmonary aspergillosis.[46,116] Bacterial contamination, particularly with *Pseudomonas aeruginosa*, of the acid-fast bacilli cultures from patients with cystic fibrosis has been a major problem that has rendered isolation of mycobacteria more difficult.[150] Another confounding problem is the difficulty in differentiating infection from colonization in these patients.[84]

The American Thoracic Society recommends radiographic changes, isolation of multiple colonies of the same species, and the absence of other potential pathogens as criteria for the diagnosis of pathogenic infection with nontuberculous mycobacteria.[2] Discernment is even more difficult in the setting of the chronic lung disease seen in patients with cystic fibrosis. Kilby and associates[84] suggest that repeated isolation of nontuberculous mycobacteria associated with pulmonary cavities or infiltrates that do not improve with aggressive standard antibacterial treatment could indicate active mycobacterial disease in patients with cystic fibrosis.

M. xenopi has been described in adults as a cause of infection of the pulmonary tract.[148] The mean age at infection was 62 years, and it occurred in a mainly Canadian population. Eighty-six percent of the patients had underlying pulmonary pathology, including chronic obstructive pulmonary disease, previous pulmonary tuberculosis, carcinoma of the lung, sarcoidosis, and cystic fibrosis. Additionally, a case was reported of a 7-year-old boy with leukemia in whom pneumonia with *M. xenopi* developed and was treated successfully with 2 years of therapy that included ethambutol and clarithromycin.[95]

Mycobacterium simiae has been isolated in adults with underlying pulmonary abnormalities.[10,88] *M. simiae* is the most drug-resistant of all the nontuberculous mycobacteria. Some isolates are resistant even to all drugs tested.

Mycobacterium szulgai has been described in several case series as a cause of lung disease.[106,180] Disease occurred in elderly white men and resembled chronic tuberculosis. Therapeutic regimens effective against *M. avium* seemed to provide good clinical outcomes.

SKIN INFECTIONS

Mycobacterium marinum

M. marinum is photochromogenic and was identified as a pathogen in fish in 1926 by Aronson.[100] The skin lesions usually result from light trauma (abrasions) in swimming pools or other bodies of water when the surfaces of the pool are colonized by *M. marinum*.[34,113] Fish tanks also have been implicated and generally involve the upper limb or a finger.[8,162] Most cases occur in children aged 10 to 16 years old. The most common sites are the elbows, knees, and ankles. Cooler superficial portions of the body are affected most frequently. Other exposed body areas can be involved, depending on what part of the body has made contact with the surface containing the mycobacterium (e.g., the nose in divers).[114] Regional spread of lesions has been reported.[154]

The incubation period from exposure to formation of a small indurated area that ulcerates generally is 3 weeks. The lesion then crusts and forms a granuloma with a small crater. The lesions usually are painless and resolve in several months; occasionally, they can last longer. In contrast to other mycobacterial diseases, regional nodes are not involved.

Infection with this organism usually is benign. A main consequence is, however, that patients with *M. marinum* infection frequently have conversion of their PPD-T test to positive.[100] The natural reservoir for *M. marinum*, which requires a cool incubator (32° C), is in fish and other cold-blooded animals. Generally, only a few organisms may be isolated in some granulomas.

Treatment of *M. marinum* has been successful with rifampin and ethambutol,[171,190] and one report showed good results with rifampin alone.[40] An accompanying editorial cautioned against the use of rifampin alone, however, and recommended using rifampin with ethambutol.[17] The duration of therapy, according to the literature, varies from several weeks to 18 months. Generally, response to therapy is rapid, and treatment should be continued for 4 to 6 weeks after clinical resolution.[40]

Mycobacterium ulcerans

In 1948, MacCallum[105] reported the first cases of disease caused by *Mycobacterium ulcerans*. Most cases since then have occurred in remote, tropical, or subtropical areas of the world, including parts of Africa and Australia.[104,130] In a 1-year period, 23 cases of Buruli ulcer caused by *M. ulcerans* occurred in Lambarene (Gabon).[19] Cases also have been reported in Mexico.[100] The natural reservoir for *M. ulcerans* is unknown, although one report suggests the spines of a tall prickly grass known as *Echinocloa pyrimidalis*.[155] The lesions caused by *M. ulcerans* occur mainly on the cooler superficial portions of the body. Patients harboring this organism are in otherwise good health without underlying immunodeficiency.[27] Scraping of the skin by thorns or pieces of wood has been implicated as the route of inoculation in many of the cases. The organism is very fastidious, with growth seen only between 30° C and 35° C.

The incubation period for this painless infection also is approximately 3 weeks. Regional lymphadenitis rarely occurs with this organism. The infection has three distinct stages, and knowledge of them can be helpful in making the diagnosis and providing treatment. The disease begins as a hard, mobile nodule. It frequently is associated with pruritus, and in Zaire is termed *mputa matadi* (the itching stone). This stage is known as the preulcerative stage.

In some patients, the infection resolves on its own, but in others, it progresses to the ulcerative stage. In contrast to *M. marinum*, in which the lesions are short-lived and do not progress past the ulcerative stage, the lesions of *M. ulcerans* usually last 6 to 9 months and frequently progress and lead to deformities of

limbs that may require amputation.[100] The organisms can be isolated in large numbers from the periphery of ulcers adjacent to normal tissue, which again contrasts with infection by *M. marinum*, in which very few organisms are found in the lesions.

The infection generally involves subcutaneous adipose tissue and leads to areas of fat necrosis, which then proceeds to overlying necrosis of the adjacent skin. The lesions can become enormous, sometimes involving a complete limb. Although numerous organisms are seen in the progressing edge of the infection, little evidence of a cellular immune response is apparent. Additionally, anergy to skin reagents prepared from *M. ulcerans* (burulin) frequently is noted at this stage.[156] Finally, the next stage, called the *reactive phase*, is reached. Cellular infiltrates with granuloma formation occur in the lesion. The number of organisms in the lesion decreases dramatically, and a positive skin test reaction develops to the burulin. Infection with *M. ulcerans* also can cause conversion of a patient's PPD response to positive; however, conversion is seen in only approximately 50 percent of cases.[27] Finally, healing may occur, but with fibrosis left in its wake.

Treatment of *M. ulcerans* infection is anecdotal at best. Treatment choices are based on the stage of infection. Lesions in the pre-ulcerative stage are best treated with excision and primary closure.[57] Successful therapy in the anergic progressive stage is considered the most difficult and involves appropriate antimycobacterial therapy for the infection. Success has been reported with isonicotinic acid hydrazide and streptomycin or diaminodiphenylsulfone and oxytetracycline combinations[27] and sulfamethoxazole, rifampin, minocycline,[153] and clofazimine.[104] In the final stage, healing should be promoted with as little deformity or loss of function as possible, the use of skin grafting and splinting, and excision of fibrous tissue.[57,130] Disseminated infection in an immunocompetent child along with the development of multifocal osteomyelitis has been described.[69] (See also Chapter 109.)

Other Mycobacteria in Skin Disease

M. haemophilum has produced painful subcutaneous nodules in immunocompromised patients, particularly patients with renal transplants.[36,188] In addition, *M. haemophilum* has produced disseminated disease, including bacteremia, osteomyelitis, and pulmonary disease, in immunocompromised patients.[160] *M. chelonae* has been found to be a cause of disseminated cutaneous infection.[175] Steroid use is the predisposing factor for infection with this organism. *M. fortuitum* has been implicated in cutaneous lesions in a child involved in a motor scooter accident, with the subsequent development of lesions at the site of knee lacerations; regional adenopathy of the inguinal nodes also developed.[146] *M. fortuitum-chelonae* complex has been responsible for superficial skin abscesses in children.[13] *M. fortuitum* in adult studies also has been implicated in severe infections in immunocompromised hosts; these infections usually are rapidly disseminating, with high mortality.[188] *M. avium* has been isolated from an eyelid abscess with drainage.[143] Treatment of cutaneous disease caused by these organisms is difficult at best. Four- or five-drug therapy has been tried, but with poor results.

ORGANISMS SEEN IN CHILDREN

Specific organisms and treatment guidelines are discussed in the following sections. Table 108–3 provides a quick guide to some of the more commonly used antimycobacterial agents.

MYCOBACTERIUM AVIUM–INTRACELLULARE COMPLEX

MAC consists of *M. avium* and *M. intracellulare*. These organisms are slow-growing, obligate aerobes that require 2 to 6 weeks for colony formation on solid media. Colonies usually are smooth but may be rough and can be transparent or opaque. These organisms grow on routine bacterial media, but growth is achieved best on selective mycobacterial media, such as Löwenstein-Jensen medium or Middlebrook 7K10 and 7K11 agar. Nucleic acid hybridization probes using target sequences of ribosomal RNA are available commercially for rapid identification of clinical isolates.[99,115] MAC infection is diagnosed most commonly by culture of blood or bone marrow.

TABLE 108–3 Antimycobacterial Agents*

Drug	Dosage	Form
Amikacin (A)	15-20 mg/kg/day divided q8h	IV or IM
Azithromycin (Z)	500 mg bid (adults/adolescents); 10-12 mg/kg/day (children)	PO
Cefoxitin (X)	80-160 mg/kg/day divided q4-6h	IV or IM
Ciprofloxacin (C)	20-30 mg/kg/day divided q12h (adults only in U.S.)	PO or IV
Clarithromycin (CL)	15-30 mg/kg/day divided q12h	PO
Clofazimine (CLO)	1-2 mg/kg/day	PO
Doxycycline (D)	2-4 mg/kg/day divided q12h (>8 yr old)	PO, IV
Ethambutol (ETB)	15-25 mg/kg/day	PO
Ethionamide (ETH)	10-20 mg/kg/day divided q12h	PO
Isoniazid (I)	10-14 mg/kg/day	PO
Pyrazinamide (PZA)	15-30 mg/kg/day	PO
Rifabutin (RIB)	5-10 mg/kg/day; maximum of 300 mg/day (adults)*	PO
Rifampin (RIF)	10-20 mg/kg/day divided q12-24h	PO or IV
Streptomycin (S)	20-30 mg/kg/day	IM

Infections
Disseminated MAC: HIV infected: CL (or Z) + ETB (± RIB)
Disseminated MAC: HIV-negative, immunocompromised: RIF + ETB + INH + S or A
Mycobacterium abscessus: CL alone or A alone
Mycobacterium chelonae: A ± CLO or CL alone
Mycobacterium fortuitum: A + X + probenicid or A + C + sulfonamide
Mycobacterium kansasii: RIF + ETB + I
Mycobacterium marinum: ETB + RIF, or D or TMP-SMX

**Not approved for use in children.*
HIV, human immunodeficiency virus; MAC, M. avium complex; TMP-SMX, trimethoprim-sulfamethoxazole.
Data based on references 60, 73, 97, 98, 136, 171, 177, 179, 188, and 190.

In a study of 56 isolates from pediatric patients involving sequence analysis of the ribosomal internal transcribed spacer, Hazra and colleagues[66] showed that the closely related Mav-B and Mav-A sequevars caused most disease. Patients from geographically diverse areas of the United States (Boston, Miami, and Los Angeles) had isolates with closely related patterns. The finding of related strains causing disease in epidemiologically unrelated patients is most consistent with two hypotheses: a similar subset of *M. avium* strains is more virulent and more likely to cause disease in humans, and pathogenic strains are more prevalent in the environment.

M. avium was recognized in 1890 as the causative agent of disease in chickens.[188] *M. intracellulare* was designated in 1967 and at the time was difficult to distinguish routinely from *M. avium*-thus the name *M. avium-intracellulare*. Today, with the use of DNA probes, most seroagglutination types have been discerned between the two groups. *M. avium* is the most common nontuberculous mycobacterium causing disease in humans, but isolates from environmental sources are more likely to be *M. intracellulare*. Both organisms can be found in birds, soil, dust, and fresh or salt water. Infections caused by MAC strains isolated from adult patients with AIDS could be identified as either serotype 4 or 8, in contrast to patients without AIDS, in whom no predominant serotype has been identified.[83,192] Nearly all isolates of MAC from patients with AIDS have been identified as *M. avium*; in patients without AIDS, the rate of *M. avium* is approximately 55 percent, and the rate of *M. intracellulare* to 32 to 40 percent.[60,192]

Lung disease has been the major manifestation of MAC infection in nonimmunocompromised adults. Most investigators thought that MAC infection occurred mainly in patients with deficient immunity or underlying lung disease. Later reports seemed to indicate, however, that normal adult hosts are at risk for development of infection with MAC, and that rates are increasing.[76,126] Case reports involving children are lacking in detail because they usually appear within discussions of adult patients.[128]

Pediatric case reports of disseminated disease caused by MAI/MAC have appeared in the literature. Children have had ulcerative lesions of the colon[33]; mesenteric disease with abscess formation[143]; hematogenous spread to the liver, spleen, kidneys, and adrenal cortex; lesions of the epididymis[151]; bone lesions[174]; and skin lesions. Disseminated osteomyelitis rarely is caused by nontuberculous mycobacteria, but if it occurs, *M. intracellulare* most commonly is isolated.[25,86] Septic arthritis also has been reported in association with osteomyelitis.[51] Immunocompromised patients with disseminated MAI infection historically require multiple-drug therapy, including a combination of isoniazid, ethambutol, clofazimine, and rifabutin.[97] Some reports indicate, however, that disseminated disease in HIV-infected patients may respond to only two agents, as mentioned earlier in the AIDS section. The addition of other agents may be necessary because of the high incidence of resistant organisms. A preliminary report showed that interferon-γ may be effective when combined with conventional therapy in some patients who are refractory to standard chemotherapy alone.[71]

Bacterial peritonitis is a common occurrence in patients regularly undergoing ambulatory peritoneal dialysis for chronic renal failure. Reports of nontuberculous mycobacteria causing peritonitis have been noted.[63,122,184] In cases involving nontuberculous mycobacteria with foreign bodies, such as Tenckhoff catheters, the development of infected sinus tracts is frequent. Additionally, antituberculous drug regimens in these cases generally are unsuccessful. Although the mycobacteria were sensitive to the agents used, the patients continued to have sinus tract drainage without improvement, even after removal of the foreign body.

MYCOBACTERIUM SCROFULACEUM

M. scrofulaceum has many characteristics similar to *M. avium* and *M. intracellulare* and can be found in soil, water, and dairy products. This organism is associated most commonly with lymphadenitis in children 1 to 5 years old and rarely causes other manifestations in humans. Skin and bone lesions have been reported in two children chronically infected with *M. scrofulaceum* for 10 years.[43,181] Few data are available on chemotherapeutic agents for treatment of infection with this organism. Based on susceptibility patterns, three or more drugs may be necessary for treatment of serious disease. Lymphadenitis can be cured with complete excision of the lymph node.

MYCOBACTERIUM KANSASII

Of the photochromogens, *M. kansasii* is the one most commonly isolated in humans. In contrast to MAI and *M. scrofulaceum*, *M. kansasii* rarely is isolated in soil, but has been cultured from water and milk.[22,23] Chronic pulmonary infection is the most common manifestation of this disease and is seen mainly in adults, particularly adults with AIDS. A survey from Israel of 56 adults with *M. kansasii* pulmonary infection showed that 64 percent occurred in men, 59 percent had underlying lung disease, and none were HIV-infected.[145] Pulmonary disease occurs infrequently in children. Some children have a course similar to that of adults, with underlying pulmonary disease caused by previous tuberculosis or chronic pulmonary disease.[12,112] In contrast, other children have acute symptoms of classic bacterial pneumonia with an abrupt onset of fever and sputum production and lung consolidation on physical examination and radiographs.[12,21] Pleural effusions also can occur.

In contrast to some other nontuberculous organisms, *M. kansasii* is sensitive to most of the antituberculous drugs, particularly rifampin. Most authorities recommend the use of three drugs, including rifampin, isoniazid, and ethambutol. The treatment course usually requires a minimum of 12 months, with therapy for 24 months needed in some patients. A study of 18 patients showed that thrice-weekly clarithromycin, ethambutol, and rifampin was effective, with a mean follow-up of 46 months.[58] Patients with AIDS and *M. kansasii* infection have responded to this three-drug regimen, but the total duration of therapy is unknown at this time. In children with AIDS, the diagnosis of *M. kansasii* infection is rare, and the clinical response to therapy has been poor.[73] Cases have been reported in other immunocompromised children, including a 7-month-old boy from Texas with disseminated *M. kansasii* infection and numerous organisms found in his spleen at autopsy.[111] *M. kansasii* also has been reported to cause meningitis; the patients died despite the use of antimycobacterial therapy.[75,140]

MYCOBACTERIUM MALMOENSE

Buchholz and coworkers[18] reviewed infections with *M. malmoense* in the United States from 1993 to 1995. Only one of 73 patients was younger than 10 years. This patient had cervical lymphadenitis and was cured with surgical excision alone. This organism, which frequently is overlooked on standard Löwenstein-Jensen egg medium, grows at 25° C to 37° C. The organism is slow growing, and it may require 8 to 12 weeks for colonies to become visible on solid media. The BACTEC system was shown to be superior in isolating *M. malmoense* in one study of children with lymphadenitis.[70] Bone marrow involvement also was described in a patient with chronic granulocytic leukemia.[45] The aforementioned study by Buchholz and colleagues[18] showed that prolonged combination therapy with isoniazid, rifampin,

ethambutol, and pyrazinamide after surgical excision was effective in some cases.

MYCOBACTERIUM CHELONAE AND *MYCOBACTERIUM FORTUITUM*

M. chelonae is the most important rapidly growing pathogenic mycobacterium, but its taxonomy is quite confusing.[56] Since Grange[56] made a presentation in 1981, the organism's taxonomy has continued to be in flux. The *M. chelonae* group consists of *M. chelonae* (formerly *M. chelonae* subsp. *chelonae*), *M. abscessus* (formerly *M. chelonae* subsp. *abscessus*), and a third biovariant known as *M. chelonae*–like organisms.[92] The *M. fortuitum* group consists of *M. fortuitum*, *Mycobacterium peregrinum*, and a third unnamed biovariant.[92] *M. fortuitum* is associated closely with *M. chelonae*. The two groups can be differentiated on the biochemical basis of nitrate reduction and iron uptake. Wallace and associates[175] have provided the largest series of patients with skin, soft tissue, and bone involvement with *M. chelonae*. Steroid use seemed to be the factor associated most commonly with the development of disease.

M. fortuitum and *M. chelonae* have been implicated in sternal wound infections and endocarditis and have occurred in outbreak-type settings.[91,136,163] Patients responded to surgical débridement and amikacin with cefoxitin. A case series from Hong Kong reported successful treatment of *M. fortuitum* sternotomy infections with the use of single daily dose ofloxacin as monotherapy in three patients.[194] Adult renal transplant patients also have been described with skin and subcutaneous tissue involvement caused by *M. chelonae*.[31] *M. chelonae*, likewise, has been described as an etiologic agent for otitis media, probably from contamination of ear, nose, and throat instruments with colonized water sources.[103]

M. abscessus, as stated earlier, is related closely to *M. chelonae* and should be designated as a separate species.[92] Manifestations of infection with this organism usually are related to pulmonary, cutaneous, or disseminated infections.[178] Clarithromycin may be effective for *M. chelonae* infection.[179] Maxson and associates[110] reported a case of osteomyelitis caused by *M. abscessus* that was controlled with long-term clarithromycin monotherapy.

Mycobacterium smegmatis, which resembles *M. fortuitum* except for the absence of a positive 3-day arylsulfatase test result, is a rapid grower that is responsible for skin and soft tissue infections.[176] A case of disseminated infection has been reported in a child with inherited interferon-γ receptor deficiency.[123]

Mycobacterium septicum is a newly described, rapidly growing species associated with catheter-related bacteremia.[142] It resembles *M. fortuitum* and *Mycobacterium senegalense*.

OTHER SITES OF INFECTION

Carpal tunnel syndrome in adults has been reported as being caused by *M. szulgai*, an uncommon scotochromogenic mycobacterium.[159] Effective treatment included débridement, ethambutol, and rifampin. Other infections in humans include choroiditis,[29] panniculitis,[139] genitourinary tract infection,[15,164] and synovitis.[161] Ear infections with nontuberculous mycobacteria also have been reported, as has mastoiditis.[49,119,158] More recently, infection of Broviac catheters in pediatric patients with leukemia and hemodialysis catheters has been described.[24,95] In all cases, removal of the catheter was required for resolution of the infection.

With the continued proliferation of immunocompromised patients because of AIDS and new treatment modalities that induce an immunocompromised state (e.g., organ transplantation, new immunosuppressive drugs), the atypical mycobacteria probably will continue to remain important pathogens. With newer isolation techniques and new technology such as DNA probes, the ability to diagnose these infections and understanding of the pathogenesis of the infections that these organisms produce should improve, as should the ability to treat these infections.

CHAPTER 109

Leprosy and Buruli Ulcer: The Major Cutaneous Mycobacterioses

Wayne M. Meyers ✪ Douglas S. Walsh

Mycobacterial infections in humans date to at least the 10th millennium BCE. Bartels[15] in 1907 detected convincing evidence of tuberculosis in a Neolithic skeleton found near Heidelberg, Germany, and Ruffer[263] in 1910 noted Pott disease in an Egyptian mummy from approximately 1000 BCE. The origins of mycobacterial infections in humans are unknown, but most authorities speculate that domestication of animals in the Neolithic era promoted the transmission of mutants of *Mycobacterium tuberculosis* from livestock to humans. The origins of leprosy and Buruli ulcer and their respective etiologic agents are understood less well but may involve interplay among environmental mycobacteria, animals, and humans.[273] After tuberculosis, leprosy and Buruli ulcer are the second and third most common mycobacterial infections in humans. Leprosy and Buruli ulcer are the two most common cutaneous mycobacterioses.

Tuberculosis and other cutaneous mycobacterial infections are discussed in Chapters 107 and 108. This chapter is devoted to the two cutaneous mycobacterioses that are of greatest medical importance: leprosy and Buruli ulcer.

LEPROSY

Leprosy is a chronic infectious disease that is caused by *Mycobacterium leprae* and that principally affects the cooler parts of the body, especially the skin, upper respiratory tract, testes, eyes, and superficial segments of peripheral nerves.[27] Although leprosy has affected nearly every part of the world at some time, its geographic origin is only now being unraveled.[210]

The World Health Organization (WHO) reported that in 1999, approximately 800,000 patients were being treated for active leprosy and that also in 1999, 738,000 new patients were reported.[349] By 2005, the numbers had decreased to 220,000 and 296,000.[352] Many authorities consider that the total global prevalence of patients with active leprosy is much higher (1.5 to 2 million), however, and that new case rates are not rapidly declining.[11] Several more million patients experience serious sequelae.[168]

In the Middle Ages, leprosy was common in Europe and may have been transported to the Western Hemisphere by Portuguese and Spanish explorations beginning in the 15th century and later by slaves from Africa. At least two foci in the United States were established in the 19th century by specific immigrations: Asians brought leprosy to the Hawaiian Islands and started an epidemic in the highly susceptible Hawaiians[213] and Scandinavians introduced leprosy into the northern Midwest region of the United States.[178]

Patients with leprosy frequently experience severe stigmas, and, in Western cultures, this is attributable at least partially to a misunderstanding of what is called leprosy in the Old Testament.[28] Other cultures not influenced by Judaic laws and traditions have similar or more severe attitudes toward patients with leprosy. The Chinese literature indicates that in the 8th century BCE, patients with symptoms now recognized as symptoms of leprosy were stigmatized.[288] Because of enduring irrational attitudes based on the premise that relevant Old Testament references are to the same single disease now called leprosy, a brief explanation of "Old Testament leprosy" follows.

The Hebrew word *tsara'ath* was rendered *lepra* when the Old Testament was translated into Greek in the 3rd and 2nd centuries BCE. In preparing the Latin Vulgate version in AD 405, Jerome used the word *lepra* directly from the Greek. In the first English translation from the Vulgate in 1384, Wycliffe translated *lepra* as *leprosy*, perhaps because leprosy, then common in Europe and Great Britain, seemed to portray an image of an unholy and loathsome human condition. In the original text, *tsara'ath* was not a specific disease but probably a group of diseases, the identities of which are obscure, and the word more generally referred to ceremonial uncleanness. Old Testament *tsara'ath*, as described, for example, in Leviticus 13 and 14, had none of the distinctive clinical features of leprosy.

No rationale exists for attitudes toward leprosy that are based on Old Testament *tsara'ath*. Continuing efforts must be made to minimize the stigma peculiarly associated with leprosy. To help achieve this goal, the Fifth International Leprosy Congress in 1948 adopted a resolution to abandon the word *leper* for leprosy patient.[166] Some physicians prefer Hansen disease as a synonym for leprosy. Because of the stigma of leprosy, physicians must consider carefully the social implications of a diagnosis of leprosy, especially in children.

ORGANISM

M. leprae is a species in the order Actinomycetales and the family Mycobacteriaceae. This bacillus was seen first by Hansen in 1873 in Bergen, Norway, in lepromas from Norwegian patients, and this organism was the first reported bacterium causing chronic disease in humans.

M. leprae is an acid-fast bacillus (AFB) 0.3 to 0.5 μm wide by 4 to 7 μm long. The acid-fastness of *M. leprae* is weaker than that of other mycobacteria, but as in other mycobacteria, the acid-fastness is related to mycolic acid in the cell wall.[14] Viable, undamaged *M. leprae* organisms stain solidly, but degenerating bacilli first stain irregularly, then become granular, and eventually lose acid-fastness completely. The persistence of bacillary carcasses can be verified by silver staining techniques.[323] Staining quality provides a rapid method for determining the effectiveness of therapy. In vitro cultivation of *M. leprae* frequently is claimed, but all claims have been refuted or are as yet unsubstantiated.[152,256] Because *M. leprae* still cannot be cultivated, identification depends on criteria other than those used routinely for cultivable mycobacteria. Current criteria for *M. leprae* are the following: (1) It does not grow on routine laboratory media, (2) it infects the footpads of mice in a characteristic manner,[167,280] (3) acid-fastness is extractable with pyridine,[47] (4) the organism invades nerves of the host, (5) suspensions of dead bacilli produce a characteristic pattern of reactions when injected into the skin of patients (lepromin reaction) with the various clinical forms of leprosy, (6) it produces the species-specific antigen phenolic glycolipid-1 (PGL-1),[94] and (7) it exhibits species-specific DNA sequences.[344]

Electron micrographs of *M. leprae* reveal a cell wall 15 to 20 nm thick around a cytoplasmic membrane that gives rise to mesosomes extending into the cytoplasm. *M. leprae* divides by transverse fission. Its cell walls contain arabinogalactan, mycolates, peptidoglycan, and protein.[185]

The genome of *M. leprae* is small (3,268,203 base pairs) compared with that of *M. tuberculosis* (approximately 4.4 million base pairs).[41] Gene deletion and decay have markedly limited the metabolic activities of *M. leprae* and may contribute significantly to failure to cultivate the organism and to its long generation time in the mouse footpad (14 days).[25,76] In suitable hosts, the generation time of *M. leprae* has been speculated to be considerably shorter than 14 days.[117] Very young infants may have highly bacilliferous leprosy.[30,103] Localization of infections to the cooler parts of the body,[23] selective growth in the footpads of immunologically intact mice and in the ears of hamsters, and the high susceptibility of the armadillo (central body temperature of 32° C to 35° C [89.6° F to 95° F]) to disseminated infections all suggest that the optimal temperature for growth of *M. leprae* is less than 37° C (98.6° F).[189]

TRANSMISSION

The modes of transmission of *M. leprae* in nature have not been fully established. The frequency in children of a single early lesion in skin that usually is covered by clothing argues against the development of such lesions at the site of contact with *M. leprae*.[16] For many years, skin-to-skin contact between the patient and healthy subjects was considered the most important means of transmission, and this concept cannot be abandoned readily.[165] Intact skin of heavily infected patients discharges a few *M. leprae*, but ulcers in the skin may be a source of numerous bacilli. Skin-to-skin contact and fomites containing *M. leprae* could be sources of infection, but this mode has been minimized in recent years in favor of the nasorespiratory route.

That the nasal mucosa of lepromatous patients harbors massive numbers of *M. leprae* has been known since Hansen's original discovery, and studies suggest that the respiratory passages could be an important source of infecting bacilli.[66] *M. leprae* may bind to nasal mucosal cells by first binding fibronectin and attaching to fibronectin receptors on mucosal cells.[35] *M. leprae* organisms ejected in nose blowing remain viable under ambient conditions

for 1 week,[58] and disseminated leprosy develops in immunosuppressed mice after the inhalation of aerosol that contains *M. leprae*.[250] Breast tissue and milk from lepromatous patients contain *M. leprae*, and infants may acquire infection from this source.[230]

Placental transmission of leprosy has been a subject of conjecture for some time, but evidence is growing for a significant influence of leprosy on fetal development and for intrauterine infection of the fetus. In a study of 116 pregnant leprosy patients in Ethiopia, the placentas were small, birth weights were low, and growth rates of the infants were retarded.[72] Mean birth weights of infants of lepromatous and healthy control mothers were 2558 and 3280 g. Estrogen excretion levels at 32 to 40 weeks' gestation are reduced in patients with leprosy, which suggests fetoplacental dysfunction.[74] Immunoglobulin A (IgA) and IgM antibodies for *M. leprae* are present in the cord blood of 30 to 50 percent of infants delivered by mothers with lepromatous leprosy.[186] Evidence is strong for synthesis of fetal antibodies to *M. leprae* or antigens thereof. Occasionally, *M. leprae* has been shown in placentas and cord blood.[127,313] *M. leprae*–specific IgA and IgM levels increased in infants of lepromatous mothers during the 3- to 24-month period after birth,[187] and two such infants had clinical leprosy at 9 and 17 months of age.[73]

Leprosy in young infants may be a common occurrence in areas of high endemicity.[103] In a report combining cases on file in the Leprosy Registry at the Armed Forces Institute of Pathology, cases cited in the literature, and personal observations by experienced leprologists, a total of at least 49 patients with leprosy younger than 1 year of age were identified.[30] In only half of these infants did the mother have leprosy or a history of leprosy. The youngest infant was 2.5 months old at the time the diagnosis was established. The fact that many of the mothers never had clinical leprosy suggests that they had an evanescent *M. leprae* bacteremia during gestation. A substantial bacteremia is a common finding in multibacillary disease[70,159] and is detectable in 15 percent of paucibacillary patients.[153]

The discoveries of a naturally acquired leprosy-like disease in recently captured wild armadillos in Louisiana,[331,333,334] chimpanzees,[69,107] a mangabey monkey from West Africa,[200] and a cynomolgus macaque from the Philippines provide reason to consider that leprosy is a zoonosis.[191,314,332] Reports of naturally acquired leprosy in armadillos range from 3 to 53 percent in the southern region of the United States.[137,305-307] In all these species, the histopathologic features resemble those in leprosy in humans, and the bacilli that cause the infection cannot be distinguished from *M. leprae*.[22,192,199] Leprosy has been transmitted successfully from the mangabey monkey to other mangabey, rhesus, and African green monkeys.[139,346]

Some authorities suggest that insects may ingest *M. leprae* during a blood meal from lepromatous patients and harbor viable bacteria. The natural transmission of leprosy by insects remains unproved, however, and generally is disregarded.

EPIDEMIOLOGY

The highest prevalence rates of leprosy are found in tropical Africa, South America, and Southeast Asia. Approximately 73 percent of all patients live in Southeast Asia (65% in India), 12 percent live in Africa, and 8 percent live in the Americas.[27] Based on limited whole-population surveys in endemic areas, the total number of active patients may exceed the number reported by WHO by a significant margin. The stigma of the disease and inefficiency in health care delivery systems contribute to this disparity in statistics.[164] In 1995, approximately 6000 patients with a history of leprosy resided in the United States,[129] with 101 new patients (L. Pfeifer, National Hansen's Disease Programs, Baton Rouge, LA, personal communication) reported in 1998, down from an annual high in recent times of 361 in 1985.

Most patients in the United States are immigrants, but a few indigenous patients regularly come from Hawaii, Louisiana, Texas, and other southeastern states.[160] No instances of secondary transmission from imported cases within the United States have been reported; immigrants with leprosy present no known public health risk to the population of the United States. The same situation probably is true for other nonendemic countries that receive many immigrants from endemic areas.

Hansen's discovery of the leprosy bacillus developed from his conviction that leprosy was a specific contagious disease, based on clinical and anatomic findings and, more importantly, on epidemiologic observations. In 1871 and 1872, he studied 69 families in western Norway in which several members had leprosy. The prevailing concept of that era was that leprosy was hereditary, but from data gathered on these families, Hansen showed that patients always had contact with another leprosy patient. Members of the same families with no such contacts were free of leprosy.[114] Hansen reasoned, after his pioneering observation of the leprosy bacillus in 1873, that the spread of leprosy depended on dissemination of this etiologic agent in a susceptible population.

The leprosy epidemic in Nauru in the central Pacific area shows how rapidly leprosy can spread in a leprosy-naive population.[108] Leprosy was introduced into this small island in 1912, and by 1924, one third of the 2500 inhabitants had leprosy.

The prevailing concept has been that an individual becomes infected only after experiencing repeated exposure. This concept now is doubted, and a single exposure may be sufficient in optimal conditions. One report describes leprosy transmission occurring after a single exposure from a patient to a surgeon who practiced in a leprosy non-endemic area.[2] In any patient-contact situation, the number of viable *M. leprae* being shed by the patient and the degree of susceptibility of the contact both may vary. Long periods of association may be necessary before optimal conditions for infection exist.

Lymphocyte transformation studies show that occupational contacts of leprosy patients in Ethiopia have the highest rate of sensitization (58%) to *M. leprae*, followed closely by household contacts (47%). Noncontacts living in endemic areas have a lower rate of sensitization, but approximately 29 percent of the population still is sensitized.[104]

Geographic, ethnic, and socioeconomic factors may contribute to the spread of leprosy by affecting the number of untreated or ineffectively treated bacillary-positive patients and the opportunities for exposure. The percentage of patients who harbor large numbers of bacilli—generally, patients with lepromatous leprosy—is related to ethnic background. In some Asian populations, 50 percent or more of patients with leprosy have lepromatous leprosy; in Africans, this figure is 5 to 10 percent. Socioeconomic factors are difficult to assess, and their relationship to the prevalence or clinical severity of leprosy is unknown. Nutritional status may or may not be important. The Nauru leprosy epidemic, indolent from 1912 through 1920, became rampant after a devastating epidemic of influenza (30% mortality) left a debilitated population with marked dietary deficiencies. During the next 4 years, the incidence of leprosy increased from 4 to 346 patients, but the role played by malnutrition is obscure.[108] Ryrie[264] in Malaya noted that during the Japanese occupation, the severity of leprosy worsened, which he attributed to a combination of malnutrition and psychic trauma. Skinsnes and Higa[289] drew similar conclusions from a study of mortality in leprosaria in China during World War II. Nonetheless, convincing evidence that the prevalence of leprosy is unusually high in chronically malnourished populations is lacking.

Improvements in housing and other living conditions may play a role in the declining prevalence of leprosy. No other factor satisfactorily explains the virtual disappearance of leprosy from northern Europe after the Middle Ages and from Scandinavia in

the 20th century, long before any effective chemotherapy was available. If the disease is predominantly airborne, the construction of dwellings that provide less confined sleeping quarters in this era could have contributed in a major way to the disappearance of leprosy in northern Europe and Scandinavia. Consistent with this concept is the inadequate housing that prevails in all geographic areas in which leprosy is common today.

The presumed increased susceptibility of children is difficult to establish and may depend more on exposure to contagious patients and genetic predisposition than on other factors. The proportion of children among all detected patients is 20 to 30 percent.[95,222] Of the 615 known patients who were diagnosed in Louisiana between 1855 and 1970, 5 percent had disease onset at 0 to 9 years of age, and 19 percent were in the 10- to 19-year-old age group.[84] Lara,[162] in a study of 2000 children who lived in a leprosarium in the Philippines in an era when effective chemotherapy was unavailable, noted that leprosy developed in 470 (23%). Of these 470 patients, 254 were monitored closely, and in approximately 75 percent, the lesions healed spontaneously. Active, persistent disease developed in approximately 6 percent of the children who were heavily exposed to leprosy. In most populations studied, only 5 to 10 percent of individuals are susceptible to leprosy.

In adults, leprosy occurs more commonly in men than in women (2:1 to 3:1). In children, the sex ratio is approximately 1:1.

Genetic factors likely influence the susceptibility of some individuals to leprosy and the form of disease that develops.[27,85,88,89,282] Earlier studies found that if one twin has leprosy, the chance of leprosy developing in a monozygotic twin is 60 to 85 percent versus a 15 to 25 percent risk for dizygotic twins.[115] More recently, genome screening in Indian patients found an association with leprosy susceptibility on chromosome 10p13, near the gene for mannose receptor C, a phagocytic receptor on macrophages, and on chromosome 6, within the major histocompatibility complex (MHC).[284] Within the MHC, associations exist between leprosy and MHC class II genes in Indian patients, and with the tumor necrosis factor (TNF) gene in Brazilian patients.[279] Polymorphisms in the "promoter regions" of the interleukin-10 (IL-10) and TNF genes are associated with leprosy,[268] and the TNF promoter especially for the development of lepromatous or multibacillary leprosy.[262]

Certain human leukocyte antigens (HLA-DR) seem to be associated with specific forms of leprosy. HLA-DR2 and HLA-DR3 alleles are associated with tuberculoid disease, and HLA-DQ1 is associated with lepromatous disease.[50] In Suriname, HLA-DR3 is found frequently in mixed populations with tuberculoid leprosy and rarely in lepromatous patients; however, in Indians with tuberculoid leprosy, HLA-DR2 predominates.[317] HLA-DR antigens may influence the presentation of antigens of *M. leprae* to T cells and may affect the immune response to leprosy.[225]

Growing genetic evidence supports inter-population heterogeneity in leprosy susceptibility. On chromosome 6, within the leprosy susceptibility locus region q25-q26,[202] further investigation revealed a significant association between leprosy and 17 markers near the Parkinson disease gene *PARK2* and the co-regulated gene *PACRG* in Vietnamese and Brazilian families.[201] Having two of the alleles was associated with increased susceptibility to leprosy. In Malawi, a large case-control candidate gene study of leprosy susceptibility found that homozygotes for a silent T-to-C change in codon 352 of the vitamin D receptor gene were at higher risk, whereas homozygotes for the McCoy b blood group defining variant K1590E of the complement receptor 1 gene seemed to be protective.[88]

Toll-like receptors, molecules present on the surface of innate or native immune cells, mediate cytokine production on encountering a foreign invader, including mycobacteria, and ultimately may influence the pattern of specific immunity, which is especially relevant in leprosy.[180,258] Studies in Korea found that lepromatous leprosy occurred more commonly in patients with a mutation in the Toll-like receptor-2, associated with altered production of IL-10 and IL-12, underscoring the role early cytokine responses against *M. leprae* may play.[142-144] In African patients, polymorphisms in the *NRAMP1* gene, a gene that also is associated with cellular immunity to *M. leprae*, are associated with lepromatous leprosy,[184] as shown in the Mitsuda reaction.[7,245]

In Texas and Louisiana, the ratios of autochthonous to imported leprosy patients are the highest in the continental United States. Indigenous leprosy is highly prevalent in armadillos in only those two states,[23,290,332,334] and contact with such wild infected armadillos probably transmits leprosy to humans.[160,170,341] No cases of transmission of leprosy to humans from naturally infected mangabey monkeys or chimpanzees have been reported, but this potential exists.[107,193]

PATHOGENESIS AND PATHOLOGY

M. leprae causes disease by its ability to survive and multiply in macrophages (Fig. 109–1).[273] If macrophages of the host digest the bacilli early, disease is undetectable, or the patient has only minimal lesions. If the macrophages are totally incapable of destroying the organisms, a widely disseminated lepromatous leprosy follows. Survival of *M. leprae* in macrophages depends on the immune response of the patient; knowledge of immunity to *M. leprae* is necessary for understanding the mechanism of pathologic changes in leprosy.

IMMUNITY

The immunopathogenesis of leprosy can be understood by examining the spectral or polar nature of the condition, whereby polar tuberculoid disease is characterized by one or several well-demarcated lesions, borderline disease manifests with a modest number of medium-sized lesions, and lepromatous disease manifests with widespread poorly demarcated lesions (Table 109–1). Each type is associated with a different immunologic profile, especially within the lesions.

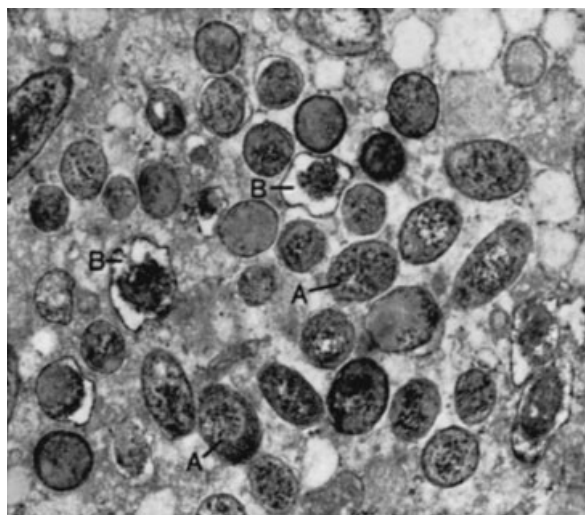

Figure 109–1 Electron micrograph of a portion of a globus of *M. leprae* within a histiocyte in a leproma in the skin. Cross sections of well-preserved (A) and degenerated (B) bacilli are presented (×45,000). *(Courtesy of Dr. S. C. Chang.)*

TABLE 109–1 Criteria for Classification of Leprosy

Group	Clinical Features	Histologic Features	Lepromin Reaction (Mitsuda)	Bacillary Density
Tuberculoid (TT)	A single or few anesthetic macules or plaques Borders well-defined Peripheral nerve involvement common	Epithelioid-lymphocyte granulomas, with or without giant cells, in skin and nerves No subepidermal clear zone Bacilli in nerves, but rare	Strongly positive	Rare
Borderline-tuberculoid (BT)	Lesions similar to those of TT, but more numerous Borders of lesions less distinct Satellite lesions sometimes present around larger lesions Peripheral nerve involvement common	Granulomas similar to those in TT Nerves are infiltrated Bacilli frequently found in nerves	Positive	Scanty
Borderline (BB)	More lesions than in BT Borders more vague Satellite lesions often seen Peripheral nerve involvement common	Epithelioid cells and histiocytic infiltrations focalized by lymphocytes Nerves show increased cellularity Bacilli readily found in nerves	Negative or weakly positive	Moderate
Borderline-lepromatous (BL)	Lesions are numerous and similar to those of BB Some nerve damage	Histiocytic infiltrations show a tendency to evolve toward epithelioid cells and foamy cells Lymphocytes present Nerves have less cellular infiltration Bacilli plentiful in nerves	Negative	Heavy
Lepromatous (LL)	Multiple, nonanesthetic, macular or papular, symmetrically distributed lesions No neural lesions until late Late complications of madarosis, leonine facies, testicular damage	Foamy histiocytes containing large numbers of bacilli Few or no lymphocytes Subepidermal clear zone Numerous bacilli in nerves and perineurium without significant intraneural cellular infiltration	Negative	Very heavy
Indeterminate (I)	Vaguely defined hypopigmented or erythematous macule	Often indistinguishable from "mild nonspecific dermatitis" Lymphocytes and histiocytes around skin appendages and nerves	Weakly positive or negative	Negative or scanty

The ability of an individual to resist *M. leprae* is assessed readily by the induration provoked by an intradermal injection of a suspension of killed *M. leprae* prepared from lepromatous tissue. Lepromatous nodules of patients were the traditional source, but now infected tissue from armadillos commonly is used.[194] The reagent is known as "lepromin," and the response is known as the "lepromin reaction." This reaction, first studied by Hayashi and later evaluated by Mitsuda,[204] has two components: an early response at 48 hours (Fernandez reaction) and a late response at 3 to 4 weeks (Mitsuda reaction). The Mitsuda reaction is the most consistent and is used by clinicians as an aid in classifying the clinical forms of leprosy.

Mitsuda reactions are strongly positive (>5 mm in diameter) in tuberculoid patients, weak or negative (0 to 2 mm) in lepromatous patients, and intermediate (3 to 5 mm) in borderline patients. The reactions are a direct measure of delayed hypersensitivity or cell-mediated immunity (CMI) to *M. leprae* antigens; lepromatous patients are anergic to *M. leprae*. The lepromin reaction has no value in establishing the diagnosis because a high percentage of any population is Mitsuda-positive. Even in children without leprosy, the Mitsuda reaction is positive in 20 percent of children younger than 5 years old and in two thirds of children aged 7 to 9 years old.[112] Modifications of the lepromin reaction with the use of concentrated lepromin show that macrophages at the test site in lepromatous patients cannot clear *M. leprae* from the skin, whereas in tuberculoid patients, the bacilli are destroyed efficiently.[46]

Nonspecific factors participate in host defense against *M. leprae*. Complement promotes phagocytosis of leprosy bacilli.[271] After phagocytosis occurs, phagolysosomal fusion and intracellular killing ensue, perhaps by oxygen-independent mechanisms.

Although the precise mechanisms of specific immunity remain elusive, abundant experimental evidence indicates that in a lepromatous patient, CMI to *M. leprae* is markedly suppressed. Delayed hypersensitivity skin test reactions to many antigens often are depressed, but they are depressed most consistently and most severely to *M. leprae*.[32] The degree of suppression is gradually less pronounced in clinical forms of disease that are progressively nearer tuberculoid leprosy.[330]

A continuous decrease occurs in the sensitivity of peripheral blood lymphocytes to *M. leprae* that proceeds from tuberculoid to lepromatous patients.[217] Many investigators consider that the defect in CMI to *M. leprae* is in T-lymphocyte function or in the

interaction of T lymphocytes with macrophages. Total numbers of circulating T lymphocytes are decreased in lepromatous patients,[75] but no consistent alteration occurs in the percent distribution of circulating T-cell subsets, particularly in the helper-suppressor (T_H1-T_H2) cell ratio.[246]

Within tuberculoid and lepromatous lesions, immunophenotypic and functional profiles of the infiltrating T cells differ markedly and are important factors in understanding the immunopathogenesis of leprosy.[208,209,244] In tuberculoid lesions, the CD4-to-CD8 T cell ratio is about 2:1, and the lesions are characterized by a T_H1 or T_H1-like profile, containing abundant mRNA transcripts for numerous proinflammatory cytokines that confer strong CMI, including IL-2, interferon-γ (IFN-γ), and IL-12.[356] Notably, $CD4^+$ T cells in tuberculoid lesions produce IFN-γ.[266] In lepromatous lesions, the CD4-to-CD8 ratio is approximately 1:2, and the lesions are characterized by a T_H2 or T_H2-like profile, containing mRNA transcripts for anti-inflammatory cytokines that include IL-4 and IL-10, factors associated with weak CMI, but strong humoral responses.[356] The $CD8^+$ T cells in lepromatous disease produce IL-4.[266] In contrast to Buruli ulcer (see later section on Buruli ulcer), induction of apoptosis in the lesions does not seem to play a major role in pathogenesis.[326] This immunologic dichotomy between tuberculoid and lepromatous lesions is consistent with the paradigm that robust CMI limits disease progression, and that humoral immunity has little or no effect.

The factors that determine whether a host generates a T_H1 or T_H2 response after having an infection with *M. leprae* are not completely understood. In addition to genetic predisposition (see section on epidemiology), an important immunologic factor may relate to host innate responses, when *M. leprae* is first encountered. Toll-like receptors on innate immune cells may recognize mycobacterial lipoproteins, generating cytokines that mediate specific or adoptive responses toward a T_H1 or T_H2 direction.[26,205]

In lepromatous lesions, T_H1 and T_H2 cells are admixed among the macrophages. Suppressor activity is generated by lepromin in vitro in peripheral leukocytes from lepromatous patients but not in cells from tuberculoid patients.[183] This suppressor activity also may be induced by the unique phenolic glycolipid (PGL-1) of *M. leprae*,[123,182] but it is unrelated to the type of leprosy.[241] PGL-1 abounds in the tissues of lepromatous patients. Secondary immunosuppression in advanced lepromatous leprosy may result from blockade of thymus-dependent areas of lymph nodes by *M. leprae*–laden macrophages.[309] Specific suppressor T-cell activity in immunosuppression in leprosy remains controversial.[147]

Macrophages of lepromatous patients are thought to have the capacity to kill, digest, and clear *M. leprae* if they are activated.[122] Patients with lepromatous leprosy fail to produce IL-2, but IL-2 restores the proliferation of lymphocytes in response to specific antigens.[116] Defective IFN-γ is produced by lymphocytes from lepromatous patients on stimulation by *M. leprae* antigens.[221] IL-2-bearing lymphocytes are reduced markedly in lepromatous infiltrations in tissues.[207] Suppressor T cells may influence IL-2 production in situ and reduce the proliferation of specifically sensitized T cells to release IFN-γ, with the result that macrophages are not activated. The injection of IFN-γ or recombinant IL-2 into the skin of lepromatous patients causes a local influx of $CD4^+$ T cells along with the formation of epithelioid and giant cells and a reduction in bacillary load.[146,320] IL-2 and IFN-γ, when available in quantity, may prove to be important immunotherapeutic agents for lepromatous leprosy. Therapy with IL-2 or IFN-γ induces the secretion of TNF-α; however, the activity of this toxic molecule may be inhibited by thalidomide or pentoxifylline.[145,302] Whether the increasing use of TNF-α antagonists such as infliximab, generally used for autoimmune disorders such as rheumatoid arthritis, would be associated with the development of leprosy from latent infections and perhaps be useful in the management of leprosy reactions remains unclear.[80,274]

Immunoglobulin production (IgG, IgA, and IgM) usually is elevated only slightly in tuberculoid patients but is elevated markedly in lepromatous patients, consistent with the predominant T_H1 versus T_H2 responses.[33] The total number of B lymphocytes is increased in the blood of lepromatous patients, as is the circulating antibody to mycobacterial antigens.[92,219]

The role of immunologic processes in damage to nerves in leprosy is poorly understood. Some observations suggest that antineural antibodies in the sera of many patients, especially patients with lepromatous disease, are related to such damage.[228] TNF-α is associated with macrophage infiltration of peripheral nerves in reversal reactions.[155] Infected Schwann cells present antigens to T cells, rendering them targets for immune attack.[273]

HISTOPATHOLOGY

Biopsy specimens from well-defined lesions of leprosy should be taken from the active border and fixed in buffered 10 percent formalin or other suitable fixative. The Fite-Faraco staining method is used because the Ziehl-Neelsen stain does not show *M. leprae* optimally in tissue sections. A histopathologic diagnosis of leprosy must not be made unless the evidence is convincing. The pathologist must avoid making ambiguous evaluations, such as "consistent with leprosy." DNA probes specific for *M. leprae* are available and are useful in identifying leprosy bacilli in tissue or nasal secretions.[66,344] Specimens for DNA evaluation or polymerase chain reaction (PCR) amplification, techniques that have been steadily improved over the past decade, should be preserved in 70 percent ethyl alcohol.[37,86,109]

Indeterminate Leprosy

In indeterminate leprosy (Fig. 109–2), the immune potential of the patient is not portrayed clearly in the cellular reaction. Only a mild chronic inflammation is found, with small infiltrations of lymphocytes or histiocytes along neurovascular channels and sometimes around appendages (Fig. 109–3). If leprosy is suspected, all nerves in the dermis and subcutaneous tissue in numerous sections of the biopsy specimen must be searched for AFB, even if no inflammatory changes within the nerves are present. Sometimes AFB appear only in the arrector pili muscles or subepidermal zone.[252] A histopathologic diagnosis of leprosy cannot be made unreservedly in indeterminate leprosy without showing AFB. Molecular biologic studies are rarely helpful in diagnosing indeterminate leprosy.

Tuberculoid Leprosy

Patients with tuberculoid (TT) leprosy (Fig. 109–4) have a high level of CMI to *M. leprae*, which is reflected in the cellular reaction. Granulomata composed of epithelioid cells, Langhans giant cells, and lymphocytes are present in the dermis or subcutaneous tissue (Fig. 109–5A). Frequently, upper dermal granulomata invade the lower layers of the epidermis (see Fig. 109–5A). Damage to nerves is a distinctive feature—in old advanced lesions, all cutaneous nerves may be damaged beyond recognition (see Fig. 109–5B). Occasionally, S-100 immunostaining helps reveal a neural pattern of Schwann cells if a question exists of whether or not nerves are damaged. Schwann cells are increased in number in early lesions, and the nerves are invaded by mononuclear cells. Bacilli rarely are found, and often many sections must be searched to locate a single bacillus. The bacilli usually are within remnants of dermal nerves but sometimes are located just beneath the epidermis.

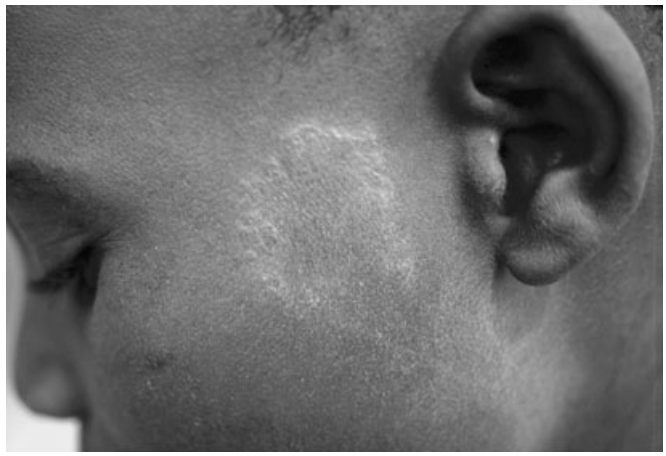

Figure 109–4 Tuberculoid leprosy in a 12-year-old Congolese boy. This was the only lesion, and it has a well-defined papulated border with central healing. (See companion Expert Consult web site for color version.)

When major nerve trunks are involved, they contain typical tuberculoid infiltrates that eventually may replace the entire nerve. Occasionally, caseous "abscesses" are present in large nerves, but they are rare in children.

Borderline Leprosy

Borderline leprosy represents a broad spectrum of clinical (Fig. 109–6) and histopathologic variations (see Table 109–1). In the borderline-tuberculoid (BT) variety, strong CMI still is evident by the large numbers of epithelioid cells and lymphocytes. The nerves usually are damaged less and are identifiable more readily than in TT leprosy. *M. leprae* often remain rare but are seen more readily than in TT in nerves (Fig. 109–7) or in the subdermal zone. In the central portion of the borderline area of leprosy (BB), the epithelioid cells are not surrounded by large numbers of lymphocytes, and Langhans giant cells are uncommon. The subepidermal area is free of infiltrating cells, and nerves are not damaged severely, but the perineurium often is thickened by epithelioid cells. Some histopathologists do not recognize BB leprosy as an entity because there is usually a suggestion that the lesion is either on the BT or the borderline-lepromatous (BL) side of the spectrum of the disease.[136] BL lesions reveal a low level of CMI. The granulomata are composed mostly of macrophages, but contain many irregularly distributed lymphocytes. A few nests of epithelioid cells may be present. The perineurium of the nerves is infiltrated with cellular exudates. Nerves are easily identified and contain many bacilli.

Lepromatous Leprosy

Pre-lepromatous lesions show only a mild proliferation of macrophages around vessels, nerves, and appendages. AFB are few and often difficult to show.

Anergy to *M. leprae* becomes apparent early in the lepromatous lesion (Fig. 109–8), with the bacilli-laden macrophage (Virchow cell or lepra cell) being the predominant inflammatory cell. In early lesions, they tend to accumulate around vessels, nerves, and appendages, but they eventually may replace the entire dermis (Fig. 109–9A). The infected macrophages are supported by a delicate stroma and supplied by a rich network of capillaries. As the macrophages age, they become vacuolated (foamy), largely from their lipid content. In developing lesions, the intracellular bacilli are arranged in small bundles (see Fig.

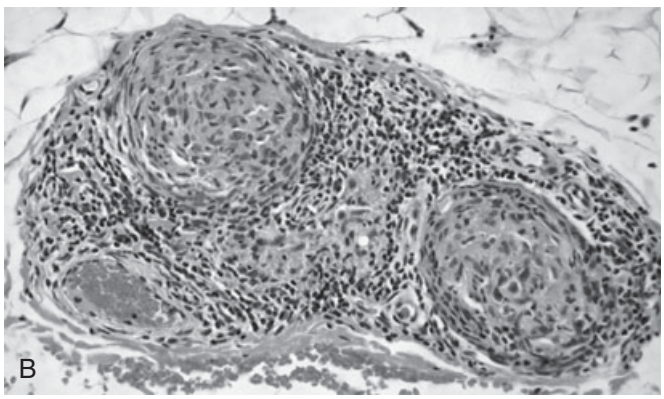

Figure 109–5 **A**, Tuberculoid leprosy with a dense granulomatous infiltration that invades the epidermis. Granulomata contain epithelioid cells, Langhans giant cells, and lymphocytes (hematoxylin and eosin stain). **B,** High magnification of a nerve bundle in the subcutaneous tissue of section in **A**. Granulomata have nearly completely destroyed the nerves. Remnants of nerves contained rare acid-fast bacilli (hematoxylin and eosin stain). (See companion Expert Consult web site for color version.)

