Although disease occurs most commonly in children, clinical infection occurs in individuals of all ages.[1,4,8,10,13,17,28] Data are insufficient to determine whether the lower incidence of disease in adults is due to immunity acquired from previous subclinical infections.

CLINICAL MANIFESTATIONS[5,9,10,13,36]

An initial period of nonspecific prodromal symptoms and signs, such as fever, headache, nausea, vomiting, muscle pain, and photophobia, is followed within 2 to 5 days by drowsiness, mental obtundation, confusion, disorientation, incongruous behavior, ataxia, speech disturbance, or convulsions, sometimes with a grand mal character. Neurologic signs were present in most patients on admission to the hospital, and additional signs appeared as the disease progressed. In some cases, the signs fluctuated from hour to hour. Bennett[5] recognized three groups of patients according to eventual clinical outcome:

1. Patients with mild disease commonly had disturbed mentation short of coma, incoherent or slurred speech, aphasia, speech perseveration, incontinence, neck stiffness, intention tremor, and limb hypertonicity but rarely required assistance for respiration. The neurologic changes stabilized in 5 to 10 days, and the patients' clinical conditions improved.
2. Patients with severe disease showed more profound central nervous system (CNS) involvement consisting of impairment of consciousness to coma, more marked signs of upper motor neuron involvement, and pharyngeal or respiratory paralysis requiring artificial respiration.
3. In fatal cases, patients had either spastic quadriplegia progressing to almost complete loss of nervous function or severe disease with superimposed infection.

The differential diagnosis of Murray Valley encephalitis may be assisted by attention given to signs attributable to spinal cord involvement and to cranial nerve palsies, tremor, and frequency of seizures (seizures rarely develop in adults with Murray Valley encephalitis, whereas they may occur in up to 90% of children). Although computed tomographic scans in these patients may be normal, and electroencephalograms may not show focal features,[10] magnetic resonance imaging reveals changes similar to those reported in the brains of patients with Japanese encephalitis[24]—thalamic edema, hypointensity on T1-weighted images, and hyperintensity on T2-weighted images.[19,25] Changes also were noted in the reticular formation, the substantia nigra, and the cervical spinal cord.[19] In the absence of serology, the magnetic resonance images might be regarded as diagnostic of an infection with herpes simplex virus rather than with Murray Valley encephalitis virus.[39]

PATHOLOGY

A period of viremia probably precedes infection of the CNS, during the 1- to 3-week incubation period,[1] but it has not been demonstrated. Pathologic changes in fatal cases were restricted to the CNS and included extensive perivascular cuffing (especially in the cortex), lymphocytic infiltration of the meninges, neuron degeneration and neuronophagia in the cerebellum and spinal cord, and thalamic necrosis. Evidence of repair, including calcification, was described in patients who died late in the course of the disease.[6,10,11,33,35] These pathologic changes do not distinguish Murray Valley encephalitis from other arthropod-borne encephalitides.

In rodents infected peripherally with Murray Valley encephalitis virus, the virus enters the CNS through the olfactory pathway after replicating in regional lymph nodes. From the olfactory lobe, it spreads through interconnected neural circuits to the cortex, hippocampus, thalamus, cerebellum, medulla oblongata, and spinal cord. Extensive neuronal necrosis was observed in the olfactory bulb and hippocampus. The severity of the subsequent encephalitis correlated with the magnitude of mononuclear and polymorphonuclear cell infiltrates. Infiltration of neutrophils was preceded by increased expression of tumor necrosis factor–α and the chemokine N51/KC in the CNS. Previous depletion of neutrophils or inhibition of inducible nitric oxide synthetase resulted in prolonged survival and decreased incidence of mortality in mice infected with Murray Valley encephalitis virus.[3,30] However, the pronounced mononuclear cell content of cerebrospinal fluid in some patients with Murray Valley encephalitis[10,19] contrasts with the picture in rodents.[30]

DIAGNOSIS

Clinical and epidemiologic features may suggest the diagnosis of Murray Valley encephalitis, especially during recognized epidemics, but individual cases may be difficult to distinguish from cases of encephalitis or encephalopathy of other cause (e.g., herpesvirus or Japanese encephalitis or Kunjin viruses).[5,32,39] Establishment of a specific diagnosis depends on serologic evidence of infection concurrent with disease. Detection of IgM antibody that reacts with Murray Valley encephalitis virus in hemagglutination-inhibition[20,38] or in enzyme-linked immunosorbent assays is the most useful indication of recent infection. Other flaviviruses, especially Kunjin virus, may cause encephalitis, subclinical infection, or minor illness during epidemics of Murray Valley encephalitis,[37] and interpretation of serologic cross-reactions between Kunjin and Murray Valley encephalitis viruses may require specific tests (e.g., neutralization) with several viruses.[17] Serologic tests for the laboratory diagnosis of Murray

Valley encephalitis are not available commercially and so are performed only at larger regional laboratories. Isolation of virus has not been successful for antemortem diagnosis. However, some reports[19,31] document the detection of Murray Valley encephalitis viral RNA in serum or cerebrospinal fluid from patients by use of the reverse transcription–polymerase chain reaction (RT-PCR). Subsequent serology confirmed these RT-PCR data. Given the need for rapid clinical intervention in this disease, more extensive use of RT-PCR in a diagnostic setting is warranted.

TREATMENT AND PROGNOSIS

No specific antiviral therapy is available. Administration of corticosteroids has been recommended during the acute phase of the illness to reduce brain edema. Artificial respiration has been lifesaving, and all patients should be transported to base hospitals with facilities for the management of patients with respiratory paralysis.[5] Most patients also require parenteral nutrition or nasogastric feeding.[10]

The early epidemics left some patients with neurologic and psychiatric sequelae, but the lower case-fatality rate in recent outbreaks, presumably because of use of modern intensive care techniques, has been associated with a high rate of residual disability.[10,13] Bennett[5] observed 18 patients up to 16 months after they experienced infection. Four of 11 patients with mild disease had emotional problems and mild degrees of impaired motor coordination and mental acuity. All 7 patients with severe disease had serious defects, including paraplegia or quadriplegia and mental disturbance.

This pattern of high residual disability has continued to the present.[10,13]

PREVENTION

Because of the irregularity of outbreaks and the large areas over which they occur, institution of measures to prevent Murray Valley encephalitis is difficult. However, both government and personal programs for restriction of exposure of humans to the common mosquito vector *C. annulirostris* are likely to minimize the incidence of disease.

No vaccine is available, but there may be value in assessing the capacity of the next generation of live attenuated Japanese encephalitis virus vaccines to provide cross-protection against infection with Murray Valley encephalitis virus.

CHAPTER 188g

Tick-Borne Encephalitis

Christoph Aebi ● Theodore F. Tsai

Tick-borne encephalitis (TBE) refers here to the neurotropic tick-transmitted flaviviral infections that occur across the Eurasian land mass from the Far East to western Europe. The Far Eastern form of the disease frequently is called Russian spring-summer encephalitis (RSSE); in Europe, where the disease is distinctly milder and often biphasic, it is called tick-borne encephalitis, spring-summer meningoencephalitis, central European encephalitis, or, because sometimes it is transmitted by raw infected milk, biphasic milk fever.[23,31,66,100]

HISTORY

After an outbreak of encephalitis in the Far Eastern region of Russia in 1932, Zilber isolated the virus from viremic humans and from *Ixodes persulcatus* ticks. A milder form of the disease with a similar seasonality had been described previously in Sweden and Austria, but its etiology was not defined until 1948, when the virus was isolated in the Czech Republic and Slovakia. Milk-borne transmission of TBE virus (TBEV) from infected livestock animals first was recognized in an outbreak in 1951 and 1952.

ETIOLOGIC AGENT

TBEV and the closely related viruses of RSSE and Powassan encephalitis are flaviviruses placed antigenically within a complex of tick-borne flaviviruses that also includes the agents of Kyasanur Forest disease, Omsk hemorrhagic fever, and an encephalomyelitis syndrome in sheep variously called louping ill in the British Isles and Spanish, Greek, or Turkish sheep encephalomyelitis in their respective countries.[39] Molecular taxonomic studies based on nucleotide sequence differences in the E glycoprotein gene of the virus show the early divergence of a mammal-associated clade from seabird-associated agents. Viruses in the mammal-associated clade exhibit a continuous east-to-west cline consistent with an evolutionary origin of TBEV in the Far East and dispersion westward to Europe and the British Isles (Fig. 188–12).[27]

ECOLOGY

The viruses of RSSE and TBE are transmitted principally by hard ticks in the *Ixodes ricinus* complex: *I. ricinus* in Europe and *I. persulcatus* in the Far East.[23,31,66,100] Other tick vectors include *Ixodes arboricola*, *Ixodes hexagonus*, *Haemaphysalis punctata*, *Haemaphysalis concinna*, *Dermacentor marginatus*, and *Dermacentor reticulatus*. Viral circulation is maintained by continuous horizontal infection between ticks and animals and through the winter by vertical transmission in vector ticks and by latent infection in hibernating animals. The viruses are transmitted trans-stadially from larval to nymphal to adult tick stages and transovarially. All stages of the tick and both male and female ticks transmit infection to animals and humans. Ixodid ticks feed on three hosts, one for each of the stages, during the typical 3-year life cycle. Larval and nymphal ticks feed preferentially on birds and small mammals, such as wild mice, voles, and dormice; adult ticks feed on larger mammals, such as roe deer, hedgehogs, foxes, hares, badgers, deer, domestic livestock (pigs, goats, sheep, and cows), dogs, cats, and humans. RNA sequence heterogeneity of the 5′ noncoding region in different TBE virus isolates recovered from the same biotope suggest that virus populations consist of a number of subtypes with specificities for individual vertebrate hosts.[13] Infections in animals, except occasionally in dogs, are asymptomatic, and the viremia is of brief duration. Therefore, a large population

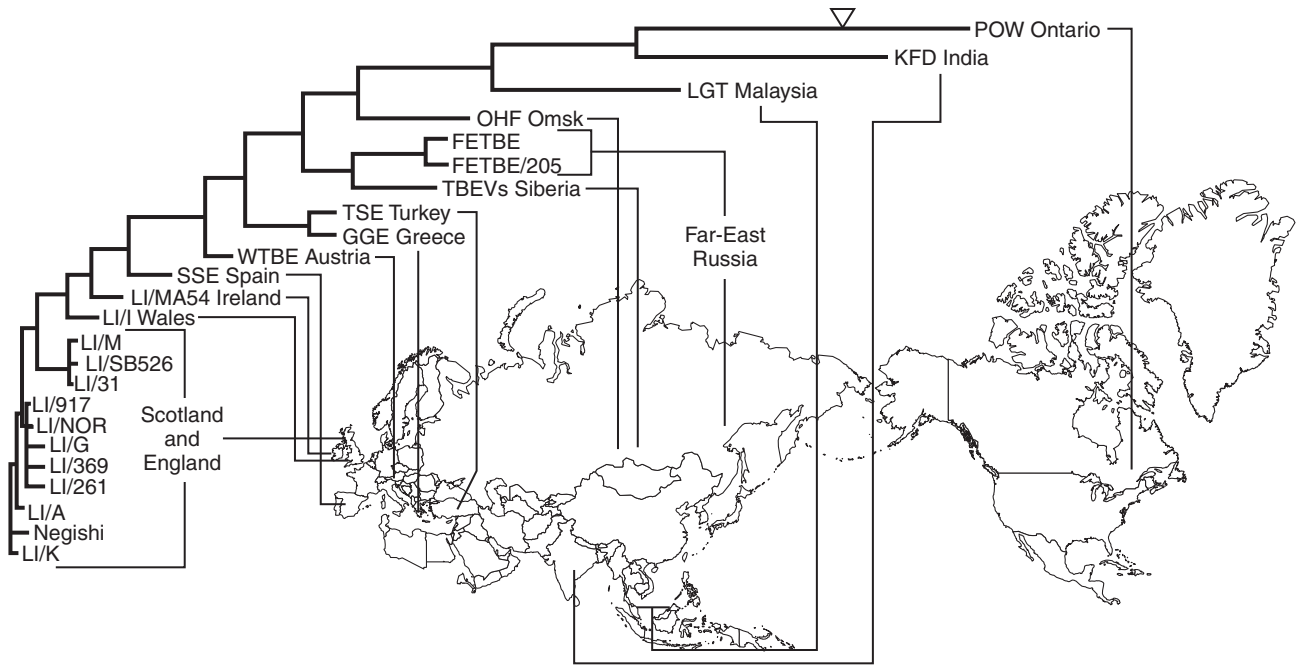

Figure 188–12 Cladogram of tick-borne encephalitis complex viruses based on E gene sequences presented from west to east with respect to louping ill (LI) virus. FETBE, Far Eastern tick-borne encephalitis; GGE, Greek goat encephalitis; KFD, Kyasanur Forest disease; LGT, Langat; OHF, Omsk hemorrhagic fever; POW, Powassan encephalitis; SSE, Spanish sheep encephalitis; TSE, Turkish sheep encephalitis; WTBE, western tick-borne encephalitis. The phylogenetics of these and other mosquito-borne flaviviruses are rooted in the Powassan branch indicated by the triangle. *(From Zanotto, P. M., Gao, G. F., Gritsun, T., et al.: An arbovirus cline across the Northern Hemisphere. Virology* 210*:152-159, 1995.)*

of susceptible vertebrate hosts is needed to maintain viral transmission. Human infections are incidental to the natural cycle of transmission. Birds and large mammals contribute to the spread of vector ticks and viral foci.

Ticks in the *I. ricinus* complex require high soil and ambient humidity (>80-90% relative humidity) and moderate temperature, within the 8° C isotherm. They typically are found in the transitional vegetation zone from the forest edge to fields or meadows or in areas where dense brush or ground vegetation provides a sheltered microenvironment. Vector ticks are absent from mountainous areas with an elevation above 1000 to 1500 m. Foci of TBE transmission are restricted geographically and ecologically to these biotopes and have tended to be highly stable from year to year. However, global warming has been speculated to underlie the changes, both expansion and contraction of transmission foci, in northern and central-southern Europe, respectively.[75,100] New data also suggest a shift of tick activity to higher altitudes in recent years, potentially allowing vertical expansions of TBE foci.[20]

Tick activity varies with seasonal temperature and humidity. In central Europe, activity begins in March and April, reaches a peak in May, and declines during the summer in July and August. With the return of cooler temperatures, a second peak of activity occurs in September. In temperate regions, tick activity begins later and is greatest in the summer months. In Mediterranean climates, ticks are most active from November to January.

In foci with hyperendemic transmission, tick density may exceed one per square meter. Viral infection rates in ticks generally are in the range of 0.1 to 5 percent. These rates typically are 10-fold lower than *Borrelia burgdorferi* (sensu lato) infection rates in *I. ricinus* in the same areas, although *I. persulcatus* infection rates greater than 10 percent have been reported.[58] The mechanisms underlying this difference are unclear but may include the variable infectiousness of the agents and their interactions with modulatory factors in tick saliva; the relatively brief duration of TBE viremia in animals, which lasts only a few days and thus results in a reduced chance of transmission of virus to feeding ticks, as opposed to the persistent *B. burgdorferi* infections in rodents, with tick feeding more likely to result in infection; and potential differences in the principal reservoir hosts for the respective infectious agents, with a more limited and focal distribution of important hosts for TBEV, such as goats.[93] The two agents evidently do not interfere with each other in their infection of *I. persulcatus* ticks; dually infected ticks and singly TBE-infected and *Borrelia*-infected ticks stand in a ratio of approximately 1:4:14.[58] *I. ricinus* also can be infected with and transmit *Francisella tularensis* and *Anaplasma phagocytophilum*, the agent of human granulocytic ehrlichiosis.[131]

The geographic distributions of RSSE and European TBE correspond to the ranges of their principal tick vectors; however, transmission is highly focal within this range because of the locations of biotopes that support viral circulation (Fig. 188–13). New foci are reported periodically as a result of better recognition of the disease, its natural spread, human modifications of the landscape, and environmental and climate changes (e.g., global warming).[26,49,75,100]

EPIDEMIOLOGY

TBE has been recognized in all countries of Europe except Portugal and the Benelux countries, but endemic transmission is most intense in central Europe.[66,100] The incidence of TBE previously ranged as high as 50 per 100,000 population in Austria, Poland, Hungary, Russia, the Czech Republic, Slovakia, and former Yugoslavia; in certain areas, similar levels of transmission still may prevail. Vaccination has reduced the incidence of disease regionally, especially in Austria, where a national program of immunization in effect since 1981 has reduced the incidence to less than 1 per 100,000 population.[135] Currently, isolated cases are reported from Norway, Denmark,[121] France,[35] Greece, and Liechtenstein, and fewer than 200 cases are reported annually in Sweden, Germany, and Italy. Switzerland recently reported a threefold increase in human TBE cases between 2004 and 2006,[136] which resulted both from more infections in endemic areas and from infections in newly recognized foci. In the Far East, cases of RSSE occur principally in forest workers. The disease is recognized in Russia and China, and the first cases acquired in Japan (transmitted by *Ixodes ovatus*) were reported recently.

Within each country, the distribution of cases is highly focal in certain areas. Local seroprevalence may exceed 20 percent, but the general seroprevalence usually is less than 1 per 100,000 population. Frequent exposure during long-term residence leads to a general trend of increasing seroprevalence with age. Seroprevalence rates as high as 50 percent have been observed in groups at high risk for exposure, such as farmers and forestry workers. Although, in general, rates are lower (1 to 5%) and in certain groups are similar to the seroprevalence of hantaviruses, lymphocytic choriomeningitis virus, and *Anaplasma* spp., *Borrelia burgdorferi* seroprevalence rates are 10-fold higher or more.[85,91] The frequency of clinical cases of TBE, borreliosis, and dual infection closely approximates the relative frequency of tick infection, singly and dually. Adults 20 to 50 years of age characteristically accounted for most of the cases. In some studies, cases in males (adults and children) predominate by a ratio of 2:1.[24,36,74]

Cases have occurred in children as young as 3 weeks,[46,50] but generally, risk in children increases with age as a result of their increased mobility and activity in the sylvatic environment.[74] These epidemiologic patterns are changing in areas with high immunization coverage.[135] Vaccination effort has focused principally on hyperendemic areas and on high-risk occupational groups such as forestry workers. The low number of cases currently reported from areas where vaccination coverage is high belies the continued transmission of virus in these locations.

Cases may be acquired during outdoor activities, such as berry picking and mushroom gathering, and infection occasionally has been acquired from ticks brought from endemic areas on Christmas trees and other objects. One study found that the seroprevalence in Swedish orienteers (1%) was not substantially different from the general seroprevalence in residents of Stockholm County (5%), an area where TBE is endemic. The absence of a higher risk of acquiring TBE in persons with occasional sylvatic exposure reflects the low infection rate of ticks and the generally low risk to persons with sporadic or short-term exposure. Neither of two studies of American soldiers stationed in central Europe found a clinical case, although one seroconversion in 3297 person-months of exposure, an infection rate of 0.9 per 1000 person-months, and four seroconversions in 959 persons (0.4%) were detected.[83,110] With the dissolution of the former Soviet Union and increasing commerce with eastern Europe, interest in the risk of TBE's being acquired by travelers to Europe and Russia has increased. The available data suggest that the risk is low for most travelers and that vaccination is not indicated except for unusual circumstances of prolonged stay in an endemic area.

The seasonal distribution of cases lags roughly 1 month behind that of tick activity and extends from April until November. The peak incidence in Sweden is in August; in Austria, the peak occurs in June and July, with a secondary rise in October.

Milk-borne TBE previously accounted for 10 to 20 percent of all cases in central Europe. Infections frequently were acquired from consuming unpasteurized milk or cheese from infected goats, sheep, and cows, and outbreaks resulting in thousands of cases have been reported. Transmission from infected milk now

Figure 188–13 The geographic distributions of Russian spring-summer encephalitis and European tick-borne encephalitis correspond to the ranges of their principal tick vectors; however, transmission is highly focal within this range because of the locations of biotopes that support viral circulation.

is a rare occurrence, but as recently as 1994, an outbreak in Slovakia led to 7 cases in a group that regularly drank raw milk from a family goat.[58] Also, an outbreak of 21 human cases caused by contaminated cheese produced from unpasteurized sheep milk has been reported.[132] Contact infection, acquired during slaughter of an infected goat, also has been observed.

CLINICAL MANIFESTATIONS

Seroepidemiologic studies indicate that as many as 90 percent of human infections with TBEV remain asymptomatic or result in a nonspecific illness.[2,6,34,54] The classic manifestation of the European form of TBE is an acute febrile illness characterized by a biphasic course consisting of a nonspecific prodromal syndrome followed by central nervous system (CNS) disease (Fig. 188–14).[30,129] Infection with TBEV may occur solely as the primary, nonspecific phase without the secondary CNS phase.[23,78] Infection with Far Eastern strains of TBEV results in a more severe, monophasic illness that progresses directly to neurologic involvement with a poorer prognosis for survival and full recovery. TBE has been observed in all age groups. The median age in pediatric case series is 8 to 10 years (range, 0 to 17 years).[16,36,74,76,127] The youngest patient with serologically and virologically documented TBE described in the literature was a 17-day-old infant.[50] Congenital infection has not been reported.

The clinical features of TBE in children are summarized in Table 188–4. The diagnosis of TBE should be considered in all acutely ill patients with fever, CNS abnormalities, and a history of potential tick exposure or ingestion of raw milk in an area

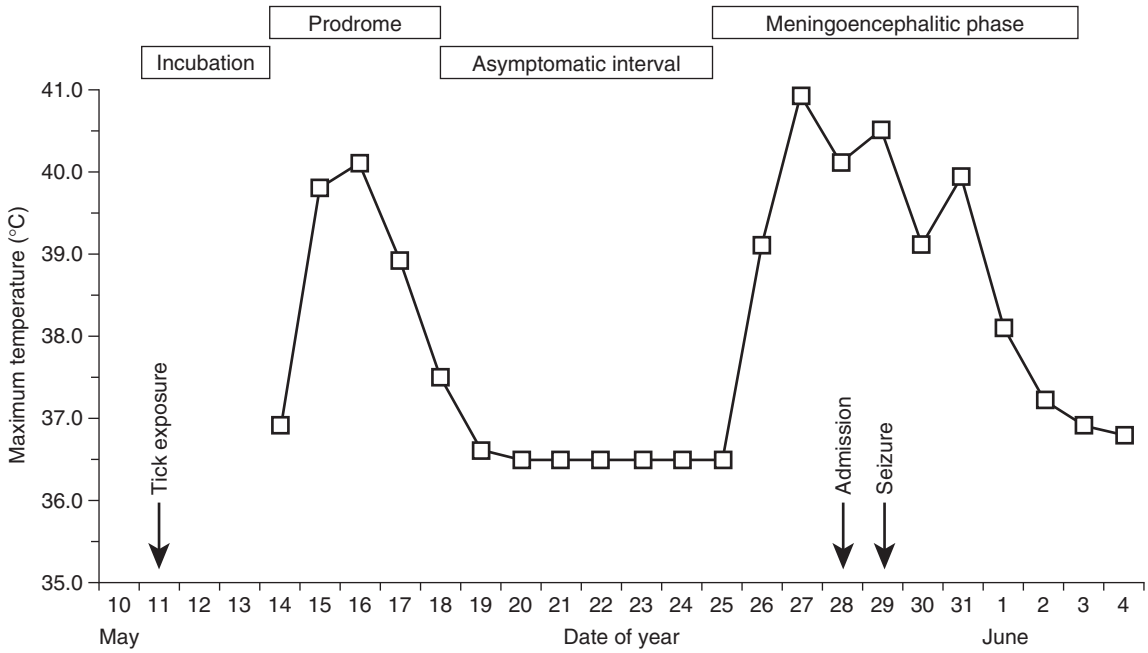

Figure 188–14 Clinical course of tick-borne encephalitis (TBE) in a 5-year-old boy exposed to a tick bite in a known endemic area for TBE in the pre-alpine region of central Switzerland. Lumbar puncture on admission revealed mild cerebrospinal fluid (CSF) pleocytosis (14×10^6/L, 50% polymorphonuclear cells). Serum anti-TBE virus IgM and IgG were present; serum and CSF antibodies against *Borrelia burgdorferi* were absent. CSF enteroviral polymerase chain reaction was negative. Recovery was uneventful.

TABLE 188–4 Clinical Features of Serologically Documented Tick-Borne Encephalitis in 5 Pediatric Case Series (333 children)

	Rate (%)
History	
Tick exposure	47-78
Biphasic illness	77-90
Major Symptoms at Presentation	
Fever >38.0° C	100
Headache	90-100
Vomiting	60-90
Central Nervous System Signs	
Nuchal rigidity	74-90
Photophobia	10-25
Impaired consciousness	9-11
Ataxia or tremor	5-26
Seizures	0-5
Paresis	0-5
Extent of Central Nervous System Involvement	
Meningitis alone	49-89
Meningoencephalitis	9-48
Meningoencephalomyelitis	0-5
Fatal outcome	0
Cerebrospinal Fluid Parameters	
Pleocytosis >15 × 10^6/L	98-100
Glucose normal	100
Protein elevated	9-55
Abnormal electroencephalogram	80-87

Data from references 16, 36, 52, 74, 76, 127.

endemic for TBE. A high degree of diagnostic awareness is required because the clinical presentation of TBE itself is nonspecific. After an incubation period of 2 to 28 days, in most cases 7 to 14 days,[24,36,74,76,129] the patient may have a prodromal illness consisting of fever, malaise, nausea and vomiting, headache, myalgia, and, occasionally, upper respiratory tract symptoms.[24,36,60,129] Defervescence occurs after 2 to 7 days, and the patient subsequently remains asymptomatic for 1 to 20 days, usually 2 to 10 days.[24,36,60,74,127] This prodromal illness may be absent. In various case series, a biphasic course was reported in 30 to 90 percent of children with TBE.[36,52,74,76,127] An abrupt onset of fever, headache, emesis, and symptoms of meningeal irritation heralds the beginning of the second phase of disease.[76] In adults, no association exists between the length of the incubation period and the severity of clinical illness.[52] The typical evolution of fever in a child with TBE is shown in Figure 188–14.

In this second phase of illness, most affected children (50 to 90%) have meningitis without clinical evidence of parenchymal CNS involvement.[36,59,64,76,88,105,127] In adult patients, by contrast, meningitis without encephalitis or myelitis occurs in 20 to 60 percent of cases.[2,52,60,101,120] On physical examination, fever, signs of meningeal irritation, and photophobia are the most common features.[76,127] In uncomplicated cases, patients defervesce within 5 to 10 days.[36,74,76,127] Meningoencephalitis or meningoencephalomyelitis (or both) manifested by impaired consciousness, seizures, and focal neurologic signs, including limb paresis, occurs in 0 to 34 percent of children.[16,36,52,74,76,127] In a large series of 139 pediatric patients with TBE meningoencephalitis, Lesnicar and coworkers[74] observed tremor in all patients, impaired consciousness in 27 (7%), ataxia in 18 (5%), behavioral changes in 16 (4%), cranial nerve paresis in 14 (4%), and limb paresis in 11 (3%). In a series of 13 children, Harasek[36] observed ataxia in 10 patients, somnolence in 4, paresthesias and seizures in 2 each, and central facial palsy and nystagmus in 1 each. In 2 of these patients, transient unilateral shoulder girdle weakness that occurred during the second week of CNS disease suggested involvement of the cervical anterior horn or radiculitis. Overall, limb or cranial nerve pareses occur in 0 to 5 percent of children with TBE (see Table 188–4). In a series of 133 children with TBE, Cizman and colleagues[16] reported transient pareses in 5 patients and irreversible hemiparesis in 1.

In large case series of predominantly adult patients, a paralytic course secondary to bulbar, spinal, or radicular injury was

observed in 5 to 25 percent of cases.[52,56,83,120,124,129] Unilateral, flaccid paresis of an upper extremity is the most common manifestation of lower motor neuron disease complicating adult TBE.[83,124,129] Involvement of the cranial nerves occurs somewhat less frequently and is revealed most commonly by external ocular muscle paralysis (usually cranial nerve VI), peripheral facial palsy (VII), otovestibular manifestations (VIII), or involvement of the pharyngeal muscles (IX, X, XI).[24,52,83,122] Lower extremity weakness and, occasionally, autonomic nervous system affliction manifested as bladder dysfunction also may occur.[24,53,122] Whereas most manifestations of parenchymal CNS involvement evolve during the acute stage of TBE, paralysis resulting from radiculitis may develop up to 14 days after the onset of CNS disease.[36,66]

As many as 5 percent of children with TBE experience seizures during the acute stage of TBE.[16,36,127] Because most patients are older than 6 years and thus are unlikely to suffer from febrile seizures, these episodes probably reflect encephalitis. In adults, seizures have been observed in less than 2 percent of patients.[24,52]

Extracerebral manifestations of TBE seldom are reported and are of minor clinical relevance. Mild hepatitis[41,52] and electrocardiographic abnormalities have been described in adults.[125] A single case of myopericarditis in a child with TBE has been reported.[25]

The peripheral white blood cell count is not altered in a characteristic way. Although it is usually in the normal range, both leukopenia and moderate leukocytosis may be found.[36,76,122] In adult patients, several investigators observed leukopenia during the viremic prodrome and normal or moderately elevated white blood cell counts during the second phase of illness.[52,60,76,80] In a report describing hematologic values during the prodromal phase of TBE, 23 of 28 (82%) patients had mild to moderate thrombocytopenia (60 to 130×10^9/L), with values returning to normal during the second phase of illness.[80] Cerebrospinal fluid (CSF) analysis in children with serologically proven TBE reveals predominantly mononuclear pleocytosis in all patients. However, as with enteroviral meningitis, neutrophils may predominate during the first 1 to 3 days of illness.[48] Typically, the CSF white blood cell count is 100 to 1000×10^6/L.[36,63,74,76,122,127] On occasion, lower values occur, as reported by Krausler and associates,[59] who found less than 100×10^6/L in 24 of 75 (32%) pediatric cases. Wahlberg and colleagues[129] reported an absence of pleocytosis in 18 percent of 94 adult patients examined. Harasek[36] could not find any correlation between the CSF leukocyte count and the severity of clinical disease. In contrast, some investigators[52,53,56] reported that adult patients with a high CSF white blood cell count (>300×10^6/L) were more likely to experience a severe course of TBE and persistent neurologic sequelae. CSF pleocytosis disappears within 4 to 5 weeks of the onset of acute CNS disease. The CSF glucose concentration is normal,[76] and the protein concentration is normal or moderately elevated (<1000 mg/L),[36,60,76,122] with evidence of dysfunction of the blood-brain barrier in most patients.[53]

Electroencephalographic examination findings during acute TBE usually are abnormal and characterized by a nonspecific reduction in rhythmic background activity, bilateral periodic slowing, and, rarely, focal abnormalities.[36,51,52] Attenuation of background activity with periodic delta groups has been shown to correlate with parenchymal CNS involvement in adult TBE patients.[51] Reorganization of electroencephalographic activity commonly lags behind clinical improvement, and abnormalities may persist for months to years.[36,51,127]

The limited information available on magnetic resonance imaging in children with severe TBE indicates that parenchymal lesions characteristically are located in the thalamus (Fig. 188–15).[16,52,55,130] The diagnostic and prognostic value of neuroimaging studies in pediatric TBE has not been established. In adults, magnetic resonance imaging studies may detect abnormality in approximately 20 percent of patients.[52] Focal lesions are more likely to be found in those with severe neurologic abnormalities[52] and are confined mainly to the thalamus.[5,9,52,77,98,128,130] Less frequently, lesions are located in the basal ganglia,[5,52,77,98] cerebel-

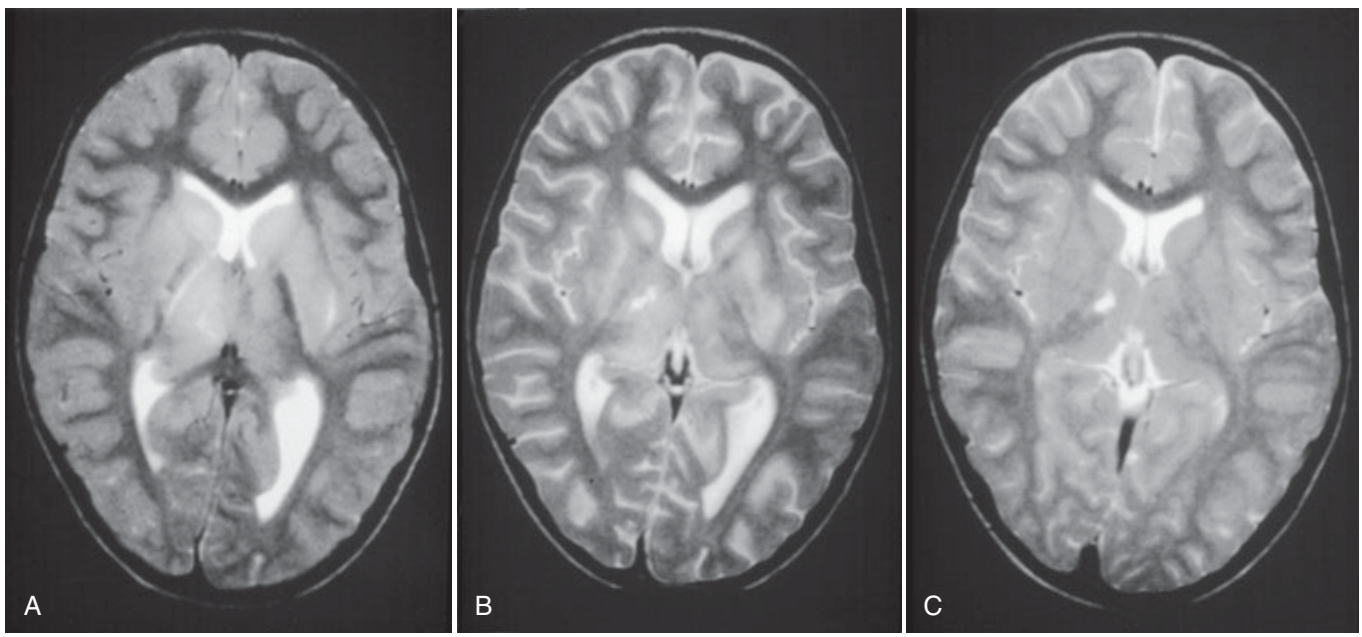

Figure 188–15 T2-weighted magnetic resonance imaging series of a 5-year-old girl with a severe course of tick-borne encephalitis. **A,** Acute phase. Note the T2 hyperintensity in the right side of the thalamus, basal ganglia, and diencephalon. **B,** One month later, partial recovery of T2 hyperintensity and enlargement of cerebrospinal fluid spaces can be seen. **C,** Three months later, normal T2 intensity and a cerebrospinal fluid–filled cavity in the right side of the thalamus are apparent. *(Courtesy of Professor David Nadal, M.D., University Children's Hospital, Zurich, Switzerland.)*

lum,[9,52] brain stem,[10,16,52] and anterior portions of the cervical spine.[9,16]

PATHOLOGY

CNS findings are mainly those of acute meningeal inflammation and focal gray matter encephalomyelitis. The white matter rarely is involved. Macroscopic findings include congestion of the leptomeninges and swelling and hyperemia of the cerebral parenchyma, particularly in the brain stem and cervical region of the spinal cord.[31,90] Petechial hemorrhages are seen in the brain stem, the anterior horns of the spinal cord, and, less consistently, the cerebellum and the anterior central region of the cortex. Histologic changes are dominated by infiltration and ganglion cell damage in the gray matter of these same areas. Changes are particularly pronounced in the anterior horns of the cervical spine (consistent with the poliomyelitis-like manifestations of paralytic courses of TBE),[114] the medulla oblongata, the cranial nerve nuclei of the pons, and the Purkinje cell layer of the cerebellum.[31] Inflammatory foci are characterized by lymphocytic perivascular infiltration and various stages of degenerative changes in neuronal cells. Areas of neuronal necrosis are characterized by perifocal edema, lymphocytic and neutrophilic infiltration, and, at a later stage, nodular microglial proliferation at sites of complete neuronophagia. The presence of granzyme, B-expressing, cytotoxic T cells in close contact with TBE-expressing neurons indicates that immune mechanisms contribute to tissue injury in these areas.[28] Rarely, the spinal nerve roots, spinal ganglia, and peripheral nerves are involved. Spongiform changes, particularly after protracted illness, appear as sharply defined areas of softening with minimal inflammatory reaction. In the Far Eastern form of the disease, extensive poliomyelitis of the spinal cord with destruction of anterior horn cells, particularly in the upper cervical and lower lumbar areas, and poliomyelitis of the brain stem are noted.

PATHOGENESIS

Tick-mediated inoculation of TBEV and viral replication within local dermal cells are followed by lymphatic spread to regional lymph nodes, where further replication occurs.[53] Subsequently, viremia leads to generalized infection, especially of reticuloendothelial cells, followed by secondary rounds of viremia that result in neuroinvasion. Viral penetration of the CNS occurs through capillary endothelia and by TBEV-infected, infiltrating mononuclear cells. Envelope glycoprotein E, the immunodominant TBEV-encoded surface protein, mediates attachment to and fusion with the host cellular membrane.[82] The molecular mechanisms of neural invasion by TBEV have not been elucidated in detail. Current knowledge of the molecular pathogenesis of TBEV has been reviewed elsewhere.[37-39]

LABORATORY DIAGNOSIS

Because neither clinical nor CSF findings differentiate TBE from other causes of meningitis or meningoencephalitis, the diagnosis of TBE rests on demonstration of specific antibody by serologic testing. The presence of specific serum IgM or a significant rise in titer of specific IgG antibody in paired sera (or both) is diagnostic of TBE[44,45,53] unless the patient previously received TBE vaccine doses. Enzyme-linked immunosorbent assay (ELISA) has replaced complement-fixation, hemagglutination-inhibition, and neutralization assays in the routine laboratory diagnosis of TBE.[43,45] ELISA technology offers increased sensitivity, reliably differentiates between IgM and IgG antibodies, and, in contrast to neutralization, uses nonviable viral antigens.[40,105] For the detection of specific anti-TBEV IgM, an IgM capture ELISA system has proved to be more sensitive and specific than is the conventional three-layer ELISA system because high titers of specific IgG and rheumatoid factor do not interfere with IgM binding.[40,105] With this method, specific IgM virtually always can be demonstrated during the acute illness and thereafter may persist for as long as 9 months.[44,53,105] The highly sensitive capture ELISA format allows a determination of anti-TBEV IgM, even in serum samples obtained late during the acute illness, when high titers of specific IgG already are present. A potential problem of TBEV IgG ELISA systems is cross-reactivity with other flaviviruses, notably yellow fever virus, dengue virus, and Japanese encephalitis virus.[21,22,92] This limitation should be considered in the interpretation of seroprevalence studies and in patients with a relevant travel or immunization history.

Specific IgM and IgG also can be measured in CSF.[40,105] Detection of TBEV-specific intrathecal antibody production by ELISA is highly specific for the diagnosis of TBE but somewhat less sensitive than is determination of serum IgM during the first several days of CNS disease.[45,53] Intrathecal TBEV antibody assays are less widely used in clinical practice, but they may be useful if serum antibody titers fail to differentiate between infection- and vaccine-induced immunity.

Detection of virus or viral RNA is technically feasible, but it is not used routinely in clinical practice. TBEV can be recovered from blood by viral culture, but because detectable viremia occurs during the prodromal stage (when the diagnosis of TBE seldom is considered), culture is not useful in clinical practice. TBEV may be recovered from the brain tissue of patients who died at an early stage of disease.[17] Amplification of TBEV-specific RNA by reverse transcription–polymerase chain reaction (RT-PCR) has been established for detection of TBEV in ticks[99] and in humans.[119] Primers that amplify the highly conserved 5′ noncoding region of the TBEV genome have been shown to be sensitive and specific.[118] Successful amplification of TBEV-specific RNA from blood, CSF, or brain tissue has been reported.[18,119,126,130] However, like culture, RT-PCR usually is positive only during the prodromal stage and thus generally is not useful in clinical practice.[50]

DIFFERENTIAL DIAGNOSIS

The clinical course of TBE is nonspecific in most cases, and a history of exposure to ticks in an endemic area can be elicited in 40 to 75 percent of pediatric patients.[36,52,74,76,88,117,127] Because serologic confirmation of the diagnosis is not available immediately in most cases, the differential diagnosis includes a wide spectrum of diseases causing fever and CNS manifestations.

Enteroviruses are the most common cause of symptomatic CNS infection in children during the warm seasons in regions where TBE is prevalent. Fever in enteroviral infection may occasionally be biphasic,[86] although the duration of both the first phase and the asymptomatic interval usually is shorter than that noted in TBE.[14] Routine tests of CSF do not differentiate between the two entities. Skin and mucosal manifestations are indicative of enteroviral infection rather than of TBE, whereas encephalitis and myelitis can occur in both. Enteroviral meningitis is diagnosed most readily by PCR of CSF[111] or by culture of virus from CSF and mucosal surfaces. Mumps meningitis is to be considered in the differential diagnosis in cases without parotid enlargement, particularly in areas with low rates of mumps immunization.[123] The diagnosis of mumps meningitis is made by viral culture of CSF or by detection of specific serum IgM antibody. Although it is a rare occurrence in childhood, herpes simplex virus (HSV) encephalitis always should be considered in the differential diagnosis. Because the case-fatality rate of HSV encephalitis is greater

than 90 percent if it is left untreated, therapy with intravenous acyclovir should be initiated without delay, if that diagnosis is thought possible. The combination of fever, which may be biphasic,[106] and localizing signs observed by neurologic examination, electroencephalographic studies, or magnetic resonance imaging[47] suggests HSV encephalitis and rarely occurs in pediatric TBE, particularly if the temporal lobe or the orbital portion of the frontal lobe is affected. Meningeal irritation usually is absent in HSV encephalitis. The diagnosis of HSV encephalitis is confirmed by PCR of CSF.[8,72] Epstein-Barr virus encephalitis can occur in immunocompetent children, and Epstein-Barr virus shares with TBEV a preference for causing thalamic and basal ganglia lesions.[52,95] Other viral causes include common respiratory tract viruses such as influenza, parainfluenza, and adenovirus.

Among bacterial infections, partially treated pyogenic meningitis, encephalitis in association with *Mycoplasma pneumoniae* infection,[108] and encephalopathy caused by *Bartonella henselae* may resemble TBE. Tuberculous meningitis runs a subacute course, and although near-normal CSF chemistry may be recorded very early in the disease, hypoglycorrhachia invariably develops and CSF protein rises to high levels. CNS infection by *B. burgdorferi* is particularly important in the differential diagnosis because in Europe, this pathogen and TBEV are transmitted by the same tick vectors, *I. ricinus* and *I. persulcatus*, and because one of the most prevalent European genospecies, *Borrelia garinii*, is more neurotropic than is *B. burgdorferi* sensu stricto.[107] In contrast to TBE, the incubation period for early neuroborreliosis in children generally is 4 to 10 weeks, high-grade fever is unusual, and most patients have cranial nerve paresis. However, several cases of concomitant infection with TBEV and *B. burgdorferi* have been reported in the literature,[1,15,62,94] and coexistence of TBEV and *B. burgdorferi* in ticks has been documented.[58] In some cases of TBE, persistent or late-appearing limb paralysis has been suggested to be attributed to concomitant, but undiagnosed, borrelial radiculoneuritis rather than TBE-related myelitis with anterior horn involvement.[62] In this situation, diagnostic evidence of Lyme borreliosis should be sought because this condition requires antimicrobial therapy. Seroepidemiologic and clinical evidence indicates that concomitant infection with TBEV and *Anaplasma phagocytophilum*, the agent of human granulocytic ehrlichiosis, also may occur.[58,79]

TREATMENT

No specific antiviral therapy is available to treat TBE. Specific hyperimmune globulin is indicated exclusively for passive immunization within 96 hours of exposure to ticks. Anecdotal evidence suggests that the administration of TBE hyperimmune globulin thereafter may have a detrimental effect on the course of disease.[3,70] In severe cases, supportive therapy is aimed at preventing the development of sequelae related to increased intracranial pressure, seizures, and bulbar dysfunction. After the acute stage, neurorehabilitation may be necessary for patients with motor, cognitive, or emotional disturbances. Because TBE rarely causes a chronic seizure disorder, prolonged anticonvulsive therapy seldom is indicated in patients who had convulsions during acute disease.

PROGNOSIS

The main risk factor for neurologic residua and a fatal outcome of TBE is advanced age.[2,52,120] Substantial sequelae appear to be infrequent in children,[36,52,64,76,115,127] although no prospective long-term follow-up studies of pediatric TBE patients have been performed to date. Individual cases of children with persistent neurologic damage, including hemiparesis,[16,50,55,130] unilateral arm paresis,[129] epilepsy,[50,55,104] and extrapyramidal movement disorder, have been reported.[55] Recent evidence, however, indicates that subtle abnormalities in attention and psychomotor skills may persist in many children for prolonged periods.[115] In adult patients, long-term neurologic defects are observed in 2 to 10 percent of patients with clinical evidence of parenchymal CNS involvement during the acute illness.[2,30,52,56,129] Risk factors for persistent sequelae have been assessed by Kaiser[52] and, by univariate analysis, include impaired consciousness (i.e., Glasgow Coma Scale score <7), ataxia, paresis, abnormal findings on magnetic resonance imaging, CSF pleocytosis greater than 300×10^6/L, and CSF protein concentration of more than 600 mg/L. Gunther and colleagues[33] reported that encephalitic symptoms were associated with low levels of intrathecal IgM in early stages of TBE. Paresis of the extremities and ataxia are the most common persistent findings on neurologic examination.[2,24,52,56,81,120] Much more common, however, are ill-defined manifestations such as chronic fatigue, headache, sleep disorders, memory dysfunction, and emotional disturbances, which are reported by most adults recovering from TBE and persist for months to years.[24,73,120] In some patients, electroencephalographic findings may remain abnormal for prolonged periods, with seizure activity occasionally demonstrated.[36,115] Most of these patients are asymptomatic, although epilepsy secondary to TBE has been described infrequently.[36,89] The reported case-fatality rate in adult TBE patients is approximately 1 percent in large series,[2,24,30,52,56,81] with most deaths being attributed to severe bulbar encephalitis or related to underlying cardiovascular disease in elderly patients.[24] Fatal outcome of TBE in children is exceedingly rare.[84]

PREVENTION

General preventive principles include avoidance of known endemic areas of TBE, use of protective clothing, and rapid removal of ticks attached to the skin. The topical repellent DEET (*N,N*-diethyl-*m*-toluamide) has a definite albeit moderate effect against ticks.[109] Because of its potential neurotoxicity, the content of DEET in products used for children should not exceed 15 percent.[12,96] These measures are effective in reducing tick exposure and transmission of TBEV to some degree. Pasteurization of raw milk prevents enteric transmission of TBEV.[4,57]

Reliable protection, however, requires active immunization against TBE. Inactivated whole-virus vaccines are produced in Austria (Baxter), Germany (Chiron), and Russia. The vaccines are made from different central European TBEV strains and are produced by concentrating and purifying cell culture fluid from infected chick embryo cells. Adjuvants (aluminum hydroxide) are added to the formalin-inactivated cell culture fluid. The Russian vaccine is an inactivated, unconcentrated cell culture fluid from infected African green monkey kidney cells. TBE vaccine is available in the United States under investigational drug exemption to military personnel deployed in endemic areas.[11,19]

Currently approved TBE vaccines are approved for children 12 months of age and older. Basic immunization consists of three doses given at 0, 1 to 3, and 5 to 12 months. Rapid immunization schedules also are available. The vaccines are immunogenic and safe.[29,30,32,97,116] Seroconversion rates for neutralizing antibodies after the first, second, and third dose are 70, 95, and 99 percent, respectively.[65,69] Reliable protection is achieved 2 weeks after administration of the second dose.[134] Data on the kinetics of vaccine-induced serum antibodies led to the recommendation for booster doses every 3 years.[65,67] Recent data on the decay of neutralizing antibodies, however, indicate that protection may last considerably longer.[102,103] Minor adverse events (fever and local reactions) are reported by 4 to 15 percent of vaccinees after receiving the first dose and less frequently after receiving subse-

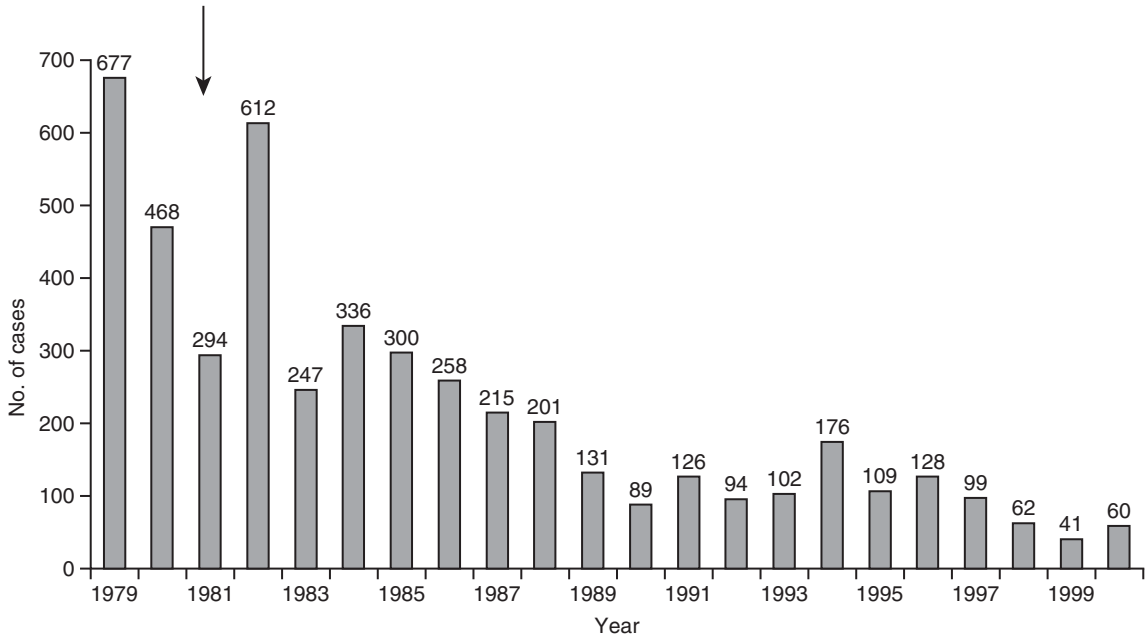

Figure 188–16 Annual number of cases of tick-borne encephalitis in Austria before and after the introduction of mass immunization in 1981 *(arrow). (Data obtained from the International Scientific Working Group on Tick-Borne-Encephalitis, www.tbe-info.com/report.)*

quent doses.[67,97,133] Mostly transient neurologic adverse events temporally associated with the administration of TBE vaccine have been reported rarely.[29,30,112,113,116] Their true incidence has not been established. Based on passive notification of adverse events, an incidence of one neurologic illness in 1 million doses of TBE vaccine has been calculated.[42] Placebo-controlled trials of vaccine efficacy have not been conducted. Observational studies in Austria using historical controls indicate that the effectiveness of the vaccine is greater than 90 percent.[68,71]

In Austria, the TBE vaccine is recommended for mass immunization of all potentially exposed individuals. Since the beginning of the vaccination campaign in 1981, a dramatic reduction in nationally notified cases has been observed (Fig. 188–16).[71,135] Mass immunization is the probable cause of this decrease because neighboring countries (e.g., Switzerland, southern Germany, Slovenia) reported stable or increasing numbers of cases of TBE during the same time. In these and other endemic countries of central and eastern Europe, authorities recommend immunization of school-aged children and adults who live in endemic areas and have a risk of exposure to ticks.[16,91] In younger children, TBE vaccination is not recommended routinely because neurologic complications are exceedingly rare.[16,74]

A commercial TBE hyperimmune globulin for pre-exposure and postexposure immunoprophylaxis is available in Europe.[3] In several countries, however, this product is not approved for use in children younger than 14 years because numerous breakthrough TBEV infections have been observed in recipients of postexposure prophylaxis.[52,55,77,128] Among these recipients, some unusually severe cases raised concern about a causative role of TBE immunoglobulin in enhancement of disease.[7,77,130] Antibody-dependent enhancement, a mechanism of pathogenicity proposed in dengue hemorrhagic fever,[87] was discussed as a possible explanation,[55] but experimental data in support of this hypothesis in TBE are lacking.[61]

CHAPTER 188h

Other Flaviviral Infections

Theodore F. Tsai

POWASSAN ENCEPHALITIS

Powassan virus was isolated from a fatally infected patient and named after the patient's Ontario town of residence. The virus is classified within the antigenic complex of tick-borne flaviviruses. Two viral lineages in North America may represent genotypes circulating in separate enzootic cycles.[11] More than half of surviving cases suffer from residual neurologic deficits, frequently associated with upper cervical damage leading to upper extremity muscle weakness and wasting.

EPIDEMIOLOGY AND ECOLOGY

More than 30 cases of naturally acquired Powassan encephalitis have been reported from North America and others from Russia. Two cases of laboratory-acquired Powassan infection have been reported as well. Approximately one third of the cases from North America have occurred in children younger than 15 years, and the preponderance of cases have been in males. With one exception, infections have occurred in the summer or early fall; one patient had an onset in December.[16,21,31]

The probable sites of exposure of cases have been confined to the eastern states and Canadian provinces, principally Maine, Vermont, New York, Pennsylvania, and Massachusetts and Ontario and Quebec.* However, two cases have been reported from upper Wisconsin and Michigan, and the known and suspected geographic distribution of the virus is even wider, with isolation of virus recorded from Connecticut, Massachusetts, West Virginia, Colorado, South Dakota, and California, and serologic evidence of infection in humans or animals reported from Wyoming, North Dakota, British Columbia and Alberta, and Sonora, Mexico.[22] Viral isolates also have been recovered from ticks, mosquitoes, and birds from southeastern Russia, and evidence of viral transmission in China and Southeast Asia has been reported.[19-21]

In North America, the virus is transmitted by *Ixodes cookei*, *Ixodes marxi*, *Ixodes spinipalpus*, and *Dermacentor andersoni* to small mammals (ground hogs, *Marmota monax*; red squirrels, *Tamiasciurus hudsonicus*; weasels, *Mustela*; skunks, *Mephitis*; foxes, *Vulpes*; chipmunks, *Tamias straiatus*; mice, *Peromyscus*; snowshoe hares, *Lepus americanus*; voles, *Microtus*; and gray squirrels, *Scurius carolensis*). In Russia, the virus is transmitted by *Ixodes persulcatus* and various *Haemaphysalis* ticks; *Apodemus* mice and *Microtus* voles are the principal vertebrate hosts. Powassan virus is transmitted trans-stadially in *D. andersoni* and *Ixodes pacificus*, and transovarial transmission has been shown in other species. Powassan virus infection in humans probably is rare because the implicated ixodid ticks are encountered infrequently and usually confine themselves to host animal burrows and people. Human infections are associated with outdoor activities and subsequent exposure to infected ticks. In one case involving a 13-month-old infant, however, the infecting tick was brought into the home by a domestic cat.[38] Animal serosurveys indicate that infections occur in dogs, and exposure to ticks on domestic animals may be an alternative source of infection. In a human serosurvey from Ontario, 3 percent had Powassan antibody; however, in other areas, the prevalence of antibody has been less than 1 percent. Experimental studies have shown that *Ixodes scapularis*, the vector of Lyme disease, can transmit Powassan virus, and a field isolate has been reported.[8] The absence of a Powassan epidemic paralleling that of Lyme disease suggests differences in the agents' transmission cycles.

Although no Powassan cases have been attributed to milk-borne transmission, experimental studies have shown that domestic goats can be infected with Powassan virus and can shed virus into milk. In a survey of New York goats, 2 percent had serologic evidence of past Powassan virus infection, which indicates the possibility of milk-borne Powassan virus infection in the United States.[40]

Clinical and pathologic signs of encephalitis have been produced in experimentally infected horses. Unlike Lyme disease and some rickettsial infections, Powassan virus infection can be transmitted after a brief period of tick attachment.[12]

CLINICAL MANIFESTATIONS

The incubation period may be several weeks after known exposure to a tick. Fever, headache, lethargy, retro-orbital pain, and photophobia are early symptoms that may be followed abruptly by changes in sensorium, generalized or focal seizures, paresis, and paralysis. Focal neurologic signs have been observed in most patients in whom clinical descriptions have been reported. In one patient, olfactory hallucinations, focal seizures, and localizing electroencephalographic irregularities were concordant and thus suggested a temporal lobe focus.[13,16]

Three deaths have been reported, and significant neurologic sequelae (hemiplegia, quadriplegia, aphasia), including residual shoulder girdle atrophy and weakness analogous to sequelae that occur after European and Far Eastern tick-borne encephalitis, are common occurrences. In another patient, wasting and weakness of a leg consistent with lumbosacral poliomyelitis were reported.[7,23]

Clinical and experimental observations of tick-borne encephalitis suggest that chronic central nervous system infection characterized by a convulsive disorder (epilepsia partialis continua), weakness, and dementia may occur after recovery from the acute phase of illness. A retrospective study of 22 Canadian patients with a similar clinical syndrome and in whom histologic changes in the brain resembled those of chronic tick-borne encephalitis showed no evidence of Powassan virus infection. However, none of these patients had a history of acute encephalitis.

LABORATORY DIAGNOSIS

Virus has been recovered from the brains of patients with fatal cases of the disease. A serologic diagnosis can be achieved more rapidly by detecting specific IgM antibody in acute-phase serum or spinal fluid. A serologic diagnosis by hemagglutination inhibition and complement fixation is specific in most instances, but heterologous antibodies from other flavivirus infections (e.g., dengue, St. Louis encephalitis) or vaccinations (yellow fever) may obscure some results.

DIFFERENTIAL DIAGNOSIS

The clinical findings of encephalitis in a patient with a history of a tick bite acquired in an endemic area should suggest the possibility of Powassan encephalitis. However, because ixodid tick bites may be inconspicuous, a negative history does not exclude the diagnosis. Other viral agents of encephalitis, especially eastern

*See references 5, 7, 10, 13, 16, 18, 23, 31, 35, 36, 38, and 40.

equine encephalitis virus and California group viruses, which are prevalent in New York State and eastern Canada, should be considered in the differential diagnosis. Lyme disease, because of its known geographic distribution and association with a tick vector, also may be associated with neurologic complications; however, a history of having a typical rash and arthritis should differentiate the conditions. In a series of 145 clinical encephalitis cases at a Canadian tertiary pediatric hospital, one was attributed to Powassan virus.[24] An imported case of tick-borne encephalitis, encountered in Ohio but acquired in Austria, underscores the value of obtaining a travel history.

TREATMENT AND PREVENTION

No specific therapy for Powassan encephalitis is available. Personal protective measures to avoid tick bites are advised. Consumption of unpasteurized goat milk should be avoided because of the theoretical risk of contracting Powassan virus infection and the well-documented risk of acquiring other infections associated with raw milk. Inactivated tick-borne encephalitis vaccines licensed in Europe do not cross-protect against Powassan virus infection.

ROCIO ENCEPHALITIS

Rocio encephalitis virus was isolated from the brain of a fatal case of encephalitis in a patient during an outbreak in 1975.[15] The virus is related peripherally to viruses in the Japanese encephalitis viral antigenic complex. The disease has occurred exclusively in the coastal São Paulo State and adjacent Paraná State, Brazil, principally in the Ribiera Valley and Santista lowlands. More than 1000 cases were documented in outbreaks between 1975 and 1977; only one symptomatic case (in an infant) has been recognized subsequently, although recent infections (IgM in asymptomatic individuals) were documented in later serosurveys in northeastern and southeastern Brazil. Thus, the virus may be transmitted undetected in an area beyond the Ribiera Valley. The viral transmission cycle has not been elucidated; however, field and laboratory observations suggest transmission between birds and *Psorophora* or *Aedes* mosquitoes. Humans are dead-end hosts. Human cases have occurred principally in men with outdoor occupations, especially fishermen.

The incubation period is estimated to be 7 to 14 days. Prodromal symptoms of fever, headache, malaise, vomiting, and conjunctivitis are followed by mental status changes, meningismus, and motor impairment. Cerebellar signs occur commonly. Signs of bulbar involvement also are seen. Coma and a fatal outcome occur most commonly in children (30%) and in the elderly; overall, 10 percent of cases are fatal and 20 percent of patients have neuropsychiatric sequelae. Pathologic findings of encephalitis principally involve the thalamus, cerebellar dentate nucleus, brain nuclei, brain stem, and spinal cord.

The diagnosis should be suspected in patients with acute encephalitis and a consistent history of exposure. Virus has been isolated from autopsy brain specimens. The presence of virus-specific IgM in cerebrospinal fluid or a fourfold change in serum antibody titer confirms a case. IgM in serum is presumptive evidence of recent infection. Treatment is supportive. Emergency application of adulticides and larvicides has been used to control epidemics.

LOUPING ILL VIRUS

Louping ill virus derives its name from an old Scottish term describing the leaping motions of encephalitic sheep. Historical accounts of the disease in sheep date from 1795, and the virus was isolated from ill sheep in 1931. Louping ill virus, a member of the antigenic complex of tick-borne flaviviruses, is transmitted by *Ixodes ricinus* to sheep, deer, mountain hares, and grouse.[19-21] Grouse may become infected by ingesting infected ticks.[17] The disease is enzootic in pasturelands of Scotland, England, Wales, and Ireland. Naturally acquired human infections have occurred mainly in sheep farmers, veterinarians, and abattoir workers or butchers who had direct contact with animals. Antibody prevalence is 10 percent in abattoir workers in enzootic areas. Laboratory-acquired infections are common and account for half of all reported human cases. These observations suggest that infections are transmitted easily by direct mucous membrane or respiratory infection. Tick-transmitted cases also have been reported. Hospital surveillance in an enzootic area found louping ill virus to be a rare occurrence that was responsible for less than 0.5 percent of encephalitis cases. Related tick-borne viruses in Spain, Greece, Norway, and Turkey have not been associated with human disease. The virus is shed in sheep and goat milk, but unlike tick-borne encephalitis, milk-transmitted cases have not been reported.

The incubation period can be as short as 3 days. Three clinical syndromes have been described.[9] Approximately a third of patients have a self-limited influenza-like illness with fever, headache, dizziness, and myalgias. The febrile illness is followed by clinical improvement and a second encephalitic phase in more than half the cases. Neurologic symptoms include meningismus, severe headache, vomiting, drowsiness, and tremor; one fatal case was reported. A poliomyelitis syndrome with muscle weakness or paralysis has been described in a few cases. Hemorrhagic fever also was reported in one atypical laboratory-acquired case.

The diagnosis should be suspected in febrile patients with occupational or other exposure, especially if central nervous system symptoms are present. The diagnosis is confirmed serologically by demonstrating virus-specific IgM in cerebrospinal fluid or serum or by a fourfold rise in antibody titer or real-time polymerase chain reaction.[29] Treatment is symptomatic. The use of unpasteurized milk products should be avoided. Persons with outdoor exposure in enzootic areas are advised to use repellents and other protective measures against tick bites.