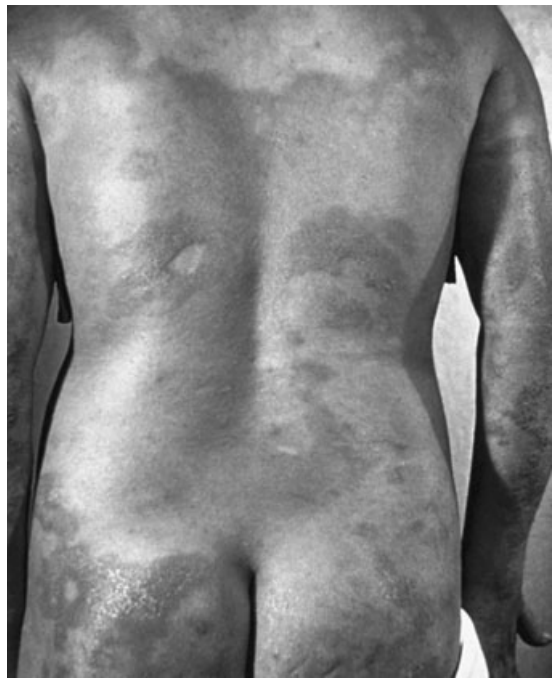

Figure 109–6 Borderline lepromatous leprosy in a Filipino. There are many plaques, some with well-defined borders and others vaguely defined. The erythematous plaques indicate that the patient is undergoing an upgrading reversal reaction (type 1). (See companion Expert Consult web site for color version.)

Figure 109–7 Electron micrograph of a portion of a damaged dermal nerve in borderline leprosy. A nonmyelinated axon (A) is surrounded by a Schwann cell (SC) that contains a single *M. leprae* bacillus (ML) (×60,000). *(Courtesy of Dr. S. C. Chang.)*

109–9B); in advanced lesions, dense masses of bacilli termed *globi* may replace nearly the entire cytoplasm of the macrophage. Infiltrating cells do not invade the epidermis but leave a narrow subepidermal clear zone. Many bacilli are found in the dermal nerves and frequently in endothelial cells, walls of blood vessels, arrector pili muscles, and epithelial cells of hair follicles.[215] Plasma cells vary in number and probably reflect B-lymphocyte hyperactivity.[92] Few lymphocytes are in a lepromatous lesion. Large nerve trunks may show typical lepromatous infiltrations.

Occasionally, in patients with lepromatous (LL) leprosy, elevated firm nodules form in the skin, especially in relapsing disease. Because of the characteristic histologic pattern of these lesions, in which the histiocytes resemble fibrocytes, this form is called *histoid leprosy*.[324] LL leprosy is disseminated widely, and lepromatous infiltrations frequently are found in the upper respiratory tract as far down as the larynx and in the eyes and testes. In adults, the testes sometimes are densely infiltrated, with subsequent development of sterility and gynecomastia, but these complications are rare findings in children. Lymph nodes often are infiltrated by bacilli-laden macrophages, especially in the medulla and paracortical areas.

CLINICAL MANIFESTATIONS

The incubation period varies (usually 2 to 5 years), and no prodromal manifestations are well established. Some experienced clinicians working in areas of high prevalence recognize early signs of nerve involvement (localized paresthesia, itching, or numbness) before any visible lesions develop.

After the incubation period, various lesions appear. The nature of the lesions depends on the immune response of the patient to *M. leprae*. So far, no strain variations of the bacillus except in drug sensitivity have been detected.[342,343] Most clinicians

Figure 109–8 Advanced lepromatous leprosy in an adolescent Filipino. Skin of most of the face, especially the alae nasi, is diffusely thickened. Eyebrows are thinned. (See companion Expert Consult web site for color version.)

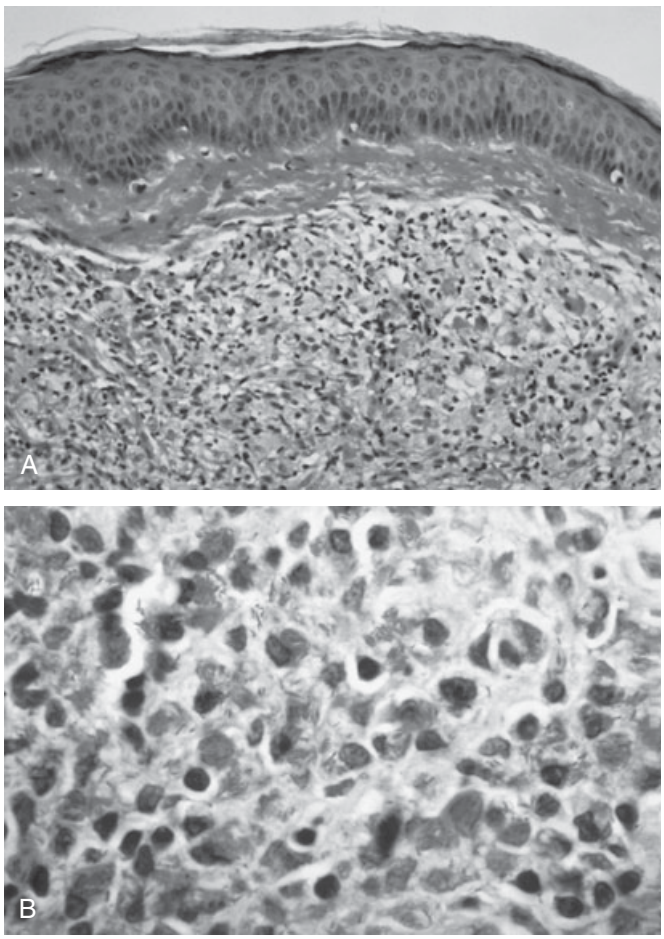

Figure 109–9 **A,** Advanced lepromatous leprosy showing replacement of dermis by foamy histiocytes and very few lymphocytes. (See companion Expert Consult web site for color version.)

today follow the classification scheme outlined by Ridley and Jopling (see Table 109–1).[253] Classification is important because it aids in establishing the prognosis and treatment program for the patient.

Virtually all patients with leprosy have peripheral neuropathy if cutaneous sensory changes are included, and approximately 25 percent have significant deformity. In experimental studies, the pathogenesis of peripheral neuritis in leprosy involves bacillation of the endothelial cells of epineural and perineural blood vessels and lymphatics.[272,273,275] Surface proteins of *M. leprae* may bind the bacillus to Schwann cells via lamimin.[243,283] Detailed discussions of peripheral neuropathy in leprosy can be found elsewhere.[265]

Ocular complications in leprosy are well known.[51,56,57,120] All patients with leprosy should be evaluated by an ophthalmologist at diagnosis and periodically thereafter, especially during any reactional episodes.

INDETERMINATE LEPROSY

An indeterminate lesion is the first manifestation of leprosy in most patients and may heal spontaneously, remain unchanged for months or years, or gradually progress toward TT or LL disease. Patients with indeterminate leprosy have a single or a few macules in the skin (see Fig. 109–2). The macule is defined poorly and is mildly hypopigmented in deeper pigmented skin and slightly erythematous in lighter skin. Skin texture, sensation, and sweating within early macules are normal or only slightly altered. Peripheral nerves are normal, and skin smears from lesions rarely contain bacilli. The definitive diagnosis can be made only by finding AFB in histopathologic sections.

TUBERCULOID LEPROSY

Patients with TT leprosy have a single or several asymmetrically distributed hypopigmented skin lesions (see Fig. 109–4). Tuberculoid lesions arise de novo or evolve from indeterminate macules. The lesion may be macular or infiltrated, but the borders always are sharply demarcated from the surrounding normal skin and frequently are finely papulated. Lesions range in size from less than 1 cm to large enough to cover entire regions such as the thigh or buttock. Many TT lesions heal spontaneously. In large, active lesions, the centers often are healed and repigmented, although somewhat atrophic.

In TT lesions, sensory loss with impaired sweating and eventual loss of hair occurs. On the face, because of its rich innervation, the detection of hypoesthesia in early lesions requires discriminating tests. Conversely, clinicians may mistakenly diagnose leprosy in areas of the body that normally are hypoesthetic (e.g., over the elbows or knees).

Involvement of peripheral nerves commonly occurs in TT leprosy (Fig. 109–10), and cutaneous nerves often can be palpated adjacent to or within lesions. The regional nerve trunks most commonly enlarged are the ulnar from the olecranon groove to midarm, lateral popliteal just distal to the head of the fibula, and posterior tibial in the medial aspect of the ankle. Enlarged or tender nerves anywhere should alert the clinician to the possibility of leprosy. Any readily palpable cutaneous nerve probably is enlarged, but evaluating the size of nerve trunks requires experience because of the wide range in normal size.

BORDERLINE LEPROSY

Borderline leprosy, sometimes called *dimorphous* or *intermediate leprosy*, has features of the LL and the TT forms and

Figure 109–10 Enlargement of the great auricular nerve in an adolescent Congolese boy. A large macule of tuberculoid leprosy over the angle of the mandible is now nearly inactive and barely visible. (See companion Expert Consult web site for color version.)

Figure 109–11 Progression of lepromatous leprosy in a Hawaiian boy. The photograph on the *left* was taken in 1931, when the patient was 13 years old, and the photograph on the *right* was taken 2 years later. No effective chemotherapy was available in that era.

represents a continuous spectrum of disease ranging from near-tuberculoid to near-lepromatous. It is an unstable form of leprosy and may evolve gradually toward TT leprosy by undergoing reversal reactions or be downgraded toward LL leprosy. Table 109–1 describes the three major subgroups of borderline leprosy: borderline-tuberculoid (BT), borderline (BB), and borderline-lepromatous (BL).

In BT leprosy, the number of lesions usually is greater than in TT leprosy, and the borders of each lesion, macule, or plaque are defined less sharply than in TT leprosy. Small satellite lesions may develop around larger macules or plaques. BL leprosy often manifests with widespread nodular infiltrations or plaques of varying size (see Fig. 109–6).

Damage to nerves and the resulting deformity develop early and often are widespread. Pain in nerves or neurotropic changes (e.g., sensory changes that lead to damaged hands or feet or a muscular weakness such as footdrop) frequently bring the patient to the physician. Severe damage to nerves occurs infrequently in young children, but can be disastrous. Prevention of this complication is an important goal of leprosy detection programs and of treatment of every patient with leprosy.

LEPROMATOUS LEPROSY

In LL leprosy, the bacilli multiply freely, and the disease disseminates widely, often before striking cutaneous manifestations develop, in contrast to the strict localization of lesions in TT leprosy. LL leprosy may evolve from indeterminate or BB leprosy or may be the first recognizable form. In its earliest form, LL leprosy manifests as "juvenile leprosy," a clinical entity delineated from observations of large numbers of children in homes for children of patients with leprosy in India.[214] This form, also called *pre-lepromatous leprosy*, is difficult to detect and frequently goes unrecognized until a more advanced stage develops. Skin texture may be altered slightly, but the vague macules with indistinct borders are detected only under appropriate lighting, preferably daylight. No changes in sensation or sweating occur in the macules, and frequently AFB are not detectable in smears from skin. Histopathologic sections may reveal a few bacilli to confirm the diagnosis; however, if leprosy is suspected, the patient should be monitored until an explanation for the mild skin changes is found. If leprosy is present and not detected and treated, advanced forms of LL leprosy develop in many of these patients (Fig. 109–11).

The hypopigmented or slightly erythematous macules of early LL leprosy, similar to those of juvenile leprosy, are missed easily because they are vague and have slight, if any, sensory changes. These macules usually are small but gradually may coalesce and cover large areas of skin, even nearly the entire body. Clinical diagnosis often is missed, and over the course of a few years, advanced LL leprosy develops. If skin smears or biopsy specimens are taken in the macular stage, diagnosis is virtually ensured. If the disease is not diagnosed and treated in the macular stage, infiltration of the skin increases gradually, and nodules may develop. The skin is infiltrated most heavily in the cooler portions of the body, notably the ears (pinnae) and face. By this time, nerves usually are enlarged, with early signs of sensory loss in the hands and feet. Eyebrows are thinned and eventually lost, beginning at the lateral edges. These advanced changes of LL leprosy are not common findings in young children but are well known.

Patients of Latin American ancestry, especially patients from Mexico and Costa Rica, may contract the highly anergic diffuse form of LL leprosy called *Lucio leprosy*. The disease may be so diffuse that it is not recognized until sensory changes appear in the hands and feet, and the eyebrows and other body hair begin to disappear. In advanced forms of Lucio leprosy, a marked obstructive vasculitis in the skin is present, with the production of dermal infarcts and irregular ulcers (Lucio phenomenon).[163,247] Lucio leprosy has been reported in children 7 years old.[270]

NEURITIC LEPROSY

Rarely, leprosy involves one or more major nerve trunks unaccompanied by cutaneous lesions. These patients have anesthesia, paresis, or wasting of muscles in the affected area. Nerve trunks frequently are painful, enlarged, and tender. Leprosy must be suspected in patients with any peripheral neuritis that has these features. Chronic neuritis with pain and enlargement and tenderness of peripheral nerves often persists for years after the patient has completed chemotherapy for leprosy.[119] Large leprotic nerve abscesses are rare occurrences but are exquisitely painful and may require surgical intervention for drainage.[278] Most clinicians prefer to treat such lesions with corticosteroids.

REACTIONS

The course of leprosy, treated or nontreated, often is interrupted by acute episodes known as reactions, which fall into two general categories: reversal reactions (or type 1) and erythema nodosum leprosum (ENL) (or type 2).

REVERSAL REACTIONS

Reversal reactions complicate borderline leprosy and represent delayed hypersensitivity reactions, with an upgrading of CMI toward TT leprosy. Lesions become erythematous and edematous, and neuritis is a common manifestation (Fig. 109–12). Patients who are lepromin-positive and have IgM antibodies to PGL-1 are most at risk for having reversal reactions.[254] Proliferation of sensitized T lymphocytes initiates reversal reactions, releasing lymphokines that amplify the inflammatory response, calling in and activating macrophages.[259] Immunohistopathologic evidence has shown that effective chemotherapy for paucibacillary and multibacillary patients may activate CMI and provoke clinical or subclinical reversal reactions. Expression of HLA-DR is increased, which may enhance production of IFN-γ by lymphocytes in granulomata.[53] Histopathologically, edema is accompanied by an increase in the number of lymphocytes, often with epithelioid cells and giant cells. In severe reactions, necrosis may occur, almost always in nerves. Increased levels of TNF-α may partially explain this necrosis.[20] Cyclooxygenase-2 levels are elevated in nerves and blood vessels during reversal reactions, a finding that explains why nonsteroidal anti-inflammatory drugs, including selective cyclooxygenase-2 inhibitors, often improve the condition.[231]

Patients experiencing such reactions must be observed closely so that sensory loss and deformities are minimized. By repeated reversal reactions, borderline leprosy, even cases close to LL disease, may be upgraded gradually to TT leprosy, often with disastrous peripheral neuropathy.

Differentiating reversal reactions from relapsing lesions frequently is difficult and requires careful correlation of clinical and histopathologic findings. This correlation is becoming increasingly important in endemic areas, where shorter term chemotherapeutic regimens of fixed duration are used.[90,188] The following criteria for differentiating relapses and reversal reactions are suggested: A relapse involves an increased number of lesions, positive skin smears for AFB (for patients with BB and BL leprosy), tissue reaction inconsistent with a reversal reaction, and a favorable response to chemotherapy; a reversal reaction involves an exacerbation of existing lesions, skin smears negative for AFB, tissue reaction consistent with a reversal reaction, and a rapid response to anti-inflammatory drugs.

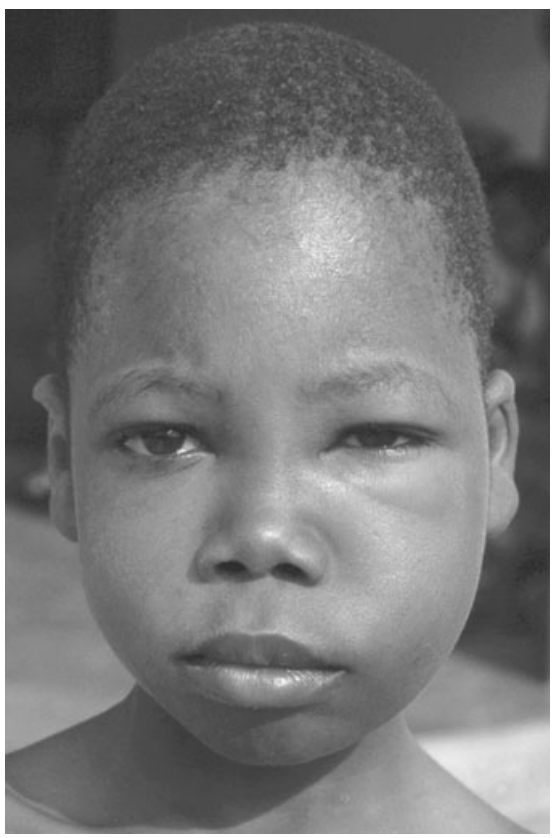

Figure 109–12 Reversal reaction (type 1) in an 8-year-old Congolese boy with borderline-tuberculoid leprosy. The left side of his face is swollen and displays mild palsy from facial nerve damage. The patient responded rapidly to oral steroid therapy. (See companion Expert Consult web site for color version.)

ERYTHEMA NODOSUM LEPROSUM

Formerly, ENL developed in approximately 50 percent of LL patients after they had undergone a few months of chemotherapy; however, with the addition of clofazimine to the standard therapeutic regimen, frequency of ENL is much reduced.[82] Tender erythematous subcutaneous nodules develop rapidly (Fig. 109–13); the nodules often are accompanied by fever and occasionally by synovitis and iridocyclitis.[234] ENL resembles the Arthus reaction and is thought to result from immune complex formation.[96] Immune complexes may form within lesions by the local release of antigens of *M. leprae* and could modulate the development of T-cell populations in situ. Numbers of helper T lymphocytes are increased in lesions of ENL.[206] Serum TNF-α is elevated in ENL.[20,269]

In the nodule, neutrophils and sometimes an intense vasculitis are present. Ulceration of the skin frequently accompanies severe ENL. Glomerulonephritis sometimes complicates ENL; secondary amyloidosis is a late sequela of repeated reactions and may be a consequence of the neutrophilic leukocytosis.[177] Although neutrophilic infiltration is considered by many physicians to be the hallmark of the tissue reaction, tissue from a rare patient with clinically typical ENL may not show neutrophils. In such patients,

Figure 109–13 Erythema nodosum leprosum in a Filipino adolescent girl with lepromatous leprosy. (See companion Expert Consult web site for color version.)

demonstration of serum amyloid A and C-reactive protein may aid in establishing the diagnosis of ENL.[124] Occasional patients may have mixed reversal (upgrading) reactions and ENL. These patients usually have leprosy in the BL area of the spectrum.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The cardinal signs of leprosy are hypoesthetic lesions of the skin, enlarged peripheral nerve or nerves, and AFB in skin smears. In the absence of another clear explanation, any one of these signs strongly suggests leprosy.

An experienced observer can establish a clinical diagnosis in most patients, except those with early leprosy, with a high degree of accuracy. Because leprosy is considered one of the "great imitators,"[329] however, histopathologic evaluation is strongly recommended to supplement and confirm the clinical diagnosis.

Patients with leprosy may be found in almost any geographic area, an awareness of which would minimize missed and delayed diagnoses, especially in areas of low prevalence. In the United States, the usual delay in establishing the diagnosis after the patient's first visit to a physician for symptoms related to leprosy is approximately 1.5 to 2 years. This delay often significantly worsens the prognosis.

History is important. Contact with patients with leprosy or residence in an endemic area raises suspicion of leprosy in a patient with a chronic lesion of the skin. Sensory loss or unexplained damage to hands or feet suggests damage to nerve trunks. Sometimes, a footdrop or clawhand brings the patient to a physician. Occasionally, patients with LL leprosy consult an otolaryngologist first because of a chronic stuffy nose.

Clinicians must evaluate sensory changes in a lesion by using the precautions already mentioned. The modalities usually tested are light touch with the use of a few fibers of cotton or calibrated nylon threads and heat-cold discrimination with the use of warm and cold water in test tubes. Much patience and repeated testing often are necessary in evaluating young children. Spontaneous sweating can be observed directly, or induced sweating can be evaluated. Hair may be completely preserved in early lesions but lost in advanced lesions.

The main nerve trunks must be palpated for tenderness and enlargement. Skin in the area of discrete lesions also must be palpated gently to detect enlargement of cutaneous nerves. In the world population, leprosy is the most common cause of peripheral neuropathy and must be considered in any patient with peripheral neuropathy.[265]

Obtaining and examining smears for AFB is an important diagnostic procedure and should be controlled carefully by experienced laboratories. Briefly, smears are made from the edge of discrete macules or plaques, nodules, ear lobes, and nasal mucosa. Skin smears are made by squeezing and holding a fold of skin between the thumb and forefinger to avoid getting blood in the smear and by making a short, shallow slit in the skin with a razor blade or scalpel. The instrument is turned at a right angle to the slit, and the edges of the incision are scraped. The cells and fluid thus obtained are spread on a slide, heat-fixed, and stained by the Ziehl-Neelsen method.[319] Evaluation of smears should not be done by researchers unfamiliar with their interpretation. An occasional AFB may be a harmless contaminant in the staining reagents.

The lepromin reaction is useless for the diagnosis of leprosy. Currently available skin tests with soluble *M. leprae* antigens are unreliable.[113] Enzyme-linked immunosorbent assays and gelatin particle agglutination tests for antibodies to the PGL-1 of *M. leprae* are available.[38,106,128] Although specificity for *M. leprae* is high, these tests detect antibodies to PGL-1 in only approximately 50 percent of paucibacillary patients. Other serologic tests for antibodies to *M. leprae*–specific epitopes on protein moieties of the bacillus are being evaluated.[229] PGL-1 antigen is detectable in the serum and urine of most multibacillary patients.[223,357]

Reliance on DNA probes and PCR technology may prove useful in establishing the diagnosis of leprosy in tissue sections, skin smears, and nasal smears.[66,301,342,344] Because these methods can detect a single leprosy bacillus, interpreting results, particularly in highly endemic areas, is difficult. Careful clinicopathologic correlation is essential when basing a diagnosis on DNA findings.[315]

The differential diagnosis of leprosy in children is an extensive subject and can be discussed only briefly here. Superficial mycoses and postinflammatory changes commonly are confused with early leprosy. Changes in pigmentation may be caused by scars, birthmarks, and actinic dermatitis. In areas where dermal filariasis is endemic, vague macules in a black-skinned patient may appear identical to the early macules of leprosy.[29,179,190] Among the many infiltrated lesions of the skin that can resemble leprosy are leishmaniasis, lymphoma, granuloma annulare, granuloma multiforme (Mkar disease), lupus erythematosus, psoriasis, pityriasis rosea, sarcoidosis, and neurofibromatosis. Peripheral neuropathies that may simulate leprosy are those seen in Morvan syndrome, syringomyelia, lead intoxication, diabetes mellitus, primary amyloidosis of nerves, and familial hypertrophic neuropathy. Cardiolipin antibody assays of sera from patients with advanced LL leprosy frequently give false-positive reactions for syphilis.

PROGNOSIS

Without chemotherapy, the prognosis in all patients except those with limited and self-healing disease potentially is poor. Patients with borderline or advanced TT leprosy frequently become mutilated because of damage to nerves. Borderline patients can downgrade toward LL leprosy. In patients with LL leprosy, the disease is progressive and can cause death from laryngeal obstruction. Secondary amyloidosis is a frequent late sequela. Blindness may result from lagophthalmic keratitis or repeated episodes of iridocyclitis. General debility and deformity eventually prevent gainful employment in many patients.

With adequate specific chemotherapy and control of reactions, the prognosis is good in nearly all patients. If therapy is started early, the prognosis usually is excellent, and deformity and mutilation are prevented. Even after receiving successful chemotherapy, however, some patients continue to experience significant neuritis and loss of peripheral nerve function. Sometimes this "silent neuropathy" goes unnoticed by the patient and the physician.[59,338] Appropriate early attention to anesthetic hands and feet and restoration of function by reconstructive surgery can prevent most mutilation.

The lepromin test is a valuable prognostic tool because it measures the CMI potential of the host to acquisition of infection by *M. leprae*.[135] Patients with early macular lesions who are lepromin-negative have a poorer prognosis than patients who are lepromin-positive if treatment cannot be administered. Histopathologic evaluation made before instituting chemotherapy is important for determining the prognosis and, if available, should not be neglected.

TREATMENT

When a diagnosis of leprosy is established, chemotherapy must be initiated, and appropriate measures must be instituted for preventing or correcting deformity in patients with neurotropic changes.[40,91,161] The three chemotherapeutic agents most commonly used are dapsone, clofazimine, and rifampin.[212] Although WHO recommends only clinical findings for assessment of the therapeutic response in field programs, clinicians may wish to use

additional evaluations. The effectiveness of chemotherapy is assessed readily in patients with LL or near-LL leprosy by the staining quality of *M. leprae* in skin smears. The response to chemotherapy in TT patients and most borderline patients is determined by the clinical response and by histopathologic evaluation. Viability of *M. leprae* in tissues is assessed in unusual cases in the mouse footpad.

Combined chemotherapy is being accepted increasingly for all forms of active leprosy. Although experimental data are limited,[281] the growing body of clinical data indicates that multidrug therapy has replaced monotherapy.[67,164] Monotherapy with any chemotherapeutic agent no longer is advised. The regimens recommended currently for multidrug therapy are given later, after a brief discussion of the most used individual drugs.

DAPSONE

In 1941, Faget and associates[81] at Carville, Louisiana, introduced the sulfones as the first chemotherapeutic agents regularly effective for leprosy and revolutionized the care of leprosy patients. The sulfone in common use is diaminodiphenylsulfone, or dapsone, available in the United States as Avlosulfon and Dapsone. Dapsone is an antimetabolite for *M. leprae* and is a bacteriostatic agent. The drug usually is given orally at 6 to 10 mg/kg body weight per week, divided into equal daily doses. The effect of dapsone on the bacilli is slow; 3 to 6 months of treatment is necessary to render bacilli from patients with LL leprosy noninfectious for the mouse footpad. Sulfone-resistant strains of *M. leprae* are being detected with increasing frequency,[337,338] and monotherapy with dapsone is not recommended. Dapsone usually is well tolerated but may provoke one or more of the following side reactions: dermatitis, anemia, hepatitis, or psychosis.[5]

CLOFAZIMINE

Clofazimine (Lamprene) is a bacteriostatic riminophenazine dye that has anti–*M. leprae* and anti-inflammatory activities, which render it a useful drug for the treatment of patients who are prone to having ENL reactions.[82] The mechanism of bacteriostasis may involve enhancement of oxygen-dependent killing of *M. leprae* and binding to bacterial DNA. The adult dose of clofazimine ranges from 50 to 300 mg daily, and some authorities recommend 1 mg/kg/day for children. The lower dosages are used for maintenance therapy when a good clinical response has been achieved, and the higher dosages may be needed to control ENL. The major side reactions to clofazimine are hyperpigmentation of skin and enteritis. Enteritis is experienced only at the higher dosages generally used for ENL. The hyperpigmentation subsides with the clinical improvement in leprosy, and hyperpigmentation and enteritis resolve after drug withdrawal. Although two instances of clofazimine-resistant *M. leprae* infection have been reported, the validity of these observations is uncertain.[148,336] For some time, clofazimine has been considered safe in pregnancy, but one report described three neonatal deaths in 15 observed pregnancies.[83] Whether the drug was associated with the deaths was not established. Monotherapy with clofazimine is not recommended.

RIFAMPIN

Rifampin is an antibiotic that inhibits bacterial DNA-dependent RNA polymerase and is rapidly bactericidal for *M. leprae*. A single large dose can render a highly positive LL patient noninfectious within 1 week. Dosages of 15 to 20 mg/kg/day have been given to children (maximal dose 600 mg/day). Optimal doses for children with leprosy have not been reported. Adult doses range from 300 to 600 mg daily.[347] Many side reactions to rifampin have been described, and the relevant literature must be consulted.[32] Rifampin-resistant leprosy has been reported,[130,345] so monotherapy with rifampin is not recommended.

MULTIDRUG THERAPY

Because of the existence of drug-resistant *M. leprae*, combined drug regimens are mandatory for the treatment of all forms of leprosy.[77,281,337,338] The first large-scale multidrug therapy for leprosy was initiated in Malta in 1972. Rifampin, dapsone, prothionamide, and isoniazid were used. Evaluation of the patients approximately 20 years later revealed a single relapse; however, presumed "persisting" *M. leprae* organisms were detected.[93,141]

Combined drug therapy minimizes development of drug-resistant strains of *M. leprae* and may eliminate some "persisting" organisms. Persisting *M. leprae* are viable bacilli that can be isolated in small numbers from patients who are clinically responding well to therapy. These persisting *M. leprae* bacilli are sensitive to the drug in question when tested in the mouse footpad and may account for relapses when treatment is discontinued. Persisting *M. leprae* organisms have been detected after 5 years of therapy with rifampin, 6 years of clofazimine therapy, and 22 years of dapsone therapy.

In 1982, a WHO study group recommended the multidrug therapy regimens that are described hereafter.[348] Patients were divided into paucibacillary and multibacillary groups. Paucibacillary patients (usually indeterminate, TT, and BT) were defined originally as patients with negative skin smears at all sites or patients who have fewer than four lesions and no clinical peripheral neuritis. Subsequently, for field programs, paucibacillary patients are classified only as patients who have fewer than four lesions, without reference to skin smear evaluation. All other patients are multibacillary.

The multidrug therapy regimens were designed primarily for field programs, and they use pulsed supervised monthly rather than daily rifampin.[18] Multidrug therapy is well tolerated, and compliance in large-scale control programs has been satisfactory. The efficacy of multidrug therapy has been promising.[36,338] In two surveys involving approximately 112,000 multibacillary patients monitored for 9 years after receiving therapy, the cumulative risk of relapse was 0.77 percent. Anecdotal descriptions of certain groups of highly bacilliferous patients with relapse rates of 20 percent and recurrences developing 5 years or more after therapy have been reported.[132] These and other results suggest that therapeutic regimens for multibacillary patients should be given for longer than 2 years.

In most reports, relapse rates in paucibacillary patients exceed those in multibacillary patients. In our experience in evaluating histopathologic specimens, many patients classified clinically as paucibacillary were multibacillary. The potential for relapse after receiving multidrug therapy regimens must await long-term, large-scale follow-up results.[36,131] Peripheral neuropathy sometimes persists after completion of these therapeutic regimens.[4,119]

The trend since 2001 has been to reduce the duration of treatment and change the therapeutic regimens—even to the extreme of a single-dose regimen composed of rifampin, ofloxacin, and minocycline for single-lesion therapy. Many of these innovations are interwoven into WHO Elimination of Leprosy Program and have provoked critical concern by some authorities.[87,168,218,291]

Regimen for Paucibacillary Patients (Indeterminate, Tuberculoid, and Borderline-Tuberculoid)

In adults, rifampin, 600 mg once a month, plus dapsone, 100 mg daily, is given for 6 months, and treatment then is stopped. After

the conclusion of multidrug therapy, the patient should be seen every 3 to 6 months. All apparent relapses require histopathologic examination for establishing whether the lesions represent relapses or reversal reactions. Relapsing patients must be treated again. The aforementioned multidrug therapy is not used alone in patients with concurrent tuberculosis.

Regimen for Multibacillary Patients (Lepromatous, Borderline-Lepromatous, and Borderline)

In adults, rifampin, 600 mg monthly; dapsone, 100 mg daily; and clofazimine, 50 mg daily, are given. If patient compliance is questionable, the rifampin and 300 mg of clofazimine should be given monthly under supervision, in addition to the 50 mg daily. These drugs must be given for 2 years. For patients in whom the hyperpigmentation caused by clofazimine is unacceptable, daily doses of 250 to 375 mg of prothionamide or ethionamide may be substituted for clofazimine. Another alternative therapy suggested by WHO for patients unwilling to accept the hyperpigmentation of clofazimine or who are noncompliant with other regimens consists of rifampin, 600 mg; ofloxacin, 400 mg; and minocycline, 100 mg, coined "ROM," all of which are administered on a single day, once monthly, for at least 2 years.[321]

Dosages of Multidrug Therapy for Children

Pediatric dosages of multidrug therapy are given in Table 109–2.[140]

Recommendations for the United States

The National Hansen's Disease Programs, Baton Rouge, Louisiana, recommends the following variations of WHO's recommended multidrug therapy regimens for adult patients in the United States:

- Paucibacillary disease: dapsone, 100 mg daily, plus rifampin, 600 mg daily, for 1 year.
- Multibacillary disease: dapsone, 100 mg daily, plus rifampin, 600 mg daily, and clofazimine, 50 mg daily, for 2 years. Minocycline, 100 mg daily, is substituted for clofazimine in patients who refuse to take clofazimine.
- Because the National Hansen's Disease Programs may change their recommendation for patient management, we advise clinicians in the United States to consult it before treating any patient with leprosy (telephone, 1-800-642-2477 or 1-225-756-3709, or e-mail, Mtemplet@hrsa.gov; it also has a website available at www.bphc.hrsa.gov/nhdp/).

OTHER DRUGS UNDER INVESTIGATION

Other potential antileprosy drugs that are undergoing advanced clinical evaluation and may gain general use include fluoroquinolones (pefloxacin and ofloxacin), the macrolide clarithromycin, and the tetracycline minocycline.[97,99,110,134]

TABLE 109–2 Dosage of Multidrug Therapy for Children with Leprosy

Rights were not granted to include this table in electronic media. Please refer to the printed publication.

From Jopling, W. H.: Handbook of Leprosy. London, William Heinemann, 1984.

TREATMENT OF REACTIONS

Patients experiencing a reaction should be observed daily in the early stages and hospitalized if the symptoms are severe. Formerly, specific therapy was stopped or the dosage reduced during reactions, but these measures no longer are recommended.[348] Damage to eyes and neurotropic changes may ensue rapidly without immediate attention. Nerve tenderness and function must be assessed frequently during reactions. Acute inflammation of isolated lesions without damage to nerves is likely to be of little consequence except for cosmetic considerations, but the patient should be monitored closely.

Reversal (Type 1) Reaction

Patients with painful, tender nerves must receive immediate care, usually in the hospital. Analgesics are given, and the affected area is rested. Large daily doses of corticosteroids are started and tapered to a minimal effective dose until the reaction subsides. Conversion to alternate-day steroid regimens may be attempted when long-term treatment is necessary. Some clinicians use clofazimine for chronic reversal reactions, but it is not recommended for the initial treatment of reactions with acute neuritis. For reactions, clofazimine probably is consistently efficacious only for ENL.[126]

Erythema Nodosum Leprosum (Type 2) Reaction

Mild ENL is treated with analgesics; more severe ENL is treated with thalidomide or corticosteroids.[322] Pediatric doses of thalidomide in ENL have not been established, but the initial adult dose is 100 mg four times daily followed by a minimal effective dose, usually 100 mg daily. The teratogenic action of thalidomide demands that appropriate measures be taken in the treatment of fertile women. For the rare patient who does not respond to thalidomide or in fertile women, corticosteroids or clofazimine is used. Corticosteroids, if used, are administered in the usual dosage schedules, beginning with large doses and tapering to a minimal effective level. Some clinicians use an alternate-day regimen when long-term steroid therapy is necessary, minimizing the well-known side effects. A few studies suggest that pentoxifylline or pentoxifylline plus clofazimine is effective for ENL.[220,302,340]

Clofazimine is effective in most patients with ENL and does not have the disadvantages of thalidomide or corticosteroids. The anti-inflammatory action of clofazimine is not manifested until after 4 to 6 weeks of continuous use. The dosage must be adjusted to the minimal effective level.

Iridocyclitis requires emergency measures. Local corticosteroids must be added to systemic anti-inflammatory regimens. Ophthalmologic consultation should be obtained.

PREVENTION

Precise recommendations for the prevention of leprosy in individuals have not been formulated. Control programs today are based on the general principles that (1) the number of contagious patients is reduced by chemotherapy and (2) the surveillance of contacts detects early leprosy. To accomplish these goals, appropriate education of the public and medical personnel and population surveys in areas of higher prevalence must be implemented. In endemic areas, improved housing probably is a highly important preventive measure by reducing close contact of patients with healthy individuals.

The most important obstacles to improving control of leprosy include persistence of *M. leprae* in treated patients, the cost and toxicity of antileprotic medications, the long-term nature of

therapeutic regimens, patient compliance, and the social stigma of leprosy.[249] For the total eradication of leprosy, zoonotic sources of *M. leprae* must be taken into account.[193]

CHEMOPROPHYLAXIS

Chemoprophylaxis with dapsone for close contacts has limited usefulness, but it is not recommended for large populations.[59] This recommendation is based on the probability that long-term use would be irregular, and dapsone-resistant *M. leprae* may develop.[347] Rifampin prophylaxis may have some value, at least in the short-term,[10] but the risk of increasing the rates of drug-resistant tuberculosis, or even leprosy, must be considered.

VACCINATION, IMMUNOPROPHYLAXIS, AND IMMUNOTHERAPY

WHO initiated an Immunology of Leprosy Program (IMMLEP) in 1974 with two primary goals: (1) development of a vaccine against leprosy and (2) development of reagents for detecting subclinical leprosy. Achievement of both goals could diminish profoundly the incidence of leprosy. *M. leprae*, or specific antigens thereof, for the IMMLEP studies were obtained from experimentally infected armadillos. Vaccines composed of heat-killed whole *M. leprae* alone or in combination with live bacille Calmette-Guérin (BCG) have been found to be safe and to induce delayed-type hypersensitivity to *M. leprae* in a high percentage of lepromin-negative individuals. Several other vaccines based on cultivable mycobacteria (*Mycobacterium vaccae*, *Mycobacterium* "w," and the Indian Cancer Research Centre bacillus) induce similar responses.[19,149,293]

Field trials of these vaccines for the immunoprophylaxis of leprosy have been conducted; however, because of the chronicity and low prevalence of the disease, meaningful evaluation of their efficacy would require extended follow-up observations.[21] Because infection-induced immunity is not observed regularly in leprosy, a reasonable doubt exists that vaccines containing only *M. leprae* would be protective. Combined vaccines of killed *M. leprae* and live BCG have been studied. Such vaccines convert lepromin-negative contacts of patients with leprosy to positive reactors and upgrade LL patients toward the tuberculoid region of the disease spectrum.[45,195] Vaccines based on cell wall fractions of *M. leprae* are being studied.[98] WHO does not recommend BCG vaccination for the prevention of leprosy.[17] This decision was based on the highly variable results of extensive studies in Burma, Papua New Guinea, and Uganda.[348] Another trial in India involving 270,000 individuals confirmed that during a 12.5-year follow-up, BCG vaccination was shown to be only approximately 25 percent effective against leprosy.[304]

Initial evaluations of a large-scale immunoprophylaxis trial of heat-killed *M. leprae* plus BCG vaccine in humans in Venezuela showed no better protection than did BCG alone 5 years after vaccination.[48] A randomized trial of a single BCG vaccination, repeated BCG, or BCG plus killed *M. leprae* involving 121,020 individuals in Malawi gave the following results over a 5- to 9-year follow-up: A single BCG vaccination afforded 50 percent protection against leprosy, a second BCG vaccination added appreciably to this protection, but the addition of killed *M. leprae* to BCG did not enhance protection against leprosy.[150]

LEPROSY AND ACQUIRED IMMUNODEFICIENCY SYNDROME

Because *M. tuberculosis*, *Mycobacterium avium–intracellulare*, and *Mycobacterium kansasii* are frequent opportunistic pathogens in patients with acquired immunodeficiency syndrome (AIDS), observations of AIDS in patients with leprosy are of interest.[312] In one study in Zambia, antibodies to human immunodeficiency virus (HIV) were found in 33 percent of new leprosy patients versus 7 percent of controls.[181] Perhaps the positivity of some of these patients with leprosy can be explained by cross-reactivity between antibodies to HIV-1 and the lipoarabinomannan of *M. leprae*.[151] In other populations in Africa, HIV infection constituted an overall risk factor of 2.2 for leprosy, with 4 to 23 percent of cases of multibacillary leprosy attributable to HIV co-infection.[24]

Other prospective studies show that HIV infection may not be a risk factor for acquisition of leprosy in some populations.[154,276] Only a few detailed clinicopathologic reports on individuals co-infected with *M. leprae* and HIV exist.[133,158,211] In these patients, no consistent deleterious effect of HIV infection on the clinical or pathologic findings of leprosy occurred. These observations are supported by a study of the parameters of CMI in co-infected patients in Brazil.[267] In these patients with borderline leprosy, the quality of the granulomata in the infiltrations of leprosy were not altered significantly despite low $CD4^+$ T-cell counts. The incidence of reversal reactions (type 1) and neuritis is increased in multibacillary patients co-infected with HIV.[34] Perhaps, as previously and perceptively suggested,[169] observations in patients co-infected with HIV and *M. leprae* will lead to some revisions of the immunopathogenesis of leprosy.

BURULI ULCER

Mycobacterium ulcerans causes indolent, necrotizing cutaneous ulcers that are known classically as *Buruli ulcers*.[171,287,316] Other names for these lesions include Bairnsdale or Searles' ulcer in Australia and Kumusi ulcer in Papua New Guinea. Buruli ulcer seems most appropriate, however, because Clancey and colleagues[39] were the first to name the disease, after the site of the first large epidemic, which was located in Buruli County, Uganda.[68] Cook[49] in Uganda described lesions that fit Buruli ulcer in 1897. Today, researchers recognize that many infections with *M. ulcerans* are not manifested as ulcers, and *M. ulcerans* infection is a technically more appropriate name for the disease. A few infections have been acquired by North American or European travelers to endemic countries,[44,78,277] and patients with Buruli ulcers frequently come to European medical centers for treatment.[12,242]

WHO has recognized Buruli ulcer as a re-emerging infectious disease in western Africa with an important public health impact. WHO Global Buruli Ulcer Initiative has held annual meetings to evaluate all aspects of the disease since 1998, and in 2004, the World Health Assembly adopted a resolution for all member states to intensify research to develop tools for diagnosing, treating, and preventing Buruli ulcer.[351]

ORGANISM

MacCallum and associates[172] in 1948 in Australia were the first to isolate the etiologic agent in culture. *M. ulcerans* is strongly acid-fast, with an optimal growth temperature of 30° C to 32° C on routine mycobacteriologic media such as Löwenstein-Jensen medium. *M. ulcerans* is a slow-growing organism, and several months may be required to achieve isolation in primary culture. Microaerophilic conditions promote the growth of *M. ulcerans*, and the organism is strikingly sensitive to temperatures of 37° C or greater.[196,227] This temperature sensitivity often reduces rates of cultivation of the etiologic agent in laboratories remote from endemic areas.

M. ulcerans is the only mycobacterial pathogen of humans known to elaborate a necrotizing and immunosuppressive toxin.[55,233,248] This toxin is a polyketide and has been named *mycolactone*.[100,101] The genomic sequences of the plasmid-encoded synthases that produce mycolactone have been described more recently.[299] Animal studies and immunohistologic evaluations of human lesions indicate that at least one mechanism by which mycolactone mediates tissue destruction is by triggering massive levels of apoptosis.[102,328]

Although mycolactone is viewed as the dominant virulence factor of *M. ulcerans*, other factors may participate (e.g., phospholipases).[105] The phenolic mycosides of *M. ulcerans* and *Mycobacterium marinum* are identical, and sequences for the 16S rRNA gene differ by only one base pair.[54,255]

Specific insertion sequences for *M. ulcerans* have been characterized and are available for identification of the organism by PCR.[1,285,297] Variations in the 3′ end of the 16S rRNA gene sequence are related to geographic origin and are used to divide the organism into African, American, Asian, and Australian strains.[240]

TRANSMISSION AND EPIDEMIOLOGY

Endemic foci of *M. ulcerans* infections usually appear in rural settings near permanent wetlands in warm countries, especially in terrain subject to seasonal flooding. Reports of patients with Buruli ulcers have come from at least 27 countries, principally in the tropics.[335] A few patients live in nontropical climates, such as China,[79] Japan,[308] and southern Australia.[318] Today, the largest numbers of reported patients live in West Africa (Benin, Burkina Faso, Côte d'Ivoire, Ghana, Guinea, Liberia, and Nigeria).[238,316,335] In these countries, the disease is re-emerging rapidly, with an estimated total annual incidence exceeding 7000 patients. Other countries in which the disease is well known to be endemic include Malaysia, Indonesia, Papua New Guinea, Peru, Suriname, French Guiana, Cameroon, Equatorial Guinea, Gabon, Angola, Democratic Republic of Congo, and Uganda.[60,121,188,232]

Observers attribute this re-emergence to environmental factors such as deforestation, artificial topographic alterations (dams and irrigation systems), increasing populations engaged in basic manual agriculture in wetlands, and possibly climactic changes.[198] In North America, two cases of Buruli ulcer were reported in 2005 in central Mexico, the nearest location to the United States to date.[42]

Individuals of all ages are affected, but the highest frequencies are in children 15 years of age or younger—usually approximately 75 percent of all cases.[176] The sexes are affected equally, and a racial predilection is unknown.[61] Anecdotal observations of children in families of multiple parentage have suggested a possible genetic predisposition, now supported by molecular studies.[295] Seasonal variations in incidence occur in some foci.[118,251] Approximately 80 percent of the lesions are on the limbs, with the highest frequencies involving the lower extremities.

Although Buruli ulcer long has been associated with riverine environments, repeated long-term studies (1960 through 2005) on a large variety of flora, fauna, water, and mud samples from many endemic foci failed to reveal *M. ulcerans* in nature by culture.[13,71,235] After the development of molecular biologic techniques for the identification of *M. ulcerans*, the organism was detected in the environment in Australia by PCR.[260,261,296] With the increased understanding of this fastidious organism now available, researchers expected in 2001 that successful culture of *M. ulcerans* from nature would soon be achieved.[238] In 2006, two strains of *M. ulcerans* cultured from nature were reported.[287]

Although the ultimate source of *M. ulcerans* remains obscure, the organism has been discovered in aquatic insects, such as water bugs, firefly larvae, and beetles, obtained from stagnant water in endemic areas of West Africa.[175,238,239] In some cases, the organisms were found only in the salivary glands of aquatic insects, supporting the notion that insect bites may play a role in transmitting *M. ulcerans*.[173,174]

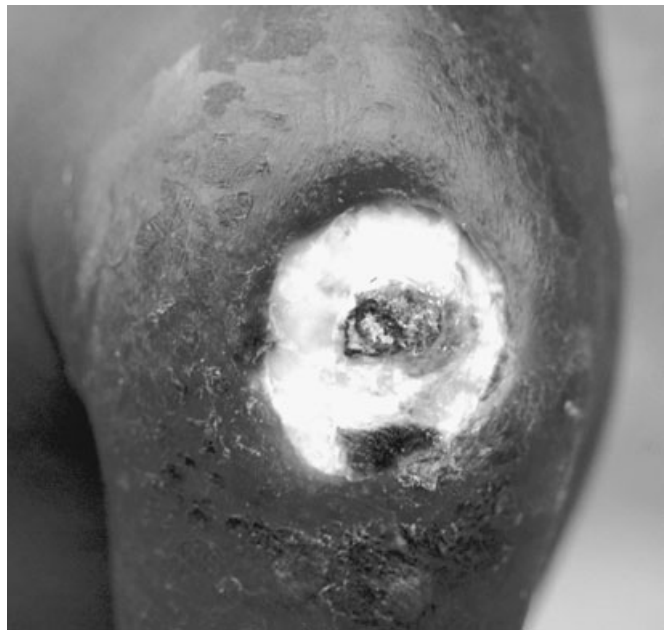

Figure 109–14 A major Buruli ulcer in the deltoid area of a 12-year-old Angolan boy. This pristine ulcer developed 3 months after a documented hypodermic anticholera vaccine injection at this site. Typical Buruli ulcer features are represented—undermining of borders, necrotic base, and induration of the adjacent skin. (See companion Expert Consult web site for color version.)

Some authorities speculate that *M. ulcerans* is a saprophytic or commensal organism that thrives in the mud, flora, or fauna of the cool microaerophilic environment of the bottom of stagnant water, well protected from the lethal ultraviolet radiation that prevails in the tropics. Koalas and possums in Australia acquire infections in the wild that are typical of Buruli ulcer.[203,238]

Buruli ulcer rarely, if ever, is contagious. The distribution of patients, even in highly endemic foci, is random, suggesting that each patient is exposed to environmental sources, such as swamps where villagers work their gardens and obtain water for domestic use and especially where children play.

The mode or modes of transmission to humans have not yet been delineated completely; however, the most plausible route is by trauma at sites of skin recently contaminated by *M. ulcerans*.[71,197] Many patients give a history of specific antecedent penetrating trauma at the site of their initial lesion, which may include wounds from a gunshot or land mine, thrown stones, hypodermic injection, and even a human bite (Fig. 109–14).[64] The organism may be spread by aerosol from the surface of ponds or be carried by fomites or insects to skin surfaces. Insects may introduce *M. ulcerans* into the skin, but this means of transmission has not been proved. Although proposed by some authorities, transmission by nasorespiratory passage with a subsequent bacteremia seems to be unlikely.

PATHOGENESIS AND PATHOLOGY

The pathologic features of early *M. ulcerans* infection are determined primarily by two properties of the etiologic agent: optimal growth at 30° C to 33° C and elaboration of the toxin mycolactone. The temperature requirement tends to favor the development of lesions in the skin, and the toxin destroys tissues and

suppresses immune responses. The spectrum of clinical and histopathologic forms of infection suggests that some patients have innate resistance, or resistance develops soon after infection is acquired, whereas others acquire resistance later or, occasionally, never.

A skin test with burulin, a purified sonicate of *M. ulcerans*, reveals that most patients do not have delayed-type hypersensitivity to *M. ulcerans* early in the course of the infection but mount a cellular response as healing begins.[292] Very few studies have investigated the immunology of Buruli ulcer. *M. ulcerans* profoundly suppresses B and T lymphocytes in vitro.[233] Mycolactone, a toxin of *M. ulcerans*, is thought to prevent sensitization of T lymphocytes to mycobacterial antigens and to inhibit production of TNF-γ by monocytes and IL-2 by T lymphocytes.[3,52,100,101,226] In a study of tissue sections of Buruli ulcer lesions, IL-10 was increased in ulcerative lesions without granulomata, whereas IFN-γ was abundant when granulomata were present.[156] These activities partly explain the immunologic unresponsiveness and reduced inflammatory reaction at the site of the lesion.

Based on the current understanding of the natural history of *M. ulcerans* infection, pathogenesis may proceed as follows: After inoculation of the etiologic agent deep into the skin or subcutaneous tissue, a latent phase occurs during which the mycobacterium proliferates slightly, probably initially intracellularly,[224] and begins to elaborate small amounts of toxin that causes necrosis, especially of fatty tissue. This necrosis provides a microaerophilic environment and perhaps nutrients favorable for the accelerated growth of *M. ulcerans* and elaboration of increased amounts of toxin. During this necrotic phase, no significant cellular response occurs.[43,44,68]

In some patients, at this stage, a subcutaneous nodule begins to develop, with clusters of *M. ulcerans* in the center surrounded by a zone of necrosis. In highly resistant patients, this lesion may self-heal, perhaps without ulceration, or form a small, sharply delineated ulcer. In others, the skin is undermined by the necrosis and eventually breaks down into larger ulcers with widely undermined skin. In the least resistant individuals, a nodule never develops, and the necrosis spreads rapidly and widely to cover large body surface areas, but ulceration, if it occurs at all, is a late event.

Eventually, the necrotic stage ceases in most patients, either because the toxin is neutralized or because production is interrupted. At this time, a granulomatous stage begins to develop, followed by healing and scarring. Some of the variability in clinical presentation and progression of the disease may be related to heterogeneity in the *M. ulcerans* genome and in the plasmid that encodes the production of mycolactone.[1,216,298,300]

Microscopically, the active ulcer shows extensive coagulation necrosis of the subcutaneous tissue down to and often including the fascia (Fig. 109–15).[111] The deep layers of necrosis reveal masses of AFB, often with mineralization and extensive vasculitis. Marked edema is present, and fat cells enlarge and die, with only their cellular ghost outlines remaining (Fig. 109–16). The dermis and surrounding tissue seldom contain AFB. Lesions sometimes provoke a reactive (contiguous) osteitis that leads to necrosis of cortical bone and osteomyelitis. Metastatic lesions may develop in the skin and bone from bacteremia and produce skin lesions distant from the original lesion and frequently focal or multifocal osteomyelitis. Regional lymph nodes may show massive necrosis and contain large numbers of AFB, especially in the capsule. Visceral organs are not known to be involved, but no necropsies of patients who died of disseminated disease have been reported.

An understanding of the pathogenesis and developing improved therapies for Buruli ulcer has been slowed by the lack of an experimental animal model that replicates the spectrum of features found in human disease. Laboratory rats and mice develop skin lesions after intradermal inoculation with *M. ulcerans*, but they lack the extensive ulceration found in human disease. Multimammate rats (*Mastomys natalensis*) rapidly develop systemic infections and die.[286] In the mouse footpad, *M. ulcerans* multiply, but necrosis without ulceration destroys the limb and causes death.[248] Guinea pigs develop inflammatory lesions at the inoculation sites that may resolve without formation of ulcers.[157,248] The nine-banded armadillo is susceptible to *M. ulcerans* and develops cutaneous lesions after experimental intradermal infection, approximating those of the human disease but is phylogenetically distant.[327] The cynomolgus monkey is moderately susceptible to experimental *M. ulcerans* infection and develops some of the clinical and histologic features of Buruli ulcer.[325]

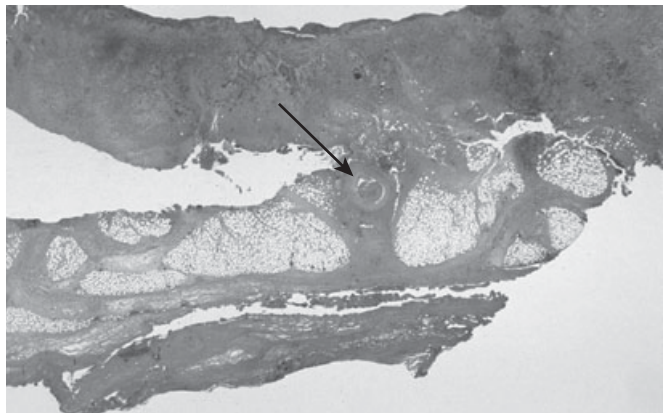

Figure 109–15 Histopathologic section of the undermined edge of a major Buruli ulcer. Note the coagulation necrosis of the entire panniculus and fascia, and vasculitis with thrombosis of a blood vessel *(arrow)* (hematoxylin and eosin stain). (See companion Expert Consult web site for color version.)

CLINICAL MANIFESTATIONS

INCUBATION AND FORMS OF LESIONS

In one study of specific trauma related to lesions, the incubation period ranged from 2 weeks to 3 years, with a mean of 3 months.[197]

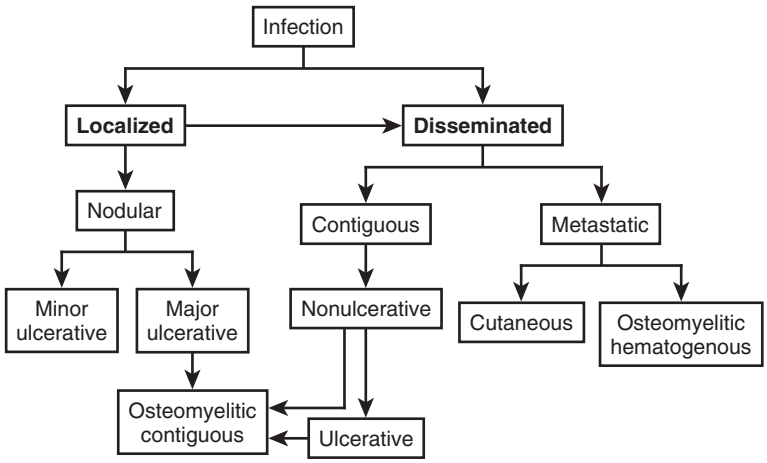

Figure 109–17 Proposed classification of clinical forms of *M. ulcerans* infections, indicating possible progression of lesions after the initial cutaneous infection. Without treatment, lesions may self-heal at any stage, or advance according to the schema shown at left.

Figure 109–18 Edematous form of *M. ulcerans* infection in a 6-year-old Ghanaian girl after surgery to remove all necrotic tissue. There was never any ulceration. Note ablation of breast tissue. (See companion Expert Consult web site for color version.)

The following are the various forms of lesions of *M. ulcerans* infection according to WHO designations.[353,354] Figure 109–17 presents a proposed classification of the clinical forms of *M. ulcerans* disease and their possible inter-relationships.

Papule

The papular stage has been described only in patients from Australia. These papules are painless and elevated and measure up to 1 cm in diameter.