KYASANUR FOREST DISEASE

Kyasanur Forest virus was isolated in 1957 after an outbreak of hemorrhagic fever, initially suspected to be the first outbreak of yellow fever in Asia, appeared in India in the Kyasanur Forest of Mysore (now Karnataka).[2,32] The virus, including the Alkhurma subtype, is a member of the tick-borne flaviviral antigenic complex.[19-21,28] It is transmitted by *Haemaphysalis spinigera* (among numerous other ixodid ticks) to forest rodents, insectivores, and possibly bats; cattle and other large animals are important tick hosts but do not appear to amplify the virus. Langur monkeys sicken in epizootics and die of the infection. Human cases occur in dry-season epidemics, chiefly in persons who have contact with forests. The disease has spread contiguously as villagers clear forests for pastureland. Between 1982 and 1988, 1847 cases were reported, 254 of which were fatal. Hyperendemic transmission in Karnataka state continues despite the introduction of mass vaccination.[32]

After an incubation period of 3 to 8 days, illness begins abruptly with fever, headache, myalgias, chills, and gastrointestinal symptoms.[33,34] Facial hyperemia, conjunctival suffusion, lymphadenopathy, hepatomegaly, papulovesicular enanthem, and petechiae are the principal physical findings. Bradycardia and hypotension are present and may progress to become life-threatening. Epistaxis, hemoptysis, and gastrointestinal bleeding may be prominent. Bronchopneumonia and hemorrhagic pulmonary edema complicate the illness in 40 percent of cases. Renal failure may develop. After the resolution of symptoms and an afebrile interval of 1 to 3 weeks, fever, recurrence of symptoms,

TABLE 188–5 Less Commonly Recognized Flaviviral Infections

Virus	Clinical Syndrome	Geographic Distribution	Transmission Cycle	Mode of Transmission

DC, direct contact with infected sheep; E, experimental infection; L, laboratory-acquired infection; V, vector-borne infection; Z, zoonotic infection.

and meningoencephalitis develop in 15 to 50 percent of cases, as occurs in tick-borne encephalitis. Leukopenia with a left shift, thrombocytopenia, and an elevated hematocrit reflecting hemoconcentration are seen. Elevations in liver enzymes occur commonly. The case-fatality rate is 3 to 15 percent; keratitis and iritis occur as sequelae. The virus frequently can be isolated from acute-phase blood specimens (<12 days after onset), or the diagnosis can be confirmed serologically. A formalin-inactivated chick embryo cell culture vaccine is produced locally in India and is distributed in epidemic areas.

OMSK HEMORRHAGIC FEVER

Omsk hemorrhagic fever virus was isolated from a viremic human during a series of outbreaks in the Omsk region of western Siberia from 1945 to 1949.[37] Two subtypes have been differentiated.[32] Between 1945 and 1958, approximately 1500 cases were reported in the forest-steppe zones within the Omsk, Novosibirsk, Kurgan, and Tjumen regions. The virus is related antigenically and genetically to other tick-borne flaviviruses. It circulates among microtine rodents and *Dermacentor* ticks, which results in a spring–early summer peak of infected ticks with a smaller peak in early autumn. The disease epidemiology changed after muskrats were introduced into the region; extensive muskrat epizootics occurred and led to an increase in human cases and geographic spread of the disease. Muskrat trappers, who may be infected by direct contact with infected tissue or blood, continue to account for most cases, but tick-borne infections also occur in other local residents, including children. Seroprevalence rates range to higher than 30 percent in some locations. Laboratory-associated cases frequently have occurred in workers not immunized with tick-borne encephalitis vaccine.

The incubation period may be as brief as 2 to 4 days. The illness is similar to Kyasanur Forest disease, but with an earlier onset of hemorrhagic phenomena (e.g., epistaxis). Hemorrhages tend to be less severe, neurologic complications are less frequent, and the overall mortality rate is lower (less than 3%). Neuropsychiatric sequelae, however, occur commonly. Uncomplicated cases usually resolve within 7 to 10 days. The diagnosis is made serologically. Vaccine produced against tick-borne encephalitis virus is reported to provide some degree of cross-protection.

OTHER FLAVIVIRAL INFECTIONS

Flaviviral infections of lesser public health importance or that are recognized less frequently are listed in Table 188–5. Several of the viruses are known to cause human illness only after laboratory exposure. The clinical manifestations of these infections may differ from naturally acquired infection because of their mode of transmission by respiratory, mucosal, or other routes of infection. Other viruses that cause nonspecific syndromes of febrile illness were discovered through fever surveys; although few cases may have been reported, their prevalence may be underestimated because few cases are recognized. Because immune responses to repeated flaviviral infections lead to broadly cross-reactive responses, serologic diagnosis may be misleading unless extensive cross-neutralization assays are undertaken. An outbreak of Zika virus infection in Yap, causing fever and arrhythmias, could easily have been misdiagnosed as dengue had PCR and cross-neutralization assays not been undertaken.[25] Of the zoonotic flaviviruses (transmitted from animal to animal without an arthropod vector), only Rio Bravo and Modoc viruses are known to cause human illness.

CHAPTER 189

Hepatitis C Virus

Alan N. Mayer ✪ Maureen M. Jonas

Since 1990, when hepatitis C virus (HCV) was recognized as the primary cause of non-A, non-B hepatitis, this infection has assumed a prominent role in the field of hepatology and infectious disease. Substantial progress has been made in understanding the virology, epidemiology, and natural history of HCV infection. An estimated 4 million people in the United States have been infected with this virus, of whom 3.2 million are chronically infected. HCV has become the most common cause of hepatitis, cirrhosis, and end-stage liver disease in this country. However, HCV does not always cause significant morbidity, at least in the first 2 or 3 decades after infection, a finding that raises specific issues for treatment of pediatric patients. HCV remains the subject of numerous studies around the world, in laboratory and clinical settings, and significant advances in defining the molecular virology, viral-host interactions, and effective therapy are being accomplished.

VIROLOGY

Before the discovery of HCV, the agent responsible for most transfusion-associated non-A, non-B hepatitis was presumed to be a small, enveloped virus. This conclusion was based on the ability to pass the infectious agent through an 80-nm filter and to inactivate it with organic solvents. In 1989, a group at the Chiron Corporation[41] identified a cDNA derived from human plasma that shares sequence similarities with flaviviruses and pestiviruses. Intrahepatic inoculation of the full-length RNA transcribed from this clone subsequently was shown to induce hepatitis in chimpanzees.[109,202] Until recently, research in the molecular virology of HCV was hampered by the lack of a cell culture system in which to propagate the virus. In 2005, a critical technologic breakthrough was achieved in the establishment of such a cell culture system.[124,194] Although much remains to be learned about the molecular virology of HCV, henceforth progress should be rapid.

HEPATITIS C VIRUS VIRION

HCV is the prototype virus within the new *Hepacivirus* genus of the family *Flaviviridae*. The HCV virion particle is approximately 30 to 60 nm in diameter, based on filtration studies[2,3] and electron microscopy.[18,175] The capsid is thought to be enveloped by a lipid bilayer because infectivity is inactivated by chloroform.[78] The envelope contains two viral glycoproteins, E1 and E2, and the nucleocapsid contained within is composed of core protein and the viral RNA genome.

HEPATITIS C VIRUS GENOME

The HCV genome is a 9.6-kb positive, single-stranded RNA (Fig. 189–1). A single open-reading frame (ORF) encodes a 3000-

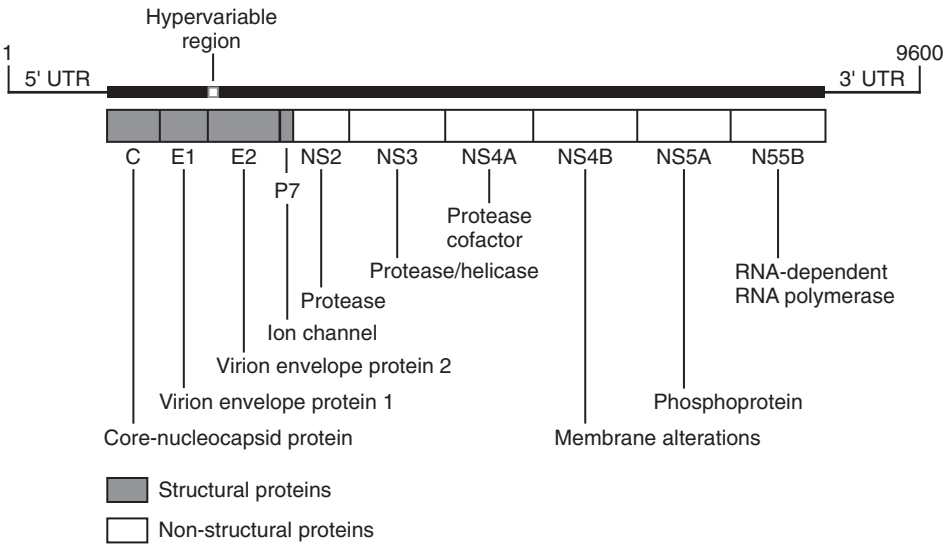

Figure 189–1 Schematic of the hepatitis C virus genome and encoded proteins.

amino acid polyprotein that undergoes proteolytic processing to yield at least 10 individual gene products. Structural proteins (core and envelope) are encoded in the 5′ quarter of the genome. Downstream is a small integral membrane protein, p7, which appears to function as an ion channel.[74] Nonstructural proteins (proteases, helicase, and RNA polymerase) comprise most of the remaining portion. The flanking 5′ and 3′ nontranslated regions (NTRs) contain conserved sequences that regulate both genome replication and ORF translation.

The HCV 5′ NTR is approximately 340 nucleotides long and forms a structure similar to that of the 5′ NTRs of the related pestiviruses and GB virus B (GBVB).[33] Computer modeling and cleavage protection studies of the HCV 5′ NTR predict the formation of a similar internal ribosome entry site (IRES)–like structure that includes the canonical four stem loops, suggesting a similar 5′ cap-independent mechanism of translation.[189] Furthermore, in vitro expression[165] and mutational analysis of the HCV 5′ NTR support this conclusion. Deletion analysis reveals both positive and negative regulatory elements in the 5′ NTR. Deletion of stem loop I increases translation efficiency, whereas domains II and III are essential for IRES activity. The base of domain III and the initiation codon are particularly important for several interactions subsequent to binding of the 40S ribosomal subunit, leading to initiation complex formation.[152] Stem loop IV contains the initiator AUG, and its destabilization leads to more efficient translation initiation.[82,83,86] Both viral and host-derived factors can bind to the IRES region and alter its activity in vitro,[3,66,77] but in vivo roles of the 5′ NTR remain to be defined. The 5′ NTR also contains sequences that are essential for HCV replication.[64]

The 3′ NTR contains sequences required for viral replication and has a three-part structure composed of (1) a variable region immediately downstream of the stop codon of the polyprotein, (2) a polypyrimidine tract of variable length, and (3) a highly conserved 98-nt-long RNA element designated the X-tail.[64,110,185] The X-tail forms three stem loops, one of which (SL2) forms long-range base pairs with sequences located in the coding sequence of NS5B that are essential for viral replication.[63]

Translation of the single ORF results in a single polyprotein precursor that is cleaved by both host and viral proteases to produce 10 viral proteins.[123] The structural proteins (core, E1 and E2) are processed by host signal peptidase, and the nonstructural proteins subsequently are cleaved by virally encoded NS2-NS3 and NS-3 proteases. The core protein is at the polyprotein N-terminus, and, together with the viral RNA genome, it comprises the HCV nucleocapsid. The core protein is highly conserved[34] and may be involved in other processes such as apoptosis,[84] intracellular signaling,[104] transcription,[177] and modulation of the host immune response.[106] The envelope proteins, E1 and E2, are *N*-glycosylated with hydrophobic C-termini that anchor the proteins to the lipid envelope. E2 binds specifically to the host protein CD81,[156,157] a finding suggesting that it mediates viral entry into the cell. Unlike the core protein, E1 and E2 demonstrate considerable sequence heterogeneity from different isolates. In particular, the N-terminal of E2 contains a hypervariable region (HVR1) that is an important viral neutralization determinant.[176] HVR1 is also a T-cell determinant, able to activate helper T-cell responses during HCV infection. The sequence variability of E2 may account, at least in part, for the ability of HCV to elude the host immune system and establish persistent infection.

The 3′ region of the genome encodes seven nonstructural proteins that participate in post-translational proteolytic processing and replication of HCV genetic material. The HCV polyprotein undergoes processing through a sequence of successive cleavage steps.[201] Initially, host protease generates the NS2-NS3 fusion protein precursor. This intermediate species autoproteolyzes to liberate the individual NS2 and NS3 proteins. NS3, which encodes a multifunctional serine protease, then cleaves the remaining junctions of the HCV polyprotein. NS4A complexes with NS3 and serves as a cofactor for the cleavage of the NS3/4A and NS4B/5A junctions. Whereas the N-terminal domain of NS3 contains the proteolytic domain, its C-terminal contains an RNA helicase that may function during viral replication. NS4B is an integral membrane protein that alters membrane structure and contains a guanosine triphosphate–binding domain essential for HCV replication.[55] Its function may be related to the observation that HCV replicates in a subcellular structure termed the *membranous web*. NS5A is a multifunctional protein with key roles in modulating viral replication and altering the intracellular milieu in response to viral infection.[130] NS5A is localized to the membranous web of infected cells, and mutations in NS5A are found in culture-adapted strains. NS5A is found in single- and multiple-phosphorylated forms. Adaptive mutations that favor increased viral replication in vitro are associated with a decrease in hyperphosphorylated NS5A. Despite these observations, the exact biochemical function of NS5A remains unknown.

Some investigators have designated amino acid residues 2209 to 2248 of the NS5A protein the "interferon sensitivity determining region" (ISDR) because mutations within the region are

thought to be associated with variations in responsiveness to interferon (IFN) therapy.[56,143,196,200] However, this designation remains somewhat controversial.[148,170] Additional variables such as virus genotype (see later) and synergistic mutations (in the NS2 gene) may play a role in modulating IFN responsiveness.

The NS5B protein is the RNA-dependent RNA polymerase thought to be the replicative polymerase for HCV.[121] The enzyme lacks proofreading activity, and this characteristic may account for the high error rate and consequent sequence divergence.[58,149] NS5B activity requires a primer for initiation of polymerization, which is thought to occur in vivo by self priming at the 3′ terminal NTR hairpin.[17] The crystal structure of the NS5B apoenzyme reveals a globular shape unique among polymerases and implicates new structural features important for binding the RNA template and cognate ribonucleotide substrates.[128] These crystallographic results also provide a structure-based framework for biochemical analyses and drug design efforts. In vitro inhibitors of HCV RNA-dependent RNA polymerase have been reported.[2] Yet to be elucidated are the exact steps by which the polymerase replicates the HCV genome, such as in vivo primer requirements, replicative intermediates, and post-replication processing, all of which may provide targets for antiviral agents.[123]

HCV exhibits extensive genetic heterogeneity. Isolates from around the world have been divided into 6 major genotypes, designated 1 through 6, and more than 100 subtypes. The genomes of the most divergent HCV isolates differ by up to 35 percent. The impact of HCV genotypes on clinical factors, such as viremia level and severity of liver disease, remains controversial. However, clear differences in response to antiviral therapy have been demonstrated, with improved response to treatment correlating with genotypes 2 and 3 versus genotype 1 or genotype 4.[76,80,102,132,137,193] Within infected individuals, HCV circulates as quasispecies, a mixture of closely related but distinct genomes. Viral genomes of quasispecies typically differ by 1 to 2 percent. In an infected person, quasispecies may either be present from the onset, the product of simultaneous transmission, or develop over the course of time as a result of accumulations of mutations. Such mutations may enable more efficient HCV replication or evasion of host immune responses. Certain regions of the genome are hypervariable and are responsible for most, but not all, of the genomic differences in quasispecies. HVR1 is found at the N-terminus of the envelope E2 protein, at amino acids 384 to 410. This site probably is on the surface of the folded envelope protein and represents a neutralization epitope for humoral immunity. Although the mutation rate at this site is rapid, it may be even further accelerated in patients subjected to immunostimulation. Conversely, the rate is decreased in individuals with agammaglobulinemia. Appearance of antibodies against HVR1 in infected subjects is followed by emergence of new variants in the region. For these reasons, HVR1 is thought to play a role in HCV persistence and chronic infection. HVR2 is a second hypervariable region in the E2 protein, identified in genotype 1b isolates.

REPLICATION CYCLE

Hepatocytes are the primary site of viral replication. HCV entry into the cell is mediated by a specific interaction between viral envelope proteins and a host-cell surface receptor, and this interaction may underlie host specificity and cellular tropism. The HCV envelope protein E2 has been shown to bind the host-cell surface protein CD81,[157] and using an in vitro cell fusion assay, researchers demonstrated that both E1 and E2 proteins are required for fusion.[183] Additional host proteins other than CD81, such as the low-density lipoprotein receptor, may be required for viral entry.[174] Evidence from studies of other *Flaviviruses* support a model in which entry through receptor-mediated endocytosis is followed by envelope fusion with the endosomal membrane to release the nucleocapsid into the cytoplasm. There, ribosome binding to the viral genome enables translation of the encoded polyprotein, with the formation of a replicative ribonucleoprotein complex. The resulting negative-strand intermediate then serves as a template for the production of positive-strand RNA. Virion assembly begins with interaction between the noncoding region of the RNA genome and the capsid proteins to assemble the nucleocapsid. As with other *Flaviviruses*, budding of virus likely occurs into intracellular vesicles, which release free virus from the cell by exocytosis. How HCV acquires its envelope or specifically excludes cellular proteins and RNAs during virion assembly is not known.

IMMUNOPATHOGENESIS

HCV persists in approximately two thirds of those it infects, and the outcome (clearance versus persistent infection) is determined within 6 months of exposure to the virus. Which path an infection takes depends on the effectiveness of the adaptive immune response. As described later, cell-mediated immunity seems to play a critical role in resolving the infection, whereas the role of humoral immunity is less well understood. Antibodies to several HCV proteins can be detected by 7 to 30 weeks after infection is established. However, the extraordinarily high rates of chronic disease and persistent viremia observed in humans suggest that HCV fails to induce an effective neutralizing antibody response. After a primary HCV infection, repeat challenge of convalescent chimpanzees with the same or different strains of HCV results in the reappearance of viremia, caused by infection with the subsequent challenge virus.[60] This reappearance of viremia is associated with mild elevations of alanine aminotransferase (ALT) and histopathologic signs of acute hepatitis. Conversely, resolution of HCV can occur in the absence of anti-HCV antibodies in chimpanzees.[47] Although antibodies to the E2 region of the HCV genome have been identified as potential neutralizing antibodies, their effectiveness is extremely limited, and their role in protection has not been demonstrated.[61,176] Individuals with acute, self-limited HCV infection have early, vigorous responses from both T-helper lymphocytes ($CD4^+$) and cytotoxic T cells ($CD8^+$).[47,119] The sequences that are recognized by HCV-specific T-helper cells are immunodominant (the NS3 protein in particular) and conserved among HCV genotypes.[52] Individuals with various major histocompatibility class (MHC) haplotypes demonstrate efficient presentation and recognition of a set of common viral epitopes.[114] These findings suggest that these antigens may be important factors in development of immune reactivity and possibly may be considered in vaccine development. HCV-specific T-helper ($CD4^+$) and T-suppressor lymphocytes become detectable in blood 3 to 4 weeks after infection occurs. T-cell infiltration of the liver correlates with increase in ALT activity because cytotoxic lymphocytes lyse HCV-infected cells. Effector functions of the $CD4^+$ and $CD8^+$ cells include synthesis of a series of proinflammatory and anti-inflammatory cytokines. After a patient recovers from HCV infection, circulating HCV-specific T-helper and cytotoxic lymphocytes may be present for decades, even when the humoral response declines and HCV antibodies become undetectable.[182]

Although the exact mechanism for viral persistence and the frequent development of chronic infection is not known, HCV-specific cytotoxic lymphocytes are found at only very low levels in the blood of chronically infected individuals.[79] In contrast, in one report, patients with resolved infection had cytotoxic lymphocytes directed against a broader distribution of epitopes, and the cells exhibited stronger responses to stimulation.[118] Consistently, patients with stronger polyclonal cytotoxic lymphocyte responses in blood and liver have lower levels of HCV viremia.[79] Both HCV-specific and nonspecific $CD8^+$ T cells are found in

the liver of infected persons; immune-mediated liver disease is thought to be initiated by the HCV-specific cells but amplified by the nonspecific cytotoxic cells.

Several mechanisms have been postulated to explain HCV persistence.[30] They include escape of innate immune response by up-regulation of MHC expression on infected cells, viral sequence variations and mutations that eliminate humoral and cellular target epitopes, and lack of susceptibility of HCV to T-cell cytokines. Viral variant sequences are seen more commonly in the presence of cytotoxic lymphocytes than in the absence of these cells.[39] HCV may actively interfere with the host immune response; inhibition of activation of the IFN-inducible protein kinase has been demonstrated by sequences in the HCV E2 and NS5A proteins.[111,186] The cellular immune defect is HCV-specific and does not seem to affect the response to other infectious agents.

EPIDEMIOLOGY

An estimated 3 percent (170 million) of the world's population has been infected with HCV.[10] It is the most common cause of non-A, non-B hepatitis. In a report from the United States, the prevalence of anti-HCV positivity was 1.6 percent (4.1 million persons), and of these, approximately 80 percent tested positive for HCV RNA. This percentage translates to 3.2 million persons chronically infected with HCV.[14] Approximately 28,000 new infections occur each year.[4] This figure represents a substantial decline in incidence starting in the 1990s[13] (Fig. 189–2), when the first-generation anti-HCV test was used for screening donated blood.

Young adults are at highest risk for HCV acquisition because they are most likely to engage in high-risk behaviors. As risk of HCV from transfusion has diminished, the proportion of cases associated with intravenous drug abuse has increased rapidly, up to more than 40 percent. Heterosexual contact is reported in 6 percent of infected individuals, household contact in 3 percent, and occupational exposure in only 2 percent. In those with repeated percutaneous exposures, such as injecting drug users, the prevalence is 60 to 90 percent, whereas in health care workers, it is 1 percent. Volunteer blood donors, who represent the lowest-risk group, have a seroprevalence of less than 0.5 percent. In several early studies, the proportion of cases of HCV infection with no identifiable risk factor had been consistently 35 to 40 percent.[5] However, although high-risk behavior may not be documented within months of establishing an HCV diagnosis, a history of more remote risk factors can be obtained in most of these cases. Thus, more than 90 percent of new cases can be attributed to parenteral or sexual behaviors.[4]

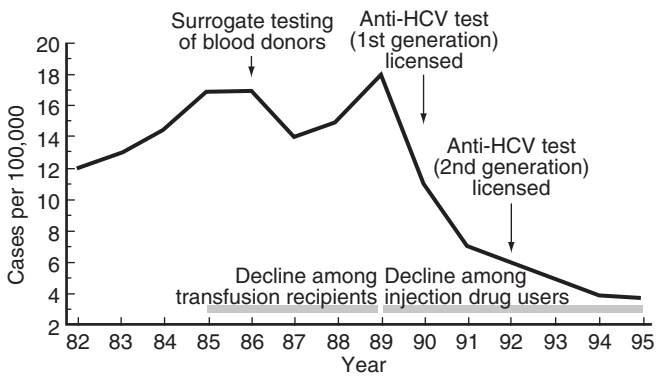

Figure 189–2 Estimated incidence of acute hepatitis C in the United States from 1982 to 1995. The incidence did not change substantially from 1995 to 1999. HCV, hepatitis C virus.

In the United States, a wide variation in seroprevalence exists among different subgroups.[14] The male population is twice as likely to have anti-HCV antibody as is the female (2.1% versus 1.1% prevalence). Among persons with a history of injection drug use, the seroprevalence is 57.5 percent. A positive correlation exists between HCV exposure and lifetime number of sexual partners, ranging from 0.5 to 12 percent seroprevalence in those having no sexual partner or a single sexual partner versus more than 50 partners, respectively. The peak prevalence with regard to age remains among those born between 1945 and 1964.

The distribution of the different genotypes of HCV varies geographically.[53,140] Genotypes 1 and 2 are distributed widely throughout the world. Genotype 1 is predominant in North and South America, Europe, and Asia, although the relative frequencies of the different subtypes vary. Genotypes 1a and 1b both are common in the first three continents, but only 1b is predominant in Asia. In the United States, genotypes 1a and 1b each account for more than 40 percent of isolates. Type 3 also is distributed widely, and subtype 3a has been seen with increasing frequency among persons who acquired their infection recently. However, subtype 3b has been identified only in Japan, Nepal, Thailand, India, Bangladesh, and Indonesia. Type 4 is predominant in northern and central African countries, and type 5 occurs in southern Africa. Type 6 has been found in 20 to 30 percent of isolates in Hong Kong and Vietnam.

INCIDENCE AND PREVALENCE IN CHILDREN

Infection with HCV occurs throughout the world, in children as well as in adults. The prevalence in pediatric groups varies both by risk factors and geographic location. No large seroprevalence studies have been done in the general pediatric population in the United States, but one survey in an adolescent population revealed very low seroprevalence.[98] Data from other countries disclose widely varying frequencies of HCV infection. A Japanese study of 1442 healthy children found a prevalence of 0 percent anti-HCV positivity.[184] At the other end of the spectrum, 14.5 percent of 696 randomly sampled children in Cameroon were anti-HCV seropositive.[146] Studies looking at household contacts of known HCV-infected individuals found intermediate seroprevalence rates, which increased proportionally to the age of the contact,[1,159,166] a finding indicating that duration of contact was an important risk factor. Mechanism of transmission in these settings has not been defined clearly, but the association with low socioeconomic status indicates the role of crowding and hygiene.

In the United States, the HCV antibody seroprevalence is 0.2 percent in children younger than 12 years old and 0.4 percent in those aged 12 to 19 years.[7] Children at risk for acquiring HCV infection are listed in Table 189–1. Before 1990, the predominant risk for acquisition of HCV infection by children was by blood or blood product transfusion. Although this mode of transmission is responsible for many current cases of pediatric HCV infection, new infections in children are caused primarily by perinatal (vertical) transmission, as was demonstrated in Italy.[26] The incidence of new infections in children through this mechanism is not known, but it could be estimated from the prevalence of HCV infection in women of child-bearing age and the risk of transmission with each pregnancy.

TRANSFUSION-ASSOCIATED INFECTION IN CHILDREN

Until screening became routine in 1992, receipt of blood or blood products had been the major mode of transmission of HCV to children.[24,147] In addition to erythrocyte and platelet transfusions, implicated products included clotting factors,[21,103] plasma,

Children Repeatedly Transfused with Blood or Blood Products for
Thalassemia
Sickle cell anemia
Other congenital anemias
Hemophilia
Hemodialysis
Hypogammaglobulinemia or other immunodeficiency (intravenous immunoglobulin)
Children with a History of Transfusion before 1992 for
Childhood malignant disease, especially leukemia
Major surgery: cardiac, orthopedic
Prematurity, neonatal intensive care
Conditions requiring extracorporeal membrane oxygenation
Adolescents with the Following High-Risk Behaviors
Intravenous drug use
Intranasal drug use
Body piercing or tattooing
Infants of Hepatitis C Virus–Infected Mothers

and intravenous immunoglobulin.[32] Transmission to children by transplanted organs or tissues also has been demonstrated.[73,155] In general, as described for adults, the risk of acquisition of HCV increases with the number or units of blood or blood products received.[99,105,145] Children from all parts of the world who have been transfused multiple times with either blood or acellular blood products, such as patients with thalassemia[113,164] or hemophilia,[21] have infection rates from 50 to 95 percent. Children with moderate but not ongoing exposure to transfusions, such as those who have been treated for childhood malignant diseases,[125,168] those who have been treated with hemodialysis[73,99] or extracorporeal membrane oxygenation,[145] or those who have undergone surgery for congenital heart disease,[147] have intermediate seroprevalence rates of 10 to 20 percent. Screening of donated blood for anti-HCV, the use of recombinant and heat-inactivated clotting factors, and the addition of virus-inactivating physicochemical processes in the production of immunoglobulin have reduced the incidence of HCV transmission drastically. However, these advances are relatively recent; many children infected with HCV through blood products are followed in clinical practices, and others are yet to be identified.

VERTICAL TRANSMISSION

Vertical transmission of HCV currently is the principal route of HCV infection in children. Both intrauterine and perinatal routes appear to be important. Since the mid-1990s, numerous studies have sought to identify the factors that could correlate with the rate of HCV transmission. The most important principle to emerge from these studies is that vertical transmission occurs almost exclusively when mothers have detectable HCV RNA. In the absence of HIV co-infection, the likelihood of HCV transmission increases with higher levels of maternal HCV viremia. In several studies, no women with fewer than 10^6 copies/mL of serum HCV RNA transmitted the infection to their newborns,[69,72,122,150] although such was not the case in one report from Italy.[163] Studies in the United States and Europe suggested a 4 to 6 percent perinatal transmission rate from viremic mothers.[46,57,70,135] This rate compares to a frequency of 40 to 90 percent for the perinatal transmission of hepatitis B virus. The frequency of anti-HCV seropositivity in newborns of HCV-infected women was shown to be 14 to 100 percent; in most instances, this antibody was present only transiently, a finding indicating that it had been acquired passively through placental transfer.[62,69,162,188]

Maternal co-infection with HIV increases the rate of perinatal HCV transmission four- to fivefold,[167] even without concomitant transmission of HIV. However, aggressive treatment of HIV-infected pregnant women that results in low or undetectable HIV levels at delivery may mitigate this increase in transmission of HCV.[46]

The question remains open as to when vertical transmission of HCV occurs. The possibility of in utero transmission in at least some cases was suggested by the detection of viremia in six infants on the day of birth.[163] However, in a prospective study, infection documented at birth by detection of HCV RNA in cord blood often was transient and not always predictive of eventual newborn infection.[46] A European study tested 54 HCV-infected children within 3 days of birth and noted that 17 (31%) of those infants infected with HCV were positive for HCV RNA, a finding suggesting in utero transmission.[142] If infection is not detected at birth, as is most often the case,[46,70] transmission around the time of delivery may be more important. The role of peripartum factors, such as prolonged rupture of amniotic membranes (≥6 hours) and the use of scalp monitors, has been examined, and there appears to be a correlation between these variables and increased risk of HCV transmission to neonates.[70,72,135,136] Cases of HCV transmission after cesarean births have been reported.[153] In one report, transmission frequency after vaginal delivery was 4 percent, and after cesarean delivery it was 6 percent.[163] When this topic was examined by taking into account the duration of ruptured membranes and comparing emergency with elective cesarean deliveries, once again the likelihood of transmission seemed to correlate with this factor rather than with the mode of delivery.[70] HCV transmission has been documented in women who have acute infection during the last trimester of pregnancy.[131] As noted earlier, in some instances, viremia in the neonates was transient and was not associated with the development of liver disease.[69]

Despite the detection of HCV in breast milk and colostrum,[142,169] breast-feeding does not appear to affect the rate of vertical transmission of HCV.[78] However, breast-fed babies of mothers co-infected with HIV have an increased risk of HCV transmission.[57] For example, none of 17 breast-fed infants born to HCV-positive, human immunodeficiency virus (HIV)–negative mothers was infected after follow-up of 12 to 27 months.[133] In another study, the perinatal transmission of HCV in breast-fed infants was 7 percent compared with 4 percent in formula-fed infants, but this difference was not statistically significant.[163] None of 76 breast milk samples from 73 anti-HCV positive German women contained HCV RNA, even though 62 of these women were HCV RNA seropositive.[158] Only 1 child had evidence of HCV infection detected 1 month after birth. Based on these data, currently there is no recommendation to avoid breast-feeding by HCV-infected women *unless* co-infection with HIV is present.

INTRAFAMILIAL AND OTHER HORIZONTAL TRANSMISSION

Horizontal transmission refers to transmission to children after the perinatal period or to transmission from infected children to others, such as family members or schoolmates. Studies of household transmission from Europe, South America, and Asia have been accomplished by screening household contacts of index cases for anti-HCV positivity; in some instances, further testing of seropositive contacts with polymerase chain reaction (PCR) for HCV RNA and even comparative genotype analysis[85] was done. In these studies, prevalence of anti-HCV seropositivity in household contacts varied from 0 to 14.8 percent.[1,12,35,40,49,144,159,181] Non-spouse seroprevalence rates were 0 to 6.5 percent. Risk of anti-HCV positivity increased with age or duration of exposure, or both.[40,159] Rates were particularly low in households of HCV-

infected patients with hemophilia.[31] The risk to children in the households of chronically HCV-infected individuals separate from perinatal risk was difficult to ascertain, but prevalence rates were very low (approaching zero) in the youngest children and increased steadily with increasing age.[1,50,144] Because the mechanism of nonsexual, nonperinatal infection of children in these families is not known, counseling to prevent this transmission is limited to avoidance of sharing household items such as razors, toothbrushes, and fingernail clippers. No justification exists at this time to have family members avoid sharing of eating utensils or bathrooms. HCV-infected adults should be educated about the extremely low likelihood of spreading HCV to their children by routine family contact, including kissing and day-to-day care.

Few data exist regarding the transmission of HCV from infected children to others. In a Spanish study, 80 household contacts (without independent risk factors for infection) of 27 HCV-infected children were tested. None of the parents was found to be infected, but an infected sibling (1/32) was identified.[36] In an Italian study of 44 index children, 1 parent was infected through an accidental needle stick, and no transmission to other children was demonstrated.[191] Thus, it appears that horizontal transmission of HCV between children is quite rare. There is no need to restrict school or daycare attendance, or participation in any routine activity including contact sports, for HCV-infected children.[9] In addition, notification of school personnel of a child's HCV infection is not required because routine universal precautions already recommended are adequate for children with HCV.[8]

OTHER MODES OF TRANSMISSION IN CHILDREN

The most frequent mode of transmission of HCV in adults is sharing of needles for the purpose of intravenous illicit drug injection. To the extent that older children and teenagers participate in this activity, they are at risk for acquiring infection. In fact, HCV infection occurs within 6 to 12 months after beginning injection drug use in most individuals.[67] Other percutaneous exposures that may be more common than is intravenous drug use in children and adolescents, such as body piercing and tattooing, have been implicated as risk factors in Italy,[139] but not in the United States.[45] Studies to evaluate these risks in the United States are ongoing. Intranasal administration of cocaine is considered a risk factor.[7] Sexual transmission of HCV is thought to occur by both homosexual and heterosexual activity,[6,187] but its importance to the overall prevalence of HCV infection is controversial.[151] The prevalence and causes of sporadic or community-acquired HCV infection in children, in the absence of a risk factor, are not known.

DIAGNOSIS

The use and significance of methods for diagnosing hepatitis C infection are summarized in Table 189–2 and Figure 189–3. Direct tests for the viral antigens of HCV in serum are not available. Assays for antibodies directed against several viral antigens have been facilitated by the genomic sequencing of HCV. Currently, the third-generation enzyme-linked immunosorbent assay (ELISA)-3 is the most widely used. It is based on several antigens from both the core (c22-3 antigen) and nonstructural (c200 antigen) regions, the latter including the c100-3 antigen used previously. Seropositivity for anti-HCV by ELISA indicates current or past infection with HCV. A nonreactive test result does not completely exclude either current or past infection because levels of anti-HCV positivity may be undetectable in early infection or may remain undetectable in individuals with altered immunity.

TABLE 189–2 Serologic Diagnosis of Hepatitis C Virus Infection

	Acute HCV	Resolved HCV	Chronic HCV
Anti-HCV ELISA-3	±	±	+*†
Anti-HCV IgM (experimental)	+	–	–
HCV RNA by PCR	+	–	+

**Should be confirmed with another test.*
†May be negative in immunosuppressed individuals.
ELISA, enzyme-linked immunosorbent assay; HCV, hepatitis C virus; IgM, immunoglobulin M; PCR, polymerase chain reaction.

Early problems with sensitivity and specificity of ELISA led to the development of a recombinant immunoblot assay (RIBA) for antibodies to the c100-3 antigen, as well as another viral antigen, 5-1-1, and superoxide dismutase.[54] Further refinement of this test led to the development of the RIBA-2, which incorporates recombinant antigens c33-C and c22-3.[190] RIBA has been replaced largely by PCR-based tests (see later).

Detection of HCV genomes in serum and tissue through the use of PCR currently is the principal method used to detect active infection. HCV RNA can be quantified using a variety of methods that differ in sensitivity, linear range, precision, and reproducibility. The most widely used quantitative PCR test can detect levels of virus down to 100 copies/mL of serum. A less cumbersome assay that uses branched DNA and alkaline phosphatase–labeled probes to detect and quantify viral nucleic acid has been applied to the detection and quantification of HCV RNA[117] (Quantiplex HCV-RNA Assay, Chiron Diagnostics, Emeryville, CA). The Quantiplex bDNA 2.0 test is as sensitive as are some quantitative PCR tests, and it has great accuracy at high viremia levels.[91] Real-time PCR based on the TaqMan chemistry system (Roche Molecular Diagnostic Systems, Indianapolis, IN) has increased sensitivity to less than 100 copies/mL, as well as high precision, good reproducibility, and a broad linear range. At this point, caution must be used because the values obtained by the different tests are not interchangeable. However, changes in viral load over the course of time using the same assay are meaningful. The adoption of the standardized measure of international units (IUs) has mitigated interassay variability.

In summary, the diagnosis of HCV infection in an individual with chronic hepatitis, defined as infection persisting for more than 6 months, includes the detection of anti-HCV positivity in serum; confirmation with a determination of HCV RNA should be determined by a qualitative PCR assay. The diagnosis of acute HCV infection is more problematic because anti-HCV positivity may not appear in serum for up to 2 months. In addition, immunocompromised individuals, including patients with hypogammaglobulinemia and immunosuppressed transplant recipients, may not mount an anti-HCV response. For these latter situations, the diagnosis is made by detection of HCV RNA in serum by either the PCR or branched DNA amplification technique. Quantitative HCV RNA testing is reserved for determination of therapeutic response.

CLINICAL FEATURES

In adults, acute HCV infection typically is mild and most often subclinical. There are no reports of the clinical manifestations of acute HCV infection in children infected either perinatally or through blood transfusion. Acute, severe hepatitis, with atypically high ALT values, jaundice, malaise, anorexia, and hepatomegaly, was seen in some of the children who were infected during the outbreak associated with intravenous immunoglobulin.[96] The reasons for this unusually severe presentation are not clear, but possibilities include greater amounts of virus inoculated, repeated

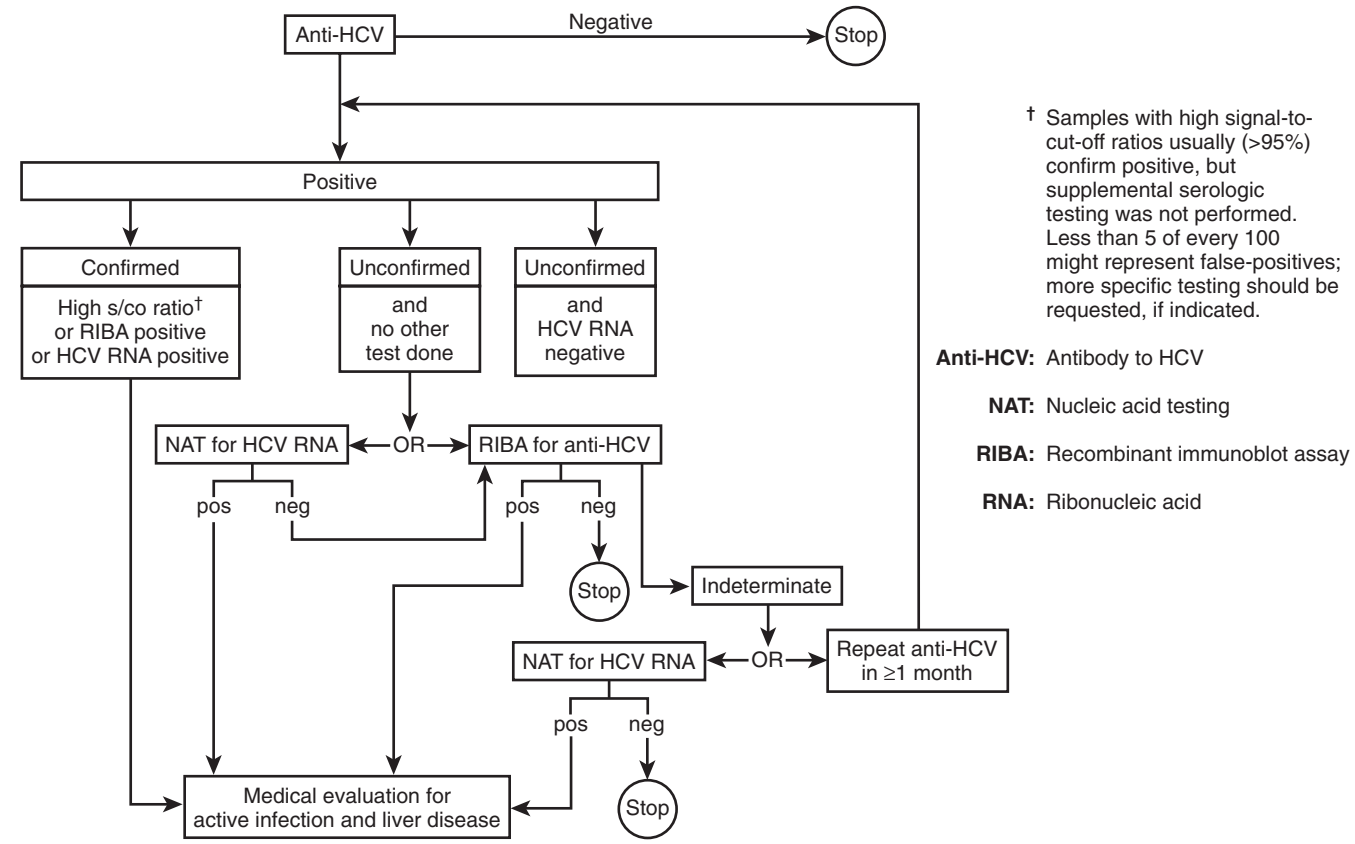

Figure 189–3 General algorithm for diagnosing chronic hepatitis C in children who are more than 1 year of age and in adults. inoculations, or the underlying immunodeficiencies in the hosts. Individuals who have clinically apparent acute hepatitis C with symptoms and jaundice have a higher likelihood of having acute, self-limited infection. No reports focus specifically on clinical features of chronic HCV infection in children. Studies of epidemiology, natural history, and treatment often describe the children as being asymptomatic or having nonspecific fatigue or abdominal pain, or both.[24,25,28,29,88,97,125,147] Most cases are identified by testing asymptomatic children who are recognized to have a risk factor for acquisition of HCV infection, such as receipt of transfusion before 1992 or an HCV-infected mother. Once infection is identified and serial ALT values are followed, most children are found to have modest elevations in the first years of infection, with normal or near-normal values for many subsequent years (Fig. 189–4). Non–organ-specific autoanti-bodies sometimes are found: antinuclear antibodies have been described in 7.5 to 11 percent, smooth muscle antibodies in 9 to 17.5 percent, and type 1 liver-kidney microsomal antibodies in 10 to 13 percent of European cases.[27,116] However, clinically apparent autoimmune manifestations are rare. One of us cared for a 13-year-old girl with HCV-associated cirrhosis who also had membranoproliferative glomerulonephritis with nephrotic syndrome,

a 6-year-old boy with chronic HCV and lichen planus, and a 17-year-old girl with HCV infection and cutaneous vasculitis that disappeared with antiviral therapy (unpublished data). HCV-associated cryoglobulinemia and porphyria cutanea tarda have not been reported in children. This low frequency of clinical signs or symptoms and the fact that "routine" serum ALT determinations are not done as part of pediatric medical care indicate that chronic HCV infection in children probably is underrecognized.

NATURAL HISTORY

Studies of the natural history of HCV infection in children are fewer and less definitive than are those in adults. Factors that influence the natural history of HCV infection in adults include age at infection, mode of acquisition, co-morbid disease, ethanol ingestion, and obesity. In children, age and mode of acquisition often are difficult to separate because most infections acquired in infancy are perinatal. Children treated for leukemia typically receive many blood transfusions, and such patients treated before 1990 have a very high rate of HCV infection.[11] In one cohort, prolonged follow-up (13 to 27 years) did not reveal serious liver disease.[126]

In contrast, an American study of individuals treated for childhood cancer revealed one death from liver disease and two deaths from hepatocellular carcinoma in the decades following HCV acquisition.[180] The same report described three (9%) cases of cirrhosis that developed 9 to 27 years after the diagnosis of the primary malignancy was established. Clearly, some cases of HCV infection acquired in childhood by transfusion are associated with serious liver disease in the decades following infection.

Children with thalassemia requiring chronic transfusions have a very high prevalence of HCV infection. Many individuals with hemophilia contracted HCV during childhood, before the availability of heat-inactivated and recombinant clotting factors. The natural history of transfusion-associated HCV infection may differ according to the underlying disease for which the transfusion is required. Secondary hemochromatosis in thalassemic patients may contribute to the hepatic injury as well as affect the response to therapy for HCV infection.[43,113]

Two studies addressed the natural history of HCV infection acquired early in life at the time of surgery for congenital heart disease. In a Japanese study, 29 children were followed for at least 4 years, and only 50 percent had persistent viremia. Although these children had histologic chronic hepatitis, none had cirrhosis in this time period.[138] A more recent study from Germany reported similar findings after a longer follow-up period. In that study, 14.6 percent of children who were transfused at the time of cardiac surgery were positive for anti-HCV 20 years later, but only 55 percent of these subjects were viremic at follow-up.[192] Only one of these HCV RNA–positive patients had an abnormal ALT value, which possibly was explained by the fact that the patient also was in congestive heart failure. Only 17 of the children underwent liver biopsy, and 1 child (5.9%), who had been co-infected previously with hepatitis B, had cirrhosis. Overall, the clinical course of these children seemed more benign than would be expected if they had been infected as adults. The frequency of viral persistence is lower than that reported in adults who were infected through transfusion. The reason for this relatively high spontaneous clearance rate is not clear. Conversely, few of the patients underwent liver biopsy, so the frequency of occult chronic liver disease is not known.

Understanding the natural history of perinatally acquired HCV infection has become increasingly important given that perinatal acquisition has become the major route of infection for pediatric patients. Because the chronic liver damage is thought to result largely from the immune response to the infection rather than to direct cytotoxicity, the immaturity of the host immune system at the time of infection conceivably could alter the course of the disease as compared with adults. Initially, several small reports from Japan and Italy were published regarding this issue.[25,154,171] More recently, larger patient series provided a broader perspective on chronic, perinatally acquired HCV. Infection acquired vertically frequently is associated with biochemical evidence of hepatic injury early in life. Spontaneous resolution of infection in some of these infants, even those with active hepatitis as suggested by abnormal ALT values, can occur, but in most children, perinatally acquired HCV follows a persistent course. In most cases, it causes only mild chronic hepatitis in the first 1 to 2 decades, and the degree of fibrosis correlates with the duration of infection. Cirrhosis can occur within a decade of acquisition of infection, but this outcome is much less common. A report of HCV 35 years after the initial acquisition of perinatal infection[38] described a more benign course than the other reports referenced earlier, with a higher spontaneous resolution rate and milder liver disease. A conclusion to be drawn from these studies is that the long-term management of chronic HCV in children will need to take into account the cumulative effects of the infection over the course of decades of life. Although the incremental progression of the disease may be slow and insidious, the long-term progression of fibrosis ultimately may lead to end-stage liver disease in a substantial number of middle-aged individuals infected when they were neonates. Balancing treatment side effects (see later) against the possibility of progression of disease thus can be difficult because of the high variability among individuals. The aggregate cost of medical care associated with HCV in children has been addressed.[94] Using epidemiologic data, estimates of treatment efficacy (sustained virologic response [SVR]), and severe complications (end-stage liver disease requiring transplant), the authors of this article projected the costs directly stemming from pediatric HCV infection during the next decade to approximately 250 to 350 million U.S. dollars. Approximately two thirds of this cost consists of monitoring, and one third consists of treatment costs. Childhood HCV may, therefore, exact a significant financial burden in the coming years.

HISTOPATHOLOGIC FEATURES OF THE LIVER IN HEPATITIS C VIRUS INFECTION

Histologic features of the liver associated with HCV infection in adults have been described in several series.[19,108,120,172] The major features are portal inflammation with lymphoid aggregates, varying degrees of steatosis, and bile duct injury (Fig. 189–5). In HCV-infected adults, severity of histologic abnormalities does not correlate with biochemical parameters of hepatic dysfunction, such as ALT levels. The implication is that patients may have progressive liver disease in the absence of clinical signs. Thus, histopathologic examination of the liver is an important tool in the understanding of childhood HCV infection.

Although histologic features in small numbers of HCV-infected children were described in several reports,[24,90,113,138] most cases were not systematically examined and scored by conventionally accepted scoring systems.[19,107,172] Varying degrees of necroinflammatory activity were noted, but fibrosis was not described uniformly; cirrhosis was reported in 0 to 11 percent of cases. Three articles focused primarily on histologic findings, with scoring, in large series of children.[15,75,100] In all series, the characteristic histopathologic lesions of HCV infection (see Fig. 189–5), including portal lymphoid aggregates or follicles, steatosis, sinusoidal lymphocytes, and steatosis, were seen with approximately the same frequency as in adults. In 109 Japanese children primarily infected through transfusion,[100] the average histologic activity was 3.8 by the Scheuer system.[172] No cases of cirrhosis were encountered, and only 3.6 percent of the children had bridging fibrosis with architectural distortion. Viral genotypes

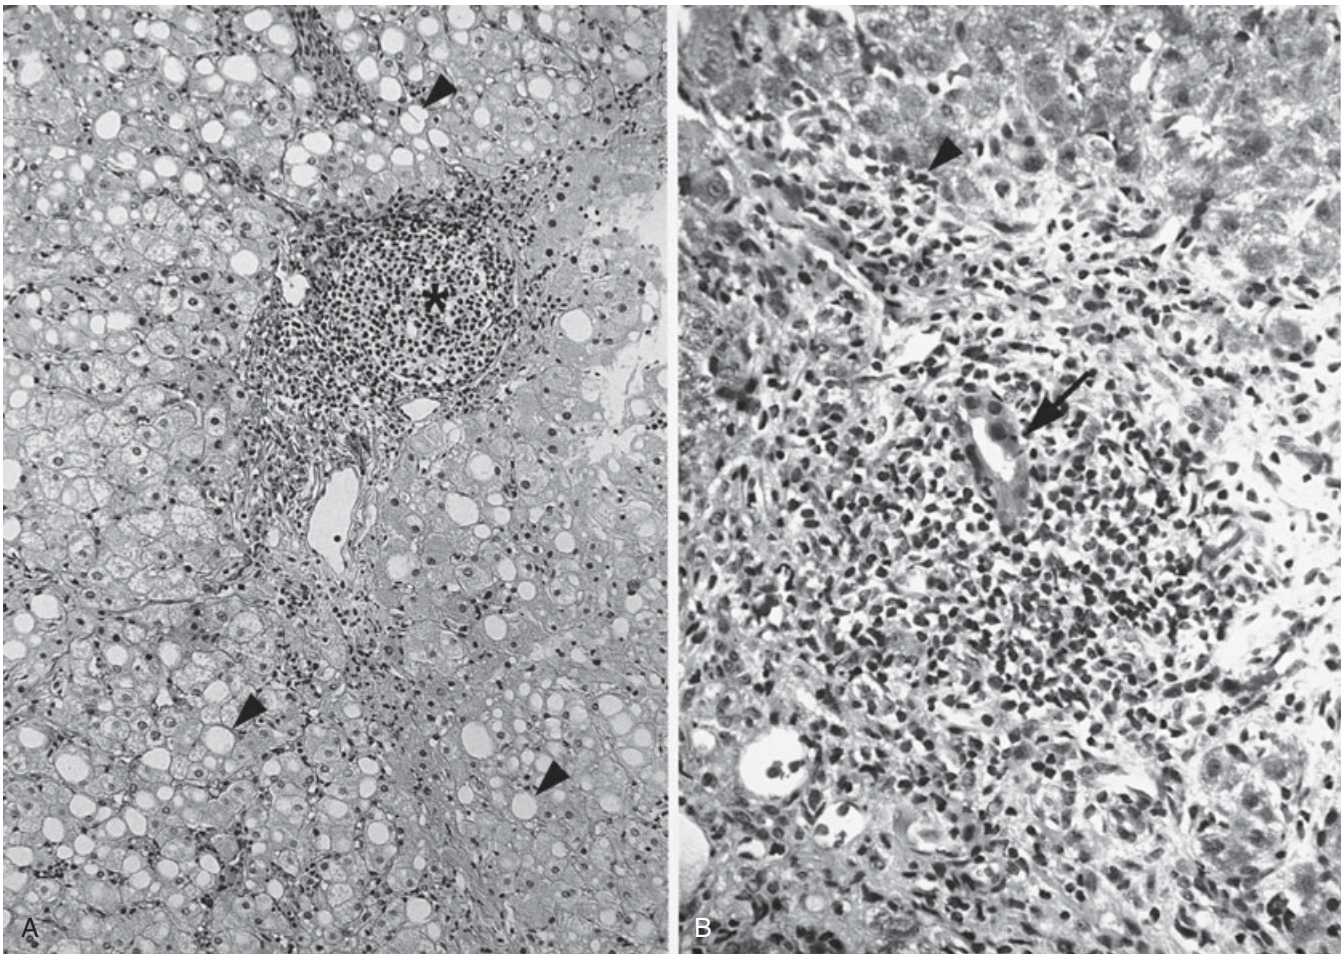

Figure 189–5 Photomicrograph of the liver in pediatric patients with chronic hepatitis C. **A** demonstrates portal lymphoid aggregate *(asterisk)* and moderate steatosis *(arrowheads)* (hematoxylin and eosin stain). **B** depicts bile duct injury *(arrow)* and interface hepatitis *(arrowhead)* (trichrome stain). These features are typical of chronic hepatitis C virus infection in children and adults.

were not reported, and the mean duration of infection was only 2.6 years. In contrast, although histologic activity (Scheuer[172] and METAVIR[19] schemes) generally was mild in a series of children in the United States, portal fibrosis was much more frequent, seen in 78 percent of specimens from 40 children.[15] Fibrosis was mild in 26 percent, moderate in 22 percent, and severe in 22 percent, and cirrhosis was found in 8 percent. Two of the children with cirrhosis were young adolescents who had acquired HCV infection perinatally. A newly described finding was pericellular fibrosis, typically around the central veins, in 52 percent of specimens; whether this abnormality is unique to pediatric HCV infection has yet to be determined, and this fibrosis was not included in the histologic grading. In this series, 60 percent of children had HCV of genotype 1a, and 32 percent had genotype 1b. The mean duration of infection, in those children in whom it could be accurately determined, was 6.8 ± 5.3 years. In a series of 80 children from Italy and Spain,[75] most of whom were infected with HCV genotype 1a or 1b, with a mean duration of infection of 3.5 ± 4.3 years, inflammatory scores generally were quite low. The frequency and severity of the bile duct damage and lymphoid follicles increased with the age of the patients. Fibrosis was present in 72.5 percent of cases and increased with duration of disease and age, just as in the American series. Only one (1.25%) child had cirrhosis.

These studies demonstrate that histologic features of chronic HCV infection in children are quite similar to those reported in adults. Necrosis and inflammation usually are mild, but fibrosis is seen commonly and, most importantly, progresses with increasing age and duration of infection. Thus, the natural history of HCV infection acquired in childhood may in some instances be associated with significant morbidity as the children progress into young adulthood.

TABLE 189–3 Guidelines for Prevention of Perinatal Hepatitis C Virus Infection

Recommended (Supported by Current Data)
Targeted testing of pregnant women who have risk factors for HCV
Aggressive treatment of HIV in co-infected pregnant women
Testing of infants for anti-HCV when they are 12 to 15 months of age
Considered (Suggested by Current Data)
Avoidance of internal fetal scalp monitoring during labor
Delivery of infant within 6 hours of rupture of membranes
Not Recommended (No Current Data to Support)
Universal testing of pregnant women
Elective cesarean delivery
Avoidance of breast-feeding
Immunoglobulin administration to newborns

HCV, hepatitis C virus; HIV, human immunodeficiency virus.

MANAGEMENT

Current recommendations regarding perinatal HCV transmission are listed in Table 189–3. Because the rate of perinatal

transmission of HCV is low, the risk factors that increase this rate are not fully defined, and because intervention for the neonate does not exist at this time, routine screening of all pregnant women is not warranted. Pregnant women, or those considering pregnancy, who have risk factors such as intravenous drug use, blood transfusions before 1992, or unexplained ALT elevations, should be offered screening for anti-HCV. However, in a study that screened more than 4000 pregnant women for HCV, most (16/22) newly identified cases were without prior identifiable risk factors.[195] Pregnant women found to be anti-HCV seropositive should undergo testing with PCR to confirm the presence of current infection. At the present time, no specific recommendations are made to physicians caring for HCV-infected pregnant women in attempts to reduce the frequency of perinatal transmission.[89] Based on preliminary data, prolonged amniotic membrane rupture and fetal scalp monitors should be avoided if possible. Post-exposure prophylaxis with immune globulin is not effective in preventing transmission of HCV infection and is not recommended for infants born to HCV-infected women. Infants born to mothers infected with HCV during pregnancy or at delivery should be tested for anti-HCV positivity after they reach 12 to 18 months of age; a positive test at that time is likely to correlate with true infection because maternal antibody will have disappeared by that age. If anti-HCV is positive, testing for HCV RNA at 12 to 18 months of age will determine whether the infection has resolved spontaneously or has become persistent. The algorithm for identification of women at risk, as well as for detecting perinatally acquired infection, is depicted in Figure 189–6.

Acute infection, which may be acquired from a transfusion, other parenteral exposure, or at the time of birth, rarely causes symptoms recognizable as acute hepatitis. Fulminant hepatitis attributed to HCV is an extremely rare event in children, as it is in adults. Whereas no reports exist of treatment of acute HCV infection in children, successful treatment of adults with acute HCV, using IFN monotherapy, has been reported.[37] In an open-label study, Jaekel and colleagues reported SVR of 98 percent.[93] More recently, an 8-week course of pegylated IFN was shown to induce SVR in 95 percent, 92 percent, and 76 percent of acutely infected patients at week 8, 12, or 20 after infection, respectively.[101] Similar results were reported by Wiegand and colleagues.[197] Fulminant hepatitis attributed to HCV is an extremely rare occurrence in children, as it is in adults.

When chronic HCV infection is diagnosed in children, the duration of infection is likely to be shorter than that in many adult patients who present for treatment. Liver disease typically is mild, with low necroinflammatory and fibrosis scores. Children are less likely to have serious co-morbid conditions, such as HIV infection, chronic alcohol use, and autoimmune disorders, although some will have secondary iron overload secondary to chronic transfusion therapy, and some will be obese and have varying degrees of fatty liver. However, overall, the lower frequency of co-morbid conditions may confer a higher likelihood of therapeutic response. Children have a longer life expectancy, with the expectation that over the course of time, progressive hepatic injury and scarring will develop. These considerations provide some compelling reasons to examine the role of treatment in children.

IFN monotherapy trials in children with chronic HCV infection yielded SVRs ranging from 33 to 45 percent.[92,95] In general, biochemical responses paralleled virologic responses, and histologic findings in liver biopsy specimens improved in treated patients irrespective of complete virologic response, as noted in adult studies.

This rate is significantly higher than the SVR rates reported in large trials of IFN monotherapy in adult patients. Unfortunately, even with these higher response rates, most children remain infected after undergoing treatment. In addition, this medication is associated with important adverse side effects. The flu-like illness described in adults is seen commonly in children but typically resolves after one or two doses. Dosage reductions frequently are required because of development of neutropenia, although serious infectious complications have not been described. Although coexisting autoimmune diseases are seen less commonly in children, type II autoimmune hepatitis, associated with liver/kidney microsomal antibody, can be mistaken for or coexist with HCV infection, and it may be exacerbated with administration of immunoreactive fibronectin IFN.[27,75] A frequent side effect of IFN is weight loss with or without anorexia. Children may lose up to 10 percent of their body weight, with serious implications for growth if the condition is not addressed promptly.[97] A study in children treated for chronic HBV infection suggested that this weight loss and accompanying decrease in linear growth velocity may be transient and improves rapidly once the IFN is discontinued.[44] Significant depression was described in adults receiving IFN for chronic hepatitis; although serious mental illness was not reported in children treated with IFN-α, irritability, decreased school performance, and other behavioral disturbances may be precipitated by this medication. One child developed seizures while receiving IFN-α for HCV infection.[141] Infants treated with IFN-α for life-threatening hemangiomas were noted to have an increased incidence of spastic diplegia.[16] Judicious use of this drug and careful monitoring are

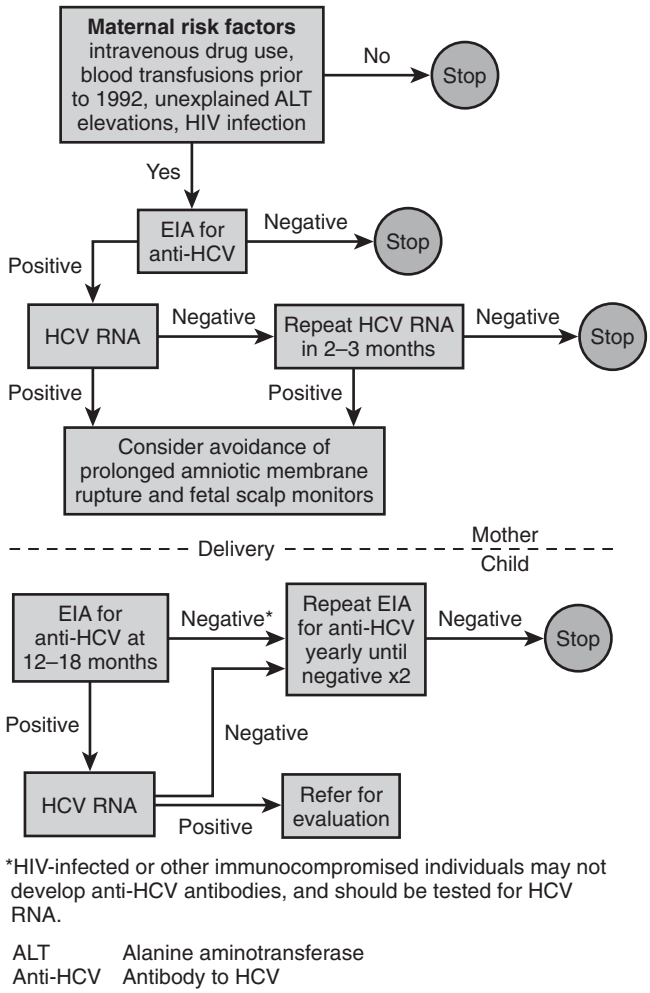

Figure 189–6 Algorithm for identification of women at risk, as well as detecting perinatally acquired infection. ALT, alanine aminotransferase; EIA, enzyme immunoassay; HCV, hepatitis C virus; RIBA, recombinant immunoblot assay; RT-PCR, reverse transcription polymerase chain reaction.

required in young patients. These concerns and others that include the expense of IFN-α, the potential for serious side effects, and the necessity for parenteral administration have led some clinicians to conclude that treatment with IFN is not warranted in children. No cost-to-benefit analysis has been performed in this patient group (see the earlier discussion of financial burden, however).

Combination therapy with IFN-α-2b and ribavirin is the treatment approved by the U.S. Food and Drug Administration (FDA) for chronic HCV in children aged 3 years and older. However, ribavirin has the potential for serious toxicity, including hemolytic anemia, mutagenicity, and teratogenicity. Clinical trials during the past few years have shown the efficacy of this regimen to be similar in children and adults.[65,71,198] In an earlier trial, 41 children were treated with either 3 or 5 MU/m^2, resulting in an SVR of 61 percent. The side effects of treatment were fever, flu-like symptoms, anorexia, and thyroid function abnormalities, but only one patient dropped out because of side effects. In a more recent study, 118 children aged 5 to 17 years were treated with IFN-α-2b and ribavirin (8, 12, or 15 mg/kg/day).[71] The SVR was 46 percent overall, but several notable subgroups were identified. Among patients with genotype 1, those with viral levels of 2 million or fewer copies versus 2 million or more copies/mL had SVR rates of 48 percent versus 26 percent, respectively. As observed in adults, patients infected with HCV genotypes 2 or 3 had substantially higher SVR (84%, 21/25) than those with genotype 1 (36%). In the phase II trial included in the same report, the pharmacokinetic properties of the drugs were similar to those in adults. Although ribavirin was associated with dose-dependent anemia, the anemia was less severe than in adults, and the higher dose (15 mg/kg) was associated with a higher rate of SVR. Severe adverse events, the most common of which was neutropenia, occurred in 19 percent (23/118) of the subjects. Depression was reported in 13 percent and was mild to moderate in severity. Based on these data, the recommended dose of IFN-α-2b is 3 MU/m^2 three times weekly, to a maximum of 5 MU per dose. Ribavirin is given at 15 mg/kg/day in two divided doses. A liquid preparation of ribavirin (40 mg/mL) is available and has bioavailability similar to that of the capsules.[71]

Pegylated IFN is a modified form of IFN in which an attached polyethylene glycol moiety prolongs the clearance of the drug. This confers the advantage of weekly dosing, but it may affect drug toxicity and efficacy. In adults, pegylated IFN in combination with ribavirin has become the standard treatment and has resulted in SVR rates approximately 10 percent higher than those of combination treatment with standard IFN.[65] The safety and efficacy of pegylated IFN in children has been investigated. One open-label trial[199] showed an overall SVR rate of 59 percent. Among the children infected with genotype 1, the SVR rate was 48 percent (22/46). In those infected with genotype 2 or 3, the SVR was 100 percent (13/13). The side effects were similar to those reported in trials of standard IFN.

Important differences exist between HCV infection in adults and in children that may have a significant impact on therapy. These differences are listed in Table 189–4. As transfusion-associated infection declines, the most prevalent means of HCV acquisition in children will be perinatal transmission. If, as it seems from small preliminary studies, more of these infections are likely to resolve without treatment or cause less severe liver disease, then treatment of the youngest children may not be necessary. Conversely, young adolescents with cirrhosis and end-stage liver disease caused by vertically acquired HCV have been encountered. More data are needed about the factors that cause rapid evolution of this disease in pediatric patients, so that cogent decisions regarding patient selection and timing of treatment can be made.

TABLE 189–4 Special Considerations Regarding Treatment of Children with Hepatitis C Virus infection

Differences in Natural History
Mode of acquisition: perinatal
Shorter duration of infection
Co-morbid diseases
Longer anticipated life expectancy
Differences in Liver Disease
Milder grades of necroinflammation
Less frequent severe fibrosis or cirrhosis
Differences in Response to Interferon-α Treatment
Higher frequency of response*
Lower frequency of relapse*
Less correlation of ultimate response with HCV RNA at 12 weeks*
Fewer instances of drug discontinuation resulting from side effects
Unknown long-term side effects
No cost-to-benefit data

**Studies leading to these conclusions include relatively small numbers of patients.*
HCV, hepatitis C virus.

CO-INFECTION WITH HUMAN IMMUNODEFICIENCY VIRUS

Because HCV and HIV share the route of acquisition and risk factors for infection, co-infection with both viruses is not an uncommon finding. The prevalence of HCV infection in HIV-infected adults is 33 percent.[179] In the highest-risk groups, patients with hemophilia and injection drug users, 66 to 100 percent of HIV-infected patients also are infected with HCV.[22] Although sexual transmission of HCV is an uncommon occurrence, the rate is substantially higher in the presence of HIV co-infection.[51] The same is true for perinatal HCV transmission.[153,203,204]

HCV infection has a more aggressive course in the presence of HIV co-infection.[173] The progression of chronic liver disease is accelerated in co-infection; advanced fibrosis and disease activity correlate with a low CD4 count.[20] A significantly higher fraction of HCV/HIV–co-infected patients develop liver failure and hepatocellular carcinoma.[23,59,134] The presence of HCV infection does not seem to exacerbate HIV infection.[161]

The pathogenic mechanism of this accelerated HCV liver disease is not known, but it is thought to stem from direct cytopathic effects of the virus on hepatocytes, perhaps more so than in immunocompetent individuals. Lower CD4 counts are associated with HCV RNA levels in the blood 10 to 100 times higher than those in controls, but no correlation exists between HCV RNA and ALT levels or disease severity.[68] Additional mechanisms, such as drug toxicity, likely play roles in hepatic injury in HIV-infected patients.

Antibody-based tests such as enzyme immunoassay (EIA) and RIBA have a higher incidence of false-negative results in immunosuppressed individuals, including those with HIV infection.[129] If anti-HCV testing is negative, direct testing for HCV RNA using PCR should be performed to exclude HCV infection in the HIV-infected patient.

The treatment of HCV/HIV–co-infected patients has been studied only in adults. In a study of 90 HCV/HIV–co-infected patients, the response rate to IFN-α therapy was similar to that of the non–HIV-infected group (29% versus 34%), but the relapse rate was higher in the HIV-infected group (31% versus 12.5%).[178] One study of 20 HIV/HCV–co-infected patients reported the use of ribavirin in combination with IFN and showed viral clearance rates comparable to those of singly infected patients (50%).[115] However, the toxic side effects of drugs, such as hemolysis induced by ribavirin and myelosuppression by IFN, may be more severe in combination with the antiretroviral medications used to treat HIV,[112] and these patients should be monitored closely.[42]

FUTURE TREATMENTS AND PREVENTION OF HEPATITIS C

Vaccine development for prevention and therapy of HCV infection is an active focus of research.[87] Numerous strategies, including injecting recombinant envelope proteins, plasmid DNA encoding viral components, and recombinant attenuated viruses containing HCV antigens, have been employed. These approaches and others provide hope that HCV ultimately will be a preventable disease. Obstacles include extensive heterogeneity of the HCV envelope proteins and the apparent lack of immunity following a resolved infection. However, neutralizing antibodies do exist; they most likely target one or both of the envelope proteins. Conversely, neutralization may be a short-lived phenomenon, given the rapid development of HCV quasispecies in infected individuals. In both humans and chimpanzees, acute self-limited HCV infection does not confer protection against either heterologous or homologous strains of the virus.[60,160] Autonomous replication of subgenomic HCV RNA has been demonstrated in a human hepatoma cell line after transfection of constructs composed of nonstructural HCV genes and the neomycin phosphotransferase gene.[127] In addition, purified HCV-like particles have been synthesized in insect cells from a recombinant baculovirus expressing C, E1, and E2 proteins.[18] These particles are being evaluated as potential immunogens. Synthetic vaccines that include peptides corresponding to cytotoxic T lymphocyte and helper T-cell epitopes of the HCV core are being used experimentally to induce cytotoxic T lymphocyte responses and memory in an attempt to stimulate cell-mediated immunity,[81] which may be the more important protective mechanism.

The incidence of new HCV infections in the United States has decreased markedly.[7,14] The cause of this decrease is not entirely clear because prevention of transfusion-associated infections is responsible for only a small proportion of this dramatic change in incidence. However, as yet no clear indication exists that the incidence of new infections in children is decreasing, especially because many currently infected individuals are women of child-bearing age. Although pediatric cases represent a minority of HCV infections and may not commonly progress to serious liver disease during the childhood years, certainly instances of significant morbidity and even mortality from this disease have occurred.

Available therapy is cumbersome, uncomfortable, not without risk, and ineffective in many cases. For these reasons, consideration must be given to measures that may be instituted to prevent new pediatric HCV infections. With recognition of the predominant role of perinatal transmission as the source of most new pediatric infections, this process is the logical target for development of prevention strategies. Research to develop better treatments for HCV has focused mostly on inhibiting the virally encoded enzymes that are required for virus propagation. They include the NS3-NS4A protease and the NS5B polymerase. In addition, synthetic nucleic acid–based agents and novel immunomodulatory drugs are in development phases. The ability of the virus to mutate rapidly allows resistance to single agents to develop rapidly. In all likelihood, a cocktail of drugs likely will be required for maintenance of adequate viral suppression and, possibly, cure.[48]

SUBSECTION 6

Orthomyxoviridae

CHAPTER 190

Influenza Viruses

W. Paul Glezen

Influenza is an acute respiratory infection caused by strains of the orthomyxoviruses. The first of the human respiratory viruses to be isolated and characterized,[278] influenza viruses also have been studied the most extensively and are the best understood of these agents from biologic, epidemiologic, and clinical standpoints.[100,161] Yet despite great sophistication in our understanding of it as a disease, influenza remains "the last great plague of man."[161]

Despite the improvements that have been made in living standards and the introduction of antibiotics, the overall impact of influenza on mortality rates has not diminished. In fact, the average number of excess deaths has increased since 1984 to 1985 to at least 51,000 per year,[290] and the number of hospitalizations attributable to influenza is approximately 385,000 annually.[291] Population dynamics—increasing population density and aging of the world's population—dictates that these numbers will continue to increase.[96] The specter of a recurrence of the catastrophic 1918 to 1919 epidemic, in which an estimated 550,000 deaths occurred in the United States alone,[50] has re-emerged with the avian influenza epizootics.[303] Annual epidemics have continued unabated. Each year, the peak of influenza virus activity coincides with the peak of health care visits and hospitalizations for acute respiratory tract disease.[47] Despite a decline in mortality rates from other causes, an increasing number of deaths is attributed to influenza each year.[273-275,290]

As other agents capable of causing respiratory tract infection in children have been identified, influenza has received relatively less attention. Yet the morbidity and mortality rates of influenza in children can be considerable, and the spectrum of clinical manifestations resulting from influenza viral infections is broad.[17,244]

HISTORY

Although the authenticity of influenza in medical antiquity is difficult to establish, the disease has existed for more than 2000 years. The epidemic in 412 BCE described by Hippocrates and Livy probably was influenza.[289] Epidemic influenza-like disease occurred in Europe in the 6th and 10th centuries, but the first generally accepted influenza epidemic occurred in December 1173.[134] Hirsch[134] noted 299 epidemics of influenza between 1173 and 1875. The first pandemic involving Europe, Asia, and North Africa occurred in 1580, and the first epidemic recorded in the Western Hemisphere occurred in 1647. From 1580 until 1918, at least eight pandemics of influenza occurred.

In more recent times, pandemics of influenza caused by different influenza A subtypes occurred in 1874, 1889, 1900, 1918, 1957, 1968, and 1977. The most noteworthy of all pandemics of influenza occurred in 1918. This event has the dubious distinction of producing the greatest morbidity and mortality rates of all time: more than 40 million deaths occurred in the world.[6,168]

The term *influenza* may have come from the Latin word *influo*, "to flow in," perhaps indicating its airborne transmission. It may be Italian, relating to an "influence," such as the weather or mystical astrologic causes.[168]

PROPERTIES OF THE VIRUS

CLASSIFICATION

Classified taxonomically as orthomyxoviruses, the influenza viruses are negative-sense, single-stranded RNA viruses of three major types—A, B, and C—and with multiple subtypes of influenza A viruses.[161] Influenza A and B viruses are the most important in human disease and have been studied far more extensively than have influenza C viruses. All these viruses have the property of hemagglutination and, with the exception of influenza C, possess the enzyme neuraminidase. For types A and B, these properties reside on a pair of surface glycoproteins, hemagglutinin (HA) and neuraminidase (NA), but influenza C has a single glycoprotein with HA, esterase, and fusion activity.[172] The current World Health Organization (WHO) system of nomenclature for influenza virus strains specifies type, host (for strains of animal origin), geographic source, strain number, and year of isolation, to which code designations of HA and NA subtypes are appended.[212] Thus, the "Russian" influenza A strain was designated A/USSR/90/77 (H1N1); the "Philippines" influenza A strain was designated A/Philippines/2/82 (H3N2). Strains are characterized and named at the WHO influenza reference centers in Atlanta (Centers for Disease Control and Prevention [CDC]), London, Melbourne, and Tokyo.

PHYSICAL PROPERTIES

In electron-microscopic preparations, influenza viruses are irregular, spherical particles 80 to 120 nm in diameter that also may exhibit filamentous or icosahedral structures (Fig. 190–1).[212] Numerous HA and NA "spikes" bristle from their surfaces. The virion proteins all are specified by the segmented viral genome, but the lipid bilayer and the carbohydrate constituents of glycoproteins and glycolipids in the viral envelope are derived from the host cell (Fig. 190–2). Besides the HA and NA, eight other virus-coded proteins have been characterized (Table 190–1). Matrix or membrane protein (M1) is the most abundant protein and the major structural component of the viral envelope. The M2 protein of influenza A virus is a smaller tetrameric protein that acts as an ion channel extending through the viral envelope. M2 has an important role in the penetration and release of viral RNA into the host cell.[284] The function of the comparable polypeptide of influenza B virus, BM2, is similar even though the structure of BM2 differs from the M2 of A viruses.[172] Nucleoprotein is associated with the RNA genome of the virus in ribonucleoprotein complexes in which multiple nucleoprotein molecules are associated with eight segments of the single-stranded RNA. Proteins PB2, PB1, and PA, the largest proteins of the virus, are

TABLE 190–1 Virus-Coded Proteins of Influenza Virus

Gene Segment	Protein Designation	Function	Antigenicity
1	PB2	RNA synthesis	?
2	PB1	RNA synthesis	?
3	PA	RNA synthesis	?
4	HA	Hemagglutinin	Subtype specific
5	NA	Neuraminidase	Subtype specific
6	NP	RNA synthesis	Type specific
7	M1, M2	Matrix	Type specific
8	NS1, NS2	Nonstructural	?

so designated because two are basic proteins and one is an acidic protein.[140] They are involved with the synthesis of three different kinds of virus-specific RNAs. Evidence suggests that the PB2 protein is the cap-recognizing protein and that PB1 and PA are involved in chain initiation or in chain elongation.[20,21,171,234,294] Nonstructural proteins, although not incorporated into viral progeny, are virus-coded proteins, NS1 and NS2. NS1 has an anti-interferon effect,[87] and NS2 promotes nuclear export of the viral ribonucleoprotein.[227]

The biologic and antigenic diversity of influenza viruses is attributable in part to their unique, segmented RNA genome. Interchange of corresponding segments of a linear genome, in the traditional sense of genetic recombination, did not account for this extraordinarily high frequency. Hirst,[135] in 1962, proposed the hypothesis that the influenza genome consists of subgenomic pieces capable of semiautonomous replication and random "reassortment" during the process of assembly. This theory accounted for observed recombination frequencies and subsequently was supported by the finding that the RNA of influenza virions was indeed segmented on analysis by polyacrylamide gel electrophoresis.[247] More refined electrophoretic studies in urea-polyacrylamide gels established that the influenza A genome consists of eight segments (Fig. 190–3). Reassortment in nature has been documented for the 1957 and 1968 pandemic viruses as well as for other A viruses.[212] The 1918 pandemic virus probably was an avian virus that mutated in a manner that allowed facile transmission in human populations.[293]

ANTIGENIC COMPOSITION

Of the protein constituents of influenza viruses, four are known antigens. The "internal" nucleoprotein and matrix protein are antigenically type-specific and stable. Nucleoprotein is the antigenic basis for typing strains as A, B, or C and is the predominant constituent of the "soluble" antigen employed for complement-fixation serologic testing. Antibodies to the nucleoprotein are used in tests for direct detection of virus in clinical specimens. Although antibody against nucleoprotein is formed regularly after natural infection occurs and antibody against matrix protein has been detected after severe illness, these antibodies are short-lived and appear to have limited protective value.

In contrast, HA and NA antigens are subtype-specific and variable. HA is required for attachment of infecting virus to host-cell membranes. HA-inhibiting antibodies neutralize viral infectivity and are the most important index of immunity against influenza in humans.[136] NA appears to be required for release of virus from infected cells. Specific anti-NA antibodies reduce the size of the plaque, mitigate the pathogenic effects of

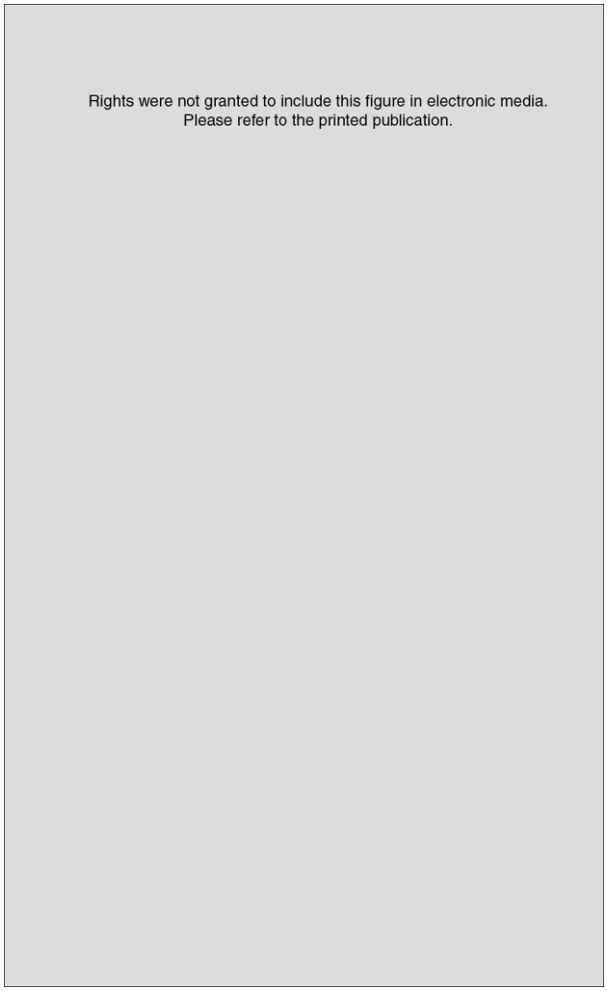

Figure 190–3 Polyacrylamide-urea gel electrophoretic maps of the RNA genome of influenza A/PR/8/34 (H0N1) and A/HK/68 (H3N2). *(From Ritchey, M. B., Palese, P., and Schulman, J. L.: Mapping of the influenza virus genome. III. Identification of genes coding for nucleoprotein, membrane protein, and nonstructural protein. J. Virol. 20:307-313, 1976.)*

influenza in experimentally infected mice, and correlate inversely with viral shedding and severity of illness.[214] Thus far, three HAs, H1, H2, and H3, and two NAs, N1 and N2, have been recognized in influenza A viruses that spread readily in human populations.

Variation in HA and NA specificity is the basis for antigenic *drift* and *shift* in prevalent viruses. *Drift* implies a minor change in either antigen, without a change in subtype; *shift* implies a major change in either or both antigens, with a change in subtype. Antigenic drift occurs in influenza A and B viruses; antigenic shift occurs only in influenza A.

Antigenic drift is the result of point mutations. Selective pressure in an immune population results in selection of mutant viruses with altered antigenic determinants that allow a growth advantage in the presence of prevalent antibody. Supporting this concept are the in vitro studies of Laver and Webster,[175] in which antigenic mutants isolated by serial egg passage in the presence of low-avidity antiserum developed changes in the peptide makeup of their HA subunits.

Antigenic shift occurs when an influenza A virus acquires HA or NA components that differ from antecedent strains by a quantum jump. The phenomenon has been well studied in influenza A viruses. The H3 HA, by chromatographic analysis of peptide composition, is sufficiently distinctive to make highly improbable its emergence by point mutation from the H2 HA of a preceding Asian strain.[176]

Considerable evidence indicates that antigenic shift strains arise by reassortment of gene segments between human and animal influenza viruses during chance simultaneous infection. The 1957 Asian H2N2 virus derived the HA, NA, and PB1 gene segments from an avian virus and the remaining five gene segments from the circulating A (H1N1) strain. The so-called Hong Kong influenza that appeared in 1968, A (H3N2), had avian HA and PB1 gene segments combined with six gene segments from the preceding A (H2N2) virus.[212]

An analogous event initially was suspected as the origin of the swine-like A/New Jersey/8/76 (H1N1) virus recovered from infections in Fort Dix military recruits in 1976. However, the RNA genome of A/NJ was shown by polyacrylamide gel chromatography to be virtually identical to contemporary strains of influenza virus isolated from swine.[229] It shows no RNA homology to human strains. The spread of virulent avian viruses with the H5 HA to humans beginning in Hong Kong in 1997 is another alarming event that supports the possibility of the emergence of pandemic strains by direct infection of humans with an avian virus possessing surface antigens not previously prevalent in the human population.[139] As this virulent avian virus, A(H5N1), continues to spread in Southeast Asia, eastern Europe, and Africa, the possibility that mutations would allow human-to-human transmission increases. Furthermore, examination of the viral nucleic acids recovered from persons who died in the 1918 pandemic indicates that this A(H1N1) virus was entirely of avian origin. Thus, the emergence from animal reservoirs of influenza strains with sufficient virulence to cause widespread human epidemics remains a valid hypothesis.

TISSUE CULTURE AND CHICKEN EMBRYO GROWTH

Influenza viruses grow well in a variety of culture systems, although embryonated chicken eggs and the Madin-Darby canine kidney cell line are used most widely. Primary rhesus monkey kidney tissue culture and other monkey cell lines are alternative choices for isolation of influenza virus. Intra-amniotic and intra-allantoic inoculation of 10- to 11-day-old eggs is followed by incubation for 3 to 4 days at 33° C. Fluid samples are harvested and tested for the presence of hemagglutinating virus by addition of guinea pig or chicken red blood cells. Monkey kidney cells have maximum sensitivity to influenza viruses when they are maintained after inoculation in a serum-free medium. Subtle cytopathic effects may appear but are variable. Detection of virus is carried out in the Madin-Darby canine kidney cells or with use of the rhesus kidney cell line, then hemadsorbing with guinea pig red blood cells. Influenza C viruses grow best in eggs; Madin-Darby canine kidney and monkey kidney cells generally give higher yields of influenza A and B viruses. Although parainfluenza viruses also may be isolated in these tissue culture lines, they can be distinguished from influenza viruses by their characteristic syncytial cytopathogenicity and their poor growth in embryonated eggs.[79,80] Identification of respiratory viruses can be expedited by use of "shell vial" cultures with a mixed cell monolayer culture and low-speed centrifugation.[280] Definitive identification of virus isolates is performed by indirect immunofluorescence or hemagglutination inhibition with use of specific antisera. Antigen detection and identification of influenza viruses by use of enzyme-linked immunosorbent assays (ELISAs) have been valuable additions to the diagnostic laboratory.[16,59,126,262,301] Reverse transcription–polymerase chain reaction (RT-PCR) techniques have the possibility of revolutionizing the diagnosis of respiratory virus infections.[4,68]

ANIMAL SUSCEPTIBILITY

Influenza virus types replicate and produce disease in the ferret.[161] This animal commonly is used for experimental studies. Influenza viruses also can be adapted to grow in mice for research purposes. Other animals, including hamsters, guinea pigs, monkeys, squirrels, chipmunks, chinchillas, and mink, have varying degrees of susceptibility to influenza viruses.

Horses, swine, and birds are infected naturally by type A influenza viruses. In most instances, these animal strains are different from those that spread readily in humans. Avian strains are the most important reservoir for viruses with pandemic potential.[212] Influenza A(H5N1) avian virus has produced a prolonged epizootic in Southeast Asia and Africa. Infection with this virus is usually benign for migrating wild aquatic birds, but mutations have produced strains that are extremely virulent when introduced into domestic fowl—chickens, turkeys and quail.[303]

EPIDEMIOLOGY

INCIDENCE AND PREVALENCE

Influenza is the most important cause of acute respiratory illnesses that lead patients to seek medical care.[91,93,209] Population dynamics that includes increasing population and increased population density resulting from urbanization throughout the world facilitates the spread of these viruses.[96] Rapid movement of persons throughout the world allows new variants or subtypes to spread readily in a short time. Transmission by small-particle aerosol, as well as by direct contact, facilitates dissemination.[288] Unless new control measures are added, the impact of epidemics will increase steadily as the population ages.[273,290,291] Studies have demonstrated that the hospitalization rates for preschool-age children equal those of elderly persons.[148,209,220,244] Furthermore, influenza viruses are the most important causes of acute respiratory tract illnesses leading to hospitalization of schoolchildren.[102,104,235]

Although local outbreaks and individual cases of influenza are reportable optionally in all states, information about disease activity as it varies from year to year derives mainly from ongoing surveillance in public health departments and university medical centers.[184] Longitudinal studies of viral respiratory tract illnesses in families,[73,119,150,287] in hospitalized children,[104,107] in private pediatric practices,[103,106,116] and in public clinics[99] have provided useful data about the community impact of influenza infections.[156] Schoolchildren have the highest attack rates for infection each year, ranging from 30 to 50 per 100 children. Detection of new influenza variants and their spread is facilitated by reporting of virus isolations and serologic responses in specimens submitted to an international network of WHO laboratories.[33]

Weekly tabulations of deaths from "pneumonia" and "influenza" from larger cities in the United States provide a valuable index of mortality from influenza.[274] Several methods have been used to estimate the expected number of deaths in the absence of influenza so that excess mortality can be derived from the observed number during epidemics. Reported deaths in excess of an epidemic threshold usually correlate well with the occurrence of widespread influenza activity (Fig. 190–4).[108,173,274] The CDC now requests reporting of all laboratory-confirmed deaths in children. A total of 153 deaths were reported during the first year, 2003 to 2004.[17] These deaths comprise only a fraction of the projected total, but the sample provides some insight into the problem. Many of the deaths were unexpected; the children died at home or in the emergency room; 29 percent died within 3 days after onset of symptoms, and 31 percent died outside the hospital setting. Thirty-three percent had an underlying condition recognized to increase the risk of developing influenza-related complications, but 20 percent had other chronic conditions; 47 percent had been previously healthy. The highest mortality rate was calculated for infants younger than 6 months of age, at 0.88 per 100,000 children.

Influenza spreads first among children in school, which allows introduction into the household and community spread to adult populations.[36,93,99,100] Although deaths caused by influenza occur most frequently at both extremes of age, increases in pneumonia

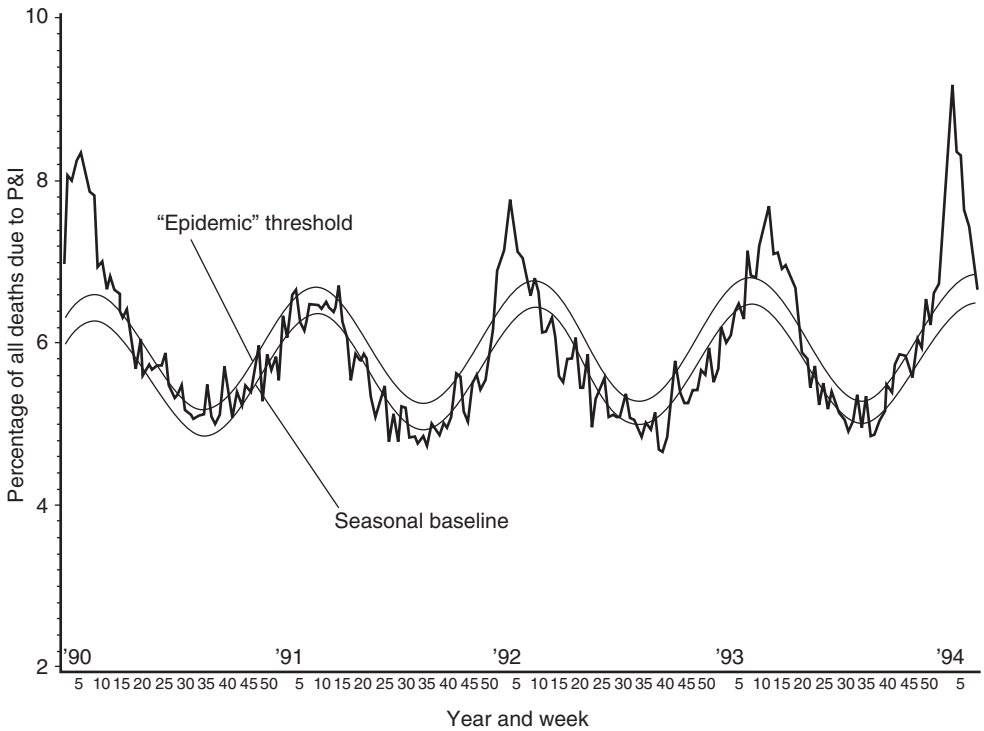

Figure 190–4 Percentage of deaths attributed to pneumonia and influenza (P & I) in 121 cities, United States, 1990 to 1994. *(From Centers for Disease Control and Prevention: United States Influenza Surveillance, March 4, 1994.)*

and influenza deaths in recent years have been greatest among elderly persons.[74,273-275,290] Regardless of age, influenza is fatal more frequently in persons with preexisting heart disease, chronic pulmonary disorders, diabetes mellitus, chronic renal disease, neuromuscular disorders, and neoplasms.

ECOLOGY AND RECAPITULATION

A remarkable ecologic feature of influenza viruses has been the tendency of one particular virus subtype to achieve worldwide distribution at the same time its predecessor disappears from human circulation.[161] Since their first isolation in the 1930s, three major subtypes of influenza A viruses have circulated widely. At the transition years of these "influenza eras," a major antigenic drift or shift has occurred. The prototypic strains for these time intervals are as follows: 1933 to 1957, influenza A/Puerto Rico/8/34 (H1N1); 1957 to 1967, influenza A/Japan/305/57 (H2N2); and 1968 to 1977, influenza A/Hong Kong/8/68 (H3N2). In 1977, influenza A/USSR/90/77 (H1N1) made its appearance; since then, both influenza A(H1N1) and A(H3N2) strains have been prevalent.

The antigenic make-up of viruses prevalent before the 1930s has been inferred by seroepidemiologic studies. By this means, investigators have determined that persons born before 1924 have a high prevalence of antibodies against the swine-like H1 HA that appeared in 1918.[272] Similarly, in serum specimens collected before the emergence of H2N2 and H3N2 strains, antibodies against the H3 HA were found in persons born before 1889.[191] Thus, the number of influenza A viruses that circulate among human populations may be finite, and the three major subtypes may recycle periodically. This concept is supported by the re-emergence of A/USSR/90/77 (H1N1). Antigenically and genetically, this strain of influenza A was found to be identical to influenza A/Fort Warren/1/50 (H1N1), the H1N1 variant prevalent between 1950 and 1953.[105,217,322]

SEASONAL AND GEOGRAPHIC PATTERNS

Influenza infections generally have sharp seasonality.[100] In temperate zones, epidemics usually occur in winter months. Beginning in 2000, an alarming tendency for earlier arrival of epidemics was noted; epidemic disease was confirmed as early as November in 2000, 2002, and 2003.[96] Winter circulation in the Southern Hemisphere sustains influenza viruses during the summer months of the Northern Hemisphere. Occurrence of influenza is less predictable in tropical areas. Some regions may have two annual outbreaks, whereas others may have outbreaks in the rainy season. Geographic variations in the incidence of influenza also may reflect global patterns of spread of new virus strains that is facilitated by increased international travel. Isolated populations may escape the dispersion of new viruses; when outbreaks do occur in such highly susceptible populations, explosive spread and high attack rates in all age groups have been observed.[28,93]

TRANSMISSION

Microdroplet spread, with inhalation of airborne particles produced by coughing and sneezing, generally is accepted as the most common mode of natural influenza transmission.[288] Spread also may occur by direct contact and large-particle aerosols. Small-particle aerosol, by which virus particles are deposited directly into the lower respiratory tract, is the most efficient means of inducing influenza in volunteer studies. In one such study, a human infectious $dose_{50}$ (HID_{50}) of influenza A/Bethesda/10/63 (H2N2) by aerosol was equivalent to 0.6 to 3.0 tissue culture infectious doses ($TCID_{50}$).[1] In contrast, studies in which influenza A/Aichi/2/68 (H3N2) was given by direct instillation or coarse spray into the nose revealed a range of HID_{50} of 127 to 320 $TCID_{50}$.[45,51] The contribution of small-particle aerosol to transmission of influenza under natural conditions is controversial,[288] but it may be important in the pathogenesis of primary influenza pneumonia.[100]

Once infection is established, virus shedding generally follows the development of clinical symptoms. Virus may be recovered 1 day before the onset of symptoms with influenza B and up to 6 days in the case of influenza A. Virus shedding is detected for a variable period in children but usually persists for 1 week for influenza A and for up to 2 weeks after influenza B infection.[83] At the height of illness, respiratory tract secretions may contain 10^6 or more infectious viral particles per milliliter.[211]

The incubation period of influenza ranges from 1 to 7 days but commonly is 2 to 3 days. This brief incubation period, coupled with the quantity of infectious virus in secretions and the relatively small dose necessary for infection to occur in susceptible contacts—particularly by small-particle aerosol—accounts for the intensity of outbreaks of influenza. Spread occurs most rapidly in closed populations, such as schools, colleges, military barracks, and nursing homes. In community outbreaks, school-age children usually have the highest attack rates, with secondary spread to their parents and younger siblings (Fig. 190–5).[36,53,91,100,109] Surveillance cultures from patients presenting with acute respiratory illness show that the incidence in school-age children predominates in the early stages of an influenza epidemic. As the epidemic progresses, the proportions of adults and preschool children increase, whereas the proportion of school-age children decreases. Several studies have taken advantage of this mode of spread, and several field trials have demonstrated protection of adults and younger children by immunization of schoolchildren. Herd protection by immunizing the main spreaders of influenza is a promising strategy for control of epidemic influenza.[98]

Nosocomial infection may occur during community epidemics of influenza and has been documented in hospitalized adults,[22] infants,[115] and premature infants.[196,209] In hospital settings, separating highly susceptible patients from other patients and personnel with acute respiratory tract illness is a reasonable measure. It can be accomplished by performing rapid antigen detection at the time of admission to the hospital to identify those infected with influenza viruses. Prompt treatment with specific antiviral drugs will reduce not only the risk of complications but also the concentration of virus in respiratory secretions and thereby the risk of transmission to contacts in the hospital.

PATHOGENESIS AND IMMUNITY

VIRAL INFECTION AND PATHOGENESIS

To establish infection, influenza viruses must penetrate the mucous blanket lining the respiratory tract and escape inactivation by nonspecific inhibitors as well as specific local antibodies. The major site of infection is the ciliated columnar epithelial cell.[100,133] The receptor on the viral HA attaches to a sialic acid moiety on the cell membrane. The virus is endocytosed and creates an acid environment by the ion channel activity of the M2 protein, which exposes the fusion activity of the HA to allow fusion of the lipid coat with the cell membrane. This process allows entry of the viral RNA into the cytoplasm. Necrosis of ciliated epithelial cells occurs as early as the first day after the onset of the symptoms. Many of the symptoms may be attributed to the release of proinflammatory cytokines and chemokines from the infected epithelial cells.[128,277] The levels of cytokines and chemokines in nasal secretions coincide with the intensity of symptoms.[84] Local edema and cellular infiltration by lympho-

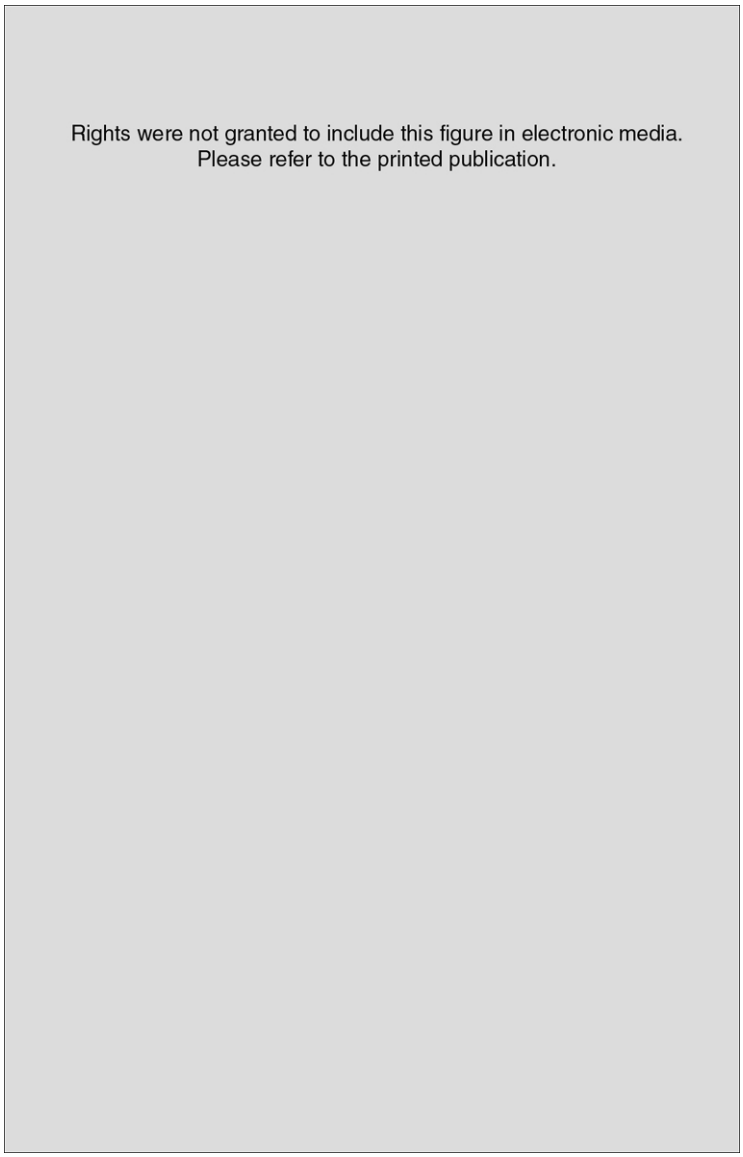

Figure 190–5 Epidemic curve of infections by influenza B in Hazleton, Iowa, 1961 to 1962. Note that the epidemic wave in school-age children precedes the epidemic wave in household contacts.[36] *(From Chin, T. D. Y., Mosley, W. H., Poland, J. D., et al.: Epidemiologic studies of type B influenza in 1961-1962. Am. J. Public Health 53:1068-1074, 1963.)*

cytes, histiocytes, plasma cells, and polymorphonuclear cells follow. Repair of the epithelium begins between the third and fifth days, as indicated by mitoses in the surviving basal cells. A pseudometaplastic response of undifferentiated epithelium reaches its maximum 9 to 15 days after the onset of the infection. After 15 days, cilia and mucus production reappear. With secondary bacterial infection, more extensive inflammatory cell infiltration and destruction of the basal cell layer and basement membrane are seen, with consequent delay in regeneration of the ciliated epithelium.

Pneumonia associated with influenza virus infection may result from primary viral infection, bacterial superinfection, or combined bacterial-viral infection.[185] Fatal primary influenza pneumonia, fortunately a relatively rare occurrence in children, is characterized at autopsy by diffuse hemorrhagic alveolar exudates, necrosis of bronchiolar epithelium, peribronchial lymphocytic infiltration, and marked lymphocytic infiltration of the alveolar walls and interstitial lung tissue.[208]

Although the major pathologic process in influenza occurs in the respiratory tract, focal and diffuse myocarditis, mediastinal lymph node disorganization and necrosis, and diffuse cerebral edema also have been noted in fatal cases. The pathologic entity of diffuse encephalopathy and fatty degeneration of the liver (Reye syndrome) has been established as a complication of influenza, particularly type B, in children.[178] Reye syndrome is associated with administration of salicylate-containing products to children with influenza or varicella and has declined in incidence as the use of salicylates has decreased.[143] Encephalopathy and encephalitis associated with influenza have been reported frequently in Japan, where an estimated 100 children die each year.[271] Recognition of this complication is increasing in the United States and warrants consideration for universal immunization of children.[189] The hypotheses for pathogenesis include direct viral invasion of the central nervous system and inflammation secondary to high levels of proinflammatory cytokines.[147]

IMMUNOLOGIC EVENTS

Immunity against influenza results from a complex interplay of humoral, secretory, and cell-mediated mechanisms. Because of the brief incubation period of the disease, anamnestic stimulation of antibody affords little protection. Thus, some degree of preexisting antibody appears to be essential to prevent infection. The

sequential point mutations of the HA and NA gene segments result in antigenic changes that allow the virus to evade immunity generated by previous infections. The major antigenic changes that accompany antigenic shifts render total populations susceptible and account for pandemic spread.

After natural influenza infection occurs, both mucosal and humoral antibodies are elicited against HA, NA, nucleocapsid, and matrix protein antigens. Antibodies to the HA are critical for neutralization of virus. Antibodies against NA are associated with diminished severity of illness and reduced rates of person-to-person transmission. Antibodies against nucleocapsid and matrix proteins do not appear to provide protection or to modify transmission. Because influenza is a respiratory epithelial surface infection rather than a systemic infection, some uncertainty exists about the relative degree of protection afforded by mucosal and humoral antibodies. Studies in human volunteers demonstrated good protection against experimental challenge by influenza A/HK/1/68 in subjects who possessed serum antibodies but lacked detectable mucosal antibodies.[46] Subjects challenged by influenza B/Eng/65 also demonstrated a better correlation of protection with serum antibody levels than with nasal antibodies.[63] Moreover, in a large experience with volunteers that was summarized by Hobson and associates,[136] an impressive linear correlation between serum hemagglutination-inhibiting antibody titers and protection was evident. Thus, although an important role for local antibodies as a "first line of defense" against influenza is accepted, serum antibodies clearly contribute to resistance.

Waldman and colleagues[299] demonstrated that the predominant influenza-neutralizing antibody in nasal secretions is secretory immunoglobulin A (IgA), whereas the predominant neutralizing antibody in tracheobronchial secretions is IgG. A synthesis of the available data suggests that local secretory IgA in nasal secretions may be important in the prevention of infection that is transmitted by droplet spread and that originates in the upper respiratory tract. Serum and local IgG antibodies appear to be of greater importance in neutralizing infection transmitted directly to the lower respiratory tract by aerosol or in preventing extension of upper respiratory tract infection to the lungs.[320]

Cell-mediated immune mechanisms of several varieties have been demonstrated in influenza infection and vaccination. A T-cell "helper" function was demonstrated in strain-specific humoral antibody response against HA.[298] Both nonspecific and specific mechanisms of lymphocyte cytotoxicity were found in model systems,[67] but only type-specific cytotoxic T cells were found in humans.[18,24,65] Cytotoxic T lymphocytes are important for recovery from infection in susceptible hosts. Antibody-dependent cell-mediated cytotoxicity was shown to correlate with the titer of serum anti-HA antibody.[111] This mechanism also may play a role in recovery.[57,267]

The immunologic imprint made by the first influenza infection of childhood has lasting effects. According to the "doctrine of original antigenic sin," developed by Francis and colleagues[77] from seroepidemiologic data, hemagglutination-inhibiting antibody against the strain of first infection is recapitulated with each subsequent infection by an antigenically distinctive strain of influenza A. Since 1957, however, researchers have found that infections or immunizations with H2N2 or H3N2 strains do not recall antibody against earlier strains in persons primed by H1N1 viruses.[188] Therefore, the doctrine holds only within groups of influenza A strains possessing some degree of homology of antigens. Virelizier and associates[297] analyzed the basis for the phenomenon using irradiated mice immunologically reconstituted with bone marrow from immune donors. These studies indicated that antigenic "original sin" derives from cross-stimulation of a population of committed memory B lymphocytes that persist after primary infection.

After natural infection occurs, the duration of immunity and the degree of protection against challenge by heterologous variants appear to be variable. On the basis of clinical experience in a Yorkshire general practice, Pickles and associates[236] concluded that natural immunity against influenza A strains lasted at least 4 years. Conversely, serologic reinfection rates of 2 and 12 percent against influenza A and influenza B, respectively, were noted by Hall and colleagues[119] during a 3-year observation period in children in Seattle. Some protection against the re-emerged influenza A (H1N1) virus of 1977 was noted for persons who had been infected with a similar virus in the 1950s.[105] The cross-immunity was lost gradually as new H1N1 variants appeared since 1977, a finding demonstrating a divergence in antigenic properties of variants that appeared after 1950 and 1977.

Frank and colleagues[78,81] reported that variations in reinfection among young children may be multifactorial but, most important, may be related to the age at first infection and the antigenic differences of virus variants in subsequent challenges. Thus, protection against clinical disease appears to persist for many years after influenza infection occurs in older children but may be of much shorter duration in infants and very young children; subclinical reinfection probably occurs after much shorter intervals. A gradual increase in duration and breadth of immunity against related virus strains probably occurs over a period of years. Frank and associates[82] found that, unlike the findings for influenza A (H3N2) infections, infection with influenza B virus provided consistent protection for most persons against infection with the next influenza B variant. The protection decreased somewhat for subsequent variants and longer intervals. Beginning in 1987, two antigenically distinct lineages of influenza B have been prevalent.[33] These lineages are identified as the B/Yamagata/16/88 lineage and the B/Victoria/2/87 lineage. Generally, infections with viruses of one lineage fail to provide good cross-protection against infection with the other, especially for children with limited prior experience.

CLINICAL MANIFESTATIONS

Disease caused by epidemic influenza A virus may occur in persons of all ages and results in a febrile respiratory illness. In contrast, although other respiratory tract viral agents (respiratory syncytial virus [RSV], rhinoviruses, parainfluenza viruses) also may cause community epidemics that involve both children and adults, the illness is different in the two age groups; young children with primary viral infections with non-influenzal agents have febrile illnesses, whereas older children and adults with similar infections most commonly have common colds and other upper respiratory tract involvement with little or no fever.[90,94]

The symptoms and signs in children and adults of type A influenza caused by the Asian subtype (H2N2) are compared in Table 190–2.[150] The following findings have occurred significantly more frequently in children: sudden onset, anorexia, abdominal pain, vomiting, nausea, cervical adenopathy, and temperature higher than 38.9° C. Influenza C viruses cause illnesses similar to influenza A infection, but the severity of disease usually is less and the duration shorter. In addition, because antigenic changes in influenza B viruses are less frequent, illnesses may be milder in adults. Influenza B may cause an epidemic in which children will have typical influenza with fever, but many adults in the population will have only upper respiratory tract[101] illnesses without significant fever. In other outbreaks caused by antigenically variant influenza B virus, significant illness has been identified in adults.[102,121]

OLDER CHILDREN AND ADOLESCENTS (CLASSIC INFLUENZA)

care are high. Even uncomplicated illnesses significantly disrupt family activities.[218] The symptoms and signs of classic influenza in older children and adolescents are presented in Table 190–3. The onset of illness is abrupt, with fever and associated flushed face, chills, headache, myalgia, and malaise.[30,243,252,268] The temperature ranges between 39° C and 41° C (102° F and 106° F), with a general inverse correlation with age. The systemic symptoms are reported to be more severe in older children, probably because of the children's ability to describe them. Although a dry cough and coryza also are early manifestations of influenza, these symptoms may be overlooked in the early stages because of the predominance of the systemic manifestations. Sore throat occurs in more than half of the cases and usually is associated with nonexudative pharyngitis. Ocular symptoms include tearing, photophobia, burning, and pain with eye movement.

In uncomplicated illness, the fever usually persists for 2 to 3 days but may last as long as 5 days. A biphasic temperature pattern may occur, even without apparent secondary bacterial complications. By the second to the fourth day, respiratory tract symptoms become more prominent, and the systemic complaints begin to subside. The cough is dry and hacking and usually persists for 4 to 7 days; cough, in association with some degree of general malaise, occasionally persists for 1 or 2 weeks after the rest of the illness has subsided. Illness caused by influenza B virus generally is associated with more prominent nasal and eye complaints and fewer systemic findings, such as dizziness and prostration, than is influenza A illness. In a study in which both influenza A (H1N1) and influenza C were noted in a population of young adults, the illnesses could not be differentiated by clinical findings.[64]

In uncomplicated classic influenza, the leukocyte count most often is normal, but leukopenia (<4500 cells/mm^3) has been noted in approximately 25 percent of cases. The differential cell count is of no diagnostic value because approximately one third of patients will have normal values, one third will have relative lymphopenia, and one third will have relative neutropenia. The relative proportion of each white blood cell type may depend on the time during the course of infection when the differential count is determined.[167] Approximately 10 percent of older children and adolescents have clinical signs and radiographic evidence of pulmonary involvement.

YOUNGER CHILDREN

General Considerations

Clinical expression of influenza in younger children and infants has been studied intensively, a reflection of increasingly sensitive and specific respiratory tract viral diagnosis. With some exceptions,* most studies have contained disproportionate numbers of hospitalized patients† and thus may tend to exaggerate the more severe end of the influenza spectrum.

In younger children, the manifestations of influenza viral infections frequently are similar to those resulting from other respiratory tract viruses (parainfluenza, RSV, rhinovirus, and adenovirus) (Table 190–4). Laryngotracheitis, bronchitis, bronchiolitis, pneumonia, and upper respiratory tract illness all occur.[160]

Clinical descriptions of these illnesses are presented in other chapters. The overall rate of hospitalization of children with lower respiratory tract involvement is the same for influenza virus infections as for other viruses, but influenza tends to affect older children.[92]

Primary infection with influenza A in these age categories typically is seen as an undifferentiated febrile upper respiratory tract illness.[314] Infants younger than 2 months old frequently are hospitalized with fever to rule out bacterial sepsis, particularly when influenza A (H3N2) viruses are epidemic.[107] Fever tends to be high, and temperature exceeds 39.5° C in most patients. Affected children appear moderately toxic, with clear nasal discharge, cough, and irritability as almost constant findings. Pharyngitis usually is present, with diffuse erythema and boggy, enlarged tonsillar tissue. Acute otitis media is a frequent complication and has been found in 30 percent of those patients with laboratory confirmation of disease.[95] Between 5 and 10 percent of those infected have some degree of pulmonary involvement; in hospitalized children, this percentage may be as high as 50 percent. Fleeting erythematous, macular, or maculopapular discrete rashes have been observed.

Because of the explosive nature of influenza epidemics, clinics that provide urgent care may be severely taxed during outbreaks.[209,220,244] Preschool children present to health care facilities in large numbers, with resulting long waiting periods for care. Universal vaccine recommendations may reduce this burden, but these recommendations should be combined with rapid antigen detection tests and early intervention with antiviral treatments to reduce morbidity and reduce spread of influenza to contacts.[23,223,245]

Gastrointestinal Symptoms

In contrast to illness patterns in older children and adults, gastrointestinal symptoms have been noted in several studies of influenza infection in young children. Among 68 children admitted to the hospital during a community epidemic of influenza B/Hong Kong/72 in 1974, Kerr and colleagues[159] encountered acute abdominal pain, with minimal associated respiratory tract symptoms, as the presenting complaint in 37 patients. This symptom was noted most frequently in children 4 to 10 years of age and led to performing unnecessary laparotomies in two patients. In infants, infection by influenza A virus may elicit diarrhea and vomiting. Of 18 infants aged 6 months or younger with proven influenza A/HK/68 infections, Price and associates[248] noted prominent anorexia, diarrhea, or vomiting in 13 (72%), and only 5 (23%) had respiratory tract symptoms alone. Five of the infants with gastrointestinal disturbance had moderate to severe dehydration. Similarly, among 53 hospitalized infants younger than 1 year old with infections of influenza A, Paisley and associates[228] found diarrhea to be a prominent symptom in 18 patients (34%). Thus, unlike adults with influenza, infants and young children indeed may display "gastric flu."

Febrile Convulsions

Febrile convulsions precipitated by fever of abrupt onset have been cited as common presenting complaints in several studies of hospitalized children with influenza. Among 75 children with infections by influenza A/Hong Kong/68 (H3N2), 26 (35%) of the patients described by Price and associates[248] presented with a febrile convulsion. Of the 77 hospitalized children described by Brocklebank and colleagues,[27] 31 (40%) had convulsions at onset; 27 of the children in this series were 3 years of age or younger, a distribution consistent with the usual age-specific susceptibility pattern of febrile seizures. In a large series from Hong Kong, almost 20 percent of children admitted with influenza virus infection had febrile seizures.[35]

Croup

Acute laryngotracheobronchitis (croup) has been noted as a prominent feature of influenza A in young children during the H3N2 era. Illness tends to be more severe than is the rule for the croup syndrome induced by parainfluenza viruses, and tenacious tracheal secretions may necessitate tracheostomy or endotracheal intubation in a higher proportion of hospitalized patients. During the peak month of a composite of 13 consecutive influenza A outbreaks, influenza A virus was demonstrated in 68 percent of patients with croup who were hospitalized in Washington, D.C.[150] Severe croup caused by influenza virus infection may occur in children at an older age than that of those usually infected with parainfluenza viruses.[66,142,246]

NEONATES

In neonates, influenza infection may suggest bacterial sepsis: lethargy, poor feeding, petechiae, poor peripheral circulation with mottling of the skin, and apneic spells. Nosocomial influenza A outbreaks have occurred in neonatal nurseries in association with symptomatic illnesses among nursery staff and parents.[8,196,210] Six of the eight infants in one study had apneic spells.[196] Two infants required mechanical ventilation for frequent apneic spells for a period of 6 to 8 days.

HIGH-RISK CHILDREN

Other host characteristics generally considered to influence the clinical expression of influenza include preexisting chronic pulmonary, cardiac, and neuromuscular disease. Most deaths occur in these vulnerable patients.[292] The basis for this doctrine, however, is derived mainly from pathologic and epidemiologic analysis of influenza in adult patients,[132] but several studies

addressed the vulnerability of children with underlying conditions. Among the 77 hospitalized children with influenza A described by Brocklebank and colleagues,[27] 13 of 23 (56%) with chronic diseases or congenital malformations developed lower respiratory tract infection, compared with 10 of 54 (19%) children without preexisting chronic conditions. Kempe and colleagues[158] studied influenza virus infection in children with malignant neoplasms and found that affected children had both more frequent and more severe influenza-related illnesses than did their healthy contacts or age-matched controls. Neuzil and colleagues found influenza-attributable hospitalization rates of 19.2, 7.6, and 2.3 per 1000 for children younger than 1, 1 to 2, and 3 to 14 years of age, respectively, over a period of 19 years.[221] The rates for influenza-related outpatient visits were 122, 202, and 126 per 1000 children and for antibiotic courses were 65, 141, and 125 per 1000 children, respectively, for the same age groups. Asthma was the most common underlying condition among these children.

The few comprehensive virologic studies conducted in asthmatic children yielded conflicting results. In a longitudinal study of young children (<3 years) hospitalized for prolonged periods because of severe extrinsic asthma, McIntosh and associates[194] serologically documented 11 episodes of infection by influenza A/Hong Kong/68, all of which were mild and none of which was associated with exacerbations of wheezing. Studies of pediatric outpatients who were more than 3 years old and who had intrinsic asthma found that influenza virus infections played important roles in triggering asthma attacks. A population-based study in Houston found that influenza was the most common infection triggering hospitalization of school-age children with asthma; 21 percent of all hospitalizations during a 4-year period were associated with influenza virus infection.[104] Other investigators documented influenza virus infections with exacerbations of asthma in children.[200,201,258] A retrospective cohort study showed that influenza vaccine protects against severe exacerbations in asthmatic children after adjustment for asthma severity.[170] A controlled trial in the Netherlands found no reduction of laboratory-proven asthma exacerbations by the use of the inactivated vaccine.[29] In contrast, a direct comparison of live attenuated influenza vaccine (LAIV) and inactivated vaccine showed superior protection with the live vaccine in school-age asthmatic children.[72] Therefore, the preponderance of evidence from clinical studies incriminates influenza as an important instigator of asthma attacks in children.[97]

DIAGNOSIS

Infection with influenza virus often can be deduced more accurately from epidemiologic features than from clinical presentation. Epidemics occur each winter and usually begin with a sudden increase in presentation to primary care facilities of school-age children with febrile respiratory tract illnesses.[91] Routine laboratory studies provide little help in the differentiation of influenza from other viral respiratory tract diseases. Serial monitoring of induced infections in adults has revealed a characteristic moderate increase in total white blood cell count, with relative lymphopenia, during the height of symptoms and low serum iron values.[58,60,69] In children, however, hematologic manifestations are variable, with marked leukocytosis frequently observed in infants.[115] Chest radiographs are useful primarily for determining the presence of complicating interstitial or lobar pneumonia. Transient alterations in pulmonary function tests have been documented in a high percentage of normal adults with uncomplicated influenza.[120] Thus, oxygen saturation determinations may be useful in children with influenza and clinical evidence of lower respiratory tract involvement, even if chest radiographs do not show infiltrates.

Definite diagnosis of influenza depends on detection of antigen or isolation of virus from respiratory tract secretions or a significant rise in serum antibody during convalescence. In contrast to shedding of adenoviruses or herpes simplex virus from the respiratory tract, asymptomatic carriage of influenza viruses is a rare occurrence. Thus, detection of virus alone is considered conclusive evidence of the cause of an illness. Hemagglutinating agents often can be detected in embryonated eggs, Madin-Darby canine kidney, or primary monkey kidney tissue culture within 72 hours of inoculation. However, longer incubation and serial passage are required before cultures can be regarded as negative.[61] Rapid detection of influenza antigens in nasopharyngeal epithelial cells with specific fluorescent antibody conjugates has been successful in many studies.[180,226] A combined approach employs short-term incubation of clinical specimens in tissue culture, followed by rapid identification of hemadsorbing agents with fluorescent antibody.[9] Shell vial techniques that include low-speed centrifugation of the clinical specimen onto a tissue culture monolayer and detection of virus with fluorescent antibodies after a short (<72 hours) incubation period provide rapid confirmation of influenza infection. Enzyme immunoassay can be used for early detection of influenza A antigen.[59,301] When this information is available to the clinician in a timely fashion, antibiotic use is curtailed, and the use of specific antiviral treatment is enhanced.[215] Tests that detect both influenza A and B are now available in primary care settings.[223-225] Other studies confirmed the utility of rapid identification of influenza virus infections.[23,245,270] Usually, clinicians are not taking advantage of the opportunity to apply specific treatment.[244] Further advances in diagnosis of influenza result from incorporation of techniques for RT-PCR. PCR provides greater sensitivity (95%) than do other antigen detection methods (usually 60% to 75%).[4] Multiplex quantitative RT-PCR may allow identification of all the important respiratory viruses of children: influenza, parainfluenza, and RSV.[68,131]

Serologic diagnosis may be accomplished by use of complement-fixation or hemagglutination-inhibition techniques.[61] The complement-fixation test detects antibody against the "soluble" nucleoprotein antigens that are common to all strains of influenza A or influenza B. Reagents are commercially available, and the test is provided by most clinical laboratories. Complement-fixing antibodies are of relatively brief duration; titers wane within 6 months of infection. Hemagglutination-inhibiting antibodies, which are subtype-specific, provide more definitive evidence of infection. However, subtype-specific reagents are required and are less widely available in clinical laboratories. Titers persist for years and are boosted by infection with related strains. The hemagglutination-inhibition test has the added advantage of greater sensitivity. Neutralizing antibodies correlate best with protection against reinfection and are more sensitive indicators; the microneutralization test is preferred for evaluation of vaccine effectiveness.[80] Rises in NA-inhibiting antibody also may be detected after infection, but such studies are technically cumbersome and are restricted to specialized applications. A versatile method for measuring antibodies against influenza antigens employs ELISA.[19,215] This system is technically simple and has the advantage of permitting specific identification of IgA and IgM antibodies as well as IgG subclasses. It is particularly useful for measuring antibodies in respiratory secretions that reflect mucosal immunity.

COMPLICATIONS

BACTERIAL INFECTIONS

The most frequent complications of influenza are bacterial infections of the respiratory tract, particularly pneumonia, otitis media, and sinusitis.[70,130,179,185,202,228,269,282] Characteristically, these

complications arise in early convalescence, with bacterial invasion of portions of the respiratory tract resulting in denuded ciliated epithelium and defective mucociliary transport. In 37 young infants experiencing their first infections by influenza A viruses, Wright and colleagues[314] noted otitis media in 10 and pneumonia in 7. Hall and Douglas[115] documented complicating bacterial pneumonia in 5 of 12 patients who developed nosocomial infection by influenza A on an infant ward; most of these patients had underlying chronic cardiorespiratory disease. The incidence of complicating bacterial infections in community studies, including children of all ages, is approximately 10 percent, and otitis media is the most frequent finding.[150] A 14-year longitudinal study of young children demonstrated a 28 percent incidence of otitis media after influenza A and B virus infections and an increased risk of recurrent disease.[130] Studies of vaccine effectiveness support reports of influenza-associated acute otitis media of 30 to 40 percent for children in daycare during the respiratory disease season.[95]

Although most cases of bacterial pneumonia complicating influenza are pneumococcal,[269] the two most feared pulmonary complications are progressive primary viral pneumonia and staphylococcal pneumonia.[185] Progressive primary viral pneumonia has been observed most frequently in adult patients with preexisting rheumatic heart disease, but it may occur in previously healthy children as well.[148,151,220,228] It is characterized radiographically by diffuse bronchopneumonic infiltrates and clinically by intense dyspnea and a relentless downhill course, despite administration of antimicrobial and supportive therapy. Staphylococcal pneumonia may occur as a postinfluenzal lobar pneumonia progressing to pneumatoceles and empyema. More characteristically, staphylococcal pneumonia in association with influenza occurs as a fulminant, synergistic, viral-bacterial process with diffuse involvement on radiographs, leukopenia, intense dyspnea, blood-tinged sputum, and rapid death. Necrotizing pneumonitis with microabscesses and positive lung cultures for both influenza A virus and *Staphylococcus aureus* are characteristic.[185]

ACUTE MYOSITIS

Acute myositis occurs in the setting of early convalescence from a typical influenzal illness.[7,55,199] Severe pain and tenderness in the calves of both legs come on suddenly, and the patient often refuses to walk. Other muscle groups may be involved as well, but the gastrocnemius and soleus muscles are affected in virtually all cases. Elevated levels of serum creatine kinase and aspartate aminotransferase are characteristic. Influenza B virus was isolated in 20 of 26 such cases by Middleton and associates[199] and in 11 of 17 cases by Dietzman and colleagues.[56] Infection by influenza A was documented in one case of the former series. The condition generally is self-limited, but rhabdomyolysis with myoglobinuria and acute renal failure has been described in severe cases occurring in association with influenza A.[37,55,157]

ENCEPHALOPATHY AND REYE SYNDROME

Encephalitis or encephalopathy is a common complication of influenza in children.[10,54,193] Alarming reports of the occurrence of encephalitis and encephalopathy in young children emerged from Japan beginning in 1995.[271,283] This timing coincided with the discontinuation of the influenza vaccine program in Japanese schoolchildren.[254] More than 200 cases per year have been reported, and more than 100 cases have been fatal or associated with permanent neurologic sequelae.[154] Evidence of influenza virus infection has come from isolation of virus or PCR detection in the cerebrospinal fluid (CSF).[85,147] The usual presentation is sudden onset of fever with convulsions followed by progression to a comatose state. In older children, the onset may be more subtle, with headache and disorientation. Since the outbreak associated with influenza B virus infection was reported in Chicago in 1971,[137] the reports in the United States have become more frequent.[187,242] The pathogenesis of these illnesses is unknown but may result from direct viral invasion of the central nervous system or from high levels of proinflammatory cytokines that breach the blood-brain barrier.[147,205]

Reye syndrome is a condition of obscure pathogenesis characterized by fatty degeneration of the liver and diffuse cerebral edema.[255] Although the condition has been recognized under varying nomenclatures since its partial description by Brain and colleagues[25] in 1929, only more recently was influenza infection implicated as an inciting factor. Of 85 patients treated at Cincinnati Children's Hospital, 74 (87%) had a respiratory tract prodrome clinically indistinguishable from influenza, and 11 patients (13%) had varicella.[232] During the 1974 outbreak in Cincinnati, influenza B/HK/8/73 was isolated from the nasopharyngeal secretions of 9 of 23 affected children, and an additional 3 children had serologic evidence of influenza B.[178] Numerous other reports demonstrated similar associations of influenza A (H1N1 and H3N2) as well as influenza B with subsequent outbreaks of Reye syndrome.[43,125,146,285,310] Surveillance data indicate a significant decline in both the incidence and the mortality ratio.[2,5] In a survivor of Reye syndrome, who was studied intensively by Partin and colleagues,[232] influenza A/Vic/3/75 (H3N2) virus was recovered from nasotracheal secretions, CSF, liver, and skeletal (gastrocnemius) muscle, findings that led the investigators to postulate visceral dissemination of virus as an element in the pathogenesis of this condition. Clinically, Reye syndrome, most common in white, male, school-age children, is marked by nausea, vomiting, and stupor during convalescence from a viral illness, most commonly characterized by respiratory tract symptoms.[2,5] In this setting, the finding of elevated serum transaminase and blood ammonia levels, with unremarkable CSF, is sufficient for establishing the diagnosis. During the 1974 outbreak, Reye syndrome was estimated to have occurred at a rate of 31 to 58 cases per 100,000 infections with influenza B in children,[43] although a lower incidence was reported among Colorado children in association with the H1N1 outbreak of 1978 to 1979.[125] The case-fatality ratio is 26 percent.