Nodule

Nodules are primarily subcutaneous and firm, measure approximately 2 cm in diameter, and are painless, although they are often pruritic. The overlying skin may be discolored. This stage is the initial one in most Africans, and in the Kikongo language, the disease is called *mputa matadi* because the nodule is a "rock-hard lesion."

Plaque

Plaques are firm, elevated, painless, well-defined lesions more than 2 cm in largest dimension. Their borders are irregular. This stage often is the one in which physicians initially see the patient, but the lesion may or may not arise from a nodule. The skin over the lesion is reddened or discolored. These lesions may ulcerate in the late stages.

Edematous Form

Most edematous lesions do not begin in the nodular stage but spread directly from the initial nidus of infection. Spread often is rapid and wide and covers entire limbs or major portions of the trunk (Fig. 109–18). This type of lesion is characterized by diffuse nonpitting swelling and vague margins. Lesions are firm and frequently painful, with changes in color and scaling on the skin surface.

Ulcerative Forms

Classically, when fully developed, pristine ulcers have undermined edges surrounded by a zone of induration and often desquamation of the epidermis (see Fig. 109–14). In the base of the ulcerated area, a whitish necrotic slough and sometimes eschar develop. An oily exudate frequently oozes from the dependent area. Old ulcers tend to begin healing in the uppermost part while activity continues in the dependent portion. Collections of fluid in this area probably continue to support the growth of *M. ulcerans*, which sustains progression of the lesion.

The ulcerative forms are divided into major and minor ulcers. Both forms tend to self-heal. A major ulcer is large and chronic. Minor ulcers are small (1 to 2 cm in diameter), are sharply delineated, and heal early. Both ulcerative forms begin as subcutaneous nodules.

BONE INVOLVEMENT

Contiguous Osteomyelitis

Reactive osteitis occasionally develops beneath destroyed overlying skin and soft tissue. Bone becomes devitalized and necrotic, with the development of sequestra (Fig. 109–19).

Metastatic Osteomyelitis

M. ulcerans–specific osteomyelitis develops in approximately 10 percent of all patients, underscoring that Buruli ulcer should always be considered a potentially systemic disease.[242] Most likely, metastatic osteomyelitis is a result of lymphohematogenous spread of *M. ulcerans* from a distant, earlier cutaneous lesion (Fig. 109–20). The overlying skin ordinarily is intact, but swelling and inflammation occur over the site of bone involvement. If the

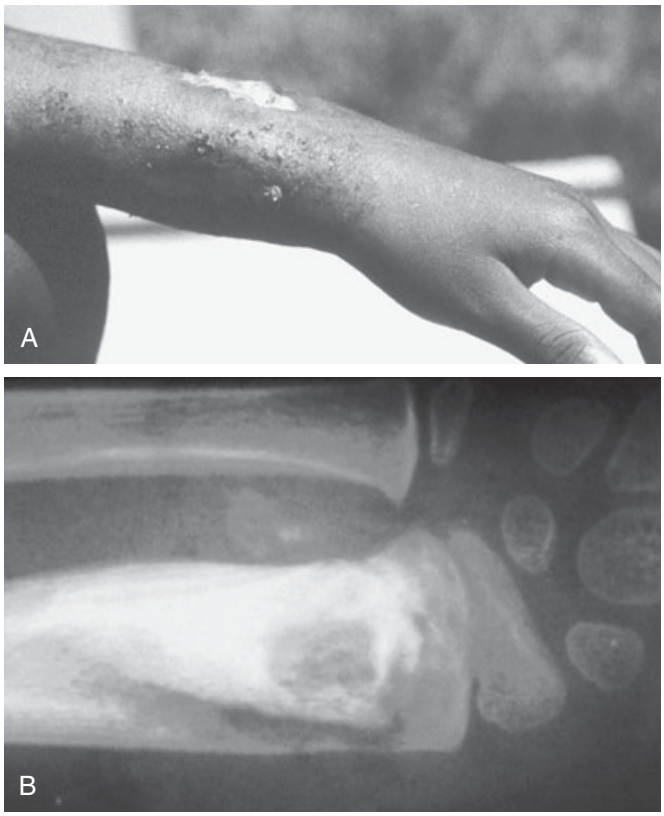

Figure 109–19 **A,** *M. ulcerans* infection in a young Congolese boy. Note swelling and ulcer on dorsum of forearm. (See companion Expert Consult web site for color version.) **B,** Radiograph of forearm shows reactive osteitis, necrosis of cortex of distal end of the radius, and early sequestration with osteomyelitis.

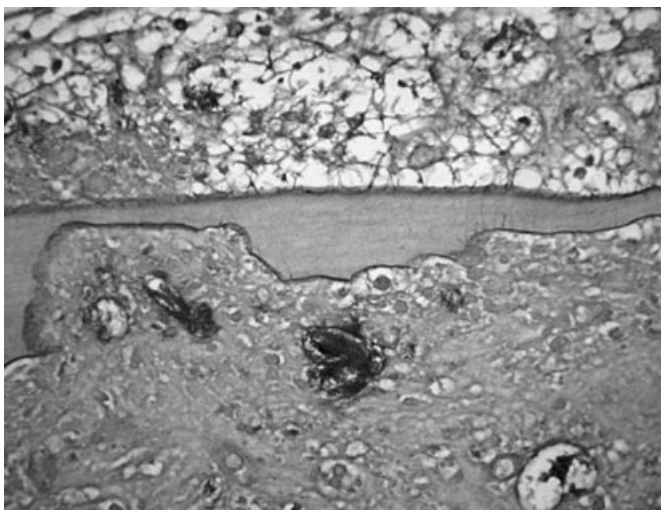

Figure 109–20 Ziehl-Neelsen–stained section shows metastatic osteomyelitis of the tibia in a 6-year-old boy in Benin. This lesion developed after *M. ulcerans* infection of the contralateral leg. Note necrosis of marrow, erosion of a trabecula, and many clusters of acid-fast bacilli (Ziehl-Neelsen stain). (See companion Expert Consult web site for color version.)

Figure 109–21 This 13-year-old girl in Benin initially had a cutaneous lesion of Buruli ulcer. Subsequently, metastatic spread to bones of the lower extremities occurred, resulting in bilateral high-thigh amputations. Note also the spread to bones of both wrists and left hand. (See companion Expert Consult web site for color version.)

Figure 109–22 Ghanaian adolescent girl with healed *M. ulcerans* infection that extended from the wrist to the shoulder. The scarring resulted in contraction deformities of the wrist and elbow and disuse atrophy of the entire extremity. Appropriate physiotherapy would have minimized these sequelae. (See companion Expert Consult web site for color version.)

condition is suspected, and where available, bone scans may be helpful in diagnosis.[242] If the condition goes untreated, a draining fistula usually develops. Osteomyelitis often requires an amputation (Fig. 109–21).

Complications

Infection may traverse the deep fascia and damage tendons, nerves, joints, genitalia, and periorbital tissues, requiring subsequent enucleation of the eye. Healing leads to fibrosis and scarring and can severely limit movement, with attendant lifestyle alterations.[294] The scar may form keloids and often causes major contraction deformities, especially in lesions that cross joints (Fig. 109–22). Squamous cell carcinoma may develop in healed lesions, especially nonpigmented lesions. Skin grafting and physiotherapy prevent most of these complications. Most disease-related deaths result from septicemia, gas gangrene, or tetanus.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

To an experienced observer, an accurate clinical diagnosis often can be made with ease.[353,355] In the ulcerated forms, a Ziehl-Neelsen stain of exudate from the undermined edge obtained with a cotton swab reveals clusters of extracellular AFB. The same material, obtained by swab after decontamination, may be used for culture on Löwenstein-Jensen or other suitable mycobacterial media. The incubation temperature must be 30° C to 32° C. If culture cannot be performed locally, transport media may be inoculated with material from the cotton swab and maintained at 4° C while in transport to a specialized laboratory. The transport medium is composed of Middlebrook 7H9 broth supplemented with polymyxin B, amphotericin B, nalidixic acid, trimethoprim, azlocillin, and 0.5 percent agar. Molecular biologic analysis techniques consisting of PCR for the identification of *M. ulcerans* are available and increasing in popularity and convenience.[1,285,296] Tissue for histopathologic analysis should be obtained from the edge of the ulcer and must include all levels, including the fascia. Fixation in 4 percent buffered formalin is adequate.

Following are some differential diagnostic possibilities:

1. Papules—insect bites, verruca vulgaris, pityriasis, granuloma annulare
2. Nodules—lipoma, sebaceous cyst, onchocerciasis, furuncle
3. Plaques—leprosy, mycosis, necrobiosis, psoriasis
4. Edema—bacterial cellulitis, actinomycosis, elephantiasis, pyomyositis
5. Ulcers—tropical phagedenic ulcer, noma, stasis ulcer, leishmaniasis

PROGNOSIS

Without treatment, Buruli ulcer often leads to deforming depressed scars, contraction deformities, or amputation. The stigma of the deformities and the socioeconomic burden of the disease often are marked.[9] With early appropriate treatment, including excision and grafting, the prognosis usually is excellent. Metastatic lesions and local recurrences occur frequently enough, however, to warrant vigilant follow-up.[6]

TREATMENT

Treatment options for Buruli ulcer include antibiotics and surgical intervention. The choice is usually based on the morphology and extent of the lesions and the availability of antibiotics and surgical facilities. Current WHO guidelines are available.[350,354]

Briefly, antibiotic treatment as recommended by WHO, although still empiric, currently includes at least 8-week courses of daily oral rifampin (10 mg/kg) and streptomycin (15 mg/kg) given as an intramuscular injection. Rifampin is supplied in tablet and syrup forms, the latter being helpful for small children. Streptomycin and, to a lesser extent, rifampin, are associated with rare but important side effects, some of which require stopping treatment. For streptomycin, treatment should be stopped if hearing impairment or vertigo with nystagmus develops. For rifampin, treatment should be stopped if hepatitis, jaundice, or acute renal failure occurs, side effects that generally are associated with intermittent therapy of more than 10 mg/kg. Streptomycin also is contraindicated during pregnancy. In our opinion, antibiotic therapy for advanced lesions remains a subject for inquiry, and the above-described regimens do not constitute established recommendations at this time.

If surgical intervention is chosen, to minimize the danger of development of *M. ulcerans* bacteremia, many surgeons prescribe clarithromycin and rifampin 1 to 2 weeks before performing surgery and have the patients continue antibiotic therapy for several weeks after surgery. Although reasonable, this antibiotic complement to surgery is not of proven efficacy. Papules and pre-ulcerative nodules seldom are diagnosed, even in endemic areas; however, wide excision and primary closure usually are curative.[311]

Plaques and edematous forms are excised widely down to the fascia, or through the fascia if it is necrotic. Muscle usually is not damaged, but if so, the excision is extended into muscle. The lateral extent of excision often is difficult to determine. By careful palpation, the physician can establish an approximate limit of the disease. Exploratory incisions and blunt dissection may help determine the limit of induration and necrosis. Use of real-time PCR for determining the extent of disease is being evaluated.[257]

Very small ulcers can be excised and closed primarily, as for nodules. Large ulcers are excised widely. The required extent of surgery may be determined by exploratory lateral excision and blunt dissection. Split-skin autografting of surgical defects usually is performed after a bed of granulation tissue has formed. Postoperative care, including physiotherapy, should be designed to prevent contractures.

Bone lesions should be referred to specialists. Heat therapy without surgical excision has been successful for appropriate lesions, but must be applied assiduously with all necessary controls.[196] Recurrences after surgical treatment are frequent, but rates are not well established.[62]

PREVENTION

In an endemic tropical rural setting where children usually are scantily attired, prevention of contamination of the skin from environmental sources is virtually impossible. Wearing long trousers seems to prevent development of infection.[176] Protected water supplies in villages would reduce exposure; however, such protective measures usually are futile in rural areas of developing countries. Other risk factors have been analyzed extensively.[63]

Vaccination with BCG has a moderate protective effect against *M. ulcerans* infections for 6 to 12 months.[310] Studies are projected to determine whether repeated BCG vaccination may render the population more immune to *M. ulcerans* infection,[236,237] as was found for leprosy.[150] Other vaccines based on virulence factors of *M. ulcerans* (e.g., the toxin) also are being studied.[125]

HUMAN IMMUNODEFICIENCY VIRUS AND BURULI ULCER

Because Buruli ulcer primarily is a disease of children in rural areas, very few patients have been reported with Buruli ulcer and HIV infection.[8] Relevant reports available indicate, however, that HIV infection may render Buruli ulcer disease highly aggressive; rapidly spreading *M. ulcerans* osteomyelitis has developed in several patients with AIDS.[138,303]

CHAPTER 110

NOCARDIA

Nada Harik ✪ Richard F. Jacobs

Nocardia spp. are obligate aerobic bacilli that exist throughout the world as soil and dust saprotrophs. These organisms are non–spore-forming, thin, branching, gram-positive, partially acid-fast, filamentous bacteria. Humans become infected with *Nocardia* by two primary routes: inhalation of contaminated airborne dust particles or traumatic implantation of the bacterium into subcutaneous tissue. Pulmonary disease is the form of nocardiosis recognized most commonly in the United States.[2] The pulmonary event may be subclinical or transient, or it may provoke an acute or chronic process mimicking staphylococcal or fungal pneumonia, tuberculosis, or carcinoma. Hematogenous dissemination may occur, especially in immunocompromised hosts. The central nervous system (CNS) is the most common site of dissemination, with involvement manifested most often as a brain abscess. Cutaneous nocardiosis may be acute, subacute, or chronic. This form of disease is seen predominantly in immunocompetent hosts, with *Nocardia brasiliensis* being the agent identified most frequently.

In 1888, Nocard, a veterinarian, noted an aerobic actinomycete in bovine farcy, a chronic wasting disease in cattle characterized by pulmonary abscesses and draining cutaneous sinus tracts. Eppinger first described human disease in 1890. The earliest pediatric case was documented in 1895 in a boy with pulmonary and subcutaneous infection.[5]

ORGANISM

Nocardia spp. are included among the aerobic actinomycetes. They are gram-positive bacteria that are filamentous and branched and grow more slowly than other aerobic and facultatively anaerobic bacteria. They commonly produce a fungus-like mycelium that fragments or breaks up into rod-shaped and short coccoid forms. *Nocardia* spp. grow well aerobically on a variety of simple media (e.g., blood agar, brain-heart infusion agar); adding carbon dioxide (10%) promotes more rapid growth. The organisms are inhibited by antibiotics and antifungal agents, so media containing such agents do not support the growth of *Nocardia*. Because of their growth on commonly used fungal media (e.g., Sabouraud dextrose agar) and on some mycobacterial media (e.g.,

Löwenstein-Jensen medium), many *Nocardia* samples may be misdirected to the mycology or mycobacteriology section of clinical laboratories for identification.

In the past, microscopic and colonial morphology, biochemical tests, chemotaxonomic methods, or antimicrobial susceptibility patterns were used to speciate *Nocardia*. 16S rRNA gene sequencing and polymerase chain reaction (PCR) restriction fragment length polymorphism (RFLP) analysis are the current methods most frequently used for speciation; use of these molecular techniques has resulted in changes in the nomenclature of *Nocardia* spp.[10,44]

More than 30 species of *Nocardia* of human clinical significance have been identified.[10] The term *Nocardia asteroides* complex formerly was used to account for the heterogeneity in antimicrobial resistance patterns seen among *N. asteroides.* Detailed molecular analyses and susceptibility testing have established clearly that *N. asteroides* complex represented many different *Nocardia* spp.[10] The most medically important species of *Nocardia* include *N. asteroides*, *Nocardia abscessus*, *Nocardia brevicatena/paucivorans* complex, *Nocardia farcinica*, *Nocardia nova* complex, *Nocardia brasiliensis*, *Nocardia otitidiscaviarum* complex, *Nocardia pseudobrasiliensis*, and *Nocardia transvalensis* complex.

Nocardia spp. grow best at temperatures of 25° C to 45° C; growth at higher temperatures may be used for differentiation. In pure culture, small, chalky white, heaped, wrinkled, or verrucous colonies appear in 3 to 5 days. Mature colonies usually are light orange and have a velvety appearance caused by the production of rudimentary aerial mycelia. They have the odor of a musty basement or freshly turned soil. Detection of colonies from clinical specimens, such as respiratory secretions, may require 2 to 4 weeks. In mixed culture, rapidly growing bacteria may obscure small *Nocardia* colonies. Use of modified Thayer-Martin medium may enhance recovery.[39]

Gram stain of a portion of a colony shows delicate, branching filaments no more than 1 μm in diameter. The delicate filaments may fragment and produce bacillary or coccoid forms. Many *Nocardia* spp. are partially acid-fast (i.e., compared with *Mycobacterium* spp., they retain fuchsin less tenaciously). A modified Ziehl-Neelsen or Kinyoun stain that decolorizes with 1 percent sulfuric acid instead of the more active acid alcohol is best for showing acid-fast *Nocardia* in clinical specimens. Acid-fastness is characteristic of *Nocardia* in tissue or primary colonial isolates but is lost quickly on subculture; not all pathogenic strains of *Nocardia* are acid-fast.[6] *N. asteroides* often survives the *N*-acetylcysteine digestion procedure (without sodium hydroxide) that is performed on sputum or bronchial washings; however, some positive sputum specimens may be rendered falsely negative.[38] Cultures of sputum and bronchial washings for isolation of *Nocardia* should be performed before and after the digestion procedure.

EPIDEMIOLOGY, TRANSMISSION, AND PATHOGENESIS

Nocardia spp. occasionally can be skin contaminants or upper respiratory tract saprotrophs.[21,44,53] Bronchial obstruction or decreased bronchociliary clearance predisposes to colonization.[44] The presence of signs and symptoms that correlate with nocardiosis can help ascertain the clinical significance of a positive *Nocardia* culture.

Most infections occur in the lungs, presumably via inhalation, with dissemination to the CNS occurring in one third of affected patients. Although nocardiosis occurs in immunocompetent individuals, 70 percent of patients are immunosuppressed by medications or underlying disease.[23] The typical patient has compromised cellular immunity (secondary to steroids, organ transplantation, cytotoxic chemotherapy, chronic granulomatous disease, chronic alcoholism, diabetes mellitus, or human immunodeficiency virus [HIV] infection). Nocardiosis also is seen more commonly in patients with chronic pulmonary disease or a history of surgery or trauma.[35] Person-to-person communicability has not been a problem. The incidence of nocardiosis in the United States has been estimated to be approximately 500 to 1000 new cases per year.[3] This number most likely is an underrepresentation, however, given the marked increase in the number of immunocompromised individuals. In addition, nocardial infections can be difficult to recognize, resulting in underestimation of the true incidence of nocardiosis. Presumed nosocomial nocardiosis has been reported.

Cutaneous nocardiosis usually is an infection of immunocompetent hosts. *N. brasiliensis* is isolated from approximately 80 percent of cases of primary cutaneous or subcutaneous nocardiosis.[46] Traumatic implantation of aerobic actinomycetes into deep subcutaneous tissue may result in an indolent condition termed *actinomycotic mycetoma* (to distinguish it from the eumycotic mycetomas caused by true fungi). Mycetoma is a chronic, progressive infection that can extend to underlying bone. Actinomycotic mycetomas usually involve the lower extremities or hands and typically are caused by *Actinomadura* spp., non–acid-fast aerobic actinomycetes, or *Streptomyces* spp. Actinomycotic mycetomas caused by *Nocardia* frequently involve the chest and back. Mycetomas, the cause of which may be *N. brasiliensis*, have been described in Mexican and South American field workers. This *Nocardia* spp. also has been documented as an opportunistic pathogen prevalent in Florida, with a predilection for diabetics.[49]

In addition to the classic mycetoma, traumatic introduction of *Nocardia* spp. from soil may result in wound infections that occur after a more acute or subacute course. Over a 5-year period, 31 cases of localized cutaneous nocardiosis with *N. brasiliensis* were identified in immunocompetent children in South Texas.[19] The organism can be introduced into the skin by tick[31] and other insect bites[19,41] or by a cat scratch,[19,45] and result in cellulitis, pustules, or pyoderma; these conditions occasionally disseminate in immunocompromised individuals.[26,27] Post-traumatic endophthalmitis[20] and post-sternotomy mediastinitis[54,61] have been described.

Nocardiosis previously was considered a rare disease in humans; however, it is being recognized more frequently.[37] It has been diagnosed in individuals ranging from 4 weeks to 82 years of age, and, except in cases of cutaneous nocardiosis, almost all patients have one or more severe underlying diseases (e.g., lupus erythematosus, asthma, glomerulonephritis, ulcerative colitis, bronchiectasis, tuberculosis, rheumatoid arthritis, sarcoidosis). Patients with lymphoreticular neoplasms and transplant recipients seem to be particularly at risk. In addition, the risk of acquiring infection is increased in patients with chronic pulmonary disease and in any patient who is receiving long-term corticosteroid treatment. Infliximab treatment has been associated with the development of nocardial infection.[60] Severe infection with this catalase-positive organism may develop in children with chronic granulomatous disease.[24] Although *Nocardia* is not a surveillance organism for acquired immunodeficiency syndrome (AIDS), patients with AIDS may contract nocardiosis.[25] In a review of all cases ($n = 25$) of nocardiosis at an urban adult teaching hospital from 1999 to 2004, 76 percent of patients with nocardiosis also were infected with HIV; all had $CD4^+$ counts less than 100 cells/mm^3.[12]

In a retrospective review of cases of pediatric nocardiosis admitted to Arkansas Children's Hospital, 5 children with nocardiosis were identified from more than 100,000 admissions in a 10-year period. Four of the five patients had received a transplant within the previous year. Three of these patients had pulmonary disease caused by *N. asteroides*, and one transplant recipient had skin involvement with *N. brasiliensis* at a central venous line site.

One immunocompetent 5-year-old boy contracted CNS infection caused by *N. asteroides* 2 months after incurring a penetrating brain injury.[22]

N. farcinica is a medically important pathogen.[48,59] In a series of 200 cases of *Nocardia* infection reported by Wallace and associates,[59] the isolates designated *N. farcinica* were from patients with severe illness, 56 percent of whom had disseminated infections. *N. farcinica* isolates were characterized by increased resistance to antimicrobials, specifically third-generation cephalosporins. Evidence from mouse models also indicates that *N. farcinica* seems to be more virulent than are other *Nocardia* spp.[16] Because the various species of *Nocardia* seem to have different pathogenicities, determination of the infecting species of *Nocardia* is important.

The immune response to *Nocardia* is multifaceted.[2] Neutrophils are mobilized to the site of infection and are the predominant cell type found in lesions. Neutrophils only inhibit the organisms, however, and limit the spread of infection until an adequate cell-mediated immune response develops, or until effective antimicrobial agents are administered. Immune T cells are vital in clearing *Nocardia* from the lung and preventing dissemination; many predisposing conditions for nocardiosis involve inadequate cell-mediated immunity. Activated macrophages induce cytotoxic T cells effective against *N. asteroides*. *Nocardia* may survive inside neutrophils and macrophages by inhibiting phagosome-lysosome fusion and by the production of catalase and superoxide dismutase, which inactivate the myeloperoxidase system. *Nocardia* organisms exhibit a differential ability to evade phagosome-lysosome fusion that depends on their state of growth, possibly related to specific cell wall mycolic acids detected only in log-phase cells.[4] Differential cell wall characteristics also may influence the ability of *Nocardia* organisms to exhibit specific organ tropism (e.g., the brain).[7] Antibody may play a role in host defense through enhancement of macrophage activities. Although antecedent conditions of nocardiosis frequently involve dysfunctional cellular immunity, other preconditions include neutrophil and immunoglobulin disorders.

PATHOLOGY

The lesions of nocardiosis are suppurative, whether in the lung or in subcutaneous tissue, and they involve primarily proliferation of neutrophils rather than formation of granulomas. Pulmonary nocardiosis in immunocompetent patients often resembles pulmonary actinomycosis in that it results in a chronic localized pneumonia that often abuts the pleura.[23] Indolent progressive fibrosis resembling fibronodular tuberculosis may occur. Nocardiosis is more aggressive in immunocompromised patients and is manifested as multifocal necrotizing pneumonia with confluent abscess formation. *Nocardia* spp. tend to invade the pleura and chest wall, with tissue planes disregarded in the process. Little evidence of encapsulation is characteristic of all organs invaded and probably accounts for the ready dissemination of organisms from the initial pulmonary focus.

N. asteroides organisms appear as delicate, beaded, branching filaments in tissue stained with Gram stain or modified acid-fast stain (Fig. 110–1). *Nocardia* spp. are invisible in hematoxylin and eosin preparations or in sections stained with periodic acid–Schiff for fungi. Methenamine silver preparations sometimes detect tissue organisms; overstaining with silver enhances visualization.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The most common manifestation of nocardiosis (>40% of all cases) in the United States is pulmonary disease in a patient with underlying immunosuppression.[14,42,44] Infection may remain localized to the lung or may disseminate hematogenously to the CNS and skin and, more rarely, to almost any organ in the body. In high-risk patients, the diagnosis should be suspected when CNS manifestations, particularly signs of a brain tumor, abscess, or soft tissue swelling, develop in conjunction with a current or recent subacute or chronic pulmonary infection. Although sulfonamides are the most effective drugs for treatment of nocardiosis, invasive infections have been described in immunocompromised individuals receiving oral trimethoprim-sulfamethoxazole (TMP-SMX) as prophylaxis for *Pneumocystis* pneumonia[58] and in patients with chronic granulomatous disease who are receiving TMP-SMX prophylaxis.[50]

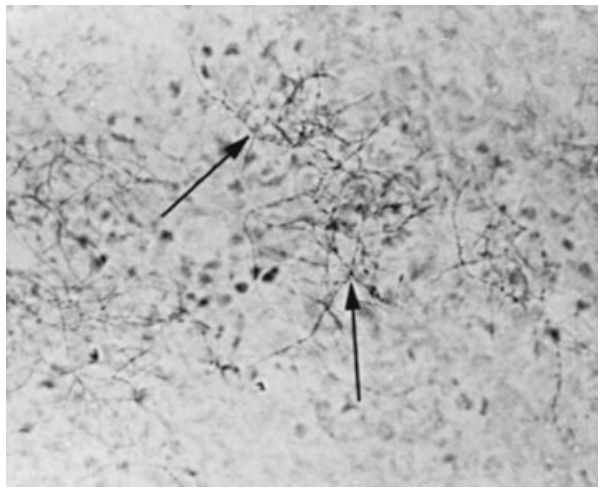

Figure 110–1 Appearance of *Nocardia asteroides* and *Nocardia brasiliensis (arrows)* in a properly decolorized acid-fast smear. Organisms appear as fragmented bacilli with stain concentrated in a beaded fashion along portions of the filaments (×160).

Clinical manifestations of pulmonary nocardiosis are not specific and include anorexia, weight loss, productive cough, pleural pain, dyspnea, and, occasionally, hemoptysis.[14] Untreated pulmonary nocardiosis usually runs a chronic course, similar to tuberculosis, but it also may clear spontaneously and obscure the source of subsequent metastatic infection. The diverse clinical and radiographic manifestations, including acute bronchopneumonia, lobar pneumonia or necrotizing pneumonia with single or multiple abscesses, and pleural empyema, may mimic more common pulmonary infections, such as mycobacterial, staphylococcal, and fungal pneumonia. Normal hosts or patients with only slightly impaired host defenses may have only mild respiratory tract symptoms of several months' duration.[17]

The CNS is the most common secondary site of infection, and such infection occurs in one third of patients.[2] Most experts recommend performing routine cranial computed tomography for patients with pulmonary nocardiosis even when they are asymptomatic because of the frequency of involvement of the CNS. Brain abscesses are the most common manifestation; meningitis is reported less frequently.[9]

Other reported clinical manifestations include tracheitis, peritonitis, iliopsoas abscess, hematogenous endophthalmitis, endocarditis, mediastinitis, septic arthritis, and osteomyelitis.[14] Traumatic inoculation may result in localized disease manifested as cellulitis, subcutaneous abscess, or a lymphocutaneous syndrome in which one or more cutaneous nodules are associated with regional adenopathy or suppurative lymphadenitis.[30] *Nocardia* spp. may cause cervicofacial disease and cervical adenitis in children.[29]

Bacteremic nocardiosis is reported rarely and usually is associated with endovascular foreign bodies in patients receiving long-

term steroid therapy.[28] In a report of six cases of central venous catheter–related *Nocardia* bacteremia, four cases were in children 18 years or younger.[18] All six patients received antibiotic therapy; the catheter was retained in three of the six. Relapse occurred in one of the three patients in whom the catheter was not removed.[18]

The diagnosis of nocardiosis is established in one third of cases by sputum analysis and culture. Humoral methods used to diagnose nocardiosis generally lack specificity because of the high degree of serologic cross-reactivity that occurs among *Nocardia* spp. and between *Mycobacterium* and *Streptomyces* spp.[8] The probable decreased sensitivity for detection of an antibody response in immunocompromised individuals also likely is a limitation of serologic testing. It is important to notify the laboratory when nocardial infection is suspected so that steps can be taken to optimize its recognition and recovery. Although *Nocardia* colonies usually are evident by 3 to 5 days after culture, prolonged incubation may be necessary.

Although *Nocardia* spp. sometimes can be respiratory saprotrophs, withholding therapy from immunocompromised patients when cultures repeatedly are positive is difficult. Bronchoalveolar lavage or lung biopsy may be required to establish the diagnosis. Although these procedures are invasive, given the overlap in symptoms with other infectious and neoplastic processes and potential for rapid progression of disease, bronchoalveolar lavage or lung biopsy should be considered early in immunodeficient patients to establish a definitive diagnosis. The demonstration of tissue invasion confirms active infection. Tentative species identification of most *Nocardia* can be made by biochemical methods, by chemotaxonomic methods, or via antimicrobial susceptibility patterns. Only *N. brasiliensis*, *N. farcinica*, and *N. pseudobrasiliensis* can be identified reliably by these methods, however.[10] Molecular confirmation (e.g., DNA probes, PCR and PCR-RFLP molecular analyses, DNA sequencing, pyrosequencing, ribotyping) of species identification is the method of choice. Molecular testing by *hsp65* PCR and 16S restriction enzyme analysis identifies greater than 90 percent of currently recognized clinical species.[10]

TREATMENT AND PROGNOSIS

Sulfonamides have been the best-studied drugs for the treatment of nocardiosis.[47,50,57] In the United States, TMP-SMX, the only intravenous sulfonamide formulation available, has been the agent of choice for treatment of nocardiosis. TMP-SMX has been used successfully at doses of 15 mg/kg/day of TMP and 75 mg/kg/day of SMX, either parenterally or orally.[50,55,57] No prospective randomized trials have established the optimal antimicrobial therapy for nocardiosis, however. Recommended antimicrobial therapy regimens are based on efficacy in animal models of nocardiosis and in vitro susceptibility and synergy testing.[10] TMP-SMX as a single agent usually is sufficient for patients with cutaneous nocardiosis.

Many infectious disease specialists administer empiric combination drug therapy, consisting of TMP-SMX, amikacin, and a third-generation cephalosporin, or a carbapenem, for patients with severe disease, CNS nocardiosis, or disseminated disease, and for immunosuppressed patients because of documented treatment failure and mortality associated with sulfonamide monotherapy in those settings.[33,37,51] Currently, no *Nocardia* spp. are resistant to amikacin and a β-lactam in vitro; the use of both (plus TMP-SMX) ensures that all clinical isolates would be susceptible to at least one other drug.[10] Antimicrobial therapy can be narrowed to two agents when results of in vitro susceptibility testing become available. Because antimicrobial resistance patterns vary by species, clinical isolates identified initially as *Nocardia* should be speciated further using molecular techniques.

The 2003 Clinical and Laboratory Standards Institute document on susceptibility testing of mycobacteria and other aerobic actinomycetes recommends that all clinically significant isolates of *Nocardia* spp. be tested for susceptibility to multiple antimicrobial agents.[40] No published prospective clinical trials have correlated in vitro susceptibilities with clinical outcome for nocardiosis. Susceptibility testing is the best available guide for selecting appropriate combination therapy and alternative therapies if sulfonamides fail or cannot be given because of patient intolerance or allergy.

Clinical experience with minocycline, the tetracycline with best in vitro activity against *Nocardia*, has been encouraging. Amoxicillin-clavulanic acid has been effective in treating infections with *N. brasiliensis*, commonly a β-lactamase producer.[56] A case of acquired resistance to β-lactamase inhibitor antibiotics has been reported, however.[52] Other species with susceptibility to amoxicillin-clavulanic acid include *N. abscessus* and *N. farcinica*, whereas isolates of the *N. nova* complex are ampicillin susceptible/intermediate but resistant to amoxicillin-clavulanic acid.[10] Susceptibility of some *Nocardia* spp. to fluoroquinolones has been reported. In an in vitro study, the newer fluoroquinolones, gatifloxacin and moxifloxacin, generally were more active than was ciprofloxacin against isolates of *Nocardia*, especially against isolates of *N. farcinica* and *N. brasiliensis*.[10] A patient with disseminated *N. farcinica* nocardiosis initially treated with aspiration, TMP/SMX, and imipenem had recurrence of brain lesions after a change to monotherapy with moxifloxacin despite in vitro susceptibility to moxifloxacin.[15]

The oxazolidinone linezolid is the first antimicrobial shown to be active in vitro against all clinically important *Nocardia* spp.[11] Linezolid, which is available for oral administration, was used successfully to treat six patients with nocardiosis.[36] Linezolid-associated hematologic toxicity was seen in three of the six patients.[36] Myelosuppression may occur more commonly in individuals receiving linezolid for longer than 2 weeks. The use of linezolid for nocardial infection is limited by the prolonged treatment required for nocardiosis.

Clinical improvement typically is seen within 7 to 10 days after initiation of appropriate therapy.[35] Patients with unchanged or worsening symptoms after receiving 2 weeks of therapy should be reassessed thoroughly. Intravenous antibiotic therapy may be changed to an oral regimen after at least 3 to 6 weeks if clinical improvement is noted. The variable and chronic course of nocardiosis precludes determining precise therapeutic end-points. Metastatic lesions can appear during or after an otherwise effective course of sulfonamide therapy with maintenance of the recommended 100- to 150-μg/mL level in serum or plasma. Because the tendency for relapse or the late appearance of metastatic disease is a concern, therapy often is continued for many months. Patients with mycetomas may require 6 to 12 months of therapy; localized cutaneous nocardiosis usually is treated for 3 to 6 months. Therapy for 6 to 12 months is suggested for patients with serious infection. Therapy for 12 months is indicated for patients with CNS nocardiosis and for immunocompromised patients.[32] Patients with CNS disease should be monitored with serial neuroimaging studies. Patients with AIDS probably should be treated with suppressive therapy indefinitely.

Surgical drainage of abscesses is important because metastatic abscesses can appear in the face of adequate therapy until surgical drainage is achieved.[21] Select brain abscesses may respond to antimicrobial treatment without surgery.[34]

Despite specific therapy, the overall mortality rate is 25 to 40 percent.[43,44] Most reported cases involving dissemination to the CNS have been fatal.[43] Disseminated nocardiosis has a poor prognosis, with a mortality rate of greater than 85 percent in immunocompromised hosts.[3] Factors associated with increased mortality rates in one reported patient series were treatment with corticosteroids or antineoplastic agents, underlying Cushing

disease, disseminated disease involving two or more noncontiguous organs or the CNS, and the presence of symptoms for less than 3 weeks before initial evaluation.

CHAPTER 111

Miscellaneous Gram-Positive Bacilli

Randall G. Fisher

The gram-positive rods encompass a vast number of species. They are widespread in the environment and are part of the normal flora of animals and humans. This chapter focuses on gram-positive bacilli seldom encountered as pathogens in healthy individuals. Many of these organisms show increasing prominence as causes of disease in immunocompromised patients.[12] Bacteria from the following genera are discussed: *Corynebacterium* (other than *Corynebacterium diphtheriae*) and *Rhodococcus*.

CORYNEBACTERIUM

The genus *Corynebacterium* comprises a wide number of organisms possessing little pathogenic potential, with some notable exceptions. The most infamous member of this genus, *C. diphtheriae* (see Chapter 101), is a cause of a potentially lethal pharyngeal infection with systemic manifestations. *Corynebacterium jeikeium* (formerly *Corynebacterium* group JK) can be a major nosocomial agent of bacteremia and endocarditis; other species commonly are associated with infections in animals and rarely cause invasive infection in humans.[70,98] For an exhaustive consideration of coryneform bacteria, the reader is referred to the review by Funke and colleagues.[41]

BACTERIOLOGY

Corynebacterium spp. derive their name from their club-like shape. Because of their resemblance to *C. diphtheriae*, they are included in the heterogeneous group of diphtheroids. Snapping division produces the angular and palisade arrangement of cells responsible for their characteristic gram-positive, "Chinese letters" microscopic appearance.[21] Organisms are facultatively anaerobic or aerobic and do not produce spores. They are nonmotile and catalase-positive and contain mycolic acid in their cell walls. Clinically relevant species include *C. diphtheriae*, *C. jeikeium*, *C. pseudotuberculosis*, *C. xerosis*, *Corynebacterium amycolatum*, *Corynebacterium pseudodiphtheriticum*, *Corynebacterium minutissimum*, *Corynebacterium striatum*, *Corynebacterium ulcerans*, and *Corynebacterium urealyticum*. Species can be differentiated according to biochemical tests and fermentation of sugars.[21,41,95]

EPIDEMIOLOGY

Corynebacterium spp. can be part of the normal skin and upper respiratory tract flora and commonly colonize hospitalized patients. Nosocomial acquisition of *C. jeikeium* has been characterized most completely. Thirty-five percent of hospitalized patients may be colonized with *C. jeikeium*, and the organism may be isolated at the time of admission.[42] The skin, groin, and rectum are common sites of recovery. Wounds and suppurative sites quickly become colonized.[42] Longer duration of hospitalization, receipt of broad-spectrum antimicrobial agents, and impaired skin integrity are risk factors for invasive infection. Hospital personnel caring for oncology patients have higher rates of hand colonization with pathogenic *Corynebacterium* spp. than do nurses caring for dermatology patients.[55] Transmission from patient to patient in the hospital environment can occur, and selective antibiotic pressure has been shown to augment colonization with *Corynebacterium* spp.[68,78,128] Outbreaks of bacteremic infection have been reported in hematology wards,[92,110] and DNA restriction fragment analysis and hybridization techniques have been used to document spread.[68,89]

PATHOPHYSIOLOGY

C. jeikeium and *C. urealyticum* are lipophilic, which may account for their ability to proliferate on skin that has a higher lipid content; organisms have been isolated from sebum-filled eccrine gland biopsy specimens in an adolescent with malignancy.[59] Breach of the integrity of the skin is an important risk factor for acquisition of local infection and bacteremia with *Corynebacterium*. Plastic intravascular catheters increase the risk of infection.[93] Certain isolates of *C. pseudotuberculosis* and *C. ulcerans* can express diphtheria-like toxins,[126] which may confer virulence.

Some *Corynebacterium* spp., notably *C. jeikeium* and *C. urealyticum*, commonly show resistance to penicillins, cephalosporins, aminoglycosides, erythromycin, and tetracycline.[30,42,70,78,84,95,108] Strains with a significant DNA relationship to the *C. jeikeium*–type strain show penicillin resistance.[94] Resistant organisms have been noted to have significantly thickened cell walls compared with susceptible strains, but the functional importance of this feature is unknown.[14]

CLINICAL MANIFESTATIONS

Systemic infections with *Corynebacterium* spp. generally are not clinically distinguishable from serious infections caused by other pathogens. Immunocompromised patients are at the highest risk of developing disease caused by *Corynebacterium*,[51,97] but infections also have been described in neonates and immunocompromised older children.[13,30,62] Risk factors include male gender, neutropenia, broad-spectrum antibiotic exposure, and prolonged hospital stay.[92,110] Catalase production may be responsible for the rare infection with non-JK *Corynebacterium* spp. in children with chronic granulomatous disease.[62] *Corynebacterium* spp. are responsible for approximately 9 percent of early-onset and 4 percent of late-onset prosthetic valve endocarditis.[125]

C. jeikeium is a pathogen of particular concern. In 1976, this agent first was described as a cause of serious infection in four patients, including an 11-year-old boy with a ventriculoatrial shunt.[51] The other three patients had hematologic malignancies and were neutropenic at the time of infection. Immunocompromised patients, particularly patients with leukemia, are vulnerable to bacteremia. These high-risk subjects may show a local inflammatory lesion at the site of infection or a disseminated, hemorrhagic, or necrotic papular exanthem. Subcutaneous nodules also may be seen. *C. jeikeium* has been recovered from disseminated lesions in a 14-year-old boy with leukemia.[59] A literature review of 83 neutropenic patients (nearly all adults) with *C. jeikeium* sepsis found the following risk factors for development of infection: presence of a central venous catheter, being male, profound and prolonged neutropenia, and exposure to multiple antibiotics. Skin lesions were reported in 48 percent and pulmonary

infiltrates in 36 percent of patients. The overall case-fatality rate was 34 percent, but it was reduced to 5 percent in patients with recovery of neutropenia.[119]

Infections with *C. jeikeium* also have been reported after trauma, ventriculoperitoneal shunting procedures,[2,64] orthopedic procedures,[20] bone marrow aspiration,[30] and central venous catheter placement.[30] *C. jeikeium* now is recognized to be one of the most common causes of prosthetic valve endocarditis in adults.[84] Cutaneous findings of bacteremia so commonly observed in patients with cancer generally are absent in patients with endocarditis.[26] In a series of 38 patients with *C. jeikeium* endocarditis, 74 percent of patients had prosthetic valves. The mortality rate was 33 percent and was not altered by valve replacement surgery.[82] Exit-site infections in patients on continuous ambulatory peritoneal dialysis also may be caused by *Corynebacterium* spp.; in the largest series published to date, *C. striatum* caused almost twice as many of these infections as did *C. jeikeium*. Most infections are manageable without removal of the dialysis catheter.[102]

Although primarily a pathogen in farm animals, *C. pseudotuberculosis* can cause localized suppurative granulomatous lymphadenitis in humans[70]; almost all cases are associated with animal contact, particularly sheep and goats.[43] Presentation and histology may mimic the much more common cat-scratch disease, and Gram stain and culture are required to differentiate the two entities.[70] Most cases have been reported from Australia.[88]

C. xerosis has been reported as a rare cause of endocarditis, arthritis, and ventriculoperitoneal shunt infection.[7,15] Most individuals with endocarditis have a prosthetic heart valve.[34,72] *C. xerosis* also can be a cause of eye infections in patients with superficial corneal foreign bodies; in one study of 101 patients, *C. xerosis* caused 3 of 15 culture-positive cases.[73] It also is an extremely rare cause of post-LASIK (laser-assisted in-situ keratomileusis) infectious keratitis.[29] Using chemical testing and molecular genetic investigation, Funke and colleagues[40] showed that many isolates tentatively identified as *C. xerosis* are actually *C. amycolatum*. *C. amycolatum* is much more likely to be multidrug-resistant than *C. xerosis*.[41] A case of fatal sepsis in a premature newborn caused by *C. amycolatum* has been reported.[13]

C. pseudodiphtheriticum, a commensal of the oropharynx, can cause pneumonia, bronchitis, or tracheitis.[1,22,25] Lung disease usually occurs in the context of underlying cardiopulmonary pathology or immunocompromise.[49] Onset typically is acute, but fever may be noticeably absent.[74] At least 18 cases of *C. pseudodiphtheriticum* endocarditis, including three infections in children with congenital heart disease, have been reported.[83] Infection of allograft material is a common finding; native heart valves may be involved but usually in the context of preexisting lesions or intravenous drug abuse. Three cases of exudative pharyngitis with a pseudomembrane mimicking diphtheria, including one in a 4-year-old girl from Arkansas, have been reported to be caused by *C. pseudodiphtheriticum*.[58] In one case, a surface swab from a draining wound after arthroscopy was reported to harbor "normal skin flora," but joint fluid grew the same organism, and it was finally identified as *C. pseudodiphtheriticum*. Treatment resulted in resolution of symptoms of septic arthritis.[63] Patients who are immunocompromised and have corneal epithelial defects can get severe eye infections with this organism.[69]

C. minutissimum traditionally has been regarded as the cause of the mild cutaneous disease erythrasma, which is characterized by scaly, pruritic red-brown patches, usually occurring in the axilla or groin. Although *C. minutissimum* may play a role, erythrasma probably is a polymicrobial process.[41] *C. minutissimum* is recognized as a rare nosocomial infectious complication of malignancy and dialysis and has been implicated in a case of pyelonephritis in an 8-month-old infant with posterior urethral valves.[24] An adult who developed native-valve endocarditis caused by *C. minutissimum* has been reported.[6]

C. striatum has been recovered from purulent sputum of hospitalized patients and from infected central venous catheter sites.[103] It also is a cause of exit-site infections in patients on long-term ambulatory peritoneal dialysis.[102] It has been reported as a cause of fatal pulmonary infection and endocarditis.[68,77,98] *C. striatum* was responsible for a nosocomial outbreak among 14 patients over a 12-month period in a surgical intensive care unit. Endotracheal intubation for longer than 24 hours was the only risk factor found to predispose to acquisition of infection.[17] *C. striatum* also has been reported as a cause of meningitis and ventriculoperitoneal shunt infections.[56,123]

C. ulcerans derives its name from its association with ulcerative pharyngitis. Although it is more commonly a pathogen of nonhuman primates,[87] infection can occur in humans after contact with an animal or consumption of contaminated raw milk.[11,27] Toxigenic strains of *C. ulcerans* can produce a syndrome indistinguishable from that caused by toxigenic *C. diphtheriae*.[4,5] Skin lesions that exactly mimic cutaneous diphtheria, caused by diphtheria toxin–secreting strains of *C. ulcerans*, also have been reported.[121]

C. urealyticum (formerly *Corynebacterium* group D2) is a cause of alkaline-encrusted cystitis and pyelitis, primarily in the elderly.[36,108] A case series of four children with encrusted cystitis and pyelitis has been published. The mean age was 9 years (range, 4 to 13 years). Treatment was with prolonged antibiotics and endoscopic debulking. Cure was effected in three of the four patients; the other patient was a renal transplant recipient who lost the graft.[80] Routine urine culture may miss the organism; it may grow with prolonged incubation of sheep's blood agar.[105] It is associated less commonly with infection at other sites and with bacteremia.[107] An 8-year-old boy with chemotherapy-induced neutropenia and a necrotic soft tissue infection of the scrotum caused by *C. urealyticum* has been reported.[99]

DIAGNOSIS

Diagnosis of *Corynebacterium* infection is based on isolation of the organism from clinical material. This organism commonly is accompanied by other pathogens. Similar to *Mycobacterium* and *Nocardia* spp., *Corynebacterium* organisms have mycolic acids in their cell wall. The chains are shorter, however, and the organisms are not acid-fast. *Corynebacterium* spp. may be difficult to distinguish from some *Rhodococcus* spp.[21] Colonies of *C. jeikeium* may show a metallic sheen when grown on agar.[51] Growth of *C. jeikeium* is enhanced by the addition of lipids to the medium. Most *Corynebacterium* spp. can be differentiated quickly from each other by sugar fermentation, hydrolysis of urea, and reduction of nitrate.[116] Selective media containing kanamycin or trimethoprim-sulfamethoxazole have been useful in the recovery of multidrug-resistant strains of *Corynebacterium*.[50] Erythrasma usually is diagnosed by the typical coral red fluorescence under Wood lamp examination.

TREATMENT

Empiric therapy for infection must account for the frequency of infection with *C. jeikeium*, which often are multiresistant to antibiotics but are susceptible to vancomycin.[41] In some series of immunocompromised patients, this organism is the most common *Corynebacterium* spp. encountered.[109,124] Vancomycin is recommended for empiric therapy of suspected *Corynebacterium* infection until susceptibilities are known. Treatment can be changed to a penicillin or cephalosporin, if appropriate. In vitro, *C. jeikeium* is sensitive to linezolid,[45] and most strains also are sensitive to quinupristin-dalfopristin[100] and daptomycin.[44] Linezolid is bacteriostatic against all species of *Corynebacterium*, and in vitro its activity is slower against *C. jeikeium* than it is against

C. striatum and *C. amycolatum*.[45] Clinical experience using these newer antimicrobial agents is lacking.

Two-drug therapy generally is recommended for treatment of *Corynebacterium* endocarditis; for gentamicin-susceptible strains, penicillin-gentamicin combinations have been shown to be synergistic, regardless of whether the strains are susceptible to penicillin.[84] Rarely, resistance to vancomycin is encountered. A woman with prosthetic valve endocarditis caused by a vancomycin-resistant *Corynebacterium* spp. was treated successfully with imipenem and ciprofloxacin.[10] Removal of infectious sources, such as central nervous system shunts and central venous catheters, may be required for cure. Scrupulous attention given to skin hygiene may reduce colonization of hospital personnel and the incidence of patient-to-patient transmission of pathogenic strains.[32,92] Management of toxigenic *C. ulcerans* infection is identical to that for infection caused by toxigenic *C. diphtheriae*, including the use of antitoxin.[5] Erythrasma usually responds to treatment with a macrolide.

RHODOCOCCUS

The genus *Rhodococcus* contains at least 15 species, of which *Rhodococcus equi* is the most clinically relevant to humans. Infections with other species are rare. Suppurative keratitis caused by *Rhodococcus ruber* after penetrating trauma has been described.[65] This organism derives its name from its role as a cause of pyogranulomatous pneumonia in young horses to occur.[90] It has assumed a prominent role as a cause of human pulmonary disease in immunocompromised patients, particularly in patients with acquired immunodeficiency syndrome (AIDS).[35,52,103] For a comprehensive discussion of this organism, the reader is referred to the review by Cornish and Washington.[23]

BACTERIOLOGY

R. equi is a catalase-positive, urease-positive, oxidase-negative, gram-positive rod. The organism assumes a more coccoid morphology in solid media and a more bacillary form in liquid media. Its cell wall contains mycolic acid, rendering it acid-fast when grown on Lowenstein-Jensen media and stained with Kinyoun stain.[46]

EPIDEMIOLOGY

R. equi is a soil organism, and its growth is enriched by the manure of herbivores. Despite the common occurrence of this pathogen as a cause of veterinary infections, exposure to animals apparently is not necessary for human infection to occur[90]; most reported human patients have not had farm or animal exposure.[52] Hospital outbreaks of infection associated with patient-to-patient transmission have not been reported. In a retrospective analysis of 24 cases of *R. equi* infection, however, six patients had shared a hospital room with a patient with *R. equi* pneumonia, raising the possibility of nosocomial transmission.[8] Most patients diagnosed with *Rhodococcus* infection are immunocompromised; AIDS is the most common underlying diagnosis, but infection also has been reported in transplant patients[9] and rarely in patients thought to be immunocompetent.[118]

PATHOPHYSIOLOGY

The prominence of pulmonary infection suggests that the respiratory tract is a common portal of entry. After gaining access to the lower respiratory tract, organisms are taken up by alveolar macrophages; Mac-1 macrophage receptors and complement are required for binding.[53] The appearance of pyogranulomatous lesions is consistent with the role of *R. equi* as an intracellular parasite containing mycolic acid, a possible virulence factor in the cell wall.[47,91] Surface 15- and 17-kd antigens expressed by an 85-kb plasmid seem to confer virulence in mice and foals,[111] and virulent strains seem to have an increased capacity for intracellular survival in macrophages.[54]

Most *R. equi* isolates from patients with AIDS express either the 15- to 17-kd antigens or a 20-kd antigen that seems to confer intermediate virulence. Most isolates from patients without AIDS express none of these antigens, however.[112] Other factors may play a role in promoting *Rhodococcus* disease in humans.[113] Death of parasitized macrophages may release enzymes, which contribute further to tissue damage. $CD4^+$ lymphocytes are essential for pulmonary clearance of *R. equi* in a mouse model,[61] which may help to explain the high risk of infection associated with cellular immunodeficiency.

CLINICAL MANIFESTATIONS

Infection typically manifests as a subacute pneumonia developing over several weeks. Symptoms such as cough and fever are common, but progression of disease may be silent. Although most infections currently occur in patients with AIDS, malignancy and transplantation also pose risks. Pulmonary infection in children with leukemia has been described.[3,79] Infection may be accompanied by other pathogens, particularly in patients with AIDS.

Pulmonary infection often is pleura-based and associated with cavitation.[52] Empyema may occur as a complication. Computed tomography scan most frequently reveals pneumonia with cavitation, but other patterns, including "ground-glass" opacities, peribronchial nodules, and centrilobular nodules, may be seen.[75] Lung tissue showing malakoplakia, an unusual-appearing granulomatous inflammation with aggregates of histiocytes that contain concentrically layered basophilic inclusions, should raise suspicion of the presence of *R. equi* infection.[19,48,101]

Extrapulmonary disease is seen at diagnosis in 7 percent of patients with pneumonia.[120] Manifestations of infection include otitis/mastoiditis,[3,57,71] abscesses,[37] osteomyelitis,[16,38,86] meningitis,[28,104] pericarditis,[67] lymphadenitis,[67] and endophthalmitis.[33] The organism has been grown from a biopsy of a granulomatous skin lesion in an immunocompetent 7-year-old girl.[76] *R. equi* also has been reported as a cause of peritonitis in patients receiving long-term peritoneal dialysis.[18,114]

DIAGNOSIS

Diagnosis relies on isolation of *Rhodococcus* from clinical material. Although sputum specimens may be positive, bronchoalveolar lavage or lung biopsy may be required. Blood cultures may be positive in half or more of patients with AIDS and with focal pneumonic disease.[117] The physician should be alert to the possible coexistence of *R. equi* with other pathogens. In the laboratory, confusing this organism with *Corynebacterium*, acid-fast organisms, and other gram-positive coccobacilli has been shown to delay establishment of the diagnosis.[31] Positive findings on Gram stain and Kinyoun stain should be interpreted in the context of clinical information.[103] Organisms appear salmon-pink when grown on blood agar and orange on Lowenstein-Jensen medium.[12] Differentiating from acid-fast bacteria on smear sometimes can be difficult. Combined use of a siderophore detection medium, ethylene glycol degradation, and β-galactosidase activity may help differentiate *Rhodococcus* from *Nocardia* and

rapid-growing mycobacteria.[39] DNA restriction fragment analysis and ribotyping show promise in aiding the identification and tracking of *Rhodococcus* spp.[66] A *Rhodococcus equi*-specific polymerase chain reaction has been used to confirm infection in some cases in which identification was difficult.[127]

TREATMENT

Clinical isolates commonly are resistant to penicillins and cephalosporins. Even if susceptible in vitro, β-lactam antibiotics should be avoided because of rapid development of resistance.[60] Erythromycin, clindamycin, rifampin, aminoglycosides, vancomycin, fluoroquinolones, and imipenem are active against *R. equi*.[85] Moxifloxacin is more active in vitro than is either ciprofloxacin or levofloxacin.[96] Synergy has been shown with various combinations of these agents. Including rifampin or erythromycin in a two-drug combination has been recommended because of penetrance of macrophages.[12,106] Combinations of antibiotics that included vancomycin were found to be most effective in clearing infection in a mouse model.[85] Cure rates in adults with lung infection are approximately 60 percent when antibiotic therapy alone is employed but may reach 75 percent when combined with surgical resection of infected pulmonary tissue.[52] Surgery has not been shown to increase survival rates, however.[8]

Pediatric patients generally have fared better than adults, but most reported cases in children have been in non-AIDS patients.[12] Relapse is a common occurrence, but the optimal duration of therapy to prevent relapse is unknown. For patients with AIDS, some authors recommend a minimum of 2 months of therapy followed by long-term suppressive therapy.[60] Relapse has been reported to occur at extrapulmonary sites in 13 percent of immunocom-promised patients,[120] often without reappearance of pulmonary disease. Treatment of *R. equi* peritonitis in patients receiving peritoneal dialysis has been reported to be successful with intraperitoneal imipenem or vancomycin for 14 days.[18,115] Removal of the peritoneal dialysis catheter may be required for cure.

Acknowledgments

The author thanks Dr. William Gruber and Dr. Thomas Boyce for their invaluable assistance with earlier versions of this chapter.

SUBSECTION 4

Enterobacteria

CHAPTER 112

CITROBACTER

Randall G. Fisher

Citrobacter, a genus of enteric gram-negative rods closely related to *Salmonella*, has been associated increasingly with human disease. Although *Citrobacter* strains usually are not considered normal inhabitants of the intestinal tract of humans and animals,[44,76] a study using 16S rDNA polymerase chain reaction showed that normal newborns are colonized with these organisms by day 6 of life.[52] They have been associated with urinary tract infections,[6,19,34,40,43,44] osteomyelitis,[43] diarrhea,[15,25,79] and invasive disease in the immunocompromised host.[32,34,43,44] As detailed in a review by Doran,[13] *Citrobacter* commonly is associated with sepsis, meningitis, and brain abscess in neonates.