An ever-increasing body of data reveals a strong association between the use of salicylates or salicylate-containing medications and Reye syndrome, and as a result, strict warnings have been issued against the use of salicylates in children with influenza.[124,143,281,300,319] The decreased use of aspirin for children with influenza and varicella has paralleled the decline in the number of reported cases of Reye syndrome.[2]

OTHER COMPLICATIONS

Neurologic Disease

Apart from encephalopathy or Reye syndrome, other severe neurologic illnesses have been reported rarely in association with influenza viral infections.[197,263] As noted earlier, the most common manifestation is encephalitis in association with a respiratory tract illness. In most instances, no evidence of concomitant meningitis is present. Guillain-Barré syndrome and transverse myelitis also have been associated with influenza.[304]

Cardiac Disease

Pericarditis and myocarditis have been noted rarely in association with influenza viral infections.[42,48,202,282] Cardiac involvement has occurred in normal children and adults as well as in those with preexisting heart disease.

Sudden Deaths

During influenza epidemics, sudden, unexpected deaths are observed occasionally. They occur in persons of all ages, and postmortem examination most frequently indicates respiratory tract involvement. Cases of sudden infant death syndrome have been associated with influenza viral infection.[62,286]

Other Observations

Glomerulonephritis and renal failure have been associated with influenza viral infections.[306,308] In two instances, acute parotitis occurred in patients with influenza A infection.[22] Although evidence of the transplacental passage of influenza virus to a 30-week-old male fetus was reported,[318] no epidemiologic evidence of influenza virus teratogenicity is known.[187,309]

TREATMENT

SPECIFIC THERAPY

Specific treatment has not been used routinely for children in the United States. With the development of rapid tests for influenza diagnosis, treatment should be considered. Early treatment has the potential not only to shorten the course and reduce complications, but also to reduce spread of the virus to contacts.

The antiviral agents amantadine and rimantadine are active in vitro against influenza A viruses and have been shown to provide prophylactic and therapeutic benefit in both adults and children.[40,44,49,118] Amantadine acts by blocking the function of the M2 protein, the ion channel that functions to facilitate fusion of viral and cell membranes and permits entry of viral RNA into the host cell.[302] Amantadine lacks activity against influenza B viruses. Numerous pediatric studies also have documented the prophylactic effect of amantadine or its analogue, rimantadine, against community-acquired influenza A.[40,49,233,259,260] Few pediatric treatment trials have been performed.[71,165] The use of rimantadine, administered to young children with limited prior experience with the infecting subtype, resulted in the emergence of resistant viruses.[15,118] Amantadine-rimantadine resistance of influenza A virus results from point mutations of the M2 protein.[11,15] In some instances, the resistant viruses have been noted to infect susceptible contacts.[127] Until 2005, fewer than 1 percent of field isolates of influenza A were found to be resistant to rimantadine.[323] A dramatic change occurred in 2005 when the CDC reported that approximately 90 percent of influenza A viruses were resistant to amantadine; use of the M2 inhibitors was discouraged for the 2005 to 2006 season. The mutability of influenza viruses dictates sustained surveillance of sensitivity of circulating influenza A viruses because of the regular introduction of new strains. In any case, precautions should be taken to limit contact between young patients being treated with M2 inhibitors and subjects receiving prophylaxis.[203] This situation allows transmission of resistant viruses.

The armamentarium of antiviral drugs for influenza has been supplemented by the addition of NA inhibitors. The inhaled inhibitor zanamivir is approved for use in children 5 years of age and older.[129] Early treatment with zanamivir twice daily shortened the course of illness by 1.25 days compared with placebo. Zanamivir-treated children resumed normal activities 1 day sooner than did placebo recipients and used less relief medication than did placebo recipients. Adverse events occurred with comparable frequency in treated patients and controls. The drug is effective against both influenza A and B, and no resistant viruses were detected with treatment. The inhaled route of administration results in delivery of drug to the site of infection, but this route limits utility in young children unable to use the inhaler and may not be tolerated by persons with reactive airway disease (RAD). If this drug is used for patients with RAD, short-term bronchodilators should be available.

An oral NA inhibitor, oseltamivir, is efficacious for treatment of both influenza A and B in children as young as 1 year of age.[307] In children given a dose of 2 mg/kg twice daily for 5 days starting early in the illness, the resolution of influenza was accelerated by 1.5 days compared with controls. The duration of viral shedding and the quantity of virus in respiratory secretions were significantly decreased in treated children. The incidence of acute otitis media was reduced by 44 percent in the treated children, a medically significant benefit that was reflected in decreased use of antibiotics. The frequency of vomiting in treated children was 5 percent in excess of that in placebo recipients but usually did not result in cessation of therapy. Nausea was reduced by administration with food. Viral isolates with higher than pretreatment values for 50 percent inhibitory concentration for NA inhibition were detected in 5.5 percent of oseltamivir-treated children with influenza A infection; no increased resistance was found for influenza B isolates. In Japan, where oseltamivir has been used frequently to treat children, influenza B infections have been less responsive to treatment with oseltamivir.[155] The clinical significance of this observation is unknown; resistant strains generally have been less virulent and less transmissible in laboratory studies.

The broad-spectrum antiviral agent ribavirin was used successfully in the treatment of both influenza A and B in adult patients when it was administered as an aerosol.[167,169,192,311] Experience with this treatment modality in children is limited mainly to other viruses, but use of this drug has resulted in no significant adverse reactions.[88,117,195,257] Combination therapy has been recommended by some investigators who have shown increased benefit by simultaneous treatment with both M2 and NA inhibitors.[110] This approach may be especially important if a new pandemic strain emerges; if so, the possibility of combining ribavirin with one of the other drugs may be an important option for treatment of patients hospitalized with severe infections.

PROGNOSIS

The prognosis for clinical recovery from uncomplicated influenza generally is considered excellent. Of the complications of influenza, primary influenza pneumonia, staphylococcal pneumonia, encephalitis, and Reye syndrome have a guarded prognosis. However, a bewildering array of chronic pulmonary conditions has been noted to begin with undifferentiated childhood respiratory tract infections, among which "influenza" often is cited but infrequently proved.[174,265] These conditions include the following: lobar atelectasis; localized and generalized bronchiectasis; and such clinicopathologic entities as Swyer-James syndrome (unilateral hyperlucent lung), bronchiolitis obliterans, Hamman-Rich syndrome (diffuse interstitial pneumonia), and desquamative interstitial pneumonitis. Only precise virologic diagnosis of acute respiratory tract disease, especially viral pneumonia, will delineate the long-term complications that may occur in a small proportion of cases. Universal immunization in healthy children will also assist in sorting out rare outcomes by reducing disease occurrence.

PREVENTION

Immunization offers the best hope for prevention of influenza. Influenza is an uncontrolled epidemic disease that is vaccine-preventable. Despite the availability of effective vaccines, excess mortality and hospitalizations attributable to influenza have continued to rise. To be effective, vaccines must contain antigens

similar to those of the prevalent influenza viruses. Predicting the epidemic potential of new influenza virus variants is difficult. In years when a new variant arises and causes widespread outbreaks, the available vaccine may contain the previous variant with only modest heterologous immunizing potential. Conversely, in years in which new variants do not arise, vaccines may be formulated ideally, but the epidemic potential of virus strains that have already circulated may be diminished, although this is not always true. The A/Sydney (H3N2) variant that predominated from 1997 to 2000 produced severe epidemics for three consecutive seasons. Thus, prevention of epidemics through the use of inactivated vaccines has been limited. Currently, two types of influenza vaccines are licensed in the United States—the traditional inactivated vaccine given by intramuscular injection and the LAIV administered by nasal spray.

INACTIVATED INFLUENZA VACCINE

Many improvements have been made in the formalin-inactivated influenza vaccines since their introduction in the late 1930s.[198] These innovations have included enhanced vaccine production by use of high-yield reassortant viruses that grow rapidly in eggs,[230] exclusion of host antigens and other toxic impurities by zonal ultracentrifugation (current "whole-virus" vaccines),[206] disruption of viral particles with ether or detergents (current "split-product" vaccines),[51,113] and, most recently, physical purification of HA and NA (HANA or "subunit" vaccines).[177]

The antigenicity and reactogenicity of whole-virus and split-product vaccines were studied extensively in children during the trials of A/New Jersey/76 (H1N1) monovalent and A/New Jersey/76 (H1N1)-A/Victoria/75 (H3N2) bivalent vaccines in 1976.[316] Whole-virus vaccines were more immunogenic and, at the same time, more reactogenic than were split-product vaccines because they contained a greater concentration of antigens. In two-dose regimens, the split-product vaccines produced adequate antibody levels without acute reactions. The A/Victoria/75 component of the bivalent vaccines had significantly greater immunogenicity than did the A/New Jersey/76 component in children, a finding that reflects previous priming by H3N2 viral strains but a lack of previous exposure to H1N1 viruses. The consensus of these studies was that split-product vaccines, by virtue of their minimal reactogenicity, should be preferred for vaccination of children. Additional large-scale trials in 1978 evaluating monovalent A/USSR/77 (H1N1) and trivalent A/USSR/77 (H1N1), A/Texas/77 (H3N2), and B/Hong Kong/72 inactivated influenza virus vaccines were in agreement with previous results.[312] Protective efficacy, which with whole-virus vaccines had ranged from 50 to 95 percent after homologous challenge,[162] was comparable for split-product vaccines,[45,112,237,250] even against antigenic drift virus strains.[45,237] Gruber and associates[114] reported a protective rate of 60 percent with B/USSR/83 vaccine against the next variant, B/Ann Arbor/86, in children 3 to 18 years of age. A double-blind, placebo-controlled trial in 6- to 18-year-old asthmatic children failed to show any protection against culture-positive asthma exacerbations over a 2-year period from 1999 to 2001.[29]

Inactivated vaccines generally are less immunogenic for younger children, but the incidence of acute otitis media could be reduced by 30 to 40 percent in children in daycare.[87] During the 1996 to 1997 epidemic, children in daycare received two doses of inactivated vaccine in a controlled trial; protection was 45 percent against influenza B infection and 31 percent against influenza A (H3N2) infection.[144] Children with preexisting antibodies had better responses than did those without, a finding indicating that priming by natural infection improved antibody response to the inactivated antigens. A single dose of inactivated antigen is sufficient for primed children.[219] Two doses of inactivated vaccine are necessary for toddlers aged 6 to 23 months, and protection is not evident until 2 weeks after the second dose is administered. Vaccine effectiveness in fully vaccinated children in this age group was 25 percent against influenza-like illness in 2003 to 2004.[256]

The side effects of vaccination with inactivated vaccines in children deserve further comment. Reactions to whole-virus vaccines, when they occur, include fever, "flu-like" symptoms of malaise and myalgia, and local tenderness at the site of inoculation.[316] In the past, febrile convulsions were cited as a particular risk of vaccination in the very young.[190,315] In the large trials cited, however, 813 children aged 6 months to 5 years received varying doses of whole-virus and split-product vaccines.[112,316] None of these children had febrile convulsions. During the 1978 trials with subunit vaccines, standardized for HA content, local and systemic reactions were minimal in high-risk children.[312] Current subunit inactivated influenza vaccines are minimally reactogenic and are well tolerated.

Guillain-Barré syndrome occurred in roughly 1 in 100,000 older adult recipients of the A/New Jersey/76 vaccine in the National Influenza Immunization Program.[261,266] The incidence of this complication among pediatric vaccine recipients, as well as among members of the military services who were younger than 25 years of age, was not increased. Surveillance of subsequent years revealed no excess occurrence of Guillain-Barré syndrome among pediatric influenza vaccine recipients.[33,145,152,153] The risk of developing Guillain-Barré syndrome after acquiring natural influenza virus infection is unknown; although sporadic cases have been reported, influenza infection is not an important triggering agent for this syndrome.[304]

LIVE ATTENUATED INFLUENZA VACCINE

The LAIV was developed originally by Maassab, who selected temperature-sensitive, attenuated strains by serial passage at gradually lower incubation temperatures down to 25° C ("cold-adapted").[52] Live vaccines, administered intranasally, correspond most closely to natural infection in their capacity to produce both secretory and humoral immunity. LAIV was licensed in the United States after the pivotal efficacy trial was performed in children 15 to 71 months of age.[13,14] These vaccines have been administered to adults and children; both local and systemic antibody responses resulted, with no significant side effects.[31,39,216,313,320] These vaccines also have been shown to be safe and nontransmissible in both these populations and result in protection against challenge with wild influenza virus.[31,34,38,213,313] LAIV is genetically stable, with no reversions to virulence after human passage.[296] Jefferson and colleagues assessed the efficacy and effectiveness of influenza vaccines in healthy children older than 2 years of age in 2005; these investigators reported overall efficacy of 79 percent for LAIV and 65 percent for inactivated vaccines.[149] They found no evidence of benefit of inactivated vaccines for children younger than 2 years of age, but they did not include all the trials cited earlier.

Live attenuated, cold-adapted vaccines administered by nasal spray appear to be the most promising new approach to influenza control.[183] In the pivotal trial, LAIV administered to children aged 15 months to 6 years gave 93 percent protection against culture-positive illness.[14] In the follow-up year, the A/Wuhan (H3N2) vaccine strain provided 86 percent protection against the new variant, A/Sydney (H3N2).[13] The vaccine is well tolerated and accepted by children. Attributable reactions were limited to mild rhinitis in 9 percent and low-grade fever in 5 percent on day 2 for first-time recipients. No reactions were discernible with subsequent doses.[241] Comparable protection against influenza A (H1N1) and a variant B strain was demonstrated in the Central Texas Field Trial. A single dose was sufficient to provide 92

percent protection against A (H1N1), and the protection persisted to a second season.[86,122] Direct comparisons of LAIV and inactivated vaccines were carried out in Europe and Israel. One study showed superior relative efficacy of LAIV in young children aged 6 to 71 months.[3] The other study found that LAIV was well tolerated by asthmatic children aged 5 to 19 years and provided significantly greater relative efficacy of 34.7 percent against culture-confirmed influenza than did the inactivated vaccine.[72] LAIV also was found to be superior to inactivated vaccine in a large head-to-head comparison that enrolled more than 8000 children aged 6 to 59 months[12]; 54.9 percent fewer culture-confirmed illnesses occurred among LAIV recipients. Another advantage of LAIV is the observation of almost immediate protection after intranasal administration, as demonstrated during the Central Texas Field Trial in 2003 to 2004.[123,239]

Vaccination of normal children aged 6 months to 18 years now is recommended routinely in the United States.[33] The risk of hospitalization for children younger than 3 years of age is as high as that for elderly persons,[148,220] and unlike in the elderly, fewer than 20 percent of young hospitalized children have a chronic underlying condition.[235] Because children are the most important population group in the propagation of epidemics, a vaccine strategy aimed at epidemic prevention would necessarily be focused on the pediatric age group, particularly children in school and daycare.[93,305] Supporting this concept, mass vaccination of schoolchildren had a measurable effect on the overall incidence of influenza A/HK/68-associated illness in Tecumseh, Michigan, during the 1968 pandemic.[204] The protective effect was most evident in adults 20 to 30 years of age, a finding suggesting that immunization of children lowered the incidence of influenza in their parents. Even more impressive was the large trial in Moscow, where vaccine was offered only to children in a defined geographic area including more than 400,000 people.[89] Rates of influenza-related illness were compared with a similar district where vaccine was not offered to children. Vaccine was not given to any elderly or high-risk adults; however, significant protection of unvaccinated elderly persons was found for those living in the area where the children were immunized. Rates for medical encounters in elderly persons were the same for both populations during the summer months, a finding establishing the comparability of the two areas.

Proof of the concept of indirect protection afforded by childhood immunization is the Japanese program for universal vaccination of schoolchildren.[254] Japanese schoolchildren were required to have two doses of inactivated influenza vaccine for school attendance for many years, particularly during the decade between 1977 and 1987. As many as 80 percent of children aged 9 to 15 years were immunized annually. The program declined when the requirement was relaxed in 1987, and the program was stopped in 1994. Subsequently, total excess mortality has increased remarkably. In retrospect, definite flattening of the mortality curve occurred during the program, in contrast to sharp seasonal peaks of mortality rates coinciding with influenza epidemics before and after the program. The only exception was seen in 1975 to 1976, when a new variant, A/Victoria (H3N2), appeared unexpectedly and produced a severe epidemic; the previous variant, A/Port Chalmers (H3N2), provided no cross-protection against A/Victoria. The immunization of schoolchildren in Japan is estimated to have saved 37,000 to 45,000 lives each year. Vaccine was not recommended for elderly or high-risk persons whose lives were spared; the reduction in mortality rates resulted from the indirect effect of immunizing schoolchildren. The sparing of elderly and high-risk individuals could not be attributed to the economic recovery of Japan following World War II; the summertime baseline mortality rate was unrelated to the wintertime excess mortality.[253]

Universal immunization of children in school or daycare would reduce significantly the serious morbidity in this age group and the social disruption created by school absence, necessity for health care visits, and parents' work absence.[218] The school-based program designed by King and colleagues showed significant amelioration of the morbidity and social consequences by offering LAIV to schoolchildren.[164] School-based programs also would have the potential for dampening epidemics and reducing risk of exposure to virus for vulnerable high-risk patients,[93] as demonstrated by Piedra and colleagues.[238] The cold-adapted, attenuated vaccine developed by Maassab has broader and longer-lasting immunity for children younger than 10 years.[41,86,122,237] The administration by nasal spray is accepted better by children and is easier to administer than is the inactivated vaccine given by injection.

Universal immunization of children in the United States would not replace but rather would supplement the current vaccination strategy, focused on the prevention of complicated illness in population groups at highest risk of dying or requiring hospitalization during epidemics. The current list of those given priority for influenza vaccine includes more than 250 million persons.[33] Also given priority for vaccine are pregnant women as well as health care providers and household contacts (including children) of high-risk patients and children younger than 5 years of age.[33] Vaccinating pregnant women has the potential to protect two persons at a vulnerable period in their lives—both the pregnant woman and her infant, who will benefit from the passive immunity provided during the first months of life.[249] Maternal immunization not only will reduce pregnant women's risk of needing hospitalization for pneumonia but will boost the amount of protective antibodies transmitted to their newborn infants and reduce the occurrence of serious infections in the first 6 months of life.[109,249,321] Vaccination programs must be supplemented by better surveillance and viral diagnosis. Early specific treatment of influenza-infected children with appropriate antiviral drugs will not only shorten the course of illness but also reduce virus in respiratory secretions.[307] This effect should allow reduction in transmission of virus to contacts, another effort to contain this venerable foe.

SUBSECTION 7

Paramyxoviridae

CHAPTER 191

Parainfluenza Viruses

Caroline Breese Hall

> Physical ills are the taxes laid upon this wretched life;
> some are taxed higher, and some lower,
> but all pay something.
>
> *Philip Stanhope, Lord Chesterfield*
> *Letter to the Bishop of Waterford, 1757*

The human parainfluenza viruses (hPIVs) are ubiquitous agents with well-earned recognition as being among the most important viral respiratory pathogens of humans. The three major hPIVs (1-3) have been estimated as being among the three most frequent causes of hospitalizations for young children with respiratory tract illnesses.[66,67,73] The impact of these three hPIVs on our health care resources is well illustrated in the estimates of their causing among children under 5 years of age approximately 16,000 to 100,000 hospitalizations each year.[29] Hospitalizations from hPIV-3 alone are estimated to range from about 9,000 to 52,000 each year. The rates of outpatient visits for hPIV infections among young children are even higher, estimated to be tenfold the hospitalization rates.[40a] The taxes imposed by the burden of all the hPIVs, types 1 to 4, and at all ages are unestimated.

Respiratory tract illnesses from the hPIVs may occur and recur throughout life, and they are subordinate only to respiratory syncytial virus (RSV) in the morbidity caused by acute lower respiratory tract disease in infants and young children. Among the agents of acute laryngotracheobronchitis, the hPIVs are second to none. The frequently epidemic nature of hPIV types 1 and 2, the prolonged seasonal occurrence of type 3, and the ability of all types to cause repeated infections indicate why their import has not been diminished, despite the technologic advances available toward control of viral diseases.

HISTORY

The historical delineation of the parainfluenza viral family is intertwined with the discovery of the related animal viruses and marked by the colorful names descriptive of their origin (Table 191–1). The first strain of PIV was discovered in Japan and named *Sendai*, or the hemagglutinating virus of Japan (HVJ).[88] This agent was recovered from mice that had been inoculated with postmortem lung tissue of infants with pneumonia. The first PIV from human sources was recovered several years later by Chanock[19] from infants with croup, and thus it became known as the croup-associated (CA) virus. Subsequently, three additional hPIVs that were distinct antigenically were isolated from children with acute respiratory illness.[22,77] In contrast to the CA virus, which was recognized by its ability to produce syncytia in tissue culture, the strains of the next two types of PIVs produced few or no cytopathic effects but were recognized by their ability to cause hemadsorption of guinea pig erythrocytes to infected tissue culture. These viruses thus were called hemadsorption type 1 (HA-1) and hemadsorption type 2 (HA-2) viruses.

Once the similarity of the familial characteristics of the CA virus with those of the other three viruses was recognized, the viruses were renamed the hPIVs, type 1 (HA-2), type 2 (CA), and type 3 (HA-1).[4] The fourth hPIV, discovered subsequent to this reclassification, is without a sobriquet and simply is termed *hPIV-4*, with two subtypes, A and B. The first type 4 strain was recovered in monkey kidney cell culture from a college student afflicted with a common cold.[77]

Several animal species appear to be natural hosts to the PIVs (see Table 191–1), with the exception of hPIV-4, which has been found only in humans. In animals, PIVs may be important pathogens. Bovine PIV (bPIV), similar to hPIV-3, often in combination with infection by *Pasteurella* organisms, causes an illness of considerable morbidity and cost in cattle called *shipping fever*. Naturally acquired antibodies to the PIVs are found not only in cows but also in rodents, monkeys, rabbits, and other mammals. Various rodents, along with ferrets, dogs, and lambs, have been used for experimental infection. The virus previously called *equine Morbillivirus* has been demonstrated to be in the Para-

TABLE 191–1 Parainfluenza Viruses

Parainfluenza Virus Type/ Related Animal Virus	Natural Host	Experimental Infection	Preferred Tissue Culture for Initial Isolation	Cytopathic Effect	
				Initial Isolation	Passage
Parainfluenza type 1, hemadsorption type 2 (HA-2)	Human, guinea pig, rabbit, monkey, marmoset	Hamster, ferret	Monkey kidney, human diploid, human embryonic kidney	±	Rounding, cell destruction
Sendai, hemagglutinating virus of Japan (HVJ)	Mouse, pig				
Parainfluenza type 2	Human, monkey, rabbit, guinea pig	Hamster, dog	Monkey kidney, human embryonic kidney	+ (syncytial on monkey and human cells)	Syncytial, "Swiss cheese"
Simian virus 5 (SV 5)	Monkey				
Simian virus 41 (SV 41)	Monkey				
Parainfluenza type 3, hemadsorption type 1 (HA-1)	Human, guinea pig, monkey	Hamster, ferret, cotton rat, mouse, lamb	Monkey kidney, human embryonic kidney	±	In monkey cells: elongated, detachment of cell sheet In human cells: syncytial
Shipping fever (SF-4)	Cow	Hamster, guinea pig	Primary kidney	±	Rounding granular, vacuolated
Parainfluenza type 4	Human				

myxoviridae family and named *Hendra virus*. This virus, which causes lethal illness in horses, was recognized to cause illness in humans also. Individuals in close contact with the horses in Australia contracted the virus, and two died.[124] Subsequently, in 1998, an outbreak of severe, often fatal encephalitis occurred in Malaysia and Singapore in individuals who had close contact with pigs.[25,49] The agent of this outbreak, called *Nipah virus*, is phenotypically and antigenically similar to Hendra virus (80% genomic homology).

CHARACTERIZATION OF PARAINFLUENZA VIRUSES

CLASSIFICATION AND STRUCTURE

The five hPIVs, hPIV types 1, 2, 3, 4A, and 4B, are members of the Paramyxoviridae family, belonging to the *Respirovirus* and *Rubulavirus* genera (Fig. 191–1). When discovered in the late 1950s, the PIVs were distinguished quickly from the orthomyxoviruses (influenza viruses) in size, nucleocapsid structure (non-segmented), antigenic composition, and laboratory growth characteristics.

hPIVs are single-stranded, negative-sense, enveloped RNA viruses appearing as pleomorphic particles of medium size, with an average diameter of 150 to 200 nm.[21,81a,147] The genomes of all the hPIVs, consisting of an average of approximately 15,000 nucleotides, code for at least 6 structural proteins (3′-N-P-M-F-HN-L-5′) and one or more nonstructural proteins (C, V, D) (Fig. 191–2). Enclosed within the spherical virion is the helical nucleocapsid, with its herringbone core tightly wrapped by the nucleocapsid protein (NP). It is surrounded by the envelope, derived from the host cell, which is studded with spikes of surface glycoproteins, the hemagglutinin-neuraminidase (HN) and fusion (F) proteins, which are the major protective antigens. The large (L) polymerase protein and the phosphorylated nucleocapsid-associated protein also form clusters within the nucleocapsid structure. The sixth structural protein is the nonglycosylated matrix (M) protein, located between the nucleocapsid and the envelope.

Replication and assembly of the virus occur solely in the cytoplasm of the host cell.[21,81a,147] The NP, along with the P and L proteins, is responsible for the primary transcription that occurs sequentially, producing predominately nonoverlapping subgenomic messenger RNAs from which the viral proteins are translated. The genome also is replicated from the formation of a full-length antigenome with positive-sense RNA. The NP and the genomic RNA comprise the helical structure, and with the subsequent addition of the P and L protein complexes, the nucleocapsid is formed. The envelope proteins are assembled at the cell surface. The M protein is the smallest of the major structural proteins and is the most abundant of the virion's proteins. The M protein facilitates the interaction between the nucleocapsid and the surface glycoprotein by the attachment and the insertion of the surface glycoproteins to the host cell and recruitment of the completed NP to the budding site of new virions, which are released from the cell surface by evagination of the plasma membrane.

The HN protein is a dimer of two polypeptide portions held together by a disulfide link in the hydrophilic region and at the bases by hydrophobic bonds. The HN is the major immunogenic and type-specific determinant. It is important in multiple viral functions, including mediating the attachment of the virus to the host cell by binding to sialic acid–containing mucoprotein receptors present on the cell. The hemagglutination component of the HN protein mediates the hemagglutination of mammalian erythrocytes. The neuraminidase component of the HN protein functions during late infection to release progeny virions by dislodging the cellular bond by cleaving the sialic acid residues and prevents reattachment of the viral particles to the cell surface.

The F protein effects entry of virus by fusing the host and viral cellular membranes. Once adsorption of the virus occurs, the F protein precursor, F0, is cleaved by host proteases into the active F1 and F2 protein fragments, which mediate penetration of the virus into the cell, with subsequent fusion of the viral and cell membranes and hemolysis. The N-terminal residues of the F1 protein (the fusion peptide) promote the penetration and fusion of the virus with the cellular membrane. In contrast to the foregoing proteins, the nonstructural C, V, and D proteins are not encoded by all the hPIVs but are produced variably by the different hPIV types and appear to have roles in transcription, replication, production, and pathogenicity of the virions.[21,64]

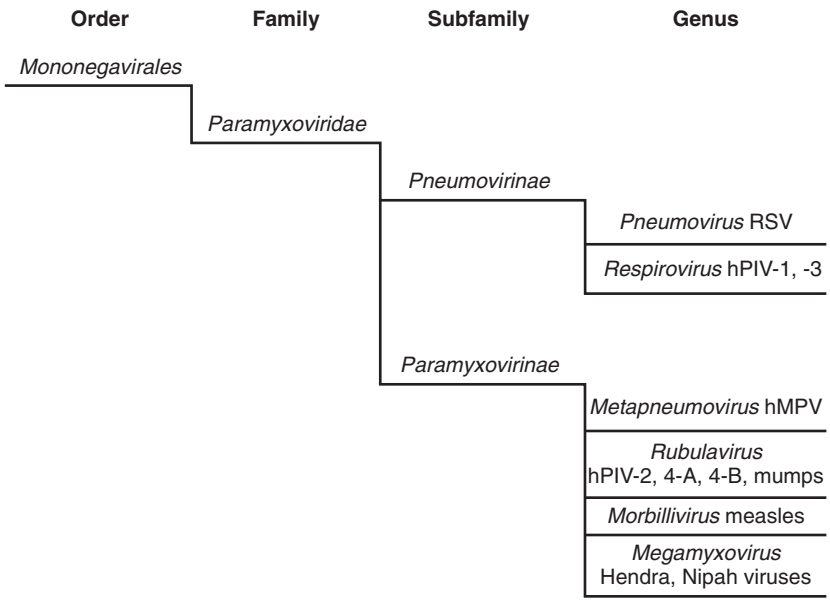

Figure 191–1 Classification of parainfluenza viruses that cause human infection.

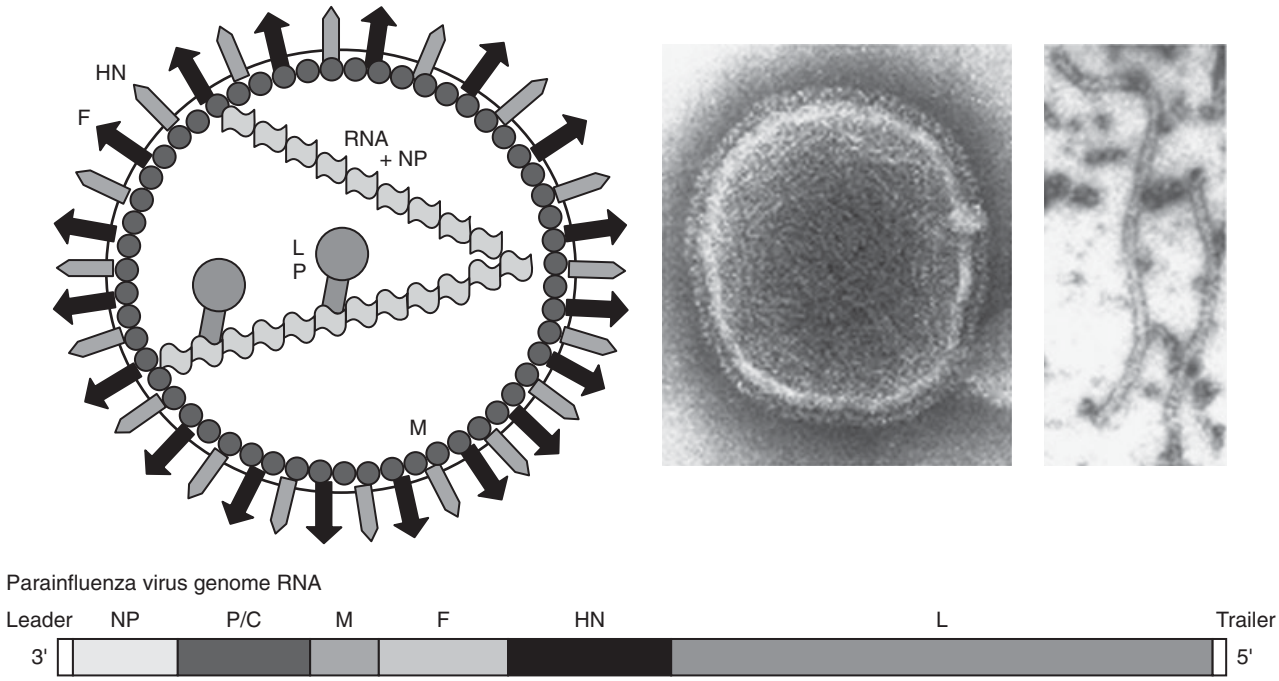

Figure 191–2 Structure of parainfluenza virus (Sendai virus, *top left*) and its genomic RNA *(bottom)*. Electron micrograph of Sendai virus *(top middle)* and its helical nucleocapsid *(top right)*. *(From Takimoto T: Parainfluenza viruses.* In Harper, D. (ed.): *Encyclopedia of Life Sciences. Chichester, U. K., John Wiley and Sons, pp. 678-684, 2006.)*

hPIVs share common antigens but also may be differentiated into two antigenic groups. hPIV-1 and hPIV-3 are within the *Paramyxovirinae* genus *Respirovirus*, and hPIV-2 and hPIV-4A and -4B are within the *Paramyxovirinae* genus *Rubulavirus*[21] (see Fig. 191–1). Their common antigenicity is illustrated by serologic heterotypic antibody responses to infection with hPIV-1, hPIV-2, and hPIV-3 and mumps virus. Although the hPIVs do not undergo major antigenic alterations in their surface antigens similar to influenza virus, genetic and antigenic variations within all four types have been detected, and their evolution can be determined by analyses of strains obtained over time.[21,64,81a,167]

ISOLATION AND IDENTIFICATION

The hPIVs are inactivated rapidly by acid at a pH of 3.0 and by exposure to lipid solvents, such as ether and chloroform, which destroy the envelope of the virus. They also are relatively labile to temperatures higher than 37° C.[32,33] Media containing protein, however, tend to protect against loss of infectivity when the virus is exposed to heat and when it is frozen at –70° C.[32,72]

Isolation of the hPIVs occurs in permissive cell cultures after an incubation period of 3 to 7 days at 35° C to 37° C. The preferred cell cultures for the isolation of the hPIVs are primary or continuous monkey kidney cells, such as LLC-MK and human embryonic kidney cells, along with a continuous line of mucoepidermoid human lung carcinoma cells, NCI-H292.[21,41,62,64] In general, the growth of hPIVs is best in primary monkey kidney cells, although the growth of hPIV-2 may be variable in monkey kidney cells. hPIV-1 also grows well in human embryonic lung and less well in diploid fibroblastic lines. In other types of kidney tissue, the growth of the hPIVs is more variable. hPIV-3 replicates in bovine and canine kidney cells, and hPIV-4 replicates in bovine and hamster kidney cells. After passage, hPIVs can be propagated in a variety of other cell lines. Persistent infection of some cell lines has been observed with hPIV-1, hPIV-2, and hPIV-3.[42,108] Cells persistently infected with hPIV-3 have little or no cytopathic effect, which is related to the lack of cell fusion, despite the production of large amounts of the cleaved active form of the F1 protein.[157] The growth of the hPIVs in embryonated eggs is poor or inconsistent according to the type and strain. hPIV-1, hPIV-2, and hPIV-3, but not hPIV-4, have been adapted to grow in the amniotic cavity of embryonated chicken eggs, although some strains appear resistant to such adaptation.

The production and characteristic type of cytopathic effect in tissue culture vary according to the hPIV strain (see Table 191–1).[127] hPIV-1 and hPIV-3 on initial isolation are unlikely to demonstrate distinctive cytopathic effects, but, depending on the cell line, they may on passage. hPIV-4 is the most difficult hPIV to grow and identify in tissue culture because the cytopathic effect is not evident, and 2 to 4 weeks may be required before identification by hemadsorption is possible. Identification of hPIVs in tissue culture traditionally has relied on the ability of the hPIVs to hemadsorb erythrocytes, most commonly guinea pig, human group O, or chicken erythrocytes, at 4° C or 25° C. However, the sensitivity of this method is variable, especially for the rubulaviruses hPIV2 and hPIV4.[64] Isolation and identification of the hPIVs may be accelerated by use of shell viral cultures and subsequent identification by immunofluorescence assay (IFA) techniques.[127]

Rapid antigen identification methods, such as direct visualization of exfoliated cells by IFA and enzyme-linked immunosorbent assays (ELISA), have generally had highly variable sensitivity, and antigen assays for the hPIVs have not been widely available.[52] Reverse transcriptase-polymerase chain reaction (RT-PCR) with differential hybridization techniques, such as hybridization with enzyme immunoassays, has markedly increased the detection and specific identification of the hPIVs in patient specimens.[17,38,64-66,133,158] RT-PCR assays can detect a single respiratory virus or multiple viruses simultaneously, and, although previously confined to research laboratories, these assays are becoming more widely available commercially.

EPIDEMIOLOGY

GEOGRAPHIC DISTRIBUTION

The ubiquitous nature of the hPIVs has been illustrated by many serologic and viral isolation studies in varied populations, in many parts of the world, and in differing climates.[45,101,106,118,144,158] Despite the wide variations in climate and geography, experience with the hPIVs is similar in most countries.

PREVALENCE AND AGE AT INFECTION

The frequency and impact of hPIV infections are greatest in preschool-aged children and are estimated to account for approximately one third of the lower respiratory tract infections in this age group.[45,64,67,87,132] Among the hPIVs, the type most commonly isolated is hPIV3, which usually is acquired first, followed by hPIV-1 and hPIV-2 (Fig. 191–3).

Like RSV infection, hPIV-3 infection is a common occurrence during the first few months of life. One half to two thirds of infants have acquired infection by the time they reach 12 months of age.[45,106,111] Experience with hPIV-1 and hPIV-2 usually occurs later, most commonly during the preschool years.[45,46,106,132]

The frequency of hPIV infection in the young child has been well illustrated by the Houston Family Studies, in which infections were detected by both viral isolation and serology among children observed from birth.[45,46] By the time they reached 2 years of age, 92 percent of the children had experienced at least one infection with hPIV-3, and 32 percent had been infected more than once. hPIV-3 is the most frequent cause among hospitalizations associated with hPIV infections. hPIV-1 and hPIV-2 are associated primarily with hospitalizations of children aged 2 to 6 years. The age distribution of children with hPIV-1 and hPIV-3 viral infections seen in private pediatric practice, however, may overlap substantially (see Fig. 191–3). In outpatients in Rochester, New York, approximately half of the hPIV-3 viral infections occurred in children younger than 24 months, compared with approximately one third of the hPIV-1 infections.[87] Among children aged 2 to 5 years, the reverse was true, with half of the hPIV-1 infections and approximately one third of the hPIV-3 infections occurring in this older age group.

The epidemiology of hPIV-4 is less well described. In part, the reason may be that clinical disease is infrequent or mild, thus rendering identifying hPIV-4 infection difficult and the prevalence underestimated.[1,12,89,134] Some serologic studies, however, suggest that infection with hPIV-4 is a common occurrence during the preschool years, and between 50 and 90 percent of 5-year-old children possess antibodies.[44,85,90]

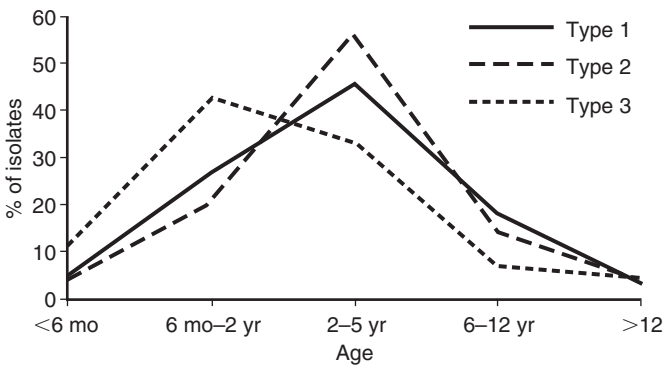

Figure 191–3 Age distribution of infections with human parainfluenza virus types 1, 2, and 3 in outpatient children in Rochester, New York, from 1976 to 1992. *(From Knott, A., Long, C. E., and Hall, C. B.: Parainfluenza viral infections in pediatric outpatients: Seasonal patterns and clinical characteristics. Pediatr. Infect. Dis. J. 13:269-273, 1994.)*

SEASONAL OCCURRENCE

The seasonal patterns of the hPIVs may vary according to location and year, but they remain distinctive in their predictable and repetitive behavior. Before the early 1960s, the hPIVs were mostly endemic.[19] Since the mid-1960s, however, hPIV-1 began changing its profile by preferentially appearing in the fall and settling into its most common current pattern of causing outbreaks every other year in the autumn.[45,87,132]

The behavior of hPIV-2 has been more erratic.[45,64,87,132] During 20 years of surveillance in Rochester, New York, hPIV-2 appeared sporadically in low numbers, usually at the end of the fall outbreaks of hPIV-1 in the odd-numbered years (Fig. 191–4).[56,87] hPIV-3 may be present in a community in low numbers for many months, but it does produce swells of more epidemic activity in the spring to fall.[45,56,87] During long-term surveillance, approximately 75 percent of hPIV-3 isolates were recovered in the spring and summer, and most of the remainder were obtained in the autumns of the even-numbered years, when hPIV-1 was absent.[87]

PATHOGENESIS

TRANSMISSION

Clinical and experimental observations indicate that the hPIVs are able to spread readily and effectively.[5,28,59,81,111] Close contact with an infected individual or their secretions appears necessary, to allow spread of infection to occur through large droplets or by fomites followed by self-inoculation. Contagiousness, therefore, depends on the following: (1) the quantities of virus contained in the nasal secretions[16,59]; (2) how effectively the infected secretions are propelled into the environment, such as through sneezing and coughing; and (3) how well the infectious virus can survive in the environment.[16]

Children with primary infection caused by hPIV-1 have considerable quantities of infectious virus in their nasal secretions, an average of approximately 1000 tissue culture infective doses ($TCID_{50}$) per milliliter.[59] With the tendency of hPIVs to cause illnesses associated with frequent sneezing, coughing, and profuse nasal discharge, contamination of the environment from infected individuals, especially young children, is inevitable. Thus, spread of infection occurs readily by fomites and by the other putative major mode of spread, large-particle aerosols of secretions from an infected individual. For large particles (>10 μm in diameter) to be inhaled, close person-to-person contact is required. Although the routes of inoculation that occur naturally have not been studied adequately, adults have been infected experimentally by intranasal and oropharyngeal inoculation. The eye as a site of inoculation has not been examined similarly, but it may be an important portal of infection from self-inoculation with contaminated hands.

Experimental data suggest that hPIV secretions survive well on hard, nonporous surfaces, such as those found in hospitals, workplaces, and homes. The hPIVs remain infectious on nonporous surfaces for as long as 10 hours and on porous surfaces for as long as 4 hours, but survival may be diminished by drying.[16] hPIVs may remain infectious after being transferred to hands from environmental surfaces, a finding further suggesting that fomites are an important mode of dissemination. A curious conundrum is the survival and persistence of hPIV-1 and hPIV-3

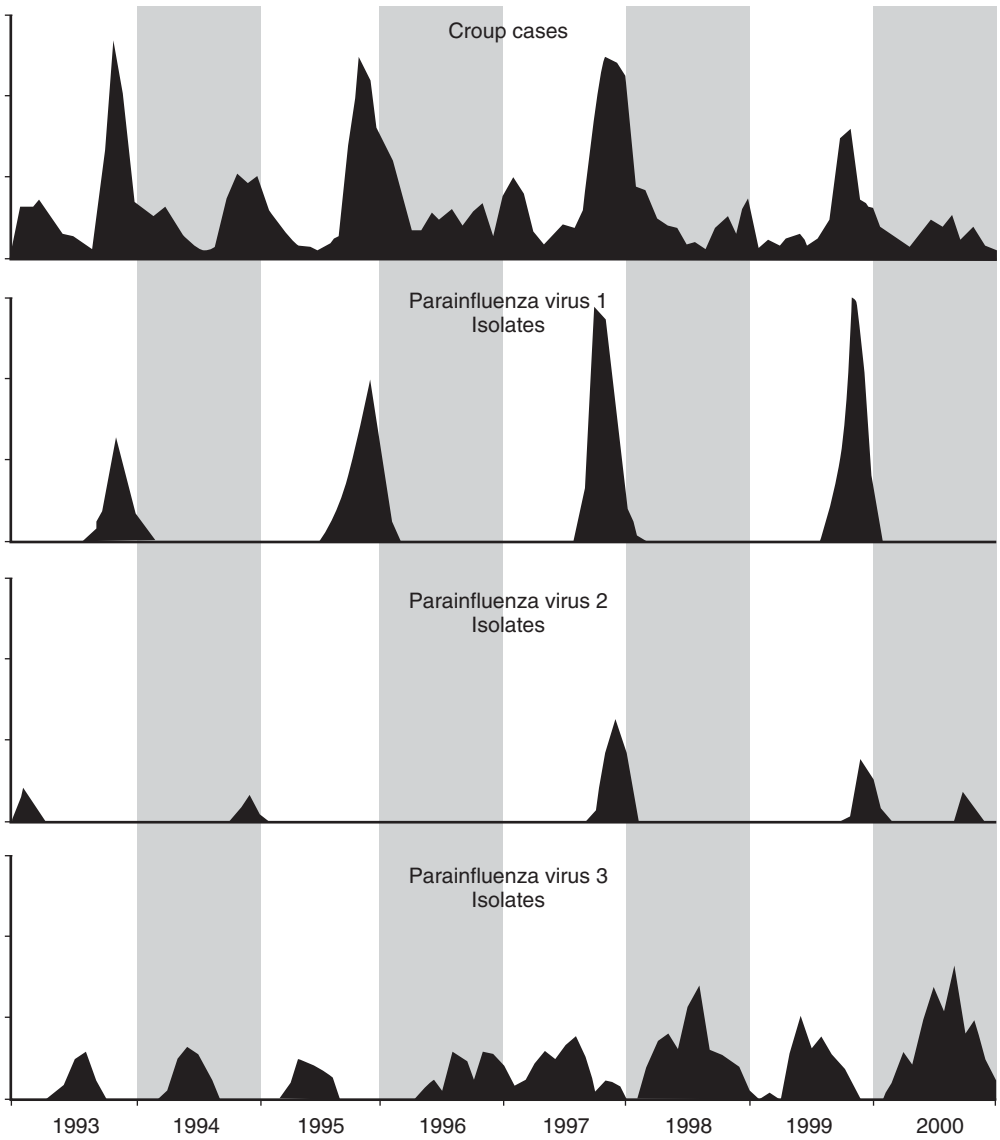

Figure 191–4 Number of cases of croup reported by the primary care physicians in Rochester and Monroe County, New York, from 1993 through 2000, to the Community Infectious Disease Surveillance Program of the University of Rochester School of Medicine, Rochester, New York. Numbers of cases are shown in relation to the periods of isolation of the parainfluenza viruses.

infections in a group of individuals isolated in the frigid environs of the South Pole for 8.5 months.[110,122,123] Despite no outside contacts, infection with hPIV-1 and hPIV-3 occurred repetitively in the quarantined individuals. This phenomenon raised the possibility that persistent infection may be engendered not only in tissue culture but also in humans under such circumstances as extreme environmental conditions.

PATHOLOGY

Inoculation of the hPIVs into the upper respiratory tract results in infection of the nasal epithelium and nasopharynx and the appearance of clinical signs after an incubation period of 2 to 4 days. The hPIVs appear to replicate preferentially in the superficial ciliated epithelial cells lining the airways of the upper and lower respiratory tract. The factors determining the tropism and extent of the viral infection are incompletely understood. Such factors may include host immunity, the protease activity of various tissues, and virus-specific determinants, such as the cleavage phenotype of the F0 protein.[21,107]

The importance of factors that affect the degree of viral replication is indicated by the clinical and experimental correlation of pathogenicity with the level of productive infection.[15,54,59] The development of live attenuated PIV vaccines by reverse genetics confirmed this correlation by the correlation of precise viral mutations with clinical attenuation.[10,34,80,116]

Pathologic studies of children with hPIV infections are limited. The few cases of confirmed hPIV infection examined have shown that in the young child with primary infection, inflammation, marked primarily by necrosis of the epithelium, is evident throughout the respiratory tract. The subglottic tissues in croup appear particularly involved, but with primary infection, the conducting airways at all levels and the alveoli may be affected.[20,168]

Viral shedding is most abundant and prolonged in young children with primary and severe disease.[59] Children with hPIV-1 infections may shed the virus for an average of 4 to 7 days but for as long as 12 days. With hPIV-3 infections, shedding tends to be longer, occasionally for 2 to 3 weeks, and in adults with chronic lung disease, shedding may be both prolonged and intermittent.[53,64]

Experimental infection of animals with PIVs provided a model for the study of the pathophysiology of these infections.[21,121,129] Inoculation of rodents with hPIV-3 produced histologically evident, but usually asymptomatic, interstitial pneumonitis or bronchiolitis. Ferrets also can be silently infected, but in newborn ferrets, PIV infection may be progressive and fatal.[104] Chimpanzees and several species of monkeys may be infected, but clinical manifestations generally are lacking, except with hPIV-3 infection of chimpanzees and African green monkeys. Inoculation of hPIV-2 into the respiratory tract of a canine model produced clinical signs of cough and rhinitis accompanied by histologic changes in the airways.[155]

IMMUNE RESPONSE: ROLE IN PATHOGENESIS AND PROTECTION

Innate immunity's role in controlling PIV infection and how it is elicited are of increasing interest but currently of limited clarity. Better understanding of the pathogenesis of the innate response and its effect on the transition to adaptive immunity may lead to novel and better means of controlling the ubiquitous hPIV infections that occur during infancy and thereafter.

The innate antiviral responses to infection of viruses of the *Paramyxoviridae* family have been studied in experimental models. The response is elicited within the respiratory tract once the viral genome enters and replicates in the cytoplasm of the host cell and is characterized by the production of a cascade of immunomodulatory mediators, chemokines, and proinflammatory cytokines.[30,119,120] Toll-like receptors (TLRs), a class of pattern-recognition receptors, appear to be important early in the innate antiviral defense.[30,102] The products of viral replication trigger and activate specific TLRs that allow the binding of the virus to the host cell and the expression of the genes associated with the host immune response. TLRs may help mediate the immune response, both by their interaction with infected respiratory epithelial cells and by the induction of dendritic cell maturation that is integral in the subsequent development of adaptive immunity with the production of effector and memory T cell and B cells.[94,137] Although TLRs appear to have a pivotal place in innate antiviral defense, experimental evidence suggests that replicating infection of paramyxoviruses and other respiratory viruses may induce and enhance the innate immune response by other pathways that are not dependent on TLR-mediated signaling.[91,94,96]

How representative the findings of these experimental studies are to the pathogenesis of the innate immune response in children with hPIV infection remains unclear because the number of studies in young children is limited. Experimental PIV infection can induce interferon-α and interferon-β, and interferon production has been demonstrated during natural parainfluenza infection in young children. [21,50,58,166] However, some PIVs may be able to evade this protective response by inhibiting interferon production through accessory proteins (C and V) expressed from the P gene.[21,50,84]

The major components of the adaptive immune response to hPIV infection and reinfection are both humoral and cellular. The protective effect engendered by serum and mucosal antibodies to hPIV is variable according to age, past infection, and hPIV serotype.

In contrast to infection with hPIV-1 and hPIV-2, the most serious illness caused by hPIV-3 infection usually occurs during the first year of life, when infants possess maternally derived specific antibody. This finding has raised the question whether interactions of maternal antibody and virus may be detrimental.[101] In animal models, however, passively administered PIV antibody and monoclonal antibodies against the F and HN proteins appeared protective. Furthermore, the trials with an inactivated trivalent hPIV vaccine in the 1960s did not suggest a pathogenic role for antibody.[43] Although not protective, the vaccine was immunogenic and produced serum antibody in the vaccinees. Subsequently, the vaccinees did not experience augmented disease, as observed with the simultaneously tested formalin-inactivated RSV vaccine.

Clinical observations also show that the more severe infections involving the lower respiratory tract occur during initial infection in young, seronegative children, but recurrent infections usually are mild. Naturally acquired immunity, therefore, although not complete and of variable durability, does provide protection against more severe disease.[21,46] Antigenic variation in the hPIVs is not sufficient to explain the lack of complete or durable immunity. More likely is the waning of both humoral and cellular immune responses that occurs during the intervals between repeated exposure to one of the hPIVs.

Serum hemagglutination-inhibition antibody and neutralizing antibody are detectable within 1 to 2 weeks.[82] Neutralizing antibody is directed primarily to epitopes on the HN and F proteins. Both of these proteins are important in the immunologic and protective responses, but in experimental animals, some evidence exists that antibody against the HN protein is more protective than is antibody formed against the F protein.[131,146] Infants with primary hPIV infection usually produce a greater antibody response toward HN than F. With repeated infections, an anamnestic and broader humoral antibody response occurs, producing antibodies with cross-reactivity against the different hPIV types. In young children with primary hPIV-3 infection, the antibody response to the HN protein has been shown to be directed at multiple neutralizing antigenic sites.[150] The response to the F protein, whether with primary or recurrent infection, appears to be more variable in magnitude and restricted in terms of antigenic sites. The presence of maternal antibody, however, inhibits the infant's ability to produce specific humoral antibody.

The normal mucosal immune response is characterized predominantly by secretory immunoglobulin A (IgA), but IgG and IgM also are produced.[21] Primary and secondary infections with a heterotypic strain result in low and transient levels of secretory IgA antibody, whereas homotypic reinfection produces an enhanced response.[160] The presence of specific mucosal antibodies was shown to be pivotal to protection against PIV infection in experimental models. Passive administration or induction of mucosal IgA antibody was demonstrated to be more protective than serum IgG antibodies.[143,149] In adult experimental infection, resistance to hPIV infection correlated better with the neutralizing activity in the secretions than in the serum. The titer of IgA antibody, however, did not correlate with the neutralizing activity or with the severity of illness. The production of IgE antibody in the secretions of infants, in contrast, was correlated with more severe respiratory tract disease.[161]

The cell-mediated immune response to hPIV infection is not well defined. The increased severity and prolonged period of viral shedding in immunocompromised hosts, such as those receiving organ transplants, indicate the importance of intact cellular immunity in the control of disease and recovery from hPIV infection.[37,92,152] In animal models, CD8 cytotoxic T lymphocytes were demonstrated to be central to recovery and clearance of PIV infections.[71,83] In the peripheral blood lymphocytes of healthy adults, both CD8 and CD4 cytotoxic T lymphocytes that responded in vitro to hPIV antigens were detected.[31,141] Cell-mediated responses to hPIV infections in children have been suggested as important in the pathogenesis of more severe hPIV disease. Children who have croup from hPIV infection compared with those children experiencing milder hPIV infections have been shown to have increased lymphoproliferative responses and decreased histamine-induced suppression of lymphocyte transformation responses to hPIV.[159]

CLINICAL MANIFESTATIONS

PRIMARY INFECTION

The types of illnesses caused by hPIV infections have characteristic associations with the age of the child, the season, and the hPIV serotype (see Fig. 191–3; Figs. 191–5 and 191–6).[46,48,73,87,90,132,158,165] Most primary infections are symptomatic, and many affect the tracheobronchial and lower respiratory tract. Of the primary infections that involve only the upper respiratory tract, fever and laryngeal or tracheal signs are common occurrences. Reinfections occur frequently in persons of all ages and usually are mild and limited to the upper respiratory tract, or sometimes they are asymptomatic.[46]

In a general practice in Britain, the attack rates of hPIV infections per 1000 population were 43.2 for those 0 to 4 years of age, 12 for those 5 to 14 years of age, and 3.7 for those 40 years of age or older.[8] Among 20- to 50-year-old patients in the Tecumseh study, 16 to 28 percent were infected with hPIVs each year, and the hPIVs ranked second only to the rhinoviruses as the most frequently identified agents of upper respiratory tract infections.[105]

The hPIVs cause a greater proportion of acute respiratory illnesses in outpatients than of the respiratory illnesses in hospitalized children.[87,90] Of all viral respiratory illnesses examined in a pediatric practice, the hPIVs caused approximately two thirds of the croup cases, one fourth of the tracheobronchitis cases, and approximately one half of the upper respiratory tract illnesses, including colds, laryngitis, pharyngitis, and otitis media.

The proportion of children with hPIV infection who require hospitalization, mainly those with croup, has markedly diminished in recent years, primarily because of better outpatient management and therapy of croup (see "Management and Therapy").[138,165] Currently, most children hospitalized with hPIV infections are infants with pneumonia and bronchiolitis from hPIV-3, and they are most likely to be admitted during the spring.

The onset of the typical primary hPIV infection generally is acute and associated with mild fever and upper respiratory signs of the common cold, such as rhinitis, sore throat, and cough. Laryngeal involvement manifesting as hoarseness is apt to be more prominent than with other viruses that commonly produce colds in young children. After 3 to 4 days, these upper respiratory tract symptoms may progress, primarily in infants with hPIV-3 infection, to involve the lower respiratory tract. The characteristic manifestations of pneumonia or bronchiolitis, including dyspnea, crackles, wheezing, and hyperaeration, follow. Children with hPIV-1 or hPIV-2 infection, who usually are aged 2 years or older, also have acute onset of fever and upper respiratory tract signs, but if the infection progresses in this age group, it is more likely to evolve into croup. Children with hPIV-1 infections who were seen in a private pediatric practice during a community outbreak of hPIV-1 predominantly had fever, upper respiratory tract signs, and tracheobronchial or tracheolaryngeal signs of croup.[59] Fever, which frequently was high, occurred in 75 percent. Only 12 percent had an afebrile upper respiratory tract illness.

In children with croup, upper respiratory tract signs are followed by a harsh, barking cough (the "seal's bark"), which heralds the classic manifestations of stridor, retractions of the chest wall, and dyspnea. The course of croup characteristically is variable, with unpredictable waxing and waning in the intensity of the stridor and dyspnea. The acute symptoms usually last for 3 to 4 days. In more severely ill children, hypoxemia may occur from viral involvement of the lung parenchyma, which, although important in management, may not be recognized because of the focus on the apparent major site of inflammation, the subglottic area (see Chapter 22).

Otitis media may complicate the upper respiratory tract manifestations in young infants and older children with hPIV infection.[24,63,87,109,130] Of the otitis media cases associated with hPIV, the serotype most frequently identified is hPIV-1, followed by hPIV-3. hPIVs have been detected in middle ear aspirates as the sole agent or with a bacterial agent. In some children with hPIV upper respiratory tract infections, only bacterial agents are recovered from the middle ear aspirates. hPIV infection, therefore, appears to play both primary and secondary roles in predisposing these patients to middle ear infection.

The association of acute hPIV infection with a nonrespiratory illness or the isolation of hPIV from sites other than the respiratory tract occurs rarely. Case reports have associated hPIV infections with a variety of diseases, including adult respiratory distress syndrome, parotitis, myopericarditis, and diseases of the central nervous system.[6,70,74,153,164,169] Anecdotal reports also have associated hPIV infection with collagen vascular diseases and sporadic severe hepatitis, characterized histologically by syncytial giant hepatocytes.[125,126]

The clinical manifestations associated with hPIV-4 are less well described, which may be explained partially by the technical difficulty of isolating hPIV-4.[1,12,18,68,89,93] With the use of multiplex RT-PCR, hPIV-4 has been identified in specimens from patients with respiratory disease at rates varying from about 3 to 15 percent.[1,18] Most hPIV-4 isolates have been associated with a

mild, usually afebrile, upper respiratory tract infection. However, lower respiratory tract illness associated with hPIV-4 has been reported.[93]

REINFECTION

The common reinfections that occur with hPIV infections usually are mild, with symptoms of the common cold. In adults, hPIV-1, hPIV-2, and hPIV-3 constitute approximately 2 to 5 percent of the upper respiratory tract infections, but one fifth or more of these infections may be asymptomatic.[14,68] Of persons with clinical illness, approximately 30 to 92 percent develop fever, which is commonly associated with malaise, sore throat, and cough. Rhinorrhea, which occurs in less than 25 percent of the adult infections, is not seen as frequently as in children.

hPIV infection may cause more severe disease in elderly persons and also may exacerbate symptoms in both children and adults with chronic lung disease, including chronic bronchitis, asthma, and cystic fibrosis.[27,47,78,115,148] On occasion, pneumonia has been described with hPIV infections in previously healthy adults, such as among military recruits, but is a rare development in normal, healthy populations of adults and school-aged children.[39,163]

INFECTION IN IMMUNOCOMPROMISED PATIENTS

As demonstrated by multiple reports of outbreaks of hPIV infections occurring on transplant units, children and adults with compromised immunity, especially those with deficient cellular immunity, are at high risk for development of severe, and sometimes fatal, hPIV disease.[13,37,92,99,100,136,151,152,162] Among patients who have received bone marrow transplantation, close to half of hPIV infections involve the lower respiratory tract, and approximately 15 to 40 percent of these infections are fatal.[92,136,162] In approximately one third of these bone marrow recipients with hPIV lower respiratory tract disease, the virus may be recovered from the upper respiratory tract.[162] Frequently, the period of viral shedding is prolonged with hPIV infection, a feature that increases the risk of an outbreak of infection among patients and personnel on transplant units. Furthermore, hPIV infection often is not considered among the opportunistic infections that plague these patients, and diagnosis is confounded by the lack of sensitivity of detecting the virus in specimens from the upper respiratory tract.

The incidence of hPIV infections among lung transplant recipients has been estimated to be 5.3 per 100 patients and is most associated frequently with hPIV-3.[152] Infection in these patients often manifests initially by nondistinctive upper respiratory tract symptoms. Progression to involvement of the lower respiratory tract follows in approximately 10 to 70 percent of cases, depending on multiple host factors, including the degree of immunosuppression and the type of transplantation procedure. The risk of developing lower airway disease in transplant recipients is further augmented because of mechanical factors present in transplanted lungs and because of altered or absent mucosal immunity.[152] The bronchus-associated lymphoid tissue (BALT) in the lung, which is integral to the protective immune response against pulmonary infections, is injured during transplantation, thus resulting in diminished control and clearance of the viral infection.

Therefore, the high rate of symptomatic infection (95%) with hPIV infections among lung transplant recipients is not surprising.[152] Cough has been reported as present in 70 percent, dyspnea in 66 percent, fever in 16 percent, and lower respiratory tract disease, which is diagnosed as viral pneumonia, in 16 percent. Of growing recognition and concern is the observation that subsequent to the transplantation, hPIV and other viral infections may lead not only to graft rejection, but also to severe long-term complications. Thirty-two percent of lung transplant recipients have developed acute bronchiolitis obliterans, which has occurred an average of 6 months (range, 1 to 14 months) after their hPIV infection.[37,152]

Among children with immunodeficiency syndromes who have diminished cellular immunity, especially children with severe combined immunodeficiency syndrome, hPIV has been notably severe and frequently fatal.[75] Complicated disease and lower respiratory tract involvement are observed less frequently with hPIV infection among children with less severely compromised cellular immunity, such as patients with human immunodeficiency virus (HIV) infection.[79,97,103] The clinical severity of hPIV infection among patients with HIV infection is variable, but even in those with mild disease, the shedding of hPIV usually is prolonged and may persist beyond the period of clinical symptoms.