BACTERIOLOGY

In 1931, Werkman and Gillen[76] proposed the generic term *Citrobacter* for citrate-positive coliaerogenes intermediates isolated from stool. This genus now includes 11 species, of which the most commonly identified are *Citrobacter freundii*, *Citrobacter koseri* (formerly *Citrobacter diversus*), and *Citrobacter farmeri* (formerly *Citrobacter amalonaticus*).[7] *Citrobacter* are straight, facultatively anaerobic bacilli possessing peritrichous flagellae that confer motility. In addition to using citrate, these organisms hydrolyze urea and ferment glucose, with production of gas.[65] They grow on ordinary media as gray, opaque, round colonies that produce a strong, fetid odor. In contrast to *Salmonella*, *Citrobacter* grows in the presence of potassium cyanide. Indole-negative strains that produce hydrogen sulfide are classified as *C. freundii*. Indole-positive, hydrogen sulfide–negative strains are differentiated by their ability to ferment malonate; *C. koseri* ferments malonate, whereas *C. farmeri* does not.[2] Antigenic schemata have been developed to classify the O somatic antigens of *Citrobacter*[20,24,79]; these antigens show cross-reactivity with O antigens of other Enterobacteriaceae.

EPIDEMIOLOGY

Meningitis caused by *Citrobacter* was reported first in 1960, with two cases of *C. freundii*.[29] In the decade from 1970 to 1979, 69 cases of *Citrobacter* meningitis were reported,[21] and 4 percent of neonatal meningitis cases reported in the First Neonatal Meningitis Cooperative Study Group were caused by *Citrobacter*.[48] *C. koseri* is the species usually isolated with meningitis; central nervous system (CNS) infection caused by *C. freundii* occurs less commonly.[13,21] Most of the cases in the United States are reported from southern states; biotype d or serotypes O2 and O1[21] are the most common isolates of *C. koseri* encountered.

Most cases of neonatal meningitis caused by this organism have been sporadic. The source of sporadic cases usually is unknown, but nine cases clearly have been documented to be vertically transmitted from mother to infant.[13] In addition, several well-documented nosocomial outbreaks of infection have been reported.[16,19,20,42,53,60,79] The source usually is the gastrointestinal tract or hands of nursery staff. One cluster was associated with contaminated formula.[71] When *Citrobacter* is introduced into the neonatal nursery, colonization may exceed 79 percent.[20] Parry and associates[53] described a nursery outbreak in which 11 of 128 infants were colonized with *C. koseri* over an observation period of 3 months; two of the colonized infants developed meningitis. Additional colonization of neonates seemed to be eliminated by removal of a nurse with persistent hand carriage of the organism.

In another outbreak,[79] introduction of *C. koseri* into the nursery was linked to an infant admitted with meningitis. Thirty-one percent of infants in the nursery subsequent to the index case were found to be colonized with *C. koseri* of the same serotype and biotype. A second infant from this study developed meningitis with the organism during the observation period. Umbilical colonization of infants in this cluster was more common than was rectal colonization, but rectal colonization was more persistent, lasting 4 months. Two nurses were found to have hand colonization with the organism, and the reintroduction of these bacteria into the nursery was linked to a pregnant nurse who had perineal cultures at delivery yielding the epidemic strain. She was implicated in the colonization of her own infant and three other neonates. Corresponding culture data from a reference hospital revealed an overall neonatal colonization rate with *Citrobacter* of 1 to 10 percent over a 5-year period, with no invasive disease.

Although *Citrobacter* has been isolated increasingly from debilitated adult patients,[77] particularly as a urinary tract,[34,43,44] soft tissue,[22,43,44] and bone[44] pathogen, *Citrobacter* infection in children is unusual after the first 2 months of life. One case of meningitis was reported in a teenager who lacked apparent risk factors or immunodeficiency.[59] In older children, *Citrobacter* spp. are more likely to cause opportunistic infection in an immunocompromised host or, occasionally, urinary tract infection. One study showed *Citrobacter* spp. to be responsible for 37 (1.4%) urinary tract infections in children over a 3-year period.[17] One quarter of infections were nosocomially acquired, and one third occurred in children with urinary tract abnormalities.

PATHOPHYSIOLOGY

Citrobacter infrequently colonizes the intestinal tract and perineum of humans.[34] Vertical transmission of strains shown to be identical by DNA typing shows that the newborn can acquire colonization at the time of passage through the birth canal of a colonized mother.[30,51] Onset of disease beyond the first week of life is related commonly to colonization of the infant in the nursery. As with other types of gram-negative neonatal meningitis, CNS infection results from bacteremia in a colonized infant, leading to seeding of the meninges.

The basis for the particular invasiveness of *Citrobacter* in the neonate and its propensity to cause multiple brain abscesses are largely unexplained. *Citrobacter* spp. possess the ability to invade, transcytose, and multiply within human brain microvascular endothelial cells in vitro.[3] Additionally, in the neonatal rat model, after being taken up into macrophages, *C. koseri* is able to survive phagolysosomal fusion and replicate therein.[72] Many strains of *C. koseri* seem to be able to produce brain pathology in the mouse, but the degree of damage seems to be related to virulence of the strain and the age of the mouse.[39,66] Differences in strains, related to the presence of an outer-membrane protein with a molecular weight of 32,000, have been associated with differences in brain histopathology in one infant rat model of *C. koseri* meningitis.[38] Strains isolated from cerebrospinal fluid (CSF) of infants with meningitis more commonly possess this outer-membrane protein than do strains isolated from other body sites.[39]

In an immunocompromised patient, broad use of antimicrobial agents may produce selective pressure, leading to increased colonization with *Citrobacter*. Increased bacterial density combined with a blunted immune response may result in invasive disease. Some strains of *C. freundii* have been shown to produce Shiga toxins (verotoxins) nearly identical to those produced by enterohemorrhagic strains of *Escherichia coli*.[63] At least one outbreak of gastroenteritis and the hemolytic-uremic syndrome caused by Shiga-toxin–producing *C. freundii* has been reported.[73]

CLINICAL MANIFESTATIONS

Citrobacter, similar to other neonatal pathogens, can cause early-onset and late-onset infection. In a review of 74 cases of neonatal meningitis caused by these bacteria,[21] the mean age of onset reported for early disease was 7 days; 85 percent of patients were included in this group. Fifteen percent of cases occurred after 3 weeks of age. Twenty-three (31%) of 74 patients were younger than 36 weeks' gestational age at birth, suggesting that preterm infants are at increased risk for acquisition of *Citrobacter* infection. Prematurity is even more common (71%) in cases that are proven to be vertically acquired.[13]

Clinical signs and symptoms are typical of neonatal sepsis. Fever, lethargy, poor feeding, vomiting, irritability, bulging fontanelle, seizures, and jaundice are common presenting features. Umbilical infection and surgical manipulation of colonized umbilical stumps occasionally have preceded development of bacteremia and meningitis.[53] The white blood cell count may show leukocytosis or leukopenia. CSF fluid findings are consistent with most types of neonatal bacterial meningitis and usually show polymorphonuclear cell elevation, elevated protein, and depressed glucose; gram-negative rods may be seen on smear. Although growing the organism in culture normally is not difficult, in one reported case standard cultures were negative, but the organism was recovered by direct inoculation of CSF into a BacTec blood culture bottle.[11] Of *Citrobacter* meningitis cases in which the results of blood cultures are reported, 80 percent document concurrent bacteremia.[13]

Citrobacter is a particularly devastating cause of neonatal meningitis. The most common *Citrobacter* spp. causing neonatal meningitis is *C. koseri*, which accounts for more than 80 percent of the cases.[13] CNS infection with this organism produces multiple brain abscesses with unusually high frequency.[21,27,35,39,41] In the extensive reviews by Graham and Band[21] and by Doran,[13] three quarters of *Citrobacter* meningitis cases resulted in intracerebral abscesses. By comparison, the incidence of abscess formation in non-*Citrobacter* gram-negative meningitis is reported to be as low as 10 percent.[21] The case-fatality rate for *Citrobacter* meningitis is approximately 30 percent, and at least three quarters of surviving infants have neurologic sequelae, such as mental retardation, hemiparesis, seizures, and developmental delay.[13]

The presence of brain abscess seems to contribute significantly to morbidity and mortality.[12,20,21] For unknown reasons, neonates with vertically acquired *Citrobacter* meningitis seem to be less likely to develop intracerebral abscesses.[13] At least three cases in which diffuse pneumocephalus developed in association with *Citrobacter* meningitis have been reported; in one, gas was noted to accumulate within the brain and in the anterior chamber of the eye, a condition known as *pneumatosis oculi*.[1,58] Rarely, *Citrobacter* infection in the neonatal period may lead to focal infection not involving the CNS. A case of septic arthritis and osteomyelitis of the shoulder in a 3-week-old infant has been reported.[31]

In adults, *Citrobacter* is isolated most commonly from the urinary tract.[34,43,44] In earlier studies, 5 to 12 percent of bacterial isolates from urinary tract infections in adult patients were *Citrobacter*.[15,78] More recently, in a health maintenance organization, *Citrobacter* spp. accounted for only 0.8 percent of 4342 isolates from women with acute uncomplicated cystitis.[26] *Citrobacter* spp. are a similarly uncommon cause of urinary tract infection in children.[17] Sputum is the second most common clinical specimen to yield *Citrobacter* in adults[34]; lung abscess,[18] pneumonia,[43,44] bronchitis,[32] and septic arthritis[43] have been reported. *Citrobacter* is an occasional cause of bacteremia in hospitalized patients, accounting for approximately 0.5 percent of blood culture isolates.[56,64] In one series, all 45 patients had at least one underlying disease, with malignancies (particularly intra-abdominal tumors) and hepatobiliary stones being the most frequent coexisting conditions.[64] Polymicrobial bacteremia occurred in one third of patients. The case-fatality rate was 18 percent.

Gastrointestinal disease occasionally has been attributed to *Citrobacter*, but frequent isolation of this agent from normal stools often renders this diagnosis equivocal. This genus was implicated first in an outbreak of mild gastroenteritis by Barnes and Cherry[5] in 1946, and an outbreak of watery diarrhea in a Virginia infant care unit included two infants in whom isolates of enterotoxin-liberating *Citrobacter* were obtained from the stool.[25] Some studies have found higher incidences of *Citrobacter* isolation from the stool of patients with enterocolitis syndrome than from stools of control patients.[79] Shiga-toxin (verotoxin)–producing *C. freundii* isolated from organically grown parsley was associated with an outbreak of diarrhea and hemolytic-uremic syndrome in a daycare setting.[73] *C. freundii* has been found as a cause of appendicitis in a healthy adult,[43] peritonitis in adults with liver disease or pancreatitis,[43] neutropenic colitis following chemotherapy for breast cancer,[10] and meningitis in adults as a complication of neurosurgery.[70] A case of Meleney gangrene occurring after cesarean section delivery has been reported.[69] A patient with diabetes developed necrotizing fasciitis caused by *C. freundii* associated with injury from a fish fin.[9] Bone and soft tissue infections occur[8,67]; 3 percent of *Citrobacter* pathogens were isolated from joint or bone in one adult series.[43]

DIAGNOSIS

Biochemical characteristics of *C. koseri* include lack of hydrogen sulfide production on triple-sugar iron agar, negative Voges-Proskauer reaction, use of citrate, motility, production of indole, decarboxylation of ornithine but not lysine, and production of acid from adonitol.[2] Identification of this organism as a pathogen in a nursery setting should heighten suspicion of its possible role in subsequent neonatal infections. *C. freundii* is indole-negative and hydrogen sulfide–positive, which differentiates it from *C. koseri*. *C. farmeri* differs from *C. koseri* because of the former's inability to ferment malonate. *C. freundii* and *C. farmeri* account for a significant portion of disease caused by *Citrobacter* in immu-

nocompromised individuals and should be suspected particularly in this group of patients.[32]

Infants with invasive *Citrobacter* disease present in a similar fashion to infants with sepsis and meningitis of other causes. Such infants should undergo a thorough evaluation, including blood and urine culture and CSF studies. Brain imaging studies should be done when the diagnosis is established. Computed tomography is the most common test used, although ultrasound often is more feasible for an unstable neonate and may be nearly as sensitive in detecting abscesses.[41,49,80] Serial imaging studies should be done because abscesses may develop during the first few weeks of illness. In cases in which the CSF cultures are negative because of prior antimicrobial therapy, surgical aspiration of abscesses sometimes enables identification of the organism.

TREATMENT

Most *C. koseri* organisms are resistant to ampicillin (97% in one series)[43] and sensitive to aminoglycosides and third-generation cephalosporins.[13] A 4-year experience with neonatal septicemia caused by *C. koseri* has been described, however, in which all of 13 isolates were resistant to gentamicin, but susceptible to third-generation cephalosporins.[16] The resistance patterns of *C. freundii* were reported in a national surveillance study of nosocomial bloodstream infections.[56] Of the 23 *C. freundii* isolates tested, resistance to piperacillin, piperacillin/tazobactam, ceftriaxone, and ceftazidime was a common (39-48%) finding. Isolates generally were susceptible to the aminoglycosides and ciprofloxacin (91-96%), and all *C. freundii* tested were susceptible to cefepime and imipenem.

Some *Citrobacter* isolates contain chromosomally mediated group I β-lactamases. These bacteria possess a gene that, when triggered by exposure to cephalosporins or by spontaneous mutation, produces a cephalosporinase capable of inactivating cephalosporins.[33] Clinically, it manifests as treatment failure and emergence of drug resistance to various cephalosporins despite initial susceptibility.[45] In one study, the presence of group I β-lactamases was much more common with *C. freundii* (9 of 22 isolates) than with *C. koseri* (0 of 7 isolates).[33] Resistance was associated with previous receipt of an extended-spectrum, β-lactam antibiotic. Reliable estimates of the percentage of *Citrobacter* strains that contain the chromosomal resistance gene are difficult to obtain because most studies lump *Citrobacter*, *Enterobacter*, and *Serratia* isolates together. In one Korean study, of 152 *Enterobacter/Citrobacter/Serratia* isolates, 45 (30%) were derepressed AmpC mutants.[52] In an in vitro study, AmpC production was inducible in eight of nine clinical isolates of *C. freundii* and in one of three isolates of *C. koseri*. AmpC synthesis was stably derepressed in one of the nine *C. freundii* isolates.[14] Cefepime seems to be less likely to induce production of these β-lactamases and more resistant to hydrolysis by them,[62] although a highly cefepime-resistant strain has been described.[4] Ninety-nine percent of 3030 ceftazidime-resistant Enterobacteriaceae in a U.S. study retained susceptibility to imipenem, and 96.7 percent of ceftazidime-resistant *Citrobacter* isolates were susceptible to cefepime.[57] Many different types of β-lactamases, including a novel TEM-type (TEM-134),[54] the class A β-lactamase CKO,[55] and a VIM-1 metallo-β-lactamase, have been described in various isolates of *Citrobacter*.[75]

Treatment of *Citrobacter* meningitis often requires a multidisciplinary effort involving the neurosurgeon and the pediatrician. Although cerebral abscesses usually are aspirated or drained surgically, some patients are treated with antibiotics alone, and neither approach is clearly shown to be superior. When abscesses are inaccessible or small and not progressive, conservative management may be considered.[13] Ventriculostomy and craniectomy with open drainage of abscesses have been required in some children to effect bacteriologic cure, and placement of a shunt for hydrocephalus often is required.

Generally, antibiotic therapy for gram-negative neonatal meningitis has proved disappointing (see Chapter 78).[46,47] No evidence supports one combination of antibiotics over another in the treatment of *Citrobacter* meningitis. Usually a third-generation or fourth-generation cephalosporin or a carbapenem (usually meropenem) is used in combination with an aminoglycoside initially.[13] Chloramphenicol,[12,20,28] imipenem/cilastatin,[15,28] and trimethoprim-sulfamethoxazole[23] also have been used successfully.

Poor meningeal penetration of aminoglycosides in addition to the presence of intracranial abscesses renders antibiotic therapy for *Citrobacter* meningitis especially difficult. The ability of this organism to persist in the brain is shown by its recovery 4 years after neonatal infection.[15] Cranial computed tomography usually is used for evaluation of complications such as hydrocephalus and multicystic encephalomalacia (Fig. 112–1). Administration of antibiotics intrathecally or directly into abscess cavities has been tried but has not been shown convincingly to be beneficial.[23,24,27,37,42,50,61,68,74] In a randomized controlled trial, intraventricular administration of gentamicin in the treatment of neonates

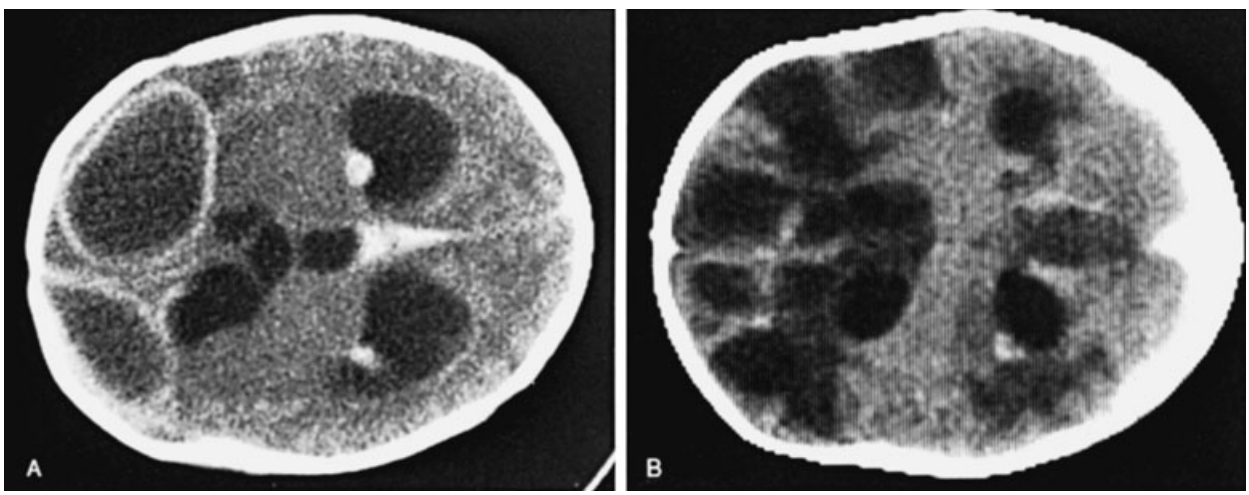

Figure 112–1 **A** and **B,** Computed tomography scans showing progressive abscess formation and encephalomalacia in an infant at 3 weeks of age **(A)** and 6 weeks of age **(B)**, despite bacteriologic "cure" of *Citrobacter* meningitis.

with gram-negative meningitis was associated with a poorer outcome.[48]

Neonates with gram-negative meningitis should undergo repeat lumbar puncture approximately 72 hours after beginning therapy to document sterilization of CSF. Duration of therapy with intravenous antibiotics generally is a minimum of 21 days for gram-negative neonatal meningitis. For cases complicated by intracranial abscesses, prolonged therapy (usually 4 to 6 weeks after sterilization of CSF) is indicated.[13,56]

Scrupulous attention given to preventive infection control practices has been recommended to stem nursery outbreaks.[20,53,79] These prophylactic measures include care of skin and the umbilical cord, elimination of crowding with isolation of infected infants and carriers, and good handwashing practices. Exclusion of colonized personnel and temporary closing of the nursery have been followed by a reduction in neonatal *C. koseri* colonization. Although cohorting of colonized infants is a reasonable practice, multiple sources of introduction of *Citrobacter* may limit the efficacy of this approach in some outbreaks.[19]

Treatment of *Citrobacter* infection beyond the neonatal period requires choice of an appropriate antibiotic, with drainage of abscesses and appropriate débridement of wounds. Therapy should be guided by antimicrobial susceptibility testing. Outcome depends largely on the preceding debility of the host and location of the infection. Significant mortality is associated with immunocompromised patients with septicemia or pulmonary disease.[32,34,43,44,64]

CHAPTER 113

ENTEROBACTER

Laura A. Sass ✪ Randall G. Fisher

Enterobacter is a genus of Enterobacteriaceae that is an increasingly frequent cause of nosocomial pediatric infection. *Enterobacter* can cause infection of postsurgical wounds; meningitis; and infection of the gastrointestinal, urinary, and respiratory tracts. Development of resistance to antibiotics commonly used for treatment of infection is an increasingly common challenge. For a more detailed overview of *Enterobacter* spp., the reader is referred to the review by Sanders and Sanders.[132]

BACTERIOLOGY

Enterobacter spp. are named for their enteric recovery as gram-negative bacteria.[128] They commonly are found in soil, water, and sewage. They also are causes of botanical disease. These organisms are facultatively anaerobic and motile by peritrichous flagella, with the exception of *Enterobacter asburiae*. Most species yield positive results on malonate, citrate, sucrose fermentation, and Voges-Proskauer tests. *Enterobacter sakazakii* is distinguishable from the other species by its yellow-pigmented colonies. Taxonomic studies have led to several classifications of species contained in this genus. With the reclassification of *Enterobacter agglomerans* as *Pantoea agglomerans* (see Chapter 124), *Enterobacter cloacae*, *Enterobacter aerogenes*, and *E. sakazakii* are the most common species recovered from clinical material.[5,17,29,41,50,69,156,158]

Additional species in the *Enterobacter* genus rarely recovered from human infections include *Enterobacter amnigenus*, *E. asburiae*, *Enterobacter gergoviae*, *Enterobacter cancerogenus* (formerly *Enterobacter taylorae*), *Enterobacter kobei* (formerly NIH group 21), *E. cloacae* subsp. *dissolvens* (formerly *Enterobacter dissolvens*), *Enterobacter nimipressuralis*, and *Enterobacter hormaechei*.[1,53,99,100,109,128] NIH group 42 strains now have been proposed to become *Enterobacter cowanii*.[67] *Enterobacter intermedius* now has been reclassified

to *Kluyvera intermedia* (formerly *Kluyvera cochleae*).[116] *Enterobacter ludwigii* is another new species isolated from clinical specimens that is closely related to *E. cloacae* complex.[65]

EPIDEMIOLOGY

Enterobacter is encountered most commonly as a hospital-acquired pathogen in patients with chronic illness.[5,17,29,41,69,156,158,165] A surveillance study at 50 American medical centers showed *Enterobacter* as the eighth most common cause of nosocomial bloodstream infections, accounting for 230 (5%) of 4725 isolates.[121] Of these, 71 percent were *E. cloacae*, 23 percent were *E. aerogenes*, and 6 percent were other species of *Enterobacter*. *Enterobacter* infections are particularly common in intensive care units (ICUs).[102] A report from the Centers for Disease Control and Prevention describing the epidemiology of health care–associated infections in 61 pediatric ICUs in the United States revealed that *Enterobacter* spp. were isolated with increasing frequency from patients with pneumonia and were the most common gram-negative isolates from bloodstream infections.[69] The frequency of *Enterobacter* spp. increased from 7 to 12 percent of reported pathogens over a 6-year period. *Enterobacter* spp. also were found to be second only to *Pseudomonas aeruginosa* in prevalence in health care–associated sinusitis.[129]

In another Centers for Disease Control and Prevention survey focusing on data from the National Nosocomial Infections Surveillance system, *Enterobacter* was one of the five pathogens most commonly encountered in ICUs, and accounted for 8.6 percent of reported infections.[69] During a 10-year period in six Brazilian neonatal ICUs, gram-negative pathogens accounted for more than half of all bloodstream infections, with *Enterobacter* spp. representing 2 percent.[32] In one pediatric hospital, *Enterobacter* spp. (primarily *E. cloacae*) were the most common cause of enteric bacteremia, and accounted for 14 percent of all bacteremic episodes occurring during a 3-year period.[5] Multiple outbreaks caused by *Enterobacter* have been described in neonatal ICUs.* *E. cloacae* has been found in some neonatal ICUs as the predominant pathogen, representing almost 40 percent of the bloodstream isolates.[93] In some series, one third of *Enterobacter* bactere-mias are polymicrobial, which represents a greater prevalence than that of bacteremia caused by other gram-negative organisms.[20,50]

The most frequently cited risk factor for *Enterobacter* infection is the recent receipt of antibiotics, particularly third-generation cephalosporins.[3-5,16,23,50,70,154] Other risk factors include prolonged hospital stay, especially in an ICU, presence of serious underlying illness (e.g., burns, malignancy, and diabetes), prematurity in a neonate, immunosuppression, and the presence of a foreign device.[34,132,151]

Vertical spread of *Enterobacter* from mother to infant may occur at the time of birth.[48] Environmental sources implicated in outbreaks of infection have included intravenous fluids,[6,25,94,96,142,152,155,157] chronic hand dermatitis of a care provider,[11] contaminated infant formula,[7,14,30,33,108] blood gas machines,[2,82] contaminated transesophageal echocardiography probes,[72] cardioplegia ice,[22] therapeutic bed mattresses and mattress covers,[147] and rectal thermometers.[146]

Ribotyping, pulsed-field electrophoresis, and restriction-fragment polymorphism analysis of DNA from clinical isolates have been useful in discriminating possible sources of contamination and patient-to-patient transfer of individual strains.[15,22,29,30,33,57,60,84,132] Plasmid profiles often are of little value because many strains of *Enterobacter* possess few, if any, plasmids.[132] Integrons, discrete mobile units of DNA that can confer antibiotic resistance, have been reported in *Enterobacter* spp. and are more common findings in infections acquired in a health care setting.[34]

Most cases are not outbreak-associated, and endogenous origin of infection is a more common means of acquisition than is the patient's environment.[121] This factor explains why recent antimicrobial use by the patient is such a strong predictor of infection.

PATHOPHYSIOLOGY

Newborns often are colonized by *Enterobacter* spp. in the gastrointestinal tract soon after birth,[13,113] and acquisition of hospital strains in immunocompromised newborns is common.[13,44,49,149] *Enterobacter* may contaminate the compromised respiratory tract. The oropharynx commonly is colonized by *Enterobacter* by the time the infant is 1 month of age; colonization rates generally are lower in breast-fed infants.[10] Newborns with gastrointestinal abnormalities requiring prolonged parenteral nutrition have higher rates of colonization with *Enterobacter* and a higher incidence of sepsis.[122] Other risk factors for increased *Enterobacter* colonization in neonates include prematurity and prior antibiotic use.[117] Enteric organisms are recovered less frequently from the oropharynx of healthy older children and adults, but increased colonization, including increased risk for third-generation cephalosporin–resistant strains, especially with prior cephalosporin treatment of at least 3 days, is noted during illness (see also Chapter 115).[160]

The ability of *Enterobacter* spp. to develop inducible resistance to penicillins and cephalosporins increases their pathogenic potential. All *Enterobacter* spp. possess an inducible chromosomally encoded class C (Bush group I) β-lactamase (*ampC*), which usually is produced in small amounts.[132] An inducible plasmid-encoded *ampC* (gene $bla_{\text{ACT-1}}$) also has been described and can be present in *Enterobacter* spp. and other Enterobacteriaceae.[130] Both enzymes have a high affinity for third-generation cephalosporins but a low maximum hydrolysis rate.[99] Consequently, β-lactamase mediates resistance to these antibiotics only when it is produced in large quantities or large numbers of plasmids are present.[88,127]

Resistance emerges after a mutation occurs in the *ampD* gene, which normally prevents high-level expression of β-lactamase.[68,71] Such mutants are considered "stably derepressed" and may be induced by exposure to β-lactam antibiotics, especially ampicillin and cephalosporins. Mutations in the *ampR* gene produce similar effects.[81] The addition of a β-lactamase inhibitor (e.g., clavulanic acid) does not increase the activity of β-lactam antibiotics against *Enterobacter* spp; rather, it may decrease the activity against the organism by inducing the class C β-lactamase, as can the presence of *ampR* mutants.[71,81,150]

Emergence of resistance can occur during therapy for an isolate that initially is shown to be susceptible.[62,132] Resistance can be detected 24 hours after initiation of therapy or may be delayed 2 to 3 weeks.[28] In addition, more reports of resistant strains of *Enterobacter* that produce plasmid-mediated, extended-spectrum β-lactamases (ESBL) have been published.[66,95,123] Various ESBL genes, including genes from the TEM, SHV, and CTX-M families, have been found.[26,114,138,171] This variation can complicate choosing antimicrobial agents because discerning the source of the β-lactam resistance in the clinical microbiology laboratory often is difficult without performing specific testing, such as the double disk diffusion method. A survey of 11 clinical laboratories in Germany to determine ESBL prevalence found that 40 percent of *E. cloacae* complex organisms were resistant to extended-spectrum cephalosporins, and only 6 percent carried ESBL

*See references 8, 46, 61, 82, 91, 120, 133, 147, 148, 161.

genes.[66] This finding is in contrast to other reports with prevalences of 36 percent in some Asia-Pacific regions.[12]

In one study, gram-negative fecal aerobic flora was eradicated completely after 24 hours of ceftriaxone therapy, only to be replaced within 10 days (mean 6.7 days) of therapy by *Pseudomonas aeruginosa*, *Enterobacter*, and *Citrobacter* resistant to all β-lactam antibiotics.[58] Although uncommon, the combination of reduced outer-membrane permeability and high-level β-lactamase production renders some clinical isolates of *Enterobacter* resistant to carbapenems (imipenem, meropenem, and ertapenem) and fourth-generation cephalosporins (cefepime).[18,37,85,87,99,119,139,144]

Other than the presence of endotoxin, factors responsible for the virulence of *Enterobacter* spp. are not well defined.[76,112] In vitro, it is possible to transfer and express an *Escherichia coli* enterotoxigenic plasmid in *Enterobacter*, implying the potential for transfer of virulence factors to *Enterobacter* spp. from other species.[170] Shiga-toxin–producing *E. cloacae* has been isolated from the stool of a 5-month-old girl with hemolytic-uremic syndrome.[115] *E. coli* OR:H9, which also produced Shiga toxin, also was isolated from the child's stool, rendering the cause of the child's symptoms unclear. Similar to other organisms associated with central venous catheter infections, *Enterobacter* spp. may adhere irreversibly to catheter material, promoting colonization and infection.[77,118] Certain ribotypes have been encountered more commonly as community or bloodstream isolates, indicating the presence of as yet undefined factors affecting virulence.[159] The propensity of *E. sakazakii* to produce neonatal meningitis complicated by abscesses and cerebral infarction is unexplained.[14,30,112,164] Proposed mechanisms have included brain capillary and intestinal endothelial cell invasion, persistence in human macrophages, and biofilm formation.[77,107,141]

CLINICAL MANIFESTATIONS

Infection caused by *Enterobacter* commonly is indistinguishable from illness caused by other enteric pathogens. Sources of infection include central venous catheters and the urinary and biliary tracts.[5,9,50,63,69,90] *Enterobacter* commonly colonizes the respiratory tract secretions of intubated patients, and it is implicated increasingly as a cause of nosocomial pneumonia.[69,129] It also is one of the most common causes of pneumonia after lung transplantation[92] and can be found as part of the oral flora in patients with strokes.[56] Neonatal infection warrants special mention because of the prominence of *E. sakazakii* as a cause of devastating meningitis.

Similar to *Citrobacter diversus* (see Chapter 112), *E. sakazakii* causes neonatal meningitis complicated by cerebral abscesses or infarctions.[14,30,39,74,164,166] Poor feeding, irritability, jaundice, a full anterior fontanelle, and fever or hypothermia are presenting features that are shared with other gram-negative causes of bacterial meningitis. The mortality rate has been reported to range from 33 to 80 percent, and almost all survivors experience severe neurologic complications, including quadriplegia, developmental impedance, and impaired sight and hearing.[39,164] This severe morbidity is consistent with the development of multiple cystic lesions of the brain in 50 percent of surviving neonates. Serial computed tomography scans commonly reveal evolution of lesions most consistent with initial cerebral infarction, rather than primary abscess formation.[51,83,164] Subsequent cystic lesions may be purulent abscesses, from which the organism can be cultured; alternatively, they sometimes represent sterile fluid collections.[24] Meningitis tended to develop in infants of greater gestational age and birth weight than in infants with only bacteremia, but they tended to be younger in chronologic age.[21]

Enterobacter also may be associated with necrotizing enterocolitis in the newborn, which became more apparent during the outbreaks of *E. sakazakii* associated with contaminated powdered infant formula.[83,145] *Enterobacter* spp. were the third most common isolate recovered from peritoneal fluid in a series of patients with necrotizing enterocolitis.[83,105]

In older immunocompromised children, bacteremia complicated by sepsis is a significant risk. Central venous catheterization and gastrointestinal tract pathology seem to pose greater risks for development of bacteremia than infection of the urinary tract.[5,29,50,90] Bacteremia is accompanied by shock in almost one third of patients, but disseminated intravascular coagulation occurs in less than 5 percent.[16,20,50] Seeding of metastatic foci is uncommon. Overall case-fatality rates with bacteremia vary but usually are approximately 30 percent.[132] Factors associated with a poor prognosis include age younger than 18 months, inadequacy of antimicrobial chemotherapy, septic shock, type of underlying disease, presence of pulmonary infection, thrombocytopenia, unknown primary site of infection, and requirement for intensive care.[16,20,36,50,73] Absence of fever during the course of infection may be a particularly ominous sign; four of five afebrile subjects died in one series.[16] One study found that the use of an aminoglycoside as part of the empiric antibiotic management was a factor contributing to survival of *Enterobacter* or *Citrobacter* bacteremia.[36]

Some *Enterobacter* spp. recovered from children with diarrhea have been reported to produce enterotoxin,[27] although a causative role in enteritis has not been established. Other presentations of *Enterobacter* infection include endophthalmitis,[78,101,103] endometritis,[54] wound infections,[50] diskitis,[124,136] endocarditis,[143] and osteomyelitis.[31,40,75,137] *Enterobacter* also has caused syndromes classically associated with other agents, such as gas gangrene,[45] childhood purpura fulminans,[59] ecthyma gangrenosum,[125] and necrotizing fasciitis.[80]

DIAGNOSIS

Diagnosis of infection caused by *Enterobacter* relies primarily on isolation of the organism in culture from clinical material. Motility, production of ornithine decarboxylase, and the absence of deoxyribonuclease help to distinguish the genus from *Klebsiella* and *Serratia*. The presence of yellow pigmented colonies can help identify *E. sakazakii*. Patterns of sugar fermentation and production of decarboxylase also distinguish the species. The ability to detect pathogens directly in tissue using biotinylated probes offers promise for rapidly establishing the diagnosis but remains primarily in the clinical research arena.[97] Other molecular techniques becoming available for rapid identification of bacteria include polymerase chain reaction (PCR)–single strand conformation polymorphism analysis using 16S ribosomal DNA. This technique allows the potential identification of pathogens to be made from a wide range of clinical specimens with low numbers of bacteria and shows promise for clinical applications.[162,168] In light of the increase of *E. sakazakii* invasive disease after ingestion of contaminated powdered infant formula, several techniques have been introduced for the rapid identification of this pathogen clinically and in foodstuffs. The use of a specific PCR amplification of the outer membrane protein A gene (*ompA*) is being investigated,[104] as is reverse-transcriptase PCR[89] and the use of selective media.[38] Ribotyping is a highly discriminatory and reproducible method for the typing of *E. cloacae*, the most common cause of infection.[52] Other useful molecular techniques include restriction endonuclease analysis of chromosomal DNA, pulsed-field gel electrophoresis, random amplification of polymorphic DNA, and amplification of short interspersed repetitive sequences.[132] Most often, molecular typing methods are used in concert with biotyping, serotyping, or bacteriocin typing.

TREATMENT

Treatment of *Enterobacter* infection is made problematic by inducible resistance to cephalosporins and intrinsic resistance to aminopenicillins, cefazolin, and cefoxitin.[19] The increasing recognition that *Enterobacter* spp. can carry ESBL plasmids in addition to expressing chromosomal *ampC* β-lactamases can be problematic using automated ESBL detection systems. The use of the double-disk synergy method for ESBL detection can indicate the presence of plasmid-mediated resistance but is challenging because high production of *ampC* can mask the inhibition of ESBL by clavulanic acid.[163]

Antibiotic resistance may be present at the time of initial isolation or may develop during therapy.[29,62] This problem is compounded by the common observation of resistance to extended-spectrum penicillins and, to a lesser extent, aminoglycosides. The risks for development of resistance to cephalosporins, piperacillin, and aminoglycosides have been reported to be higher at a tertiary care center than at a primary care hospital.[43] Previous administration of third-generation cephalosporins increases the risk of having multiresistant *Enterobacter* isolates in an initial positive blood culture.[5,28,106] Hospitalized newborns quickly may acquire multiresistant strains, even though they themselves have not been treated with cephalosporins.[13] Isolation of multiresistant *Enterobacter* spp. in blood culture is associated with a higher case-fatality rate compared with mortality after isolation of a more sensitive *Enterobacter*.[28,134] Although less common, resistance to imipenem has been reported.[42,85,140] Cefepime, a fourth-generation cephalosporin, generally maintains activity against *Enterobacter* spp. that possess the class C β-lactamase,[131] although minimum inhibitory concentrations may be higher.[99]

Emergence of cefepime resistance during therapy has been described in a liver transplant recipient with a hepatic abscess caused by *E. aerogenes*.[87] The accompanying editorial warns about the risk of failure using cefepime in patients who have high-density infections (e.g., poorly drained liver abscess) caused by ceftazidime-resistant strains of *Enterobacter*.[99] The presence of an SHV-type ESBL has been associated with cefepime resistance, highlighting the need to identify those strains.[138]

In a nationwide survey of nosocomial bloodstream infections, rates of *Enterobacter* resistance to third-generation cephalosporins (ceftazidime, ceftriaxone) and broad-spectrum semisynthetic penicillins (piperacillin) with or without a β-lactamase inhibitor (tazobactam) was high, ranging from 35 to 50 percent.[121] Cefepime and imipenem inhibited 97 to 100 percent of isolates. Susceptibility to aminoglycosides and fluoroquinolones ranged from 92 to 98 percent, and 85 to 96 percent of isolates were susceptible to trimethoprim-sulfamethoxazole. Fluoroquinolone resistance is now being reported and likely is plasmid-mediated.[111,169] Because resistance patterns may vary based on geographic location, local susceptibility data should be used to guide initial therapy.

Some investigators recommend initial combination therapy that includes an aminoglycoside plus either cefepime or a carbapenem (imipenem or meropenem), until results of susceptibility testing are available. Third-generation cephalosporins should be used with caution, even when initial susceptibility results seem favorable. When strains are resistant to gentamicin and tobramycin, amikacin may be a suitable alternative. Good responses to therapy and return of gentamicin susceptibility of hospital *Enterobacter* strains have occurred after routine substitution of amikacin for gentamicin.[126,135] Trimethoprim-sulfamethoxazole alone (or combined with an aminoglycoside) and quinolones seem to be good alternatives for the treatment of *Enterobacter* infections, including meningitis.[5,35,55,100,166] Fluoroquinolones may be another option, depending on local resistance rates. They have been reported to be effective in bone and joint infections, in combination with cefepime.[86] As newer antimicrobial agents become available, more testing will be required to determine their effectiveness. Tigecycline may have promise, but further studies are needed to determine its usefulness in clinical treatment.[153,167]

Enterobacter meningitis creates special concerns. As is common with other forms of neonatal enteric meningitis, even susceptible organisms often persist in cerebrospinal fluid for 5 days or longer.[74] Monotherapy with a cell wall–active agent seems to be less effective than combination therapy with an aminoglycoside. Trimethoprim-sulfamethoxazole also has been used successfully.[47,166] Intrathecal administration of antibiotics does not seem to be beneficial in infants,[98] but it has been used with some success in adults.[110] The physician should anticipate the potential development of cerebral abscesses, infarctions, and cysts in newborns with *E. sakazakii* infection. Serial computed tomography scans should be considered, and a neurosurgeon should be sought for drainage of abscesses and management of fluid accumulation.

CHAPTER 114

Diarrhea-Causing and Dysentery-Causing *Escherichia coli*

Andrea A. Berry ✪ Jorge J. Velarde ✪ James P. Nataro

Escherichia coli has long been recognized as the most common facultative anaerobe in the human gastrointestinal (GI) tract. Virtually all *Homo sapiens* (and most other mammals) harbor this bacterium. Yet within the *E. coli* biomass lurk highly evolved pathogenic subtypes that have adapted themselves to a new niche—human pathogenicity. These pathotypes may prefer the GI tract, the genitourinary tract, or disseminated sites (including the meninges)—the last almost exclusively in neonates. This chapter focuses on *E. coli* associated with enteric infections.

The first implication of *E. coli* with diarrhea occurred more than 75 years ago, when Adam[3] postulated the existence of a group of "dyspepsia" *E. coli* responsible for neonatal and infantile diarrhea. In the 1940s, Bray reported that many, but not all, *E. coli* from severe infant diarrhea cases in summer agglutinated with antiserum prepared from a diarrheal isolate, whereas *E. coli* organisms from other sources did not.[7] The isolate used by Bray to develop the antiserum was later serotyped by the Kauffman scheme as O111:B4, one of the now classic serogroups of enteropathogenic *E. coli* (EPEC) (Table 114–1). Although this initial description was made possible by serologic fingerprinting, the advent of molecular biology rapidly produced a plethora of reports describing the several discrete *E. coli* pathotypes.

CAUSATIVE ORGANISMS

Six distinct diarrheogenic pathotypes are recognized currently on the basis of clinical, biochemical, and molecular/genetic criteria (Table 114–2), as follows:

1. Enterotoxigenic *E. coli* (ETEC), a major cause of traveler's diarrhea and infant diarrhea in developing countries, elaborates the heat-stable (ST) enterotoxin or the heat-labile (LT) enterotoxin, or both, and causes infection of the small intestine.

TABLE 114–1 Serotypes Characteristic of the Diarrheogenic Pathotypes of *Escherichia coli*

Enteropathogenic	Enterotoxigenic	Enteroinvasive	Enterohemorrhagic	Enteroaggregative
O44:H34	O6:H -, 12, 16, 40	O28:H -	O26:H11	Nontypeable
O55:H6, 7, 32	O8:H -, 42	O29:H -	O77:H18	Rough
O86:H2, 34	O25:H -, 42	O32:H -	O103:H2	O3:H2
O111:H2, 7, 12	O27:H7	O42:H -	O104:H21	O6:H1
O114:H2	O29:H21	O89:H -	O111:H8	O11:H16
O119:H6	O63:H -, 12	O112:H -	O113:H21	O15:H21
O124:H?	O78:H11, 12	O121:H -	O128:H2	O44:H18
O125:H21	O117:H4	O124:H -	O145:H -	O92:H23
O127:H4, 6, 21	O125:H30	O136:H -	O157:H -, 7	O111:H21
O128:H2, H21	O126:H10, 27	O144:H -	O178:H19	O126:H2, 27, H -
O142:H6, 34	O127:H2	O152:H -		
O158:H23	O128:H8, 35			
	O143:H -			
	O146:H39			
	O148:H28			
	O153:H45			
	O159:H4, 21			

TABLE 114–2 Relationship of *Escherichia coli* Virulence Genes to Clinical Patterns of Diarrhea

	Virulence Genes†									
Pathogen Group*	*EAF*	*A/E*	*LA*	*AA*	*LT/ST*	*CFA*	*Invasion Factors*	*Stx*	*ShET-2*	Clinical Disease
ETEC	–	–	–	–	+	+	–	–	–	Watery
EPEC	+	+	+	–	–	–	–	–	–	Watery
EHEC	–	+	–	–	–	–	–	+	–	Bloody (hemorrhagic colitis)
EIEC	–	–	–	–	–	–	+	–	+	Bloody (dysentery)
EAEC	–	–	–	+	+‡	–	–	–	–	Watery (persistent)

**ETEC, enterotoxigenic E. coli; EPEC, enteropathogenic E. coli; EHEC, enterohemorrhagic E. coli; EIEC, enteroinvasive E. coli; EAEC, enteroaggregative E. coli.*
†EAF, EPEC adherence factor; A/E, attaching and effacing changes; LA, localized adherence pattern; AA, autoaggregative attaching pattern; LT/ST, heat-labile and heat-stable toxins; CFA, colonization factor antigens; invasion factors, chromosomal and plasmid factors mediating cell invasion; Stx, Shiga family cytotoxins; ShET-2, plasmid-encoded Shigella enterotoxin-2, highly homologous to the plasmid-encoded EIEC toxin.
‡Enteroaggregative stable toxin (EAST) is a member of the ST family.

2. EPEC, the original pathotype defined by Bray,[7] causes infant diarrhea in less-developed countries. The bacteria induce a characteristic attaching and effacing lesion in the small intestine. Classic EPEC requires the chromosomally encoded locus of enterocyte effacement (LEE) and a high-molecular-weight virulence plasmid termed EPEC adherence factor (EAF) plasmid.

3. Enterohemorrhagic *E. coli* (EHEC) causes outbreaks of hemorrhagic colitis and hemolytic-uremic syndrome (HUS) in temperate climates. The essential virulence factor is the Shiga toxin (Stx), which circulates through the bloodstream and acts by inhibition of protein synthesis in the target cell.

4. Enteroinvasive *E. coli* (EIEC) is an unusual cause of diarrhea and dysentery. It is similar to *Shigella* epidemiologically and pathogenetically and shares similar virulence genes.

5. Enteroaggregative *E. coli* (EAEC) causes diarrhea in individuals of all ages in industrialized countries and in less-developed areas and in travelers. The organism adheres to the intestinal mucosa and secretes several enterotoxins and cytotoxins.[95]

6. Diffusely adherent *E. coli* (DAEC) is the sixth category. The epidemiologic scenario for this organism has not been elucidated.

TRANSMISSION AND EPIDEMIOLOGY

Diarrheogenic *E. coli* strains are worldwide in distribution. The route of infection is fecal-oral, predominantly via contaminated food and water, although person-to-person transmission may occur with EHEC and possibly EPEC in infants.[111] As discussed subsequently, environmental contamination by EHEC is an emerging problem in industrialized countries, whereas ETEC continues to be ubiquitous worldwide. Table 114–3 lists the age-specific predilections of the various *E. coli* pathogens.

TABLE 114–3 Age-Related Patterns of *Escherichia coli* Diarrhea

Pathogen Classification	Age at Highest Risk	Characteristics of Diarrhea		
		Bloody	*Watery*	*Inflammatory*
EAEC	<6 mo	–	+++	–
EPEC	<1 yr	–	+++	–
ETEC	<1 yr	–	+++	–
EIEC	>2 yr	++	+	+++
EHEC	2-10 yr	+++	+	–

EAEC, enteroaggregative E. coli; EHEC, enterohemorrhagic E. coli; EIEC, enteroinvasive E. coli; EPEC, enteropathogenic E. coli; ETEC, enterotoxigenic E. coli.

ENTEROTOXIGENIC *ESCHERICHIA COLI*

The infectious dose for ETEC is approximately 10^8 bacteria.[47] The incubation period is 14 to 50 hours.[107] Transmission typically occurs via contamination of food and water,[145] and person-to-person transmission is thought to be uncommon. In developing

countries, contamination of food and water sources occurs commonly.[132] ETEC has been detected in the United States in numerous food samples, including cheese, hamburger, sausage, and seafood.[103,145] A domestic U.S. outbreak of diarrhea at Crater Lake National Park in Oregon was traced to ETEC organisms in the water supply.[143] Because large numbers of organisms are required for experimental infection, transmission probably would require multiplication of the inoculum within the vehicle, which probably contributes to the well-documented propensity of ETEC infection to occur in warm months.[132]

ETEC is a major cause of diarrhea in infants and children in the developing world.[64,132] The incidence typically increases during the first 6 months of life and decreases after 12 months. ETEC has been estimated to cause approximately 20 percent of diarrheal episodes in the developing world,[132] although this percentage varies substantially by location. A study in rural Egypt[134] found that ETEC accounted for 66 percent of all first episodes of diarrhea, with an incidence of 1.7 episodes per child-year during the first 6 months of life and 2.3 during the second 6 months. In Tehran,[148] researchers found that ETEC could be isolated from 15.5 percent of patients younger than 5 years old with diarrhea. The prevalence was 18 percent in Bangladesh[131] and 33 percent in Mexico.[36] A study in Hanoi[117] found, however, that only 2.2 percent of diarrheal episodes could be attributed to ETEC, and the frequency in Mongolia[150] was similarly low.

ETEC disease is primarily a childhood problem, with the incidence decreasing after the child reaches 5 years of age.[131,132] After infection with a particular ETEC strain, the host is resistant to disease but still may excrete the organism asymptomatically, a characteristic that contributes to the environmental burden.[111,162] Adults still may be susceptible to ETEC diarrhea.[64,132] In a study of elderly individuals in Dhaka, Bangladesh,[54] researchers found that 13 percent of adults older than 60 years with diarrhea were noted to have ETEC. Although the incidence of ETEC diarrhea decreases after age 5 years, the incidence seems to increase again in patients older than 15 years, and 25 percent of ETEC infections are seen in adults.[131,132]

ETEC is the most common cause of traveler's diarrhea, typically accounting for approximately 30 to 40 percent of cases.[2,84,152] Illness is acquired by ingestion of contaminated food or water. The diarrhea is acute and watery and typically resolves spontaneously without severe limitation of activities.[2] ETEC also has been implicated as the cause of diarrhea among cruise ship travelers, introduced when the ship docks in a foreign port.[40]

ETEC organisms are extremely diverse, and children in endemic areas experience multiple infections. The basis of immunity, which increases with repeated exposure, is unknown.[162] Strains producing ST cause more severe disease than strains producing only LT, and the former is not immunogenic. Colonization of the small intestinal mucosa is mediated by surface fimbriae called *colonization factor antigens* (CFAs), which are immunogenic and which may elicit some element of protective immunity.[135] Despite the existence of more than 20 CFAs, a few are overrepresented among clinical isolates; in a study from Bangladesh, 7 CFAs constituted greater than 75 percent of the CFAs isolated.[131] In an analysis of multiple studies, Wolf[180] suggested that most ETEC express CFA I, II, or IV. In some epidemiologic studies, most strains do not express known CFAs, however.[156]

ETEC is predominantly an infection of warm weather months in endemic areas, coincident with conditions promoting bacterial replication in the environment. Some sites report that a second peak occurs after the rainy season.[131,132]

ENTEROPATHOGENIC *ESCHERICHIA COLI*

Neter and associates[116] first coined the term EPEC to denote a group of *E. coli* serotypes associated with dramatic and highly lethal nursery outbreaks of diarrhea in the United States and the United Kingdom (see Table 114–1). We now recognize that these serotype antigens serve as surrogate markers for a package of chromosomal and plasmid-borne virulence genes, which together orchestrate enteric pathogenesis. The epidemiology of EPEC has changed since its original description was provided. Gone are the lethal outbreaks formerly reported in industrialized countries, to be replaced by sporadic endemic disease in resource-poor countries. The infection retains its dramatic predilection for infants and children younger than 24 months, is rarely seen in older children and adults, and is not a cause of traveler's diarrhea.[35,36,65,170] The basis of this age-dependent incidence is unknown.

Globally, EPEC is among the most common causes of infant diarrhea.[35,36,65,140] EPEC has a propensity to cause persistent infection and wasting, suggesting that its burden may comprise more than simple dehydration. Breast-feeding offers some protection against EPEC because of the presence of immune factors and oligosaccharides that inhibit adherence of EPEC to epithelial cells.[38] In industrialized countries such as the United States, EPEC generally is no longer considered to be a cause of endemic diarrhea, although EPEC may be present in infants immigrating from or visiting resource-poor settings. Rare indigenous cases may occur.[67] In an outpatient setting in the United States, 2 of 147 cases of non-dysenteric acute diarrhea were caused by EPEC.[27] In 166 Swiss children admitted to hospitals with diarrhea, 13 (7.8%) had EPEC isolated from stool cultures.[53]

As noted previously, EPEC strains of the classic serotypes (also known as typical EPEC) require the LEE chromosomal locus and the EAF plasmid to cause diarrhea. Controversy exists over whether or not so-called atypical EPEC (which are LEE-positive and EAF-negative) are a cause of diarrhea.[109] The description of an outbreak of diarrhea in Japan caused by an atypical EPEC strain suggests that at least some of these strains are pathogenic.[182]

ENTEROHEMORRHAGIC *ESCHERICHIA COLI*

Since its discovery in 1977, EHEC has emerged as an important and increasingly common human pathogen. The organisms may be excreted asymptomatically by cattle herds, and large outbreaks of human infection have been associated with the ingestion of undercooked hamburger and other foods contaminated indirectly by cattle manure. Careful prospective epidemiologic surveillance in Minnesota has revealed an increase in the incidence of EHEC from 0.5 to 2 per 100,000 children younger than 18 years old during the period 1979 to 1988,[101] similar to the incidence of EHEC determined in the state of Washington in the late 1980s: 2.1 per 100,000. In a multicenter study of mild acute diarrhea in outpatients in the United States, 5 (3.4%) of 147 cases were caused by EHEC,[27] a frequency similar to that in Swiss children hospitalized for community-acquired diarrhea.[53] Very young children are not commonly infected; rather, infection occurs most commonly and severely in children 2 to 10 years old or in the elderly.

Ground beef is identified as the most common source of EHEC infection. Several outbreaks have been associated with fast-food consumption.[133] In meat-processing plants where bulk ground beef is prepared for the fast-food industry, meat from one contaminated carcass can contaminate and distribute the organisms to a huge number of beef patties. Several other food sources of transmission that have been documented include other beef; produce, including spinach and lettuce; milk; water; and processed foods, including unpasteurized apple cider, mayonnaise, and dry fermented sausage. Person-to-person, cattle-to-person, and waterborne outbreaks have been described. Person-to-person spread as sequelae of point-source epidemics is common.[155] Many

unusual modes of transmission linked with cattle have occurred and include poorly washed apples dropped in cow pastures and used to make cider, surface water supplies in proximity to areas where cattle graze, spread of aerosolized particles at agricultural fairs, and transmission by contact at petting zoos. Contaminated swimming holes have been implicated in several outbreaks.

A multistate outbreak of O157:H7 EHEC infections associated with the consumption of fresh bagged spinach occurred in the United States in 2006, affecting 26 states and resulting in 205 confirmed illnesses, 103 hospitalizations, 31 cases of HUS, and three deaths.[11,28] This outbreak exemplifies the widespread effect of a foodborne outbreak caused by the mass production and distribution of produce.

Strong epidemiologic evidence associates EHEC with HUS. In one series of patients from Canada, 60 percent of patients with HUS had either neutralizable free Shiga toxin (Stx) or Stx-producing *E. coli* in their stool, and 75 percent had serum antibody against Stx.[124] A review of O157:H7 outbreaks (defined as two or more cases) reported to the Centers for Disease Control and Prevention in the United States from 1982 to 2002 found 350 outbreaks representing 8598 cases, 1493 (17%) hospitalizations, 354 (4%) cases of HUS, and 40 (0.5%) deaths.[133] During a large outbreak of *E. coli* O157:H7 infection associated with fast-food restaurant hamburgers on the West Coast of the United States in 1993, of the 732 affected individuals identified, 195 were admitted to the hospital, HUS developed in 55 (7.5%), and 4 died.[67] Investigation of this outbreak showed that small numbers of bacteria (in the range of a few hundred) constituted an infectious dose. Among 93 cases of O157:H7 infection reported in Washington State in 1987, HUS or thrombotic thrombocytopenic purpura (TTP) developed in 11 (12%), for an approximate incidence of 0.23 per 100,000.[122]

The highest incidence of HUS occurs in children younger than 5 years, in whom the age-specific incidence ranged from 2.6 to 5.8 per 100,000 in Minnesota,[101] Washington,[122] and Oregon.[142] In the 2000 FoodNet Annual Report, *E. coli* O157:H7 accounted for 2 cases of HUS per 100,000, and more than 40 percent of cases with confirmed infection were hospitalized. The incidence of HUS in Argentina, 21.7 per 100,000, is four to eight times higher and is the highest reported incidence of HUS in the world.[99]

In the United Kingdom and the United States, HUS and TTP are associated predominantly with Stx2-producing *E. coli* O157:H7[101,123]; however, this finding may represent more facile detection of this serotype. In addition, the incidence of non-O157:H7 infections in the United States is increasing (serotypes associated with EHEC infection are presented in Table 114–1).[25,85,179] In Argentina, non-O157:H7, Stx2-producing strains are isolated most commonly.[99] Similarly, in Australia, other serotypes, especially O111, have been associated with major outbreaks and a significant number of HUS cases.[9] Many of these serotypes have been implicated in sporadic and outbreak disease in the United States[24] (e.g., an outbreak caused by O104:H21 acquired from contaminated milk[10]).

Non-O157:H7 EHEC infections have increased in prevalence in the United States and are now known to account for 20 to 50 percent of all EHEC infections.[85] Although some non-O157 strains are not pathogenic, others have been shown to cause disease as severe as that caused by O157:H7 strains, suggesting that a clinical suspicion for EHEC should be maintained even when testing for O157:H7 is negative.[85] Non-O157, Stx-producing *E. coli* infection was made a reportable disease in the United States in 2000.[25]

HUS occurs seasonally in the United States and Canada (most common during the summer months), although no specific seasonal risk factor or factors for infection with Stx-producing *E. coli* are known. Other epidemiologic data suggest that poor children are at lower risk for the development of HUS, perhaps because they already have immunity to EHEC or Stx toxins through early contact with the organisms in their environment.[32]

ENTEROINVASIVE *ESCHERICHIA COLI*

EIEC is closely related to *Shigella* microbiologically and pathogenetically. The pathotype typically is found in areas with a high burden of *Shigella*. The infectious dose may be higher than that of *Shigella*, and person-to-person transmission seldom is reported. Food-borne outbreaks occur sporadically.[66,100] The first description of EIEC as a pathotype occurred in 1971, when bloody diarrhea was traced to the consumption of French Camembert cheese contaminated with *E. coli* O124.[100] Small outbreaks or sporadic cases involving a limited number of serotypes have been reported from numerous countries, including the United States, France, Japan, and Brazil.[100,120,160,171,174] Prospective studies in Thailand using DNA probes for EIEC pathogenicity genes indicated that 6 percent of cases of dysentery may be caused by EIEC strains.[48] The epidemiology of the cases is complicated by the fact that in contrast to the initial descriptions of EIEC-associated disease, most EIEC infections probably are neither dysenteric nor characterized by bloody diarrhea but instead manifest as watery diarrhea with low-grade fever, similar to that caused by viral agents and ETEC.