DIAGNOSIS

The diagnosis of hPIV infections often may be surmised on clinical and epidemiologic grounds, such as the patient's age, the type of illness, and the seasonal patterns of hPIV in the community. Specific laboratory diagnosis may be made during the acute phase of the illness by isolation of the virus or by identification of the viral antigen in specimens from the patient and during the patient's convalescence by serologic assays (see "Isolation and Identification," earlier).

Serologic diagnosis has been accomplished by numerous assays, including complement fixation, hemagglutination inhibition, hemadsorption inhibition, neutralizing, enzyme immunoassay, and immunofluorescence.[40,65] However, serologic diagnosis is confounded by heterotypic antibody responses. During reinfection, both homotypic and heterotypic antibody rises may occur, or sometimes little antibody response is detected, despite shedding of the virus from the nasopharynx.[21,123] Less is known about the antibody response to hPIV-4 infection, but in primary infection, a homotypic response is usual.[85] Detection of specific IgM antibodies, which usually persist for 2 to 11 weeks after infection, has been of limited success as a diagnostic technique.[154]

DIFFERENTIAL DIAGNOSIS

Most of the other major respiratory viral pathogens can mimic the illnesses produced by hPIV infections. Clinical differentiation rarely is possible. More helpful are such epidemiologic clues as the differing seasonal patterns and age-related attack rates of the common viral agents of respiratory illnesses in children.[57]

Croup from hPIVs or any other virus must be differentiated from bacterial tracheitis and epiglottitis, which have rapidly progressive courses and a potentially fatal outcome. With the widespread use of the *Haemophilus influenzae* type b vaccine, epiglottitis now rarely occurs. However, bacterial tracheitis has been increasingly observed.[69] Croup associated with hPIV usually has a more gradual onset, with a preceding upper respiratory tract infection. Its fluctuating course and prominent "seal's bark" cough without drooling help differentiate it from epiglottitis and bacterial tracheitis. Children with croup associated with hPIV infection usually have peripheral white blood cell counts that are normal or initially slightly elevated with a mild left shift. In contrast, among children with stridor from epiglottitis or bacterial tracheitis, the left shift usually is marked.

In countries that continue to have diphtheria, laryngeal diphtheria may be a consideration in an unimmunized child. However, laryngeal diphtheria usually is gradual in onset and manifests with characteristic membranous pharyngitis. Stridor and other signs of croup also may be present in children with other congenital or acquired conditions that obstruct the laryngeal airflow, such as aspiration of a foreign body, tracheomalacia, and acute angioneurotic edema.

MANAGEMENT AND THERAPY

Most hPIV infections are self-limited and require no treatment. Specific therapy currently is not available for hPIV infections. Ribavirin inhibits hPIV replication in vitro and has appeared in a few studies to provide some benefit in controlling hPIV infections among a limited number of immunocompromised patients.[26,35,36,114,145] Controlled trials, however, are lacking. Among potential therapies being explored are sialic acid inhibitors, such as those used in treating influenza, which inhibit hPIV F and HN activities.[2,51,113,128] Other therapeutic approaches include interference with viral attachment and replication with the use of inhibitors of protein and nucleic acid synthesis, synthetic peptides, and antivirals inhibiting *S*-adenosyl-L-homocysteine hydrolase.[11,21,64,147]

Management of croup in the home is primarily supportive.[165] The armamentarium used during the past century has been varied and usually anecdotal, ranging from cold night air to steam to

antiemetics. No such home therapies have proved beneficial. Their long tenure as helpful modes for treating croup may result from the characteristic fluctuating course of croup and its usual self-limited course. Most children with croup improve spontaneously within a few days.

Children who are more severely affected require outpatient evaluation, usually in an emergency department. With the current management offered in emergency departments, few children's symptoms progress such that hospitalization is required.[29,138,165] The current consensus and recommendations for the management of acute viral laryngotracheobronchitis for the child who is hospitalized or being evaluated in the emergency department have evolved since the 1980s and have resulted in a more consistent beneficial outcome.[3,165] Administration of aerosolized epinephrine has been demonstrated to provide rapid relief to the airway obstruction. Nebulized racemic epinephrine initially was preferred over L-epinephrine because nebulized racemic epinephrine generally was thought to be accompanied by fewer side effects. However, this consensus subsequently proved to be erroneous.[156] The relief afforded by nebulized epinephrine is transient, usually lasting no longer than 2 hours. Furthermore, hypoxemia, if present, and the outcome are not affected by treatment with nebulized epinephrine.[140,165]

Currently, administration of corticosteroids has become the cornerstone of management for the more severely affected child who fails to improve with the usual supportive care. Corticosteroids administered intramuscularly, intravenously, orally, and by nebulization have been shown to provide significant and lasting benefit on the clinical course and outcome, compared with placebo and to other therapies.[3,135] Parenteral dexamethasone in high doses (>0.3 mg/kg or its equivalent) or oral dexamethasone (0.15 to 0.6 mg/kg) has been shown to diminish the severity of disease and need for hospitalization in children with moderate to severe disease.[3,76] The recommended dose most commonly used is a single dose of 0.6 mg/kg of dexamethasone intramuscularly or intravenously.[165] For more mildly affected children treated as outpatients, a lower dose of oral dexamethasone (a single dose of 0.15 mg/kg) has been shown to be effective.[3,165] The treatment of croup is discussed more thoroughly in Chapter 22. Antibiotic therapy should be reserved for documented episodes of secondary bacterial infection, which infrequently are associated with hPIV infections.

PROGNOSIS

Most previously healthy children recover from hPIV infections completely and without complication. Follow-up studies of normal children with hPIV infections support the generally good prognosis. Some children who have had croup have pulmonary function abnormalities detected subsequently, but proof that these abnormalities were caused by their hPIV infection is lacking.[55,95]

The potential for development of acute complications, morbidity, and mortality is related to the presence of a co-morbid condition such as an immunodeficiency and diseases that affect cardiopulmonary function, including congenital malformations and acquired conditions obstructing the airway.[165] Of children hospitalized with hPIV infections who were studied during a 4-year period, 35 percent had preexisting pulmonary or cardiac abnormalities, prematurity, or asthma.[61] Compared with the children who previously were normal, the children with underlying conditions had significantly more severe disease and more complicated courses requiring longer hospitalization. Immunodeficient patients, as described previously, have particular difficulty in controlling and clearing hPIV infections, and, thus, these children have complicated, prolonged, and recurrent respiratory infections. Prolonged or persistent infection with hPIVs, especially with hPIV-3, has been noted to occur in some patients with chronic bronchitis, possibly related to the lack of a sufficient specific antibody response in the sputum.[53] The possibility that PIV-like viruses may be latent in the human central nervous system also has been suggested by the occasional detection of such viruses in the central nervous tissue of patients with chronic neurologic conditions, such as multiple sclerosis, and by the recognition that PIVs are capable of establishing persistent infection.[108,117,123,157]

PREVENTION

For decades, attempts to prevent hPIV infections focused on the development of effective vaccines. The current lack of a licensed vaccine for hPIV infections attests to the problematic nature of infection with hPIVs and of the response of the human host at different ages. Many of the hurdles encountered in the development of an effective vaccine for hPIV are similar to those for RSV. The vaccine, at least for hPIV-3, would have to be administered during the first few months of life when the infant's immunologic system is not fully developed and when the potential inhibitory effect of passive maternal antibody exists. Furthermore, to elicit durable protection, the vaccine would have to produce an immunologic response superior to that derived from natural infection because recurrent infections occur throughout life.

Hence, the goals of immunization for hPIVs, like those for RSV, currently may need to be modified toward prevention of more serious disease in targeted high-risk groups, which may require multiple vaccines tailored for these individual groups. Because the greatest clinical and economic burdens have been estimated to occur with hPIV-3 infection among infants, compromised patients, and elderly individuals, many of the candidate vaccines have been aimed at providing protection against hPIV-3 infection.[21,34,112,147]

Initially formalin-inactivated, parenteral hPIV vaccines, along with formalin-inactivated vaccines for RSV, were developed and evaluated in clinical trials.[23,43,86] In general, these vaccines, whether monovalent, trivalent, or combined with other respiratory vaccines, were immunogenic, inducing a variable humoral antibody response, but they were not protective.[23,43] Subsequent natural hPIV infection in the vaccinees, however, did not result in more severe disease, as occurred following administration of the alum-precipitated RSV vaccine.[23,43]

Development of candidate vaccines currently focuses primarily on live-attenuated and subunit vaccines. Live-attenuated vaccines compared with inactivated or subunit vaccines have the potential advantages of inducing immunity more closely mimicking natural infection by eliciting both humoral and mucosal immunity and a longer duration of protection. Furthermore, because significant yearly antigenic change, as observed with the influenza viruses, does not occur with hPIVs, a single monovalent or polyvalent vaccine may suffice, although later booster doses may be required. The potential disadvantages of a live vaccine are more adverse or symptomatic reactions, the possible transmission of the vaccine virus, and insufficient genetic stability to prevent reversion to the more virulent virus from which it was derived.

Cold-passage hPIV-3 mutant strains derived from a wild-type hPIV-3 strain produced in cell culture were demonstrated to be stable and to grow well at the lower temperatures of the nasal passages, but not at the higher temperatures of the lower respiratory tract, and they were attenuated clinically.[34] The *cp* 45 mutant strain was developed into a candidate hPIV-3 vaccine containing 20 point mutations with the desired characteristics of cold adaptation *(ca)*, temperature sensitivity *(ts)*, attenuation *(att)*, and genetic stability.[9,10,139] A second candidate hPIV-3 vaccine was

developed from a closely related bPIV-3. The protective surface glycoproteins, HN and F, of bPIV-3 and hPIV-3 share amino acid identities of 75 and 78 percent, respectively. The bovine virus has restricted replication in humans and, thus, is attenuated. Nonetheless, immunization with bPIV-3 induced sufficient immunity to resist challenge with hPIV-3.

Both these vaccines were evaluated in phase I and II clinical trials in adults, seropositive children, and seronegative infants as young as 1 month of age. In seropositive children and adults, the vaccines were not sufficiently immunogenic or protective. In some trials of seronegative infants, the hPIV3-*cp*45 vaccine was too reactogenic and was associated with otitis media.[34] In a subsequent trial of hPIV3-*cp*45 vaccine involving seronegative children 6 to 18 months old, the vaccine was immunogenic and was not associated with the occurrence of otitis media.[10] Clinical evaluation of both bPIV-3 and hPIV3-*cp*45 candidate vaccines are on going. Other candidate intranasal vaccines also are being developed from unmanipulated bPIV-3 and, for immunization against hPIV-1, Sendai virus, the murine PIV-1.[34,142,147]

The use of reverse genetics is particularly applicable and beneficial in advancing the development of PIV vaccines because the molecular virology of the PIVs has been relatively well deciphered.[112] This technology has allowed the development of such PIV candidate vaccines as those produced by recovering infectious hPIV and bPIV from cDNA. The systematic introduction of mutations into the viral genome resulted in potential recombinant and chimeric vaccines with more precise and promising profiles. Among them are chimeric human-bovine vaccines for PIV-3, in which the HN and F glycoproteins of bPIV-3 are replaced by those of hPIV-3, or the NP of hPIV-3 replaced by that of bPIV-3.[7,60] Potential vaccines for hPIV-1 and hPIV-2, some of which contain the internal genes of hPIV-3 with the surface glycoproteins of hPIV-1 or hPIV-2, also have been produced by recombinant technology. Multiple other approaches to developing candidate hPIV vaccines through recombinant DNA technology are being explored and include chimeric PIV vaccines with heterologous paramyxoviruses and with viruses for which concurrent immunization would be desirable, such as RSV and influenza.[34,98,112,116]

Subunit vaccines containing HN and F proteins from hPIV-1, hPIV-2, and hPIV-3 are being investigated concurrently as single- or multiple-valent vaccines. These glycoproteins have been produced through viral purification procedures and by expression of recombinant viruses with the use of vectors such as vaccinia and baculovirus. Neutralizing antibodies are produced by vaccination with either the HN or the F protein, but protection against infection may require immunization with both glycoproteins. On the basis of the encouraging studies with these subunit vaccines in rodents and in primates, some vaccines have reached initial clinical trial evaluation.[21,147] Multiple unique approaches combined with these creative techniques, such as novel adjuvants, immunomodulators, and vehicles for incorporation and administration of the vaccine, are evolving and may enhance further the protective immune response from PIV immunization.

CHAPTER 192

Measles Virus

James D. Cherry

Measles virus is a singular agent that causes a relatively distinct, exanthematous disease characterized by fever, cough, coryza, conjunctivitis, an erythematous maculopapular confluent rash, and a pathognomonic enanthem. Clinical measles is an epidemic disease, the incidence of which in the United States was reduced by the use of attenuated vaccines from 315 reported cases per 100,000 persons in the pre-vaccine era to less than 1 per 100,000 in 1992. At present, measles no longer is an endemic disease in the United States. However, measles is still a major problem because of its worldwide prevalence, associated morbidity and mortality, and changing epidemiologic patterns in countries where vaccine use has been less than optimal.

HISTORY

In antiquity, measles and smallpox frequently were confused with each other, as well as with other exanthematous diseases.[26,332] Major epidemics of both measles and smallpox occurred 1800 years ago in the Roman Empire and China.[44,288] The first written record of measles generally is credited to Rhazes, a 10th century Persian physician.[26,44,227,455] However, Rhazes quoted writers, including El Yahudi, a famous Hebrew physician, who lived 300 years earlier.[44] Rhazes identified measles as an entity distinct from smallpox.

During the Middle Ages in Europe, smallpox and measles continued to be confused. By the beginning of the 17th century, however, differentiation between the two diseases was relatively clear; death reports by London parish clerks in 1629 listed measles and smallpox separately.[455] Repeated epidemics of measles were described in the English medical literature during the 17th and 18th centuries.[227]

The first account of measles in America was given by John Hall, who described epidemic disease in Boston in the fall of 1657.[67] The next epidemic in colonial America was reported in 1687. During the next 150 years, the interval between epidemics in Boston gradually decreased from 30 years to approximately 3 years. Epidemics during the 17th and 18th centuries involved persons of all ages, including neonates; coincident with a reduction in the interval between epidemics was a reduction in the age-specific incidence of measles. The reduction in time between epidemics can be attributed to the increased incidence of importation of measles that occurred as more and faster ships crossed the Atlantic and the population density in North America gradually increased. By the turn of the 19th century, both Boston and Philadelphia had sufficient populations for measles to propagate itself.

The first recognition of the contagiousness of measles is unclear. Shakespeare in *Coriolanus* was aware of its human-to-human transmission.[455] Home[201] in 1758 attempted to immunize against measles by applying a technique similar to the variolation used in smallpox.[362] In 1911, Goldberger and Anderson[165] produced clinical measles in monkeys by injecting filtered material from acute cases of human disease.

The classic epidemiologic study of measles is the account described by Panum[350] of the 1846 epidemic in the Faroe Islands. In this study, Panum confirmed that spread occurred solely through human-to-human contagion by the respiratory route, the incubation period was 14 days, and infection conveyed lifelong immunity.

The enanthem of measles, which is pathognomonic, was described carefully and presented by Koplik[242-244] in 1896, 1898, and 1899.[38] However, Koplik spots clearly were recognized specifically about a century earlier by John Quier, a physician in Jamaica,[38,163] as well as by Richard Hazeltine, a general practitioner in rural Maine.[67]

Although Plotz[363] reported cultivation of measles virus in 1938 and Rake and Shaffer[368] noted similar findings in 1940, reliable tissue culture methods were not available until approximately 10 years later. In 1954, Enders and Peebles[127] isolated eight agents (from cases of measles) in human or simian renal cell cultures. These investigators also demonstrated the ability of convalescent-phase serum from a patient with measles to neutralize the viral cytopathogenic effect. The stage for vaccine development was set by recovery of tissue culture of the virus,[127] adaptation of

viral growth in chicken embryos,[295] and, finally, cultivation of the virus in chicken embryo tissue culture cells.[229]

After extensive trials were conducted from 1958 through 1962, tissue culture–grown, inactivated ("killed"), and attenuated ("live") measles viral vaccines became available for general use in 1963.[90,226,247] In the United States, a nationwide immunization effort instituted in 1965 and 1966 led to a dramatic reduction in the incidence of epidemic measles for several years. Epidemic measles recurred in 1971, 1977, and 1989, but at overall levels less than those in the pre-vaccine era.[22,68,69,76,90,248] After initiation of the Childhood Immunization Initiative in 1977 and the Measles Elimination Program in 1978, the incidence of measles in the United States fell in 1981 to fewer than 1.5 cases per 100,000 population and remained at this low level until 1986.[22,74,75] In 1990, the rate was 11.2 cases per 100,000 population, which was the highest it had been since 1977. After 1990, a substantial decline in the incidence of measles occurred in the United States, to a low of 86 confirmed cases in 2000.[77] Currently, endemic transmission of measles no longer is occurring in the United States.[345] However, approximately 1 million children worldwide die of measles each year.[160,344]

PROPERTIES

CLASSIFICATION

Measles virus is a relatively large virus with helical capsid symmetry and an RNA genome.[35,133,256] It is a singular virus, but antigenically it is related closely to canine distemper. These agents, as well as peste des petits ruminants virus, dolphin morbillivirus, phocine distemper virus, and rinderpest virus, currently are included in the genus *Morbillivirus*; they are members of the family *Paramyxoviridae*. Measles virus differs from the other paramyxoviruses in that it does not possess specific neuraminidase activity and does not adsorb to neuraminic acid–containing cellular receptors.[307,327,359,444] Measles virus hemagglutinates, whereas the other members of its genus do not.

PHYSICAL PROPERTIES

Measles virus is a roughly spherical but pleomorphic virus that ranges from 100 to 300 nm in diameter.[35,133,177,319,332,444,445] The virion is composed of an outer lipoprotein envelope and an internal helical nucleocapsid. The virion contains eight proteins. The outer viral envelope is 10 to 22 nm thick, has short surface projections (peplomers), and contains three virus-coded proteins (F, H, and M).[92,307,332] F protein is a dumbbell-shaped peplomer that causes membrane fusion of the virus and host cell and enables penetration of the virus into the host cell. H protein is the hemagglutinin and is a conical peplomer. In infection, H protein reacts with a host cellular receptor. CD46 appears to be the cellular receptor for attenuated measles vaccine strains but not wild-type viral strains.[54,119,272,273,321,342] More recent data suggest that the signaling lymphocyte activation molecule (SLAM) is the cellular receptor for wild-type virus.[117,342] M (matrix) protein is nonglycosylated and associated with the inner lipid bilayer of the envelope. It plays an important role in the maturation of the virus. The nucleocapsid (N) protein (Fig. 192–1) is a coiled rod with a diameter of 18 nm and a length of 1 μm that contains the viral genomic RNA.[330-332,442,444] N protein has a molecular weight of approximately 60 kd. Approximately 5 percent of the nucleocapsid is RNA.[188,431,443] The other internal proteins of the virus are the L (large), P (phospho), C, and V proteins.

The virus genome has a molecular weight of 4.5×10^6 d. It is a linear, single strand of RNA that contains approximately 15,900 nucleotides.

Measles virus is labile.[227,228,314] It is inactivated rapidly by heat, ultraviolet light, lipid solvents such as ether and chloroform, and extreme degrees of acidity and alkalinity (i.e., pH < 5 and >10). Longevity is prolonged when protein is present in the viral suspending medium and when the virus is lyophilized with a protein stabilizer. Protein specifically protects against the adverse effects of heat and light. Protein-stabilized measles virus can be stored at –70° C for 5 or more years without significant loss of infectivity. At room temperature, a 60 percent loss in titer occurs in 3 to 5 days; at 56° C, the virus is inactivated within 30 minutes.[41,314]

ANTIGENIC COMPOSITION

Clinical and epidemiologic data and early laboratory study suggested antigenic homogeneity of all measles strains.[228] More recent nucleotide sequence analysis identified distinct lineages among wild-type measles virus isolates.[35,314,383,423] The following properties have been associated with measles virus: a hemagglutinin (for simian cells), complement-fixing antigens, hemolytic activity, and a giant-cell–inducing factor.[56,189,227,228,328,329,336,359,393] Human measles virus infection results in serum antibodies that are capable of neutralizing viral infectivity, fixing complement with viral antigen, and inhibiting viral hemagglutination and hemolysis.

Cross-seroreactivity occurs among members of the genus *Morbillivirus* but not with other members of the family *Paramyxoviridae*.[47,62,210] Measles virus serum antibody in humans reacts with distemper virus, but canine serum after a case of distemper does not react with measles virus. A two-way cross between measles and rinderpest viruses has been demonstrated.

TISSUE CULTURE GROWTH

Measles virus can be propagated in many different primary and cell line tissue cultures.[47,228,282] However, for isolation of virus from patient specimens, primary human and monkey kidney cultures have been most successful over the years. In one study, an Epstein-Barr virus–transformed marmoset lymphocytic line (B95-8) was found to be superior to primary monkey kidney cell culture for isolation of virus from nasopharyngeal specimens.[238] In tissue culture, measles virus has two distinct cytopathogenic effects. With initial isolation, syncytial formation occurs as a result of cell fusion, and the resulting giant cells may contain 10

to 50 or more nuclei (Fig. 192–2). On stained preparations, both the nuclei and cytoplasm contain eosinophilic inclusions. The second type of cytopathogenic effect is characterized by the alteration of single cells into spindle shapes or stellate forms. In general, tissue culture-adapted measles viral strains are more likely to cause this cytopathogenic effect than is giant-cell formation. In most cultures, both forms of cytopathogenic effect are evident, and changes in medium composition render one or the other type predominant.

Infection in tissue culture is associated with an attachment-adsorption phase lasting approximately 1 hour and an eclipse period of 6 to 12 hours.[282,307] Antigen first is noted in the perinuclear cytoplasm by 12 hours; by 24 hours, it is distributed throughout the cytoplasm. By 30 hours, most antigen is detected at the cell surface. In mature cultures, more cell-associated virus is present than is found free within the medium.

ANIMAL SUSCEPTIBILITY

Humans are the natural hosts of measles virus, but with human contact, monkeys also are infected easily.[292] Laboratory strains of measles virus have been adapted to suckling mice and hamsters.[55,61,211,439]

EPIDEMIOLOGY

PREVALENCE

The prevalence of measles throughout history has been affected markedly by population density and, since the 1960s, by the use of measles vaccine. Reported cases of measles in the United States from 1963 to 1998, analyzed by year, are presented in Figure 192–3. After the universal use of measles vaccine began in 1965, the number of cases in the United States fell to 22,231 in 1968.[76] In 1971 to 1972 and 1976 to 1977, modest epidemics occurred; then, after a national commitment to measles immunization, the number of cases of measles fell to an all-time low of 1497 cases reported in 1983. Beginning in 1986, the number of measles cases again increased, with 27,786 cases reported in 1990. After 1990, measles in the United States declined, with only 100 cases reported in 1998.[77] Since 1998, the endemic transmission of measles in the United States has been eliminated.[345] In 2005, 66 cases were reported in the United States, and 95 percent of these were linked to importations.[78] Half of all the cases in 2005 were traced to one unvaccinated traveler who was infected in Europe. All but two of the contact cases in this outbreak were unvaccinated because their parents had declined immunization. In the 20th century, before the widespread use of measles vaccine, between 200,000 and 600,000 cases of measles were reported annually in the United States.[99,258] Careful survey suggested that in the past, reported cases accounted for only approximately 15 percent of the actual number of cases of measles.[90]

In the pre-vaccine era in the United States and other concentrated populations throughout the world, measles epidemics occurred regularly. In the United States, urban-centered measles epidemics took place every 2 to 5 years, with each epidemic lasting 3 to 4 months.[26,44,186,195,266,450,463] In general, the larger the community, the shorter the interval between epidemics. In the vaccine era, the epidemic pattern has been changed. As noted in Figure 192–3, the total number of cases has been reduced, and the cycle between peaks has lengthened.

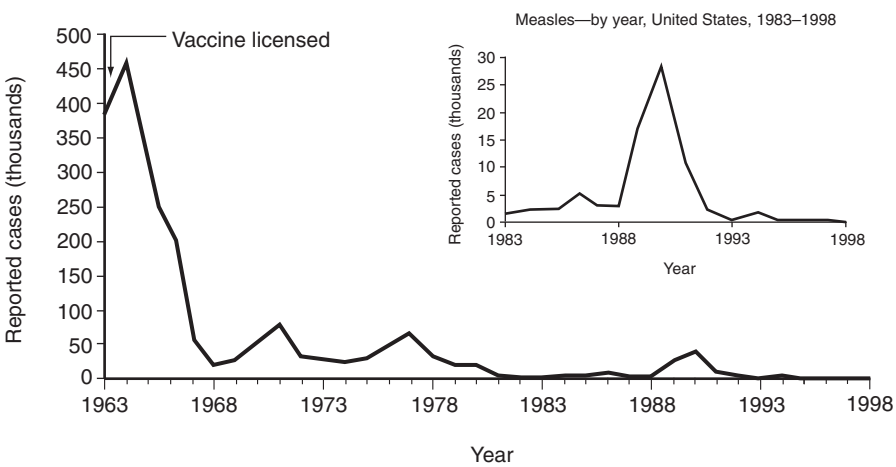

Figure 192–3 Reported measles cases by year in the United States, 1963 to 1998. *(From Summary of notifiable diseases—United States, 1998. M. M. W. R. Morb. Mortal. Wkly. Rep. 47:48, 1999).*

AGE INCIDENCE AND PREVALENCE

In modern times in populous areas, measles has been a disease of children. The age-specific incidence in the United States for selected years is presented in Table 192–1. In the pre-vaccine era during the 20th century, the highest measles attack rate occurred in children aged 5 to 9 years.[26,44,195,454] In the period 1960 to 1964, data from five reporting areas showed that more than half of all measles cases occurred in this age group.[191] Before the present vaccine era, infections and epidemic loci centered in elementary schools. Younger children acquired measles as secondary cases from their older siblings who were attending school. In rural areas, the interval between measles epidemics tended to be greater; therefore, a broader spread in ages occurred in the percentage of measles cases. In a nationwide serum survey of U.S. military recruits in 1962, Black[43] found that 99 percent had measles antibody.

As noted in Table 192–1, the age-related incidence and percentage of measles cases by age group have changed markedly since 1964. In 1991, more than 40 percent of measles cases occurred in persons older than 10 years; in the period from 1960 to 1964, fewer than 10 percent of the patients were older than 10 years. Approximately a third of the cases in 1991 were in adolescents and young adults. Evidence also indicates high primary measles attack rates in newborns to 4-year-old children in areas of suboptimal vaccine utilization.[22,77,90,146,193] In 2005, 66 measles cases were reported.[78] Seven cases (10.6%) were in infants, 4 (6.1%) in children aged 1 to 4 years, 33 (50%) in persons aged 5 to 19 years, 7 (10.6%) in persons aged 20 to 34 years, and 15 (22.7%) in adults aged 35 years or older. Most measles cases that have occurred in the United States since 1994 have been imported or importation-associated.[77,382,384] Measles in heavily populated but developing countries has its greatest incidence in children younger than 2 years.[96,139,194,308,337]

GEOGRAPHIC DISTRIBUTION

In the 20th century, measles occurred regularly throughout the world in all but the most remote areas.[26,44] In island and other isolated populations, intervals between epidemics can be 10 years or more, and the occurrence of disease depends on its introduction from outside the area.

SEASONAL PATTERNS

Epidemic measles is a winter-spring disease in temperate climates, with peak activity in the Northern Hemisphere occurring in March or April. In equatorial regions, epidemics of measles are less marked but tend to occur in the hot, dry seasons.[26,310,377,420]

HOST AND SOCIAL FACTORS

No difference is found in the incidence of measles in the male and female population. One suggestion, however, is that complication rates are higher in boys or men than in girls or women. Tidstrom[425] found that acute laryngitis occurred more than twice as frequently in male patients as compared with female patients. In other studies, otitis media, pneumonia, and death occurred slightly more often in male patients.[26,338] Miller,[294] in a large survey in England in 1963, found no difference in the incidence of complications in male and female patients. Christensen and associates,[93] in studies of an epidemic in Greenland, noted a greater number of complications in female patients older than 15 years, attributable primarily to an increased incidence of pneumonia. In a review of 375 confirmed cases of subacute sclerosing panencephalitis (SSPE), the male-to-female ratio was 2.4:1.[303] According to Black,[44] antibody titers are slightly higher in women than in men. Our studies involving young adults failed to reveal a similar sex-associated difference in antibody levels, however.[406] Green and associates[172] noted that a group of women had a higher postimmunization geometric mean antibody titer than did vaccinated men.

Although the severity of disease in certain populations appears to suggest differences based on race, this difference may be the result of nutritional and other environmental factors. Deseda-Tous and associates[113] were unable to demonstrate any differences in measles antibody by human leukocyte antigen (HLA) or by ABO blood types. In a more recent study, the findings of Ovsyannikova and coworkers[347] suggested that HLA alleles relate to antibody responses after immunization. The following alleles were positively associated with hyperseropositivity: HLA-B*7, -DQA1*0104, and -DPA1*0202. In contrast, HLA-B*44, -DRB1*01, -DRB1*08, -DQB1*0301, and -DPD1*0401 alleles were negatively associated with hyperseropositivity. In another study, the same group looked for associations between HLA homozygosity and measles antibody levels.[415] They found a negative correlation between homozygosity (=1 loci) and antibody value.

In the pre-vaccine era, the age of patients at the time of acquiring measles infection was related inversely to the number of siblings in the family.[26,44,459] In general, measles occurred at an earlier age in city dwellers and those of lower socioeconomic classes than in rural families and well-educated, upper-income groups.

In the present era of antibiotics and other medical modalities, the greatest factors in measles-related morbidity and mortality are age and nutritional status. The mortality rates for measles are highest in children younger than 2 years and in adults.[26,44] The severity of measles and rates of mortality correlate in general with the severity of malnutrition.[44,337] However, extensive investigations by Aaby and others[3,4,159] since the 1980s suggest that overcrowding and intensive exposure may be more important

determinants of measles-related mortality than is nutritional status alone.

Studies of measles conducted early in the 20th century and in developing countries indicated that secondary cases in households were likely to be more severe than were primary cases.[2-4,159] However, more recent studies in the United States found no difference in severity between primary and secondary cases in families.[58,417]

SPREAD OF INFECTION

Measles is a highly contagious disease in nonimmune persons. It is spread from an infected ill person to a new host by the respiratory route.[26,44,374,375,378] Although monkeys can acquire measles from humans, practically speaking, no animal reservoir exists.[292] Available evidence suggests that infection is spread by persons ill with measles. Asymptomatic contagious carriers are unknown, and persons with acute asymptomatic infection probably are not contagious or only minimally so. The period of greatest contagion occurs during the prodromal period.[165]

Transmission of measles is thought to occur mainly by aerosolized droplets of respiratory secretions. Acquisition of infection by a new host is by the nose and possibly the conjunctivae.[351] Infection can be initiated by small-droplet nuclei, which stay suspended in air for considerable periods of time, or by direct hits of large droplets at close range.[48,372] Also possible is that spread involves close person-to-person contact in young children, with large virus-containing droplets of nasal secretions being picked up on the hands of the future host and then applied to the nose.

PATHOGENESIS AND PATHOLOGY

VIRAL INFECTION

The sequence of viral events in uncomplicated measles is presented in Table 192–2. Although much is known about measles virus infection in humans, considerable gaps exist regarding specific events. Experimental studies in other primates have been performed in an attempt to fill in the gaps and thereby provide a more complete picture.[224,283,326,341,396,461] The primary site of infection appears to be the respiratory epithelium of the nasopharynx. Measles vaccine virus instilled into the nose or by aerosol results in infection.[45,246] Papp[351] reported studies suggesting that infection resulted from conjunctival contact and proposed that this means was the primary portal of entry. However, experiments with vaccine virus generally have been unsuccessful when conjunctival inoculation has been performed.[45] Initial infection of the respiratory epithelium appears to be minimal; a more important event is the early spread of virus to regional lymphatics. A presumption based on data derived from Fenner's ectromelia-mouse experimental model[132] is that after such spread, primary viremia occurs, followed by extensive multiplication of virus in the reticuloendothelial system at both regional and distant sites. Multiplication of virus also continues at the site of initial infection.

During the fifth to seventh days of infection, extensive secondary viremia takes place and results in the establishment of generalized measles viral infection. The skin, conjunctivae, and respiratory tract are obvious sites of infection, but other organs may be involved as well. From the 11th to the 14th days, the viral content of the blood, respiratory tract, and other organs peaks and then rapidly diminishes over the ensuing 2- to 3-day period.

In immunologically compromised patients with defects in cell-mediated factors, measles virus is not cleared from the secondary infection sites, and progressive, frequently fatal illnesses occur.[8,128,297,299,311] During infection, measles virus replicates in endothelial cells, epithelial cells, and monocytes and macrophages.[180,304]

TABLE 192–2 Sequence of Measles Virus Infection in Uncomplicated Primary Disease

Day	Event
0	Measles virus in droplet nuclei or large droplet comes in contact with the epithelial surface of the nasopharynx or possibly the conjunctiva
	Infection of epithelial cells and virus multiplication
1-2	Extension of infection to regional lymphoid tissue
2-3	Primary viremia
3-5	Multiplication of measles virus in respiratory epithelium at the site of initial infection and in the reticuloendothelial system regionally and at distant sites
5-7	Secondary viremia
7-11	Establishment of infection in the skin and other viremic sites, including the respiratory tract
11-14	Virus in blood, respiratory tract, skin, and other organs
15-17	Viremia decreases and then ceases
	Viral content in organs rapidly diminishes

Data from references 175-177, 180, 184, 224, 230, 235, 262, 326, 341, 358, 378, 386, 396, and 461.

PATHOLOGY

The characteristic pathologic feature of measles is the widespread distribution of multinucleated giant cells, which are the result of cell fusion.[47,224,227,262,282,326,341,379,396,461] Two main types of giant cells occur in measles: (1) Warthin-Finkeldey cells, which are found in the reticuloendothelium; and (2) epithelial giant cells (Fig. 192–4), which occur principally in the respiratory epithelium but also on other epithelial surfaces.[262]

Warthin-Finkeldey giant cells are found throughout the reticuloendothelial system in the adenoids, tonsils, Peyer patches, appendix, lymph nodes, spleen, and thymus. They vary in size and contain as many as 100 or more nuclei. The cells contain both cytoplasmic and intranuclear eosinophilic inclusions, with cytoplasmic inclusions more common than intranuclear lesions. During the prodromal stage of measles, epithelial giant cells regularly are present on respiratory surfaces and frequently are sloughed free (see Fig. 192–4).

Measles Exanthem

Hematoxylin and eosin–stained sections of skin biopsy specimens have revealed typical epithelial syncytial giant cells with nuclear and cytoplasmic inclusions.[235,416] The giant cells contain 3 to 26 nuclei. Other findings include the following: focal parakeratosis, dyskeratosis, spongiosis, and intracellular edema. The superficial blood vessels are dilated, with a sparse, surrounding lymphohistiocytic infiltrate.

Koplik Spots

Suringa and colleagues[416] observed that the histopathologic features of Koplik spots were similar to those of the rash. These investigators noted more giant cells with more nuclei, a greater degree of edema, and a lessened inflammatory response in the enanthem biopsy sample, however.

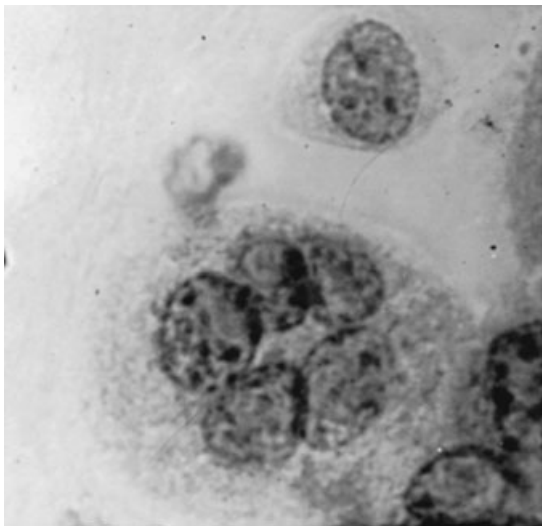

Figure 192–4 Epithelial giant cell with five nuclei. Pharyngeal smear. *(Courtesy of Dr. John M. Adams.)*

Respiratory Tract

The extent of respiratory involvement in uncomplicated measles is not known. However, clinical symptoms and the extensive radiographic studies of Kohn and Koiransky[240] suggested that pharyngitis, tracheitis, bronchitis, and pulmonary infiltration are the rule rather than the exception. Unfortunately, the human pathologic data available have been obtained mainly from complicated cases, so the findings cannot be considered representative.[111,379] In a study in monkeys, Nii and colleagues[326] noted giant cells in the mucosal epithelium of the trachea, bronchi, and bronchioli. The lumina of these airways contained sloughed syncytial cells. Warthin-Finkeldey cells were found in the adjacent lymphatics.

In the lungs of experimentally infected monkeys, interstitial pneumonitis was observed with giant-cell formation.[326] Infiltration of neutrophils, eosinophils, and mononuclear cells also was noted.

IMMUNOLOGIC EVENTS

After natural or attenuated measles virus infection develops, large numbers of specific and nonspecific immunologic responses occur. Many questions relating to immunity in measles remain unanswered, although a considerable body of knowledge has been gathered since the 1950s.

Antibody

After measles viral infection develops, an antibody response regularly occurs. Serum antibodies to the N, F, H, and M proteins of measles virus can be demonstrated by hemagglutination-inhibition (HI), complement-fixation (CF), neutralization, immune precipitation, hemolysin inhibition, enzyme-linked immunosorbent assay (ELISA), and fluorescent antibody (FA) methods.[105,156,170,236,249,322,328,333,433] Antibody-dependent cellular cytotoxicity and antibody-dependent complement-mediated lysis also have been demonstrated.[144,145,233] In natural infection, HI and neutralizing antibodies appear at approximately the 14th day, peak at around 4 to 6 weeks, and decrease approximately fourfold from the peak over the course of a year. Most naturally infected persons have demonstrable HI and neutralizing antibodies for life. Krugman[248] noted an average 16-fold reduction in HI antibody titer 15 years after natural infection in a group of children who had no measles exposure during the observation period.

After immunization has been administered, both HI and neutralizing antibodies are present by the 14th day.[156,249] CF antibody appears slightly later than does HI antibody and in general does not persist as long as does either HI or neutralizing antibody. Primary infection is characterized by the initial appearance of antibody in the immunoglobulin M (IgM) and IgG serum components.[142,196,394,395,428] The IgM-specific response is short-lived, and rarely can measles antibody in this fraction be demonstrated more than 9 weeks after infection. IgA secretory antibody also occurs regularly after vaccine viral infection and after natural infection.[33,151]

IgG antibody appearing after infection is primarily subclasses IgG1 and IgG4.[280] Antibody detected by neutralization and by HI is mainly to H protein and correlates with clinical protection against illness.[114,180,328] Antibody to N protein is the main antibody detected by CF.[328] Antibody to F protein is demonstrated by inhibition of hemolysis of monkey erythrocytes by measles virus or by immunoprecipitation.[329,333] Antibody to F protein may contribute to neutralization by disrupting the fusion of virus membrane with host-cell membranes. Only small amounts of antibody to M protein are elicited after infection with wild virus or vaccine virus.[170]

Specific Cell-Mediated Responses

Investigators recognized in the 1960s that patients with defective cellular resistance factors frequently died of progressive measles virus infections.[318] In the 1970s, techniques became available that demonstrated measles-specific lymphocyte sensitization.[158,171,173,245,255,385] Graziano and colleagues[171] found that lymphocytes from persons who previously had measles had a blastogenic response in vitro when these cells were incubated with measles antigen. Labowskie and associates,[255] using an in vitro lymphocyte-mediated cytotoxicity assay, noted that lymphocytes from persons who previously had measles caused cell destruction in a tissue culture chronically infected with measles virus. Ruckdeschel and colleagues[385] observed that two physicians without detectable measles antibody who had experienced repeated recent exposure to measles without developing illness had strong in vitro cellular responsiveness to measles virus. Krause and associates[245] demonstrated excessive measles-specific lymphocyte blastogenic responses in some persons previously immunized with killed measles vaccine.

Today, T cells are appreciated to be important both in B-cell antiviral antibody responses and as effector cells for the clearance of virus-infected cells from tissues.[180] Both helper ($CD4^+$) and suppressor ($CD8^+$) cells participate in the cellular response.[441] During infection, $CD8^+$ T cells eliminate virus-infected cells by major histocompatibility complex class I–restricted cytotoxic mechanisms.[180] $CD4^+$ T cells respond to measles virus infection by the secretion of cytokines. After initial exposure to virus occurs, $CD4^+$ T cells mount a T-helper cell (T_H1) response. Before the rash develops, levels of plasma interferon-γ (IFN-γ) are increased, and with the rash, interleukin-2 (IL-2) appears. With clinical recovery, plasma levels of IL-4 increase (a T_H2 response) and stay elevated for several weeks, whereas the initial T_H1 response subsides.

On re-exposure, T_H1 and T_H2 responses occur as indicated by the production of INF-γ, IL-2, and tumor necrosis factor-β (TNF-β), IL-4, IL-5, and IL-10. The T_H1 cytokine response is important for macrophage activation (through the action of INF-γ), lymphocyte proliferation (through IL-2), and major histocompatibility complex class II–restricted cytotoxicity (through TNF-β). The T_H2 cytokine response is important for macrophage deactivation (through the action of IL-4 and IL-10) and B-cell help (through IL-4, IL-5, and IL-10). In studies in rhesus

monkeys, researchers found that humoral immunity had only a limited role in the control of measles virus replication in primary infection.[360]

Ovsyannikova and colleagues[348] found a predominant T_H1 cytokine pattern following measles vaccine viral infection. This pattern occurred after both primary immunization and revaccination. In this study, no relationship was found between any specific cytokine level and serum measles antibody values. In another study, the same research group found a subset of vaccinees in whom the cytokine responses were skewed towards the T_H2 type.[118] These investigators suggested that this response in this subset may not be sufficient for long-term immunity.

Other Responses

Listed in Table 192–3 are nonspecific, immunologically related responses that can be demonstrated during natural or vaccine measles virus infection. Anderson and colleagues[16] demonstrated a temporary defect in neutrophil motility during acute measles that resolved by the 11th day after the onset of rash. Leukopenia has been observed in natural measles[36] and after immunization.[46] With immunization, the numbers of both neutrophils and lymphocytes are reduced; this reduction lasts approximately 1 week, with an onset occurring approximately 7 days after vaccination. Coovadia and colleagues[100,102] showed that the numbers of T, B, and null cells in the lymphocyte population are reduced. With a reduction in the number of T lymphocytes, no change occurs in the ratio of helper and suppressor-cytotoxic cell phenotypes.[10,19,218]

Thrombocytopenia occasionally has been associated with natural measles[207] and vaccination.[11,452] Oski and Naiman[346] noted a mild reduction in the peripheral platelet count during routine measles immunization. Transitory complement defects vary in measles; Charlesworth and associates[81] found evidence of pathologic complement activation in 20 of 50 patents studied. Coovadia and colleagues[102] noted slight but significant reductions in serum IgA levels and elevated IgM values in acute measles virus infections. These investigators found the IgG concentrations to be normal. Increased levels of serum or plasma IgE were noted in two studies.[178,397] Delayed hypersensitivity responses in skin are suppressed in both natural and vaccine measles virus infection.[136,407] Similarly, in vitro lymphocyte blastogenic responses to common antigens are suppressed.[451]

MECHANISMS IN RECOVERY FROM MEASLES VIRAL INFECTION

Acute clinical measles is characterized by viral multiplication in many organs of the body and then rapid subsidence of the infection by the 17th day. As noted earlier, measles virus infection is associated with both serum and secretory antibody responses and specific cell-mediated responses that coincide with clinical recovery. All three factors would seem to be important in recovery from acute measles virus infection, but confusing information clouds the issue. For example, researchers have noted that children with simple agammaglobulinemia in whom measurable measles antibodies do not develop after measles virus infection recover from the disease normally.[167] This finding suggests that development of measles antibody is not important for recovery from acute infection. However, by using a sensitive plaque-reduction measles neutralizing antibody technique, Black[42] found small amounts of antibody in the sera of three agammaglobulinemic patients.

In contrast to antibody data, data on patients with defects in the cell-mediated immune system show that they clearly do poorly with measles virus infection and frequently succumb to progressive infection despite the administration of large doses of measles antibody-containing immunoglobulin. T cells (both $CD4^+$ and $CD8^+$) clear virus-infected cells from tissues by cytotoxicity. INF-α, which is released by a variety of cells, including T cells, inhibits the spread of virus infection.

In studies in a transgenic mouse model system, Tishon and associates[427] showed that CD4, CD8, or B cells alone controlled measles virus infection. However, combinations of CD4 T cells and B cells or CD4 and CD8 T cells were essential in clearing infection. In contrast, the combination of CD5 T cells and B cells was ineffective.

MECHANISMS IN PREVENTION OF REPEAT ILLNESS IN PERSONS PREVIOUSLY INFECTED WITH MEASLES VIRUS

In contrast to mechanisms of recovery in acute measles, the role of serum antibody in protection against recurrent disease is solid. Before the present vaccine era, researchers repeatedly demonstrated that the administration of measles antibody-containing immunoglobulin could prevent clinical measles.[214,413] Similarly,

TABLE 192–3 Nonspecific, Immunologically Related Responses during Measles Virus Infection

Category	Findings	Reference
Leukocytes	Defective neutrophil motility	16
	Leukopenia (both lymphocytes and neutrophils)	36, 44
	Decreased T, B, and null lymphocytes	10, 19, 100, 102, 218
	Decreased natural killer cell activity	183
	Decreased helper T cells	106, 234
	Prolonged suppression of interleukin-12 production	21
	Prolonged depression of virus-specific interferon-α production	320
Interferon-α	Elevated plasma levels	182
Neopterin	Elevated plasma levels	182
Interleukin-2 receptor (soluble)	Elevated plasma levels	181
Platelets	Reduction in peripheral count	346
Complement	Frequent pathologic activation of the complement system; reduction of C1q, C4, C3, and C5	81
Serum immunoglobulins	IgA reduced and IgE and IgM elevated	102, 178, 397
In vitro lymphocyte response to phytohemagglutinin	Suppressed in presence of autologous serum; normal in presence of calf serum	451
In vitro lymphocyte response to *Candida*	Suppressed	451
Cutaneous delayed hypersensitivity	Depressed	136
C-reactive protein	Elevated at onset of rash	179
Circulating immune complexes	Noted in 25% of patients 7 to 13 days after rash onset	467

Ig, immunoglobulin.

infants with transplacentally acquired measles antibody are immune.[249] Whether other factors also are important in protection against reinfection is not clear. Often cited is that patients with agammaglobulinemia do not have repeated measles virus infections, so other factors must be involved.[167]

Of interest is that patients have been described in whom antibody did not prevent acquisition of atypical measles after immunization with killed measles vaccine.[264] The data of Krause and associates[245] suggested that persons in whom the capacity for exaggerated measles-specific lymphocyte activity persists (some previous killed vaccine recipients) may be subject to illness in spite of the presence of antibody. However, the antibody produced after receipt of killed measles vaccine was incomplete; it lacked specific antibody to F protein.[92] Black[42] noted one child with a low measles neutralizing antibody titer, presumably from natural measles virus infection, in whom measles later developed. Chen and coinvestigators[83] found that some students with measurable but low neutralizing antibody titers were not protected from clinical measles on exposure.

CLINICAL MANIFESTATIONS

Before the present vaccine era, measles was an inevitable disease of childhood that was recognized readily by parents and other laypersons, as well as by physicians. Despite the occasional confusion with other exanthematous diseases,[85] the epidemic character of measles usually resulted in an accurate diagnosis. Currently in North America, few of the new generation of parents, physicians, and other medical personnel have seen measles, and therefore the illness can be misdiagnosed.

TYPICAL ILLNESS[26,86,90,227,252,378,412]

Incubation Period

The incubation period of measles is approximately 10 days (range, 8-12 days). Although extensive virologic and immunologic events occur during this period, the individual has virtually no outward sign of illness. Goodall[168] suggested (and Partington and Quinton[353] presented supporting data) that some patients have mild transient respiratory symptoms and fever shortly after initial acquisition of the virus.

Prodromal Period

The prodrome of measles lasts approximately 3 days (range, 2-4 days). Initial symptoms are respiratory and suggest the possibility of a cold, except fever is an early sign. In fact, in situations of close observation, slight temperature elevation has occurred and then subsided for a day or so before the appearance of typical respiratory symptoms.[412]

The onset of clinical measles is characterized by general malaise, fever, coryza, conjunctivitis, and cough. These symptoms worsen during a 2- to 4-day period. Early in the prodromal phase, a transitory rash occasionally has been observed. It has been urticarial or macular, has occurred with the initial onset of fever, and has disappeared before onset of the typical exanthem.

During the prodromal period, the temperature increases gradually to a value of 39.5° ± 1.1° C (103° ± 2° F) over the course of a 4-day period. The nasal symptoms resemble those of other respiratory viral infections and are similar to those of the common cold or acute nasopharyngitis. Sneezing, rhinitis, and congestion are common symptoms. The degree of prodromal conjunctivitis varies considerably. Initially, the conjunctival infection is divided by a transverse marginal line across the lower lids.[411] The conjunctivitis is associated with considerable lacrimation, and older patients in particular are bothered by photophobia, which frequently is severe. Slit-lamp examination reveals both corneal and conjunctival lesions.[25,138]

The cough in prodromal measles frequently is troublesome. It worsens throughout the period and often has a brassy quality suggesting laryngeal and tracheal involvement. On approximately day 10 ± 1, Koplik spots, the pathognomonic enanthem of measles, first appear (see Fig. 64–1). Koplik[242-244] originally described the lesions as bluish-white specks on a bright red mucosal surface. In my experience, the lesions always have appeared white, and a blue component has not been observed. Koplik spots first arise on the buccal mucosa opposite the lower molars but usually spread quickly to involve most of the buccal and lower labial mucosa. The lesions are approximately 1 mm in size at first but occasionally seem to coalesce into larger lesions. Initially, only a few lesions appear, but within 12 hours, the number usually is uncountable. Of equal importance in establishing the diagnosis is the appearance of the background mucosal surface, which is always bright red and granular. Frequently, 1-mm lesions (Fordyce aphthae), which commonly occur normally in adolescents and adults, are confused with Koplik spots.[84] These lesions, however, can be differentiated easily because they appear on a normal pale mucosal surface rather than the bright red background of measles.

During the prodromal period, erythematous maculopapular lesions also are observed occasionally on the palate. At the end of the prodromal period, the posterior pharyngeal wall usually is erythematous and infected, and the patient may complain of a sore throat.

Exanthem Period

In typical measles, the exanthem appears on approximately the 14th day after exposure. The exanthem occurs at approximately the peak of the respiratory symptoms and when the temperature usually is approximately 39.5° C (103° F). At this time, the manifestation of Koplik spots has peaked, and during the next 3 days they disappear. However, after the specific white spots have disappeared, the red, sandpapery mucosal background remains present for a day or so.

The measles exanthem first appears behind the ears and on the forehead at the hair line. Spread of the rash is centrifugal from the head to the feet. By the third day, the rash has involved the face, neck, trunk, upper extremities, buttocks, and lower extremities sequentially. The rash initially is erythematous and maculopapular but progresses to confluence in the same centrifugal manner as it is spread. Confluence always is more prominent on the face; frequently, the lesions on the lower extremities remain discrete. At the height of the rash, the appearance suggests microvesicles on top of a generalized erythematous confluent base (see Fig. 64–2).

The exanthem begins to clear on the third to fourth day, again following the centrifugal course of progression. During the initial stages of the rash, its color is red, and it readily blanches on pressure. As the rash fades, it takes on a coppery appearance, after which a brownish discoloration is seen that does not clear with pressure. With healing, a fine desquamation frequently occurs in confluent areas with brownish discoloration. The duration of the exanthem usually is 6 to 7 days.

During the exanthem period, the fever generally peaks on approximately the second or third day of the rash and then falls by lysis during a 24-hour period. Fever that persists after the third or fourth day of exanthem usually is an indication of a complication. Conjunctivitis and nasal symptoms generally subside at about the time of defervescence. Continued nasal dis-

charge, whether purulent or not, suggests bacterial secondary infection. With the appearance of the rash, the cough loosens up, and in older persons it frequently becomes productive. The cough may persist for 10 days or more.

Pharyngitis is a common development during the exanthem period, as is enlargement of cervical lymph nodes. Generalized lymphadenopathy with suboccipital and postauricular involvement is not an uncommon finding, nor is splenomegaly. Young children occasionally have diarrhea, vomiting, laryngitis, and croup. Abdominal pain also can be troublesome.

Laboratory Findings

Laboratory studies rarely are indicated for acute uncomplicated typical measles because the diagnosis can be established on a clinical and epidemiologic basis, and the results of studies rarely affect management of the patient. During the periods of prodrome and rash, the total leukocyte count is low. Numbers of neutrophils and lymphocytes are reduced, but the most marked reduction, when absolute counts are considered, is in the number of lymphocytes.[36] In difficult cases, such as the first apparent case in a particular locality, a specific diagnosis can be made by serologic study, most easily by measles antibody studies performed by ELISA. If an acute serum sample is obtained during the prodrome and a second serum sample is obtained 7 to 10 days later, a significant rise in IgG antibody titer usually is demonstrated. At the time that the rash is manifest, the most useful test for identification of measles antibody is the IgM fraction.

MODIFIED ILLNESS*

Modified measles is an infection that occurs in a partially immune person. It is characterized by a generally mild illness that usually follows the regular sequence of events in measles. The prodromal period is shorter; cough, coryza, and fever are minimal. Koplik spots are few and transient, and they frequently do not occur. The exanthem follows the progression pattern of regular measles, but confluence of the lesions does not occur. Because serologic studies reveal some children with measles antibody who have never had clinical disease suggestive of measles, some modified infections probably occur without exanthem and perhaps without overt symptoms at all.[42,250]

Modified measles develops under a variety of circumstances, the most important of which historically was the result of intentional alteration of disease by the administration of immune serum globulin to an exposed susceptible child. Naturally occurring modified measles is seen occasionally in infants younger than 9 months old because of the presence of transplacentally acquired maternal measles antibody.

Although the magnitude of the problem is unknown, modified measles also occurs as an occasional manifestation of failure of live vaccine. In these instances, patients have had modified illness but demonstrated a secondary measles serum antibody response (only IgG antibody).[90,91,404] With increasing time from immunization, this response possibly will occur more frequently.[112] However, few data currently support this possibility.

Recurrent measles also rarely results in modified illness. The frequency of recurrent measles is unknown. In general, most authorities have discounted the existence of recurrent measles and suggested that the recorded experiences were the result of confusion with infection by other exanthem-producing agents.[85,247] However, Cherry and colleagues,[90] Schaffner and associates,[391] and Schluederberg[395] have described children with modified illnesses, secondary immunologic responses, and well-documented instances of previous cases of measles.

ATYPICAL MEASLES

Atypical measles is a clearly defined clinical syndrome that occurs in some previously immunized persons after they have been exposed to natural measles. Most cases have occurred in persons who initially received inactivated (killed) measles viral vaccines, but some cases also have been noted in children who received only live measles vaccines.[89,264,323]

Historical Aspects

The initial studies with inactivated measles vaccines in the early 1960s demonstrated that multiple doses were necessary to stimulate an antibody response and that measurable serum antibody levels were short-lived.[155,185,225,249,456] In the initial trials, it soon became apparent that some study participants who had received killed vaccine were still susceptible to measles. On being exposed to natural measles, some children developed typical measles and others a mild, modified illness.[155] As a result, regimens were developed in which children were immunized with two or three doses of killed vaccine at monthly intervals, followed in a month or more by a single dose of Edmonston B live measles vaccine (KKL or KKKL). Studies at the time demonstrated that good antibody levels were achieved after administration of both regimens. After measles vaccine was licensed in 1963, killed-live measles vaccine regimens enjoyed modest popularity in the United States (as well as in other countries) because live Edmonston B strain vaccine frequently was associated with alarming febrile responses and occasional febrile convulsions.

In 1965, Rauh and Schmidt[370] reported an unusual illness after exposure to natural measles in some children who had received killed vaccine 2 years previously. The significance of their findings became more apparent during the following 2 years when Fulginiti and colleagues[157] and Nader and coworkers[316] noted many instances of "atypical measles" in previous recipients of KKK and KKL vaccination regimens. In these two instances, original immunization had taken place 4 to 6 years before the occurrence of atypical illness.

In 1968, killed measles vaccine was taken off the market in the United States after the distribution of approximately 1.8 million doses in the period from 1963 to 1968.[343] During the 12-year period from 1968 to 1980, atypical measles was reported frequently.* I am unaware of reports since 1980 of further cases of atypical measles. However, I observed one 26-year-old physician and a 28-year-old nurse with the syndrome in the 1980s. Sporadic cases in adults may still be occurring but are misdiagnosed because physicians caring for adults are unaware of the syndrome; therefore, the history of killed measles vaccine is not uncovered, and specific antibody studies are not performed.

In 1971, during study of an extensive measles epidemic, Cherry and colleagues[89] observed six children who had relatively mild, atypical measles-like illnesses but had received only live measles vaccine. Linnemann and colleagues[264] similarly noted two children with atypical measles-like illnesses who had received only live measles vaccine. Nichols[323] and St. Geme and associates[410] also have reported bizarre measles illnesses in patients who formerly received live vaccine.

*See references 26, 30, 83, 90, 91, 125, 155, 198, 214, 252, 355, 373, 391.

*See references 18, 82, 89, 154, 164, 187, 199, 205, 259, 286, 296, 323, 325, 335, 448, 449, 464, 465.

Clinical Characteristics*

Atypical measles was a common illness from 1967 to 1978. Because killed measles vaccines have not been available in the United States since 1968, two obvious facts need to be mentioned: with each passing year, potential patients and actual patients with atypical measles will be 1 year older and also 1 year farther from the time of receiving the primary killed measles vaccine immunization series. Both these aspects raise concern about whether the clinical manifestations of the syndrome will remain the same today as when the illness first was described. It was my opinion in 1981 that the syndrome had changed slightly but still was recognizable from original descriptions of the illness.[86]

The incubation period of atypical measles is similar to that of typical measles—between 7 and 14 days in duration. The prodromal period is characterized by the sudden onset of high fever (39.5° C-40.6° C, 103° F-105° F) and usually headache. Abdominal pain and myalgia also are common complaints. Dry, nonproductive cough is noted in most patients and vomiting in approximately one third of those afflicted. Pleuritic chest pain and weakness also are common complaints. Although few reports to the contrary exist, Koplik spots appear to be rare in atypical measles.

Two to 3 days after onset of the illness, the rash appears. It is unique in that it first develops on the distal ends of the extremities and progresses in a cephalad direction. Usually, the rash initially is erythematous and maculopapular. I have been impressed by a slight yellowish hue of the exanthem when compared with that of typical measles. The rash is particularly prominent on the wrists and ankles; it involves the palms and soles. Spread of the rash varies considerably. In some patients, only the wrists and ankles are involved, whereas in others, the entire extremities as well as the lower part of the trunk are affected. In a peculiar fashion, the rash frequently seems to end its cephalad progression in a line at the level of the nipples. Occasionally, a few erythematous, maculopapular but discrete lesions are found on the face. In some cases, the rash becomes vesicular, with the lesions approximately 2 to 3 mm in diameter; they do not proceed to scab formation as in varicella, but occasionally pruritus is a problem, and excoriation occurs from scratching. The exanthem often has a petechial or purpuric component, and urticaria also occurs frequently. Edema of the extremities has been a common finding.

Although coryza has been noted in a few reports, it is not a prominent feature, nor is conjunctivitis. Respiratory distress with dyspnea and rales occurs commonly, and radiographic examination reveals pulmonary involvement in virtually all cases. Most patients have hilar adenopathy and pneumonia. Pleural effusion also occurs frequently. The pneumonia in atypical measles usually is lobular or segmental, and the lesions often appear nodular (Fig. 192–5). Although initial descriptions of the syndrome suggested an illness of approximately 1 week's duration, later observations indicated illnesses of 2 weeks or more. In one case, fatigue and other symptoms persisted for more than 1.5 years.

In the original description by Rauh and Schmidt,[370] one patient had an exanthem that was biphasic; initially, a transitory rash suggested modified measles. Two weeks later, the more characteristic atypical exanthem developed. The same observers also noted a second case with a biphasic exanthem in which the first lesions were vesicular and occurred when the child had little fever. The second exanthem was maculopapular and associated with a febrile response. Zahradnik and colleagues[465] also noted a similar sequence in two young adults. Two patients who had received killed measles vaccine in the past had radiographic evidence of characteristic pulmonary findings, but the typical exanthem did not develop.[335,464]

Figure 192–5 Nodular pulmonary infiltrates in a child with atypical measles.

Other findings in atypical measles include marked hepatosplenomegaly,[370] marked hyperesthesia,[316] weakness,[259] and numbness and paresthesia.[286] Personal observations of cases in adolescents and young adults suggest that the exanthem is less prominent than in past cases, and the fever and overall morbidity are of greater duration.[86] Follow-up radiographic studies demonstrated the persistence of nodular pulmonary lesions for longer than 1 year in several patients and up to 6 years in one patient.[259,296,464]

Measles antibody studies in atypical measles are remarkably diagnostic. If an initial serum sample is obtained before or at onset of the exanthem, CF and HI titers usually are less than 1:5. By the 10th day of illness, both titers are elevated markedly, and most are 1:1280 or greater. In contrast, in typical natural measles at the 10th day of illness, the titer rarely is greater than 1:160.

Measles virus was not recovered from a patient with atypical measles, but only a few adequately performed studies were performed. The epidemiologic data currently available suggest that patients with atypical measles are not contagious. Other laboratory studies are not particularly useful in atypical measles. The erythrocyte sedimentation rate is elevated. When serial blood counts have been performed, slight early leukopenia and late eosinophilia have been noted.[157]

The pathogenesis of atypical measles was studied by several investigators, and several possible mechanisms were suggested,[364] including a generalized Arthus reaction, induction of abnormal measles virus–specific, delayed-type hypersensitivity, and an imbalance in antibody responses to H and F proteins caused by denaturation of F protein during formalin inactivation of the vaccine virus. In a study in monkeys, Polack and associates[364] found that atypical measles resulted from previous priming for a nonproductive type 2 $CD4^+$ T-cell response and not from the lack of functional antibody against F protein. In revaccination studies performed by our group in the 1970s, we found that vaccinees with severe local reactions had marked lymphocyte reactivity to inactivated measles virus and absent or minimal HI antibody.[245]

*See references 53, 82, 86, 89, 154, 157, 164, 187, 199, 205, 259, 286, 296, 316, 323, 325, 334, 335, 370, 448, 449, 464, 465.

UNUSUAL MANIFESTATIONS AND COMPLICATIONS OF MEASLES

In addition to typical measles, modified measles, and atypical measles, many other clinical manifestations and complications occur at a broad range of frequency. By definition, unusual manifestations are a direct result of the primary viral infection, whereas complications are a result of damage by a secondary infection with another microorganism. In many instances, determining whether a particular manifestation is just viral or involves a second agent is difficult. Combinations of infections are common occurrences.

In general, complications resulting from secondary infection are not as common today as they were before the antibiotic era; however, no evidence suggests that unusual manifestations of illness occur less frequently today than formerly. To demonstrate the magnitude of the problem today, the findings in a 1970 to 1971 hospital survey in St. Louis are revealing.[88,90] In this period, an extensive epidemic occurred, with 10,000 cases of measles. In 8 area hospitals, 130 children (1.3%) were admitted; 66 cases of pneumonia and 6 fatalities occurred, and 6 children had encephalitis.

The records of measles patients in 3 hospitals were reviewed carefully. Of this group of 71 patients, 53 had pneumonia; 37 of the patients with pneumonia had either previous cardiorespiratory or other chronic systemic disorders. Two children had mediastinal and subcutaneous emphysema. All 6 deaths were caused by fulminant pneumonia. Of the 6 children with encephalitis, severe residual neurologic damage developed in 3. One child had acute measles appendicitis with perforation and peritonitis, and another patient had mesenteric lymphadenitis.

Pneumonia

Pulmonary involvement in measles, as a result of the viral infection, is probably the rule rather than the exception. Kohn and Koiransky[240] performed careful radiographic studies in 130 children with measles and noted that 55 percent had pneumonic infiltration and 74 percent had hilar adenopathy. In most instances, the pneumonia was observed early in the course of the illness, a finding that suggested primary viral involvement rather than secondary bacterial infection. In the 1970 to 1971 St. Louis measles epidemic, approximately 1 in every 150 patients with measles was hospitalized because of pneumonia.

Pneumonia in measles has varied radiographic manifestations.[6,88,174,240,265,271,279,338,418] Clearly, viral pneumonia is characterized by bilateral hyperinflation with diffuse fluffy infiltrates that are more confluent at the hilum. Unilateral, segmental, and lobar pneumonias also are observed. Gremillion and Crawford[174] reviewed 106 cases of pneumonia that occurred in 3220 Air Force recruits with measles between 1976 and 1979. Illnesses were severe, but no deaths occurred. Bacterial superinfection was documented in 30.3 percent of the cases; bronchospasm occurred in 17 percent of the recruits with pneumonia. In one study, seven children with massive and bilateral lung consolidation had clinical findings consistent with adult respiratory distress syndrome.[6]

Clinically, young infants have a picture of bronchiolitis with expiratory distress. In severe cases at all ages, a marked ventilation-perfusion deficit is noted.[265,354] Patients with defects in the cell-mediated immune system are particularly prone to progressive fatal bilateral infection.[128,239,297,299,402,405]

Secondary bacterial pneumonia is the result of common respiratory pathogens, particularly *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Streptococcus pyogenes*, and *Staphylococcus aureus*. Co-infection with other viruses also was noted in an extensive study of measles-associated pneumonia in the Philippines.[367] In this study, parainfluenza virus and adenoviruses were isolated most frequently.

Other Respiratory Manifestations

Otitis media is the most common complication and is age-related. In the immediate pre-vaccine era in the United States, otitis media developed in approximately 5 to 15 percent of patients with measles. It now is less a problem because of the change in the age-related incidence of measles. The bacterial pathogens in otitis media associated with measles are similar to those in otitis media in children without measles. Mastoiditis was a common complication of measles in the era before antibiotics, but fortunately, today it is rare.

Laryngitis and mild laryngotracheitis occur commonly. Occasionally, frank, severe laryngotracheobronchitis occurs and may require tracheotomy.[380] Measles-associated bacterial tracheitis is not an uncommon finding.[97] Secondary bacterial infection of the cervical lymph nodes and secondary bacterial pharyngitis also are rather frequent complications of measles. Field[134] attributed 3.2 percent of cases of childhood bronchiectasis to former infection with measles virus.[134] Measles also has a deleterious effect on the course of tuberculosis.[408]

Cardiac Manifestations

Myocarditis and pericarditis occasionally occur in cases of measles.[111,135] Nonspecific, transient electrocardiographic abnormalities were noted in more than half of 71 children with measles in one study.[381] In another study, 19 percent of patients had transient but clear-cut abnormalities, including T-wave changes, atrioventricular conduction defects, and premature auricular contractions.[166] Although cardiac involvement appears to occur frequently in measles, clinical consequences from such involvement are rare developments.

Neurologic Manifestations

Neurologic involvement is not an uncommon finding in patients with measles.* Gibbs and associates[162] noted that 51 percent of 680 patients with measles who had no clinical evidence of encephalitis had abnormal electroencephalographic results during acute or immediate postacute illness. Although the incidence varies, clinically evident encephalitis occurs in approximately 0.5 to 1 of every 1000 measles cases.[26,70,90,126,226] From 1962 to 1979, the average measles encephalitis-to-case ratio was 0.73:1000.[70] Both mortality and the incidence of sequelae have varied in the reports available. LaBoccetta and Tornay[254] noted a mortality rate of 32 percent in 50 patients in a group seen before 1947 and a rate of 11.5 percent in a group seen between 1947 and 1957. Ziegra[466] reported only 2 deaths in a group of 38 cases. Long-term morbidity data also vary considerably. In general, between 20 and 40 percent of patients who recover from measles encephalitis have manifestations of brain damage. Douglas[120] could find no evidence of later subnormal school performance in a group of children who had uncomplicated measles.

Symptoms of encephalitis usually develop during the period of measles exanthem and within 8 days of the onset of illness.[5,254,379] Occasionally, the onset of central nervous system (CNS) signs and symptoms occurs during the prodromal period. LaBoccetta and Tornay[254] noted the following frequencies of signs and symptoms at the onset of measles encephalitis: convulsions, 56 percent; lethargy, 46 percent; coma, 28 percent; and irritability, 26 percent. Patients with encephalitis frequently have multiple findings:

*See references 5, 26, 37, 126, 129, 162, 169, 254, 268, 285, 349, 365, 430, 466.

headache, abnormalities in respiratory rate and rhythm, twitching and other involuntary movements, and disorientation. Cerebellar ataxia, myelitis, retrobulbar neuritis, transient mental disorders, and hemiplegia are findings noted during the subacute stages of illness. Long-term sequelae include various degrees of retardation and selective brain damage, recurrent seizures, deafness, and hemiplegia and paraplegia. An 8-year-old girl developed pseudotumor cerebri 3 weeks after having a case of measles.[421]

Examination of cerebrospinal fluid (CSF) in measles encephalitis usually reveals mild pleocytosis with a predominance of mononuclear cells, mildly elevated protein values, and a normal glucose level.[254,285,339,430] In one study, 15 percent of the cases did not have CSF pleocytosis.[254]

Considerable controversy relates to the mechanisms in measles encephalitis.* Some investigators failed to isolate measles virus or to demonstrate measles virus RNA or other viral antigens in the brains of affected patients.[161,222,231,304] These findings led to the widespread consensus that the illness is autoimmune (acute disseminated encephalomyelitis) and that viral invasion of the CSF is unnecessary. However, other investigators have recovered measles virus from the CSF and brain of affected patients, a finding indicating that the virus is involved directly in the process.[129,141,285,291] In the hamster model of measles virus encephalitis, virus can be cultured directly from the brain.[352]

Other Manifestations

Measles has been associated with many other manifestations and complications. Of historical interest was the occurrence of a severe, often fatal, form of measles called *black measles* that was characterized by a confluent hemorrhagic skin eruption.[252] Patients with this illness had signs of both encephalitis or encephalopathy and pneumonia. Extensive bleeding from the mouth, nose, and bowel frequently occurred. Severe hemorrhagic measles rarely is seen today, and little is known about its pathogenesis. Disseminated intravascular coagulation would appear to play a role.

Another complication of measles involving bleeding is thrombocytopenic purpura.[6,207] It is a post-infectious illness and different from hemorrhagic measles. Although bleeding is extensive on occasion, the ultimate prognosis usually is good. Stevens-Johnson syndrome has been noted occasionally in measles.[274] Other manifestations include pneumomediastinum, subcutaneous emphysema, hepatitis, appendicitis, ileocolitis, mesenteric lymphadenitis, cervicitis, acute glomerulonephritis, corneal ulceration, and gangrene of the extremities.†

Measles in pregnancy results in significant maternal and fetal morbidity and mortality.[24,124,217,311,409] Jespersen and associates[217] retrospectively reviewed 10 epidemics of measles in Greenland; these investigators obtained adequate data on 327 women infected during pregnancy, and they also were able to examine 252 of the offspring. Thirty-two percent of women infected during the first trimester had spontaneous abortions, and 9 percent of these pregnancies that continued to term resulted in stillbirths. Congenital malformations occurred in eight of 300 live-born infants.[217] Pneumonia is a frequent maternal complication of measles during pregnancy.[24,124]

SUBACUTE SCLEROSING PANENCEPHALITIS

SSPE is an uncommon, slowly progressive disease of the CNS, with an almost invariably fatal outcome. The disease was recognized by a number of investigators early in the 20th century.[50,109,387] Several early accounts, especially those published by Dawson in 1933,[109] suggested a viral origin of this disease; however, not until the mid 1960s was measles virus clearly demonstrated to be the causative agent.[41,81,98,203,356,423]

Epidemiology

SSPE is a rare disease that in the pre-vaccine era had an annual incidence of approximately 1 case per 1,000,000 population in most of the developed world, including the United States. The estimated incidence after wild-type measles virus infection in the pre-vaccine era was approximately 1 case per 100,000 population. The incidence of SSPE in the pre-vaccine era in some developing nations greatly exceeded that of developed nations. In southern India, the incidence of SSPE was as high as 21 per 100,000 population,[388] and in Pakistan, the rate was estimated to be 100 per 100,000.[241] A report from Papua New Guinea suggested a similarly high incidence of SSPE.[267] Several characteristics of natural measles virus infection in developing countries in the pre-vaccine era were associated with the development of SSPE and included the high incidence of measles and the frequent occurrence of measles in children younger than 2 years of age. Both these risk factors for SSPE are modifiable, if not preventable, by vaccination.

The disease has been reported in all countries of the world, and, although no outbreaks have been reported, clustering of cases prompted suggestions that environmental factors or unique strains of viruses may contribute to the development of SSPE after measles. The epidemiologic study of SSPE in the Netherlands described 4 cases of SSPE that occurred in 1 year in one city of 120,000 people, a number that calculated to 4 cases of SSPE per 6000 cases of measles, a rate 10-fold greater than that for the rest of the country.[32]

The incidence of SSPE in the pre-vaccine era was approximately five times higher in the southeastern United States than that in other regions of the country,[190,213,302] also suggesting the possibility of environmental cofactors. In addition, in the pre-vaccine era, a preponderance of cases of SSPE occurred in the United States, as well as in other developed and developing countries, in children from rural areas, independent of the incidence of measles in these areas.[59,60,190,270,301] SSPE appears to have no racial predilection, although whites represent the largest number of cases.[213,302] The incidence of SSPE consistently is two to three times more common in male than female patients.[32,213] No relationship between any human leukocyte antigen genotype and the development of SSPE has been demonstrated, and cases of SSPE in only one member of identical twins have been reported.[94,116,206] The usual age of presentation in the pre-vaccine era was between 6 and 10 years, with ranges of 2 to 35 years reported.[32,152,153,190] The youngest case reported was a 10-month-old child, and the oldest was a 52-year-old man with depressed cellular immunity.[39,419] In most cases, symptoms attributable to SSPE begin some 4 to 8 years after measles virus infection; however, in some series, older patients (>10 years of age) appeared to have experienced a prolonged interval between measles virus infection and the development of SSPE.[32,213,302]

Although several risk factors for the development of SSPE have been demonstrated repeatedly, the most consistent is the acquisition of measles before reaching the second birthday.[32,115,190,302,388] An estimated minimum of 50 percent of those with SSPE have had early measles.[190] In India, an estimated 60 percent of measles infections occurred before the patients reached 2 years of age, a factor possibly contributing to the high incidence of SSPE in this country.[388] Other risk factors have included exposure to animals.[190]

The decreased incidence of SSPE after institution of an effective measles vaccine program was demonstrated in several coun-

*See references 7, 137, 141, 161, 180-182, 220-222, 231, 285, 291, 304, 317, 356, 361.

†See references 147, 197, 226, 232, 252, 263, 287, 305, 324, 401, 426, 460.

tries.[32,49,73,293,340,446] The incidence of SSPE in the Netherlands fell 10-fold after universal vaccination was initiated.[32] The incidence in Japan fell at least 10-fold and possibly more.[340] Development of SSPE after receipt of measles vaccination has been noted to occur. In a case-control study of patients with SSPE in the United States, 17 of 52 (32.7%) patients with SSPE had received measles vaccine before they developed disease.[190] Similarly, SSPE occurring after measles immunization was noted in the Netherlands, but the incidence of vaccine-related SSPE was less than 1 case per 2.5 million immunizations.[32] In Japan, the estimated incidence of measles vaccine-related SSPE was 0.9 cases per million doses of vaccine.[340] An inherent problem common to all of these studies was the inability to identify patients with subclinical, wild-type measles virus infection before they received vaccination. Subclinical measles virus infections are thought to be common in developing countries, as illustrated by studies from India that suggested that as many as 20 to 40 percent of patients with measles may have had a subclinical infection.[388]

In the United States, the success of measles immunization clearly resulted in a profound reduction in the incidence of SSPE.[49,73,446] In the earlier years of the immunization program in the United States, rare cases of SSPE developed in vaccinees. Some of these children and perhaps all of them had unrecognized measles infection before they were vaccinated, and the SSPE was caused by the natural measles virus infection and not the vaccine virus.[446] I am unaware of any cases of SSPE in the United States since the year 2000 that can be attributed to measles vaccine virus.

Bellini and associates[34] studied brain samples from 11 patients with SSPE during the period 1992 to 2003. Nine of the patients in this group had a history of measles immunization. Nonetheless, in all 11 cases, the measles virus genotype identified was that of wild measles and was not consistent with vaccine virus. These researchers attributed the measles infections to the epidemic that occurred in the United States from 1989 through 1991.

In the period 1989 through 1997, 55,622 measles cases were reported. From these data, a rate of 22 cases of SSPE per 100,000 reported cases of measles was calculated. This rate is approximately 10 times higher than previous estimates in the United States and similar to those noted in developing countries in the pre-vaccine era.[241,267,388]

Pathogenesis and Pathology

Autopsy specimens from patients who died of SSPE reveal mild to striking changes in the gross appearance of the cerebral cortex, with ventriculomegaly in some cases. Histopathologic changes include minimal meningeal cellular infiltrate, with a perivascular accumulation of lymphocytes and plasma cells. Within involved areas of the brain, dense infiltrates of T lymphocytes and marked cellular expression of class II major histocompatibility antigens have been described.[52] A prominent microglial and astrocytic hyperplasia often is present. One of the characteristics of SSPE is the presence of intranuclear and cytoplasmic inclusion bodies.

The study of these structures by electron microscopy in 1965 led to the finding of paramyxovirus-like particles in autopsy material.[51,423] Subsequently, Connolly and colleagues[98] described the presence of measles virus antibody in the CSF of patients with SSPE, as well as the presence of measles virus antigens in brain tissue from autopsy specimens of patients who had SSPE. Shortly thereafter, several laboratories reported the recovery of defective measles virus in specimens of brain from patients with SSPE.[52,202,203] Virus was isolated only by co-cultivation and not as cell-free material. Together, these findings suggested that SSPE was caused by a persistent infection of the brain by measles virus.

Several mechanisms, such as an abnormal host immune response to a common infection or a mutant virus, have elicited the most interest. Available data suggest that it may be a combination of these two possibilities. Several observations of the natural history of SSPE are consistent with an abnormal host immune response to a primary measles infection. They include the following: (1) the chronicity of measles virus infection in children with SSPE indicated a failure to eliminate the agent; (2) the importance of early acquisition of measles virus in the development of SSPE suggested that the immature immune system may predispose the host to a persistent infection; and (3) the onset of clinical disease long after a primary infection also suggested a failure of a previously protective immune response. Early on, the consensus was that patients with SSPE had subtle defects in cellular immune responses as measured by decreased cutaneous reactivity to common skin test antigens, decreased lymphocyte proliferative responses to mitogens and measles virus antigens, and reduced production of cytokines. Subsequent studies failed to confirm these conclusions, and most investigators now suggest that patients with SSPE can generate vigorous cellular immune responses after exposure to mitogen and measles-specific antigens.[52] Studies demonstrated the presence of several cytokines, including IL-1b, IL-2, IL-6, TNF, heat-labile toxin, and IFN-γ, as well as other markers of immune activation, in brain lesions from patients with SSPE.[52] Still, some debate continues about the immunocompetence of patients with SSPE. Finally, measles virus is associated with chronic progressive encephalitis in immunocompromised patients (measles inclusion body encephalitis); however, the clinical course and histologic findings of this disease clearly are different from those of SSPE.

In contrast to the questions that surround the cellular response to measles virus in patients with SSPE, antibody responses to measles virus–encoded proteins are well preserved. Antibodies of all isotypes are produced peripherally and within the CNS. Antibodies against all the proteins encoded by measles, including the M (matrix) protein, have been detected in the sera from patients with SSPE.[52] The paradox of elevated levels of circulating anti-measles antibody as well as CSF anti-measles antibody in the presence of persistent infection suggested a possible immune-mediated origin of this disease. Evidence was presented that anti-measles antibody could interfere with spread of the virus and syncytial formation. Fujinami and Oldstone[152] demonstrated that anti-measles antibody reversibly could modulate the intracellular expression of measles virus–encoded proteins, thereby providing a mechanism by which antiviral antibody could convert an acute productive infection into a chronic persistent infection. This decrease in expression of measles antigen also could shelter virus-infected cells from immunologic recognition. This hypothesis also is supported by observations suggesting that early acquisition of measles predisposes the individual to the development of SSPE because the limited quantity of passively acquired maternal anti-measles antibody may be insufficient to prevent development of infection and dissemination of measles virus but adequate to modulate expression of measles virus. This series of events then would predispose the patient to the development of a chronic persistent infection. Animal models consistent with this disease mechanism have been described.[52]

The second general mechanism for the development of SSPE is the generation of viral mutants during acute infection that then can establish a persistent infection. Persistence may result from antigenic variability or a viral mutation leading to decreased production of viral proteins below a level recognizable by the immune system or an extension of cell tropism. That measles viruses from the CNS of patients with SSPE are replication-defective is well documented. Analysis of these isolates does not define a virulence feature of SSPE strains but does suggest several mechanisms that could account for the generation of viral mutants. Much interest has been focused on the decreased expression of the M protein in explants of brain tissue from patients

with SSPE.[52] This viral phenotype also was consistent with the decreased production of anti-M antibody in patients with SSPE, a finding suggesting the possibility of subthreshold production of antigen in these patients. Although the decreased expression of M protein was proposed originally as the mechanism for the persistence of mutant measles virus in patients with SSPE, subsequent studies showed that this is only one of many mutant phenotypes in strains of measles virus associated with SSPE.

Further studies of the replication of measles virus revealed several mechanisms that favor the production of mutant viruses. The RNA polymerase of measles viruses, like that of other RNA viruses, does not have proofreading functions and therefore frequently misincorporates nucleotides.[64] Thus, mutant progeny virus arises regularly and can be selected either by host immune responses or because of its extended host-cell tropism. In addition to this general mechanism of genetic diversity in RNA viruses, measles virus also exhibits what has been described originally as biased hypermutation and more recently as A/I hypermutation.[65,66] This mutational event results in clusters of U (uridine) to C (cytidine) or A (adenosine) to G (guanosine) transitions, possibly as the result of novel host-derived enzymatic activity referred to as *double-stranded RNA unwindase*.[52] This activity results in the replacement of A residues with inosines in duplex RNA molecules formed between genomic RNA and mRNA. Replication of the inosine-modified genomic strand then results in the replacement of U by C. Evidence of this proposed mutational event has been found in the genomes of measles viruses from the brains of patients with SSPE, in which up to 132 of a possible 266 U residues in the M coding sequence were converted to C.[64]

Studies clearly demonstrated that the M gene is the most heavily mutated of measles virus genes, often with early stop codons. Researchers stressed that this mechanism of genetic change is operative during lytic as well as persistent infection, and mutants that persist must do so as the result of growth advantage, such as evasion of the host immune response. The frequent mutations found in the M gene suggest that the measles virus can tolerate extensive genetic change in the M protein yet still replicate within cells of the CNS. The finding of clonal spread of a hypermutated measles virus genome within the brain of a patient with SSPE is consistent with this hypothesis.[28] Other genes of the measles virus also exhibit mutations that alter function, including the gene encoding the hemagglutinin (H) protein. Mutations of this protein were shown to limit cell surface expression but not the function of hemagglutinin in the replicative cycle of measles virus.[40] Cells infected with this phenotype likely are poorly recognized by the immune system because of the limited cell-surface expression of the H protein, yet enough functional activity remains to allow spread of the mutant virus within the CNS by a mechanism of cell-to-cell fusion. Thus, the generation of measles viruses that can induce disease and establish persistent infections results from viral strategies of genetic diversity coupled with selective pressure of the host immune response.

Clinical Manifestations

The initial stage of the disease can be described best as a period of progressive psychointellectual disturbances.[376] These disturbances can include lability of mood, deterioration of school performance, hyperactivity or lethargy, depression, and occasionally altered states of consciousness. Although retrospective analysis often allows precise definition of the onset of SSPE to be established, many of these disturbances are so subtle that they escape parental or physician detection. Physical findings vary and often are nonspecific. A peculiar pigmented retinopathy has been observed in a small number of patients.[62] The duration in stage I varies, depending on the clinical staging system, but in larger series, this stage is relatively short, usually lasting fewer than 6 months.[376] The duration in stage I appeared to be prolonged in older patients, compared with patients younger than 10 years of age, in the series from the Netherlands.[32] Accelerated progression to stage II has been reported.[376]

Stage II is characterized best by a variety of convulsive and motor disorders. The motor disorders are striking, ranging from akinetic drop attacks to violent myoclonic jerks. The motor disturbances have been described consistently as stereotypic and rhythmic. Rigidity or spasticity may be present in the later part of this stage.[52] Extrapyramidal findings, such as choreoathetotic and ballismic movements as well as parkinsonism with abnormalities in the basal ganglia, have been reported. Intellectual functions continue to deteriorate, but patients may retain receptive function during this stage. In one series of patients, as many as 50 percent with stage II disease had abnormal retinal findings, including optic atrophy. The duration of this stage is quite protracted; as many as 50 percent of patients remain in this stage for longer than 6 months and as many as 20 percent remain so for more than 1 year.

Progression to stage III is suggested by increased frequency of myoclonic jerks, development of spasticity or rigidity, and decerebrate and decorticate posturing. Hypothalamic dysfunction becomes prominent, with hyperpyrexia, diaphoresis, and periods of pallor and flushing. Cortical activity rapidly decreases, and patients usually become comatose in this preterminal stage of disease. Duration of this stage is relatively short, lasting fewer than 6 months in most cases. Death usually is associated with complications that accompany the vegetative state, although destruction of essential structures within the brain stem or hypothalamus may result in death.

The previous descriptions account for most patients with SSPE; however, a significant number may exhibit a less predictable course. Some 5 to 10 percent of patients can be expected to have a prolonged survival measured in years. These patients may progress to stage II or III and then remain static without relapse, or they can experience a periodic and sometimes fatal relapse of disease. Conversely, some 10 percent of patients may have a fulminant, rapidly progressive course lasting less than 3 months.[379]

Laboratory Findings

The definitive diagnosis of SSPE relies on a combination of laboratory findings and a compatible clinical course. Before the association between measles and SSPE was made, the electroencephalogram (EEG) was extremely helpful in establishing the diagnosis.[149,275,376] The classic pattern of the EEG in SSPE is described as periodic, synchronous, bilateral discharges with a frequency of 3 to 20 seconds.[95] The discharge contains high-amplitude polyphasic slow-wave complexes, often consisting of two or more delta waves.[275] Frequently, the background of the EEG is suppressed, thus creating the familiar burst suppression pattern. The EEG provides little help in predicting progression of SSPE. Also of note is that the absence of the classic findings as well as other abnormalities on the EEG has been reported in patients with SSPE.[149,209,219] Alternatively, the finding of periodic generalized bursts of fast waves should prompt consideration of SSPE.[278]

More recent advances in imaging technology have aided greatly in the diagnosis of SSPE. Computed tomographic (CT) scans are abnormal in more than 50 percent of patients with SSPE, but the findings often are nonspecific.[52,100,110,121,312] In the later stages of the disease, cortical atrophy often is a prominent finding on CT scan. Magnetic resonance imaging (MRI) of patients with SSPE has revealed the presence of focal lesions consistent with inflammation, often in the white matter, in multiple areas of the brain.[110] In some cases, the location of abnormalities detected by MRI closely reflects the clinical symptoms of the patient, whereas in others, the MRI findings do not cor-

relate with clinical findings.[422] Finally, brain biopsy has been used as an important means of establishing the diagnosis in the past and still is of considerable value in atypical cases.

Perhaps the most useful laboratory examination of the patient with suspected SSPE is the examination of the CSF. Normal to slightly increased levels of protein with an absolute increase in the gamma-globulin fraction are a consistent finding in patients with SSPE.[219] Furthermore, the increase in the gamma-globulin fraction is caused almost exclusively by elevation of immunoglobulin.[403,440] Additional studies showed that 20 to 40 percent of the CSF IgG was oligoclonal and that the oligoclonal fraction contained anti-measles antibodies.[434,435] This finding almost is pathognomonic for SSPE in patients with compatible clinical presentations. All isotypes of antibodies have been found in the CSF, although the finding of immunoglobulin M (IgM) anti-measles antibody remains controversial.[52,128,204,442] Because the levels of anti-measles antibodies within the CSF are elevated as well as oligoclonal, most investigators contend that these antibodies are produced locally within the CNS, apparently in response to ongoing measles virus replication. Other CSF findings include normal levels of glucose and slight pleocytosis consisting primarily of lymphocytes. Patients with SSPE have normal to elevated levels of circulating anti-measles antibody; in some cases, this antibody response also appears clonally restricted.[52]

Treatment

In the past, 5-bromo-2-deoxyuridine, transfer factor, ribavirin, and amantadine proved to be of little value.[52] In the 1970s, an antiviral agent, isoprinosine (Inosiplex), was introduced and was thought to have antiviral activity in vivo and in vitro, although this claim remains controversial. Some studies suggested that isoprinosine treatment may result in stabilization, prolongation of survival, or actual clinical improvement in as many as 50 to 60 percent of patients. In a large study, 98 patients with SSPE were treated continuously, and their actuarial survival was compared with that of 500 historical controls.[223] The results of this study showed that median survival for the treated patients was 3.2 years, compared with 1.2 years for the historical controls. The use of historical controls, however, raised a number of questions about the validity of the results. The results of this trial also suggested a greater benefit of treatment with isoprinosine in patients with more slowly progressive SSPE. Other studies did not demonstrate any efficacy of isoprinosine.[52] Inosiplex and intrathecal INF-α seem to elicit transit improvement in some patients.[122,123,253,269,300] INF-β combined with inosiplex also may offer benefit in patients with SSPE.[17]

MEASLES IN DEVELOPING COUNTRIES

Measles has been and continues to be a staggering problem in developing countries. The mortality rate in much of Africa is approximately 10 percent,[337] and a reasonable assumption is that the rates are similar in some regions of Central and South America and Asia.[306,377,420] In developing countries, measles is a disease of young children. For example, in Kenya in the pre-vaccine era, 25 to 30 percent of children contracted measles before reaching their first birthday and 55 to 60 percent before they were 2 years of age; virtually all children had measles by the time that they were 4 years old.[194] In Kenyan children, mortality peaked in the 17- to 20-month-old age group, and the median age for hospital admission was 14 months.

Although many factors, such as the age at infection, suboptimal medical facilities, and failure to seek medical care, contribute to the excessive morbidity and mortality in children of developing countries, the single overriding factor generally has been thought to be the nutritional status of the infected children.[309,310,337] The data of O'Donovan[337] clearly indicate a direct relationship between malnutrition and hospital admissions for measles and deaths. Studies by Coovadia and colleagues[101] and by Carney and associates[63] indicated both humoral and cell-mediated defects in protein-calorie malnutrition. The clinical picture of measles in children with malnutrition is frequently similar to that in patients with known defects in cell-mediated functions.

Low serum retinol concentrations nearly always are present in children with measles in developing countries.[29,103,208,212,276,371,436] Low retinol levels correlate directly with measles mortality, and treatment with vitamin A reduces this mortality rate.[29,208,276] Studies performed since the 1980s years indicate that the intensive exposure that occurs in children in developing countries is a major factor in measles mortality.[1,3,159]

Clinical Manifestations

Measles in children in developing countries is characterized by two different types of severe disease. One type of illness is a fulminant, toxic illness without apparent localizing complications. The other is a more prolonged illness with obvious complications; the complications may be caused by infection with secondary bacterial or other infectious agents, persistent measles virus infection, or a combination of both.

In a group of 507 hospitalized children, O'Donovan[337] noted that 301 had pneumonia, 96 had gastroenteritis, 36 had croup, 11 had convulsions, 67 had two or more complications, and 140 had nonlocalized systemic toxic effects. The measles rash in malnourished children tends to result in greater confluence and progresses to dark red and then violet.[310] Desquamation is marked and occurs in large scales.[392] After desquamation, patchy depigmentation lasts for some weeks. Other common problems are stomatitis and the resultant sore mouth, which leads to further loss of nutritional intake. Acute corneal ulceration, which occurs after measles in malnourished children, is a common cause of blindness.[389] Multiple skin abscesses and noma (cancrum oris) are rare secondary infectious problems.[226]

MEASLES IN IMMUNOCOMPROMISED HOSTS

Today, because of the extensive use of immunosuppressive therapeutic modalities and greater duration of survival in certain rapidly fatal diseases, a sizable population of children and adults is immunologically compromised. Measles virus infection in a patient with disease-induced or iatrogenically caused immune deficiency usually is severe and protracted and frequently fatal.

The most common severe measles virus infection in an immunocompromised host is giant-cell pneumonia.[128,239,289,297,298,369,402] The mode of manifestation of this illness varies. Some patients initially have severe but otherwise typical measles after a normal incubation period. Clinical findings at the time of the exanthem indicate pulmonary involvement and respiratory distress, and radiographic findings become rapidly worse over a period of approximately a week or less. Other patients initially have rather vague illness, frequently without rash. In these cases, the pulmonary process may progress over the course of a month or longer. Siegel and associates[402] reported a child with leukemia who recovered from typical measles and then died the following year of diffuse interstitial pneumonia in which characteristic measles giant cells were seen.

A unique form of measles encephalitis also is manifested in immunosuppressed patients.[8,148,192,290,312,315,366,429,457] Although the symptoms in different described cases varied, the illness appears to be intermediate between the acute encephalitis occurring in patients without known immune defects and the chronic picture of SSPE. The incubation period has varied between 5 weeks and 6 months.[8] Convulsions frequently are the initial symptom, and

they are a prominent aspect of the illness. The seizures have been focal, unilateral, or permanent localized twitching. Other findings include hemiplegia, stupor, coma, hypertonia, and slurred speech. Most cases have been fatal, and the duration of illness has been from 1 week to 2 months.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of typical measles must include all illnesses in which an erythematous maculopapular rash occurs (see also Chapter 64). The following are most important in establishing the diagnosis of measles: a consideration of possible exposure; the duration of the incubation period; the presence of Koplik spots; the presence of the typical febrile prodrome with cough, coryza, and conjunctivitis; and progression of the rash in a caudal direction. The brown discoloration and the intensity of the measles rash are such that the illness usually should not be confused with rubella, erythema infectiosum, roseola infantum, or enteroviral infection. Of greatest differential difficulty are the exanthems of infectious mononucleosis, *Mycoplasma pneumoniae* infection, and drug eruptions.

In the past, atypical measles was extremely difficult to diagnose. Today, this disease, if it occurs at all, would occur only in adults aged 40 years or older. The key to diagnosing this illness is careful elicitation of an accurate vaccination history. Even if it is not known whether the vaccination that the patient received as a child was live or killed vaccine, it usually can be determined by the number of doses given; if a child received more than one dose of vaccine in a short interval, killed vaccine almost certainly was administered. Differential considerations in atypical measles include Rocky Mountain spotted fever, anaphylactoid purpura, *M. pneumoniae* infection, and drug eruptions.

SPECIFIC DIAGNOSIS

Measles virus infection can be diagnosed specifically by the following methods: isolation of virus in an appropriate tissue culture system; demonstration of measles antigen in exfoliated cells and tissues by FA techniques or polymerase chain reaction (PCR)[281]; or the demonstration of a rise in HI, CF, ELISA, FA, or neutralizing antibody titer in two sequential serum samples or specific measles IgM antibody in a single serum sample (see Chapter 264). For practical purposes, most measles cases can be diagnosed by the demonstration of specific IgM antibody in an acute-phase serum specimen. False-positive IgM ELISA results may occur.[216,432] Acute measles also can be diagnosed by PCR using throat-swab specimens.[432]

TREATMENT

UNCOMPLICATED MEASLES

No specific therapy for uncomplicated measles exists. During the febrile period of illness, activity should be discouraged, and fluid status should be maintained by the liberal provision of soft drinks and ice. Fever may be controlled with acetaminophen. Cough frequently is distressing and can be managed by the judicious use of common antitussives. Room humidification also is useful in controlling the cough and generally can be expected to make the patient more comfortable. As the fever disappears, a gradual return to normal activity is indicated. However, measles virus infection is associated with considerable damage to the ciliated epithelium of the respiratory tract; therefore, resumption of normal activities too soon and exposure to other children and their bacterial pathogens can be associated with severe secondary infection.

Children in developing countries frequently have vitamin A deficiency. Measles morbidity correlates with this deficiency, and treatment with vitamin A is beneficial.[29,103,208,212,276,371,436] Studies in the United States indicate that vitamin A levels are low in a substantial number of measles cases and that morbidity is increased in these deficient children.[13,20,57,150] Vitamin A supplementation also has been shown to enhance IgG antibody levels and total lymphocyte numbers.[104] In 1993, the Committee on Infectious Diseases of the American Academy of Pediatrics recommended providing vitamin A supplementation for children with measles in selected circumstances.[13] Vitamin A was recommended for children aged 6 months to 2 years who require hospitalization and all patients 6 months or older with immune deficiencies or possible vitamin A deficiency. The dose of vitamin A is 100,000 IU for children aged 6 months to 1 year and 200,000 IU for children aged 1 year or older. The dose should be repeated 24 hours and 4 weeks after the first dose in children with ophthalmologic evidence of vitamin A deficiency.

ATYPICAL MEASLES

The most important aspect of therapy for atypical measles is proper diagnosis. In patients with atypical measles, Rocky Mountain spotted fever, other septic conditions, lymphoma, or collagen vascular disease frequently is diagnosed erroneously, and their work-up is associated with extensive blood cultures, other diagnostic procedures, and vigorous antibiotic therapy. Careful attention given to a history of previous administration of killed measles vaccine should clarify the diagnosis and preclude the unnecessary trauma associated with extensive diagnostic and therapeutic procedures.

In atypical measles, chest radiographs always should be obtained because the pneumonia that usually develops in these patients frequently is much more extensive than the clinical findings would indicate. Activity should be discouraged in acutely ill patients, and follow-up chest radiographs should be used as a guide to resumption of normal activity. In some patients, pulmonary abnormalities have persisted for a considerable period.

COMPLICATIONS OF MEASLES

Otitis Media

Otitis media is the most frequent complication of measles. The infectious agent of otitis media in measles is no different from that in other children without measles of comparable age, so conventional antibiotic therapy is all that is necessary (see Chapter 19).

Laryngotracheitis

Management of the laryngotracheitis caused by measles virus infection is similar to that in other patients with croup caused by other viral etiologic agents. The mainstays of therapy are the administration of humidified air and a concerted effort to relieve the apprehension of the patient. Administration of corticosteroids is contraindicated in measles, and antibiotics are indicated only in patients with laboratory or clinical evidence of secondary bacterial infection (see Chapter 22).

Pneumonia

Pneumonia is a common complication of measles, and it is the leading cause of death. Pneumonia may be a manifestation of

primary viral infection, or it may result from a superimposed bacterial infection. The differential diagnosis between primary viral and superimposed bacterial disease cannot be made with certainty. Because the diagnosis of viral pneumonia often is uncertain, most patients should be treated with antibiotics (see Chapters 26 and 27). In primary viral pneumonia, treatment with aerosolized ribavirin should be considered.

In one uncontrolled study in adult patients, intravenous ribavirin was found to be well tolerated, and its use was associated with clinical improvement.[143] In a study in pregnant women, Atmar and associates[24] were unable to demonstrate clear clinical benefit with the administration of aerosolized ribavirin.

Encephalitis

The course of measles encephalitis is unpredictable, and treatment is symptomatic and supportive. Trained nursing care is essential. Careful attention given to fluid and electrolyte balance is necessary. In prolonged states of coma, parenteral hyperalimentation is indicated. Status epilepticus should be treated vigorously with the use of a structured protocol for ensuring optimal control (see Chapter 42).

Numerous review articles indicate that measles encephalitis is a post-infectious encephalitis and is predominantly a disease of white matter (acute disseminated encephalomyelitis [ADEM]).[177,220,221] This concept resulted from a study of 19 patients with measles encephalitis that was published in 1984 by Johnson and associates.[222] I am aware of only two patients subsequent to this article who had ADEM associated with measles virus infection. Clinical evidence supports the finding that ADEM not related to measles virus infection is responsive to corticosteroid therapy.[140,284]

Considerable evidence indicates that measles encephalitis usually is not an ADEM and that active direct CNS infection is involved in the process.[129,141,285,291,357] A controlled trial of 32 children with measles encephalitis failed to find benefit in the steroid-treated group.[466] These data suggest to me that corticosteroids should not be used to treat measles encephalitis unless evidence of ADEM is clear and active measles virus infection has subsided. In patients with severe intractable seizures or other evidence of cerebral edema, the use of intravenous mannitol therapy (0.25 to 1 g/kg of a 20% solution administered over the course of a 30- to 60-minute period) is indicated. In occasional circumstances, respiratory arrest is a problem, and artificial ventilators should be used to tide patients over until respiration becomes normal. Mustafa and coworkers[315] noted improvement in an immunocompromised child with subacute measles encephalitis who was treated with intravenously administered ribavirin.

Appendicitis

Acute abdominal pain occurs occasionally in primary measles, and it can be caused by generalized mesenteric adenitis secondary to measles virus appendicitis. In appendicitis, evidence of measles virus involvement of the appendix is present. However, therapy should be similar to that in other cases of appendicitis; removal of the appendix is indicated because measles appendicitis perforates with a frequency equal to that in non–measles virus infection.

PROPHYLACTIC ANTIBIOTICS

In the developing world, secondary bacterial infections in measles are a major cause of mortality. Accordingly, interest has arisen in the use of antibiotics prophylactically.[79,398] A meta-analysis in 1997 of studies involving the use of prophylactic antibiotics noted that the available data were poor and provided only weak evidence for giving antibiotics to all children with measles.[398] The recommendation from this study was that antibiotics should be given only if a child has clinical signs of pneumonia or other evidence of sepsis. Chalmers[79] pointed out the necessity and urgency for performing controlled prophylactic trials.

PREVENTION

ACTIVE IMMUNIZATION: LIVE ATTENUATED MEASLES VIRUS VACCINE

Attenuated measles vaccines are prepared in chicken embryo tissue cultures. Vaccination produces a mild or inapparent noncommunicable infection that induces active immunity in more than 95 percent of recipients. Vaccine-induced antibodies persist for many years, and although reinfection with illness has been noted on occasion in apparently successfully immunized children, waning immunity does not appear to be of significant epidemiologic importance.[15,90,91,112,248] Symptoms associated with measles immunization are minimal and are limited to fever, mild malaise, and occasionally a faint rash occurring approximately 1 week after immunization. For complete information and recommendations related to measles immunization, the reader is referred to the most recent recommendations of the Advisory Committee on Immunization Practices,[23,74,446] the Committee on Infectious Diseases of the American Academy of Pediatrics,[12] and the manufacturer's package insert. Only a summary of recommendations is presented here.

Recommendations for Use

The widespread epidemics of measles in the United States in 1989 to 1991 were the result of a failure to immunize children at the appropriate age and the increased number of susceptible older children and adults because of vaccine failure.[22,74,75,260,277] Therefore, continued eradication of measles in the United States depends on ongoing programs that (1) enroll all children of initial vaccination age and (2) allow re-vaccination of all persons whose primary vaccine failed. Because routine immunity testing is not a viable public health option, re-vaccination of primary vaccine failures can be accomplished only by universal re-immunization.

Currently, live measles vaccine is recommended in a two-dose schedule.[12,74,446] In general, live measles vaccine should be administered at 12 to 15 months of age and the second dose at entry into school.[9,12,23,71,251,399,446,453,462] However, the second dose can be given after any interval longer than 1 month after administration of the first dose.[23] Children who have not received vaccine during infancy may be immunized at any age, and adults who have not had natural measles also should be immunized. When measles is endemic or epidemic in a community, all children aged 6 months or older should be immunized. In children who initially were vaccinated before they were 12 months of age, a second vaccination should be administered at 12 to 15 months of age, and a third dose at entry into school is necessary to complete the schedule.

Precautions

Measles vaccination should be deferred at times of febrile illness or when interference from another viral infection could cause failure of measles vaccine. Measles immunization also should be postponed for 3 to 11 months in persons who have received whole blood, blood plasma, or immunoglobulin because these products may contain sufficient measles antibody to neutralize the vaccine virus. The duration of postponement depends on the

product administered and the dose.[12,23] Children treated with intravenous immunoglobulin for Kawasaki disease should not receive measles vaccine until 11 months after receiving the immunoglobulin, whereas 3 months' time is adequate for children given immunoglobulin for hepatitis A prophylaxis.

Contraindications

Live measles vaccine should not be administered to pregnant women or to some persons with diseases or therapeutic programs associated with impaired cell-mediated immunity. These conditions in general include the following: leukemia, lymphoma, or other generalized malignant diseases; primary and secondary immunologic disorders; and therapy with steroids, radiation, antimetabolites, or alkylating agents. Measles immunization is recommended for children and adults with asymptomatic human immunodeficiency infection and for symptomatic patients who are not severely immunocompromised.[12,14]

Complications

Serious complications associated with administration of measles vaccine are exceedingly rare. Serious neurologic disease (encephalitis, Reye syndrome, cranial nerve palsy, cerebellar ataxia, and Guillain-Barré syndrome) within 30 days of immunization occurs at a rate of approximately one case per million doses of vaccine administered.[68,257] This rate is lower than the rate of occurrence of encephalitis of unknown cause in children for any 30-day period. However, the clustering of cases on days 8 and 9 after immunization noted from claims submitted to the National Vaccine Injury Compensation Program suggests that a causal relationship between measles vaccine and encephalopathy may be a rare complication of immunization.[447] In addition, recovery of measles virus from the CSF of a vaccinated child with encephalitis also suggests that rare vaccine-induced neurologic disease may occur.[141] In a large population-based study in Denmark between 1991 and 1998 it was found that measles-mumps-rubella (MMR) immunization was associated with a transient increased rate of febrile seizures.[437] However, the long-term rate of epilepsy was not increased in children who had febrile seizures after receiving vaccination compared with children who had febrile seizures related to other causative events. Thrombocytopenic purpura, anaphylaxis, hearing loss, and toxic epidermal necrolysis also have been associated with measles immunization.[11,27,31,215,390,400,414,452]

In developing countries, high-titer measles vaccines were used to induce seroconversion at a young age.[458] However, follow-up studies in some countries noted that the mortality rate was increased in female recipients of these high-titer vaccines over the course of a 3-year period when compared with children who received conventional doses of vaccine.[200,237] Nonetheless, follow-up studies in other countries showed no increased mortality rates in recipients of high-titer measles vaccine.[3,261]

Studies by Wakefield and colleagues[424,438] suggested that MMR vaccine may have a causal role in inflammatory bowel disease and autism. However, subsequent epidemiologic studies did not support an association between receipt of MMR vaccine and development of either inflammatory bowel disease or autism.[107,108,130,131]

QUARANTINE AND DISEASE CONTAINMENT

Before the use of measles vaccines became widespread, quarantine measures were practiced widely but were largely ineffective in preventing the spread of measles. However, containment of disease is practical today because the widespread use of measles vaccine has reduced the general number of susceptible young children and thus has decreased the rapidity of epidemic development. Epidemic measles now generally involves a greater age range of the population (cases in adolescents and young adults occur frequently), and progression of disease from one age group to another is slower than in epidemics that involve one uniform, largely susceptible population.

Containment is a vital part of the measles prevention policy in the United States. Measles is a reportable disease throughout the United States, and compliance is the obligation of all physicians. After receiving early reports of sporadic measles, health department workers can organize local immunization clinics so that the disease often can be contained in a small geographic area rather than developing into a widespread epidemic.

PASSIVE IMMUNIZATION: IMMUNOGLOBULIN

In the present vaccine era, little need for passive immunization exists. However, when a known susceptible child has had definite exposure to measles, immunoglobulin should be administered in a dose of 0.25 mg/kg (maximal dose, 15 mL). If this treatment is administered within 5 days of exposure, prevention of infection and disease can be expected. Administration of immunoglobulin later in the incubation period may modify the illness but does not prevent it. The use of immunoglobulin is particularly important in children who have not been immunized because of the contraindications to vaccination mentioned previously. In these children, immunoglobulin (0.5 mL/kg; maximal dose, 15 mL) should be administered when measles is epidemic in the community in which they reside. The dosage should be repeated every 4 weeks until the epidemic subsides. Intravenous immunoglobulin may be used (400 mg/kg).

CHAPTER 193

Mumps Virus

James D. Cherry

Mumps (epidemic parotitis) is an acute communicable disease caused by the mumps virus, a member of the genus *Rubulavirus*. As a result of universal immunization, mumps is an uncommon disease in children in the United States today.

HISTORY[79,145]

In the fifth century BCE, Hippocrates described an outbreak on the island of Thasus.[79] He noted that most patients had bilateral swelling near the ears and that the others had unilateral swelling. He also noted that some patients had bilateral or unilateral pain and swelling of the testicles.

The origin of the name *mumps* is not known. It may be from the English noun *mump*, which means "a lump," or the English verb *mump*, one of whose definitions is "mumble." This latter possible origin is based on the mumbling speech that patients with significant parotitis may have.

In 1790, Robert Hamilton[59,60] presented an extensive study of mumps in which he noted orchitis, associated the illness with

neurologic involvement, and described the neuropathology of a fatal case. In 1886, Hirsh[68] noted that mumps occurred throughout the world and that it was a major cause of morbidity in Confederate troops during the American Civil War. In the first half of the 20th century, investigators recognized that mumps virus infection involved multiple organs, and the causative agent was shown by Johnson and Goodpasture in 1934[40,73] to be a filterable virus.

The growth of mumps virus in embryonated eggs was reported in 1945, and 10 years later its propagation in tissue culture was noted.[57,63] This latter development led to the development and licensure of a live attenuated mumps vaccine in 1967.

PROPERTIES

CLASSIFICATION

Mumps virus is a member of the genus *Rubulavirus*, subfamily *Paramyxovirinae*, and family *Paramyxoviridae*.[91] It contains a single-stranded, nonsegmented, negative-sense RNA genome that is surrounded by a helical nucleocapsid and a surface envelope.

PHYSICAL PROPERTIES[15,82,91]

The virus generally is spherical, but marked pleomorphism occurs. Its size varies from 100 to 600 nm. Seven major proteins exist: a nucleocapsid-associated protein (NP), a phosphoprotein (P), a membrane or matrix protein (M), a fusion protein (F), a hydrophobic membrane-associated protein (SH), a hemagglutinin-neuraminidase (HN), and a polymerase protein (L). The genes for these proteins have been sequenced, and the gene order is 3-NP-P-M-F-SH-HN-L-5. The viral envelope is studded with 12- to 15-nm projections that contain either of the two structural glycoproteins (HN or F).

The P structural protein is associated with the nucleocapsid, and an RNA-dependent RNA polymerase is located within the nucleocapsid structure. The envelope has a high lipid content, and it contains the M protein.

The SH protein gene is the most variable region of the genome and, therefore, can be used to differentiate viral strains.[1,15,86,103,125] Analysis of the variations in SH gene nucleotide sequences has been used to study outbreaks, identify vaccine viruses, study vaccine adverse events, and identify new viral strains.

Mumps virus infectivity is destroyed by heat (56° C for 20 minutes), and its infectivity is reduced by ultraviolet light, Tween 80, ether, and formalin. The virus is stable at 4° C for several days, and when placed in a buffered salt solution (such as Hanks) with 1 to 2 percent inactivated fetal calf serum, it can be stored indefinitely at –70° C.

ANTIGENIC COMPOSITION

The three major antigenic components of mumps virus are the two glycoproteins (HN or V antigen and F protein) and the nucleocapsid protein (NP or S antigen).[82] The glycoproteins that project from the viral surface are the antigenic target for specific antibodies. Host antibodies to HN and F proteins confer protective immunity against the virus. Mumps viral particles agglutinate erythrocytes of several mammalian and avian species (human, avian, rodent, and simian); at 37° C, the virus causes partial hemolysis of susceptible erythrocytes when it is attached to cellular surface receptors. Specific antibody blocks hemagglutination, hemadsorption, and hemolysis.

Mumps virus is considered to have a single immunotype. However, polyclonal antibodies to parainfluenza and Newcastle disease viral antigens cross-react with antibodies to mumps virus in complement-fixation and hemagglutination-inhibition assays. With monoclonal antibodies, an antigenic relationship between the NH and NP proteins of Sendai virus (a murine parainfluenza type 1 virus) and mumps virus has been demonstrated.[104]

Although mumps is a monotypic virus, genetic variation between strains exists. A standardized nomenclature and an analysis protocol have been proposed for the genetic characterization of mumps strains to facilitate the expansion of molecular epidemiologic studies.[71] This nomenclature includes 12 genotypes (A to L) based on the nucleotide sequence of the hydrophobic (SH) gene.

TISSUE CULTURE GROWTH AND ANIMAL SUSCEPTIBILITY

Mumps virus can be propagated in many different primary and cell-line tissue cultures.[82] To isolate the virus, primary monkey kidney cells generally are used. Its cytopathic effect is similar to that of other paramyxoviruses. When stained, multinucleated giant cells and cytoplasmic eosinophilic inclusions may be observed. In culture, the addition of erythrocytes results in hemadsorption to surface virus.

Mumps virus infects monkeys, rabbits, dogs, cats, and rodents. The virus is isolated readily after inoculation of the amniotic sac of 7- to 8-day-old chicken embryos.

EPIDEMIOLOGY

INCIDENCE

In the United States, mumps was a reportable disease from 1922 to 1950 and has been again since 1967.[22] Between 1950 and 1967, incidence data were gathered from voluntary reporting by cooperating states. Incidence data from 1922 to 1982 are presented in Figure 193–1, and vaccine-era data are presented in Figure 193–2.[16,27] In the pre-vaccine era, mumps was a yearly disease, with epidemic peaks occurring approximately every 4 years. The peak epidemic year was 1944, when the rate was 250 per 100,000 population.

In the pre-vaccine era, mumps was a disease predominantly of young children.[22] However, outbreaks of mumps were a significant problem in young adults in the military.[52,95] The age distribution of mumps in the United States during selected years is presented in Table 193–1. After the mumps vaccine was licensed in 1967, mumps remained a disease of predominantly young children from 1967 to 1971. However, by 1981, most reported patients were 10 years or older. In 1987, 76 percent of the cases occurred in persons 10 years or older (see Table 193–1). In 1994, 1537 cases were reported, and of those with age noted, 21.8 percent were in patients 20 years or older. The increase in reported cases that occurred in 1987 (see Fig. 193–2) was the result of a marked increase in cases in nonimmunized persons aged 10 to 19 years. This group had been protected for a time by herd immunity because of the rapidly declining incidence of mumps as a result of routine vaccine use beginning in 1977.[33] In 1998, only 666 cases of mumps were reported in the United States.[23] Nineteen percent of the patients were younger than 5 years old, and 36 percent were 15 years or older. In 2005, 59.6 percent of the reported cases were in persons 15 years of age or older (see Table 193–1).[24]

In the pre-vaccine era, the peak incidence of mumps occurred in the winter and spring months, and this peak continued well into the vaccine era.[22] Since 1989, little seasonal variation in cases has been noted.[21,135] In the period from 2001 through 2004, an

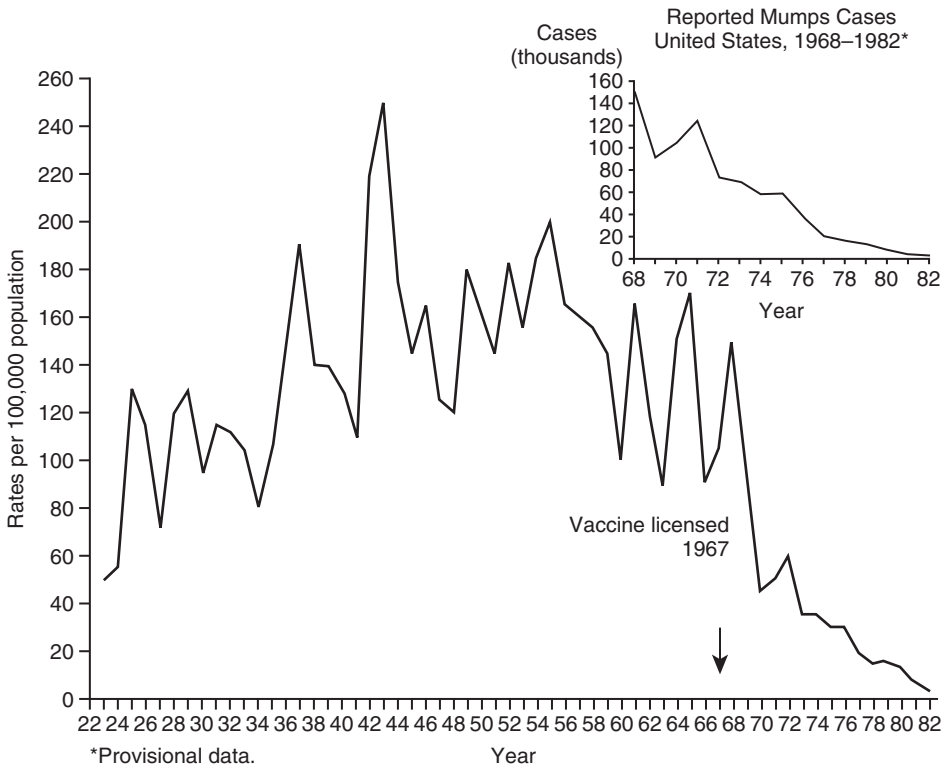

Figure 193–1 Incidence of reported mumps in the United States from 1922 to 1982 and the number of reported cases from 1968 to 1982. *(From Centers for Disease Control: Mumps Surveillance, January 1977-December 1982. Atlanta, Centers for Disease Control, 1984.)*

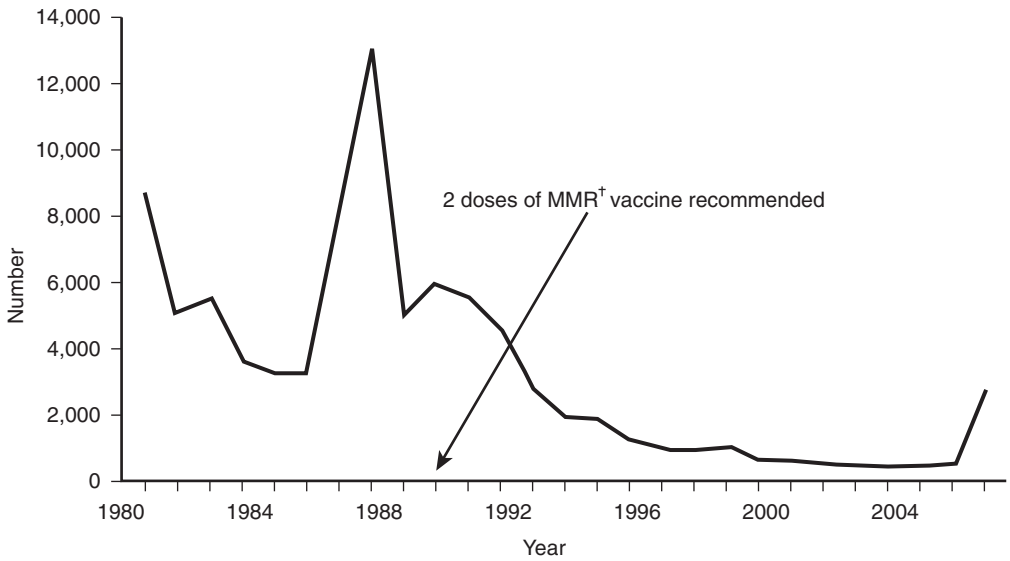

*Data for 2005 and 2006 are provisional.
†Measles, mumps, and rubella.

Figure 193–2 Number of reported mumps cases, by year in the United States, 1980 to 2006. *(From Centers for Disease Control and Prevention: Update: Multistate Outbreak of Mumps—United States, January 1-May 2, 2006. M. M. W. R. Morb. Mortal. Wkly. Rep. 55:559-563, 2006.)*

average of 265 mumps cases were reported each year.[25] However, in 2006, by March 28 a total of 219 mumps cases were reported in Iowa alone; this was a 44-fold increase in cases from the preceding decade. Of the 219 cases, the median patient age was 21 years (range, 3 to 85 years), with 48 percent of the patients aged 17 to 25 years old; 30 percent of the patients were known to be college students. This outbreak in Iowa in December 2005 was found to involve 10 additional states by May 2, 2006.[27] A total of 2597 cases was reported. For the period January 1 to October 7, 2006, 5783 cases of confirmed or probable mumps were reported from 45 states and the District of Columbia.[28] Eighty-four percent of the cases were reported in six states: Iowa (1968), Kansas (904), Wisconsin (750), Illinois (591), Nebraska (357), and South Dakota (288). The median age was 22 years, and 63 percent were female. Vaccination status data from Iowa found that 7 percent were unvaccinated; 14 percent had received one dose of measles-mumps-rubella (MMR) vaccine; and 49 percent had received two or more doses of MMR vaccine. The vaccination status of 30 percent of patients, most of whom were adults, was unknown.

In 2004 to 2005, a mumps epidemic occurred in the United Kingdom.[26] There were 56,390 reported cases. In 2004, 79.1 percent of the confirmed cases were in persons aged 15 to 24 years, and two thirds of all cases occurred in persons who had not been vaccinated. In many respects, this epidemic is similar to

TABLE 193–1 Age Distribution of Mumps Cases in the United States during Selected Years

	1967-1971*		1987		1994		2005		
Age Group (yr)	Cases	%	Cases	%	Cases	%	Age Group (yr)	Cases	%

the one in the United States in 1987; herd immunity had protected this adolescent and young adult cohort for a number of years.

MORBIDITY AND MORTALITY

The most common clinical manifestations of mumps virus infection are fever and parotitis. However, approximately 30 percent of infected persons do not have parotitis and therefore are not recognized.[85] Epididymo-orchitis occurs in 20 to 30 percent of clinical cases in postpubertal male patients. Approximately 60 percent of clinical mumps cases involve cerebrospinal fluid (CSF) pleocytosis, but only one sixth of these patients have meningeal symptoms.[6] In 1966, 628 cases of encephalitis (0.5%) were reported, and of these, 10 (1.6%) had a fatal outcome.[16] Encephalitis occurs more frequently in male patients (61%), and the rate of occurrence is greatest in adults. Deafness after a case of mumps has been estimated to occur in 0.5 to 5.0 per 100,000 cases.[42,137]

From 1966 to 1975, 200 mumps-associated deaths were reported in the United States.[16] Of these, 44 (22%) were in patients with encephalitis; in the others, the causes of death were not identified. Forty-one percent of the deaths occurred in adults 40 years or older. During the 10-year period from 1988 through 1997, only 8 deaths caused by mumps were reported.[23]

SPREAD OF INFECTION

Mumps virus is contagious in nonimmune persons. It is spread from an infected person to a new host by the respiratory route. The virus can be isolated from the saliva of infected patients from 7 days before the onset of parotitis to 9 days after onset.[82] Transmission is greatest during a 7-day period beginning 2 days before the onset of parotitis. Asymptomatically infected persons also can transmit the virus. The finding that outbreaks of mumps occurred in young adult populations in the pre-vaccine era suggests that mumps virus is less contagious than is measles; a significant number of persons passed through childhood without being infected with mumps virus. A serologic study reported by Black[9] in 1964 noted that 24 percent of army recruits lacked hemagglutination-inhibition antibody to mumps, whereas only 1 percent lacked measles antibody. The incubation period usually is 16 to 18 days, although it can vary from 12 to 25 days.[82]

PATHOGENESIS AND PATHOLOGY

VIRAL INFECTION[43,82,145]

After respiratory or perhaps oral acquisition of the virus occurs, primary viral replication occurs in the upper respiratory mucosal epithelium. Virus multiplies and is spread by drainage to local lymph nodes.[43] Subsequently, viremia develops.[76,105,133] As a result of viremia, infection occurs in multiple secondary infection sites. Most prominent is infection of the salivary glands that results in inflammation and swelling. This infection causes virus shedding for 1 to 2 weeks. Other secondary sites of infection include the inner ear (cochlea), pancreas, heart, nervous system (meninges and brain), joints, kidneys, liver, gonads, and thyroid.

PATHOLOGY[145]

In the salivary glands, virus infects the ductal epithelium and causes periductal interstitial edema and a local inflammatory reaction involving lymphocytes and macrophages.[143] Tissue damage ensues, and the involved cells desquamate. Virus enters the central nervous system (CNS) by the choroid plexus through infected mononuclear cells. Virus multiplies in choroid and ependymal cells on the ventricular surfaces, and these cells desquamate into the CSF and result in meningitis. In encephalitis, perivascular infiltration with mononuclear cells, scattered foci of neuronophagia, and microglial rod-cell proliferation occur.[12] Periventricular demyelination also takes place. In the male gonad, the primary site of viral replication is the seminiferous tubules, where infection results in lymphocytic infiltration and edema of interstitial tissue.

IMMUNOLOGIC EVENTS

Infection gives rise to serum antibodies to the HN glycoprotein (V antigen), the F antigen, and the NP protein (S antigen).[82] Antibody to NP protein develops first, 3 to 7 days after the onset of symptoms. Antibodies to NP protein are short-lived and usually are absent after 6 months; they cross-react with parainfluenza viruses. Antibodies to HN glycoprotein develop 2 to 4 weeks after the onset of illness and persist for long periods after infection.

Immunoglobulin G (IgG) and IgM antibody responses (determined by enzyme-linked immunosorbent assay [ELISA]) regularly occur after infection.[132] IgG antibody levels measured by ELISA correlate best with those derived by complement-fixation and hemolysis-in-gel assays. ELISA results are less specific than are those achieved with the plaque-reduction neutralization assay because of the high rate of cross-reacting antibodies against parainfluenza viruses detected by ELISA.[15,93,110] IgM antibodies develop early in the course of infection (second day of illness), peak within the first week of illness, and usually are undetectable 3 months after the onset of illness; occasionally, mumps-specific IgM antibody persists for 5 to 6 months.[82,132] Mumps-specific IgG antibody appears at the end of the first week of illness, peaks 3

weeks later, and persists throughout life. The IgG response is mainly the IgG1 subclass; a minor IgG3 subclass response also occurs.[15,115] Salivary IgA antibodies to mumps virus regularly appear after infection.[47]

During infection with vaccine virus, the cell-mediated response to tuberculin is diminished for up to 4 weeks.[87] During the same period, a mumps-specific, cell-mediated immune response develops.[82,145] This response has been demonstrated by skin test hypersensitivity, in vitro lymphocyte proliferative responses, and cytotoxic T-lymphocyte studies.[11,13,84]

In general, immunity against recurrent disease has been thought to be lifelong. However, Gut and associates[56] noted 26 patients with mumps who had a previous history of mumps and antibody response patterns suggestive of reinfection and not primary infection. Specifically, these patients had IgG but not IgM titer rises.