Infection with 10^8 bacteria has been shown to be necessary for experimental dysentery in human volunteers,[47] a dose substantially higher than that for *Shigella* spp. ($\leq 10^4$ organisms). In a food-borne outbreak caused by a nontypeable EIEC, secondary person-to-person transmission was not reported.[160]

ENTEROAGGREGATIVE *ESCHERICHIA COLI*

EAEC was implicated first as a cause of diarrheal disease in studies of children in Chile, Mexico, and India.[18,19,37,112] The pathogenicity of at least some EAEC strains has been established by several observations. First, volunteer studies by Nataro and associates[108] revealed that some EAEC could elicit diarrhea in healthy subjects, whereas other strains may not be pathogenic. Second, EAEC strains have been implicated in outbreaks of diarrhea, the largest of which involved nearly 2700 schoolchildren in Japan.[72,82,183] Lastly, but most emphatically, a meta-analysis performed by Huang and colleagues[79] of more than 20 years of studies revealed convincingly that EAEC is a cause of diarrhea in infants; adults, especially those with human immunodeficiency virus and acquired immunodeficiency syndrome (AIDS) in developing countries; children in industrialized countries; and adult travelers to less-developed areas. In addition, a study from the United States by Nataro and colleagues[113] suggested that EAEC was the most frequent bacterial cause of diarrhea among all ages in Baltimore, Maryland, and New Haven, Connecticut.

Nonetheless, a persisting controversy surrounding EAEC epidemiology and pathogenesis is the definition of the pathotype. The meta-analysis described earlier implicated EAEC, as defined by the characteristic stacked-brick adherence pattern to epithelial cells in culture.[79] A study of infant diarrhea in Cincinnati suggested, however, that only strains hybridizing with an EAEC gene probe (see later) were truly associated with clinical diarrhea.[33] A full understanding of what constitutes a truly pathogenic EAEC strain is unavailable.

CLINICAL MANIFESTATIONS

Diarrhea-causing *E. coli* may be responsible for a variety of clinical syndromes because virtually all known mechanisms of diarrhea, including secretory toxins, cytotoxic toxins, invasion, and

pathogenic adherence, are manifested by the various *E. coli* pathotypes. The clinical manifestations are largely a function of the complement of virulence genes (see Table 114–2), and identification of the essential pathogenicity genes provides the definitive diagnostic maneuver. As with other pathogens, invasive *E. coli* strains (i.e., EIEC) produce inflammatory diarrhea with fever, abdominal pain, nausea, vomiting, and leukocytes and blood in the stool. Noninvasive, cytotoxin-producing EHEC strains cause a frankly bloody diarrhea associated with leukocytosis but without fecal leukocytes or fever. Producers of LT or ST enterotoxins (i.e., ETEC) elicit brisk, watery diarrhea with the potential for significant dehydration.

ENTEROTOXIGENIC *ESCHERICHIA COLI*

ETEC causes watery, nonmucoid, nonbloody diarrhea in infants, older children, and adults, and it is a common cause of traveler's diarrhea.[132] The onset of diarrhea is abrupt, with an incubation period of 14 to 50 hours.[107] The frequency of stools varies from a few to more than 10 per day, and a striking absence of leukocytes is noted when the diarrheal stool is examined by light microscopy. Young affected children may vomit and commonly are febrile (38° C to 40° C), although adults typically are afebrile. ETEC disease cannot be distinguished clinically from most other causes of acute nonspecific watery diarrhea. The illness usually is self-limited to 3 to 5 days but occasionally lasts more than 1 week. Severely dehydrating illness that resembles clinical cholera can occur but is uncommon.

Variability in the clinical picture may be due to age differences and preexisting immunity, but it also may be attributed to differences in the infecting inoculum. DuPont and colleagues[47] produced mild diarrhea (three watery stools per day for 2 to 3 days) when 10^8 bacteria were fed to adult volunteers, whereas 10^{10} organisms caused more pronounced diarrhea (more than five stools per day for 4 to 5 days), with mucus but no blood observed in some subjects. Many subjects also had abdominal cramping, but no tenesmus was present, and all remained afebrile. This clinical picture is typical of traveler's diarrhea in adults.[104] ETEC diarrhea can result in severe dehydration necessitating aggressive fluid therapy.

ENTEROPATHOGENIC *ESCHERICHIA COLI*

EPEC diarrhea typically is copious and watery, without blood or fecal leukocytes.[97] Patients may have low-grade fever. In a Swiss study conducted with modern diagnostic methods, the mean age of 13 hospitalized children with EPEC diarrhea was 1.4 years (range 0.5-3 years).[53] Fever was low-grade, and vomiting occurred in 69 percent. Volume depletion was considered moderate in five and severe in two children. Although nursery outbreaks no longer occur commonly, severe illness still can develop in infants infected with EPEC,[83] with high mortality rates ranging from 25 to 70 percent.[43] The cause of death of patients in nursery outbreaks is not well documented. Investigations using an experimental EPEC infection model in adult volunteers (who are not naturally susceptible) revealed that watery diarrhea occurred 3 to 16 hours after inoculation and generally lasted less than 2 days. Diarrhea occasionally was copious and in some cases was associated with abdominal cramps, nausea, vomiting, malaise, and fever.[45] This clinical picture is consistent with disease caused by outbreaks of EPEC in adults and traveler's diarrhea caused by EPEC.

EPEC also has been implicated in chronic diarrhea in the United States and elsewhere, with serious nutritional consequences that may require total parenteral nutrition and hospital stays of 120 days.[144] In prospective studies of EPEC diarrhea in young infants in Brazil[65] and Ethiopia,[169] fever, vomiting, and dehydration all were observed commonly. The clinical significance of chronic diarrhea may be increased by the underlying malnutrition of infants in resource-poor countries. In many settings, especially where effective oral rehydration programs are in place, chronic diarrhea and associated malnutrition are now more important causes of diarrheal deaths than are acute diarrhea and dehydration.[22]

In the course of the classic, severe nursery outbreaks caused by typical EPEC strains, the first signs and symptoms were mild and nonspecific, but they commonly were followed by vomiting and diarrhea of increasing severity. Stools contained neither mucus nor blood, and the volume fluctuated over a period of weeks. Plain abdominal radiographs revealed only nonspecific dilation of small bowel loops, although severe ileus not attributable to hypokalemia developed in many patients. Infected infants lost as much as 15 percent of body weight, leading to profound electrolyte disturbances and severe dehydration along with central nervous system manifestations, such as irritability, hypertonicity, convulsions, and coma. Circulatory collapse occurred despite adequate replacement of fluids and achievement of electrolyte balance. In an epidemic in Virginia, Belnap and O'Donnell[16] described fatal infections caused by *E. coli* O111:B4 occurring after 3 weeks of illness and associated with renal failure, coma, and signs of disseminated intravascular coagulation, but blood cultures typically remained negative. The fatality rate was age-dependent; although the overall mortality was 16 percent, the rate in neonates was 40 percent.

ENTEROHEMORRHAGIC *ESCHERICHIA COLI*

In 1971, a distinctive clinical diarrheal syndrome was recognized that was characterized by afebrile bloody diarrhea in addition to cramping and colonic inflammatory changes, usually right-sided.[138] In 1983, this illness was associated with an otherwise rare *E. coli* serotype, O157:H7, and a characteristic syndrome, hemorrhagic colitis, was defined.[139] O157:H7 subsequently was recognized as the most virulent prototype of a Stx-producing pathotype designated EHEC. EHEC now has been shown to cause a wide spectrum of diseases that may be confined to the GI tract or, in a sizable proportion (typically 5-10%), can become systemic.[15,165] After an incubation period of 3 to 4 days (range 1 to 8 days), the local GI illness usually begins with nonbloody diarrhea that can progress to bloody diarrhea after 1 or 2 days. Hemorrhagic colitis occurs in 50 to 90 percent of O157:H7 infections.[122,165]

Further progression may occur over the course of the next day or two and result in the passage of frank blood, the pathognomonic clinical feature of hemorrhagic colitis. Associated manifestations include vomiting in approximately 50 percent of patients and abdominal pain. Fever may occur but typically is low-grade. This clinical picture may be confused with other conditions, such as appendicitis, intussusception, inflammatory bowel disease, ischemic colitis, and diverticulitis. The difficulty in establishing the diagnosis can lead to inappropriate drug therapy or even surgery.[68,80]

A serious complication of hemorrhagic colitis is the development of HUS or TTP.[68] HUS is characterized by the triad of acute renal failure, thrombocytopenia, and hemolytic anemia and develops in approximately 10 to 20 percent of infected children younger than 10 years.[111] HUS is the most common cause of acquired renal failure in the United States.[172,173] The acute mortality rate is approximately 5 percent, and renal failure is expected to develop eventually in many more patients during the next several decades. After renal failure, cerebrovascular accident and colonic perforation are the most common serious sequelae. TTP and HUS have overlapping clinical features, but TTP

generally occurs in older adults and is associated with prominent neurologic findings, including behavioral changes, altered consciousness or coma, and seizures, and fever.[77]

A prospective study in Canada identified *E. coli* O157:H7 in 15 percent of 125 patients with grossly bloody diarrhea over a 6-month period.[124] The age range was 15 months to 73 years; however, almost half of the patients were younger than 10 years old. The illness was similar to that described earlier, with a mean duration of 7.8 days, but it was significantly longer in children (9.1 ± 2 days) than in adults (6.6 ± 1.1 days). Sigmoidoscopy findings were abnormal in seven of eight adults examined, with hyperemic mucosa in six and superficial ulcerations in one. Biopsy samples showed mild mucosal inflammation in four of five patients. In another study, the findings on colonoscopy in 10 patients with hemorrhagic colitis caused by *E. coli* O157:H7 included severe inflammation (predominantly right-sided), marked edema, easy hemorrhage, and the frequent appearance of longitudinal ulcer-like lesions.[158]

Because local and systemic manifestations in EHEC infection are caused, at least partially, by Stx, the presence of these same toxins in the intestinal lumen in patients with non-O157:H7 infection puts them at risk for development of hemorrhagic colitis and HUS. No comparative data are available to assess the relative risk in O157:H7 and non-O157:H7 EHEC infection. Non-O157:H7 EHEC may cause similar clinical manifestations, with less aggressive transmission potential.

ENTEROINVASIVE *ESCHERICHIA COLI*

Naturally acquired EIEC infection causes a mild to moderately severe dysentery syndrome consisting of fever, malaise, diarrhea, tenesmus, and abdominal cramping.[47,174] Watery diarrhea usually occurs at the onset of the illness and progresses to mucoid diarrhea with streaks of blood or microscopic hematochezia but rarely to the classic small-volume, grossly bloody, dysenteric stool seen with *Shigella* infection. Of 204 cases reported in one study, grossly bloody stool occurred in only 4.[65] In two of these patients, sigmoidoscopy revealed superficial ulcerations in one and hyperemia alone in the second patient. As in *Shigella* infection, the stool reveals abundant polymorphonuclear cells, compatible with the inflammatory, invasive nature of the organism. Vomiting and dehydration can occur; the latter generally is mild in nature. Fever of 38° C to 39.5° C is a typical symptom that occurs early in association with malaise, myalgia, and headache and lasts for 2 to 3 days. In most instances, the diarrhea ceases in 1 week or less, but in some patients, it may continue for 2 weeks or more.

In adult volunteers with experimentally induced EIEC disease, febrile illness developed approximately 11 hours (range 8 to 24 hours) after the inoculum was ingested.[47] Chills, myalgia, headache, and profuse diarrhea or abdominal cramps and tenesmus rapidly followed. In 2 of 13 subjects, this picture was associated with systemic toxicity and transient hypotension consistent with bacteremia, even though blood cultures were negative for all patients. Clinical dysentery with bloody stools occurred in several subjects, and reddened, friable mucosa with multiple bleeding points was seen by sigmoidoscopy. Clinical illness was controlled quickly with parenteral ampicillin therapy.

ENTEROAGGREGATIVE *ESCHERICHIA COLI*

Descriptions of EAEC clinical features are derived from outbreak investigations, volunteer studies, and studies of traveler's diarrhea.[79] Most EAEC infections are accompanied by watery diarrhea, which may progress to persistent diarrhea that lasts 14 days or longer.[19,112] Bloody diarrhea is observed in a subset of patients.[37] An EAEC strain was implicated in a school lunch outbreak in Tajimi City, Japan, in 1993.[82] Of 6636 children who ate the school lunch at 16 schools, 2697 (rate of attack 40.6%) reported GI symptoms. Major symptoms were abdominal pain (73.6%), nausea (51.1%), and diarrhea (39.9%). The incubation period for the onset of GI illness was 40 to 50 hours on average. Duration of symptoms was not reported. A nursery outbreak in Serbia involved 19 normal infants. All experienced watery diarrhea, which persisted beyond 2 weeks in three patients. A report of 17 pediatric patients with illness caused by EAEC of serotype O126:H27 in Israel suggested that patients typically manifested diarrhea (in all), vomiting (in 8), and fever (in 12, ≤40° C).[157] In this report, one 6-week-old infant developed diarrhea persisting for 40 days. Studies in travelers suggest that EAEC disease may be mildly inflammatory, although fever and fecal leukocytes are present in a few patients.[79]

PATHOGENESIS

ENTEROTOXIGENIC *ESCHERICHIA COLI*

ETEC was identified first as a porcine pathogen,[71,159] which elicited fluid secretion when injected into ligated ileal loops.[71] Two secretogenic activities were characterized: one could be inactivated by heating, and the other could not; the activities could be found both in the same strain or independently. These activities now have been assigned to two well-characterized enterotoxins, LT and ST. LT is genetically, structurally, and mechanistically similar to cholera toxin produced by *Vibrio cholerae* O1 strains.[63,111] ST is actually two distinct toxins: STa is associated with human disease, whereas STb causes disease only in animals.[90,130]

The essential pathogenic strategy for ETEC involves colonization of the proximal small intestine, followed by release of one or both of the enterotoxins. Colonization of the intestinal epithelium (Fig. 114–1) is mediated by proteinaceous, hair-like bacterial surface appendages called *fimbriae* (or *pili*), of which greater than 25 antigenic types are known to exist.[180] The adherence factors are termed *colonization factor antigens* (CFA) or *coli surface antigens* (Fig. 114–2).[60]

Human STa is a small, non-immunogenic molecule that is translated as a 72-amino acid polypeptide.[161] The first 19 amino acids serve as a signal sequence for secretion into the periplasmic space; a further cleavage event occurs after secretion, which results in the final 18- to 19-amino acid active peptide.[111,136] The sequence of the mature ST has six cysteine residues that form stabilizing disulfide bonds, contributing to the high stability of the toxin to heat and proteases.[184] The ST receptor on the apical surface of the intestinal epithelial cells is guanylate cyclase C. This receptor is a large transmembrane protein with an extracellular ligand-binding domain and intracellular catalytic domain; binding to guanylate cyclase C results in its activation, which is responsible for an increase in cellular cyclic guanosine monophosphate (cGMP).[153] cGMP is an intracellular signaling molecule that induces activation of apical chloride channels and inhibition of absorptive mechanisms.[57,69,105] ST exploits an endogenous signaling pathway, the natural agonist of which is the peptide guanylin, a natural controller of electrolyte homeostasis.[39]

The LT family of toxins includes LT-I, which has significant homology in structure and function with cholera toxin, and LT-II, which does not seem to cause human or animal disease.[111] LT-I shares 80 percent identity with cholera toxin and similarly has an A_1-B_5 stoichiometry.[62,111,163] The 28-kd A subunit is the catalytically active moiety, whereas the 11-kd B subunit pentamer mediates cell binding and entry. LT interacts mainly with G_{M1} gangliosides on the surface of the epithelial cells (although additional potential receptors have been identified).[111,168] The A

subunit is composed of two domains, termed A1 and A2, which are bound via a disulfide bond. A1 has an adenosine diphosphate–ribosyl transferase, which targets the cellular guanosine triphosphate binding protein G_s, a regulator of cellular cyclic adenosine monophosphate (cAMP) levels. Ribosylation of G_s leads to constitutive activation of adenylate cyclase, which greatly increases cAMP levels. Increased cAMP leads to increased phosphorylation of chloride channels, especially CFTR, by protein kinase A.[90,154]

ENTEROPATHOGENIC *ESCHERICHIA COLI*

EPEC pathogenesis is complex and only partly understood. In contrast to ETEC, it possesses no potent secretogenic toxin but rather induces changes to the enterocyte signal transduction environment, which transforms the enterocyte from an absorptive cell to a secretory cell. EPEC pathogenesis has been described as a multistep process. The first step comprises attachment to the small bowel mucosa, an event mediated by the EAF plasmid-encoded, bundle-forming pilus (BFP). BFP is a complex surface fimbrial structure that may undergo contraction, not only tethering the bacteria to the cell but also pulling itself close to the cell's apical membrane.[92] Approach of the bacteria is followed by induction of a characteristic lesion, called *attaching and effacing*. Under electron microscopy, the normal microvillus architecture is dissolved, and the bacterium adheres tightly (<20 nm distance) to the now undulating membrane. The bacteria may be observed sitting atop a cup or pedestal of protruding cell membrane (Fig. 114–3). This deceivingly simple phenotype is mediated and accompanied by a dizzying array of invisible changes to the cell's internal environment.[43]

Cellular changes are induced largely by a platoon of protein toxins that the bacterium injects directly into the cytoplasm of the target host cell. This injection process is mediated by a complex bacterial organelle termed an *injectisome*, also known as a *type III secretion system*. The first toxin injected is called the *translocated intimin receptor* (Tir). Tir inserts itself into the apical plasma membrane, where it serves as the receptor for the bacterial outer membrane adhesion protein called *intimin*. As its name suggests, intimin mediates very close attachment of the bacterium to the cell and contributes to the resulting cytoskeletal damage.

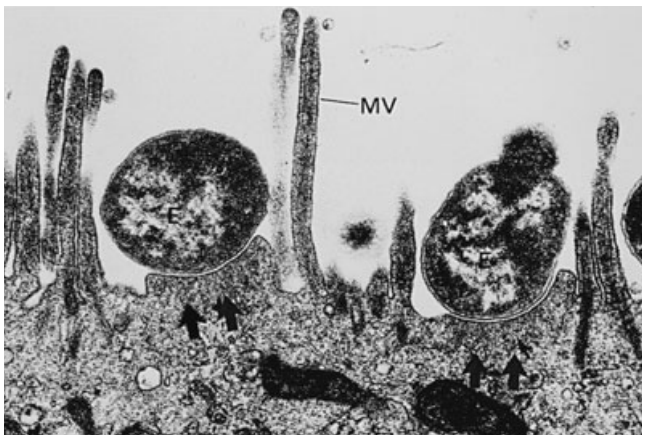

Figure 114–3 High-power electron micrograph of intestinal epithelium infected by typical enteropathogenic *Escherichia coli* strains *(E)*, with occasional intact microvilli *(MV)* and pedestal formation indicated by *double arrows*. This figure shows not only the structural alterations and loss of the brush border, but also the close apposition of the organisms to the epithelial cells. *(Courtesy of Ralph A. Gianella, Department of Medicine, University of Cincinnati School of Medicine.)*

The net effect of Tir, intimin, and other injected toxins is dissolution of the microfilament and microtubule networks, phosphorylation of membrane ion transporters, and disruption of tight junctions at the cell's periphery. Diarrhea apparently is caused by a combination of ion transport and paracellular leakage. Release of proinflammatory cytokines may complete the pathogenic cascade. The relative contributions of each of these events to EPEC disease are unknown.

EPEC adhere to HEp-2 epithelial cells in a characteristic localized pattern, which has been suggested as a diagnostic assay (Fig. 114–4).[43] Also, EPEC causes actin polymerization of target cells at sites of attachment, a virulence property readily detected in tissue culture (e.g., HEp-2 cells) by a fluorescent actin-staining test (Fig. 114–5).[91] As discussed subsequently, these phenotypic assays, although useful for pathogenesis studies, have largely been replaced by molecular diagnostic tests.

ENTEROHEMORRHAGIC *ESCHERICHIA COLI*

The cardinal pathogenic feature of the EHEC pathotype is the production of Stx, leading to the alternate name of Shiga-toxin–producing *E. coli*, accompanied by a cohort of accessory virulence factors. As with EPEC, these factors are encoded by the bacterial chromosome and a high-molecular-weight virulence plasmid. Stx is encoded on a lysogenic phage, which apparently is capable of infecting some nonpathogenic *E. coli* strains. The full package of virulence genes has been well characterized in serotype O157:H7; some evidence suggests that non-O157 pathogens share some, but not all, of the virulence traits, accounting for their reduced virulence and frequency. Stx toxins were discovered by Konowalchuk and associates,[93] who reported finding Vero cell toxic activity in culture filtrates of certain strains of *E. coli* isolated from patients with diarrhea (Stx occasionally has been referred to by the archaic synonym *Vero toxin*).

Stx toxins constitute a family of protein toxins that share identical enzymatic action and target cell binding specificity. Stx are subdivided into two families, Stx1 and Stx2, each consisting of the major Stx type and variants (i.e., Stx1c, Stx1d, Stx2c, Stx2c2, $Stx2d_{EH250}$, $Stx2d_{activatable}$, Stx2e, and Stx2f).[20] Stx2 and Stx2c have been associated with severe disease, including hemorrhagic colitis and HUS.[59,123] $Stx2d_{activatable}$ can be activated by mouse and human intestinal mucus and is associated with a severe clinical phenotype.[20] The greater pathogenicity of Stx2 may be due to greater accessibility of the active site on the Stx2 structure.[58] The *stx1* gene differs from the *Shigella stx* gene by three nucleotide changes, which result in a single conservative amino acid substitution in the A subunit: threonine to serine.[77]

Stx toxins have the same structure and mechanism of action. They have an A_1-B_5 stoichiometry, comprising a single enzymatically active A subunit and a pentamer of B subunits responsible for toxin binding. The B subunits bind to globotrioacyl ceramide (Gb_3) and related glycolipids on host cells, including epithelial enterocytes, vascular endothelial cells, smooth muscle cells, renal endothelial cells, and erythrocytes.[46,94] The catalytic A subunit cleaves the *N*-glycosidic bond in a specific adenosine of the 28S rRNA in the 60S ribosomal subunit.[49] This single cleavage event results in irreversible cessation of protein synthesis and ultimately leads to cell death via multiple signal transduction pathways.[34] Intestinal villus cells are susceptible to the action of Stx, which includes reduced absorption of sodium. Data suggest that Stx induces local inflammatory cytokine production, with potential effects on epithelial cell and mucosal integrity. This host response may induce a vicious cycle because both hydrogen peroxide and neutrophils augment production of Stx.[178]

Epidemiologic evidence strongly links Stx-producing strains to hemorrhagic colitis and to the associated systemic complica-

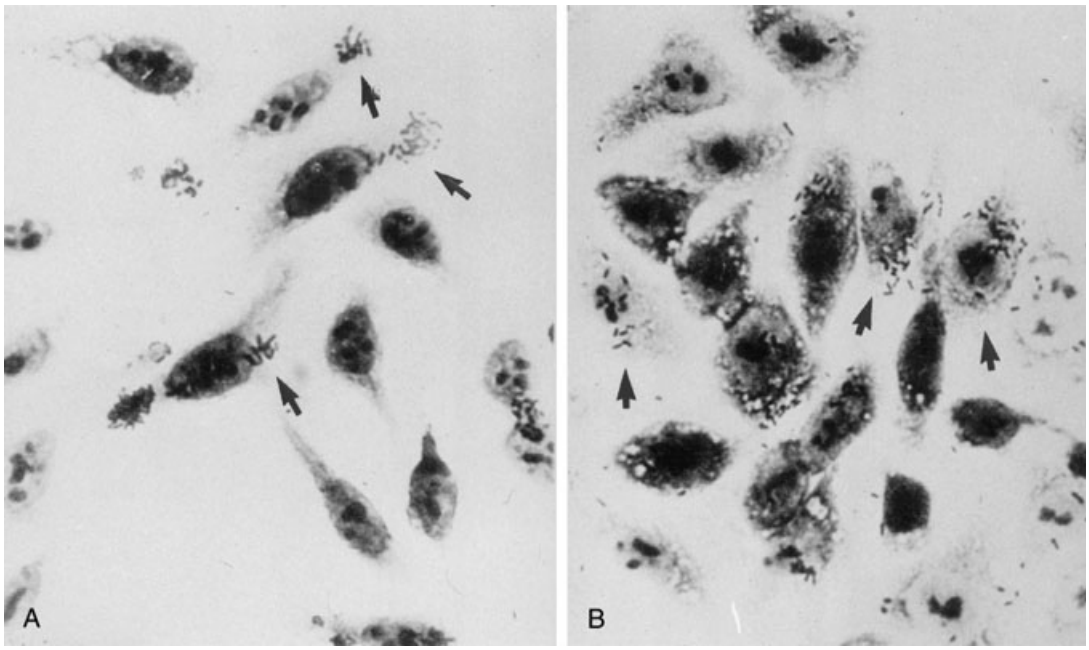

Figure 114–4 **A** and **B,** Patterns of adherence of *Escherichia coli* to HEp-2 cells in tissue culture. Typical enteropathogenic *E. coli* associates with HEp-2 cells in the pattern shown in **A,** termed localized adherence (LA). *Arrows* point to cells where growing microcolonies of bacteria are attached to focal areas of the cell membrane. Other *E. coli* organisms isolated from patients with diarrhea adhere over the entire HEp-2 cell membrane, as shown in the cells identified with *arrows* in **B**. This pattern of interaction is termed diffuse adherence (DA). Although the LA phenotype has been associated definitively with the capacity to induce diarrhea in experimental models, no convincing evidence of virulence in DA strains has been obtained to date.

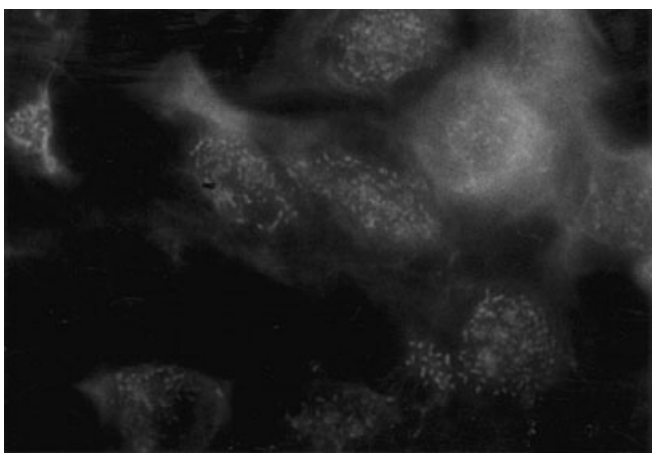

Figure 114–5 Some *Escherichia coli* strains have the capacity to attach to the eukaryotic cell membrane and induce polymerization of actin beneath the membrane. This property may be shown by the fluorescent actin staining test, in which polymerized F-actin is detected by a fluorescein-tagged mushroom toxin specific for this form of actin. In this figure, the bacteria are attached to HEp-2 cells, and the induced actin polymerization revealed by the fluorescent reagent highlights the organisms, which are seen as bright rods on the infected cells.

tions of HUS and TTP.[67,87,139] The mechanisms underlying HUS and TTP are uncertain but seem to be due to the effects of toxin on vascular endothelial cells, possibly in concert with lipopolysaccharide and a variety of cytokines, which initiate events resulting in endothelial cell injury and platelet thrombi and, subsequently, the characteristic thrombotic microangiopathy.[32,88,119] Other possible initiation factors include abnormal levels of von Willebrand factor, but whether this abnormality is a cause or a consequence of disease is unknown.[106] Stx1 has been shown to decrease production of prostacyclins; however, the role of this event in the pathogenesis of HUS is uncertain.[88]

Similar to EPEC, EHEC express the intimin outer membrane protein and a type III secretion apparatus.[111] EHEC are capable of inducing complex cytoskeletal alterations similar to those caused by EPEC infection, although certain subtle differences are observed. EHEC infects the human colon, whereas EPEC is an infection of the small bowel. The genes encoding intimin, Tir, the type III secretion system, and secreted proteins reside on a 35-kb pathogenicity island called the LEE, which may be more crucial for EPEC than for EHEC for virulence.[46] A 60-Md plasmid, pO157, which contains genes encoding an enterohemolysin, is commonly found in O157:H7 strains, but its role in production of disease is unclear.[111] Subtilase cytotoxin (SubAB), a novel cytotoxin with an A_1-B_5 stoichiometry, was described more recently and associated with HUS in diverse EHEC strains in Australia and the United States.[90,127] SubAB is heat-stable, more toxic to vero cells than Stx, and lethal when injected in mice.[90,127] Cytotoxicity is the result of direct cleavage of an endoplasmic reticulum chaperone protein, BiP.[126]

ENTEROINVASIVE *ESCHERICHIA COLI*

In 1967, Trabulsi and coworkers[171] in Brazil and Sakazaki and associates[147] in Japan described the isolation of certain *E. coli* serotypes from patients with a disease resembling bacillary dysentery, but with cultures negative for *Shigella*. These isolates possessed a critical virulence hallmark associated with *Shigella*—the ability to invade intestinal and other epithelial cells (Fig. 114–6).[119] They have been called EIEC, and a limited number of serotypes, distinct from the EPEC O groups, but often cross-reactive with *Shigella* O antigens, have been found to possess this property (see Table 114–1). The genetic and molecular basis of

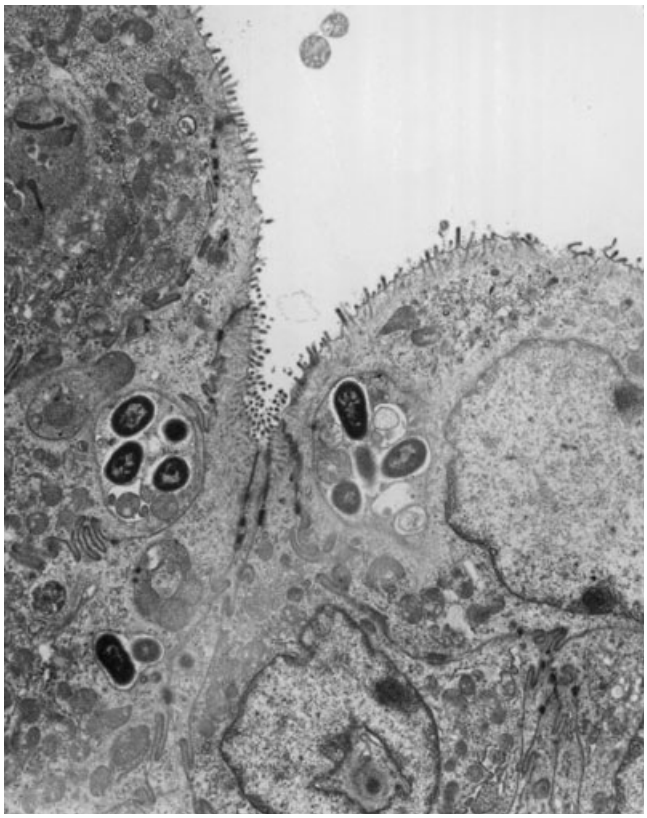

Figure 114–6 Electron micrograph of enteroinvasive *Escherichia coli* infection of intestinal mucosa. The intracellular location of the bacteria clearly is seen within membrane-bound vesicles in two adjacent infected cells. The pathogenesis of enteroinvasive *E. coli* infection involves the invasion of intestinal cells and local cell-to-cell spread, as shown here, by a mechanism identical to that of *Shigella* spp. *(Courtesy of Saul Tzipori, D.V.M., Department of Comparative Medicine, Tufts University School of Veterinary Medicine.)*

invasion by *Shigella* was well defined in the 1990s, and the same plasmid and chromosomal genes encoding invasion properties and mechanisms seem to be present in EIEC as well.[78,98,125,149]

The invasive process for EIEC is thought to be the same as that for *Shigella* spp. It has been well characterized and involves four main steps: (1) initial entry into cells, (2) intracellular multiplication, (3) intracellular and intercellular spread, and (4) host-cell killing. The process is complex and involves multiple genes on the invasion plasmid and the chromosome.[1] EIEC produces toxins reported to be structurally distinct from the Stx of *Shigella dysenteriae* type 1 and the Stx1 and Stx2 of EHEC.[55] Nonetheless, studies suggest that EIEC toxins possess many properties in common with the Stx family of toxins, including the ability to cause fluid secretion in animal models.[55] EIEC may contain a plasmid-borne gene that encodes a 63-kd protein called *ShET2* (Shigella enterotoxin 2); a mutation in this gene substantially decreases the enterotoxic activity of the parent strain.[114]

ENTEROAGGREGATIVE *ESCHERICHIA COLI*

The pathogenesis of EAEC includes adherence to the intestinal epithelium as a thick biofilm, accompanied by mucus hypersecretion, intestinal damage, and induction of an inflammatory response. Most of these phenotypes seem to be mediated by a set of bacterial cytotoxins and enterotoxins.[73]

Adherence and colonization of the intestinal epithelium are mediated by pili called *aggregative adherence fimbriae*, of which several allelic variants exist. EAEC may colonize the large and small intestines.[76] All known aggregative adherence fimbriae variants are encoded on high-molecular-weight virulence plasmids collectively termed *pAA*. Also encoded on pAA is a transcriptional activator of the fimbrial genes, called *AggR*. AggR is emerging as a global regulator of virulence functions in EAEC; also under AggR control is a gene encoding a surface protein nicknamed *dispersin*. In the absence of dispersin, the aggregative adherence fimbriae adhesins collapse onto the surface of the bacterium, rendering it unable to colonize the intestine (J. Nataro, unpublished). Several cryptic genes, including a large chromosomal locus, also are under AggR control.

Damage to the intestinal mucosa has been linked to the presence of a secreted enterotoxin called *Pet* (plasmid-encoded toxin).[52] Pet is a protease that is internalized by target epithelial cells, where it cleaves cytoskeletal proteins including spectrin. The net effect of these cleavage events is induction of fluid, secretion of electrolytes, and, ultimately, exfoliation of cells from the mucosal surface.[75]

EAEC strains also harbor a homologue of the ETEC heat-stable toxin, enteroaggregative ST,[151] and a chromosomally encoded toxin called *Shigella* enterotoxin 1.[56] Inflammation by EAEC has been linked to the expression of the bacterial flagellum, although studies in polarized epithelial monolayers suggest that additional factors under control of AggR also are required.[73]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Diarrheogenic *E. coli* can be identified best by detecting their defining virulence genes. Although many molecular tests are described for this purpose, few laboratories in the United States use them. For most pathotypes, consultation with an expert, such as the senior author or the *E. coli* reference laboratories at the U.S. Centers for Disease Control and Prevention, is recommended. Detection of *E. coli* generally is indicated for severe and persistent diarrhea lacking any other diagnosis (particularly in returning travelers), or in the setting of diarrheal outbreaks of unknown cause. With the exception of EHEC, most infections caused by diarrheogenic pathotypes are self-limiting.

Because of the potential of EHEC to cause serious sequelae, establishing a specific diagnosis is of clinical and epidemiologic importance. The earlier in the course of illness that a stool specimen is obtained, the more likely that *E. coli* O157:H7 will be recovered[166]; recovery more than 7 days after onset of diarrhea is unusual. The laboratory can use sorbitol-MacConkey (SMAC) agar to screen colonies for lack of sorbitol fermentation or substrates such as 4-methylumbelliferyl-β-D-glucuronide (MUG) for the production of β-glucuronidase; *E. coli* O157:H7 is almost uniquely sorbitol-negative and glucuronidase-negative. These techniques have limited sensitivity, with the sensitivity of SMAC agar reported as 50 to 60 percent.[89] Some sorbitol-fermenting O157:H7 isolates and many other sorbitol-fermenting, non-O157 EHEC are capable of causing severe illness and HUS that are missed by sorbitol-MacConkey agar.

Detecting *Shiga* toxin in stool specimens, either directly or after overnight broth enrichment, currently is the most sensitive nonmolecular method for identifying EHEC.[89] These tests are more sensitive than are culture techniques and are not dependent on serotype. Commercial enzyme immunoassays for Stx have been approved by the U.S. Food and Drug Administration for either confirmation of isolates as toxin producers or rapid direct diagnosis based on the detection of Stx1 or Stx2 in stool.[17,110] Despite the detection of *Shiga* toxin by these rapid assays, isolation of the organism, usually performed at reference laboratories, remains crucial for serotyping and other epidemiologic purposes.

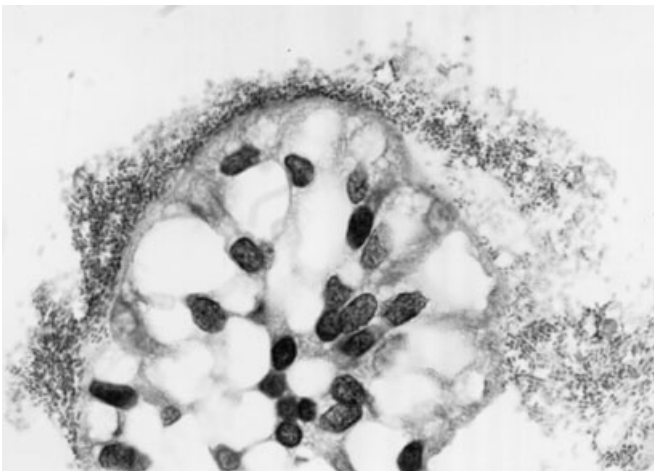

Figure 114–7 Enteroaggregative *Escherichia coli* (EAEC) infection of the gnotobiotic pig intestine. This photomicrograph shows the characteristic "stacked-brick" appearance of the aggregative organisms over the surface of the intestinal epithelium in vivo in the same manner described for EAEC adherence to HEp-2 cells in tissue culture. *(Courtesy of Saul Tzipori, D.V.M., Department of Comparative Medicine, Tufts University School of Veterinary Medicine.)*

Serotype-specific commercial antigen immunoassays also are available.[110]

Diagnosis of ETEC would require identifying the LT or ST genes in an isolate or, after isolation and growth in vitro, detecting their products by enzyme-linked immunosorbent assay. Polymerase chain reaction techniques are available that allow LT or ST genes to be detected directly from stool without the need for performing culture.[26] A retrospective diagnosis can be made by detecting an increase in antitoxin antibody, especially for LT. Enzyme-linked immunosorbent assay for CFA antigens of ETEC also could be useful.

EPEC can be detected reliably by DNA probes for the 60-Md EAF adherence plasmid or by adherence to cells in culture. The ability of *E. coli* to adhere to HEp-2 cells in culture in distinct morphologies led to the description of EPEC, EAEC, and DAEC as different pathotypes (see Fig. 114–3). After a 3-hour incubation of bacteria with cells, EPEC adheres to the cell in tight microcolonies, called the *localized adherence* pattern. Although it remains sensitive and specific for EPEC, this method has been replaced by molecular detection methods to detect the LEE island (via the intimin-encoding gene *eae*) and the EAF plasmid (often via detection of the BFP-encoding genes).[44]

EAEC can be detected by the presence of the aggregative adherence pattern in the Hep-2 adherence assay (Fig. 114–7). DNA probes and polymerase chain reaction are available to detect the AggR regulon, and these tests are likely to provide more specific detection of EAEC pathogens.[33]

EIEC is detected best using molecular techniques that are specific for detection of pathogenesis-related genes. Several multiplex polymerase chain reaction assays that allow the user to screen for multiple *E. coli* pathotypes simultaneously have been described.[13,128] They can be introduced readily into any molecular biology laboratory and produce excellent results.

PROGNOSIS

EPEC, EAEC, and ETEC do not cause systemic infections or complications except complications resulting from dehydration or the consequences of nutritional depletion. The prognosis is related directly to the availability and adequacy of fluid therapy. When this need is dealt with correctly in an otherwise healthy and well-nourished patient, the principal complication is the rare instance of monosaccharide intolerance. In infants or young children in developing countries with protein-energy malnutrition, however, chronic diarrhea and progressive worsening of nutritional status frequently are observed, sometimes resulting in mortality. When food is withheld from either well-nourished or poorly nourished children, hypoglycemia may occur and produce seizures, coma, or death. Rarely, loss of water in excess of salt causes hypertonic dehydration, with serum sodium concentrations greater than 160 mEq/L, a situation that may cause seizures, coma, and death.

As noted earlier, EAEC has been associated with persistent diarrhea lasting longer than 14 days in young infants and children. Persistent diarrhea leads to nutritional deterioration, may be difficult to control, and may culminate in death from sepsis or other infections. Inflammatory diarrhea caused by EIEC also results in nutritional deterioration, with significant protein losses occurring via the gut.

EHEC often is followed by HUS, neurologic and intestinal complications, and, especially in adults, TTP. Ten percent of patients may die early in the course of the systemic phase of either HUS or TTP. Although the renal failure of HUS generally is reversible with good management of fluid and electrolytes and the use of dialysis as needed, permanent damage to the kidneys is, contrary to earlier more optimistic assessments, likely to occur in 25 percent or more of patients over the course of 1 or 2 decades, and many of them require permanent dialysis or transplantation in the future.[61] The prognosis in TTP is related directly to initiation of plasmapheresis, which has been documented to reduce mortality rates significantly.[177] No such benefit has been noted in HUS.[177]

TREATMENT

In all age groups, the principal treatment of the intestinal manifestations of *E. coli* enteric infection is replacement of fluids and electrolytes; with maintenance of fluid balance, the disease is self-limited to 1 week or less in most patients and lasts no more than 2 weeks in nearly all patients. The earlier that fluid replacement therapy is begun, the better the prognosis, particularly when one considers that clinical signs of dehydration do not develop until a 5 percent loss of body weight occurs, and that sustained loss of more than 10 percent of body weight is incompatible with survival.

When shock is present (usually with altered consciousness and an absent or thready pulse) or oral rehydration is unsuccessful because of persistent vomiting, patients must be rehydrated by intravenous infusion of an isotonic electrolyte solution, such as lactated Ringer solution or normal saline. Three 20 mL/kg fluid boluses can be given back-to-back, with close monitoring of the patient's clinical status. When dehydration is less severe, initial replacement of losses usually can be accomplished by oral rehydration. Patients not in shock, who may have normal findings on physical examination or may manifest poor skin turgor, tachycardia, postural hypotension, and oliguria (along with irritability and a sunken fontanelle in the very young), should receive 50 to 120 mL/kg of fluid, depending on the severity of dehydration, as rapidly as they can be encouraged to drink, over 4 hours. Pulse, blood pressure, urine volume, skin turgor, general appearance, and thirst are monitored as indicators of response. Adults may need 1 L/hr to establish rehydration; adults as well as children may tire of drinking and fail to keep up with requirements.

Several prerequisites must be ensured for oral therapy: (1) the patient must not be in shock; (2) the patient must be fully conscious; (3) the patient must be able to drink (vomiting, par-

ticularly common in children, is not an absolute contraindication because frequent small oral feedings usually are largely retained; when the metabolic abnormality begins to reverse toward normal, vomiting ceases); (4) bowel sounds must be present; and (5) renal function must be normal. Current recommendations in the United States and Europe suggest the use of hypotonic fluid containing 30 to 60 mEq of sodium per liter, although specific attention given to sodium and potassium deficits may be required. In the developing world, where cholera is a common occurrence, the World Health Organization recommends that a solution containing 90 mEq of sodium be used for all cases of diarrhea because of the large sodium losses that occur in cholera, and the desire to avoid the need to choose among formulations because of difficulty in making an etiologic diagnosis. Rice-based solutions for oral rehydration currently are favored in many diarrheal centers because of their reduced osmotic load.[5]

A prospective cohort study comparing *E. coli* O157:H7 HUS patients who developed oligoanuric renal failure requiring dialysis with patients with non-oligoanuric renal failure found that the patients who required dialysis had received less intravascular volume expansion and sodium than had the patients who did not require dialysis, suggesting that intravascular volume expansion with isotonic fluid was protective for oligoanuric renal failure when given early in the course of O157 infection.[4] The authors advocate hospitalizing all children with suspected EHEC infection for volume expansion with isotonic fluids and close monitoring.

Although rehydration therapy is the cornerstone of management, antibiotic therapy should be considered in some cases. In most *E. coli*–associated diarrheal illnesses, the disease is mild and of short duration, and no specific antimicrobial therapy is required. Studies to address this issue have found antibiotics to be beneficial in some circumstances. In traveler's diarrhea secondary to ETEC, antibiotic therapy can shorten the duration of illness and decrease its severity.[8,51] Prophylactic antibiotic therapy probably carries more risk than benefit, however, and generally is not recommended. When antibiotics are used, trimethoprim-sulfamethoxazole (TMP-SMX) therapy presently is recommended for children with traveler's diarrhea caused by susceptible isolates; fluoroquinolones are the drugs of choice for adults when chemoprophylaxis is indicated.[137] A more recently approved antibiotic for adults, rifaximin, is not absorbed from the GI tract and shows promise as an effective treatment of ETEC.[50] The data in children are very limited, however, and use of rifaximin is not yet recommended in this population.

Children in developing countries with ETEC diarrhea also may benefit from receiving antibiotic therapy.[118] Resistance of ETEC to TMP-SMX was noted in U.S. troops in Saudi Arabia, where 44 percent of isolates were resistant.[121] EIEC infection theoretically would benefit even more from antibiotic therapy, given its pathogenic similarity to shigellosis and the known benefits of the early use of antibiotics. No controlled studies have validated this benefit for EIEC, however. In experimentally induced disease, DuPont and colleagues[47] reported that parenteral ampicillin produced a bacteriologic cure and rapid clinical response with defervescence and improvement of diarrhea in adults. TMP-SMX and ampicillin are the current drugs of choice, unless resistance is a problem.

Immunocompromised hosts, especially children with AIDS, may require prolonged antibiotic therapy for protracted or recrudescent diarrhea, even when it is caused by bacteria that normally produce only self-limited disease. Malnourished children and children with other serious underlying illness also fit this category. In these patients, systemic invasion may develop along with associated complications, including shock and renal failure. In addition, prolonged carrier states are common findings, with frequent relapses requiring long-term antibiotic therapy for suppression of relapse.

Epidemic EPEC infection, especially in newborns, seems to be affected favorably by antibiotic therapy.[115] The potential for this pathogen to cause prolonged disease and a history of high rates of mortality in neonates suggest the need for antibiotic trials in this age group. Based on limited data, either TMP-SMX or oral nonabsorbable antibiotics, such as gentamicin or colistin, usually are recommended, although antibiotic resistance is common and may alter the choice of antibiotics based on local susceptibility patterns.[14,176]

Antibiotic treatment of EHEC remains controversial but is not recommended. Antibiotics in clinical use do not improve the course or prevent sequelae, and they may exacerbate the illness by promoting release of Stx.[6,21,30] In vitro data suggest that subinhibitory concentrations of TMP-SMX and other antibiotics may increase expression of Stx,[86] perhaps related to enhanced release of toxin from damaged organisms.[14] The most rigorous prospective study to address this question found that the cohort who received antibiotics had a higher incidence of HUS (of 9 patients who received antibiotics, 5 developed HUS) than the cohort who did not (of 62 patients who did not receive antibiotics, 5 developed HUS; $p < 0.001$).[181] Other studies have found no association.[122]

Notably, no studies have used a randomized placebo-controlled design, so the association may reflect selection bias because both the use of antibiotics and systemic complications are associated with more severe disease. A meta-analysis[146] did not show a higher risk of HUS associated with antibiotics; however, this meta-analysis has been criticized because it included a study in which all of the patients received antibiotics[81] and because comparisons were made among different antibiotics, which may not induce similar sequelae.

Antimotility agents such as loperamide generally are not needed and should be used cautiously if prescribed, with great attention paid to dosage, especially in very young patients.[167] Dysentery is a contraindication to the use of antimotility agents, which may be a risk factor for the development of ileus and abdominal distention.[3] The prolonged use of antimotility agents is reported to be associated with more serious systemic complications of EHEC infection and is not recommended.[30,31]

In most instances of *E. coli* diarrhea, the clinician is left to make therapeutic decisions without knowing the etiologic agent responsible. For reasons already outlined, routine diagnostic microbiology laboratories cannot distinguish pathogenic from nonpathogenic *E. coli*, with the exception of classic EPEC serotypes and O157:H7 EHEC. Clinical decisions regarding the administration of antibiotic therapy are made on purely clinical grounds with criteria such as the history, duration, and severity of the illness; the age and immunologic competence of the patient; and the nature of the diarrheal stool (e.g., watery, inflammatory, bloody, or dysenteric). Empiric antimicrobial therapy is more justifiable for immunocompromised hosts, for patients with prolonged or severe illness or a history of relevant risk factors (e.g., specific food ingestion, travel, exposure to known contacts), and for cases of inflammatory or dysenteric illness.

A novel treatment approach was reported by DiCesare and associates,[42] who evaluated SP-303, a plant-derived product with antisecretory properties, in a randomized placebo-controlled study of acute diarrhea in 184 U.S. travelers to Mexico and Jamaica. SP-303 shortened the duration of traveler's diarrhea by 21 percent; ETEC was the etiologic agent of traveler's diarrhea in 19 percent of the subjects. Human breast milk contains oligosaccharides that can partially bind to ETEC and presumably block attachment to intestinal epithelial cells.[102] Bovine hyperimmune milk from cows immunized against ETEC and EPEC is not effective treatment or prophylaxis for ETEC or EPEC diarrhea.[29,164]

Research on alternative treatments of EHEC and prevention of HUS is ongoing. A synthetic verotoxin receptor, SYNSORB

Pk, was not shown to prevent death, dialysis, or serious extrarenal events in a trial of 145 children with EHEC-induced HUS.[175] Although antibodies against *E. coli* O157 intimin were protective for colonization and disease in a pig model,[41] plasmapheresis and intravenous immunoglobulin have not been shown to ameliorate HUS in humans.[141] Investigation of monoclonal antibodies directed against Stx are under way.[175] The complete genome sequence of *E. coli* O157:H7 is now known and may lead to greater understanding of the pathogenesis of hemorrhagic colitis and HUS and perhaps innovative approaches to treatment and prevention.[74]

PREVENTION

Epidemic nursery outbreaks of diarrhea in newborns can be controlled by the application of antiquated but still valid principles of preventive medicine. Prompt diagnosis and treatment and scrupulous attention given to details of handwashing and environmental sanitation to eliminate person-to-person transmission are still effective, whereas prophylactic antimicrobials have no role. Outbreaks in neonatal nurseries can be contained by epidemiologic control measures such as cohorting; by screening staff for carriage; and, if necessary, by closing the unit until it is decontaminated. In contrast, preventing sporadic cases of *E. coli* diarrhea is difficult. In communities with obvious deficits in water supply and feces disposal, correction of these problems would lead to a diminished incidence of diarrheal diseases in general.

For traveler's diarrhea, several studies indicate that prophylactic antibiotics can protect adult travelers, at least for a limited time.[70] The risk of selection of resistant organisms and drug side effects limits the use of antibiotic prophylaxis to short-term travelers with business or diplomatic missions that would be hindered significantly by an episode of diarrhea. Fluoroquinolones, tetracyclines, azithromycin, and rifaximin have been evaluated for prophylaxis and presumptive treatment, and all are efficacious. The use of tetracyclines is not recommended for children younger than 8 years, and toxicity concerns for fluoroquinolones are still present.[6] Some evidence has been presented for the efficacy of bismuth compounds, such as bismuth subsalicylate, for the prevention of ETEC diarrhea in adults. The concern for bismuth toxicity with prolonged use in young children would render it a problematic solution for pediatric *E. coli* diarrhea and its prevention.

ETEC vaccine development has been propelled by the observation that ETEC infection confers some protection from reinfection with the same strain,[162] also evident in the decreasing rates of infection in children older than 5 years.[132] The challenge is that greater than 25 CFAs have been identified, and strain serotypes vary tremendously across the world.[64] As noted previously, however, it also is known that certain serotypes and CFAs are most common (CFA I, II, and IV) and tend to co-segregate.[60,64,180] This factor would limit the antigenic variability needed in an effective vaccine. Most isolates of ETEC expressing only LT do not express fimbria colonization factors and would be unaffected by a CFA-based vaccine. Although no vaccine currently is licensed and available, several approaches have been attempted. Among the most successful to date is a vaccine composed of recombinant cholera toxin B (as a surrogate for the LTB toxin subunit) with four strains of formalin-killed ETEC expressing the most prevalent CFAs in developing countries. This vaccine was found to prevent 80 percent of ST ETEC diarrhea in travelers to developing countries.[132] It is available commercially in Europe and may provide limited, short-term protection in travelers.[96] In a study of Egyptian children, however, it was not efficacious in preventing disease.[23,132]

Other avenues of vaccine development that have been pursued include subunit vaccines. ST does not create a significant immune response; however, LT is a known adjuvant similar to cholera toxin and has been conjugated to ST.[23,64] Concerns for human use of this vaccine come, however, from the homology of ST to guanylin, which is produced endogenously.[23,39] Live, attenuated *Shigella* vaccine vectors also are being studied in an attempt to elicit a mucosal immune response. Researchers are studying new methods of delivering antigens to the mucosa, including encapsulation in microspheres and delivery in recombinant foods. A transcutaneous vaccine, composed of fimbrial antigens mixed with LT, has been shown to elicit serum antibodies in adult volunteers.[64] Work continues in this field in an attempt to decrease the incidence and severity of morbidity from dysentery in the developing world and from traveler's diarrhea.

Vaccine development for other diarrheogenic *E. coli* strains lags behind that for ETEC. Because EHEC-induced HUS is a rare disease, widespread human vaccination may not be cost-effective. Vaccine development for cattle, the major reservoir, is ongoing. A vaccine composed of type III secreted proteins resulted in decreased shedding of *E. coli* O157:H7 compared with controls, although prevalence of shedding increased over the study period. Repeat vaccination of cattle may serve as a mode to decrease human exposure to EHEC.[129]

CHAPTER 115

KLEBSIELLA

Randall G. Fisher

Klebsiella is a genus of Enterobacteriaceae, a frequent cause of nosocomial pediatric infection. Classically described by Friedländer[38] as a cause of pneumonia, *Klebsiella* can cause infections of the urinary tract, lung, and central venous catheters in high-risk newborns and immunocompromised older children.[18]

BACTERIOLOGY

Klebsiella organisms were named for Edwin Klebs, the noted German bacteriologist.[86] Distinguishing features of *Klebsiella* spp. include the absence of motility and the presence of a polysaccharide capsule that gives rise to large mucoid colonies on solid media. The organisms are oxidase-negative and citrate-positive; they ferment inositol and hydrolyze urea but do not produce ornithine decarboxylase or hydrogen sulfide. Acetoin and 2,3-butanediol predominate over acidic end-products during sugar fermentation (positive result on the Voges-Proskauer test). Four species of *Klebsiella* commonly are agreed on by microbiologists: *Klebsiella pneumoniae* (the most common human pathogen), *Klebsiella oxytoca* (a less common human pathogen), *Klebsiella terrigena*, and *Klebsiella planticola*. Previously, *K. planticola* was recovered almost exclusively from soil and aquatic environments; reports now suggest that this organism may be a relatively common neonatal pathogen in some parts of the world.[92,113] *K. planticola* may express virulence factors similar to those of *K. pneumoniae*.[93] Organisms are defined serologically by their capsular polysaccharide (K antigens) and lipopolysaccharide (O antigens). Significant cross-reactivity exists between the capsule of some pneumococci (e.g., 19F) and *Klebsiella*.[68] The reader is referred to a review by Podschun and Ullman[95] for a detailed description of *Klebsiella* spp.

EPIDEMIOLOGY

Friedländer[38] proposed that *K. pneumoniae* was the most common cause of community-acquired pneumonia, an observation that was refuted by Fraenkel's[36] observations on pneumococcal pneumonia. *K. pneumoniae* accounts for less than 10 percent of hospitalized cases of pneumonia in adults.[20] *Klebsiella* spp. now are in greatest evidence as opportunistic nosocomial pathogens of the urinary tract, respiratory tract, biliary tract, and bloodstream. In one survey of the Centers for Disease Control and Prevention, the infection rate of nosocomial *K. pneumoniae* was 16.7 infections per 10,000 patients discharged.[54] Hand-carriage generally is regarded as the common mode of transmission.[42] Environmental sources of *Klebsiella* spp. include contaminated blood-pressure monitoring equipment,[98] ventilator traps,[42] dialysate,[64] ultrasound coupling gel,[40] dextrose solution,[66] and hand disinfectant.[101] The emergence of plasmid-mediated, β-lactamase resistance can be responsible for the rapid spread of resistant organisms to susceptible patients in intensive care units (ICUs).[10,12] Outbreaks may be complex; patient-to-patient transmission of epidemic strains containing different plasmids may be interspersed with sporadic, nonepidemic *Klebsiella* infections.[12] *Klebsiella* spp. are second only to *Escherichia coli* as causes of sepsis,[41] with the highest rates of infection being reported from larger hospitals affiliated with medical schools.

Klebsiella spp. commonly are highlighted as pathogens of debilitated adults and alcoholics,[60] but by 1985, nearly 50 percent of reported outbreaks of *Klebsiella* were in neonatal ICUs.[54] Outbreaks in newborns continue to occur frequently worldwide.[2,7,24,30,49,90,100] Most outbreaks in newborns have been associated with *K. pneumoniae* infection, but scattered outbreaks of *K. oxytoca* infection in nurseries also have been reported.[6,112] A high percentage of infants in ICUs may become colonized with hospital strains of *Klebsiella*.[46] In one longitudinal study in which weekly rectal swabs were cultured, 80 (22%) of 368 neonates in an ICU harbored extended-spectrum β-lactamase (ESBL)–producing *Klebsiella* spp.[15] Infecting organisms have been isolated from care providers and from mothers of colonized infants.[24] One report described an outbreak among newborns associated with infestation of a neonatal unit by cockroaches colonized with infecting *Klebsiella* strains.[25] *Klebsiella* may spread from newborn units to adult units; interhospital and international spread of resistant strains has been described.[23,30,106]

Ribotyping, pulsed field gel electrophoresis, and DNA amplification techniques have proven valuable in characterizing *Klebsiella* strains associated with outbreaks.[70,108] Different ribotypes that share plasmids conferring antibiotic resistance can be responsible for pediatric infections in a particular institution.[12] Strains expressing ESBL may become endemic and may present a complex and diverse pattern of production of enzymes with resistance to β-lactamase inhibitors.[31,35] Although broad-spectrum resistance to β-lactams and carbapenems[72] has been described, some longitudinal studies have shown that the frequency of ESBLs in *K. pneumoniae* isolates is decreasing.[103]

PATHOPHYSIOLOGY

Pneumonias caused by *Klebsiella* most commonly arise from colonization of the upper respiratory tract, followed by aspiration of organisms to the lower respiratory tract. Some degree of gram-negative oropharyngeal colonization is a normal finding in newborns. The oropharynx of nearly one third of healthy newborns is colonized by gram-negative rods, including *Klebsiella*, by the time infants reach 1 month of age; colonization rates generally are lower in breast-fed infants.[9] Antibiotic pressure in high-risk newborns and older children has been observed to promote overgrowth of *Klebsiella*.[11,105] Enteric organisms are recovered less frequently from the oropharynx of healthy older children and adults; oral colonization with gram-negative rods is increased during illness,[57] after postoperative viral infections,[56,97] and in debilitated adults.[73] Increased adherence of gram-negative rods to oropharyngeal cells contributes to increased colonization.[56] Elastase made by polymorphonuclear cells contributes to such colonization by reducing the fibronectin coating of sugar receptors.[27] The capsule plays an initial role in interactions of epithelial cells but is not required for an adhesin interaction with the cell surface.[34] Adherence properties may be affected by plasmid content[29] and may be transferred between *E. coli* and *K. pneumoniae*.[53]

In animal models of sepsis, capsular polysaccharide (K antigens) is a virulence factor; monoclonal antibodies to the K antigens reduce the severity of illness in mice.[67] In a mouse model of urinary tract infection, the K antigens seemed to be more important in infection than was the lipopolysaccharide (O antigens), and clinical strains deficient in lipopolysaccharide retained virulence by resistance of capsule to complement.[3,19] In one series of adult patients, capsular type K2 frequently was associated with

asymptomatic bacteriuria and cystitis, but not pyelonephritis; the presence of type 1 fimbriae bore a closer relationship to upper urinary tract infection.[94] In a retrospective study, patients bacteremic with hyperviscous strains were more likely to develop invasive localized disease, such as liver abscess, meningitis, pleural empyema, or endophthalmitis.[69] Neutrophils play an important role in clearance of *Klebsiella*, and phagocytosis is augmented by leukotrienes.[74]

CLINICAL MANIFESTATIONS

Klebsiella infection shows little clinical distinction from diseases produced by other enteric pathogens. The organism generally is less common than is group B streptococcus or *E. coli* as a cause of "early-onset" or "late-onset" infection in newborns.[43,77] Investigators from Spain,[49] however, reported one 7-year interval in which *K. pneumoniae* was the most common cause of bacteremia in newborns. Risk factors for neonatal *Klebsiella* infection include prematurity, presence of indwelling catheters, previous antibiotic treatment, and parenteral nutrition.[100] Infection in newborns is characterized by typical features of pneumonia, sepsis, and meningitis.[77] In one unusual case, *K. pneumoniae* bacteremia manifested on day 4 of life as a morbilliform maculopapular exanthem, more severe on the face. The infant was afebrile, but the mother had had fever in the peripartum period, and the amniotic fluid had been meconium stained.[21]

Although hepatic abscesses have been associated principally with adults with poorly controlled diabetes mellitus, one case report described a 32-week-gestation neonate with *K. pneumoniae* sepsis who developed a liver abscess large enough to be noted on physical examination as an abdominal "lump."[110] In adults, hepatic abscess occasionally is complicated by endophthalmitis or central nervous system infection, with devastating outcomes. A study from Taiwan found that infection with genotype K1 was the only significant risk factor for these complications.[33] This series also revealed that 8 (42%) of the 19 complicated K1 strain infections occurred in patients without identifiable underlying medical disease.[33] Other investigators have emphasized that serotype K2 also can be virulent in patients with liver abscess.[39] Careful study of the pathophysiology and epidemiology of complicated *K. pneumoniae* liver abscesses is ongoing, and the picture is likely to continue to be clarified.

Klebsiella spp. have been isolated commonly from blood and peritoneal fluid in outbreaks of necrotizing enterocolitis.[44,80] Less common manifestations in infants include toxic epidermal necrolysis,[47,89] conjunctivitis,[65] parotitis,[22] retropharyngeal abscess,[26] subdural hematoma,[84] psoas abscess,[4] and renal abscess.[111]

Klebsiella is an unusual cause of infection in an otherwise healthy older child. The classic Friedländer pneumonia that occurs in debilitated adults[38] is rare in children. The identification of pulmonary infection should suggest the possibility of underlying immunodeficiency or significant malnutrition, if not suspected previously.[52,58] If pneumonia caused by *Klebsiella* does occur, progression to lung abscesses should be anticipated.

Lung abscesses may develop within days to weeks after *Klebsiella* infection. Formation of abscesses occurs more frequently during *Klebsiella* pulmonary infection than during any other community-acquired infection.[20] A rare but devastating outcome is massive pulmonary gangrene, the rapid total destruction of part of the lung presumed to be due to vascular compromise. This complication is heralded by radiographs that show small cavities that later coalesce into a large cavity with an intracavitary mass of necrotic lung.[82,85] Some researchers have speculated that *Klebsiella* lung infection is accompanied by coincident anaerobic infection that contributes to or is primarily responsible for the pathology.[20]

Catheterization of the urinary tract can be associated with urinary tract *Klebsiella* infection, but bacteremia is an uncommon complication in an immunocompetent child.[28,71] Approximately 10 percent of nosocomial urinary tract infections observed in infants after surgery are caused by *Klebsiella*.[28] Focal renal infection progressing to renal abscess has been described.[63] *K. pneumoniae* bacteremia has been associated with lesions of the gastrointestinal tract, presence of an indwelling central venous catheter, and neutropenia. Patients with short-bowel syndrome seem to be at greater risk than are patients with inflammatory bowel disease or malignancy for development of catheter-associated *Klebsiella* or *Enterobacter* bacteremia. *K. pneumoniae* was a constituent of polymicrobial bacteremia in 15 such patients (26%).[14] Mortality rates have ranged from 5 to 20 percent, with higher death rates occurring in children infected with an aminoglycoside-resistant strain.[13,54] Pneumonia, shock, and disseminated intravascular coagulation are poor prognostic factors in children with underlying malignancy. Rare clinical presentations include multifocal osteomyelitis[62] and endophthalmitis.[75] Pediatric recipients of solid organ transplants may have high rates of acquisition of drug-resistant *Klebsiella*.[99] *Klebsiella* spp. have been described as a frequent pathogen in children and adults with sickle cell disease in West Africa.[1]

Of six patients with clinical and colonoscopic findings suggestive of antibiotic-associated hemorrhagic colitis (pseudomembranous enterocolitis) but negative evaluation for *Clostridium difficile*, five had stool cultures positive for *K. oxytoca*.[51] All five patients had been receiving penicillin therapy. *K. oxytoca* was cultured from only 1.6 percent of 385 healthy controls. Additionally, the disease could be reproduced in a rat model when rats were inoculated with *K. oxytoca* and administered amoxicillin-clavulanate, but disease was not seen if rats were not given the injection and the antibiotic treatment.[51]

DIAGNOSIS

Klebsiella spp. characteristically grow as large mucoid colonies on MacConkey agar. Citrate-containing media can be used to facilitate isolation of *Klebsiella* strains because these organisms can use citrate as a sole carbon source.[86] Serotyping with specific antisera usually is determined by countercurrent immunoelectrophoresis or a Quellung test.[8] In situ hybridization techniques have been used to identify *Klebsiella* in phagocytes from blood specimens,[76] and restriction-enzyme analysis and ribotyping of clinical isolates have been used to characterize nosocomial spread of antibiotic-resistant strains.[12,45] Conventional, commonly used microbiologic methods may misidentify some *Klebsiella* spp., particularly *K. planticola* and *K. terrigena*.[81] Rarely, blood cultures have required longer than 72 hours of incubation for radiometric detection of *Klebsiella*.[78]

TREATMENT

Empiric antimicrobial therapy should be guided by an understanding of antimicrobial susceptibilities of *Klebsiella* in the hospital. Therapy with a cephalosporin plus an aminoglycoside (rather than a cephalosporin alone) has been associated with a more favorable outcome in patients with cancer who are infected with susceptible strains.[13] Antimicrobial therapy of *Klebsiella* spp. is made problematic, however, by the resistance to penicillins and cephalosporins conferred by ESBL.[10,12,16,48] *Klebsiella* with ESBL are widely distributed, and regional differences in susceptibility occur.[59] Outer membrane protein changes and porin deficiencies of some strains can augment resistance to third-generation cephalosporins.[5,102] Some investigators have reported significant correlation between production of ESBL and resistance to

ciprofloxacin.[88,107] Plasmid-mediated resistance to aminoglycosides also is common.[6,24,41,83] Endocarditis isolates that developed resistance to piperacillin-tazobactam and to ciprofloxacin during therapy have been reported.[114]

Effective treatment of multidrug-resistant isolates sometimes requires creativity or use of antibiotics no longer commonly employed. In one case report, a 15-year-old girl developed bacteremia with a meropenem-intermediate strain; bacteremia persisted despite thrice-daily administration of meropenem combined with gentamicin, to which the isolate was sensitive. Clearance was achieved eventually with meropenem administered as a continuous infusion.[32] In another case, bacteremia and peritonitis developed in a patient on continuous ambulatory peritoneal dialysis; infection persisted despite removal of the catheter and treatment with meropenem and amikacin (to which the isolate was intermediately resistant). Cure required a switch to intravenous polymyxin B.[87]

Antibiotic pressure is important in increasing the risk for development of resistant isolates.[96] In some nursery outbreaks, switching from gentamicin to amikacin has been associated with return of the susceptibility of *Klebsiella* isolates to gentamicin.[6,50] Imipenem or the combination of piperacillin and tazobactam may show good antimicrobial activity against multiply-resistant organisms.[55,91,96] The combination of β-lactamase and porin deficiency has been associated with resistance to imipenem,[17] and hyperproduction of some β-lactamases can limit the effectiveness of β-lactam–β-lactamase inhibitor combinations.[37] Experience with use of ciprofloxacin in young children is limited because of observations of irreversible cartilage injury in laboratory animals after administration of this quinolone. Successful treatment of a multidrug-resistant *K. pneumoniae* has been reported in a preterm infant, however, without observable short-term adverse effects.[61] Strict adherence to infection control policies that promote restricted antibiotic use, cohorting, and handwashing may help to prevent the spread of resistant *Klebsiella* strains.[6,24,46,79,104]

Acknowledgments

The author thanks Dr. William Gruber and Dr. Thomas Boyce for their invaluable assistance with earlier versions of this chapter.

CHAPTER 116

MORGANELLA MORGANII

Randall G. Fisher

Similar to *Proteus* and *Providencia* spp., *Morganella morganii* has emerged as an important nosocomial pathogen, most often associated with urinary tract or wound infections. Although most descriptions of infection are in adults, infections in children do occur.

BACTERIOLOGY

M. morganii (formerly *Proteus morganii*) is a motile gram-negative bacillus commonly found in the feces of humans, other mammals, and reptiles.[27] The organism was elevated to genus rank because of genetic differences from *Proteus*, with which it is otherwise biologically similar.[7] Most strains do not ferment lactose. *M. morganii*, *Proteus* spp., and *Providencia* spp. are distinguished from other Enterobacteriaceae by their ability to deaminate phenylalanine and lysine. Similar to *Proteus* and *Providencia* spp., *M. morganii* produces urease, but this enzyme is unrelated genetically and serologically to urease produced by the other two genera.[19,27] In contrast to *Proteus* spp., neither *Providencia* spp. nor *M. morganii* shows swarming activity on 1.5 percent agar[27]; *M. morganii* is ornithine-positive, whereas *Providencia* spp. are ornithine-negative. *M. morganii* organisms do not hydrolyze gelatin and do not produce hydrogen sulfide. For a detailed discussion of taxonomy and characterization of *M. morganii*, the reader is referred to the review by O'Hara and colleagues.[26]

EPIDEMIOLOGY

Similar to *Proteus* and *Providencia* spp., *M. morganii* organisms commonly are found in soil, sewage, and manure. Similar to *Proteus mirabilis*, *M. morganii* commonly invades the instrument-fitted urinary tract and surgical wounds; adults in inpatient surgical units have the greatest risk for colonization and infection.[1] Institutionalized elderly patients also are infected frequently with these organisms. Urinary tract colonization with *M. morganii* accompanying groin skin colonization in elderly individuals may account for the greater frequency of urinary tract infections in this population.[15] *M. morganii* accounted for nearly 10 percent of 145 consecutive complicated, multidrug-resistant urinary tract infections.[11] *Escherichia coli* and *P. mirabilis* account for most urinary tract infections in children, but *M. morganii* has been implicated in some cases of cystitis and pyelonephritis. In contrast to well-described nursery epidemics of *P. mirabilis* infection,[3,9] no *M. morganii* neonatal outbreaks have been described, and infections of the central nervous system are rare in newborns.[13,37] Ribotyping is a sensitive method for molecular characterization of isolates that may aid in analyzing outbreaks.[29]

PATHOPHYSIOLOGY

Factors that predispose the urinary tract to invasion by *P. mirabilis* and *Providencia* spp. also may favor *M. morganii* colonization and infection. These organisms all split urea, forming ammonium hydroxide and increasing local pH, which results in toxicity to renal cells and potentiation of urolithiasis.[6,25] The ability of *P. mirabilis* to regenerate more rapidly in urine with faster generation of alkaline pH compared with *M. morganii* may provide a selective advantage for the former organism in establishing itself as a urinary tract pathogen.[34]

CLINICAL MANIFESTATIONS

Urinary tract infection with *M. morganii* often is associated with an elevated urinary pH. Urolithiasis can occur, although perhaps less frequently than during *P. mirabilis* infection.[4] *M. morganii* has been recovered from less than 10 percent of adult bacteremic episodes, but mortality rates have exceeded 20 percent.[1] Approximately three fourths of all cases of adult *M. morganii* bacteremia

are hospital-associated.[22] In a series of 132 patients with bacteremia from tribe Proteeae, preexisting biliary or hepatic disease (especially the presence of biliary drainage catheters) was associated with *Morganella* bacteremia.[22] Other reported complications identified in immunocompromised or instrument-fitted patients include meningitis,[17,23] arthritis,[21,33] empyema,[18] peritonitis,[18] and skin infection.[2] Many cases of postoperative *M. morganii* endophthalmitis and panophthalmitis have been reported, as have rare cases of endogenous endophthalmitis, all in adults.[10,36,38,39] *M. morganii* has been recovered alone or in combination with other organisms from surgical wounds[11] and soft tissue abscesses in children.[8] Perinatal bacterial sepsis and brain abscess have been described.[30-32,37] In three more recently reported cases of early-onset neonatal sepsis, premature rupture of membranes and maternal receipt of antepartum amoxicillin were documented.[5,14]

DIAGNOSIS

M. morganii produces a reddish brown pigment when cultured on nutrient media supplemented with 5 percent tryptophan.[27] Production of urease and deamination of tryptophan help to distinguish this bacterium from other organisms. In contrast to the closely related *Proteus* and *Providencia* spp., *M. morganii* generally ferments only glucose and mannose and does not produce a red color on lysine iron agar.[27] *M. morganii* may be missed or mistaken for other organisms in the common circumstance of polymicrobial infection in a catheterized patient. In one series, *M. morganii* was among the most common bacteriuric species in patients on long-term catheterization but commonly was missed by reference laboratories.[12] The clinical laboratory should be directed to look for this organism, particularly in circumstances of nosocomial urinary tract infection and sepsis.

TREATMENT

Effective treatment of local infections or septicemia relies on appropriate choice of an antibiotic, often including an aminoglycoside, combined with surgical débridement and drainage of abscesses, as necessary. Antimicrobial susceptibility can vary widely among *M. morganii* and the related *Proteus* and *Providencia* strains, emphasizing the importance of species identification and susceptibility testing.[28] Complex combinations of aminoglycoside resistance that differ by hospital and geographic region can occur.[24] Most isolates are intrinsically resistant to ampicillin and first-generation and second-generation cephalosporins. Some carry a chromosomal broad-spectrum AmpC β-lactamase that can be stably derepressed on treatment with third-generation cephalosporins, similar to *Enterobacter* spp. Most urinary tract infections respond to third-generation cephalosporins. Failure to clear bacteriuria should alert the physician to the possibility of urolithiasis or structural abnormality[4]; stone removal or surgical correction of anatomic defects often is required for cure. The approach to the treatment of sepsis or serious infection of non–urinary tract sites should be considered carefully in light of local susceptibility patterns, keeping in mind that isolates with AmpC β-lactamases may seem to be sensitive to cephalosporins on initial testing, only to develop resistance during therapy. Treatment failure, with prolonged culture-positive ventriculitis, has been described in an infant with *M. morganii* meningitis after initial therapy that included cefotaxime led to stable derepression of an AmpC β-lactamase, showing the potentially devastating clinical relevance of this phenomenon.[35] Aztreonam has shown effectiveness in therapy for 98 percent of multidrug-resistant strains.[11]

Acknowledgments

The author thanks Dr. William Gruber and Dr. Thomas Boyce for their invaluable assistance with earlier versions of this chapter.

CHAPTER 117

PROTEUS

Randall G. Fisher

Proteus spp. are pathogens that are associated increasingly with pediatric illness. Neonatal meningitis and pediatric urinary tract infections are the most common childhood conditions in which these organisms are isolated, but infections of other organ systems have been described.

BACTERIOLOGY

Proteus spp. are motile, gram-negative bacilli that do not ferment lactose and are distinguished from other Enterobacteriaceae by their ability to deaminate phenylalanine and lysine. Rapid and abundant production of urease further differentiates *Proteus* spp. from *Providencia* spp.[33] *Proteus vulgaris* and *Proteus mirabilis* tend to form a thin, spreading growth (swarm) on the surface of moist agar media, often overgrowing other bacterial isolates. They also produce hydrogen sulfide and liquefy gelatin. *P. mirabilis* is distinguished from other *Proteus* spp. (e.g., *P. vulgaris*) by its inability to produce indole from tryptophan. Disparate DNA content and anomalous biochemical and serologic reactions have caused *Proteus morganii* to be renamed *Morganella morganii* (see Chapter 116),[33] and both terms for this organism appear in the clinical literature. For detailed discussion of taxonomy and characterization of *Proteus* spp., the reader is referred to the review by O'Hara and colleagues.[44]

EPIDEMIOLOGY

Proteus spp. commonly are found in soil, sewage, and manure. Although they are normal inhabitants of the colon and perineum, their numbers can be increased in individuals receiving antibiotic therapy.[30]

First reported by Buisine and Henninot in 1949,[12] neonatal meningitis caused by *P. mirabilis* accounts for approximately 4 percent of all neonatal meningitis cases.[41] Outbreaks in nurseries have been attributed to contaminated equipment and human carriers. Vertical transmission from mother to infant has been confirmed by DNA fingerprinting and ribotyping methods.[9] In Becker's series[6] of *P. mirabilis* neonatal meningitis, all affected infants came from the same nursery, and all were exposed to mist from an apparatus that yielded *P. mirabilis.* The importance of hand carriage was well documented by Burke and associates[13]; newborn umbilical colonization and invasive disease were linked to a single nurse from whom *P. mirabilis* was cultured from her hands, rectum, and vagina. Ribotyping is a sensitive method for molecular characterization of isolates and may aid in analyzing outbreaks.[48]

Proteus infection after the first few months of life most commonly involves the urinary tract. Although *Escherichia coli* accounts for most urinary tract infections in children, *Proteus* spp. commonly are implicated in reported series of cystitis and pyelonephritis[8,22,31,65]; in a large pediatric series, they were the third most common cause of urinary tract infection, after *E. coli* and *Klebsiella pneumoniae*.[10] *P. mirabilis* is the most common species of *Proteus* isolated. *P. mirabilis* has been cultured more frequently from the urethra of uncircumcised than of circumcised male infants and has replaced *E. coli* as the most prevalent pathogen in one consecutive series of male patients presenting with initial urinary tract infection.[31,66]

Urinary tract infection with *Proteus* spp. is one of the most common presenting signs of urolithiasis in children,[18] and *P. mirabilis* supplants *E. coli* as the major urinary tract pathogen in children prone to renal stone formation.[8] Diagnosis of greater than 50 percent of pediatric urolithiasis cases is based on preceding urinary tract infection, and *Proteus* is responsible for 65 percent of these infections.[8] Isolation of this organism as a pathogen on urine culture should alert the physician to the possible presence of a urinary tract stone.

PATHOPHYSIOLOGY

Most cases of central nervous system infection caused by *Proteus* spp. occur in neonates and are thought to arise by bacteremic spread of the organism to the brain or meninges. Contiguous spread to the brain from localized infections is reported occasionally.[40] As is the case with *Citrobacter* meningitis, a propensity for formation of abscesses of the central nervous system remains unexplained. Rabbit models of *P. mirabilis* meningitis have shown that in vivo concentrations of gentamicin necessary to produce bacterial killing are 10 to 30 times higher than the concentrations predicted from in vitro susceptibility testing.[63] Reduced aminoglycoside effect may be secondary to depressed cerebrospinal fluid pH associated with *P. mirabilis* infection.[63] Whatever the mechanism, lack of effective antimicrobial activity in the ventricles accounts partly for the persistence of organisms at these sites.

Crystallization of urinary catheters and stents leads to obstruction of outflow of urine. Urease produced by *Proteus* infection

causes calcium phosphate and magnesium phosphate to precipitate and accumulate in the catheter lumen.[62] This process is less likely to occur when the urine is dilute and acidic.[62] Mannose-resistant/*Proteus*-like fimbriae (often shortened to MR/P fimbriae) are important in the formation of biofilms on catheter material.[52] Methods of preventing this crystallization, including the use of low-energy acoustic waves generated by electrically activated piezo elements, which interferes with docking and attachment, are being studied.[26] More conventional approaches include coating the catheters with agarose[61] and impregnating catheters with chlorhexidine and triclosan.[21]

Numerous factors may predispose the urinary tract to invasion by *Proteus* spp. *Proteus* spp. split urea, forming ammonium hydroxide and increasing local pH, which results in toxicity to renal cells and potentiation of urolithiasis.[11,43] The ability of *P. mirabilis* to regenerate more rapidly in urine with faster generation of alkaline pH when compared with *M. morganii* (*P. morganii*) may provide a selective advantage for the former organism in establishing itself as a urinary tract pathogen.[55] Biochemically complex struvite ($MgNH_4PO_4$) stones provide a refuge for *Proteus* organisms and form a barrier to effective antimicrobial therapy.[8] Formation of struvite stones is a major cause of urinary bacterial persistence in women without azotemia,[60] and a similar case probably can be made for pediatric patients with urolithiasis. *P. mirabilis* ureases showed lower affinities for substrate, but hydrolyzed urea 6 to 25 times faster than enzymes from other species, which may explain the frequent association of this species with formation of stones.[27]

Organisms have been shown to be taken up by human renal epithelium, by an actin-independent mechanism.[14] Pili may enhance the virulence of *Proteus* in pyelonephritis by increasing adherence of organisms to the renal pelvis.[57] Flagella have been implicated in the spread of this organism in the urinary tract[36]; the ability to invade host uroepithelial cells is coupled closely with the ability of *P. mirabilis* to differentiate into hyperflagellated, filamentous swarm cells capable of rapid spread on the surface of moist agar media.[3] The role of fimbriae as a factor predisposing to ascending infection is less clear.[5,39] Swarming behavior might inherently assist ascending colonization of the urinary tract, as shown in a mouse model of infection.[4] A putative gene regulator for swarming behavior (RsbA) may act to identify environmental conditions that favor swarming.[7] The reader is referred to the review by Rozalski and colleagues[53] for a more in-depth review of *Proteus* virulence factors.

A growing body of literature suggests that adult rheumatoid arthritis may be triggered by infection of the urinary tract with *Proteus* spp. In one study, increased levels of total and class-specific IgG antibodies directed at three *Proteus* peptides were found in patients with rheumatoid arthritis, but not in controls.[51] Patients with active disease had measurable IgM, and a positive correlation was found between antibody indices and inflammatory markers.[51] These same investigators proposed measuring antibodies to *Proteus* hemolysin and urease as diagnostic tests for rheumatoid arthritis.[50] This association is still speculative and is being investigated; at this time, no suggestion has been made that juvenile rheumatoid arthritis is related in any way to *Proteus* infection.

CLINICAL MANIFESTATIONS

P. mirabilis can produce a broad spectrum of symptoms associated with neonatal infection. Most patients present with typical symptoms of early-onset neonatal sepsis, including nonspecific lethargy, fever, and poor feeding; manifestations of sepsis may include septic arthritis and osteomyelitis. A few patients present after the first week of life. Meningitis may occur with either early-onset or late-onset disease. Brain abscesses associated with subtle clinical abnormalities rarely develop for weeks to months before presentation.[13] *Proteus* brain abscesses are associated with a high degree of mortality, frequent complications, and increased risks of neurologic deficits in survivors.[28,35,58] Hydrocephalus is a particularly frequent complication and should be anticipated. Destruction of the brain may progress to porencephaly or compartmentalization of ventricles and often requires surgical intervention.[28] Computed tomography is useful, especially in diagnosing and following progression of cerebral complications.[58]

Urinary tract infection with these bacteria involves predominantly younger patients and often is associated with an elevated urinary pH; clinical findings and urine abnormalities often are less striking than in patients with *E. coli* urinary tract infections.[31] Thirty percent of patients may show recurrent infection during the 12 months after receiving initial treatment.[31] Indwelling urinary catheters increase the risk of *Proteus* colonization and infection. Long-term indwelling urinary catheters or stents may become blocked by encrustations of aggregated struvite crystals; prolonged colonization with urease-producing *P. mirabilis* is associated with this complication.[34] *P. mirabilis* is the most common pathogen associated with xanthogranulomatous pyelonephritis,[2] which can mimic Wilms tumor and usually is not seen in childhood except in malnourished patients.

Proteus spp. often are implicated as agents of septicemia in adult patients and account for approximately 8 percent of gram-negative bacteremias in this group.[19,32] In 60 percent of *Proteus* bacteremic episodes in adults, the urinary tract has been determined to be the source[19]; no anatomic source is identified in 20 percent of cases of *Proteus* bacteremia. *P. mirabilis* and *P. vulgaris* are the species responsible for most cases of *Proteus* bacteremia. The overall incidence of gram-negative enteric bacteremia in pediatric patients is lower than that of adults; 5 percent of such cases are caused by *Proteus* spp.[19] As in adults, the genitourinary tract is the source identified most frequently.[19] Mortality rates average less than 40 percent and strongly depend on the severity of underlying disease in the host.[19,32]

Osteomyelitis,[29,47,63] pneumonia,[19,32,49] mastoiditis,[40] and wound infections[32] also occur. Rarely, native-valve endocarditis has been caused by *P. mirabilis*.[15] Severe multifocal osteomyelitis requiring bilateral above-knee amputation for cure has been reported in a patient with human immunodeficiency virus infection despite a reasonably good $CD4^+$ cell count.[46] *Proteus* spp. have been isolated commonly from chronic suppurative otitis media on several different continents.[23,64] Reports that *Proteus* spp. are major pathogens of otogenic brain abscess in pediatric and adult patients support this association.[24,50] Pediatric osteomyelitis secondary to contiguous infection of traumatized soft tissue often is polymicrobial, and *Proteus* spp. have been implicated as co-pathogens in at least 10 percent of such cases.[47] Sickle cell anemia is a risk factor.[1,29]

DIAGNOSIS

Proteus is suspected readily because of its ability to swarm on the surface of moist agar. A selective medium developed for the isolation of protei relies on the ability of all members to produce a dark brown pigment in medium containing DL-tryptophan.[25] Production of urease, lack of indole production from tryptophan, and a positive result with ornithine decarboxylase testing distinguish *P. mirabilis* from *Providencia* spp. and other *Proteus* spp.[33]

TREATMENT

Treatment of meningitis caused by *Proteus* spp. should conform to standard regimens recommended for gram-negative meningi-

tis. *P. mirabilis* usually is sensitive to ampicillin, however, and this drug alone or combined with an aminoglycoside often is suitable therapy when the identity and susceptibilities of the infecting organism are known.[54] A third-generation cephalosporin often is an alternative, but resistant extended-spectrum β-lactamase–producing strains and β-lactamase inhibitor–resistant strains have been described in pediatric patients.[17,36] Consecutive lumbar punctures should be performed for *Proteus* meningitis until cerebrospinal fluid cultures are sterile. A minimum of 2 weeks of antibiotic therapy is recommended after bacteriologic cure has been achieved. Ventricular aspiration or drainage of abscesses may be required to direct therapy, based on persistence of organisms at these sites. Open drainage of abscesses often is necessary, but resolution of abscess formation with the use of antibiotic therapy alone has been reported.[59] Intraventricular antibiotics are not of proven benefit in terms of mortality or morbidity but have been used to clear ventricular colonization. A 15-year-old boy with *Proteus* mastoiditis and meningitis has been treated successfully with intravenous trimethoprim-sulfamethoxazole.[40]

Effective treatment of local infections or septicemia relies on appropriate choice of antibiotics, often including an aminoglycoside, combined with surgical débridement and drainage of abscesses as necessary. Many experts recommended "double coverage"—a cell wall–active agent plus an aminoglycoside—especially when the infection is severe or is caused by an indole-positive strain. In a large, three-continent longitudinal survey, approximately 5 percent of *P. mirabilis* strains exhibited phenotypic extended-spectrum, β-lactamase resistance patterns.[20] In France, 59 percent of 1008 urinary *P. mirabilis* isolates were resistant to amoxicillin, 48 percent were resistant to piperacillin, 34 percent were resistant to amoxicillin-clavulanate, and 2.8 percent were resistant to piperacillin-tazobactam.[37] One third of isolates were resistant to trimethoprim-sulfamethoxazole.[37] Complex combinations of aminoglycoside resistance that differ by hospital and geographic region can occur.[42] In one study, amikacin retained better activity than did other aminoglycosides.[37] Most *P. mirabilis* urinary tract infections respond to ampicillin, but some organisms have been shown to acquire a plasmid-mediated β-lactamase.[38] Failure to clear bacteria should alert the physician to the possibility of urolithiasis or structural abnormality; removal of stones or surgical correction of anatomic defects often is required for cure.

CHAPTER 118

PROVIDENCIA

Randall G. Fisher

The genus *Providencia* comprises pathogens most commonly associated with urinary tract infection. *Providencia* spp. are encountered most often as pathogens in hospitals or long-term care facilities and can be responsible for outbreaks of multidrug-resistant infection.[34]

BACTERIOLOGY

Providencia spp. (named after the city of Providence, RI) are motile gram-negative bacilli that do not ferment lactose and are distinguished from other Enterobacteriaceae by their ability to deaminate phenylalanine and lysine.[8,27] The genus distinguishes "urease-negative" organisms, *Providencia rettgeri*, *Providencia stuartii*, *Providencia alcalifaciens*, *Providencia rustigianii*, and *Providencia heimbachae*, from the otherwise biochemically similar "urease-positive" *Proteus* spp.[15,27] Urease is produced by most strains of *P. rettgeri* and by 15 percent or less of *P. stuartii* strains.[27] *Providencia* spp. also differ from other Proteeae in their ability to produce acid from inositol. Strains are differentiated further by reactivity with straight-chain hydroxy alcohols.[27] For a detailed discussion of taxonomy and characterization of *Providencia* spp., the reader is referred to the review by O'Hara and colleagues.[24]

EPIDEMIOLOGY

Providencia organisms are recovered uncommonly from stool in healthy humans, but they frequently colonize indwelling or condom urinary catheters, particularly in patients receiving antibiotic therapy.[5,10,16,34,35] In a Japanese study of patients with traveler's diarrhea, *Providencia* spp. were recovered, using a new selective medium, from 23 of 130 specimens tested.[36] *Providencia* spp. have been recognized as pathogens for more than 50 years[7]; *P. rettgeri* and *P. stuartii* are the most common species implicated in urinary tract infection.[10,12,13,21,35] Multiple biotypes of *P. stuartii* have been identified in hospital outbreaks, indicating the probability of multiple sources of colonization.[2] Ribotyping is a sensitive method for molecular characterization of isolates that may aid in analysis of outbreaks.[29]

PATHOPHYSIOLOGY

P. stuartii does not seem to have greater access to the urinary tract compared with other bacteria; in patients with long-term catheters, the incidence of bacteriuria caused by this organism is equivalent to that caused by other uropathogens.[34] Rather, *P. stuartii* manifests an extraordinary ability to persist within the

catheterized urinary tract.[35] Bacteriuria may take weeks to months to clear. A mannose-resistant, *Klebsiella*-like hemagglutinin may play an important role in the persistence and adherence of *P. stuartii* to urinary tract catheters.[23]

Despite the similarities between *Proteus mirabilis* (the major pathogen responsible for urolithiasis in children)[4] and urease-producing *Providencia* spp., the latter organisms rarely are associated with formation of stones. *P. stuartii* occasionally produces urease with a higher affinity for substrate, but *P. mirabilis* ureases hydrolyze urea 6 to 25 times faster.[14] Restriction-enzyme analysis of genes coding for the respective enzymes shows significant divergence.[14] These differences may explain the more frequent association of *P. mirabilis* with formation of stones.

Some strains of *P. alcalifaciens* have been isolated more commonly in children with diarrhea, and enteropathogenicity has been shown in Hep 2 cells and a rabbit model.[2,3] Ex vivo *P. alcalifaciens* strains show the ability to translocate and to resist complement-mediated lysis.[33] In children with diarrhea, *P. alcalifaciens* often is associated with other enteric pathogens, so its role in pathogenesis remains unclear.[1]

CLINICAL MANIFESTATIONS

Although *Escherichia coli* and *Proteus* spp. account for most urinary tract infections in children, *Providencia* spp. have been reported as a cause of infection in children with spinal injury and long-term urinary tract catheterization.[17,21] Most infections have been described, however, in elderly patients or adults with spinal injury who require long-term urinary tract catheterization.[34] Clinical findings are typical of those associated with urinary tract infection. Bacteremia is uncommon but devastating.[18] In a study of 132 cases of bacteremia caused by members of the tribe Proteeae, only 8 were caused by *Providencia* spp., but four of those patients died of the infection.[18] A single case of endocarditis caused by *P. stuartii* has been reported.[19]

Eye infections caused by *P. rettgeri*, including conjunctivitis, dacryocystitis, keratitis, and endophthalmitis, have been reported. These infections generally occurred in patients with compromise in ocular surface or in immunity.[25]

Providencia spp. have been implicated in the so-called purple urine bag syndrome, in which an enzyme from the organism causes 3-indoxyl sulfate to be formed, which discolors the urine blue or blue-violet. This syndrome usually occurs in patients with indwelling cystotomy or nephrostomy tubes.[20,32]

DIAGNOSIS

Infection with *Providencia* spp. should be suspected when indole-positive, urease-negative, gram-negative rods, which oxidatively deaminate tryptophan, are isolated in culture. Because patients with long-term catheterization may be colonized with multiple organisms, *Providencia* spp. frequently are overlooked or misidentified.[7] Clinical laboratories should be encouraged to identify all bacterial colonies in patients with long-term catheterization in whom infection is suspected. Identification is particularly important because of the marked differences in susceptibility of uropathogens.[28]

TREATMENT

Empiric therapy should be guided by antimicrobial susceptibility testing of the patient's isolate and knowledge of susceptibilities of previously identified *Providencia* within the care facility. Removal of urinary tract catheters speeds eradication of these pathogens. Strains of *P. stuartii* and *P. rettgeri* commonly are resistant to many antibiotics. In a longitudinal Italian study of 223 *P. stuartii* isolates, 116 (52%) were extended-spectrum β-lactamase positive. The rate of extended-spectrum β-lactamase–positive isolates increased from 31 percent in 1999 to 62 percent in 2002.[31] Since the 1970s, multidrug resistance has emerged[26]; many strains are resistant to sulfonamides, trimethoprim, nitrofurantoin, nalidixic acid, penicillins, cephalosporins, and aminoglycosides; some singular strains are resistant to most antibiotics in common use.[28] Imipenem-resistant strains have now been described.[30] Much of the observed resistance seems to be plasmid-based[11]; quinolones and aztreonam have shown some promise in the treatment of such cases.[6,9] Complex combinations of aminoglycoside resistance that differ by hospital and geographic region can occur.[22] Organisms that are resistant to gentamicin and tobramycin may remain susceptible to amikacin.

Acknowledgments

The author thanks Dr. William Gruber and Dr. Thomas Boyce for their invaluable assistance with earlier versions of this chapter.

CHAPTER 119

SHIGELLA

Theresa J. Ochoa ✪ Thomas G. Cleary

HISTORICAL BACKGROUND

The term *dysentery* classically has been used to describe the frequent, painful passage of stools containing blood and mucus. The syndrome has been recognized since the time of Hippocrates. The differentiation of dysentery into bacillary and amebic forms followed the recognition by Shiga in 1898 that one form of dysentery was associated with a bacterium in the stools of affected individuals; their sera also were found to agglutinate the bacillus. In recognition of his achievement, the genus was eventually named after Shiga.

The most important subsequent advance has been the recognition of the molecular basis of *Shigella* virulence. In the 1960s, researchers showed that shigellae invade the corneal epithelium of guinea pigs and cause keratoconjunctivitis (Sereny test). Subsequently, Formal and colleagues[70] showed that *Shigella flexneri* invades the intestinal epithelium. Since 1980, Sansonetti and other investigators[201,203,204] have identified multiple plasmid and chromosomal virulence genes. *Shigella*-like enteroinvasive *Escherichia coli* have the same or closely related genes and produce a similar clinical syndrome.

ORGANISM

Shigellae are small, nonencapsulated gram-negative rods that are members of the family Enterobacteriaceae. Technically, they are *E. coli*, but for reasons of tradition and clinical usefulness, the designation as a separate genus has been preserved. Shigellae do not ferment lactose or do so slowly and are nonmotile (lack the H [flagellar] antigen). They lack urease and do not produce hydrogen sulfide on triple sugar iron media or gas during metabolism of carbohydrate.[62] The somatic antigen (or O antigen) side chains that determine serotype and serogroup are attached as multiple repeating units to the lipid A core and core oligosaccharides shared with other members of Enterobacteriaceae. Envelope or K antigens that are heat-labile also have been described, although their clinical relevance is uncertain.

SEROGROUP CLASSIFICATION

Four serogroups, or species, of *Shigella* are defined on the basis of serologic similarities and biochemical reactions. Group A (*Shigella dysenteriae*), mannitol nonfermenters, includes 13 serotypes having O antigens that do not cross-react immunologically. Two additional provisional serovars, types 14 and 15, also are pathogenic.[9] Serogroup D (*Shigella sonnei*), ornithine decarboxylase–positive, slow lactose fermenters, share the same lipopolysaccharide. *Shigella* strains that ferment mannitol (in contrast to *S. dysenteriae*) but do not decarboxylate ornithine or ferment lactose (in contrast to *S. sonnei*) are classified as serogroups B and C. Of these, the strains that express lipopolysaccharides that are related to each other immunologically are group B (*Shigella flexneri*), whereas the strains whose O antigens are unrelated to each other or to other shigellae are group C (*Shigella boydii*). Multiple serotypes of *S. flexneri* (15 serotypes and subtypes) and of *S. boydii* (18 serotypes) exist.

EPIDEMIOLOGY

An estimated 164.7 million cases of shigellosis occur annually, of which 99 percent occur in developing countries, with 1.1 million deaths, 61 percent of which involve children younger than 5 years old.[116] Generally, *Shigella* spp. are associated with 5 to 10 percent of all diarrhea cases and 30 percent of dysentery cases.[162] Although epidemic *Shigella* dysentery is the most dramatic manifestation of *Shigella* infections in developing countries, most infections are caused by endemic shigellosis. Endemic shigellosis is responsible for approximately 10 percent of all diarrheal episodes among children younger than 5 years of age in developing countries.[63] Despite the fact that severe dehydration usually is not seen in shigellosis, 75 percent of diarrheal deaths may be due to these infections.[162] According to surveillance reports of the Centers for Disease Control and Prevention, 10,000 to 15,000 cases of shigellosis have been documented each year during the last 30 years in the United States, for annual incidence rates of 5 to 10 per 100,000.[45]

Because shigellae are spread through a fecal-oral route, they are especially prevalent where hygiene is poor. The organisms can be cultured from around toilets in homes where shigellae have caused disease. Toilet paper does not prevent contamination of fingers. Shigellae are transmitted easily from person to person because the inoculum size required to cause disease is only 10 organisms in the case of *S. dysenteriae* serotype 1[60] and a few hundred organisms in the cases of *S. sonnei* and *S. flexneri*.[59] Handwashing and wearing gloves are mandatory procedures for individuals caring for patients with bacillary dysentery. Patients who lack the acid barrier provided by a normally functioning stomach because of prior gastrectomy or use of antacid are at increased risk of acquiring infection.

Shigellae survive for 30 days in foods such as milk, whole eggs, oysters, shrimp, and flour.[147] Epidemics usually are associated with exposure to contaminated water or food, although as might be predicted from the inoculum size, outbreaks related to swimming also occur.[137] Houseflies can be colonized with shigellae in their guts without illness and pass the organisms in their feces. Feces adherent to their legs can lead to contamination of food. Flies have been implicated in epidemics of shigellosis, particularly where the fly population is large. *Shigella* infection shows seasonal variation. In North America, few cases occur in the winter, whereas in tropical regions, the peak is during the rainy season. Shigellae are worldwide and thrive where susceptible individuals are grouped together (including institutions for retarded or mentally ill individuals, prisoner-of-war camps, Indian reservations, the military, daycare centers, and the developing world).[110,178,212] Spread within families is a common occurrence.

The species of *Shigella* causing most infections vary according to regions. In developed countries, *S. sonnei* is the most common species, followed by *S. flexneri* (approximately 70% *S. sonnei* and 25% *S. flexneri*); however, in the developing world, this pattern is reversed, with *S. flexneri* being more common than *S. sonnei*. *S. dysenteriae* serotype 1 occurs primarily in Africa, India, and Bangladesh. *S. boydii* is found primarily on the Indian subcontinent.[162]

Humans and other primates can be infected with shigellae, and an age-related risk of acquiring symptomatic shigellosis exists. In contrast to *Salmonella* spp., which cause disease most frequently in the first few months of life, shigellae infrequently cause illness in the first 6 months of life. The peak incidence occurs in children between 1 and 4 years of age, with fewer cases occurring in children aged 5 to 9 years old. Adults are at lower risk.

PATHOGENESIS

INVASIVENESS AND TOXIN PRODUCTION

The ability to invade mammalian cells is the most important virulence trait of *Shigella* spp.[74,122,129,159,169] Uptake by M cells overlying Peyer patches with ingestion by macrophages under the M cells induces production of cytokines and recruitment of polymorphonuclear leukocytes. Apoptosis is induced in macrophages after ingestion of shigellae; these events are accompanied by release of interleukin-1 (IL-1), IL-1β, and IL-18, which triggers other inflammatory events.[203,227,229] Polymorphonuclear leukocytes enter the gut lumen by moving between epithelial cells. The gaps between epithelial cells may be the portal of entry of bacteria into the epithelium. After penetration of intestinal epithelial cells, shigellae are located in vacuoles derived from the cytoplasmic membrane of the mucosal cells. The bacteria lyse these vacuoles, move intracellularly, multiply, kill the epithelial cells, and infect adjacent cells. Cell death is followed by formation of ulcerations and microabscesses in the colon. In contrast to *Salmonella* infection, *Shigella* infection rarely spreads beyond the lamina propria, so bacteremia and metastatic infections are uncommon.

The genetic basis of virulence has been studied extensively.[170,174] Invasiveness is the result primarily of genes on a large 120- to 140-MDa (200- to 220-kb) virulence plasmid.[81,82,88,200-202,204] These genes encode a molecular apparatus called a type III secretion system that is capable of injecting bacterial proteins through bacterial and host membranes into host cells (translocation) or the extracellular milieu (secretion) to influence host biochemistry and cell physiology directly.[174] The invasive plasmid antigen (ipa) region includes genes for four polypeptides needed for invasion: *ipaA*, *ipaB*, *ipaC*, and *ipaD*. The proteins produced by these loci are recognized by the humoral immune system. The product of the *ipaB* locus is essential for induction of apoptosis in macrophages.[228] The mxi-spa region of the virulence plasmid is necessary for orientation of the ipa-encoded proteins into the outer membrane of the bacteria. The *virG* gene encodes a protein that causes intracellular and intercellular spread of shigellae after invasion of epithelial cells. The *virF* gene regulates a locus (*virB*) that is responsible for positive regulation of the ipa genes.[192]

Chromosomal loci also regulate virulence.[173] Chromosomal loci regulate expression of the virulence plasmid. The keratoconjunctivitis provocation (*kcpA*) gene is a positive regulator of the *virG* virulence plasmid gene that determines ability to spread within and between cells. The chromosomal *virR* gene is a temperature regulator that represses expression of ipa genes at 30° C, but not at 37° C.

Lipopolysaccharides (LPSs) play a role in resistance to nonspecific host defense mechanisms that are encountered during invasion of tissue. The *Shigella* LPS induces the trafficking of Toll-like receptor 4, the dominant mediator of the innate immune response.[42] Smooth colonies express the complete complex of LPS O side chains required for full virulence—ability to invade epithelial cells, to multiply within them, and to resist phagocytosis.[77,171] Rough colonial variants that lack complete LPS do not penetrate epithelial cells efficiently and are avirulent.

Some strains of *Shigella* spp. produce toxins that injure mammalian cells. A chromosomal locus in *S. dysenteriae* serotype 1 encodes a protein synthesis–inhibiting exotoxin (Shiga toxin) that is a major virulence factor in this serotype (and in the enterohemorrhagic *E. coli* serotypes that have the same or closely related genes).[25,207] This toxin is composed of a single copy of an A subunit (32,000 daltons) that is linked to five copies of B subunits (7790 daltons).[167] The B subunits bind to a glycolipid cell receptor, globotriaosylceramide, followed by internalization. The A subunit cleaves an adenine residue from the eukaryotic 28S ribosomal subunit. The resulting block in elongation factor 1–dependent binding of aminoacyl tRNA to the ribosome causes cell death through inhibition of protein synthesis.[167] Shiga toxin previously was considered to be a neurotoxin because its administration to mice or rabbits caused paralysis and death[37,44,92]; it now is thought to target primarily the vascular endothelium. It causes fluid accumulation in rabbit ileal loops[64,111] that probably is related to reduced fluid uptake by damaged villus cells.

The severity of *S. dysenteriae* serotype 1 infection relative to other *Shigella* serotypes is thought to be caused by production of Shiga toxin. Enterohemorrhagic *E. coli* serotypes, such as *E. coli* O157:H7, produce an identical (Shiga toxin 1) or similar (Shiga toxin 2) toxin and, similar to *S. dysenteriae* serotype 1, cause bloody diarrhea and hemolytic-uremic syndrome. Enteroinvasive *E. coli* serotypes do not produce these toxins.[50]

Shigella spp. also produce two enterotoxins, ShET-1 and ShET-2.[218] All *S. flexneri* 2a strains produce ShET-1, whereas only 3.3 percent of other *Shigella* serotypes and no enteroinvasive *E. coli* serotypes possess the gene for this toxin.[163] ShET-2 is produced by all *Shigella* spp.[218] Genes of an additional toxin, designated *Shigella* enterotoxin, or Sen, have been found in 75

percent of enteroinvasive *E. coli* serotypes and 83 percent of *Shigella* strains.[156] These enterotoxins may contribute to the high-volume, watery diarrhea often seen in the initial stages of the disease.[19] Vaccine studies using a mutant with deletions of these toxin genes have shown that one or both enterotoxins play a role in human disease.[117]

IMMUNE RESPONSE

Serum IgG, IgM, and IgA responses occur to the LPS and invasion plasmid antigens of shigellae.[166] Secretory IgA specific to both of these sets of antigens occurs in human milk and feces.[51] Protection is thought to be serotype-specific. The level of IgG antibodies to LPS present in an individual before infection occurs determines whether symptomatic shigellosis develops.[55] No clear proof currently exists about the role of antibodies to the invasion plasmid virulence proteins or to the toxins. Cell-mediated immunity against shigellae also may play a role in resolution of infection. Production of αβ T cells and natural killer cells mediates interferon-γ production that may be essential to defense from *Shigella*.[124,222] Antibody-dependent cellular cytotoxicity against shigellae has been shown.

During infection, shigellae use effectors secreted via the type III secretion system to direct various cellular signaling pathways and to modify the innate immune activation of the host. More recent evidence indicates that a large part of the mucosal inflammation is initiated by intracellular sensing of bacterial peptidoglycan by cytosolic leucin-rich receptors of the NOD family in epithelial cells.[170,175] This causes activation of the nuclear factor κB and other terminal kinase pathways, with IL-8 appearing as a major chemokine mediating the inflammatory burst that is dominated by massive infiltration of the mucosa by polymorphonuclear leukocytes.[175] The levels of cytokines tumor necrosis factor-α, IL-1β, IL-1RA, IL-6, IL-8, and granulocyte-macrophage colony-stimulating factor in stool correlate with the severity of shigellosis. In contrast to other cytokines, interferon-γ and its receptor[186] are depressed early and increase during recovery. Fecal concentrations of tumor necrosis factor-α, IL-1β, IL-1RA, IL-6, IL-8, and granulocyte-macrophage colony-stimulating factor are significantly higher in patients with *S. dysenteriae* serotype 1 than in patients with *S. flexneri* infection.[189] Elevated tumor necrosis factor-α and IL-6 levels in stool and serum have been associated with complications during infection with *S. dysenteriae* serotype 1.[85] Infiltration of polymorphonuclear leukocytes and lymphocytes into the intestine is controlled by these cytokines. Epithelial cell production of IL-8[199] and a low IL-1RA-to-IL-1 ratio[11] are responsible for the severe inflammation. T lymphocytes with suppressor-cytotoxic and helper-inducer phenotypes are recruited into the epithelium and lamina propria during infection with *Shigella*, related partly to the induction of HLA-DR expression in the rectal mucosa.[187] Peripheral blood lymphocytes of infected individuals respond to *Shigella* antigens in vitro with production of interferon-γ and IL-10.[198]

Shigella spp. elicit an inflammatory response during multiplication within macrophages and epithelial cells. *Shigella* multiplication in macrophage cytoplasm induces cell death, which is achieved by two distinctive pathways: activation of caspase-1 by IpaB secreted by the type III secretion system, and translocation of lipid A from the cytosol, which occurs independent of caspase-1 and Toll-like receptor 4 activities.[170]

PATHOLOGY

The main morphologic changes of shigellosis (superficial ulcerations, focal hemorrhages, mucosal edema, erythema, and friability) occur in the colon where the organisms invade.[97,208] The rectosigmoid and distal segments of the colon typically are involved more severely than is the proximal colon. The epithelial cell damage may cause development of a pseudomembrane composed of thick, fibropurulent exudate tightly adherent to the necrotic ulcerated colonic mucosa. Pseudopolyposis also has been reported.[39] On microscopic examination, damage to epithelial cells, ulcerations, goblet cell depletion, and intense polymorphonuclear and mononuclear infiltration with crypt abscesses are seen. Rectal mucosa shows increased numbers of $CD8^+$ and $\gamma\delta^+$ T cells.[95] Vessels in the lamina propria are congested or thrombosed. Perforation of the colon usually does not occur as part of the colitis.[23] Evidence of inflammation and proinflammatory cytokines persists for at least 1 month after clinical resolution.[185] Histologic changes generally are more severe and persistent[96] with *S. dysenteriae* than with *S. flexneri*.[8]

CLINICAL MANIFESTATIONS

The incubation period ranges from 12 hours to a few days (if a low number of organisms is ingested). Onset of high fever, toxicity, and crampy abdominal pain is sudden. During the first 48 hours, high-volume watery diarrhea may occur (small bowel phase of disease); subsequently, low-volume, bloody, and mucous diarrhea develops in association with urgency and tenesmus (large bowel or "dysenteric" disease). In some cases, the watery diarrhea persists for several days, without subsequent development of dysentery. Other children present with bloody or mucous diarrhea.

Physical examination shows fever, signs of toxicity, tenderness over the lower abdominal quadrants, and hyperactive bowel sounds. Signs of dehydration may be present. Rectal examination reveals severe tenderness. Rectal prolapse may be present, particularly when diarrhea is associated with malnutrition.

The course without therapy typically lasts 7 to 10 days. Protein-losing enteropathy occurs during shigellosis; this enteropathy is severe with *S. dysenteriae* serotype 1.[32] In addition, anorexia related to fever and abdominal pain contributes further to malnutrition, particularly in *S. dysenteriae* type 1 infection.[184] These facts may explain partly the hypoproteinemia and adverse effect on growth of severe shigellosis. Malnutrition is associated with a more severe course of shigellosis. Fever may not develop, even when severe dysentery is present. Chronic infection may last for months, despite administration of appropriate antibiotic therapy. It may cause further deterioration of the nutritional status, which together with other complications (e.g., ileus, bacteremia, and pneumonia) is associated with overall increased mortality rates from shigellosis. Surgical complications of shigellosis are rare but are associated with significant morbidity and mortality because of delay in establishing the diagnosis. In a series of 57 children with surgical complications of shigellosis,[148] intestinal obstruction (53%), appendicitis (28%), and colonic perforation (17%) were the most common (Table 119–1).

Although the organism usually is excreted for only a few days or weeks (range 1 to 30 days), carriage for many months sometimes occurs.[52,130] The illness usually is acute; a chronic carrier state can occur in malnourished individuals. Asymptomatic infection of toddlers living in an endemic area occurs commonly. Most *Shigella* infections in Mexican children who were cultured each week from birth were not associated with symptoms.[80]

EXTRAINTESTINAL MANIFESTATIONS AND COMPLICATIONS

Multiple extraintestinal complications have been described with *Shigella* infection (see Table 119–1). Seizures have been reported in 10 to 45 percent of hospitalized children with culture-proven shigellosis.[17,21,24,57,68] In outpatient settings, the frequency of seizures is very low. Children who develop neurologic complaints

TABLE 119–1 Complications of Shigellosis

Abdominal
Persistent diarrhea
Post-dysenteric irritable bowel syndrome
Ileus, toxic megacolon, intestinal perforation
Protein-losing enteropathy, malnutrition
Surgical complications: intestinal perforation and obstruction, appendicitis, intra-abdominal abscesses

Neurologic
Seizures
Headache, lethargy, disorientation, hallucinations
Coma
Severe toxin encephalopathy or ekiri syndrome

Bacteremia
In malnourished children, young infants, and AIDS patients

Hemolytic-uremic syndrome
Only with *Shigella dysenteriae* serotype 1

Urogenital
Vulvovaginitis, urinary tract infections

Other
Conjunctivitis, keratitis, corneal ulcers
Reactive arthritis
Reiter syndrome
Hepatitis
Myocarditis

may have lethargy, severe headache, disorientation, hallucinations, or self-limited convulsions lasting less than 15 minutes.[15,18,21,152] Seizures are most likely to occur in very young patients, patients with a high peak body temperature, and patients with a family history of convulsive disorders.[17,118] Seizures can be focal, although usually they are generalized.