CLINICAL MANIFESTATIONS

In epidemics of mumps, cases can be separated into five groups: (1) those with a short course whose signs and symptoms are nonspecific, (2) those in whom the disease is full-blown with salivary swelling but no complications, (3) those with severe mumps and complications (epididymo-orchitis or meningoencephalitis, or both, or other complications), (4) those with no apparent symptoms but with typical antibody responses, and (5) those with meningoencephalitis or orchitis but without involvement of the salivary glands.[124] Approximately 75 percent of all cases of apparent mumps in children belong to the full-blown type without complications. Involvement of the gonads rarely occurs before puberty.

TYPICAL MUMPS WITHOUT COMPLICATIONS[124]

The average case in children has a prodromal period of 1 to 2 days that consists of fever, anorexia, headache, vomiting, and generalized aches and pains. The headache often is particularly marked and probably is caused by mild meningoencephalitis.[45] The temperature usually rises slowly to 102° F or 103° F (38.9° C or 39.4° C) as the disease becomes full blown, but at times fever is only slight or absent.

After the prodromal period, one or both parotid glands begin to enlarge (Fig. 193–3). Mumps is bilateral in approximately 70 to 80 percent of cases. A few days to a week or more may intervene between the swelling of the two sides. A distinctive "puckering" sensation is experienced at the angle of the jaw in the early stage, and it may be increased by the application of sour liquids, such as lemon juice or vinegar, to the tongue. This sign, when present, may be useful for early establishment of the diagnosis. The swelling of the gland also is distinctive in that a brawny type of edema occurs about the parotid gland, the borders of which are not discrete, in contrast to the discrete swelling typical of lymphadenitis, in which the node generally is outlined easily. The lobe of the ear is in the center of the swelling, which usually cannot be separated by palpation from the angle of the mandible. Pressure is painful, and opening the jaw often is difficult.

The swelling of an individual gland reaches its maximum in approximately 3 days, remains at its peak for approximately 2 days, and then slowly recedes. The extent of the swelling varies considerably but at times is sufficient to distort the outline of the face and head completely. The submaxillary and sublingual glands may be involved separately or with the parotids in any combination.

During the prodromal phase, slight redness of the orifices of the Stensen or Wharton ducts, when present, has diagnostic significance. The amount of saliva usually is unchanged, although the mouth may be dry or salivation may be extreme. Gellis and Peters[51] described a few cases with edema over the upper part of the sternum, apparently caused by pressure on the lymphatics in the neck.

Figure 193–3 Note the swelling on the left side of the face related to parotitis secondary to mumps virus infection. The left ear protrudes from the side of the head.

In uncomplicated mumps, the white blood cell count usually is low, with a slight relative lymphocytosis. Serum amylase typically is elevated.

MENINGITIS, MENINGOENCEPHALITIS, AND ENCEPHALITIS

Meningitis and mild meningoencephalitis are the most frequent complications of mumps in children. Azimi and Cramblett[5] reviewed 51 children with mumps meningoencephalitis who were admitted to Columbus Children's Hospital between July 1964 and December 1967. Of this group of patients, fever occurred in 94 percent, vomiting in 84 percent, nuchal rigidity in 71 percent, lethargy in 69 percent, parotid swelling in 47 percent, headache in 47 percent, convulsions in 18 percent, abdominal pain in 14 percent, sore throat in 8 percent, diarrhea in 8 percent, and delirium in 6 percent.

Clinical findings in neurologic illness caused by mumps virus infection differ according to the age of the patient. Meningeal signs are recognized more readily in older children, adolescents, and adults, whereas nonspecific findings such as drowsiness and lethargy occur more frequently in young children.[145] Although seizures develop in 20 to 30 percent of hospitalized patients, electroencephalographic results usually are normal. Even in patients with severe obtundation, the electroencephalogram reveals only diffuse slowing with increased voltage. Focal findings are rare. The outlook in mumps meningoencephalitis generally is good and usually is better than in encephalitis of other viral causes (see Chapter 42). Even patients with profound obtundation generally recover without having residual damage. Rarely, deaths do occur, however.[23]

In the typical case, CSF has normal glucose and elevated protein levels and pleocytosis. Glucose levels are slightly low in approximately 20 percent of cases. At the onset of symptoms,

modest mononuclear pleocytosis is present. The CSF cell count peaks on the third day of illness; counts average 250/mm^3, but counts greater than 1000/mm^3 are not uncommon. Mumps meningitis usually develops in patients with parotitis approximately 5 days after the onset of illness, but CNS findings can precede the parotid findings and can develop without any salivary gland involvement.

Herndon and colleagues[65] noted that ependymitis regularly occurs in cases of mumps meningitis. A rare complication of mumps appears to be acquired aqueductal stenosis, and researchers have suggested that it may be caused by the preceding ependymitis.[65,101,123,130] In one reported fatal case, hydrocephalus developed within 5 days of onset of disease.[102] More recently, acute hydrocephalus associated with mumps meningoencephalitis was noted in an 8.5-year-old boy.[2] This child received a ventriculoperitoneal shunt and at follow-up had no neurologic deficit.

A 3-year-old boy with mumps cerebellitis, nystagmus, and focal localization of brain lesions noted by electroencephalography was described.[92] Also reported were facial palsy in a 3-year-old Japanese boy and transverse myelitis in an adult.[41,136] A girl aged 4 years and 3 months who had brain stem encephalitis and acute disseminated encephalomyelitis following mumps was described.[122] This child responded rather dramatically to treatment with glucocorticoids and intravenous immunoglobulin. Haginoya and associates[58] reported the case of a 14-year-old Japanese girl who had chronic progressive mumps virus encephalitis. This child had an illness similar to subacute sclerosing panencephalitis, and her antibody titers suggested that the infecting virus may have had a defect in the HN protein.

GONADAL INFECTION (EPIDIDYMO-ORCHITIS AND OOPHORITIS)

Epididymo-orchitis and oophoritis almost never occur before puberty.[124] However, in adolescent boys and adult men, epididymo-orchitis is second only to parotitis as a manifestation of mumps virus infection.[85] Cases of orchitis have been reported in children as young as 3 years old.[113] In postpubertal male patients, orchitis develops in 30 to 38 percent with mumps.[7,109] The rate of orchitis is highest in those 15 to 29 years of age. The greatest number of cases occur during the second, third, and fourth decades of life. Approximately 80 percent of cases of epididymo-orchitis appear during the first 8 days of involvement of the salivary gland, but a few cases occur a considerable time after the parotitis has subsided.[124]

The onset of testicular involvement usually is manifested as chills, recurrence of fever, and swelling of the testes. Pain over the renal area or in the lower part of the abdomen, bilateral or unilateral, may precede or accompany the orchitis. Occasionally, this pain, if on the right side, may suggest appendicitis.

The orchitis usually is unilateral, but bilateral involvement has been reported in 17 to 38 percent of cases.[7,109] Although atrophy may develop after orchitis, in those with unilateral involvement, sterility is not a concern. Sterility has resulted after some cases of bilateral orchitis, however. A 16-year-old adolescent with mumps epididymo-orchitis was found to have persistent mumps virus RNA in his semen for 40 days.[72] In follow-up studies, he was found to have antisperm antibodies. The development of malignant disease in affected testes also has been reported.[7,75]

Oophoritis occurs in approximately 7 percent of postpubertal female patients. Pelvic pain and tenderness are noted.[116]

PANCREATITIS

In a retrospective survey of 2482 hospitalized patients with mumps, pancreatitis was noted in 75 (3%).[4] Cases occurred in children and adults, and pancreatitis was 1.6 times more common in male than in female patients. Severe involvement of the pancreas is a rare occurrence, but mild or subclinical infection may occur more frequently than recognized.[116] It may be unassociated with salivary gland manifestations and be misdiagnosed as gastroenteritis. Epigastric pain and tenderness are suggestive; they may be accompanied by fever, chills, vomiting, and prostration. A child with acute hemorrhagic pancreatitis and a pseudocyst caused by mumps virus infection has been reported.[44]

DIABETES MELLITUS

Diabetes mellitus long has been suspected to be associated with antecedent mumps.[16,61] In experimental animals, mumps virus infection has been linked to hyperglycemia and histologic lesions of the pancreatic islets. Mumps virus can invade the human pancreas and can infect and destroy human and rhesus beta cells in vitro,[112] but pancreatic damage has not been documented in reported cases of diabetes that developed after mumps or mumps vaccination.[121]

In humans, many cases of temporal association have been described both in individuals and in siblings,[36,37,81,97,100] and outbreaks of diabetes mellitus a few months or years after outbreaks of mumps have been reported.[55,96,128] Although evidence has not established a causal association in these cases, a study in Surrey, England, suggested that a small proportion, if any, of diabetes cases that start in childhood (only 15 of the 1663 patients in the study, or <1%) may have resulted from a recent mumps virus infection.[49] Antibody studies have shown fewer positive titers for mumps in diabetic patients than in normal subjects, even in children.[114] Infection may contribute to the development of diabetes either by specifically damaging islet cells or by precipitating diabetes in patients whose disease is latent. Teng and colleagues[129] reported the case of an 11-year-old girl with mumps infection complicated by transient hyperinsulinemic hypoglycemia.

NEPHRITIS

Viruria is a common occurrence in uncomplicated mumps, and mild abnormalities in renal function occur.[133] Severe and fatal nephritis was reported as a rare complication of mumps occurring 10 to 14 days after parotitis.[116] Fujieda and associates[48] reported the demonstration of mumps virus genomic RNA by polymerase chain reaction (PCR) in a renal biopsy specimen from a 5-year-old girl with IgA nephropathy.

DEAFNESS

Deafness is an important but rare complication of mumps virus infection.[22] Its incidence has been estimated at 0.5 to 5.0 per 100,000 cases of mumps.[33,115] However, the incidence rate of minor degrees of hearing impairment, such as high-tone hearing loss, is probably much higher.[31]

Mumps-associated deafness occurs with or without meningoencephalitis and may develop after asymptomatic infection.[16,42,99] The deafness usually is unilateral and often permanent. Twenty-two of 103 cases (21%) reviewed by Everberg[42] were bilateral. Mumps virus has been isolated from perilymph fluid in a case of sudden-onset, unilateral, complete deafness that began 2 days after the onset of mumps.[14,144] Vertigo also is noted occasionally in patients with mumps; it occurs most commonly in those in whom deafness develops.[70]

MUMPS AND PREGNANCY[23]

The incidence of mumps during pregnancy was estimated at 0.8 to 10 cases per 10,000 pregnancies[117] before vaccine was licensed in the United States. No vaccine-era data are available for comparison. Maternal complications such as mastitis,[109] aseptic meningitis,[10] and fatal glomerulonephritis[39] have been reported. Mumps virus has been isolated from human breast milk.[77]

Increased rates of fetal mortality were reported in women who contracted mumps during the first trimester. In a large prospective case-control study, a 27.3 percent rate of fetal wastage was noted in women with mumps during the first trimester versus a 13.0 percent rate in matched, non-ill controls during the first trimester.[120] No significant differences in birth weight were noted among the live births.[119] Because fetal loss usually occurs in such cases within 2 weeks of development of maternal infection, investigators postulated that factors related to maternal gonadal infection with resulting hormonal changes may be responsible. A histopathologic study of the products of conception in mothers with gestational mumps revealed severe proliferative necrotic villitis and vasculitis in the placenta and viral inclusions, as seen in mumps infection, in fetal tissues.[50] Mumps virus was isolated from a spontaneously aborted 10-week-old human fetus.[89]

No evidence has shown that gestational mumps in humans increases the risk of development of fetal malformations,[118] although a few cases of various congenital malformations with no consistent pattern have been reported.[69]

OTHER MANIFESTATIONS

Other rare clinical manifestations include exanthem and enanthem,[30] arthritis,[53] myocarditis,[8] thrombocytopenia,[88,90,111] keratouveitus,[78] lower respiratory tract infection,[46] and other glandular involvement (thyroiditis, mastitis, dacryoadenitis, and bartholinitis).[85,107]

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Not all patients with mumps have parotid swelling, and mumps virus is not the only cause of parotitis. Mumps virus infection must be considered in all children with aseptic meningitis, meningoencephalitis, and encephalitis (see Chapters 41 and 42). In addition to mumps virus infection, many other infectious agents and noninfectious conditions are associated with parotitis or parotid swelling (see Chapter 16). Other viruses that can cause parotitis include Epstein-Barr virus, coxsackieviruses and echoviruses, influenza A virus, parainfluenza viruses, cytomegalovirus, human herpesvirus-6, and lymphocytic choriomeningitis virus.[14,38] Purulent parotitis can be differentiated from mumps by the exquisite tenderness of the region, an elevated white blood cell count, and the observation of pus coming from the Stensen duct. Other viral causes of parotitis can be differentiated by the respective epidemiologic and clinical characteristics of specific agents and appropriate culture, serologic study, or both.

Enlargement of lymph nodes in proximity to the parotid gland must be differentiated from parotid enlargement (see Chapter 15). The cervical lymph nodes are below the ramus of the mandible. The preparotid nodes generally are anterior to the parotid, and their enlargement usually is associated with conjunctivitis. Occasionally, an enlarged lymph node within the parotid gland may cause some confusion. Lesions of the ramus of the mandible, such as osteomyelitis, occasionally have been mistaken for parotid enlargement. In this case, the enlargement usually is persistent.

SPECIFIC DIAGNOSIS

In an epidemic situation, the diagnosis of mumps is clinically straightforward, and performing laboratory tests is unnecessary. The critical points are a history of exposure, an incubation period of 2 to 3 weeks, and a typical clinical picture consisting of fever and parotitis. In a sporadic case or in a previously vaccinated child, confirming the cause by laboratory study is important. Mumps virus, as well as most other viruses that cause parotitis, can be isolated readily from saliva, throat swabs, or mouthwashings during acute illness. In patients with meningoencephalitis, virus also can be recovered from CSF. Virus is isolated in primary monkey kidney tissue culture.

Mumps virus infection also can be confirmed by demonstrating a significant rise in antibody titer in paired serum specimens by complement fixation, hemagglutination inhibition, or ELISA. However, because mumps cross-reacts with parainfluenza viruses, these methods are not ideal.[110] Mumps-specific IgM antibody determined by ELISA is the usual test performed; the presence of this antibody indicates a recent infection. Mumps-specific IgM antibodies determined by enzyme immunoassay in oral fluid also are useful for establishing the diagnosis.[138] Mumps virus RNA also can be detected directly from clinical samples by real-time PCR.[131] In unusual cases in which the source of facial swelling is obscure, determination of a serum amylase level may be helpful; a high value indicates parotid involvement.

TREATMENT

Conservative therapy is indicated in the treatment of mumps. Adequate attention given to hydration and alimentation of patients is important. Patients may have difficulty with acidic foods such as orange juice. In addition, orange juice may cause vomiting in an already nauseated patient. The diet should be light, with a generous offering of fluids.

Occasionally, analgesics are necessary to treat severe headache or discomfort caused by parotitis. Stronger analgesics such as codeine or meperidine (Demerol) rarely are required for headache but may be useful for orchitis. Vomiting seldom is sufficiently severe to require intravenous fluids. In these instances, however, electrolytes lost by vomiting should be replaced.

Although lumbar puncture seldom is necessary for establishing a diagnosis in patients with meningoencephalitis accompanying mumps, patients often indicate that they have experienced relief of headache after undergoing this procedure. No antiviral agent is appropriate or indicated for the treatment of mumps, which is a self-limited illness.

PROGNOSIS

The overall prognosis in uncomplicated mumps is excellent. The outlook in meningoencephalitis also generally is favorable, but death and neurologic damage can occur. Deafness and sterility are rare complications.

PREVENTION

IMMUNIZATION

A summary of the recommendations of the Advisory Committee on Immunization Practices (ACIP) and the Committee on Infectious Diseases of the American Academy of Pediatrics for the use of mumps vaccine follows.[3,18,28a] For more complete information,

the reader should consult the most recent ACIP statement or the Report of the Committee on Infectious Diseases of the American Academy of Pediatrics.

The mumps virus vaccine available in the United States (official name: mumps virus vaccine, live) is the Jeryl Lynn strain and is prepared in chick embryo cell culture. The vaccine produces a subclinical, noncommunicable infection with few side effects. Mumps vaccine is available in both a monovalent (mumps only) form and combinations: mumps-rubella, MMR, and measles-mumps-rubella-varicella (MMRV) vaccines.

In initial trials, mumps vaccine was approximately 95 percent efficacious in preventing mumps disease,[67,80,126] and after vaccination, measurable antibody developed in more than 97 percent of persons known to be susceptible to mumps.[142] Vaccine-induced antibody was protective and long-lasting,[140,141] although it was of considerably lower titer than antibody resulting from natural infection.[142] The duration of vaccine-induced immunity is unknown, but serologic and epidemiologic data collected during 35 years of use of live vaccine suggested both persistence of antibody and continuing protection against infection. The epidemic occurrence of mumps in 2006 in the United States as well as in other countries resulted in further evaluations of vaccine efficacy and waning immunity.[11,28a,34,62,74,106,134] In a study in England, the effectiveness of vaccine after one dose declined from 96 percent in 2-year-old children to 66 percent in children aged 11 to 12 years old.[34] In those children who had received two doses, the effectiveness declined from 99 percent in children aged 5 to 6 years old to 86 percent in children aged 11- to 12-years old. These data suggest that waning immunity contributes to outbreaks of mumps in older, previously vaccinated populations. Studies in Belgium and Korea also demonstrated waning immunity as contributing to outbreaks of mumps.[29]

In Finland, a two-dose MMR vaccination program with the Jeryl Lynn mumps vaccine strain was launched in 1982.[108] This program was highly successful, and Finland was the first country documented to be free of indigenous mumps, as well as rubella and measles. In a study in Finland that was published in 2007, researchers found that previous vaccinees who were found to be seronegative nonetheless had mumps antigen-specific lymphoproliferative responses.[74]

General Recommendations

Susceptible children, adolescents, and adults should be vaccinated against mumps unless vaccination is contraindicated. Mumps vaccine is of particular value for children approaching puberty and for adolescents and adults who have not had mumps. MMR is the vaccine of choice for routine administration and should be used in all situations in which recipients also are likely to be susceptible to measles, rubella, or both. The favorable benefit-to-cost ratio for routine mumps immunization is more marked when vaccine is administered as MMR.[83,139] Persons should be considered susceptible to mumps unless they have documentation of (1) physician-diagnosed mumps, (2) adequate immunization with live mumps virus vaccine on or after their first birthday, or (3) laboratory evidence of immunity.

Persons who are unsure of their history of mumps disease or mumps vaccination should be vaccinated. No evidence has shown that persons who previously either received mumps vaccine or had mumps are at any increased risk for developing local or systemic reactions from receiving live mumps vaccine. Testing for susceptibility before administering vaccination, especially in adolescents and young adults, is not necessary. In addition to the expense, some tests (e.g., mumps skin test, complement-fixation antibody test) may be unreliable, and tests with established reliability (e.g., neutralization, enzyme immunoassay, radial hemolysis antibody test) are not readily available.

Dosage

Two doses of MMR vaccine separated by at least 1 month in the volume specified by the manufacturer should be administered subcutaneously.

Age

Live mumps virus vaccine is recommended at any age on or after the first birthday for all susceptible persons, unless a contraindication exists. In routine circumstances, mumps vaccine should be given in combination with measles and rubella vaccines as MMR, and the currently recommended schedule for administration of measles vaccine should be followed. It should not be administered to infants younger than 12 months old because persisting maternal antibody may interfere with seroconversion. To ensure that the patient has developed immunity, all persons vaccinated before their first birthday should be revaccinated on or after their first birthday.

PERSONS EXPOSED TO MUMPS

Use of Vaccine

When given after exposure to mumps, live mumps virus vaccine may not provide protection. However, if the exposure did not result in infection, vaccine should induce protection against infection from subsequent exposure. No evidence has indicated that the risk of vaccine-associated adverse events increases if vaccine is administered to persons incubating disease.

Use of Immunoglobulin

Immunoglobulin has not been demonstrated to be of established value in postexposure prophylaxis and is not recommended.

Adverse Effects of Vaccine Use

In field trials before vaccine was licensed, illnesses did not occur more often in vaccinees than in unvaccinated controls.[66] Reports of illnesses occurring after receipt of mumps vaccination have been episodes mainly of parotitis and low-grade fever. Allergic reactions, including rash, pruritus, and purpura, have been associated temporally with mumps vaccination but are uncommon and usually mild and of brief duration. The reported development of encephalitis within 30 days of receiving a mumps-containing vaccine in the United States (0.4 per million doses) is not greater than the observed background incidence rate of CNS dysfunction in the normal population. Other manifestations of CNS involvement in the United States, such as febrile seizures and deafness, also have been reported infrequently. Complete recovery usually occurs. Reports of nervous system illness occurring after receipt of mumps vaccination do not necessarily denote an etiologic relationship between the illness and the vaccine. In parts of Europe, Canada, and Japan, where different mumps vaccines (Leningrad 3 strain and Urabe Am 9 strain) have been used, rates of vaccine-induced aseptic meningitis have been high.[32,35,94,98,127]

CONTRAINDICATIONS TO VACCINE USE

Pregnancy

Although mumps vaccine virus has been shown to infect the placenta and fetus,[146] no evidence has indicated that it causes congenital malformations in humans. However, because of the theoretic risk of fetal damage, a prudent approach is to avoid

giving live virus vaccine to pregnant women. Women should avoid becoming pregnant for 3 months after receiving vaccination. Routine precautions for vaccinating postpubertal women include asking whether they are or may be pregnant, excluding those who say that they are, and explaining the theoretic risk to those who plan to receive the vaccine. Being vaccinated during pregnancy should not be considered an indication for termination of pregnancy. However, the final decision about interruption of pregnancy must rest with the individual patient and her physician.

Severe Febrile Illness

Administration of vaccine should not be postponed because of minor or intercurrent febrile illnesses such as mild upper respiratory infections. However, vaccination of persons with severe febrile illnesses generally should be deferred until they have recovered.

Allergies

Because live mumps vaccine is produced in chick embryo cell culture, persons with a history of anaphylactic reactions (e.g., hives, swelling of the mouth and throat, difficulty breathing, hypotension, shock) after ingesting eggs should be vaccinated only with caution and according to published protocols.[54,64] Children known to be allergic should not leave the vaccination site for 20 minutes after being vaccinated. Evidence indicates that persons are not at increased risk if they have egg allergies that are not anaphylactic. Such persons may be vaccinated in the usual manner. No evidence has demonstrated that persons with allergies to chickens or feathers are at increased risk of having a reaction to the vaccine.

Because mumps vaccine contains trace amounts of neomycin (25 μg), persons who have experienced anaphylactic reactions to topically or systemically administered neomycin should not receive mumps vaccine. Most often, allergy to neomycin is manifested as contact dermatitis, which is a delayed-type (cell-mediated) immune response rather than anaphylaxis. In such persons, the adverse reaction, if any, to 25 μg of neomycin in the vaccine would be an erythematous, pruritic nodule or papule at 48 to 96 hours. A history of contact dermatitis to neomycin is not a contraindication to receiving mumps vaccine. Live mumps virus vaccine does not contain penicillin.

Recent Immunoglobulin Injection

Passively acquired antibody can interfere with the response to live attenuated virus vaccines. Therefore, mumps vaccine should be given at least 2 weeks before the administration of immunoglobulin or be deferred for 3 to 11 months after the administration of immunoglobulin. The duration of deferral depends on the dose of immunoglobulin administered.[139]

Altered Immunity

In theory, replication of the mumps vaccine virus may be potentiated in patients with immune deficiency disease and by the suppressed immune responses that occur with leukemia, lymphoma, or generalized malignancy or with therapy with corticosteroids, alkylating drugs, antimetabolites, or radiation. In general, patients with such conditions should not be given live mumps virus vaccine. Because vaccinated persons do not transmit mumps vaccine virus, the risk of exposure to mumps in these patients may be reduced by vaccinating their close susceptible contacts.

An exception to these general recommendations is in children infected with human immunodeficiency virus (HIV): all asymptomatic HIV-infected children should receive MMR vaccine at 12 months of age.[17,139] If measles vaccine is administered to symptomatic HIV-infected children, the combination MMR vaccine generally is preferred.[18]

Patients with leukemia in remission whose chemotherapy has been terminated for at least 3 months also may receive live mumps virus vaccine. Short-term (less than 2 weeks' duration) corticosteroid therapy, topical steroid therapy (e.g., nasal, skin), and intra-articular, bursal, or tendon injection with corticosteroids are not contraindications to the administration of mumps vaccine. However, mumps vaccine should be avoided if systemic immunosuppressive levels are reached by prolonged, extensive, topical application.

CONTAINMENT OF DISEASE

Containment is important in prevention of mumps in the United States. Mumps is a reportable disease, and compliance is the obligation of all physicians. After early reports of sporadic mumps cases, health department workers can organize local immunization clinics and exclude susceptible students from school so that disease can be contained in a small geographic area.

CHAPTER 194

Respiratory Syncytial Virus

Caroline Breese Hall ❂ Edward E. Walsh

As by one bow on varied strings
the tune is played,
By both the microbe and the host,
disease is made.

—*CBH*

Respiratory syncytial virus (RSV) is the most important respiratory pathogen of infancy and early childhood and the major cause of hospitalization for bronchiolitis and pneumonia in infants.[37,123,124,125,199,220,318,323] According to 1986 estimates of the Institute of Medicine, each year approximately 91,000 infants were hospitalized with RSV infection in the United States at a cost of $300 million.[179,197] More recent studies suggest that these figures underestimate the current number of hospitalizations associated with RSV infections. Significant rises in the number of admissions for RSV bronchiolitis have been documented in both the United States and Canada.[237,364] In the United States, 62,500 to 100,000 hospitalizations for RSV bronchiolitis alone are estimated to occur annually in children younger than 5 years old.

The mien of RSV is marked by its contagiousness and by its propensity to cause the most severe disease during the first few months of life, despite the uniform presence of specific maternal antibody. RSV causes sizable outbreaks each year, with the result that most children become infected in their first 2 years of life.[127,182] Nearly all these first infections are symptomatic, and many involve the lower respiratory tract. Reinfections occur throughout life and usually are sufficiently symptomatic to cause absence from work or school.[146,149,182]

HISTORY

In 1956, Morris and associates[284] noted a cropping of colds with coryza in a colony of chimpanzees that had been under observation for the previous 3 to 24 weeks. A new virus was recovered from 1 of the 14 afflicted chimpanzees, and it was appropriately named *chimpanzee coryza agent* (CCA). Specific antibody to the CCA agent developed in the remaining 13 animals during convalescence; thus, the attack rate was 100 percent. An upper respiratory tract infection and a serologic antibody response to CCA also developed in a person working with these chimpanzees, but the virus was not isolated from his secretions. However, further evidence of the pathogenicity of CCA was obtained subsequently when the CCA virus isolated from one chimpanzee was inoculated into susceptible chimpanzees and a coryzal illness developed after 3 days.

The suspected human origin of the chimpanzee coryza agent was confirmed a year later when Chanock and Finberg[57] recovered two agents indistinguishable from the CCA virus from the throat swabs of an infant with bronchopneumonia (Long strain) and from a child with laryngotracheobronchitis (Snyder strain). These investigators also observed an antibody response to these viruses in patients with respiratory disease and noted that by the time they reached 4 years of age, 80 percent of children had neutralizing antibody against the Long strain. Nonetheless, these investigators could not determine a definite etiologic association between the virus and lower respiratory tract disease in their young patients. They proposed to call this group of viruses (Long, Snyder, and CCA) *respiratory syncytial virus* because of their similar clinical and tissue culture manifestations. Confirmation of RSV as a major agent in respiratory disease soon accumulated from studies throughout the United States, and investigators from many countries subsequently documented and further delineated the importance of RSV.[28,37,56,101,106,268,302]

PROPERTIES

and outer quill

CLASSIFICATION

The original classification of RSV with the Newcastle disease and parainfluenza group of viruses was based on their similar internal particle structure, eosinophilic inclusions, and syncytial appearance in tissue culture. However, RSV is antigenically distinct and does not hemagglutinate erythrocytes. Subsequently, the diameter of the nucleocapsid of RSV was determined to be between those of the larger paramyxoviruses and those of the smaller influenza viruses. Further study of the structure of RSV resulted in its current classification in the order Mononegavirales, family *Paramyxoviridae*, and subfamily *Pneumovirinae*.[69,335] RSV belongs, along with pneumonia virus of mice, bovine RSV, ovine RSV, caprine RSV, and turkey rhinotracheitis virus, to the subfamily *Pneumovirinae*, which consists of two genera, *Pneumovirus* and *Metapneumovirus* (MPV). The second genus, *Metapneumovirus*, contains human metapneumovirus (hMPV) first described in 2001 by van den Hoogan and colleagues[387] in the Netherlands.

STRUCTURAL AND ANTIGENIC PROPERTIES

The virion of RSV consists of a nucleocapsid enclosed within an envelope consisting of a bilipid layer derived from the plasma membrane of host cells. Transmembrane glycoprotein spikes on its surface give the virus the appearance of a thistle on electron microscopy. The genome of RSV (strain A2) has been completely sequenced and is composed of 15,222 nucleotides. It is a nonsegmented, single-stranded, negative-sense RNA genome that encodes 11 proteins. The major messenger RNAs (mRNA) (Fig. 194–1) each encodes for one of the major proteins, except for M2 mRNA, which possesses two overlapping open-reading frames that encode for two separate proteins (M2-1 and M2-2).[69,413] Eight of these, including the seven largest (L, G, F, N, P, M, and SH), are structural proteins; two (NS1 and NS2) are nonstructural proteins; and M2-2 is a regulatory protein.

Of the structural proteins, three form the viral capsid: N (nucleoprotein), P (phosphoprotein), and L (polymerase). Two are matrix membrane–associated proteins: the nonglycosylated M and M2 (the transcriptional anti-terminator protein or transcriptase processivity factor, M2-1). The other three structural proteins, the glycosylated F (fusion) and G (attachment) proteins and the small, nonglycosylated hydrophobic SH protein, are transmembrane surface proteins. The F and G proteins are integral to RSV's infectivity and pathogenicity. The primary function of G, the largest glycoprotein, appears to be in the initial attach-

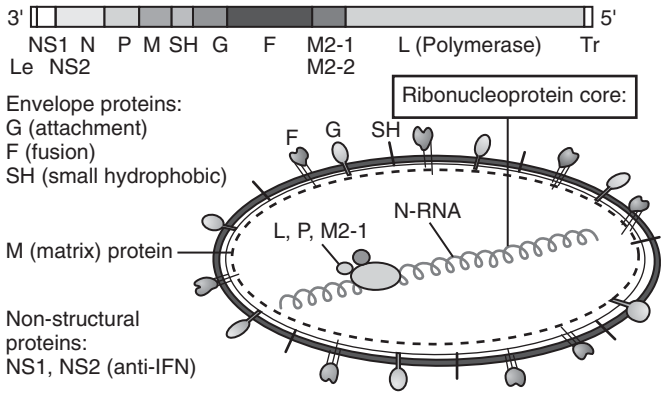

Figure 194–1 The genome of respiratory syncytial virus (RSV) and a schematic diagram of an RSV virus particle. Le, leader; Tr, trailer.

ment of the virus to the host cell and is unusual compared with the attachment proteins of other paramyxoviruses because it has no hemagglutinin or neuraminidase. Initial penetration of the virus then is mediated by the F protein by fusing the viral and host cellular membranes, a process that allows cell-to-cell spread of the virus and results in the syncytia characteristic of RSV. However, all three of the surface glycoproteins, F, G, and SH, appear to act in concert to enhance the fusion process.

Significant strain variations among RSV isolates cause strains to be divided into two major groups.[20,413] These two major groups, A and B, have intergroup and intragroup variations in several proteins, including F, G, P, and N. The primary differences reside in the largest surface glycoprotein, the G protein. The amino acid sequence of the G protein varies by approximately 50 percent between the RSV A and RSV B strain groups. Intragroup strain variation also occurs mainly within the G protein. In contrast, within F protein, the amino acid sequence is conserved relatively well, and thus, neutralizing antibody to F protein is cross-reactive between the two strain groups.[69] The F proteins of prototype strains from groups A and B have greater than 90 percent amino acid homology and a high degree of antigenic relatedness.

LABORATORY GROWTH

RSV is relatively labile and is destroyed rapidly at 55° C. At 37° C, infectivity does not diminish for 1 hour, but by 24 hours, only 10 percent remains. When placed at 4° C for 1 week, 1 percent remains.[170]

The viability of RSV depends in part on the salt and protein content of the media. At 4° C, the addition of 1 mol/L of magnesium sulfate maintains viral stability for 5 weeks.[102] The virus withstands freezing and thawing poorly.[170] Preservation is enhanced by rapid freezing in a dry ice and alcohol bath and by the addition of sucrose or glycerin to the storage media. Infectivity also is influenced by the pH of the medium; at values less than 5, infectivity rapidly diminishes. The optimal pH for preservation is 7.5.[170] RSV is inactivated rapidly by detergents such as 0.1 percent sodium deoxycholate, sodium dodecyl sulfate, and Triton X-100, as well as by chloroform and ether.

RSV can grow in a variety of human and animal cell cultures. Human heteroploid cells such as HEp-2, HeLa, and A549 cells are used most frequently for primary isolation. Additional cell cultures that may be used, but generally are less sensitive, include diploid fibroblastic, monkey kidney, human kidney, and amnion cells. However, the sensitivity of these cell lines is variable, especially with passage, and must be monitored constantly. The characteristic cytopathic effect of RSV in continuous cell lines is syncytial formation with eosinophilic cytoplasmic inclusions. The syncytia usually are evident 2 to 7 days after inoculation and progress to complete degeneration within about 4 days.[150] The cytopathic effect, however, depends on the strain of virus, the medium, the sensitivity and thickness of the cell cultures, and the number of passages. Syncytia tend to be less evident in fibroblast cell lines, and in some primary cell cultures, RSV may produce rounded, refractile cells.

The growth cycle of RSV has been shown to consist of a period of adsorption, in which 50 percent of the inoculum is adsorbed in 2 hours, followed by an eclipse period of 12 hours. New virus appears shortly thereafter and enters a log phase of replication lasting for approximately 10 hours. Viral antigen can be documented by fluorescent antibody staining 7 to 10 hours after inoculation. Shortly thereafter, cell-free virus may be demonstrated in the culture medium, but 50 to 90 percent of the virus remains associated with the cell surface at the time maximal titers are reached. Most of the cell-associated virus consists of incomplete noninfectious virions that may be released by agitation and sonication. With the laboratory Long strain (group A), peak titers usually are reached in 48 hours. For each infected cell, approximately 10 plaque-forming units generally result. Titers of virus are enhanced by inoculation of cell monolayers that are not yet confluent.

ANIMAL SUSCEPTIBILITY

Susceptible animals that could serve as a model for the lower respiratory tract disease of infants have been sought for some time. Each has advantages and disadvantages in replicating primary RSV disease in infants, but none is ideal.[84] Although RSV grows in the lung of a variety of animals, direct inoculation into their respiratory tract generally produces infection that is clinically and pathologically silent.

The natural hosts for symptomatic RSV infection are primarily humans and chimpanzees, and cows for bovine RSV.[42,84] RSV also has been recovered from asymptomatic goats and sheep. Other domestic animals, such as dogs and cats, have been found to possess antibody to RSV, the significance of which is unclear.

Chimpanzees most closely resemble humans in their clinical response to RSV. However, lung disorders and some degree of clinical disease have been induced in many other primates.[42,84,345] Infection in ferrets is age-dependent, with limited histopathologic features of the nasal turbinates and trachea developing in adults. In infant ferrets, however, the virus replicates in the lung.[330] The use of the cotton rat model resulted in major progress in understanding the pathogenesis of RSV infection, as demonstrated by the seminal studies of Prince and colleagues.[331,333,334] With intranasal inoculation, viral titers peak in the lung and nasal turbinates after 4 to 5 days. Histologic changes in the lung are present but may be inconsistent, and immunologic reagents are limited in comparison with those for mice. Active replication of RSV in other rodents generally is limited. BALB/c mice are among the most susceptible, and marked pulmonary disease may occur with high-titer, large-volume inocula, which in older mice is accompanied by evidence of clinical illness.[131,135]

A lamb model also was developed, which after challenge with ovine, bovine, or human RSV resulted in pathologic changes in the lung, fever, and tachypnea.[234] Bovine RSV in cattle has been an appealing natural model because of its clinical, epidemiologic, and histologic similarities to human RSV infection in infants.[235] Calves, despite possessing maternal antibody, can develop bronchiolitis. The disease can be severe and aggravated by bacterial superinfection, which occurs infrequently in infants. Despite this

appreciable morbidity that naturally occurs with bovine RSV, experimental infection in cattle has sometimes been difficult and inconsistent. The natural pathogen of mice, pneumonia virus of mice (PVM), a pneumovirus similar to RSV, also has been used successfully as a model for studies of pathogenesis.[84] PVM offers the advantages of good viral replication followed by severe respiratory disease and histologic changes.

EPIDEMIOLOGY

What occult power pries loose the lid
to give you winter flight,
But with the lengthening light of spring
gives cloak and leaden wing?

—CBH

GEOGRAPHIC DISTRIBUTION

Experience with RSV infection is ecumenical, as is its predominant pathogenicity for the very young and for those with underlying high-risk conditions. The timing, length, and intensity of RSV outbreaks, however, vary geographically. Outbreaks in warm and tropical climates tend to be more prolonged, with less distinctive peaks of activity.

SEASONAL PATTERNS

The distinctive epidemiologic character stems from the singular consistency and size of the outbreaks of infection it produces each year and the health care burden it leaves in its wake.[48,104,105,148] In the United States, data from the National Respiratory and Enteric Virus Surveillance System between 1990 and 2000 indicated that RSV activity usually lasts for 20 or more weeks, from November to May, and may completely encompass the outbreak of influenza.[168,199,286] The peak of activity of RSV in the United States occurs in January or February (Table 194–1). Epidemiologic patterns tend to be similar in other countries with similar temperate climates, whereas in countries with warmer climates, RSV activity may correlate with the rainy seasons or may be present throughout the year.

Outbreaks of RSV infection are associated with increased numbers of young children hospitalized with acute lower respiratory tract disease. These consistent ramifications are barometers of the onset and severity of RSV activity in a community. The peak periods each year of both admissions for children with lower respiratory tract disease and of outpatient medical visits for bronchiolitis are associated primarily with RSV activity (Fig. 194–2).[106,122,148,151,220]

STRAIN VARIATION

Variation in circulating strains of RSV has been suggested as partly accounting for the fluctuating clinical impact of RSV epidemics.[20,315,324,357] The two major strain groups, A and B, usually circulate simultaneously during an outbreak, but the proportion of strains from each group may vary by season and geography, as does predominance of the subgroups of A and B strains.[20,112,263,319,324,357] In most areas, the annual dominant strains appear to be group A. In Rochester during a 20-year period, group A strains predominated in 11 of the years, group A and B strains were relatively equal in another 5 years, and in 4 seasons group B strains accounted for more than 75 percent of the year's isolates.[167] A study of strains from 14 cities across the United States demonstrated that the variability of strains occurs both seasonally and geographically.[20] Several distinct but varying genotypes within the A and B strain groups predominate each year in a community,

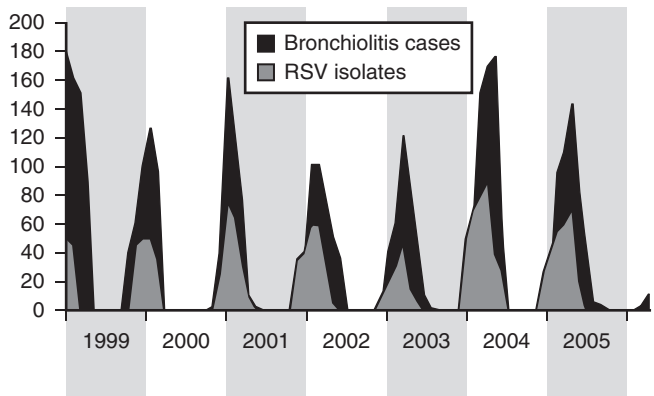

Figure 194–2 The number of cases of bronchiolitis and the number of isolates of respiratory syncytial virus from children less than 5 years of age who were evaluated in private offices and outpatient facilities from 1998 to 2005 identified by a community surveillance program in Monroe County, New York.

TABLE 194–1 Summary of Median Values of Respiratory Syncytial Virus Season Characteristics for Entire Nation and U.S. Census Regions from National Respiratory and Enteric Virus Surveillance System Data, 1990 to 2000

RSV, respiratory syncytial virus.
From Mullins, J. A., LaMonte, A. C., Bresee, J. S., and Anderson, L. J.: Substantial variability in community respiratory syncytial virus season timing. Pediatr. Infect. Dis. J. 22:857-862, 2003.

a finding suggesting that local preexisting immunity to previously circulating RSV strains may engender a selective advantage for strains with genotypes most diverse from those recently present in a community.[81,263,319,324,413] The relationship between the circulating strain group or subgroup and the size or clinical severity of an RSV outbreak, thus far, has not appeared to be strong or consistent.[36,81,315,362] Further understanding of these relationships and the molecular mechanisms, pathogenesis, and clinical importance of differing genotypes may be integral to the development of effective vaccines and the control of RSV.[413]

ACQUISITION AND RAMIFICATIONS OF INFECTION

The major burden that RSV inflicts on the health care of children is illustrated by its ubiquity and the proportion of lower respiratory tract disease it causes in early childhood, especially in young infants. RSV accounts for 30 to 90 percent of bronchiolitis cases, up to 50 percent of pneumonia admissions during infancy, and 10 to 30 percent of cases of pediatric bronchitis.[37,181,199,220,308] In contrast, only relatively small proportions, less than 10 percent, of croup cases have been associated with RSV infection. RSV is isolated rarely from patients (<1%) without respiratory disease.[58,220]

During the first year of life, approximately 50 to 70 percent of infants acquire RSV infection, despite the presence of maternal specific neutralizing antibody in the sera of all newborns.[126,181,318] The level of antibody in a term newborn is similar to the maternal level, which gradually declines during the first 6 months of life. In patients older than 7 months, detectable specific serum antibody usually is the result of natural infection. Essentially all children by 3 years of age possess specific serum antibody.

The impact of RSV infections on communities around the world has been examined in numerous studies and varies depending on the geographic location, the population, and the methods of assessment. Nonetheless, several generalizations are evident: (1) RSV is a highly contagious agent resulting in ubiquitous infection by the time one reaches 2 to 3 years of age; (2) in this age group, RSV is the major cause of lower respiratory disease, predominantly bronchiolitis and pneumonia; (3) RSV infection of the lower respiratory tract in normal children almost always is the result of primary infection; (4) reinfection occurs throughout life, and subsequent infections are milder and usually are upper respiratory tract infections; (5) the severity of illness from reinfections remains appreciable at any age in persons with co-morbid conditions; and (6) medical visits by outpatients with RSV infection comprise an appreciable portion of the burden to health care.

Infants with underlying chronic conditions are at high risk of requiring hospitalization for RSV illness, but numerous environmental and other host factors have been reported to augment the risk of a previously healthy infant's developing more severe RSV infection.[123,126,342,356] These factors include becoming infected within the first few months of life, living in crowded and lower socioeconomic circumstances, geographic location, and gender. Although the rate of infection among girls and boys is equal, boys are hospitalized 1.5 to 2 times more frequently than are girls, a finding suggesting that boys are more likely to develop severe infection.

As many as 120,000 children are hospitalized each year with RSV infection and close to 150,000 children are hospitalized with bronchiolitis.[126,191,323,364,365] The annual rate of hospitalizations caused by RSV in comparison with that from influenza or the parainfluenza viruses has been approximately three times greater for children aged 5 years and younger and six to eight times greater for children younger than 1 year of age.[168,199,300]

In the United Kingdom for more than 11 winter respiratory seasons, RSV was associated with more deaths than was influenza in young children, especially in the first year of life.[105] In the United States, the number of deaths associated with RSV infection each year among children younger than 5 years of age was estimated in 1985 to be 4500.[197] During 1979 to1997, this number was reported to have declined to an estimated 510 or less each year in children younger than 5 years of age.[237,364,365] The rates of hospitalization associated with RSV, however, have not declined but appear to be increasing from the estimate of 110,000 in 1997 in children younger than 5 years of age.[191,364] The rate of admissions attributable to RSV is markedly higher among infants within the first year of life than among children aged 1 to 4 years. In infants, the estimated rates have varied from 5 to 41 per 1000 each year, depending on the area and the methods used.[34,236,257]

Population-based studies reported annual hospitalization rates attributable to RSV in the United States of 3 to 3.5 per 1000 children younger than 5 years of age.[168,199] These rates were approximately six times greater than that associated with the influenza viruses and three times greater than that associated with the parainfluenza viruses. The rates of hospitalization for RSV among infants were even greater, 12.9 per 1000 children younger than 1 year of age, compared with 1.7 for influenza and 3.2 for the parainfluenza viruses. The youngest infants, those younger than 6 months old, had the greatest risk of requiring admission for their RSV infection, with a yearly rate of 17 per 1000 children.[168]

In other countries, population-based studies demonstrated similarly high rates of hospitalizations related to RSV among infants and young children.[94,104,106,300,403] Annual population-based hospitalization rates attributable to RSV from European countries were reported per 1000 children to be 2.5 for those younger than 4 years of age, 11 for children younger than 3 years of age, and 4 to 7 for those younger than 2 years of age. Among children within the first 12 months of life, 19 to 22 per 1000 children were admitted each year with RSV infection.

The magnitude of ambulatory visits among children resulting from RSV infection has not been well quantified and generally has received less attention. Surveillance conducted in Nashville, Tennessee, and Rochester, New York, for acute respiratory illness occurring among children aged 0 to 59 months showed that RSV was the agent most frequently identified among children evaluated for respiratory illness in outpatient practices and emergency departments.[168] Approximately one fifth of these children had laboratory-confirmed RSV infection, and an estimate of the health care burden from these RSV outpatient visits was appreciably greater than that from RSV-associated hospitalizations. The potentially greater impact of RSV outpatients visits on health care resources is further supported by a German study in which the annual incidence rate for RSV illness in outpatients was notably high at 77 per 1000 children younger than 3 years of age.[106]

Current estimates of the economic and clinical costs related to RSV infections in young outpatient children are likely to be too low because they reflect only a portion of the impact RSV imposes each year. Not included are the medical visits among older children and among healthy and elderly adults in whom illness from RSV infection occurs frequently and can be severe.[100,146,149,395]

SPREAD OF INFECTION

> Each breath's toll is virus spread and shed.[144]
>
> *—CBH*

RSV spreads effectively through exposed families, and introduction of the virus into the family appears to occur most commonly through a school-aged child.[128,129,160,282] Serious disease in infancy

TABLE 194–2 Attack Rate of Respiratory Syncytial Virus in Families According to Age

	Attack Rate*					
	Crude Rate		*In RSV-Positive Families*		*Secondary Rate*	
Age (yr)	No.†	%	No.†	%	No.†	%
<1	10/34	29.4	10/16	62.5	5/11	45.4
1-<2	2/7	28.6	2/5	40.0	0/3	0.0
2-<5	9/34	26.4	9/19	47.0	2/12	16.6
5-<17	9/48	18.7	9/24	38.0	4/19	21.0
17-45	9/55	16.8	9/21	43.0	6/18	33.3
Total	39/178	21.9	39/85	45.9	17/63	27.0

**The crude attack rate according to age is shown for all family members studied and for members of RSV-positive families. The secondary attack rate is also shown for members of RSV-positive families, excluding all primary and co-primary cases.*

†Number of persons infected with RSV/total number of persons exposed.

is likely to follow a mild "cold" in an older sibling.[160] In a prospective study of families with an infant and one or more older siblings, 44 percent of the families became infected with RSV during a 3-month epidemic. In almost all these families, older siblings (2-16 years of age) introduced the virus into the family, and the infants became secondarily infected (Table 194–2). Intrafamilial spread of the virus, according to the Tecumseh study, also was related to the number of family members.[282] Families with six members had approximately three times the rate of infection observed in families with three members.

How this labile virus can spread so effectively has remained mostly a conundrum. Transmission primarily by small-particle aerosol seems unlikely according to clinical and experimental observations.[152] Small-particle aerosols of RSV are unstable at the low relative humidity of 20 to 30 percent usually encountered indoors during the winter months.[340] At 30 and 80 percent relative humidity, RSV in aerosol was maximally inactivated. Maximal stability occurred at 60 percent relative humidity.

Spread may occur, however, through large droplets of secretions or through contact with contaminated secretions.[129,152] Infants with RSV infection have high viral loads of RSV in their secretions of both the upper and lower respiratory tract.[82,155,156,325,420] The duration of shedding also tends to be prolonged in young children. RSV in the nasal secretions of infants with acute infection remains infectious on countertops for longer than 6 hours and on cloth and tissue paper for approximately 30 minutes.[161] These nasal secretions can remain infectious after transfer from objects or hands to the hands of another person, thus indicating that contact with clothing, furniture, or tissues contaminated by the secretions of infected children can result in spread.[129,161]

This mode of spread has been supported by studies demonstrating that infection occurs in volunteers who touch surfaces contaminated by secretions and then their eyes or nasal mucosa.[152] In contrast, no infections developed in volunteers exposed to infected infants at a distance of greater than 6 feet, thus suggesting that small-particle aerosol spread of RSV was not a major mode of transmission. RSV infection, therefore, appears to require close contact with infected individuals or their secretions.

PATHOLOGY AND PATHOGENESIS

The newly born
from mother shorn,

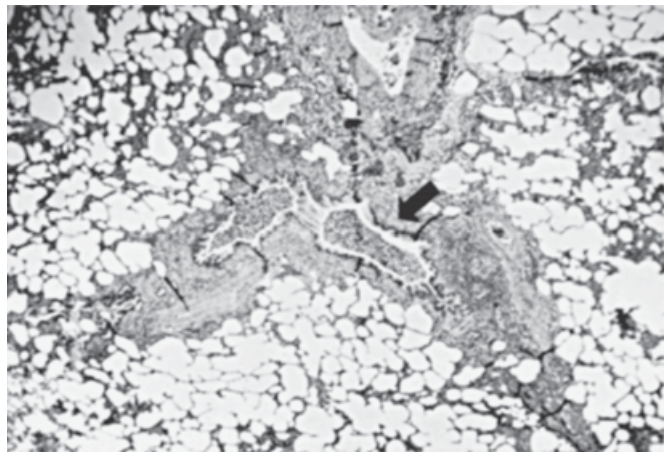

Figure 194–3 Histologic examination of an infant dying of respiratory syncytial virus bronchiolitis. The arrow denotes a bronchiole filled with inflammatory exudate and comparatively normal alveoli.

A seed just sown,
its growth unknown.

—CBH

The incubation period of illness from RSV has been reported variably as being between 2 and 8 days, most frequently as 4 to 6 days. Experimental infection in adult volunteers produced an incubation period of 3 to 6 days, with an average of 5 days.[157,202] With primary infection, the incubation period may be shorter.[157,166] Inoculation is through the upper respiratory tract, followed by infection of the respiratory epithelium. Both the eye and the nose appear to be equally sensitive routes of inoculation.[157] In contrast, inoculation by mouth results in infection much less frequently. Spread along the respiratory tract occurs mainly by cell-to-cell transfer of the virus along intracytoplasmic bridges and may involve the conducting airways at all levels.

The major pathologic findings shown in infants dying of RSV bronchiolitis are (1) peribronchiolar mononuclear infiltration, (2) necrosis of the epithelium of the small airways, (3) plugging of the lumina, and (4) hyperinflation and atelectasis (Fig. 194–3).[4,9,147,390] The initial lesions in bronchiolitis occur in the small airways (75 to 300 μm).[9] Lymphocytic peribronchiolar infiltration develops along with edema of the walls, the submucosa, and adventitial tissue. Subsequently, the epithelium of the bronchioles undergoes striking necrosis, sometimes with proliferation of the epithelium into the lumen. Sloughing of necrotic material into the lumina of the small airways impedes the flow of air, which is aggravated by increased mucus secretion.

Peripheral to the sites of partial occlusion, air trapping occurs, similar to a ball-and-valve mechanism. During the negative intrapleural pressure of inspiration, air can flow past the site of partial obstruction, but with the positive pressure of expiration the lumen narrows, resulting in more complete obstruction and the hyperinflation characteristic of bronchiolitis. The trapped air may be absorbed and result in multiple areas of focal atelectasis. Functionally, these pathologic changes translate into an increased lung volume and higher expiratory resistance in the infant. Pneumonia may be present concurrently and is marked by interstitial infiltration of mononuclear cells. Lymphocytic infiltration of the bronchiolar walls also may be observed. The lung parenchyma appears edematous, with areas of necrosis leading to alveolar filling, consolidation, and collapse.

Recovery from acute bronchiolitis may be evident in 3 to 4 days, with regeneration of the bronchiolar epithelium, but cili-

ated cells rarely are present before 2 weeks.[9] Complete histologic and functional recovery may require another 4 to 8 weeks.[169]

IMMUNE RESPONSE: IMMUNITY AND DISEASE PATHOGENESIS

The immune response to RSV is complex, governed by factors such as age at the time of infection, genetic variation of the host, and virus-specific attributes.[276,306,322] Each affects various aspects of innate and adaptive T- and B-cell immune responses that determine the outcome of infection and the level of protection from subsequent infection. Much of our knowledge regarding immune responses to RSV is derived from in vitro studies or in vivo animal experiments, supplemented by inconsistent human data. Nonetheless, a relatively consistent theme has emerged, suggesting that virus-induced chemokine and cytokine patterns and the balance between T-helper (T_H1) and T_H2 T-cell responses determine such disease characteristics as the clinical manifestations, the severity, and possibly the ultimate development of asthma (Fig. 194–4).[276] The role of the immune response in the pathogenesis of RSV disease is supported further by the observation that RSV is only moderately cytopathic in vivo. Immune mechanisms most likely also accounted for the enhanced disease that occurred after immunization with the formalin-inactivated RSV vaccine in the 1960s.[221]

MATERNALLY ACQUIRED ANTIBODY

Transplacentally acquired immunoglobulin G (IgG) provides the first line of defense to the newborn infant encountering RSV for the first time.[126,188,303] Glezen and coworkers found that the age at the time of hospitalization for infants with primary RSV infection was directly correlated with the level of cord blood neutralizing antibody titer.[126] With a half-life of approximately 21 days, the protective effect rapidly wanes, thus accounting for a relatively brief period of protection.[303] These data, coupled with studies in experimental animals, provided impetus for the development and use of high-titered RSV intravenous immunoglobulin (RSV-IGIV) and subsequently of the monoclonal antibody, palivizumab, for RSV prophylaxis in high-risk infants.[139,196,332]

INNATE IMMUNITY

Infection of respiratory epithelial cells and antigen-processing cells (macrophages and dendritic cells) triggers early innate immune responses characterized by synthesis of chemokines and proinflammatory cytokines and the recruitment of inflammatory cells, neutrophils, eosinophils, and interferon-γ (IFN-γ)–secreting natural killer (NK) cells, to the infected pulmonary tissues.[203,358,381] More recent work has emphasized the importance of Toll-like receptors [TLRs] during RSV infection in mediating and defining the inflammatory cytokine and chemokine production. TLRs may effect the polarization of the cytokine responses toward a T_H1 or T_H2 profile and potentially lead to the sensitization and subsequent hyperreactivity of the airway epithelium.

The interaction of RSV with TLRs (TLR4, TLR3, TLR7, TLR9) on mononuclear cells and alveolar macrophages results in production of antiviral and immunomodulatory mediators, including type I and III interferons, IFN-α, IFN-β, and IFN-γ, chemokines CXCL8 (interleukin-8 [IL-8]) and CCL5 (RANTES), and cytokines IL-6 and tumor necrosis factor-α (TNF-α).[140,142,174,231,262,314,351,354,360] TLR-mediated immune responses have been shown to be TLR-specific. Thus, the function and effectiveness of the components of the elicited immune response will vary according to the interaction of RSV with specific TLRs. For example, TLR4-deficient mice have impaired viral clearance, whereas TLR3 deficient mice develop T_H2-polarized responses but continue to eliminate virus with normal kinetics.[174,352]

RSV infection of respiratory epithelial cells in vitro stimulates synthesis of CC chemokines (CCL5, CCL3 [macrophage inflammatory protein 1α; MIP-1α], CCL4 [MIP-1β] and CCL2 [monocyte chemoattractant protein; MCP]), CXC chemokines (CXCL1, CXCL2, and CXCL3 [GRO-α, -β, -γ]), as well as the CX3C chemokine fractalkine.[280,423] CXCL8, CCL3, CCL5, and CCL11 (eotaxin) are chemoattractants for polymorphonuclear cells and eosinophils, whereas fractalkine induces pulmonary migration of T cells bearing the CX3CR1 receptor.[77,173,200,201,264] These cells further contribute to the local inflammatory response by secreting additional cytokines. Many of these immunomodulators are detectable in secretions of RSV-infected infants, and increased levels of CCL3, CCL5, and CXCL8 have been correlated with more severe disease, with the presentation of bronchiolitis, or with wheezing.[114,190,241,272,301,366,408]

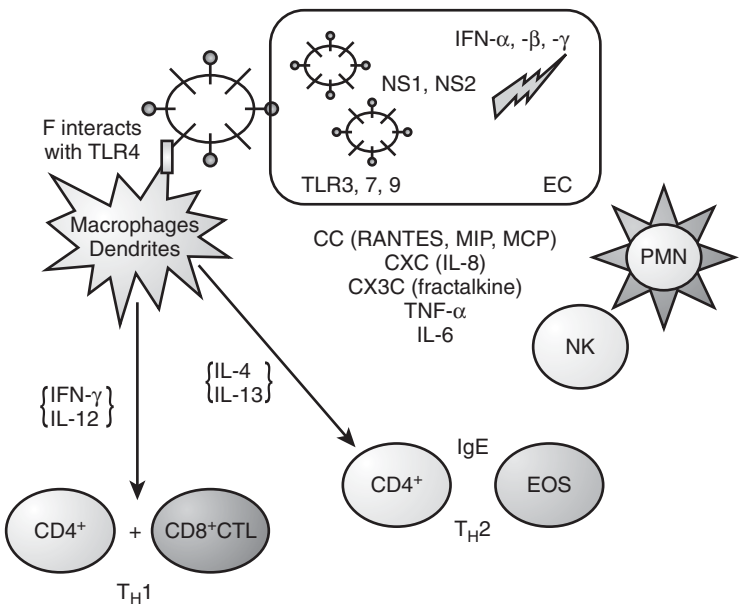

Figure 194–4 Schematic of the early innate and adaptive immune responses to respiratory syncytial virus (RSV). RSV's envelope glycoprotein G attaches to the respiratory tract epithelial cells (ECs) via glucosamine glycans expressed on the cell surface, and F interacts with antigen presenting cells (macrophages, dendritic cells) via Toll-like receptor 4 (TLR4) protein. This triggers the production and release of antiviral interferons (IFN-α, IFN-β, IFN-γ) and cascade of proinflammatory cytokines and chemokines. Two early nonstructural RSV gene products (NS1, NS2) antagonize IFN production. The chemokines recruit polymorphonuclear neutrophils (PMN), natural killer (NK) cells, $CD4^+$ and $CD8^+$ T cells. A T_H1-type cellular response becomes dominant under the influence of IFNγ and IL-12, whereas under the influence of IL-4 and IL-13 the cellular response is skewed toward T_H2 with the production of IgE and eosinophils (EOS).

Like other viruses, RSV has evolved mechanisms to avoid the antiviral effects of innate IFNs. Transcription of IFN-α mRNA is suppressed in macrophages exposed to RSV in vitro, and IFN-α is absent in nasal secretions of infected infants.[158,159,247,267,373] Studies indicate that NS1 and NS2, two early RSV gene products, effectively block induction and function of IFN-α and IFN-β in vitro, an effect that also may favor T_H2 polarization of the T-cell response.[204]

B-CELL RESPONSES

The humoral and mucosal immune responses to RSV infection in infants have been well characterized.[289,290,392,401,410] After acquiring infection, infants develop antibodies to many of the 11 RSV-specified proteins, the most important of which are antibodies to F and G proteins as they have viral-neutralizing activity. Serum-neutralizing and F and G protein-specific antibodies are observed in the majority of infected infants, regardless of the severity of their illness.[289,410] However, neutralizing and F antibody responses are blunted in those younger than 6 months of age, and diminished responses to the G protein are associated with high levels of preexisting maternal antibody.[289,383] No evidence exists that preexisting antibody suppresses RSV-specific, cell-mediated responses.[75] The antibody response to the F protein is broadly cross-reactive with both A and B strains because neutralizing epitopes are conserved between the two groups. This situation is in marked distinction to the group- and genotype-specific response to the highly variable G protein.[43,184,285] Overall, the serum IgG response to RSV is relatively weak. Titers often dissipate within a year after infection, thus requiring several additional infections before levels approximate those found in adults.[392] Nonetheless, levels of serum antibody are directly correlated to the degree of protection against natural reinfection in infants and adults, a finding confirmed in experimental challenge studies in adults.[166,239,270,394] Nonetheless, solid protection from reinfection is of brief duration, as a substantial proportion of adults can be reinfected within several months of a naturally occurring infection.[166]

During primary RSV infection, RSV-specific IgA antibody is detectable in nasal secretions and coincides with the cessation of viral shedding.[166,270,386] Using an adult challenge model, some investigators correlated high levels of RSV-specific IgA to protection.[166] In animal models, the durability of mucosal IgA antibody protection was relatively brief when compared with the lower tract protection afforded by serum IgG antibody.[331,372,412] Some investigators noted, in addition to IgA antibody, the appearance of RSV-specific IgE in nasal secretions during RSV infection, a finding correlated to an increased risk of the development of wheezing both during acute disease and later in childhood.[407,409,411] Elevated levels of cysteinyl leukotrienes in nasal secretions also have been associated with wheezing.[388]

T-CELL RESPONSES

The basis for much of our knowledge about cell-mediated immunity to RSV is derived principally from studies in the Balb/c mouse model and limited human data. A unifying theme has emerged in which generation of T_H1-dominant responses characterized by induction of IFN-γ–secreting $CD4^+$ and $CD8^+$ cytotoxic T lymphocytes (CTLs), neutralizing serum antibody and mucosal IgA antibody results in viral clearance with limited disease severity.[276,306,322] Conversely, a T_H2-polarized response, described by IL-4–secreting $CD4^+$ cells, eosinophils, and IgE production, is associated with airway hyperreactivity and more severe disease.