When symptoms related to the nervous system occur, they are likely to appear early in the illness, even preceding development of diarrhea. Death rarely has been described[90]; most children recover completely with no residual neurologic deficits.[18] In contrast, in Bangladesh, where seizures in shigellosis typically are associated with factors known to alter consciousness (e.g., hypoglycemia, hyponatremia, fever), mortality rates are high.[114] The pathogenesis of neurologic signs and symptoms during episodes of shigellosis is unclear. Hypoglycemia and electrolyte abnormalities are found in a few patients.[18] Direct invasion of the central nervous system during *Shigella* bacteremia is very rare.[223] Simple febrile seizures might explain convulsions in a few children with dysentery, but some children who have seizures during episodes of shigellosis do not experience seizures during other febrile infections and are outside the age range usually associated with febrile seizures.[18] Shiga toxin formerly was thought to cause the neurologic symptoms because it was considered to be a neurotoxin; however, data now clearly show that Shiga toxin is not responsible.[16]

Severe toxic encephalopathy has been described. This syndrome (ekiri), as originally described in Japan, was characterized by dysentery with hyperpyrexia, convulsions, sensory disturbances, and rapid progression to death.[193] The children died with cerebral edema early in the course of disease (6 to 48 hours after onset). Mild hyponatremia has been a common finding.[76] Children with ekiri did not have sepsis, disseminated intravascular coagulation, hemolytic-uremic syndrome, or severe dehydration. This toxic encephalopathy is rare. Whether this syndrome is part of a continuum of central nervous system dysfunctions with seizures and other encephalopathic symptoms or has a completely different pathogenesis is unclear.

Hemolytic-uremic syndrome (microangiopathic hemolytic anemia, thrombocytopenia, and acute renal failure) or isolated hemolysis has been reported, mainly after infections with *S. dysenteriae* serotype 1 and rarely after infection with *S. flexneri*.[182] Vascular endothelial cell damage by Shiga toxin is considered to be the initial event, although endotoxin absorbed from the gut also may play a role.[115]

Ileus that progresses to toxic megacolon with distended loops and eventual intestinal perforation occurs.[22] It is seen mainly with *S. dysenteriae* serotype 1 infection.

Septicemia in shigellosis is a rare occurrence except in malnourished children, young infants, and children with *S. dysenteriae* serotype 1 infections.[84,143,205] The mortality rate is at least twice as high in dysentery-associated sepsis as in shigellosis uncomplicated by bacteremia. The serogroup-related mortality risk in shigellemia has been reported to be 85 percent for infection with *S. dysenteriae*, 43 percent for infection with *S. flexneri*, and 25 percent for infection with *S. sonnei*; bacteremia rarely is reported with *S. boydii* infection.[141] In Bangladesh, *Shigella* bacteremia was found in 4 percent of patients.[213] When bacteremia occurs with dysentery, it is as likely to be caused by other enteric bacteria as by the *Shigella* itself. The occurrence of *Klebsiella*, *E. coli*, and other enteric pathogens in blood cultures of children with shigellosis presumably reflects loss of the barrier function during severe colitis.[158] *Shigella* bacteremia may be complicated by disseminated intravascular coagulation and multiorgan failure. Bronchopneumonia may develop in septicemic children,[4] but its pathogenesis is unclear. Children who die with shigellosis often have pneumonia at autopsy.[39]

Other extraintestinal infections rarely are caused by *Shigella* spp. Vaginitis with a bloody discharge (sometimes lasting for months in the absence of specific therapy) may occur, usually without concurrent or recent diarrhea.[56,154] *Shigella* cystitis, not always associated with diarrhea, has been described, usually in girls.[24] Conjunctivitis, keratitis, corneal ulcers, and iritis are other uncommon manifestations of shigellosis that usually are assumed to occur after autoinoculation.[24,216] Reactive arthritis or Reiter syndrome (arthritis, urethritis, conjunctivitis) may develop after episodes of shigellosis,[41] especially in adults who are HLA-B27-positive; reactive arthritis is uncommon in children. Hepatitis with mildly abnormal liver function test results has been described.[211] Myocarditis manifested clinically by hypotension despite fluid replacement, arrhythmia, heart block, or low voltage on electrocardiography and pathologically by interstitial lymphocytic infiltrates and focal necrosis has been described.[191] Post-dysenteric irritable bowel syndrome occurs in some patients after recovery.[221]

SHIGELLOSIS IN THE NEONATAL PERIOD

Bacillary dysentery is rare in newborns.[25,61,66,83,123] More than half of the reported neonatal cases occurred during the infants' first 3 days of life, consistent with fecal-oral transmission during delivery,[78,160] usually from a symptomatic mother. Although a neonate with shigellosis usually has only low-grade fever with diarrhea of variable severity,[5,120,150] septicemia[127,181] and chronic diarrhea are more common than in older children. Intestinal perforation has been reported in neonatal shigellosis.[210] Diarrhea more often is nonbloody in infants; fever also occurs less commonly than in older children.[94] Data on age-related mortality caused by shigellosis in developing countries suggest that the mortality rate of the neonate is more than twice that of older children.

SHIGELLOSIS IN ACQUIRED IMMUNODEFICIENCY SYNDROME

In patients with acquired immunodeficiency syndrome (AIDS), shigellosis not only is more common and more severe, but also is associated more often with bacteremia.[26,93] In contrast to the

usual short, self-limited course of shigellosis, *Shigella* infection in patients with AIDS may be chronic and relapsing, despite appropriate antibiotic treatment.[121,206]

LABORATORY FINDINGS

The fecal leukocyte examination is helpful in evaluating a patient with fever and watery diarrhea. Direct microscopic examination of fecal mucus stained with methylene blue shows many polymorphonuclear leukocytes in patients with colitis, including most patients with shigellosis.[87] The blood leukocyte count in patients with shigellosis often is normal, although leukopenia or leukocytosis may occur.[13] The differential of the blood leukocyte count typically shows an increased percentage of band forms. Approximately one third of children with shigellosis have more bands than segmented neutrophils in their peripheral blood smear. A leukemoid reaction, with a peripheral leukocyte count greater than 50,000/mm^3, has been reported, mainly with infections caused by *S. dysenteriae* serotype 1.[40] A leukemoid reaction has been reported in 10 percent of patients infected with the Shiga bacillus. When examination of cerebrospinal fluid is performed in children with neurologic symptoms, normal results usually are obtained, although some patients have a mild lymphocytic pleocytosis. Likewise, when electroencephalography is performed, the results usually are normal.[18]

DIAGNOSIS

Bacillary dysentery usually is suspected in children who present with bloody diarrhea, high fever, and generalized toxicity. Approximately half of children do not develop bloody diarrhea during the course of their disease. This fact is especially relevant in developed countries, where most infections are caused by *S. sonnei*. The presence of only watery diarrhea does not exclude the possibility of shigellosis in an ill patient with high fever.

ISOLATION TECHNIQUES

Proof of the diagnosis of suspected bacillary dysentery often is problematic. Definite diagnosis of *Shigella* infection depends on isolation of the organism from stool specimens or rectal swabs. The bacteria may not survive in fecal specimens during transit, however, and special selective media are necessary for isolation. Recovery of shigellae is easier early in the course of the disease than later because the number of viable organisms in stools decreases significantly during late stages of the disease. Even in adult volunteer studies, when appropriate stool cultures were obtained daily, cultures failed to isolate shigellae in approximately 20 percent of volunteers who had ingested the organism and developed diarrhea.

Several measures increase the likelihood of isolating *Shigella*. Specimens should be processed without delay. If a specimen cannot be processed immediately, a transport medium, such as buffered glycerol saline, should be used. More than one stool culture or rectal swab should be obtained and inoculated promptly onto at least two different culture media. Specimens should be plated lightly onto MacConkey, xylose-lysine-deoxycholate, or eosin–methylene blue agar, whereas a heavier plating is necessary for the more inhibitory *Shigella-Salmonella* medium.[151,215] After overnight incubation at 37° C, lactose-negative colonies are transferred to triple sugar iron and lysine iron agar slants and incubated again overnight. Slants showing characteristic reactions of alkaline red slants, acid butt, and production of gas are tested biochemically for presumptive identification and then serologically for definitive identification.

OTHER DIAGNOSTIC METHODS

Because presumptive identification of *Shigella* takes at least 48 hours and definite identification takes approximately 72 hours, attempts to develop rapid diagnostic methods are being made, especially because institution of early treatment is important in shigellosis. Identification of shigellae by specific DNA probes with use of either restriction fragments or synthetic oligonucleotides[161] based on detecting virulence genes located on the 120- to 140-MDa plasmid has been described. Because the invasion plasmids of shigellae, similar to other plasmids, may be lost spontaneously, a DNA probe derived from *S. flexneri ipaH* gene, a multicopy element that is found on the chromosome and on the invasion plasmid of shigellae, has been developed and found to be more sensitive than are probes used previously.[219] Use of polymerase chain reaction (PCR) in vitro amplification of nucleic acids, to detect shigellae directly from stool specimens, has been reported.[71] PCR can detect as few as 10 colony-forming units of *S. flexneri* in stool specimens, whereas the sensitivities of DNA probe hybridization (with no amplification) and standard biochemical methods are 10^3 and 10^6 colony-forming units. PCR for *ipaH* genes seems to be more sensitive than culture; 28 percent of patients with dysentery with a positive PCR assay result are culture negative.[73,99] Another new method for the identification of *Shigella* is microarray analysis using the *gyrB* genes.[106] This novel approach also renders it possible to identify simultaneously other enteric pathogens, such as *Salmonella* spp. and diarrheogenic *E. coli*.[106]

Serologic studies are not helpful in establishing the diagnosis of shigellosis in individual patients; humoral antibodies develop after clinical recovery. Serologic studies may be helpful, however, in epidemiologic studies to define spread of the disease in a population.[24]

Sigmoidoscopy and barium enema study are unnecessary, unless they are indicated to rule out other conditions. When these procedures are performed in patients with a possibility of having shigellosis, caution is necessary because of the diffuse acute colitis.

DIFFERENTIAL DIAGNOSIS

Colitis of any etiology manifesting with acute-onset bloody diarrhea with fever and abdominal cramps can mimic shigellosis. Etiologic agents to be considered include *Campylobacter* spp., *Salmonella* spp., *Clostridium difficile*, *Yersinia enterocolitica*, *Shigella* spp., *Vibrio parahaemolyticus*, enteroinvasive *E. coli*, enterohemorrhagic *E. coli* (e.g., serotype O157:H7), *Balantidium coli*, and *Entamoeba histolytica*. The initial presentation of inflammatory bowel disease can mimic shigellosis.

An etiologic diagnosis of acute colitis syndrome on the basis of clinical presentation is difficult to make, although some data suggest a specific causative agent. In developed countries, *Campylobacter* is the most common cause of acute infectious colitis. Shigellosis should be suspected when evidence exists of person-to-person spread, and when convulsions or other neurologic symptoms develop. In the first few months of life, *Salmonella* is the most common infectious cause of bloody diarrhea, and *Shigella* is very rare.

A history of previous antibiotic treatment suggests diarrhea related to *C. difficile*, and previous consumption of seafood suggests *V. parahaemolyticus*. *Yersinia* infections are found mainly in the cooler regions of Europe and North America; the disease may mimic acute appendicitis because of the right lower quadrant pain associated with mesenteric lymphadenitis.

Enterohemorrhagic *E. coli* infection often causes bloody diarrhea with little or no fever, in contrast to shigellosis, in which high fever is typical. Negative stool cultures for the mentioned

bacterial pathogens may suggest infection by enteroinvasive *E. coli*. Amebiasis causes a colitis similar to the colitis caused by *Shigella*,[209] although it is of slower onset, with a lower degree of fever; the findings on fecal leukocyte examination are negative. The involvement of the colon with amebiasis is less diffuse than in shigellosis; areas of normal mucosa are found between ulcerations.

A prolonged course with negative cultures should raise concern about the possible presence of either ulcerative colitis or Crohn disease. When watery diarrhea is present, the list of possible etiologic agents is even longer, although many agents that cause watery diarrhea are associated with little or no fever and are not confused with shigellosis. The diagnosis usually cannot be made by clinical presentation alone and depends on culture results or other specific laboratory assays.

TREATMENT

FLUID ADMINISTRATION

Dehydration is less a problem with shigellosis than with rotavirus or toxigenic *E. coli* infection. Some children with shigellosis, particularly young infants, have dehydration during the course of the disease. The high-volume watery diarrhea seen early in the course of the disease may cause excess losses of fluids and electrolytes; likewise, in patients with severe colitis, systemic toxicity and vomiting may cause anorexia that interferes with fluid intake.

Assessment of the hydration status of the patient on admission is mandatory, with early institution of appropriate fluid and electrolyte therapy needed. The World Health Organization's oral rehydration therapy with glucose-electrolyte solutions usually is effective.[155] This solution contains 90 mEq/L of sodium, 20 mEq/L of potassium, 80 mEq/L of chloride, 30 mEq/L of bicarbonate or citrate, and 20 g/L of glucose. Oral rehydration therapy should be given with additional water containing no electrolytes to prevent hypernatremia; this therapy is particularly important in children too young to express their need for additional free water. In infants, 2 parts of oral rehydration solution should be followed by 1 part of water without electrolytes. Oral rehydration with commercially available solutions (e.g., Pedialyte) also is acceptable. Administration of intravenous fluid therapy is necessary in children who are comatose, have an ileus, or are in shock. Early (12 to 24 hours after oral fluids are begun) reinstitution of breast milk or other food is mandatory.

ANTIBIOTIC THERAPY

Children who have dysentery always should be treated empirically with antimicrobials. Antibiotic therapy for milder illness is controversial. World Health Organization guidelines suggest that presumptive shigellosis should be treated with antibiotics, the choice being decided by the antimicrobial susceptibility pattern of locally circulating *Shigella* strains (WHO/CDR/95.3). If after 2 days of therapy, the patient's condition improves, a full course of 5 days should be given. If the patient does not improve, the antibiotic should be changed. If with the second antibiotic, the patient does not show signs of improvement, the diagnosis must be reviewed, and stool microscopy, culture, and susceptibility testing should be performed.[162]

Appropriate antimicrobial therapy of shigellosis shortens the duration of fever and diarrhea, and it apparently also reduces the risk of developing complications.[12] Shedding of the organisms in stools stops within 1 to 2 days, so that intrafamilial spread may be decreased. Although use of antibiotics may favor emergence of resistant organisms, most authorities recommend that antibiotics be started when shigellosis first is suspected clinically, before culture confirmation of the infection is obtained. Therapy should be stopped or changed on the basis of culture results (e.g., another pathogen or a resistant *Shigella* strain is isolated) and clinical response.

The choice of antimicrobial agent is complicated by the increasing frequency of plasmid-mediated antibiotic resistance.[63,67,197] Organisms resistant to ampicillin, trimethoprim-sulfamethoxazole, tetracycline, and chloramphenicol have been reported from the Middle East,[1,6,10,19,64,86,105,224] Africa,[1,35,43,108,142,157] South America,[132,156,164,180] Europe,[25,46,101,107,119,139,220] Eurasia,[23,172,225] Asia,[2,7,34,112,131,133,135,138] and the South Pacific. Currently, ampicillin and trimethoprim-sulfamethoxazole are inappropriate for empiric therapy; they should be used only if the organism has been shown to be susceptible.[12]

Multiresistant strains also are found commonly in some parts of the United States. Among 344 *Shigella* isolates, from 1999 to 2001, 95 percent were resistant to one or more antimicrobial agents, and 70 percent were resistant to two or more agents. Ampicillin resistance occurred in 80 percent of isolates, and trimethoprim-sulfamethoxazole resistance occurred in approximately 50 percent of isolates. None of the isolates was resistant to ceftriaxone or gentamicin, and only one isolate (0.3%) was resistant to ciprofloxacin. Susceptibility testing against azithromycin was not performed.[176]

Multiresistant *Shigella* spp. are particularly likely to emerge in individuals who are exposed to multiple antibiotics[214] (e.g., patients with AIDS) and individuals who recently have traveled to areas with known resistance. Likewise, children in daycare centers are at risk of acquiring resistant organisms because the frequent use of antibiotics for otitis media may favor selection and emergence of resistant enteric organisms, and because crowding and poor hygiene facilitate transmission.[36]

Generally, shigellae are susceptible in vitro to azithromycin, ceftriaxone, cefotaxime, cefixime, nalidixic acid, and quinolones in the United States and elsewhere. In vitro susceptibility does not always predict clinical efficacy or superiority of one drug over another, however. The first-generation and second-generation cephalosporins are active in vitro but have been ineffective in clinical trials. Clinical studies have shown some drugs to be clearly superior to others when susceptibility data have suggested that either might work well.

Prevalent serotypes and resistance patterns vary from year to year in a given locale. Typically, rates of resistance are related to the severity of disease caused by a given serotype. The more likely an organism is to cause severe disease, the more likely that resistant strains will emerge. *S. dysenteriae* serotype 1 is more likely to be multiply resistant than *S. flexneri*; *S. flexneri* is more likely to be resistant than *S. sonnei*. In Africa[35,108] and Asia,[28,30,49,138,153] Shiga bacilli resistant to nalidixic acid and ciprofloxacin have been reported. Nalidixic acid–resistant *S. flexneri* also have been recognized occasionally.[48] Local resistance patterns, history of travel to an area of frequent resistance,[214] and severity of illness should determine treatment.

Given the frequent occurrence of resistant organisms, optimal empiric therapy in children with dysentery should be azithromycin, a third-generation cephalosporin, nalidixic acid, or ciprofloxacin (Table 119–2).[12,27,100,126,162,176] Although less well studied, ampicillin-sulbactam and pivmecillinam also have been shown to be effective in children. In children, oral cefixime seems to be superior to ampicillin-sulbactam.[89] Adults do not respond well to usual doses of cefixime.[196] Ampicillin, tetracycline, and chloramphenicol are used infrequently now for shigellosis.

Use of quinolones has been controversial in children. An oral fluoroquinolone (ciprofloxacin, norfloxacin) seems to be optimal for adults.[14,33,89,125,140,179,195] Limited data suggest that not all of these agents are equally effective, even when in vitro data suggest

TABLE 119–2 Antibiotic Treatment of Shigellosis in Children

Antibiotic	Dosage*	Comments
Ampicillin	100 mg/kg/day divided q6h PO, IV, or IM (maximum 4 g/day)	Currently of limited value because of the high frequency of resistance; it can be used when the organism is known to be susceptible
Trimethoprim-sulfamethoxazole	10 mg/kg/day of trimethoprim divided q12h PO (maximum 320/1600 mg/day)	Currently of limited value because of the high frequency of resistance; it can be used when the organism is known to be susceptible
Azithromycin	12 mg/kg/day once daily PO on day 1, followed by 6 mg/kg/day once daily on days 2-5 (maximum 500 mg/day)	Although limited published data in children, its use is recommended by many experts
Nalidixic acid	55 mg/kg/day divided q6h PO (maximum 2 g/day)	Not available in the United States; contraindicated in infants <3 mo old
Ciprofloxacin	15-30 mg/kg/day divided q12h PO (maximum 1.5 g/day)	Alternative when other options unavailable
Cefixime	8 mg/kg/day divided q12-24h PO (maximum 400 mg/day)	
Ceftriaxone	50 mg/kg/day IM or IV q24h (maximum 2 g/day)	Current drug of choice for empiric therapy of severe dysentery in children

**Treatment should be given for 5 days.*

susceptibility. Norfloxacin is clinically superior to nalidixic acid in children and adults with shigellosis.[33,190] Nalidixic acid therapy is effective treatment,[194] although plasmid-mediated resistance to nalidixic acid of *S. dysenteriae* serotype 1 strains in Bangladesh[28,30,153] has emerged and spread rapidly. Various other quinolones have been effective in adult patients with shigellosis, but they are not approved for use in children younger than 17 years old because of potential damage to the cartilage of epiphyseal plates.[190] A considerable body of evidence from the long-term use of these drugs in children with cystic fibrosis has been accumulated, however, as has evidence from short-term use to treat typhoid fever and dysentery in children; no evidence of bone or joint toxicity or growth impairment has been found. Nalidixic acid does not cause arthropathy or limit growth when it is used for a short time.[165]

As resistance continues to increase, situations are likely to occur in which a quinolone is the only option for treatment of a child with severe shigellosis. Data for children suggest that norfloxacin at a dose of 10 to 15 mg/kg/day or ciprofloxacin at a dose of 10 mg/kg every 12 hours (maximum 500 mg/dose) for 5 days is effective therapy.[79,125,136,195] In adults, short-course therapy (1 or 2 days) with ciprofloxacin has been effective for treatment of infections caused by *Shigella* spp. other than *S. dysenteriae*, for which a 10-dose, 5-day regimen is superior.[31] Pediatric data suggest that even for *S. dysenteriae* serotype 1, a short course of ciprofloxacin (15 mg/kg/dose every 12 hours for 3 days) is as effective as a 5-day course.[226]

Because the patterns of antibiotic resistance of shigellae change, susceptibility testing should be performed on all clinical isolates, and the treatment should be changed accordingly. The recommended duration of antibiotic therapy for shigellosis usually is 5 days. Studies in adults and children have shown, however, that short-course treatment is nearly as effective as are multiple doses in terms of symptomatic improvement,[75,140] although eradication of the organism from stools is less likely to occur with a single-dose regimen.[102] Because a major goal of antibiotic therapy is to reduce person-to-person transmission, multiple doses are preferred.

After initiation of therapy, a resistant organism can be suspected in the event of persistence of fever, grossly bloody stools, or unchanged frequency of stools by day 3 of therapy.[98] Persistent presence of numerous fecal leukocytes (>50 per high-power field) and erythrocytes (>5 per high-power field) at day 5 also suggests resistance. These findings are important because morbidity and mortality rates are higher when the organism is not susceptible to the initial drug of choice.[105] Protein-losing enteropathy is a more likely occurrence with resistant *Shigella* spp. if an inadequate agent has been used.[32]

ADJUNCTIVE THERAPY

As with other forms of infectious colitis, antimotility agents should be avoided. Antimotility drugs, such as diphenoxylate (Lomotil), prolong the duration of fever, diarrhea, and excretion of the organism.[58] It has been speculated that intestinal motility and the constant fluid flow are important host defense factors for clearing of the organism and recovery from the infection.

A high-protein diet during convalescence may be important, particularly in settings in which malnutrition, growth retardation, and hypoproteinemia is a major complication of shigellosis.[103,104,145] Vitamin A (200,000 IU) has been found to speed resolution of illness in a population in which vitamin A deficiency is a common finding.[91] Zinc supplementation in a population that is commonly deficient in this mineral improves development of shigella-specific antibody responses.[183,188]

PROGNOSIS

Most patients recover eventually with or without specific antimicrobial therapy, although illness may be prolonged and severe if it is not treated.[38] The mortality rate in developed countries is less than 1 percent, and life-threatening complications are rare events. With appropriate antibiotic therapy, defervescence usually occurs within 24 hours, and the diarrhea decreases dramatically in 2 or 3 days. If left untreated, the disease usually lasts 1 week or more. In developing countries, childhood shigellosis is associated with significant morbidity and mortality (10 to 30%),[29] particularly if it is caused by *S. dysenteriae* serotype 1. Children with malnutrition are particularly likely to have a complicated course.[47] Shigellosis in malnourished children often causes a vicious cycle of further impaired nutrition, and repeated infections may be associated with impaired growth. Young infants and children whose course is complicated by bacteremia also are at increased risk of dying.[168]

PREVENTION

In developed countries where person-to-person transmission of shigellae is the major mode of infection, personal hygiene mea-

sures are most important.[113] Special attention to hygiene should be given in daycare centers, which sometimes play a central role in community-wide outbreaks of shigellosis.[149] The close contact among children too young to control their excretions renders this setting ideal for fecal-oral spread of the organism. Children attending daycare centers frequently transmit infection to their families. Washing hands after defecating and before eating or preparing meals is important and helpful in preventing spread.[113] Daycare personnel who prepare food should avoid performing diaper-changing duties. Sick children should be excluded from the daycare center or cohorted, and mothers should be educated regarding the possibility of being infected by their children and the use of the necessary precautions. Proper cooking of potentially infected food, appropriate refrigeration, and exclusion of individuals with diarrhea from handling food are important precautions. Education of staff members in proper hygiene is essential to infection control.[177]

Patients with diarrhea in institutional and hospital settings should be isolated for prevention of outbreaks. Aggressive investigation and early initiation of appropriate antibiotic therapy in cases of bacillary dysentery are important measures in reducing excretion of virulent shigellae and stopping spread of the disease. Use of antibiotics for prophylaxis is not recommended.

In developing countries, a safe water supply and appropriate sanitation systems are important measures for reducing the risk of shigellosis. Chlorination of drinking water is important. Water stored in vessels that permit hand dipping has been defined as a risk factor.[217] Food prepared by street vendors also has been recognized as a risk factor. Prolonged breast-feeding is the best practical strategy for prevention of shigellosis (and most other enteric infections) in infants in most of the developing world.[3,53,144] Educational efforts to promote breast-feeding in these areas are key to children's survival. Human milk contains specific secretory IgA antibodies against *Shigella* LPS and virulence plasmid-coded antigens.[51] Lactoferrin and other nonspecific (non-antibody) factors in human milk, the effect of human milk on the type of intestinal flora, and the supply of an uncontaminated food source all may contribute to the protective effect of breast-feeding against diarrheal disease.

Epidemiologic data suggest that prior infection with shigellae confers resistance to subsequent illness caused by organisms of the same serotype. Serotype-specific (LPS-based) vaccines have been produced.[69,70] Although early studies showed that immunization by the parenteral route with killed vaccines was ineffective, interest in this approach continues. Polysaccharide conjugate vaccines[20,54] are now in phase 3 clinical trials.[128] Several oral, live organism–based *Shigella* vaccines have been studied. Avirulent mutants of *S. flexneri* that lack the ability to invade the intestinal mucosa are safe and effective in monkeys. Multiple doses of large numbers of organisms were required to protect humans, however. Attenuated vaccines prepared from streptomycin-dependent mutant strains were effective, but unstable.[146] Genetically attenuated *S. flexneri* strains conferred protection but caused diarrhea when fed to some volunteers. Prototype-attenuated *S. flexneri* strains CVD 1208[117] and WRSS[109] have provided encouraging results in early clinical trials. Two nonliving vaccine approaches include the oral administration of proteosomes[72] or of inactivated *Shigella* bacteria. No effective, licensed vaccine against shigellosis is available.[128,134]

Whatever prototype *Shigella* vaccines prove to be well tolerated, immunogenic, and protective, the final formulation will have to confer protection against multiple epidemiologically important serotypes, including *S. dysenteriae* 1 (the cause of epidemic Shiga), all *S. flexneri* serotypes and subtypes (the most important agents of endemic disease in developing countries), and *S. sonnei* (responsible for 5 to 15% of shigellosis in developing countries, an important cause of traveler's shigellosis, and of shigellosis in diarrhea in daycare centers in industrialized countries).[128]

CHAPTER 120

SERRATIA

Randall G. Fisher

Similar to other members of Enterobacteriaceae, the genus *Serratia* contains species increasingly associated with opportunistic infection in the compromised host. One of the oldest bacterial organisms to be named,[105] S*erratia marcescens* is the chief species associated with disease in humans and has been associated with infection of the urinary tract, the respiratory tract, local wounds, and central venous catheters. Illness may be complicated by bacteremia and meningitis. Treatment of infection may be made exceptionally difficult because these organisms frequently are resistant to penicillins, cephalosporins, and aminoglycosides.

BACTERIOLOGY

S. marcescens can produce a red pigment resembling blood on contaminated foodstuffs. In the 6th century, the "miraculous" appearance of blood on food provoked superstition and scientific investigation. Troops were goaded into battle, and religious beliefs gained support because of the fortuitous growth of the saprophyte in bread.[105] In vitro, the red pigment produced by these strains is toxic to cancer cells but not to nonmalignant cell lines.[31]

In 1819, *S. marcescens* was named by Bizio, who correctly interpreted the discoloration of cornmeal to be due to a living organism.[69] The genus name honors the Italian physicist Serrafino Serrati, who Bizio thought had been slighted in favor of Robert Fulton as inventor of the steamboat; the species name *marcescens* was drawn from the Latin word meaning "to decay."

We now recognize the genus *Serratia* as straight, motile, catalase-positive, gram-negative rods. On solid agar, colonies are opaque; iridescent; and white, pink, or red. Organisms are Voges-Proskauer test-positive.[48] The genus may be distinguished from other enterobacteria (genera) by its use of caprylate or L-fucose as a sole carbon source, and its hydrolysis of gelatin.[48,100] Clinically relevant strains include *S. marcescens*, *Serratia liquefaciens*, *Serratia odorifera*, *Serratia ficara*, and *Serratia plymuthica*.[18,37] For a detailed review of the properties of *S. marcescens*, the reader is referred to the review by Hejazi and Falkiner.[49]

EPIDEMIOLOGY

S. marcescens was thought to be nonpathogenic in earlier times and was used as a biologic marker of transmission in 1906. In that year, N. H. Gordon, commissioned to study the atmospheric hygiene of the British House of Commons, gargled a liquid culture of *S. marcescens* and then quoted Shakespeare to an audience of agar plates in the otherwise empty House.[43,105] The organism subsequently was recovered from the plates, documenting the possibility of aerosol transmission of bacteria (Gordon reported no ill effects). The importance of *S. marcescens* as a biologic marker for hand-to-hand bacterial transmission, ascension of bacteria in the urinary tract in catheterized patients, and bacteremia after dental extraction is reviewed in detail by Yu.[105] Most remarkably, in investigations in 1950 and 1952 to judge the threat of biologic warfare to the United States, the Navy released *S. marcescens* into the Pacific, where it became aerosolized and drifted 80 m inland.[6] Although an epidemic of *S. marcescens* infection in a San Francisco hospital coincided with this event, subsequent serotype and biotype analyses cast doubt on any relationship to the Navy experiments.[36] Rather, the early San Francisco hospital experience heralded the increased frequency of nosocomial infections that would be observed in subsequent years.[105]

In some studies, *S. marcescens* is the organism most frequently isolated from contact lens solutions and contact lens cases.[82,107] Ex vivo mouse cornea studies show that the organism adheres to injured but not to intact corneas.[82] Commercial multipurpose disinfectant solutions all are active against the type strain but vary in their activity against actual clinical isolates. Polyquaternium-1–based solutions fared the worst in their activity against circulating strains.[52]

Sporadic nosocomial outbreaks of infection were reported first in the 1950s and 1960s.[66,83,103] Early outbreaks in a pediatric ward and neonatal nursery were attributed to contaminated intravenous solution and caps of bottles containing saline used to moisten umbilical cords.[66] As reviewed by Yu,[105] environmental sources before 1979 included disinfectants, water from ultrasonic nebulizers, respirators, arterial pressure monitors, and fiberoptic bronchoscopes. Environmental sources since have included suction traps,[74] intra-aortic pressure transducers,[11,101] contaminated handwashing brushes,[5] illicit intravenous drug paraphernalia,[27] contaminated urologic instruments,[34] colonized disinfectants or soaps,[35,64,67] contaminated infant parenteral nutrition fluid,[38] contaminated whole blood or blood products,[42,84] and inadequately sterilized breast milk pumps.[45]

Hand-to-hand transmission seems to be the primary mechanism of nosocomial spread. In one dramatic outbreak, spread of an organism with the same serotype, phage type, and antimicrobial sensitivity pattern was documented among four geographically separated teaching hospitals in the same region[89]; spread likely was due to passive carriage of *S. marcescens* on the hands of rotating personnel. By 1979, it was apparent that nosocomial

increase in *S. marcescens* infection was becoming a worldwide concern.[18]

Outbreaks in neonatal units and pediatric wards have been widespread, persistent, and associated with high morbidity and mortality rates.[5,15,74,97] At the peak of one epidemic of invasive *S. marcescens* disease in a neonatal nursery, more than 90 percent of infants were colonized with the epidemic strain.[33] Increased rates of colonization have been associated with nearly 10-fold increases in rates of *S. marcescens* bacteremia and meningitis.[108] In a case-control study, neonates with *S. marcescens* bloodstream infection were at least three times more likely to have associated meningitis than were neonates whose blood cultures grew *Escherichia coli*.[13] Outbreaks of multidrug-resistant strains have been especially troublesome in surgical subspecialty wards, and an outbreak has been reported in a bone marrow transplant unit.[19,57]

Biotyping may be successful in characterizing isolates, which can be traced in the hospital environment.[47,96] Ribotyping or identification of a unique biochemical characteristic has proved useful for showing cross-contamination across hematology, gastroenterology, and neonatology units in a pediatric hospital.[12,39] Use of typing methods may be particularly important because drug-resistant and drug-susceptible isolates of *Serratia* organisms may co-circulate.[25] Banding differences from pulse field gel electrophoresis of DNA digests are restricted in number from outbreak strains; increases in banding pattern may reflect genetic drift over time.[8] Such DNA techniques have aided decisions regarding cohorting and closure of neonatal units and have been used to show cross-contamination of wards.[51,72] DNA amplification techniques offer promise for characterizing isolates in future outbreaks and defining antimicrobial susceptibility.[50,64,92]

PATHOPHYSIOLOGY

Pathologic findings of sepsis are similar to the findings of other gram-negative enteric bacilli. Postmortem examination of the lungs of patients with radiologic findings of *S. marcescens* pneumonia reveals a focal necrotizing pneumonia in most cases and hemorrhagic manifestations in some.[10]

Several properties may enhance virulence of *Serratia* organisms in human infection. The 56-kd protease of *S. marcescens* seems to possess properties of a virulence factor. It enhances vascular permeability through activation of the Hageman factor–kallikrein–kinin pathway in vivo.[65] The protease also has the capacity to degrade host proteins important in humoral immune response, such as immunoglobulins and fibronectin,[73] and inactivates the chemotactic effect of C5a.[78] *Serratia* hemolysin indirectly may increase vascular permeability, local edema, and granulocyte accumulation. Clinical strains seem to possess increased adherence properties compared with environmental isolates.[9] Compared with some enteric organisms, *Serratia* organisms adhere better to epithelial cells of the bladder, which may facilitate development of urinary tract infection.[29]

Cell-mediated immunity and humoral immunity may be important in protection from *Serratia* infection and illness. In a murine model of immunization against *S. marcescens*, only the transfer of antiserum and spleen cells from vaccinated mice increased bacterial clearance from the liver and survival after infection developed.[61]

Resistance of *S. marcescens* to aminoglycosides generally is plasmid-mediated. Resistance to aminoglycosides may be conferred by one of several genes producing acetylating, phosphorylating, or adenylating enzymes.[1,2,19,53,70] Risk of acquiring infection with aminoglycoside resistance increases with exposure to these agents.[44,106] In some patients, repeated hospitalizations have shown greater importance, however, than aminoglycoside use as a risk factor for developing infection with resistant strains.[7] High levels of resistance to penicillins and cephalosporins are mediated by one or more plasmids. Cephalosporin resistance also may be derived chromosomally (see also Chapter 113).[25,40,68,81] Chromosomally mediated β-lactam resistance may be inducible in the presence of high levels of penicillin or cephalosporins, particularly when plasmid-derived β-lactamase is blocked by clavulanic acid.[20]

A group of researchers found and cloned a multidrug efflux pump of the major facilitator superfamily from *S. marcescens*.[94] Transposable plasmid elements may seem partly responsible for the rapid spread of multidrug resistance.[85,86,91] In one survey, 2.6 percent of *S. marcescens* isolates were deemed "multidrug resistant," defined as resistant to three or more classes of antimicrobials.[32] Plasmids conferring multidrug resistance are transferable from *S. marcescens* to *Klebsiella* spp. and may be responsible for sequential nosocomial outbreaks of different genera sharing common drug resistance patterns.[99]

CLINICAL MANIFESTATIONS

First described in a patient with bronchiectasis as a cause of "blood-tinged" sputum colored by the organism,[104] *S. marcescens* commonly is associated with urinary tract, respiratory tract, central venous catheter, and bacteremic infections.[2] Other species, including *S. liquefaciens*, *S. ficara*, *S. odorifera*, and *S. plymuthica*, are less common causes of disease.[13,23,30,37,93]

Chromogenic *S. marcescens* was responsible for the historically interesting and reportedly benign "red diaper syndrome," which persisted for 7 months in the infant of a genetics professor.[102] In at least one series, the organism has been identified as one of the top five causes of neonatal sepsis[46] and now is recognized as a major pathogen of compromised newborns. Disease in newborn intensive care units is associated commonly with high rates of underlying respiratory illness.[75] Other preexisting risk factors include necrotizing enterocolitis, surgical procedures, intravenous catheters, prolonged intubation, and cardiac disease.[13] Clinical illness shares features in common with other neonatal enteric pathogens; apnea, hypotension, and respiratory distress are seen frequently. Pneumonia with empyema has been reported.[56] Meningitis occurs as a complication in 24 percent of cases of neonatal bacteremia,[13] and antibiotic resistance may emerge during therapy for bacteremia or localized infection.[21] Significant brain injury caused by ventriculitis, brain abscesses, or porencephalic cysts is observed in most infants with meningitis.[21,62]

In older children and adults, *Serratia* spp. are isolated most frequently from the urinary tract.[2,89] Instrumentation, catheterization, and clustering of susceptibles are important risk factors.[7,22,53,87,90] By the 1970s, increased frequencies of serious infection, such as endocarditis, were noted in intravenous drug abusers.[27] In some series of respiratory and urinary tract infections, *S. marcescens* was observed to be associated more commonly with the complication of bacteremia than was any other enteric pathogen.[55,60] As is true of other causes of gram-negative sepsis, *Serratia* sepsis characterized by shock, pneumonia, or hemorrhage confers a substantially poorer prognosis.[16,88] The risk of these complications in cancer patients was observed by Saito and associates[88] to be lower, however, than their previous experience with other pathogens, such as *E. coli* and *Pseudomonas aeruginosa.* When predictive factors of mortality were sought in 385 subjects with nosocomial bacteremia, *S. marcescens* was not an independent predictor of death.[71] Other infections caused by *Serratia* include soft tissue infections, abscesses, endophthalmitis (including a case occurring after septicemia in an infant),[3,4] osteomyelitis

and arthritis,[98] spinal epidural abscess, and peritonitis in dialysis patients.[26]

DIAGNOSIS

The diagnosis of *Serratia* infection relies primarily on isolation of organisms from clinical material. Nonspecific laboratory tests occasionally may be misleading. *Serratia* meningitis in a neonate may be accompanied by a normal cerebrospinal fluid white blood cell count or only a modest cerebrospinal fluid pleocytosis.[21] Although *S. marcescens* is famous historically because of its chromogenic potential, most strains are nonpigmented. Hydrolysis of gelatin distinguishes *S. marcescens* from *Klebsiella* and *Enterobacter* in the clinical microbiology laboratory. The presence of ornithine decarboxylase and fermentation of sorbitol but not arabinose helps to differentiate further *S. marcescens* from other *Serratia* spp.[48] Biotyping,[47] DNA and RNA detection techniques,[64] and antimicrobial susceptibilities[96] can be used to characterize strains.

TREATMENT

Empiric decisions about antibiotic treatment of *Serratia* infection should rely on knowledge of hospital flora. Therapy should be tailored when susceptibilities are known. In newborns, meningitis and its complications should be suspected, and interventions should be guided by imaging of the central nervous system. Imaging techniques may be useful in guiding needle aspiration of abscesses.[77] Recommended antibiotic therapy for neonatal meningitis is a cephalosporin and an aminoglycoside for susceptible strains. Mortality rates remain high (>45%) even with appropriate antibiotic management.[21]

In older children and adults, reported response rates for bacteremic infection have been 75 percent for patients who received appropriate antibiotics, 22 percent for patients who received inappropriate antibiotics, and 29 percent for patients who received no antibiotics.[88] Patients who continue to have positive blood culture results while receiving appropriate antibiotic therapy have a poor prognosis. Inclusion of a penicillin or cephalosporin for susceptible strains should be considered. In the review by Saito and associates[88] of 118 patients with *Serratia* bacteremia, patients who received only an aminoglycoside had the poorest response rate among those who received appropriate therapy; patients who received a cephalosporin, alone or in combination, fared better. *Serratia* organisms generally have proven susceptible to third-generation cephalosporins in more recent surveys of hospitals from North America.[54] The physician needs to be wary, however, of potential resistance to cephalosporins and penicillins owing to the production of extended-spectrum β-lactamases. An extended-spectrum, metallo-β-lactamase–mediating resistance to imipenem has been described,[80] but it is uncommon. Physicians should consider strongly empiric use of a carbapenem in combination with an aminoglycoside in critically ill patients.

Amikacin historically has been effective in the treatment of gentamicin-resistant strains.[28,63] In 1985, amikacin was recommended as a first-line antibiotic for treatment of pediatric nosocomial infection when *Serratia* spp. or other enterics with resistance potential were suspected.[95] Since the 1980s, however, outbreaks of *S. marcescens* infections caused by amikacin-resistant strains have been reported.[79] Quinolones have been used successfully for treatment of organisms resistant to other agents,[41] but resistance to these drugs also has been identified.[59]

Cohorting and attempts to remove environmental sources of infection have been successful in ending epidemics but typically require several months.[24] Rarely, neonatal intensive care units have been closed to admissions to halt epidemics.[17,74]

Acknowledgments

The author thanks Dr. William Gruber and Dr. Thomas Boyce for their invaluable assistance with earlier versions of this chapter.

CHAPTER 121

SALMONELLA

Theresa J. Ochoa ❂ Thomas G. Cleary

MICROBIOLOGY

The classification of *Salmonella* is confusing because multiple nomenclature systems are used (Table 121–1). In this chapter, we use the current designation of the Centers for Disease Control and Prevention, rather than either the complete name or the traditional clinical shorthand that referred to each of the 2463 serovars of *Salmonella* as though they were separate species. In hospital laboratories, *S.* ser. *Choleraesuis* and *S.* ser. *Typhi* are distinguished biochemically from other *Salmonella* spp. Serogroup, based on O (somatic) antigen, also usually is determined on initial isolation, and organisms that are not *S.* ser. *Typhi* or *S.* ser. *Choleraesuis* are reported as *Salmonella* serogroup A, B, C1, D1, and so on. Common *Salmonella* spp. and their serogroups are shown in Table 121–2.

TABLE 121–1 Examples of Current *Salmonella* Nomenclature

CDC Designation	Complete Name	Previous Designation
S. ser. Typhi	*S. enterica** subsp. *enterica* ser. Typhi	*S. typhi*
S. ser. Enteritidis	*S. enterica* subsp. *enterica* ser. Enteritidis	*S. enteritidis*
S. IIIa 18:z_4,z_{23}: -	*S. enterica* subsp. *arizonae* ser. 18:z_4,z_{23}: -	*Arizona hinshawii* ser. 7a, 7b:1,2,5: -
S. ser. Marina	*S. enterica* subsp. *houtenae* ser. Marina	*S. marina*

**S. choleraesuis and S. enteritidis also are designations commonly used for the species. CDC, Centers for Disease Control and Prevention.*

Salmonella serotype is defined by the serogroup antigens, the flagellar (H) antigens, and the virulence (Vi) antigen. H antigens can be either phase 1 (nonspecific) or phase 2 (specific). The Vi antigen, a heat-labile polysaccharide found on *S.* ser. *Typhi*, *S.* ser. *Dublin*, and *S.* ser. *Paratyphi C*, may block agglutina-

E3	*S.* ser. *Illinois*

**Human infections with organisms in serogroups E4, F, G1, G2, H, and I and the O antigens not given serogroup designation (O17 through O67) are uncommon.*

tion caused by antibodies to O antigen. Serotyping generally is done in public health department laboratories. Although serotyping is an important epidemiologic tool for defining outbreaks, it is most useful when an unusual type is associated with disease. When a common serotype is associated with an outbreak (e.g., *S.* ser. *Typhimurium*), biochemical phenotype, antibiogram, plasmid characterization,[199] bacteriophage typing,[26,87] outer-membrane protein analysis, pulsed field gel electrophoresis, and randomly amplified polymorphic DNA may help determine whether a single-strain, common-source outbreak is in progress.

Six subgroups of *Salmonella* have been proposed on the basis of DNA relatedness. Most serotypes, including almost all of the serotypes important in human and animal disease, belong to subgroup I. The genus *Arizona* now is classified as a *Salmonella*.

Salmonellae are motile (owing to peritrichous flagella), nonencapsulated, gram-negative bacilli of the Enterobacteriaceae family. Most ferment glucose, maltose, and mannitol but do not use lactose or sucrose. All pathogenic *Salmonella* spp. other than *S.* ser. *Typhi* produce gas. *Salmonella* spp. are facultative anaerobes. Blood agar or chocolate agar supports their growth when they are present as the sole organisms in blood, cerebrospinal fluid, or joint fluid. For specimens containing mixed flora (e.g., stool), selective media such as Salmonella-Shigella (SS) agar or bismuth sulfate agar must be used.

EPIDEMIOLOGY

NONTYPHOIDAL *SALMONELLA*

Public Health Issues

In most of the world, the prevalence of *Salmonella* varies according to the water supply, waste disposal, food preparation practices, and climate. The incidence of nontyphoidal salmonellosis in the United States has been increasing steadily, however, despite implementation of good public health measures. During the last 40 years, a greater than sixfold increase in reported nontyphoidal *Salmonella* infection in the United States has occurred, with an estimate of 168,000 physician office visits, 15,000 hospitalizations, and 400 deaths annually during 1996 to 1999.[252] This increase reflects industrial-scale food production and distribution,[38] misuse of antimicrobial agents (in humans and animals) that alter the gastrointestinal flora and increase host susceptibility to *Salmonella*, and probably an increasing number of immunocompromised individuals in the population. More recently, an important decrease has occurred in the incidence of *S.* ser *Enteritidis* infections in the United States, as a result of targeted interventions, including on-farm control measures, refrigeration, and education,[153] highlighting the importance of these efforts to reduce the rate of *Salmonella* infection further.

Significance of Animal Reservoirs

In contrast to *Shigella* spp., which infect only primates, nontyphoidal *Salmonella* spp. infect a variety of animals (including poultry, livestock, and pet reptiles and rodents).[232] Animals and animal products (including meat and dairy products), water, and infected humans can be the source of infection. *Salmonella* is the number one cause of foodborne illness in the United States, and the second most common cause of death from foodborne pathogens.[146] Spread of resistant organisms from food animals to humans has been shown.[166] *Salmonella* spp. have been isolated from 50 percent of poultry,[28] 16 percent of pork, 5 percent of beef, and 40 percent of frozen egg products in retail stores. Undercooked eggs (e.g., in Caesar salad, egg-dipped bread, homemade eggnog) may be contaminated by organisms on the shell surface or transovarially directly through the egg yolk. Grade A shell eggs have been implicated in more than 40 percent of more recent outbreaks.[146] Even in the absence of recognized outbreaks, eggs probably are important vehicles of infection; foods containing eggs that have been undercooked are more likely to have been consumed during the 3 days before illness in sporadic cases than in control cases.[112]

The risk of outbreaks occurring was shown when milk contaminated with *S.* ser. *Typhimurium* was distributed in Chicago, Illinois. Reports estimated that more than 150,000 people became ill, with more than 16,000 culture-confirmed cases, 2777 individuals hospitalized, and 14 fatalities.[21] Ice cream, cream cakes, and mayonnaise commonly have been incriminated as the source of infections. Fruits and vegetables rarely are vehicles.[36]

Some serotypes are associated with particular reservoirs. *S.* ser. *Dublin* is associated with dairy cattle and frequently is found in individuals who drink raw milk.[237] *S.* ser. *Choleraesuis* is associated with pigs. *S.* ser. *Typhimurium* is associated with contact with pet rodents.[232] Infection with *S.* ser. *Marina* is associated with contact with pet iguanas. *Salmonella* group F, *S.* ser. *Typhimurium*, *S.* ser. *Muenchen*, and *S.* ser. *Java* infections have been traced to pet turtles. Reptiles, including rattlesnakes, are important *S.* IIIa $18{:}z_4{,}z_{23}{:}$ (*Arizona hinshawii*) reservoirs.

Humans as a Reservoir

After infection occurs, nontyphoidal *Salmonella* spp. are excreted in feces for a median of 5 weeks. Children younger than 5 years old may excrete the organisms for 20 weeks after having an illness, but older children and adults usually excrete *Salmonella* for less than 8 weeks. *S.* ser. *Typhi* may be excreted chronically, particularly in the presence of gallbladder disease. Food handlers who are excreting *Salmonella* spp. represent an important risk group.

Bacterial Characteristics Favoring Survival

Salmonella spp. are hardy. They survive refrigeration and sometimes heating; they may remain viable at ambient or reduced temperatures for weeks. When contaminated foods are cooked for less than 12 minutes at temperatures less than 150° F (<65.5° C), salmonellae may remain viable. *Salmonella* spp. are killed by heating to 130° F (54.4° C) for 1 hour or 140° F (60° C) for 15 minutes. Salmonellae survive for hours on the hands of slaughterhouse workers.[183] The organisms have been found to survive in flour for nearly 1 year. *S.* ser. *Tennessee* has been reported to remain viable for 2 to 8 days on glass, stainless steel, enameled surfaces, rubber mattress, linen, and a rubber tabletop.[257] Nosocomial infections have been related to contaminated medical equipment (e.g., endoscopes) and diagnostic or pharmacologic preparations, particularly those of animal origin (e.g., pituitary extracts, bile salts, pancreatic extracts, pepsin, vitamins).

Relationship of Age to Risk of Disease

The highest incidence rates occur in children younger than 5 years of age, especially infants younger than 1 year, and in individuals older than 70 years. Nursery outbreaks often can be traced to an infected mother,[1,2,16,137] with subsequent spread occurring through health care personnel.[217,258] The mother of the index case can be symptomatic[82,155,207] or asymptomatic,[258] recovering from recent infection,[2,173,221] or a chronic carrier.[214] Low-birth-weight infants seem to be at higher risk than are full-term infants for acquiring *Salmonella* infection.[19,217,258] The source of infection occasionally is contaminated food, but more often it is fomites (delivery room resuscitators,[208] rectal thermometers,[123,158] suction devices,[133] water baths for heating formula,[199] soap dis-

pensers,[165] scales,[6,20,258] tables,[258] air-conditioning filters,[258] and plumbing[162]). Outbreaks in nurseries often are extraordinarily difficult to stop. They have been reported to last months[158,177,258] to years.[82,162,234] Contamination sometimes can become so widespread that other areas of the hospital also experience cases.[156,219] These outbreaks occur far more commonly with *Salmonella* than with other bacterial enteropathogens. Such outbreaks sometimes are caused by multiresistant *Salmonella*.[137]

Seasonality

Salmonella infection occurs in warm months.

Inoculum Size Required to Cause Disease

The estimated inoculum size required to cause symptomatic disease in healthy adult volunteers is 10^5 to 10^{10} organisms,[25] but the number of organisms required to cause symptoms in infants and children probably is much lower. In contrast, large inocula are not required for *Shigella* infection, which occurs in adult volunteers exposed to only 10 organisms. In some outbreaks, very small inocula of *Salmonella* seem to have caused disease. Large inocula (e.g., 10^9 organisms) may cause severe symptoms, even in healthy children.[238] The incubation period usually is 6 to 72 hours, but it depends on inoculum size, bacterial virulence, and host immunocompetence. Communicability parallels the duration of fecal excretion. The probability of salmonellosis occuring is increased when a member of the household is infected. Infants especially may be susceptible to acquiring *Salmonella* infection directly or indirectly from ill family members. Infants also may acquire infection via exposure to raw meat while riding in a grocery cart or while having contact with infected pets.[127] In a retrospective review of 187 infants younger than 1 year old with *Salmonella* gastroenteritis, 39 percent had at least one family contact with diarrhea, and 71 percent of the contacts had stool cultures positive for *Salmonella*.[259] *Salmonella* spp. rarely have been isolated during studies of gastroenteritis in daycare centers, suggesting that larger inocula are required to cause illness in toddlers and older children.[44,142,186]

Antibiotic Selection Pressure

Since the mid-1960s, *Salmonella* spp. have become increasingly resistant to ampicillin, chloramphenicol, and trimethoprim-sulfamethoxazole (TMP-SMX). Multiresistant strains have included *S.* ser. *Typhimurium*, which is the most common serotype in Europe and the United States, and *S.* ser. *Heidelberg*, *S.* ser. *Agona*, *S.* ser. *Muenchen*, *S.* ser. *Enteritidis*, and *S.* ser. *Hadar*. Antibiotic resistance usually is transferable between organisms through plasmids that carry genes encoding resistance factors. More recent studies have revealed that some serotype-specific virulence plasmids form hybrid plasmids through recombination with resistance plasmids or acquire gene cassettes consisting of multiple resistance genes. Such evolutionary events provide a virulent strain with the advantage of survival in an unfavorable drug environment.[231] Patients who are infected with antibiotic-resistant strains are more likely to be hospitalized, to be very young, to be black, and to have been exposed recently to antibiotic agents.[138] Previous use of antimicrobial agents for treatment of other illnesses is a significant risk factor for acquiring multiresistant *Salmonella* infection.[148,200]

Perhaps the most important factor is the overuse and misuse of antibiotics in animals raised for food.[49,117,118,141,229] Subtherapeutic concentrations of antibiotics used to enhance growth and to prevent infection promote intestinal colonization by antibiotic-resistant bacteria, including *Salmonella*; these organisms may be found in feces and may contaminate meat at the time of slaughter. Plasmid analysis and antibiotic susceptibility patterns have linked *Salmonella* outbreaks to specific farms and slaughterhouses.[117,118,166]

SALMONELLA SER. *TYPHI*

The Centers for Disease Control and Prevention estimates that 21 million typhoid cases occur annually in the world, with an annual incidence varying from 100 to 1000 cases per 100,000 population.[55] The global mortality estimates from typhoid also have been revised downward from 600,000 to 200,000, on the basis of regional extrapolations.[55] *S.* ser. *Typhi* is the most common *Salmonella* isolate in many developing countries. Although the overall ratio of disease caused by *S.* ser. *Typhi* to disease caused by *S.* ser. *Paratyphi* is about 10:1, the proportion of *S. paratyphi* infections is increasing in some parts of the world.[23] The human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS) epidemic in Africa has been associated with a concomitant increase in community-acquired bacteremia caused by nontyphoidal *Salmonella*.[22,102] In the United States, approximately 1700 total cases were reported (1 case per 100,000) in 1955. In 1988, approximately 400 total cases were reported (0.018 case per 100,000). Approximately 28 percent of infections occurred in individuals 19 years old or younger. Frequently, the highest incidence is stated as occurring in individuals 5 to 12 years old. More recent population-based studies from South Asia and India suggest, however, that the incidence is highest in children younger than 5 years, with higher rates of complications and hospitalization.[23,224]

In the United States, individuals traveling to developing countries are a high-risk group; 62 to 81 percent of infections are related to foreign travel, especially to Mexico, India, the Philippines, Pakistan, El Salvador, and Haiti. Of these areas, the Indian subcontinent has the highest incidence of typhoid among travelers.[5,37,163,212]

Reservoir

Humans are the reservoir for *S.* ser. *Typhi*; infection implies direct or indirect contact with an infected person. Animal products transmit *S.* ser. *Typhi* if they are contaminated by infected humans during processing. The most common mode of transmission is food or water contaminated by human feces. Water-borne typhoid fever epidemics are especially important. Congenital transmission can occur from a bacteremic mother to her fetus transplacentally or at the time of delivery.

Relevance of Inoculum Size to Disease

As with nontyphoidal *Salmonella*, more than 10^5 organisms are required to cause clinical illness in adults.[120]

Antibiotic Resistance

The worldwide frequency of antibiotic-resistant *S.* ser. *Typhi* has been increasing since the 1960s[226] but remains much lower than that of nontyphoidal *Salmonella*. Extensive protracted outbreaks have been reported throughout Asia, the Middle East, and Central and South America. These outbreaks may have been related to widespread availability and inappropriate use of antimicrobial agents (especially chloramphenicol) as over-the-counter drugs in these areas. After sporadic outbreaks of chloramphenicol-resistant typhoid between 1970 and 1985, many strains of *S.* ser. *Typhi* developed plasmid-mediated, multidrug resistance to the three primary antimicrobials used (ampicillin, chloramphenicol, and co-trimoxazole).[205] This resistance was countered by the advent of oral quinolones, but chromosomally acquired quinolone resistance in *S.* ser. *Typhi* and *S.* ser. *Paratyphi* has been

described more recently in various parts of Asia, possibly related to the widespread and indiscriminate use of quinolones.[197,223]

PATHOPHYSIOLOGY

Host susceptibility is understood most easily in terms of specific events in pathogenesis. Tables 121–3 and 121–4 show the relevance of specific host and bacterial virulence factors in salmonellosis. The outcome of ingestion of *Salmonella* depends on the bacteria and the host.

TABLE 121–3 Susceptibility to *Salmonella* Species Infection

Patient Group at Risk	Mechanism
Newborn	Achlorhydria, rapid gastric emptying Poorly developed cell-mediated immunity Complement deficiency Immunoglobulin deficiency in premature infants
Sickle-cell anemia	Reticuloendothelial system overload owing to hemolysis Functional asplenia Tissue infarcts Defective opsonization
Neutropenia (congenital or acquired)	Polymorphonuclear neutrophils needed for killing
Chronic granulomatous disease	Defective killing by polymorphonuclear neutrophils
AIDS	Low CD4 Effects of malnutrition on cell-mediated immunity Survival of organisms in macrophages (owing to *Salmonella* genes PhoP/PhoQ, spvA-D, R)
Organ transplantation, immunosuppression	Defective cell-mediated immunity
Gastrectomy	Loss of stomach acid barrier
Malaria	Reticuloendothelial overload during hemolysis Abnormal complement levels Abnormal macrophage function
Bartonellosis	Reticuloendothelial overload during hemolysis
Schistosomiasis	*Salmonella* sequestered in schistosomes protected from host defenses and antibiotics

TABLE 121–4 Putative Pathophysiologic Basis of Selected Clinical Features of Salmonellosis

Disease Manifestation	Mechanisms and Bacterial Genes
Bloody diarrhea	*sip* A-D mediated invasion and interleukin-8 mediated inflammation
Watery diarrhea	*stn* enterotoxin (cholera-like toxin) *SopB*-mediated intestinal inflammation and fluid secretion Serotypes that induce transepithelial polymorphonuclear leukocyte migration (e.g., *S.* ser. *Typhimurium*) are more likely to cause diarrhea than are serotypes that do not (e.g., *S.* ser. Typhi)
Bacteremia	*viaB* (Vi synthesis) capsular antigen interferes with C3 binding (*S.* ser. *Typhi*, *S.* ser. *Dublin*, *S.* ser. *Paratyphi C*) *rck* resistance to serum complement (virulence plasmid encoded) *rfb* encodes lipopolysaccharide synthesis; lipopolysaccharide contributes to persistence of bacteremia
Relapses, prolonged fever, failure of certain antibiotics	Survival in macrophages (*sseABC*, *spiC*, *mgtCB*, cytotoxin and virulence plasmid genes *spvRABCD*)

Various *Salmonella* strains can (1) adhere to, invade, and multiply in intestinal epithelium; (2) produce cholera toxin–like enterotoxin that increases cyclic adenosine monophosphate levels within intestinal crypt cells, causing a net efflux of electrolytes and water into the intestinal lumen; (3) be taken up by M cells overlying Peyer patches of the distal ileum and proximal colon; (4) survive in macrophages of Peyer patches, mesenteric lymph nodes, and the extraintestinal reticuloendothelial system; and (5) survive in the bloodstream.[80,81,90] Specific genes encode virulence factors necessary for each step in these processes.

Pathologic findings include hypertrophy and hyperplasia of the intestinal and mesenteric lymphoid tissues, liver, and spleen in *S.* ser. *Typhi* infection. In contrast, *S.* ser. *Typhimurium* and other nontyphoidal serotypes cause diffuse colitis, mucosal edema, and crypt abscesses as the major pathologic abnormalities.[28,58] Some virulence genes are shared by all *Salmonella* strains, whereas others are serotype-specific. Differences in invasiveness of various serotypes exist. *S.* ser. *Typhi*, *S.* ser. *Choleraesuis*, *S.* ser. *Heidelberg*,[122,160] and *S.* ser. *Dublin*[237] are more likely to enter the blood and to seed distant sites. Virulence plasmids have been identified in *S.* ser. *Typhi*, *S.* ser. *Typhimurium*, and *S.* ser. *Dublin*.[17] The presence of virulence plasmids seems to be more common in blood isolates of *S.* ser. *Typhimurium* than in fecal isolates (76% versus 42%).[79]

Nursery outbreaks of *Salmonella* have shown dramatically the variability in severity of illness related to strain or serotype. In nursery outbreaks of *S.* ser. *Oranienburg*[234] and *S.* ser. *Newport*,[137] grossly bloody stools were found in 76 to 90 percent of infected infants, with 10 to 11 percent febrile and only 9 to 11 percent asymptomatic. Watery, green, nonbloody diarrhea has been common with *S.* ser. *Typhimurium*,[2] *S.* ser. *Virchow*,[204] and *S.* ser. *Nienstedten*.[219] A high frequency of asymptomatic infections has been seen during nursery outbreaks with *S.* ser. *Heidelberg* (38% asymptomatic),[19] *S.* ser. *Virchow* (42% asymptomatic),[204] and *S.* ser. *Tennessee* (100% asymptomatic).[258]

Which genes are required for disease in humans versus animals remains unclear. *S.* ser. *Typhimurium* has genes that allow it to cause a nondiarrheal typhoidal illness in mice; in humans, it typically causes symptoms related primarily to intestinal involvement. An estimated more than 200 genes determine *S.* ser. *Typhimurium* virulence in mice. The clinical variability in host range and disease manifestations is due to the fact that *Salmonella* strains vary in their possession and expression of virulence genes.[154]

Of critical importance for in vivo virulence are the *Salmonella* pathogenicity islands (SPI), in particular SPI-1 and SPI-2. Both SPIs encode a molecular apparatus called *type III secretion system*, capable of injecting bacterial proteins through bacterial and host membranes into host cells (translocation) or the extracellular milieu (secretion) to influence host biochemistry and cell physiology directly.[47]

Genes relevant to the intestinal phase of illness are encoded primarily in SPI-1. The *invA-H* chromosomal genes are necessary for adherence to and invasion of intestinal mucosal cells[80]; most of the genes described so far seem to be involved in secretion or transport of virulence proteins.[104,248] Genes related to the *Shigella* invasion plasmid antigens (*ipaA-D*) have been described in *Salmonella* spp.[129,130]; these *Salmonella* genes (*sipA-D*) encode the proteins that interact with host cells to cause bacterial uptake and intracellular movement. Although initially characterized as an invasiveness island, SPI-1 has additional functions related to the activation of innate immune pathway, including (1) induction of polymorphonuclear recruitment across intestinal epithelium by the SPI-1 secreted effect SipA, (2) activation of nuclear factor-κB signaling by the concerted activity of SPI-1 translocated effec-

tors, and (3) activation of caspase-1–mediated interleukin-1β (IL-1β)/IL-18 activation and proinflammatory cell death by the SPI-1 translocator effector SipB.[47]

The role of host cells in the invasion process is complex. After *S.* ser. *Typhimurium* comes in contact with epithelial cells, activation of epidermal growth factor receptor occurs, which activates a kinase that turns on phospholipase A_2 so that arachidonic acid is generated. Arachidonic acid is converted to leukotriene D_4, which opens calcium channels and causes membrane ruffling, cytoskeletal changes, and uptake of bacteria.[80] Nonphagocytic cells, including epithelial cells, are adapted poorly for killing of internalized bacteria. Not only do *Salmonella* spp. survive in vacuoles within epithelial cells, but they also can replicate actively.[81] *S.* ser. *Typhi* survives better in human than in mouse macrophages, whereas *S.* ser. *Typhimurium* survives better in mouse macrophages.[31,218] *Salmonella* is capable of infecting a wide variety of cells, including dendritic cells, macrophages, hepatocytes, neutrophils, colonocytes, and other epithelial cells. In vitro, within minutes of contact with cells, *Salmonella* organisms are internalized and take up residence in a unique membrane-bound compartment distinct from a phagosome or lysosome, the *Salmonella*-containing vacuole.[101]

SPI-2 is essential for intracellular parasitism and systemic virulence in murine typhoid and for evasion of phagocyte oxidase machinery of the host.[250] SPI-2 has additional roles in inflammatory disease, such as induction of cyclooxygenase and modulation of host cytokine expression and signaling.[244,245] SPI-2 is crucial for early and complete induction of enterocolitis and systemic disease.[47]

Several pathogen-associated molecular patterns of pathophysiologic importance are presented by *Salmonella* during infection, principally lipopolysaccharides and flagellin. The activation of toll-like receptor 4 in response to *Salmonella* lipopolysaccharides is essential for inducing host responses.[249] *Salmonella* flagellin is a potent inducer of host inflammation in polarized epithelial monolayers when delivered to the basolateral surface of the epithelium. When delivered there, *Salmonella* flagellin induces IL-8 secretion by stimulating basolateral toll-like receptor 5.[266] Flagellin stimulation of innate immune responses is crucial for intestinal inflammation but not for murine typhoid.[47]

The development of diarrhea depends on host and pathogen factors. An influx of polymorphonuclear leukocytes into the mucosa must occur for diarrhea to develop.[256] Neutropenic animals fail to develop fluid secretion when they are infected with *Salmonella*[255]; infiltration of leukocytes is thought to trigger production of prostaglandin because fluid secretion can be blocked by indomethacin.[91] A cholera toxin–like enterotoxin is made by approximately two thirds of *Salmonella* strains, including *S.* ser. *Typhimurium* and *S.* ser. *Typhi*.[125]

For most nontyphoidal *Salmonella* strains, infection does not extend beyond the lamina propria and the local lymphatics. In contrast, *S.* ser. *Typhi*, *S.* ser. *Dublin*, and *S.* ser. *Choleraesuis* rapidly invade the bloodstream with little intestinal involvement. Some virulence genes confer a survival advantage to the organisms if they get into the extraintestinal milieu. Vi capsular antigen present in *S.* ser. *Typhi*, *S.* ser. *Dublin*, and *S.* ser. *Paratyphi C* interferes with C3 binding. Mutations in lipopolysaccharide genes decrease invasiveness of *S.* ser. *Typhi* and *S.* ser. *Choleraesuis*, but not of *S.* ser. *Typhimurium*.[81,168] *S.* ser. *Dublin*, *S.* ser. *Typhimurium*, and *S.* ser. *Enteritidis* have virulence genes that confer resistance to complement by preventing the formation and insertion of the C5b-9 membrane attack complex. Patients with sickle-cell anemia have complement defects and defects in opsonization of *S.* ser. *Typhimurium*.[110] Newborns also have complement deficiencies that may explain the high frequency of *Salmonella* infection in newborns and the susceptibility of newborns to bacteremic complications seldom seen in normal hosts.

Multiple host defense strategies have evolved to deal with these virulence factors; host susceptibility often can be related directly to defects in these defense mechanisms. The host tries to kill ingested organisms in the stomach, to inhibit their growth in the gut, to limit their spread beyond the intestine, and to clear them by immune mechanisms.

At a pH of 2.0, most *Salmonella* spp. are killed rapidly.[89] When gastric pH is increased by oral administration of antacid, susceptibility increases.[88,120,200] A *Salmonella* inoculum ingested in water passes through the stomach more rapidly than when the same inoculum is ingested in food. Rapid transit through the small bowel decreases the contact time of organisms with the mucosa. Patients with decreased intestinal motility caused by medication or anatomic factors have increased severity and complications and may have a prolonged carrier state. Prior antimicrobial exposure increases the risk of incurring infection with antimicrobial-susceptible and antimicrobial-resistant strains of *Salmonella*.[182] The normal flora may compete for substrates, lower the local pH by production of short-chain fatty acids, and produce antibacterial substances such as colicins. Some patients with gastroenteritis have progression or exacerbation of symptoms when antibiotics are given.[203]

Salmonella organisms are able to survive in macrophages but not in polymorphonuclear leukocytes. Patients with neutropenia (e.g., congenital, related to chemotherapy) or neutrophil dysfunction (e.g., chronic granulomatous disease) are at high risk for development of disseminated infection. Patients who have been bacteremic with a nontyphoidal *Salmonella* strain are at increased risk for having a relapse if leukopenia is present.[85]

Cell-mediated immunity generally is thought to be more important than is humoral immunity in clearance of *Salmonella* organisms. T-cell activation of macrophages is necessary to kill intracellular *Salmonella* organisms.[150] Oral immunization with an attenuated typhoid vaccine primes lymphocytes to produce cytokines typical of a T_H1 response (high interferon-γ/low IL-4) to the flagellar antigen.[236] Healthy individuals vaccinated with either oral or parenteral typhoid vaccines develop antibody-dependent cellular cytotoxicity mediated by IgA, IgG, or both.[56] Studies of serum and secretory antibodies to O and H antigens have not shown protection, however; relapses of typhoid fever have occurred despite high antibody titers. Immunity may be short-lived. In a study of 14 individuals (17 to 28 years old) with acute typhoid fever, cell-mediated immunity persisted for 16 weeks; intestinal secretory IgA persisted for 48 weeks; and IgG, IgM, and anti-O and anti-H agglutinins persisted for 2 years, 16 weeks, 16 weeks, and 36 weeks, respectively.[216]

Cytokines play a crucial role in initiating and regulating the innate and adaptive immune response against *Salmonella*. These bacteria can trigger synthesis of cytokines and chemokines in epithelial cells, macrophages, and dendritic cells. The consequences of cytokine activation vary. Although interferon-γ, IL-12, tumor necrosis factor-α, IL-18, transforming growth factor-β, and CCL2 have protective functions during *Salmonella* infection, IL-4 and IL-10 interfere with host defenses.[70]

Impaired cell-mediated immunity probably explains the high frequency of bacteremia with nontyphoidal *Salmonella* strains in children with HIV infection[209] and with malnutrition.[225] Defective cell-mediated immunity can be congenital or acquired (tumors,[107] collagen vascular disease, organ transplantation,[72] chemotherapy, glucocorticosteroids).[195] Inherited deficiency in the IL-12/IL-23/interferon-γ pathway results in susceptibility to recurrent *Salmonella* and *Mycobacterium* infections.[64] Defects have been described in which patients have mutations in IL-12, IL-12 receptor, IL-23, IL-23 receptor, interferon-γ receptor, and STAT (signal transducer and activator of transcription). Complete and partial deficiency syndromes have been described.[10,11,128]

An increased risk of acquiring disease exists in settings in which reticuloendothelial function or cell-mediated immunity is impaired[171,228] or immature.[172] Hemolytic anemias are thought to cause reticuloendothelial overload. Children with sickle-cell anemia are at risk for developing bacteremia and osteomyelitis.[152,233,262,265] Children with sickle-cell and S-Thal also sometimes develop osteomyelitis.[48] Malaria predisposes to salmonellosis by multiple mechanisms.[147] Schistosomiasis predisposes to development of *Salmonella* infections and prolonged bacteremia[201]; reticuloendothelial cell killing of *Salmonella* is impaired, and *Salmonella* colonizes the schistosomes. Pili on *Salmonella* adhere to the surface of *Schistosoma mansoni* and *Schistosoma haematobium*.[144] In Gabonese children with bacteremic nontyphoidal *Salmonella* infection, rectal biopsy specimens showed the eggs of *Schistosoma intercalatum* in 90 percent of cases.[86]

Humoral immunity is less important. Preterm neonates who are infected with *S.* ser. *Typhimurium* may have a lower risk of developing complications (e.g., intestinal perforation, meningitis, endophthalmitis, sepsis, pyelitis), however, if they are given intravenous immunoglobulin plus cefoperazone than if given cefoperazone alone (16% versus 82%); the mortality rate also is decreased (12% versus 41%).[98]

CLINICAL MANIFESTATIONS

Salmonella spp. may cause acute or chronic asymptomatic infection. Symptomatic infections include acute gastroenteritis, bacteremia with or without local suppuration, and enteric fever.

ACUTE ASYMPTOMATIC INFECTION

Asymptomatic infections usually are identified by stool cultures obtained during prospective research studies or epidemiologic investigations. A study of Mexican infants showed that 74 percent of nontyphoidal *Salmonella* infections were asymptomatic.[54]

ACUTE GASTROENTERITIS

The most common clinical illness caused by *Salmonella* infection is gastroenteritis. Nausea, vomiting, and crampy abdominal pain begin 6 to 72 hours (median 24 hours) after ingestion of contaminated food or water. The abdominal pain may be severe enough to suggest appendicitis. Diarrhea usually is moderate in volume and, depending on the serotype, may contain blood. Headaches, malaise, myalgias, and fevers are common. These symptoms usually resolve in approximately 1 week without antibiotic therapy; symptoms may persist in very young patients and patients with underlying diseases. In neonates, loose, green, mucous stools or, less often, bloody diarrhea is seen; fever is common with *Salmonella* gastroenteritis during the first months of life.[122] Reactive arthritis develops in some adults after having otherwise uncomplicated *Salmonella* gastroenteritis; this complication rarely occurs in children.

BACTEREMIA WITH OR WITHOUT METASTATIC FOCAL INFECTION

Some *Salmonella* serotypes (e.g., *S.* ser. *Typhi*; *S.* ser. *Choleraesuis*; *S.* ser. *Paratyphi* A, B, and C; *S.* ser. *Heidelberg*; *S.* ser. *Typhimurium*; *S.* ser. *Enteritidis*; *S.* ser. *Saint-Paul*; *S.* ser. *Newport*; *S.* ser. *Panama*; *S.* ser. *Dublin*) have a propensity to invade the bloodstream; others (e.g., *S.* ser. *Tennessee*, *S.* ser. *Weltevreden*[261]) rarely seem to cause bacteremia. Fever, chills, diaphoresis, myalgias, anorexia, and weight loss may last for days or weeks. Stool cultures may be negative. A child sometimes can have afebrile diarrhea and yet be bacteremic for several days.[131] The true frequency of bacteremia is uncertain. Depending on the patient's age, geographic location, and nature of the study (prospective versus retrospective), 2 to 45 percent of infections are bacteremic.[57,122,160,172,225,241,261,263] Bacteremia probably occurs more commonly in newborns (in some studies 30 to 50%) than in older children,[122] although not all studies have reached this conclusion.[160] The true risk of bacteremia developing in the first year of life is likely to be 2 to 6 percent.[57,241]

Hemolytic anemia, especially sickle-cell anemia, is associated with a high risk of development of *Salmonella* bacteremia. Persistent or recurrent bacteremia occurs in patients with AIDS, schistosomiasis, and intravascular focal infection. Immunocompromised adults who become bacteremic with *Salmonella* are more likely to do so without having had a preceding gastroenteritis and to have a high mortality rate.[109] Children more typically are relatively immunocompetent; most often, they develop bacteremia associated with diarrhea and have a much better prognosis.[139,160] In a large study in African children, nontyphoidal *Salmonella* spp. were the second most common cause of community-acquired bacteremia in all children and in HIV-positive patients.[22] Even children with neoplastic disease may have a benign course when they are bacteremic with *Salmonella* spp.,[175] although the risk for development of focal infections during bacteremia is higher (36%) in children with underlying conditions than in previously healthy children (2.5%).[264]

Focal suppurative infections may occur almost anywhere; the most common sites are bones (particularly in sickle-cell anemia)[26,233,262] and the central nervous system.[29,66,134,145,202,264] Meningitis has a high morbidity, with acute hydrocephalus, seizures, ventriculitis, abscesses, subdural empyema, and cerebral infarction. Long-term neurologic sequelae include mental retardation, hemiparesis, chronic hydrocephalus, epilepsy, visual impairment, and athetosis.[48] Neurologic sequelae are particularly common in patients who have prolonged fever (>10 days) while receiving antibiotic therapy.[121] Mortality rates from meningitis have been 40 to 60 percent in the past, even with appropriate treatment; more recent data suggest that the mortality rate is now much lower. Relapses even after prolonged therapy occur commonly (reflecting the intracellular localization of *Salmonella* and the difficulty of achieving adequate intracellular levels of antibiotics). Of nontyphoidal *Salmonella* meningitis, 50 to 75 percent occurs in the first 4 months of life.[48]

The serotypes causing meningitis, including *S.* ser. *Typhimurium*, *S.* ser. *Heidelberg*, *S.* ser. *Enteritidis*, *S.* ser. *Saint-Paul*, *S.* ser. *Havana*, *S.* ser. *Oranienburg*, *S.* ser. *Newport*, and *S.* ser. *Panama*,[48,259] are serotypes commonly associated with bacteremia. In infants, complications include pneumonia,[19] osteomyelitis,[62,136,262] septic arthritis,[19,217] pericarditis,[108,159] pyelitis,[235] peritonitis,[2] otitis media,[2] mastitis,[169] cholecystitis,[106] endophthalmitis,[53] cutaneous abscesses,[192] and infected cephalohematoma.[62] In adults and occasionally in older children, femoral and distal aorta (mycotic aneurysms),[48] heart valves,[48] scrotum,[246] testicles,[48] prostate,[215] ovaries,[48] and fallopian tubes[215] also may be infected.

Hemolytic-uremic syndrome associated with *S.* ser. *Typhimurium*[67,157] and *S.* ser. *Typhi*[18] has been reported. Because the cytotoxins produced by various *Salmonella* strains are distinct immunologically from Shiga toxin produced by *Shigella dysenteriae* 1 and the Shiga toxins produced by enterohemorrhagic *Escherichia coli*,[12] the association of hemolytic-uremic syndrome with salmonellosis may represent undiagnosed dual infection with toxin-producing organisms.

ENTERIC FEVER

Enteric fever usually is caused by *S.* ser. *Typhi* and, less often, other invasive *Salmonella*, including *S.* ser. *Paratyphi* and *S.* ser.

Choleraesuis. In contrast to sepsis caused by other gram-negative bacilli, the onset of symptoms in enteric fever is insidious.[120] After an incubation period of 10 to 14 days (range 6 to 21 days), which generally is related to the inoculum size, fever, malaise, anorexia, and abdominal pain develop over 2 to 3 days. The incubation period tends to be shorter with paratyphoid fever. The temperature rises in small increments, usually reaching 40° C to 40.5° C by the end of the first week of illness. The temperature does not return to normal but rather rises to higher peaks each afternoon, with higher nadirs occurring each subsequent morning during the first week. Eventually, the fever is unremitting; spikes in temperature occur without return to normal.

Constipation occurs in approximately 50 percent of cases, whereas diarrhea occurs in approximately 30 percent of patients. When diarrhea develops, it usually does so after the patient has been febrile for several days. It is small in volume, resembles pea soup, and contains erythrocytes but usually is not grossly bloody. Fecal leukocytes are present in nearly all patients with diarrhea. Diarrhea occurs more commonly with paratyphoid than with typhoid fever.[242] Vomiting is mild and not sustained.

A dull, continuous frontal headache begins during the first 2 days of fever; headache is present in approximately 75 percent of patients. In adults, confusion or delirium occurs more commonly than does a normal mental status. Children commonly complain of headache; they often are drowsy, irritable, or delirious.[61] Mild arthralgia involving multiple joints and vague, poorly localized back pain occur in nearly 60 percent of patients.

Physical examination during the first week may show a relative bradycardia for the degree of fever. The patient has a dull, expressionless, toxic facies; coated tongue; a musty, "damp hay–like" odor; and a tender, doughy abdomen with slight guarding. Occasionally, a child may have a cough; it tends to be minimal and unimpressive. The skin is dry with little sweating. Meningismus may occur early in the illness.

During the second week, rose spots may appear on the abdomen or chest, and less often on the back, upper arms, and thighs. The spots typically begin between days 7 and 10 as crops of 10 to 15 lesions, each measuring 2 to 4 mm. More lesions may occur in paratyphoid. They are blanching, erythematous, slightly raised lesions that last approximately 3 days. Rose spots occur in a few patients and are difficult to recognize in dark-skinned individuals. New crops of rose spots may continue for 1 to 2 weeks.

The spleen becomes palpable, soft, and tender by early in the second week of illness. Respiratory symptoms may progress, and epistaxis occasionally may occur. If left untreated, enteric fever has a prolonged course, with continuous high temperature of 39.5° C to 40.5° C for up to 4 weeks, followed by a gradual return to normal, beginning during the third or fourth week. A rapid decrease in temperature late in illness suggests intestinal hemorrhage or perforation[24]; such a decline in temperature typically is followed by an increase a few hours later as peritonitis develops. Intestinal hemorrhage and intestinal perforation[24,33,92] may occur in the second to fourth week in 3 percent of patients with typhoid fever.[33] Late in the course of untreated typhoid, the mental status changes to a "coma vigil," in which the patient lies with open eyes, mutters, and is oblivious to the surroundings.

Complications occur in 10 to 15 percent of patients; most of these develop during the second or third week of illness. Many complications, of which gastrointestinal bleeding, intestinal perforation, and typhoid encephalopathy are the most important, have been described (Table 121–5).[140,178,180,194,260] Gastrointestinal bleeding is the most common, occurring in 10 percent of patients.[180] It results from erosion of a necrotic Peyer patch through the wall of an enteric vessel. Suppurative lymphadenitis,[126] tonsillitis,[126,215] infected prosthetic heart valves,[10] and pancreatitis[211] rarely occur. Patients who have thalassemia or glucose-6-phosphate dehydrogenase deficiency may have hemolysis during typhoid fever.[242]

TABLE 121–5 Complications of Typhoid Fever

Abdominal
Gastrointestinal hemorrhage
Intestinal perforation
Hepatitis
Cholecystitis
Pancreatitis
Neuropsychiatric
Encephalopathy
Delirium
Psychosis
Meningitis
Impairment of coordination
Cardiovascular
Asymptomatic electrocardiographic changes
Myocarditis
Infected prosthetic valve
Shock
Respiratory
Bronchitis
Pneumonia
Hematologic
Anemia
Disseminated intravascular coagulation
Other
Focal abscess
Suppurative lymphadenitis
Pharyngitis
Tonsillitis
Osteomyelitis
Arthritis
Parotiditis
Orchitis
Pyelonephritis
Miscarriage
Relapse
Chronic carriage

Modified from Parry, C. M., Hien, T. T., Dougan, G., et al.: Typhoid fever. N. Engl. J. Med. 347:*1770-1782, 2002.*

The relapse rate is 5 to 20 percent, even when appropriate therapy has been given. Relapses typically occur 2 to 3 weeks after the resolution of fever and are milder than the initial illness. The *Salmonella* isolate from a patient in relapse usually has the same antibiotic susceptibility pattern as the isolate obtained from the patient during the original episode. Re-infection also may occur and can be distinguished from relapse by molecular typing.[253]

In some geographic areas, such as Indonesia, where an exceptionally virulent *S.* ser. *Typhi* is endemic, toxemia, delirium, obtundation, coma, and shock sometimes occur.[120,140] Some serotypes in Indonesia (e.g., H1-j) seem to be less virulent than others are, suggesting that properties of the flagellar antigen may be important to virulence.[105]

Typhoid fever varies in its clinical course. Variations on the classic theme include a completely afebrile course occurring in debilitated patients, a high spiking fever from the first day (particularly in children), a focal presentation (e.g., pneumonia, nephritis), and a severe course during relapses. Infants are said to be at higher risk for development of massive hepatomegaly, thrombocytopenia, and other complications.[193] The mortality rate is high in the neonatal period.[196] Children younger than 5 years old may have a nonspecific illness that is not recognized clinically as typhoid[224]; infants and toddlers often have a febrile illness misinterpreted as a "viral syndrome." In children younger

than 2 years old, the fever may last for only 1 to 5 days, despite the presence of *S.* ser. *Typhi* or *S.* ser. *Paratyphi* in the blood; low-grade fever (temperature of 38.3° C to 38.8° C) and cough may be the only findings in such children.[77] The case-fatality rates are highest among children younger than 1 year and among elderly patients. The most important contributor to a poor outcome is probably a delay in instituting effective antibiotic treatment.[180]

Typhoid and nontyphoidal *Salmonella* infections during pregnancy increase the risk of spontaneous abortion.[165,230] Spontaneous abortion or premature labor usually can be prevented by early treatment.[222] Transmission of *S.* ser. *Typhi* rarely occurs in utero.[40] Typically, premature delivery occurs during the second to fourth week of untreated maternal typhoid fever.[103] In the pre-antibiotic era, 40 percent of women with typhoid delivered prematurely; the remainder carried to term, although only 17 percent of infants survived.[60] If infection occurs late in gestation and is treated appropriately, the infant may survive.

ASYMPTOMATIC CHRONIC CARRIER STATE

Chronic carriers excrete *Salmonella* organisms in stools for longer than 1 year after having gastroenteritis-enterocolitis or enteric fever. Approximately 1 to 4 percent of patients who recover from enteric fever caused by *S.* ser. *Typhi* chronically excrete the organism[164]; less than 1 percent of patients with nontyphoidal *Salmonella* excrete for a prolonged period.[30,39] Twenty-five percent of prolonged carriers have no history of typhoid.[180] Nontyphoidal infection is associated with excretion for a mean of 5 weeks, although children younger than 5 years old,[30] female patients, elderly patients, and patients with biliary tract disease are more likely to become carriers. The biliary tract is infected in almost all chronic carriers of *S.* ser. *Typhi*. As many as 10^6 organisms per 1 g of feces may be excreted.[164]

The significance of chronic excretion is that such patients serve as a source of infection to their contacts. Chronic carriers represent an epidemiologically important reservoir of *S.* ser. *Typhi*; they often are the source of outbreaks of typhoid fever. In the United States, although typhoid fever generally is imported, 30 percent of infections result from exposure to previously diagnosed or newly diagnosed chronic carriers.[212]

Patients who have a history of *S. haematobium* or tuberculous infections of the urinary tract may develop chronic urinary carriage after a bout of typhoid fever.[73,201] Other predisposing conditions include hydronephrosis, strictures, and kidney stones.

DIAGNOSIS

The symptoms in *Salmonella* gastroenteritis overlap sufficiently with symptoms seen in other diarrheal illnesses that laboratory studies generally are required to prove the diagnosis. On the rare occasions when proctoscopy has been done, typical findings have included mucosal edema, hyperemia, friability, and hemorrhages.[58] The fecal leukocyte examination is positive for polymorphonuclear leukocytes in 36 to 82 percent of nontyphoidal cases,[111,187] but this finding is nonspecific. Stool culture is preferable to swab culture, particularly for evaluation of long-term carriers. Overnight enrichment in selenite broth increases the yield from stool cultures. The optimal agar for isolation of the organism (SS agar, Hektoen enteric agar, MacConkey agar, xylose-lysine-deoxycholate agar, xylose-lysine-Tergitol 4 agar, brilliant green agar, or modified semisolid Rappaport Vassiliadis medium) is debated. Modified semisolid Rappaport Vassiliadis medium has a high yield but cannot be used for isolating *S.* ser. *Typhi* or nonmotile strains and has a lower specificity than SS agar.[210]

Salmonella organisms usually can be isolated readily from blood by use of conventional media if the patient is bacteremic. In patients with extraintestinal focal nontyphoidal infection, specimens from the affected areas may have positive Gram stains and grow the organism.

Enteric fever should be suspected on the basis of the setting and clinical course. Laboratory abnormalities are common but nonspecific findings. A normocytic, normochromic anemia and leukopenia or neutropenia, perhaps caused by hemophagocytosis in the bone marrow, often are present.[151] Clotting abnormalities consistent with disseminated intravascular coagulation (e.g., thrombocytopenia, hypofibrinogenemia) may occur[32] but usually are transient and not associated with clinically significant bleeding. In enteric fever, electrolyte values usually are normal, but increases in alkaline phosphatase, serum lactate dehydrogenase, serum aspartate aminotransferase, and serum cholesterol occur frequently. A transient proteinuria sometimes occurs during the first week of enteric fever.

Cultures from multiple sites should be submitted for suspected enteric fever; culture of bone marrow has the highest yield,[114,116,247] particularly if the patient has had antibiotic pretreatment. During the first week of typhoid fever, approximately 90 percent of patients have positive blood and bone marrow cultures, but negative stool and urine cultures. During subsequent weeks, the yield of blood and bone marrow cultures decreases as the yield of stool and urine cultures increases. Culture of duodenal fluid obtained by string capsules can be as sensitive as culture of bone marrow aspirates.[15,116,247] The overall frequencies of positive cultures during the course of typhoid are found in blood (40 to 54%), urine (7 to 10%), stool (approximately 35%), bone marrow (80 to 90%), rose spots (approximately 65%), and duodenal string test culture (58 to 85%).[93,116]

The Widal test measures antibodies against the O and H antigens of *S.* ser. *Typhi*. Although many patients with enteric fever may have a fourfold increase in the titer of paired sera during the second week of illness, false-negative and false-positive test results occur. Patients with acute or chronic liver disease and patients infected with other gram-negative enteric bacilli may develop cross-reacting antibodies. Recipients of the typhoid vaccine show positive Widal test results, which can be misleading. These titers may be more useful in children with typhoid who are living in a nonendemic area, such as the United States. Although patients who have a negative titer early in infection tend to maintain a negative titer, most develop titers of 1 : 80 or more.[50] Interpretation of Widal test results is aided by information about seropositivity in the population to which the patient belongs.[45,243] Some centers have found Widal's test helpful when it is used with locally determined cutoff points.[46,181]

Various diagnostic kits, including serologic tests such as passive hemagglutination, passive bacterial agglutination, latex particle agglutination slide tests, counterimmunoelectrophoresis, radioimmunoassay, and enzyme-linked immunosorbent assay with use of monoclonal antibodies, have been developed.[124] These commercial assays (Typhidot, Typhidot-M, Tubex) have not proved to be sufficiently robust in large-scale evaluations in community settings.[23] Molecular techniques used primarily in epidemiologic studies include DNA hybridization studies, phage typing, chromosome analysis, and plasmid analysis.

DIFFERENTIAL DIAGNOSIS

Salmonella gastroenteritis cannot be distinguished clinically from other infectious causes of acute diarrhea reliably, although history and epidemiology sometimes may suggest an etiologic agent. Bloody diarrhea with mucus can be caused by *Salmonella*, *Shigella*, enteroinvasive *E. coli*, enterohemorrhagic *E. coli*, *Campylobacter* spp., *Yersinia enterocolitica*, *Clostridium difficile*, *Trichuris trichiura*,

and *Entamoeba histolytica*. Watery diarrhea may be caused by rotavirus or other viral enteropathogens or enterotoxin-producing bacterial pathogens. When abdominal pain and tenderness are severe, the differential diagnosis includes appendicitis, perforated viscus, and mesenteric adenitis.

Enteric fever can mimic other infections of the reticuloendothelial system, including Epstein-Barr virus infection, disseminated histoplasmosis, tuberculosis, ehrlichiosis, brucellosis, leptospirosis, tularemia, plague, malaria, systemic *Bartonella henselae* infection, and typhus. Noninfectious illnesses with prolonged fever that sometimes can be confused with typhoid include juvenile rheumatoid arthritis and other collagen vascular diseases, Kawasaki syndrome, and lymphomas. An early diagnosis often is difficult to establish because the findings are nonspecific. Findings that are particularly helpful in discriminating typhoid fever from other prolonged febrile illnesses include severe cough and chest pain (more typical of lobar pneumonia), diarrhea with grossly obvious blood (more typical of dysentery), acute onset of chills (more typical of malaria), and marked lower abdominal pain early in the febrile illness (more typical of bacillary dysentery, *Y. enterocolitica* infection, and salpingitis). For patients in countries where typhoid is not endemic, a history of travel is crucial.

TREATMENT

For children with salmonellosis for whom antibiotic treatment is appropriate, the interpretation of antimicrobial susceptibility studies is important. Drugs such as aminoglycosides, polymyxins, tetracyclines, and first-generation and second-generation cephalosporins (e.g., cephalothin, cefazolin, cefuroxime, cefamandole) have a poor clinical track record, despite apparent in vitro susceptibility. Table 121–6 shows the drugs that typically are useful in treatment of children with *Salmonella* infections. The emergence of *S.* ser. *Typhimurium* DT104 in the United States has led to a dramatic increase in multidrug-resistant (ampicillin, chloramphenicol, streptomycin, sulfonamides, tetracycline) organisms.[97] Most nontyphoidal *Salmonella* strains in the United States still are sensitive to ampicillin, chloramphenicol, amoxicillin–clavulanic acid, and TMP-SMX; ceftriaxone resistance, although described, is rare.[113]

GASTROENTERITIS

As with all forms of gastroenteritis, fluid and electrolyte replacement and maintenance are the first order of business. For most patients, oral rehydration is all that is necessary to treat *Salmonella* gastroenteritis. Generally, *Salmonella* gastroenteritis should not be treated with antibiotics because these agents do not shorten the course of illness. Multiple agents,[11] including ampicillin, amoxicillin,[132,170,184] neomycin,[13,184] chloramphenicol,[149] TMP-SMX,[132,213] azithromycin,[43] cefixime,[43] ceftriaxone,[42] and ciprofloxacin, have been shown to be ineffective.[213] Antibiotics prolong excretion of *Salmonella*.[11,13,63,132,170,184] *Salmonella* serotypes typically have been grouped together for these treatment studies, however, as though they were all the same organism. Given the variability in expression of virulence genes, whether treatment may be useful for some serotypes that possess particular virulence traits remains an open question.

TABLE 121–6 Antibiotics Commonly Used in the Treatment of *Salmonella* Infections

Drug	Dose
Ampicillin	200 mg/kg/day in 4 doses PO, IM, or IV
Trimethoprim-sulfamethoxazole (TMP-SMX)	10 mg/kg/day TMP, 50 mg/kg/day SMX in 2 doses PO or IV
Cefotaxime	100-200 mg/kg/day in 3 doses IM or IV
Ceftriaxone	50-100 mg/kg/day in 1 or 2 doses IM or IV
Cefixime	10-20 mg/kg/day in 1 or 2 doses PO
Chloramphenicol	50-75 mg/kg/day in 4 doses PO
Azithromycin	8-12 mg/kg/day in 1 dose PO
Ciprofloxacin	10-20 mg/kg/day in 2 doses PO or IV

Exceptions to the generalization that *Salmonella* gastroenteritis should not be treated include children at high risk for developing complications, including children with underlying diseases or receiving therapies that impair host defenses. Examples of children who probably ought to be given antibiotics are infants 3 months old or younger; children with AIDS or malignant diseases; and children with hemolytic anemias, particularly sickle-cell anemia. Treatment of these patients is debatable; the data from neonates suggest that antibiotics make little difference in the course.[2,71,132,198,234] Because the risk of development of bacteremia is high, however, antibiotics likely will continue to be used in such settings. Because bacteremia occurs in a small fraction of infections, determining whether treatment of gastroenteritis prevents bacteremia is impossible without conducting a massive study.

When treatment is given, probably 5 days or fewer of antibiotics is indicated, barring complications. Although antibiotic resistance is an increasingly important problem, patients who require antibiotic therapy for *Salmonella* gastroenteritis not thought to be life-threatening usually should be given ampicillin or amoxicillin, pending susceptibility testing.

EXTRAINTESTINAL INFECTIONS

Any child who appears to be sufficiently toxic that bacteremia is suspected also should be started on antibiotic treatment until blood cultures exclude the diagnosis. For children with bacteremic nontyphoidal *Salmonella* and focal extraintestinal complications, a third-generation cephalosporin (e.g., ceftriaxone, cefotaxime) or chloramphenicol is an appropriate choice. If the patient seems to have a life-threatening infection, ampicillin should be used only if evidence exists that the pathogen is not ampicillin resistant. Children at high risk of having recurrence of bacteremia (children with congenital or acquired immunodeficiencies, such as AIDS) may require a third-generation cephalosporin or a fluoroquinolone to achieve cure; frequent recurrences of life-threatening infection sometimes necessitate use of lifelong maintenance therapy.[51,119]

Meningitis should be treated with a third-generation cephalosporin because these agents have good penetration into CSF; ampicillin and chloramphenicol use has been associated with higher relapse rates and lower cure rates than are third-generation cephalosporins.[134] Meningitis must be treated for at least 4 weeks; approximately three fourths of patients who have relapses have been treated for 3 weeks or less.[48] A bactericidal agent, such as ampicillin or a third-generation cephalosporin, is preferred for treatment of endovascular infections (e.g., endocarditis, mycotic aneurysm).

For extraintestinal infections, the duration of antibiotic treatment usually is 10 to 14 days in children with bacteremia, 4 to 6 weeks in children with acute osteomyelitis, and 4 weeks in children with meningitis. Collections of pus should be drained. Schistosomiasis, when present, must be treated to achieve resolution of the coincident *Salmonella* infection.

TYPHOID FEVER

The response to treatment with antibiotics is slow. Fever may persist for many days, even after bacteremia has resolved. The

emergence and spread of multidrug-resistant *S.* ser. *Typhi* (MDRST) since 1989 has caused a shift in empiric therapy from chloramphenicol, TMP-SMX, or ampicillin to a fluoroquinolone in adults and a third-generation cephalosporin, such as ceftriaxone, azithromycin, or a fluoroquinolone, in children (Table 121–7). MDRST is particularly common in the Indian subcontinent, Southeast Asia, and Africa; strains resistant to ciprofloxacin are being recognized increasingly.[205]

In the United States, MDRST is less problematic than it is elsewhere; most strains are sensitive to ampicillin and chloramphenicol.[212] More recent data suggest that *S.* ser. *Typhi* is still sensitive consistently to ceftriaxone and ciprofloxacin, although nalidixic acid–resistant isolates are becoming more common in individuals who have traveled to the Indian subcontinent.[5] Such strains respond poorly to fluoroquinolones and may require several courses of treatment.[254] When the patient has a history of recent travel to an area with MDRST or of contact with an individual returning from such an area, the choice of empiric treatment should take this information into account. Third-generation cephalosporins are effective against *S.* ser. *Typhi* strains resistant to ampicillin, chloramphenicol, and TMP-SMX,[74,124,134,161,167,179,227,240] and are appropriate for children with suspected or proven MDRST. Some studies suggest that cefoperazone may have advantages in typhoid fever over chloramphenicol treatment (more rapid sterilization and defervescence),[179] perhaps related to its biliary excretion.[59] Data suggest that TMP-SMX may not be as effective as is ampicillin or chloramphenicol in typhoid fever.[94] Aztreonam also is less effective than is chloramphenicol for strains susceptible to both agents.[99]

Although 2 weeks of antibiotic treatment usually is given, data suggest that shorter courses with some drugs may be adequate. A short course of ceftriaxone (once daily for 3 to 5 days) is as effective and safe as is a 2- to 3-week course of chloramphenicol in adults and, on the basis of relatively small numbers, probably in children as well.[3,167] A 5-day course of ceftriaxone (50 to 70 mg/kg/day as a single dose) was associated with a significantly more rapid defervescence (average 3.9 days until afebrile) than was oral cefixime (7.5 mg/kg/dose twice daily for 14 days) or intramuscular aztreonam (50 to 70 mg/kg/dose every 8 hours for 7 days); relapse rates were similar (approximately 5%).[96]

TABLE 121–7 Recommended Antibiotic Treatment of Typhoid Fever

Susceptibility	Antibiotic	Daily Dose (mg/kg)	Days
Full susceptible	Chloramphenicol, *or*	50-75	14-21
	Amoxicillin, *or*	75-100	14
	Trimethoprim-sulfamethoxazole, *or*	8/40	14
	Third-generation cephalosporin (e.g., cefixime), *or*	15-20	7-14
	Fluoroquinolone (e.g., ofloxacin or ciprofloxacin)	15	5-7
Multidrug-resistant	Azithromycin	8-10	7
	Third-generation cephalosporin (e.g., cefixime), *or*	15-20	7-14
	Fluoroquinolone (e.g., ofloxacin or ciprofloxacin)	15	5-7
Quinolone-resistant	Azithromycin, *or*	8-10	7
	Third-generation cephalosporin (e.g., cefixime), *or*	20	7-14
	Parenteral third-generation cephalosporin (e.g., ceftriaxone), *or*	75	10-14
	Fluoroquinolone (e.g., ofloxacin or ciprofloxacin)	20	10-14

Strong evidence supports fluoroquinolones as the most effective drugs for the treatment of typhoid fever. These drugs have proved safe in all age groups, are rapidly effective, and are associated with lower rates of stool carriage than traditional first-line drugs. There are three main issues regarding the use of fluoroquinolones: (1) the potential for toxic effects in children, (2) the cost, and (3) the potential emergence of resistance.[180] In preclinical testing, the fluoroquinolones damaged the articular cartilage of young beagles. A considerable body of evidence exists from the long-term use of these drugs in children with cystic fibrosis and from short-term use to treat typhoid fever and dysentery in children. No bone or joint toxicity or growth impairment has been found. The production of generic fluoroquinolones in many countries has reduced the price considerably. The emergence of quinolone resistance in areas where the drugs are inexpensive and readily available is likely to be the greatest limitation on their use.[180]

Concerns about toxicity of fluoroquinolones in children have limited their use to situations in which infection is caused by an organism proved to be resistant to all of the usual antibiotics but sensitive to a fluoroquinolone. If a fluoroquinolone is used, ciprofloxacin or ofloxacin is superior to norfloxacin because it has inadequate oral bioavailability. Ciprofloxacin (500 mg twice daily for 10 days in adults) causes defervescence in an average of 4.2 days with infrequent relapses, even with MDRST.[7] Children with MDRST who have been treated with ciprofloxacin (10 mg/kg/day) became afebrile in 3.3 days, and 94 percent achieved clinical cure, with no relapses or carriers detected on follow-up.[68] Ofloxacin (20 mg/kg twice daily for 10 days) is associated with more rapid defervescence than TMP-SMX.[220] Ofloxacin is associated with more rapid defervescence and better cure rates than cefixime.[35] Three days of ofloxacin (15 mg/kg/day in two doses for 3 days) causes defervescence more quickly than chloramphenicol (50 mg/kg/day in four doses for 14 days).[185] Very short courses of ofloxacin (2 or 3 days) may be followed by relapse,[251] however, especially if the organism is resistant to nalidixic acid.[174]

Other agents have been described that occasionally may be useful. Furazolidone (7.5 mg/kg/day) is nearly as effective as is chloramphenicol in strains susceptible to both drugs (86% versus 90% cure).[69] Despite low serum levels, azithromycin seems to be equivalent to chloramphenicol or ciprofloxacin; the high intracellular concentration in macrophages (>100 times serum levels) of azithromycin presumably accounts for its efficacy.[34,95] When MDRST is resistant to nalidixic acid, azithromycin is more effective than is ofloxacin.[41]

A 5-day course of oral azithromycin (20 mg/kg/day, maximum 1000 mg/day) is as effective as intravenous ceftriaxone (75 mg/kg/day, maximum 2.5 g/day for 5 days).[84] Various nonantimicrobial measures should be considered as part of the management of *S.* ser. *Typhi* infections. Dexamethasone, although potentially increasing the relapse rate,[52] is indicated for patients with severe typhoid fever presenting with delirium, stupor, shock, or coma; the dose is 3 mg/kg initially and then eight doses of 1 mg/kg every 6 hours for 48 hours. This therapy reduces mortality rates from 35 to 55 percent to 10 percent.[115,191] Parenteral fluoroquinolones are probably the antibiotic of choice for severe infections, but no randomized trials of such treatment have been performed.[68] Antipyretics were thought at one time to be dangerous in typhoid fever[65]; whether this concern is correct is doubtful on the basis of more recent experience.[176]

Intestinal hemorrhage or perforation during enteric fever generally is considered to be an indication for surgical intervention.[24,33,92,143] Resection of 10 cm of intestine proximal and distal to the perforation seems to improve outcome compared with other surgical approaches.[14] Antibiotic coverage should be broad-

ened to include anaerobes and gram-negative enterics when perforation occurs.[24]

CHRONIC CARRIERS

Generally, patients who are not food handlers probably should not be cultured or given special treatment after having a bout of gastroenteritis caused by a nontyphoidal *Salmonella* strain. Carriers of *S.* ser. *Typhi* should be decolonized to decrease the risk to close contacts. Carriers who have a normal gallbladder can be treated with high-dose intravenous ampicillin, oral ampicillin, or amoxicillin combined with probenecid for 6 weeks or, when a multiresistant organism is present, with a fluoroquinolone, such as norfloxacin[100] or ciprofloxacin.[78] Chronic carriers who cannot be decolonized are treated with cholecystectomy if cholelithiasis or cholecystitis is present; such patients should receive ampicillin intravenously for 7 to 10 days before and 30 days after cholecystectomy.

PREVENTION

PUBLIC HEALTH MEASURES

Recognition of an increased frequency of human infections with an unusual serotype should be followed by an epidemiologic investigation aimed at detecting the source and vehicle. Intervention to stop such outbreaks then can be attempted. Judicious use of antibiotics in dairy and livestock animals,[117] careful food processing and storage, and proper preparation of foods are helpful in decreasing transmission of infection. Appropriate sewage disposal, assurance of a safe water supply, prevention of sale of pet turtles, inspection of cosmetics for contamination, and adequate cleaning of medical equipment are important public health strategies. Families with small children should be informed of the risks associated with pet reptiles and encouraged to avoid such unnecessary risks.

PERSONAL HYGIENIC MEASURES

Person-to-person spread can be decreased by handwashing after defecating or changing diapers, frequent handwashing during preparation of foods that might be contaminated (e.g., meat), and excluding of infected individuals from food-handling tasks.

INFECTION CONTROL

Hospitalized children with *Salmonella* gastroenteritis should be isolated (enteric precautions) until stool cultures are negative. Children with extraintestinal infections should be isolated until stool studies exclude intestinal infection or colonization.

NURSERY OUTBREAKS

Neonatal *Salmonella* infection outbreaks should be investigated to determine the source. Cultures of fomites sometimes reveal a removable focus. Neonates and staff members caring for them should be cohorted during outbreaks, with use of enteric precautions in dealing with infants who are excreting the organism. Surveillance cultures should be done on feces of not only sick infants but also well infants to cohort more appropriately. With current early postpartum discharge policies, reporting *Salmonella* infections in infants is important in detecting outbreaks. Isolation and cohorting can be effective in controlling such outbreaks.[198]

BREAST-FEEDING

In the developing world, breast-feeding is key in prevention because human milk contains secretory IgA and other factors that protect infants from *Salmonella* spp.[27,76,83,188,189] In a case-control study conducted in the United States, breast-feeding was found also to have a strong protective effect against sporadic *Salmonella* infections.[206] Pediatric health care providers and community education programs should encourage mothers to breast-feed.

VACCINATION

Several vaccines have been developed for typhoid fever. Vaccination of children is indicated when the risk for development of typhoid fever is high (e.g., living with a chronic carrier or in an endemic area) but probably is underused.[239] Two vaccines are available: (1) an oral live attenuated Ty21a vaccine (Vivotif Berna; Swiss Serum and Vaccine Institute) and (2) a parenteral purified Vi capsular polysaccharide vaccine (Typhim Vi; Aventis Pasteur).[135,190]

The Ty21a vaccine has been evaluated in liquid and capsule forms. Ty21a oral vaccine is well tolerated; abdominal pain, nausea, vomiting, and rashes occur rarely. The form licensed in the United States is an enteric-coated capsule preparation meant to be given in four separate doses on alternate days taken 1 hour before meals. It is not recommended for children younger than 6 years of age. The four doses should be completed 1 week before potential exposure. Revaccination with the entire four-dose series is recommended every 5 years in high-risk settings. Because the Ty21a oral vaccine is a live-attenuated *Salmonella*, it should not be used in immunocompromised hosts or in individuals taking antibiotics at the time of receiving vaccination.[37] The antimalarial mefloquine inhibits growth of the attenuated organism, and vaccination should be delayed for 24 hours after its use. Malaria prophylaxis with atovaquone and proguanil does not interfere with immune response to Ty21a.[75]

Several large field trials suggest that the Vi capsular vaccine as a single 25-μg dose (0.5 mL) has an efficacy of 55 percent and 75 percent in adults and children older than 5 years.[4,190] Although fever, malaise, local pain, and tenderness occur with this vaccine, it has two major advantages over the Ty21a oral vaccines: It does not require refrigeration, and only a single dose is required for protection. It may be used in children 2 years of age. Vaccination must occur at least 2 weeks before exposure.

PROGNOSIS

Salmonella gastroenteritis usually is a self-limited disease in the normal host, although chronic diarrhea sometimes develops after an acute episode. Extraintestinal focal infections with nontyphoidal *Salmonella* strains are difficult to cure, particularly if they involve the meninges or occur in compromised hosts. *Salmonella* spp. meningitis may relapse if the course of treatment is too short. Likewise, bacteremia and focal infection recur after treatment in severely compromised hosts, particularly patients with AIDS. Relapse after typhoid fever has long been recognized as a risk.

CHAPTER 122

PLAGUE *(YERSINIA PESTIS)*

Gary D. Overturf

HISTORY

Yersinia pestis has been responsible for the most devastating epidemics in human history. Possibly the first mention of plague dates back to approximately 1320 B.C.E., in I Samuel (Old Testament), Chapters 5 and 6. The next recorded outbreak may have been in 542 during Justinian's reign, when an estimated 100 million people died.[48] In 1346, plague appeared during the siege of the city of Kaffa in the Crimea, thereafter spreading throughout most of Europe, where it became known as the *black death*. One third of the population of Europe died in its aftermath. Between the 14th and 20th centuries, plague remained endemic in most of Europe and Russia, with resultant frequent outbreaks.[43]

In 1894, Yersin and Kitasato, working independently, first described the plague bacillus,[47] and the role played by rats and fleas in the spread of the disease became known. In 1900, plague was introduced into San Francisco by rats aboard ships docking there. The disease spread to ground squirrels and then to other wild animals of the American Southwest.[46] In 1943, effective antibiotics against *Y. pestis* became available. In the United States today, plague is rare, but it continues to be endemic in many parts of the world, leading to more recent outbreaks in Madagascar, Peru, and India. Although antibiotics have been effective in the treatment and prophylaxis of plague, plasmid-borne antibiotic resistance is being noted increasingly.[19] The potential of aerosolized *Y. pestis* as a biologic weapon is being scrutinized, leading to renewed interest in the understanding and study of this organism.[29]

BACTERIOLOGY

Y. pestis belongs in the family Enterobacteriaceae and is one of 10 *Yersinia* spp. It is a small, pleomorphic, nonmotile, gram-negative bacillus. With Wayson, Giemsa, and Gram stains, the bacillus takes on bipolar or safety-pin morphologic features.[17] *Y. pestis* grows at temperatures ranging from 0° C to 40° C (32° F to 104° F); the optimal temperature is 28° C (82.4° F). On first isolation at 35° C (95° F) on 5 percent blood agar, the colonies are pinpoint in size, growing to 1 to 2 mm after 2 days. They are nonhemolytic on 5 percent sheep blood agar.

Depending on the clinical nature of the disease, blood cultures, sputum samples, or aspirates of enlarged nodes should be examined for typical bacilli. The isolated bacilli can be identified by the following criteria. *Y. pestis*, the sole *Yersinia* spp. that is nonmotile at 37° C and 22° C (98.6° F and 71.6° F), also is the sole *Yersinia* spp. that is urease-negative, but it may be positive in freshly isolated strains. The organism is positive for esculin, β-galactosidase, catalase, and methyl red. Oxidase, indole, and Voges-Proskauer reactions are negative. It ferments glucose, maltose, salicin, xylose, arabinose, dextrin, trehalose, and mannitol. It does not produce acid from lactose, sucrose, rhamnose, melibiose, adonitol, cellobiose, sorbose, or dulcitol. It does not use citrate, and it does not grow in potassium cyanide. *Y. pestis* is negative for lysine, ornithine decarboxylase, and arginine dihydrolase.[44,53]

Positive cultures show pinpoint colonies within 24 to 48 hours after inoculation. Many laboratories use fully automated or semiautomated identification systems (e.g., Vitek) that may not detect *Y. pestis*, often confusing *Y. pestis* and *Yersinia pseudotuberculosis* or *Yersinia enterocolitica* with plague bacillus. Nonautomated laboratories may require 6 days to identify the organism. Because of lack of standarized susceptibility testing procedures, suspected isolates must be referred to public health or other reference laboratories to comply with the select agent requirements of the Title II Enhanced Controls for Dangerous Biological Agents and Toxins Act.[29]

Several chromosomal-mediated virulence factors are responsible for the virulence of *Y. pestis*, including (1) an antiphagocytic capsular material known as fraction 1, (2) the endogenous purine synthesis that allows the organism to grow within macrophages, and (3) the ability to absorb iron from the medium. Several plasmids have been implicated in the development of other virulence factors. A plasmid of 9-kb pairs contains the determinant of secretory protein that kills other bacterial strains. A plasmid of 72-kb pairs, which all pathogenic *Y. pestis* strains contain, confers the requirement for environmental calcium to be present for the organism to grow at 37° C (98.6° F). When grown under this condition, *Y. pestis* produces V and W antigens that are necessary for virulence.[21] An exotoxin and an endotoxin have been found to contribute to the lethal effects of plague.[53]

TRANSMISSION

HOST

More than 200 mammalian species have been reported to be naturally infected with *Y. pestis*. Epidemics of plague usually are transmitted by the fleas of infected domestic rats, however. This form of spread is more likely to occur in urban, rat-infested, and crowded dwellings and may result in epidemics. In the United States, plague is transmitted sporadically to humans after contact with an enzootic sylvatic focus.[31] Infected wild rodents perpetuate the plague bacillus in a given ecosystem by virtue of their ability

to withstand an inoculum of *Y. pestis* many times greater than that necessary to cause disease in humans or domestic animals. After inoculation, wild rodents may become bacteremic and infect fleas that feed on them; these fleas transmit the plague bacillus to another rodent. Hibernating animals are especially resistant to clinical infection. Animals inoculated before going into hibernation may survive through the winter and not die until after they come out of their burrows, reintroducing the bacillus in the new season.[26] Carnivores are relatively resistant to infection but contribute to the spread of the organism by transporting infected fleas from one area to another.[31]