RSV long has been recognized to have an inhibitory influence on lymphocyte proliferative responses in vitro.[328,348,355] In addition, RSV-infected dendritic cells have diminished capacity to activate $CD4^+$ T cells.[60,78,141] Despite these effects, RSV infection induces a full range of T-cell responses, including T_H1 $CD4^+$ and $CD8^+$ CTLs as well as T_H2 $CD4^+$ cells.[61,194,198,266] T_H1 $CD4^+$ cells are characterized by secretion of IL-2, IFN-γ, and TNF-α, whereas T_H2 $CD4^+$ cells produce IL-4, IL-5, and IL-13.[306] Human and murine $CD8^+$ CTLs recognize F, M2, M, and NS2 epitopes in the context of class I antigens.[35,55,59,176,206,229,297,353] Each cell type and its associated cytokines have been correlated to the degree of severity of illness, the presence of wheezing, and the nature of the inflammatory response.[11,12,44,132,133,253] Both $CD4^+$ and $CD8^+$ T cells can clear virus from the lungs of infected animals, with CTLs most efficient.[12,44] IFN-γ $CD4^+$ cells (T_H1 pattern) eradicate the virus while inducing minimal disease, whereas IL-4–secreting $CD4^+$ cells (T_H2 pattern) are associated with pulmonary eosinophil infiltration and airway hyperreactivity.[11,132] Although RSV-specific $CD8^+$ CTLs clear virus rapidly, excessive numbers of CTLs can be detrimental.[12]

The balance between T_H1 and T_H2 induction depends on multiple factors, including host genetics, the local cytokine environment, and the antigen.[13,41,63,118,180,192,379,419] Replicating antigens, such as live RSV, generally induce a T_H1 response with CTLs, whereas inactivated virus (i.e., the formalin-inactivated vaccine used in the 1960s) or subunit vaccines induce T_H2-dominant responses.[133,205,374,399] The F antigen is associated with a T_H1 response, whereas the G protein tends to evoke a T_H2-type response. The mechanism by which the RSV G protein induces a T_H2 polarized T-cell response is not clear, but a highly conserved central cysteine-rich region with structural analogy to the CX3C chemokine fractalkine may be involved. The CX3C motif on the G protein competes with fractalkine binding on T cells and appears to inhibit pulmonary trafficking by CX3CR-positive CTLs.[173] Additional evidence from studies in both mice and humans suggests that RSV is a poor inducer of central memory T-cell responses that are protective, a finding that may account in part for the failure of long-term immunity.[54,346]

Peripheral blood mononuclear cells from infants with primary RSV infection secrete both IFN-γ (T_H1) and IL-4 (T_H2).[21,384] The presence of a T_H2-dominant cytokine pattern in respiratory secretions during RSV infection, or a T_H2 response induced by in vitro stimulation of lymphocytes, has been linked to disease that is more severe or associated with wheezing.[2,30,241,359] Not all studies, however, measured RSV-specific responses, and not all investigators noted this relationship between T_H2 polarization and more severe illness.[21] The patient's age at the time of infection also may influence the T-cell response. Infants younger than 3 months of age were found to have higher levels of T_H2 cytokines in nasal secretions compared with older infants, who were more likely to have a T_H1 cytokine pattern.[228] Information regarding cellular immune responses and protection from subsequent infection is sparse. In one report, RSV-specific lymphoproliferative responses were relatively short-lived after primary infection and did not boost after reinfection.[31]

In summary, the complexity of the immune response to RSV is yet to be unraveled fully. Certain basic tenets, however, appear to be supported by available animal and human data. Both humoral and mucosal antibodies provide a modest degree of protection from infection, and virus provoked innate and adaptive T-cell responses play a defining role in disease pathogenesis and in viral clearance. An environment conducive to induction of T_H1 responses, either during primary infection or with infection following prior immunization, may minimize pathologic changes, airway hyperreactivity, and disease severity.

CLINICAL MANIFESTATIONS

We view their chests ballooning, with the fears
that they're "pink puffers" of more tender years.[144]

PRIMARY INFECTION

An infant's first encounter with RSV almost always is apparent, but the symptoms may range from those of a mild cold to severe bronchiolitis or pneumonia. Rarely is a child's first encounter with RSV entirely asymptomatic. Among infants examined over the course of a 10-year period with known primary RSV infection, who initially were younger than 6 months of age, 45 percent had the clinical manifestations of bronchiolitis or pneumonia, compared with 5 percent of children aged 2 to 5 years who had experienced two or more outbreaks of RSV infection (Fig. 194–5). Higher rates of lower respiratory tract disease have been documented to occur in children with underlying cardiopulmonary disease, those in closed populations such as daycare centers, and those from certain geographic areas or with particular ethnic backgrounds.[182,252,273,342,405]

In the longitudinal Houston family studies, 69 percent of children in their first year of life acquired RSV infection, and one third of these infections were lower respiratory tract illnesses[127] (Table 194–3). By the time they were 24 months of age, essentially all children had been infected at least once, and about half had experienced two infections, such that the rate of infections during the second year of life was 83 percent. The proportion of RSV infections involving the lower respiratory tract remained appreciable during the second, third, and fourth years of life, but the severity decreased. In general, lower respiratory tract illnesses associated with RSV after the second year of life most frequently are tracheobronchitis and reactive airway disease (see Fig. 194–4).[127]

Pneumonia and bronchiolitis, the most common forms of RSV lower respiratory tract disease in infants, frequently coexist and may be difficult to differentiate clinically or radiographically. Children with hyperinflation and wheezing, the hallmarks of bronchiolitis, may have densities on a chest film that may appear similar to infiltrates from pneumonia (Fig. 194–6). However, in bronchiolitis, these shadows most likely result from atelectasis rather than from the interstitial inflammation and alveolar filling of pneumonia.

Upper respiratory tract symptoms usually precede lower respiratory tract involvement by several days. Low-grade fever is

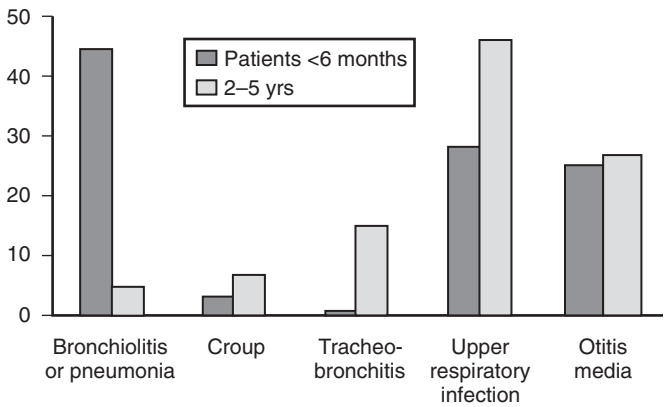

Figure 194–5 The clinical diagnoses of children with respiratory syncytial virus (RSV) infection according to age. The proportion of children presenting with each respiratory syndrome who were younger than 6 months of age and had primary RSV infection is shown in comparison with those children aged 2 to 5 years who had a repeated RSV infection. Data were obtained from 415 outpatient infants and children evaluated in Rochester, New York. *(From Hall, C. B., unpublished data.)*

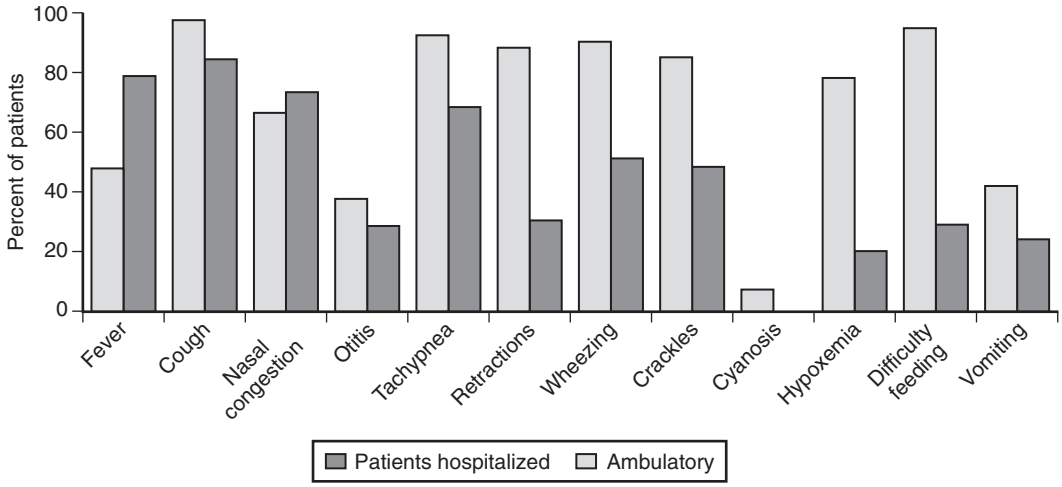

Figure 194–7 Clinical manifestations in children with respiratory syncytial viral infection who were evaluated in Rochester, New York. Shown are the proportions of 1132 hospitalized children in comparison with the proportions of 489 outpatient children with each clinical sign.

a common manifestation during this initial phase of the illness, but it may have disappeared by the time of hospitalization (Fig. 194–7). Among 565 children hospitalized with RSV infection, fewer than half had a temperature higher than 38° C at the time of admission.[165] Although fever occurs more commonly in primary infections, 20 to 40 percent of children with their second, third, or fourth infections are febrile.[182]

Increased coughing commonly heralds involvement of the lower respiratory tract, which subsequently may be indicated by an increased respiratory rate, dyspnea, and retractions of the chest wall (see Fig. 194–7). Variability of the child's clinical findings within minutes to hours is characteristic of RSV lower respiratory tract disease. Auscultatory findings of crackles may be present on initial examination but absent on reexamination shortly thereafter. Ill children who elicit concern because they are lethargic and short of breath may have minimal auscultatory signs. The correlation between the findings on auscultation, or on the chest radiograph, with severity of disease or outcome is not consistent.

RADIOGRAPHIC FINDINGS

The radiographic findings in infants hospitalized with RSV lower respiratory tract disease may be variable, but in bronchiolitis, hyperinflation with hyperluceny of the lung, flattened diaphragms, and peribronchiolar thickening usually are evident.[108,309,344,416] Patchy areas of atelectasis also may be present, most often in the right middle and upper lobes. A little less frequent are interstitial infiltrates of pneumonitis, which tend to be present in more than one lobe (see Fig. 194–6). The radiographic findings usually persist beyond the clinical illness.

With tracheobronchitis and upper respiratory tract infections, the accompanying signs and symptoms tend to be more severe in RSV infection than in infections with other common respiratory agents. Cough often is predominant and prolonged, and fever may be present. Otitis media frequently is associated with the initial RSV infection in young children, but it also occurs in older children with recurrent infection.[19,177,326] Among children with RSV infection, the virus has been detected in 30 to 74 percent of middle ear aspirates. Among children presenting with otitis media, RSV is the viral pathogen most frequently identified and has been associated with prolonged symptoms and apparent failure of therapy.[23] RSV may be detected as the sole pathogen or simultaneously with a bacterial agent, thus suggesting that RSV may play both a primary and a secondary role in the pathogenesis of otitis media.

RSV infection has been associated occasionally with a variety of neurologic, cardiac, and other conditions.[25,68,121,215,296] However, in most of these reports, the causal role of RSV is tenuous.

INFECTION IN NEONATES

Infection with RSV in the first 2 to 4 weeks of life appears to occur relatively infrequently.[318] In Washington, D.C., the incidence of RSV infection during the first month of life was noted to be only one third of that during the second month of life. The protected environment of newborns with diminished exposure to others, as well as the high levels of maternal antibody or other early immune factors, may explain in part the generally lower incidence of illness in the newborn period. RSV infection in neonates may be variable and atypical; nonspecific findings and minimal respiratory signs may result in an unsuspected or delayed diagnosis.[163,275,349]

In full-term neonates, RSV infection may be primarily an upper respiratory tract illness and usually mild.[83,113] However, in premature infants, the morbidity may be pronounced.[143,163] During a community outbreak of RSV in Rochester, New York, 25 percent of infants kept in a neonatal intensive care unit for more than 6 days acquired RSV infection.[163] Infants older than 3 weeks tended to have lower respiratory tract disease characteristic of RSV and apnea, whereas infants in the first 3 weeks of life were more likely to have nonspecific findings, without clinical evidence of lower respiratory tract disease. Fewer than half had upper respiratory tract signs; nonetheless, four (17%) of the infants died.

ACUTE COMPLICATIONS

Apnea, a major complication of acute RSV infection in young infants, occurs in approximately 10 to 20 percent of infants hospitalized with RSV infection.[17,40,65,162,225] Apnea is most likely to occur in infants born prematurely, in those with a young postnatal age, especially infants who have not yet reached a postconceptional age of 44 weeks, and in infants with a history of apnea of prematurity.[65] The apnea usually develops at the beginning of the RSV infection, often as the first manifestation of illness, and is short-lived and nonobstructive.[17,65] Most infants do not have apnea subsequently, even with later respiratory infections.

Simultaneous or secondary bacterial infection appears to be a relatively frequent complication of RSV infection in some countries in the developing world.[249,268] In the United States and other developed countries, it is an unusual complication, and most clinical and pathologic studies indicate that RSV infection rarely predisposes one to acquisition of a bacterial infection.[137,165,230,277,336,337,382]

In a 9-year prospective study of 565 children hospitalized with RSV lower respiratory tract disease, the rate of subsequent bacterial infection was 1.2 percent in the total group of children infected with RSV and 0.6 percent in the 352 children who

received no antibiotics.[165] If a bacterial infection is present simultaneously, it most frequently involves the urinary tract and is detected by a positive urine culture.[244,277,336] Whether RSV infection has any direct relationship with concurrent urinary tract infection is unclear. Other epidemiologic factors may explain the coexistence of these infections; for example, both RSV and urinary tract infection frequently are recognized in this age group, and both are more common in boys. Serious concurrent bacterial infections are unusual enough that evaluations for sepsis and meningitis are not recommended routinely.[16,337] Controlled studies with randomized antibiotic treatment of lower respiratory tract disease caused mostly by RSV have shown no difference in the severity or duration of illness or in the child's outcome.[103,107]

More frequently, co-infection with other respiratory viruses occurs.[106,110,123,242,279,300,313] Studies examining whether coexistent viral infections in normal children augment the severity of infection showed mixed results. In part, this finding may result from the studies' differing methods of assessment and the difficulty of determining the onset of infection, especially with viruses that have prolonged shedding. In addition, other viruses that infect predominantly this same young age circulate during the same months as does RSV.

Infants hospitalized with RSV infection also have been noted to be at increased risk for aspiration and subsequently for developing hyperreactive airways.[87,217-219] One study reported that during a follow-up period of 1 year, 83 percent of the infants hospitalized with RSV bronchiolitis who received no therapy for aspiration or ribavirin developed reactive airway disease, compared with 45 percent of those patients given thickened feedings and early ribavirin therapy.[87,218] Furthermore, the reduction in the episodes of reactive airway disease was greater with the combined therapy than with either ribavirin or thickened feedings alone.

PROGNOSIS

> Thus, if infected at this tender stage
> will they become "blue bloaters" as they age?[144]

PREDICTION AT TIME OF INITIAL EVALUATION

Determining whether an infant with RSV infection who initially presents as an outpatient is likely to require subsequent hospitalization has been problematic. Numerous clinical findings have been evaluated, but most have relatively poor predictive value for individual patients.[16] Among the more consistent and helpful findings at the time of evaluation are oxygen saturation and global assessment of the degree of illness. Fever does not correlate with the severity of disease.[39,271,363] Some studies have associated an increased respiratory rate with the risk of developing more severe illness, whereas others have not.[16,347] However, the lack of tachypnea (≥70/minute) has been correlated with less chance of development of lower respiratory tract infection in infants.[256,259] Although repetitive assessments may help, the rapid fluctuations in clinical manifestations, characteristic of RSV lower respiratory disease, render arriving at an accurate evaluation difficult.

Clinical scoring systems commonly are used, but their use is limited by variable design, rendering comparison and standardization impossible.[16] The Respiratory Distress Assessment Instrument has been standardized, but it is not validated in predicting the severity or outcome of children with bronchiolitis.[6,251]

Infants hospitalized with RSV bronchiolitis or pneumonia usually show clinical improvement after 3 to 4 days, and most previously normal infants are discharged within 3 to 7 days, with an average of 3 to 4 days.[323,337,338] However, children with underlying conditions that put them at risk for development of more complicated illness tend to require 2 to 7 days more of hospitalization.[338]

PATIENTS AT RISK FOR COMPLICATED RSV INFECTION

Infants most likely to develop severe or fatal RSV infections are those who were premature or have an underlying condition that compromises pulmonary function.[34,45,66,94,104,164,168,188,304,342,397] The risk of requiring rehospitalization for infants correlates inversely with birth weight and gestational age. The risk of needing hospitalization with RSV has been reported as 3.7 times greater for infants of less than 36 weeks' gestation than for those of 36 weeks' gestation or longer.[15,255,273,376] In an Australian study, the highest risk of developing an RSV infection severe enough to require hospitalization occurred among infants born weighing less than 2500 g and who had older siblings.[342]

The highest risk of development of severe and fatal RSV infection occurs in premature infants of very low birth weight, 1500 g or less, and of gestational ages of 28 weeks or less.[189] Their high rate of severe RSV infection related to their compromised cardiopulmonary status is augmented further by the lack of maternal neutralizing antibody to RSV in infants of very low birth weight.[80]

Infants with hemodynamically compromising congenital heart disease, such as conditions associated with pulmonary hypertension, have been shown to have a markedly elevated risk of dying.[254] The mortality rate of children with functionally important cardiac conditions has declined from greater than 30 to approximately 3 percent.[10,254,281,294] The improved outcome of infants with cardiac disease likely is attributable to advances in techniques for surgical correction and medical management, as well as recognition of the risk associated with RSV infection in these patients.

Innate host factors that predispose a child to development of more severe RSV infection have long been assumed but remain mostly undefined. More recent studies, however, show a correlation of genetic polymorphisms with primary RSV disease and severity. Variations within a number of genetic loci potentially associated with controlling immune function, such as the expression of IL-4 and other T-lymphocyte cytokines and chemokines associated with the production of IgE antibody and hyperactive airways, have been shown to be overrepresented in children with RSV lower respiratory tract disease and with disease that is more severe (see "Immune Response: Immunity and Disease Pathogenesis").[64,118,187,192,193,233,248,306,379]

IMMUNOCOMPROMISED PATIENTS

Recognition of the risk of complicated RSV infection in immunocompromised patients has been heightened with the concurrently increasing numbers of highly immunosuppressed patients, such as recipients of bone marrow and solid organ transplants. A close correlation generally exists between the degree of immunosuppression and the clinical severity of the RSV infection.[51,73,164,246,261,299,414] This correlation is illustrated well by the severe and potentially fatal outcome of RSV infection among children with congenital immunodeficiency syndromes who have both defective B-cell and T-cell immunity. Limited information exists about the severity of disease in children with isolated humoral or partial humoral and cellular deficiencies.

RSV infection has been reported as occurring in approximately 50 percent of bone marrow transplant recipients and often is acquired nosocomially.[1,278,339] The morbidity and clinical manifestations associated with RSV in these patients are highly variable.[1,29,79,339] Risk factors for development of more severe disease in transplant recipients include not only the degree of immunosuppression, but also allogenic transplantation, acquisition of the

RSV infection within 2 months of undergoing transplantation but before engraftment, and the presence of graft versus host disease. The associated mortality rate among transplant recipients with lower respiratory tract disease has been reported as 70 to 100 percent, but more recently it has declined to closer to 50 to 60 percent. Upper respiratory tract symptoms, sometimes with fever, may be the sole signs of the infection, or they may herald the progression to lower respiratory tract involvement.[29] Findings on the chest radiograph include focal interstitial infiltrates, sometimes associated with lobar consolidation or with hyperinflation, or more severe involvement of generalized alveolar and interstitial infiltration, and marked hypoxemia. The major findings with high-resolution computed tomography (CT) are small centrilobular nodules, airspace consolidation, ground-glass opacities, and bronchial wall thickening. These abnormalities frequently are present in both the periphery and central areas of the lung, are bilateral, and they are asymmetric in distribution.[117]

In this setting, RSV infection often is not recognized or considered because it may occur at times when RSV is not circulating in the community, and the clinical picture may mimic that of other opportunistic agents that commonly infect immunocompromised patients. Furthermore, establishing the diagnosis is problematic because the most frequently available assays, rapid antigen assays applied to swabs of upper respiratory tract secretions, often are inadequate and are relatively insensitive in these patients. A higher yield is obtained with bronchopulmonary lavage specimens.[92,414]

PATIENTS WITH HUMAN IMMUNODEFICIENCY VIRUS INFECTION

The effects of co-infection of human immunodeficiency virus (HIV) infection with RSV infection are unclear. Some, but not all, studies suggest that increased morbidity occurs with RSV infection among HIV-infected patients. In a cohort of South African children followed for 5 years, the incidence of hospitalization from RSV lower respiratory tract disease in children with HIV infection was more than two times greater than that in those not infected with HIV (45 versus 19.4 per 1000 children).[255]

A retrospective Spanish study examined viral respiratory infections in children with HIV infection compared with children with cancer found that RSV was the most common (43%) of the viral agents identified and that 38 percent of the viral infections were acquired nosocomially.[278] The RSV infection involved the lower respiratory tract disease in half of the children with cancer and also in half of those with HIV infection, and hospitalization was required for 12 and 20 percent, respectively. However, the RSV infection was fatal for 21 percent of the hospitalized children with cancer, whereas all the HIV-infected patients survived.

Other studies suggested that adverse outcomes in HIV-infected patients are unlikely to occur or are limited to greater or more prolonged viral shedding.[53,70,223,255] The reported variability in the clinical course in HIV-infected patients who also are infected with RSV likely results from the different ages, degree of immune compromise, location, and therapy of the HIV-infected populations studied. Nonetheless, the risk of developing severe disease from RSV for most HIV-infected patients appears to be less than that observed among immunosuppressed transplant recipients.

PULMONARY SEQUELAE

Clearly, many infants with RSV bronchiolitis are destined to develop recurrent wheezing during childhood.[183,213,260,307,380] Much interest and investigation have been devoted to exploring whether a link exists between RSV lower respiratory tract disease in young children and the later development of asthma or pulmonary structural and functional changes, but a definitive answer remains unclear. Both epidemiologic and immunologic evidence supported a connection between subsequent wheezing and the occurrence of bronchiolitis in young children. The great preponderance of these studies examined children who were hospitalized and, therefore, had more severe bronchiolitis. Among this population, follow-up studies, accumulated over the course of decades, indicated that 30 to 50 percent of children with previous RSV bronchiolitis subsequently will have wheezing.[183,213,260,369,375]

The wheezing episodes tend to be most frequent in the first several years after the bronchiolitis and then diminish or disappear over a period of time that has been reported as ranging from 3 years to adolescence.[195,260,321,369,370,380] Even with this clinical quiescence, these children may be at increased risk of developing asthma as adults. Atopy does not appear to play a major role in the development of wheezing subsequent to RSV infection. However, whether RSV has a direct causal role in later occurrence of hyperreactive airways is controversial. In the Tucson study of respiratory illness in children, RSV lower respiratory tract disease was found to be an independent risk factor for recurrent wheezing.[380] Similar subsequent episodes of wheezing, however, also were shown to develop after lower respiratory tract disease from other common respiratory viruses prevalent in childhood.[186,195,243]

Additional epidemiologic evidence suggested as supporting a link between RSV and asthma is the observation that in the United States and in many other countries, the incidence of children with asthma and of hospitalization for asthma has increased markedly recently.[8,88] In the United States, the prevalence of asthma among children rose from 3.6 percent in 1980 to 5.8 percent in 2003, and greater increases have been noted in other countries such as Australia and Scotland. Certain hypotheses have been suggested to explain this phenomenon. Among these is the "hygiene hypothesis," which proposes that recent technology and knowledge have resulted in an environment that is increasingly clean and devoid of the antigenic exposure early in life necessary to stimulate the development of a normal immune response. Support for this theory comes from clinical studies showing that children with early exposure to multiple infections and environmental allergens have less risk of developing asthma or subsequent wheezing.[26,88,210,311,343,380,391]

The similarities of the immune response associated with RSV infection and asthma have been hypothesized as the mechanism for their epidemiologic and phenotypic link.[95,260,304,305,307,406] The immunologic response associated with RSV infection has been characterized variably as being a mixed T_H1 and T_H2 cytokine phenotype (see "Immune Response: Immunity and Disease Pathogenesis").[86,227,385] A predominantly T_H2 response has been correlated with lower respiratory tract disease and more severe RSV disease. This finding suggests that RSV infection tips the immune response toward a T_H2 pattern that results in the release of the regulatory proinflammatory cytokines and chemokines by the epithelium of the airways with subsequent increased production of IgE in respiratory secretions, and of neuropeptides, and of other mediators implicated in the pathogenesis of wheezing and asthma.[305,385,406]

Alternative hypotheses have proposed that RSV infection in infancy alters the subsequent normal growth and development of the lung or that the virus acts as a trigger to a hyperreactive response of the airways among inherently predisposed individuals.[119,260] The development of wheezing most likely results from the multiple genetic and environmental factors, which vary among individuals, thus rendering the contribution of single factors, such as RSV infection, impossible to assess. Only intervention studies with an effective vaccine or other preventive and therapeutic measures are likely to determine whether RSV has a

direct, indirect, or no link to the development of recurrent wheezing and asthma among these young wheezers.

REPEATED INFECTION

The most striking proof of RSV's incomplete, inconsistent, and impermanent immune response is the burden of illness levied by the repeated infections it causes. RSV has no respect for age. Recurrent infections occur across the age span from toddlers to elderly persons, whether healthy or infirm. Reinfection occurs most frequently among those in close contact with young or school-age children, as in daycare facilities and primary schools, or among those in confined settings, including military recruits.[127,146,148,149,160,182,250,310] Most of these infections are upper respiratory tract illnesses, which often are more severe than is the average cold and often are complicated by sinusitis and otitis media. Recurrent infections involving the lower respiratory tract usually are manifest as tracheobronchitis or as exacerbations of wheezing. Even in young, healthy adults without asthma or other chronic pulmonary conditions, acute RSV infection may produce hyperreactivity of the airways that does not resolve for as long as 8 weeks.[169]

Recurrent Infections in Children

Among longitudinally followed children, up to three fourths have been shown to be reinfected each year. The intervals between infections often are no longer than the period between successive outbreaks of RSV infection or even less, especially among children in daycare, in whom the attack rates have been reported for the first, second, and third infections to be as high as 98, 75, and 65 percent, respectively.[182] Of note is the finding that immunity resulting from a single infection appeared to have no ameliorating effect on illness associated with reinfection 1 year later. Not until the third infection was severity reduced appreciably. Among preschool children, 20 to 50 percent of the repeated RSV infections involved the lower respiratory tract, but the illness tended to be mild.[127] Most children had lower respiratory tract illness only once, and those with repetitive lower respiratory tract infections tended to have reactive airway disease.

Infections in Adults

Healthy adults frequently are exposed to RSV in their workplace and as parents or members of families with preschool and elementary school-age children. Despite these repetitive exposures, most of them remain susceptible to RSV infection during the subsequent outbreaks and, if infected, are symptomatic.[85,99,149,161,310] Recent infection, however, may result in diminished clinical findings and virus shedding, as demonstrated in a study of 15 young healthy adults who became infected with a RSV A strain during a community outbreak and developed upper respiratory tract illnesses (Fig. 194–8).[166] These individuals subsequently were inoculated intranasally with RSV A strain at repetitive intervals over the course of 2 to 26 months. The number reinfected and the proportion manifesting any symptoms continually declined during the 26 months. Concurrently, the quantity and duration of virus shedding also diminished.

Among 211 working adults followed over the course of multiple seasons, RSV re-infection was symptomatic in 84 percent and manifested as an upper respiratory tract illness in 74 percent, two thirds of whom had accompanying fever.[149] The other fourth of the reinfections involved the lower respiratory tract, with the diagnosis of tracheobronchitis or wheezing. Some individuals became infected with RSV and, at a separate time, with both RSV and influenza virus. Comparison of the two illnesses occurring in the same individual revealed that influenza and RSV were clinically similar (Fig. 194–9). Influenza was accompanied more frequently by fever and absence from work, whereas RSV infection was associated significantly more often with sinusitis, otitis, and a longer duration of illness.

The clinical similarity of illness from RSV and from influenza among young adults and the difficulty of differentiating the two also were shown in university students and in military recruits.[250,310] In the close military environment of basic training, new military recruits frequently acquired acute respiratory tract infections, especially from RSV.[310] RSV infections in these recruits were very similar to those from influenza, except wheezing was associated more frequently with RSV infection. The proportion of patients requiring confinement to a ward was the same for those with RSV infection as for those with influenza.

The importance of RSV infection as a cause of morbidity and mortality in older adults, both those previously healthy and those with underlying conditions, has been recognized increasingly.[85,97,98,100,394,417] Between 2 and 9 percent of all lower respiratory tract hospitalizations in elderly persons have been estimated to be caused by RSV, with a cost of $150 million to $680 million annually.[18,172] Not included in these estimates are the additional hospitalizations and costs associated with exacerbations of underlying chronic conditions.

The impact of RSV infection in elderly individuals was well illustrated in a prospective study of 608 healthy community-dwelling elderly patients and 504 adults with high-risk condi-

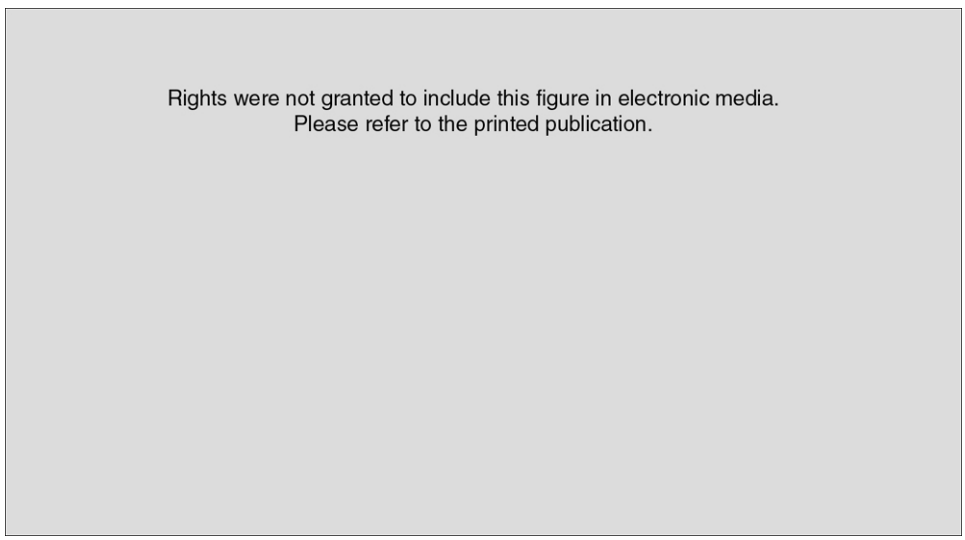

Figure 194–8 Re-infection with respiratory syncytial virus (RSV). Proportion of young adults with natural RSV A infection who become reinfected, shed virus, and were symptomatic when they were subsequently rechallenged intranasally with RSV A after intervals of 2, 4, 8, 12, 20, and 26 months from time of their natural infection. *(From Hall, C. B., Walsh, E. E., Long, C. E., and Schnabel, K. C.: Immunity to and frequency of reinfection with respiratory syncytial virus. J. Infect. Dis.* 163*:693-698, 1991.)*

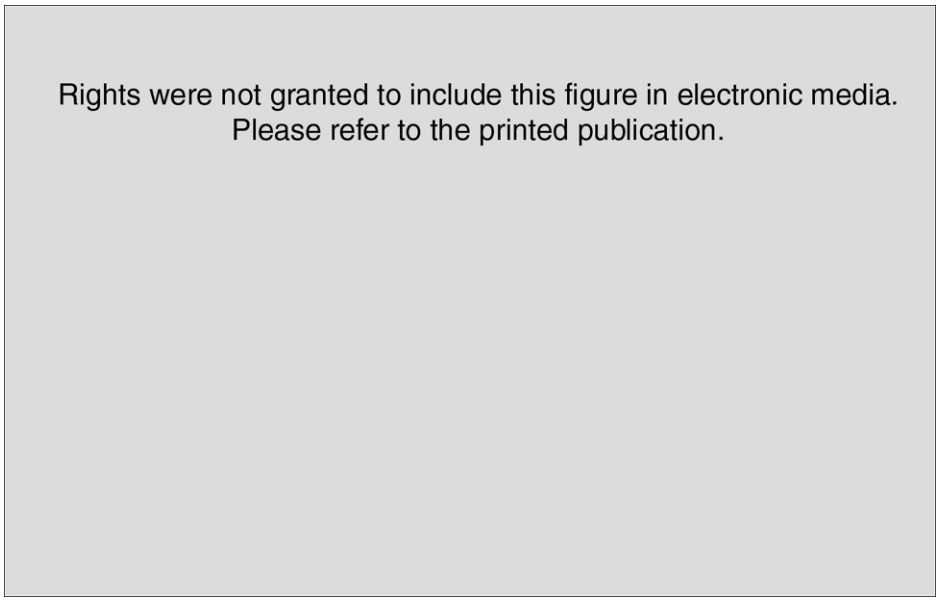

Figure 194–9 Respiratory syncytial virus (RSV) infection and influenza. Comparison of clinical findings observed during RSV infection compared with influenza infection among 211 prospectively followed previously healthy adults who acquired both infections, RSV infection at one time and influenza infection at a separate time. *(From Hall, C. B.: Nosocomial respiratory syncytial virus infections: The "cold war" has not ended. Clin. Infect. Dis. 31:590-596, 2000.)*

tions. An additional 1388 individuals who were hospitalized with acute cardiopulmonary conditions also were studied.[100] The mean age of the individuals studied ranged from 70 to 75 years. During the four consecutive winter seasons of viral surveillance, using viral isolation, reverse transcriptase–polymerase chain reaction (RT-PCR), and serology, RSV infection was identified in 102 (10%) of the patients in the two prospectively studied cohorts and in 142 (10%) of the hospitalized patients. Influenza A infection was identified in 44 (4%) of those in the prospectively followed cohorts and in 154 (11%) of the hospitalized patients. The proportion of individuals developing RSV infection each year ranged in the healthy group from 3 to 7 percent and in the high-risk group of adults from 4 to 10 percent. In comparison, influenza A infection was detected annually in 2 to 4 percent of the healthy elderly cohort and in less than 1 to 5 percent of the high-risk group. Noteworthy is that the illnesses from RSV and influenza A could not be distinguished clinically. Among the hospitalized patients, intensive care was required by 15 percent of those with RSV and by 12 percent of those with influenza A infection, and 8 percent of the RSV and 7 percent of the influenza A infections were fatal. Although RSV infection generated fewer office visits than did influenza among the healthy, older age group, those with high-risk conditions used health care services similarly if they were infected with RSV or influenza. The impact on health care services and costs by RSV is underscored by the proportion of hospitalizations caused by RSV for pneumonia (10.6%), chronic obstructive pulmonary disease (11.4%), congestive heart failure (5.4%), and asthma (7.2%). The role of RSV in elderly patients with these diagnoses frequently is unrecognized and not diagnosed.

DIAGNOSIS

Too minuscule
for human eyes,
It leaves its scent
and prints precise,
A hidden hare
for hunt and snare . . .

—CBH

Because RSV has a repetitive and distinctive behavior, the diagnosis often is made on the basis of the age of the child, the clinical syndrome, especially bronchiolitis, and the usual period of peak RSV seasonal activity which, if not monitored locally, is available nationally through the Centers for Disease Control and Prevention Surveillance.[48] An increase in the number of outpatient visits and admissions for bronchiolitis and respiratory illness in children younger than 2 years of age usually is a local indication that RSV is active within the community (see Fig. 194–2).[151,286] Other respiratory pathogens of young children, particularly parainfluenza virus type 3, hMPV, and bocavirus, may produce similar clinical illnesses, such as bronchiolitis. However, these viruses are less common causes of lower respiratory tract disease in infants and are not as closely associated with the peaks of bronchiolitis and hospital admissions for respiratory illness in infants.[168,199,207,216,226,258,269,418] The seasonal occurrence of parainfluenza virus type 3 is much broader with its peak in the spring. hMPV and bocavirus appear to have their primary activity from the fall through spring months, although it is more variable and with a less distinctive peak of activity than observed with RSV.[418] Although the parainfluenza viruses, hMPV, and bocavirus may cause bronchiolitis in children younger than 2 years of age, generally the mean age is a few months older than that for RSV. Nonetheless, for each infant with the findings of bronchiolitis or viral pneumonia who presents during a community outbreak of RSV infection, these major alternative causes should be considered.

A specific diagnosis of RSV infection may be made by isolation of the virus, or by using standard cell culture or shell vials, direct and indirect immunofluorescent assays, enzyme immunoassays (EIAs), and methods using nucleic acid amplification PCR. The specimens employed usually are upper respiratory secretions from a nasopharyngeal swab or, less frequently, nasal aspirate. A nasal wash or tracheal aspirate is more sensitive than is a nasopharyngeal swab specimen for the recovery of RSV.[150,178] Nasal wash specimens may be obtained with a suction apparatus or, more simply in young children, by the use of a tapered rubber bulb (Fig. 194–10).

In the past, tissue culture isolation of the virus was the standard technique used for establishing the diagnosis of RSV. However, culture techniques now are used less frequently. The disadvantages of viral isolation include the expense, the number of days required (an average of 3 to 5 days), the need for considerable technical expertise and time, and the need for reliably sensitive tissue culture.[98,185] Viral isolation techniques, however, do have the advantage of being able to detect co-infecting viral agents.

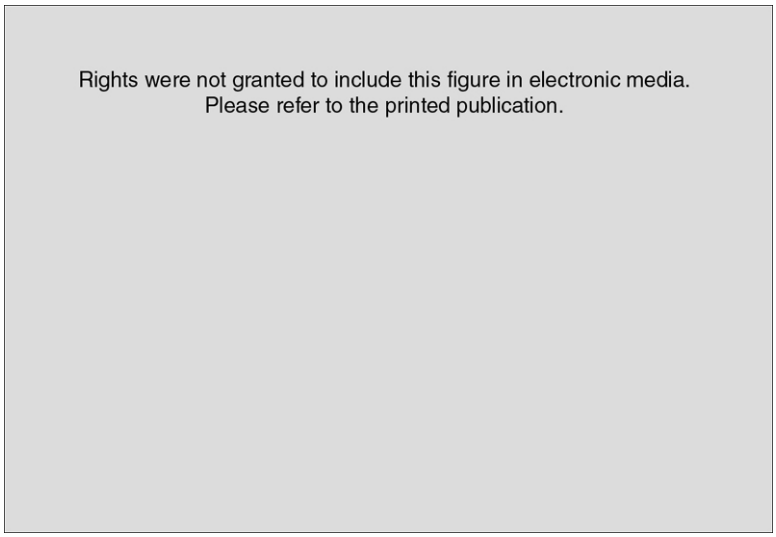

Figure 194–10 Simple method for obtaining nasal wash specimens from young children. A 1-oz tapered rubber bulb is used to inject and collect 5 to 10 mL of saline with one squeeze. *(From Hall, C. B., and Douglas, R. G., Jr.: Clinically useful method for the isolation of respiratory syncytial virus. J. Infect. Dis.* 131*:1-5, 1975.)*

Indirect and direct immunofluorescence assays applied to nasopharyngeal secretions from children have an average sensitivity and specificity of approximately 95 percent when these tests are performed by experienced personnel.[185] However, the ranges of sensitivity and specificity are wide and depend on the laboratory's expertise and on their suitability for certain populations, such as elderly persons, in whom these tests are less sensitive.[98]

Rapid antigen-based assays, primarily EIAs, and optical immunoassays (OIAs), currently are the assays most frequently used to diagnose RSV infection. Their major advantages are their rapidity, low cost, and simplicity. Nonetheless, they are screening assays, and their sensitivity and specificity vary highly, depending on the prevalence of activity of RSV in the community. During times of low prevalence (i.e., non-RSV seasons or at either end of the RSV season when RSV activity is low), their sensitivity, specificity, and positive predictive value plummet. In addition, for certain patients, such as those who are immunocompromised or elderly, these tests tend to be less sensitive.[98,185]

PCR techniques are the most sensitive and specific of current methods. Although they generally have been used primarily in research laboratories, these assays are becoming more widely available. Their sensitivity derives from the amplification of very small amounts of viral RNA in specimens that may be obtained from a variety of sources. Nested PCR assays add sensitivity, allow multiple viruses to be identified simultaneously, and help to differentiate RSV group A versus B strains. RT-PCR assays have the advantages of rapidity, from a diminished number of procedural steps, and of a decreased chance of contamination, but most are limited in the number of viruses that may be detected concurrently. Quantitative RT-PCR has the further advantage of determining the viral load, which has been well correlated with viral quantitation by other methods. PCR techniques have been shown consistently to be the optimal means for detecting viral infections and for establishing diagnoses in populations of children and adults; these tests detect approximately 30 percent or more infections than do viral isolation techniques.[99,168,250,404] However, the timing and duration of viral isolation have been shown to correlate with the timing and duration of clinical illness. This correlation has not been demonstrated for PCR techniques. These molecular techniques are constantly being improved in terms of rapidity, suitability of application to multiple viruses, and availability.[38]

Serologic diagnosis usually is reserved for research purposes because it generally is not helpful in the acute diagnosis and management of patients. Furthermore, serologic assays may be falsely negative in 10 to 30 percent of patients.[100,185] Serologic assays available include complement-fixation assays, neutralization assays, and EIAs, using purified F and G proteins of RSV for IgM and IgG antibodies. The complement-fixation assay tends to be the least sensitive. Serologic diagnosis appears to be more sensitive among elderly than younger subjects.[393] Faster diagnosis by the use of a single high titer has been tried, but it has had variable results and is not well standardized.

TREATMENT

For most children with RSV lower respiratory tract disease, supportive care is sufficient. Ensuring that the child has adequate fluid intake and, when necessary, clearing the nasal passages by gentle bulb suctioning are important in making the infant comfortable.

Supportive care also is integral to the management of the more severely ill infant. Increased production of mucus and secretions in the nasal and lower airways and respiratory rates of more than 60 to 70 per minute are apt to compromise the infant's ability to take fluids and sleep, thus resulting in an increased risk for requiring intravenous hydration and assisted ventilation.[16,67] Deep pharyngeal or tracheal suctioning and methods aimed at loosening secretions, such as chest percussion and vibration, have not been shown to be of benefit in children hospitalized with bronchiolitis.[16,298,402]

The criteria used for determining the need for administration of supplemental oxygen to previously healthy infants are controversial, in part because the usual fluctuating respiratory findings characteristic of RSV lower respiratory tract disease confound the evaluation of the oxyhemoglobin saturation (SpO_2) level at which supplemental oxygen administration provides measurable clinical improvement. SpO_2 levels on room air of less than 95 to 90 percent have been used, but current recommendations suggest that persistent measurements of SpO_2 of less than 90 percent indicate the need for initiating supplemental oxygen.[16]

The use of bronchodilating agents, corticosteroids, and antibiotics for the management of infants with RSV lower respiratory tract illness has been highly variable among centers in the United States and other countries.[27,396] Bronchodilators have been administered to an average 75 to 80 percent of infants hospitalized with RSV infection. Corticosteroid therapy has been used in 10 to 40 percent and intravenous antibiotics in 15 to 40 percent of infants admitted with documented RSV infection.[27]

Trials evaluating alpha-adrenergic or beta-adrenergic bronchodilating agents have given inconsistent results.[6,16,67,214] These trials have differed in the agents and outcomes measured. The patients studied have varied in age, presence of underlying conditions, and history of previous episodes of wheezing, rendering comparisons difficult to make.

A Cochrane systematic review of bronchodilator therapy concluded that a limited transient improvement in assessment scores may be observed in one of every seven children treated, but the clinical benefit was questionable.[214] After a comprehensive review of the clinical trials, the American Academy of Pediatrics Subcommittee on Diagnosis and Management of Bronchiolitis[16] recommended that for management of infants with a first episode of wheezing, bronchodilators should not be used routinely. The guidelines note that a carefully monitored trial of inhaled alpha-adrenergic and beta-adrenergic agents was a possible option in some cases. However, bronchodilator administration should be continued only if benefit was documented by objective means of evaluation. Some evidence suggests for trials conducted in emergency departments and hospitals, epinephrine may be the preferred nebulized agent. In the home and outpatient settings, however, racemic epinephrine would not be advisable because of its potential adverse effects and its short duration of action. Anticholinergic medications alone or in addition to bronchodilatory agents have not been shown to improve the course of viral bronchiolitis.[16,398]

Several reviews analyzing the randomized and controlled trials of administering systemic glucocorticoids in the management of acute viral bronchiolitis concluded that the evidence was not sufficient to support or recommend the use of systemic glucocorticoids on a routine basis.[6,16,115,320] The studies that were included varied in methods and in the type of patients included. Nonetheless, most of them showed no benefit in the clinical scores, the rate of hospitalization following glucocorticoid use during the initial medical visit, the length of stay in those hospitalized, or the rates of readmission or return outpatient visits. One meta-analysis showed a decrease of 0.43 days in hospitalization, but when the population was limited to only first-time wheezers, no benefit existed.[115]

Two placebo-controlled studies that examined the use of oral glucocorticoid therapy administered in the emergency department to preclude the need for hospitalization showed some benefit of glucocorticoid therapy over placebo.[76,361] More recently, however, a large study involving 20 emergency departments during the course of 3 RSV seasons examined the outcomes of 608 children aged 2 to 12 months who presented with a first episode of bronchiolitis in a double-blind, placebo controlled trial that administered 1 dose of oral dexamethasone (1 mg/kg).[71] The rate of hospitalization and the Respiratory Assessment Change Score (RACS) of these groups did not differ significantly. Furthermore, no benefit was observed among the subgroup of children with asthma or with a family history of asthma. Thus, the 2006 American Academy of Pediatrics guidelines[16] concluded that corticosteroid medication should not be used routinely in the management of bronchiolitis, and that current data do not support a recommendation for using corticosteroid therapy to prevent hospitalization. However, some evidence exists that certain subsets of children, including older children and those with prior episodes of wheezing and with asthma, may potentially benefit from the administration of systemic glucocorticoid therapy.[7,16,320]

Antibiotics should not be administered prophylactically to children with RSV infection or as therapy unless specific indications of the coexistence of a bacterial infection are present.[6,16] As noted previously, concurrent or secondary respiratory bacterial infection is an unusual occurrence, except for otitis media, among children with RSV lower respiratory tract disease, and prolonged administration of intravenous broad-spectrum antibiotics may augment the risk of development of secondary bacterial infection.[165]

The only specific treatment currently approved for children hospitalized with RSV infection is ribavirin (1-β-D-ribofuranosyl-1,2,4-triazole-3-carboxamide). This synthetic nucleoside has been administered as a small-particle aerosol for 12 to 22 hours per day until clinical improvement is evident, usually about 3 days. Much shorter, intermittent courses of higher doses also appear to be an acceptable mode of administration.[91] An analysis of the use of ribavirin for RSV lower respiratory tract disease included 11 randomized trials.[16,224] Seven of these studies showed benefit in the clinical outcome, and 4 did not. Long-term studies examining subsequent development of pulmonary function abnormalities or recurrent wheezing have had mixed results. However, the total number of patients in these controlled studies is small, the design of the trials is heterogeneous, and the degree of benefit in clinical outcome is unclear. For these reasons, plus its high cost, the American Academy of Pediatrics recommends that ribavirin should not be used routinely in the management of RSV lower respiratory tract disease.[15] Its use should be reserved primarily for infants with or at high risk for developing severe disease, on an individual basis.[16]

PREVENTION

With perseverance and
the dreamer's scanning scope,
reality is made of distant hope . . .

—CBH

BREAST-FEEDING

The number of infants who have been breast-fed has increased in recent years because of the growing recognition of the correlation of breast-feeding with both general and specific beneficial effects on the health of the infant.[49,52,116] Most studies evaluating the protective effect of breast-feeding against RSV infection show a diminished likelihood of acquiring more severe infection.[16,24,116,317] Although colostrum and breast milk contain IgG and IgA antibodies and neutralizing activity against RSV, the mechanism of the protective effect is complex and may relate more to many other multifunctional components in human milk, which during digestion inhibit infection by viral, bacterial, and other infectious agents.[295] The degree and duration of breast-feeding necessary to provide against RSV infection, however, remain undefined.[232,293]

Numerous studies performed over the course of several decades have indicated that breast-fed infants are less likely to be hospitalized with RSV and other respiratory infections than are those children who are not being breast-fed.[16,24,50,317] Breast-feeding and the risk of hospitalization for lower respiratory tract disease in healthy, full-term infants were examined in a meta-analysis of 33 studies,[24] all of which indicated a protective association. However, in this meta-analysis, only 9 studies met all the inclusion criteria. Infants who were not breast-fed were almost three times (risk ratio, 0.28) more likely to be hospitalized for lower respiratory tract disease in comparison with those exclusively breast-fed for 4 months. One study estimated that 30 percent of hospitalizations of infants for infection would have been avoided for each additional month of full breast-feeding beyond 3 months.[317] The authors thus estimated that if all 4-month-old infants had been exclusively breast-feed, 56 percent of hospital admissions for infants in the first year of life would have been prevented.

INFECTION CONTROL AND NOSOCOMIAL INFECTION

Preventing RSV infection from being acquired by normal infants and young children, as well as avoiding the RSV infections that frequently occur subsequently, is difficult, if not impossible, considering the prevalence and often covert presence of RSV during the annual outbreaks. Infection control procedures in the home should focus on interrupting the spread of RSV by using effective hand hygiene practices, including frequent handwashing and the use of hand sanitizers.[33,129,240] If the hands are not visibly soiled, alcohol-based sanitizers are preferentially recommended.[33] Their use generally has been more effective, has been better accepted by both children and adults, and has shown significant decreases in the occurrence of respiratory and diarrhea illnesses in daycare facilities and schools.[33,145,171,208,415] Objects contaminated with respiratory secretions, which act as fomites, should be cleaned, with used tissues carefully disposed.

Within medical settings, infection control procedures are the mainstay of controlling nosocomial infections from RSV.[33,47] RSV infection acquired nosocomially is recognized increasingly as a problem of magnitude, cost, and concern, considering the current number of patients with high-risk conditions.[130,145]

More than half a century ago, in 1941, Adams[3] described an epidemic of pneumonitis that occurred in January through February in the nurseries of two Minneapolis hospitals. Thirty-two infants, mostly in the second and third months of life, were affected, and 29 percent died. Cytoplasmic inclusions in the bronchial epithelium were observed in all fatal cases. The distinctive epidemiology, clinical syndrome, and pathology of these cases led Adams to propose a viral origin. Twenty years later, he and his colleagues described a markedly similar epidemic of respiratory illness in infants in whom they identified RSV as the cause.[4,5] RSV was thus indicted as the agent of the earlier, first-described nosocomial outbreak.

During community outbreaks of RSV, the risk of the nosocomial spread of RSV infection is high and, if not recognized, results in increased morbidity and prolonged hospitalization. On infant wards and neonatal units, nosocomial RSV infection has been especially hazardous and sometimes fatal for the more compromised infants.[143,145,154,175] The risk of acquiring nosocomial infection is related to the child's age, underlying disease, length of hospitalization, and, clearly, adherence to proper infection control procedures.

Among immunocompromised children and adults, nosocomial RSV infections often are serious and difficult to control.[32,72,90,93,145,245,273,378,414] Outbreaks in transplant units in particular have been associated with a high mortality rate and prolonged and intermittent transmission (see "Immunocompromised Patients").

RSV infection frequently is introduced to the ward by hospital staff, families, and visitors who may have only a mild cold. Genetic analysis has demonstrated that nosocomial outbreaks may be caused by one or multiple strains of RSV during a single outbreak or season.[22,143,265,357,377] Infection rates may be high among staff members, who often require absence from work.[145] However, even uninfected staff may spread RSV infection by fomites, through contact with infectious secretions contaminating environmental surfaces.

Various infection control procedures have been employed to prevent the nosocomial spread of RSV (Table 194–4). Because the acquisition of RSV occurs primarily by close contact with an infected person or with surfaces contaminated by secretions, rather than by small-particle aerosols that may transverse great distances, most important is careful hand hygiene practiced by all persons entering and leaving a patient's room.[145,152] Integral to this precaution is the education of the staff, including frequent reminders to ensure compliance throughout the RSV season.[33,145,238] The efficacy of additional barrier precautions such as gowns, gloves, and masks has varied in different settings. In two controlled studies, the routine use of gowns and masks did not add further benefit to conscientious handwashing and other infection control procedures.[153,292] Masks that cover the nose and mouth are of limited benefit because touching or rubbing the eyes or nose are the major modes of self-inoculation.[111,152,157] Thus, eye-nose goggles or goggles in addition to a mask appear to be more effective in diminishing nosocomial infection in both staff and infants.[111]

As facilities allow, infants with respiratory signs of unknown origin should be admitted to single rooms.[47] The use of rapid diagnostic tests as a basis for cohorting has been controversial, in part because of their varying sensitivity and specificity, especially if these tests are used other than during the period of peak RSV activity.[16]

TABLE 194–4 Infection Control Procedures, Both Standard Precautions and Contact Precautions for Prevention of Respiratory Syncytial Virus Infection, Recommended by Centers for Disease Control and Prevention

Recommendation Category or Procedure	Comment(s)
Category I-B Recommendations*	
Handwashing	Water with soap or antibacterial agent or waterless antiseptic hand rub
Wearing gloves	Combined with handwashing before and after each glove change; may diminish self-inoculation
Wearing gowns	When direct contact with patient or patient secretions is likely
Wearing masks and eye protection	Eyes and nose are major sites for inoculation
Housing patient in private room or in a cohort isolated from other patients	Patients with documented infection can be grouped and isolated from other patients; beds should be separated by >0.9 m
Use of dedicated patient-care equipment sometimes recommended with less or no supporting evidence	Equipment, including toys, assigned to specific patients
Staff assigned according to patient's RSV status	Specific staff care only for patients with RSV infection
Visitor restrictions during RSV season	Some qualify by restricting young children only
Screening visitors for illness during RSV season	Visitor assessed by trained personnel or advised by use of an educational patient information list

**Centers for Disease Control and Prevention I-B recommendations based on "strong rationale and suggestive evidence" and strongly recommended for all hospitals and "reviewed as effective by experts in the field."*

RSV, respiratory syncytial virus.

Modified from Ref. 145.

PROPHYLAXIS

Currently, prophylaxis is centered on prevention of hospitalization and diminishing the severity of RSV infection in high-risk infants with the use of passively administered humanized monoclonal antibodies against RSV.[15,350,389] Prophylaxis with passive anti-RSV antibodies was initiated by the licensure in 1996 of high-titered intravenous polyclonal RSV immunoglobulin. The subsequent licensed RSV humanized monoclonal antibody, palivizumab, was 50 to 100 times more effective than was the polyclonal immunoglobulin and circumvented many of the difficulties and adverse effects of administering a large intravenous dose to small infants.[312] Palivizumab was developed from a mouse monoclonal antibody that recognizes a protective epitope of the surface glycoprotein, the F protein. Only the antigen recognition site from the mouse monoclonal antibody was inserted into the spine of a human antibody, thus diminishing the chance of having allergic reactions to the mouse-raised antibody.[14,367] Multiple studies have evaluated prophylaxis with palivizumab and the risk of hospitalization with RSV infection in high-risk infants.[15,16,46,389] The two blind, randomized, placebo-controlled trials pivotal for the licensure of palivizumab involved 2789 infants and young children who were premature or who had underlying chronic lung disease or congenital heart disease.[196,329] The rate of hospitalization for RSV illness was reduced more than 50 percent in the infants given prophylaxis in comparison with the placebo group. In different subgroups, the reduction of RSV hospitalization rates ranged from 39 to 78 percent, with the lower rates of protection observed among infants with chronic lung disease and congenital heart disease.[46] Post-licensure studies suggested that reduction rates in the necessity for hospitalization with RSV infection may be even greater.[350]

The American Academy of Pediatrics recommended that palivizumab be administered to selected children younger than 2 years of age with chronic lung disease, of gestational age of less than 35 weeks, and with functionally important congenital heart disease.[15] Palivizumab should be administered in five doses every 30 days to cover the 5 months of major RSV circulation, which for most of the United States would mean starting in early November.[15,274,286] Prophylaxis is recommended for subgroups of these high-risk children depending on their gestational and postnatal ages, the severity of their underlying conditions, their need for recent medical therapy, and the presence of other risk factors. Prophylaxis with palivizumab should be considered for children with chronic lung disease who have required therapy within 6 months of the start of the RSV season, for infants born at 28 weeks' or less gestation during their first RSV season, for infants born at 29 to 32 weeks' gestation if younger than 6 months of age at the start of the RSV season, and for infants born at 32 to 35 weeks' gestation who have two or more risk factors for acquiring more severe RSV disease and are younger than 6 months of age at the start of the RSV season. Prophylaxis also is recommended for children with congenital heart disease if it is hemodynamically significant. Once a child has qualified at the beginning of the season for the administration of prophylaxis, it should be continued throughout the season, but with no more than the recommended five monthly doses.[15] Palivizumab has not been shown to be effective in the treatment of RSV disease.

The use of palivizumab, nonetheless, remains controversial. Economic analyses, in general, have not demonstrated an overall savings in health care costs if all high-risk children receive prophylaxis.[89,341] Cost-to-benefit analyses have been difficult to determine because of considerable geographic variation in the population of infants and hospitalization costs for such infants. Palivizumab immunoprophylaxis has not been correlated with a significantly diminished rate of mortality for infants with RSV infection who receive the prophylaxis, but the mortality rate from RSV currently is very low. The effect of palivizumab prophylaxis on subsequent sequelae, such as recurrent wheezing and pulmonary function abnormalities, is unknown.

Other products for prophylaxis that are being investigated include a humanized recombinant IgG1 monoclonal antibody that is derived from palivizumab. It also is directed against the F glycoprotein of RSV, but its greater potency has been suggested by animal experimental data showing a binding affinity that is 70 times greater than that of palvizumab.[422] In subsequent phase III trials in high-risk infants, this monoclonal antibody has been shown in comparison with palivizumab to provide significantly greater reductions in the number of hospitalizations and outpatient visits for RSV infection.[45a]

VACCINES

Control of RSV has long lured but eluded investigators. Although the outcome of infants with RSV infection has improved greatly in recent years, marked by a decrease in the mortality rate, the burden on health care that RSV imposes yearly remains notable among both children and adults.[100,120] Only effective immunization is likely to alleviate this burden. Certain characteristics of RSV infection, however, have posed barriers to the successful development of a vaccine during the 4 decades of effort.

The shroud of past experience with the formalin-inactivated vaccine s conferred caution and concern regarding the development of candidate vaccines. The unfortunate outcomes of trials with the formalin-inactivated vaccine nonetheless stimulated research that has divulged information integral to the evolution of future vaccines.[62,109,209,221] The information derived from rodent models of the exaggerated disease and lung disorder illustrated the importance of the type of immunizing agent in determining whether a beneficial or detrimental humoral and cellular immune response results; these models suggested that a successful vaccine should produce a balanced immune response with both $CD4^+$ and CTL cells.[134,305]

Furthermore, the specific antigens to be included in a vaccine potentially will alter the immune response (see "Immune Response: Immunity and Disease Pathogenesis"). Experiments immunizing mice with recombinant vaccine viruses expressing the F, G, and the transcription anti-terminator (M2) proteins illustrate the mutable immune response in animal models.[305] Immunization with the G protein, which primes T_H2 cells, tends to produce eosinophilic lung disease, whereas immunization with the F protein is associated with results in CTL priming, T_H1 response, and lung histology characterized by polymorphonuclear cell infiltration. Subsequent to immunization with M2, the observed RSV disease is dominated by cytotoxic lymphocytes. Despite the wealth of information derived from these animal experiments, the lack of a model to test candidate vaccines that is reliable, adequate, and predictive of the effect in humans remains a significant barrier.

An RSV vaccine also should reflect the immune response of natural infection yet improve its inconsistent and nondurable protection. In addition, it would need to be administered in the first few weeks of life, when the most severe disease usually occurs. Little experience exists regarding immunization with live viruses within the neonatal period, when the immature and variably developed immune system of the neonate and the presence of maternal antibody are likely to exert unpredictable hindrances.[305] Furthermore, the effect of currently growing numbers of antigens from other vaccines administered early in the first few months of life must be considered.

The initial RSV vaccine trials, with the alum-precipitated, formalin-inactivated vaccine (FI-RSV), were conducted in 1966 to 1967 concurrently with administration of an inactivated and trivalent parainfluenza vaccine. Infants aged 2 months or older and older children previously infected with RSV were given FI-

RSV in three doses. With exposure to RSV during the subsequent RSV outbreak, the FI-RSV vaccinees were more protected against infection than were the controls who had received the parainfluenza vaccine. However, among those RSV vaccinees who did become infected, the severity of the RSV disease was significantly greater among the FI-RSV vaccinees, and the severity was inversely correlated with age.[62,109,209,221] Two children died of pneumonia, and their lungs showed marked inflammation with eosinophilia, lymphocytic, and neutrophilic infiltration. Subsequent investigation indicated that the FI-RSV evoked abnormal and unbalanced cellular and humoral immune responses with antibody deficient in neutralizing and fusion-inhibiting activity.[222,288,291]

Vaccine development subsequently has been cautious and has taken mainly two approaches, production of live-attenuated or subunit candidate vaccines. Live-attenuated vaccines have the advantage over subunit vaccines of producing an immune response that more closely mimics the natural route of inoculation into the upper respiratory tract, thus eliciting more balanced local and systemic humoral and cellular responses and offering potentially broader and more durable protection.

The initial live attenuated candidate vaccines were derived from cold-passaged *mutants* propagated from wild-type RSV (wt RSV) strains grown at progressively lower temperatures, and strains were selected by growth at low temperatures, similar to that of the upper respiratory tract. Subsequent passage in the presence of chemical mutagenic agents produced candidate strains that were temperature-sensitive *(ts)* and unable to replicate at the higher body temperatures of the lower respiratory tract.[69] These candidate (*cp* and *ts*) vaccines generally produced promising results in adult volunteers and seropositive children but proved to be unsuitable for infants and young, seronegative children. These vaccines were associated with unacceptable degrees of illness, were overattenuated and not protective, or were genetically unstable; some were accompanied by prolonged shedding of wild-type virus, which most frequently was observed in infants and resulted in transmission of the shed virus to 20 to 25 percent of the unvaccinated contacts.[211]

More recent vaccine candidates have been derived from previously combined *cp* and *ts (cpts)* mutants, which contain mutations generated by reverse genetics that allow the precise desired enhancements of stability, attenuation, and immunogenicity. For example, one candidate, *cpts 248* strain, was further mutated and attenuated into *cpts 248/404*. Each of its mutations was introduced alone or in combination into wt RSV for evaluation in experimental animals of the mutations' immunogenic and attenuating effects. This candidate *cpts 248/404* vaccine was immunogenic in seropositive and seronegative children older than 6 months, but upper respiratory tract illness with appreciable nasal congestion developed in younger infants 1 and 2 months of age.[421]

Reverse genetics has produced a lineage of further "designer gene" candidate vaccines with one or combined deletions of NS1, NS2, M2-2, and SH genes. Two recombinant candidate vaccines, *cpts 248/404/ΔSH* and *cpts 248/404/1030ΔSH*, illustrate this technique's ability to correlate a vaccine's attenuating and protective effect to specific mutations but not to predict the host's mitigating factors such as age. Both appeared highly attenuated, immunogenic, and stable in initial clinical evaluations of adults and children 6 months of age and older.[212] *Cpts 248/404/1030ΔSH* produced more restricted replication in seronegative children, but only 44 percent of infants aged 1 to 2 months developed IgA antibody responses. However, despite the lack of a measurable antibody response, the infants demonstrated some protection against a second dose of the RSV vaccine, a finding suggesting that immunity not reflected in the measured humoral response was evoked. The two vaccines, *cpts 248/404/ΔSH* and *cpts 248/404/1030ΔSH*, differed only in a missense mutation (1030) in the polymerase gene, and this indicated that the 1030 mutation conferred attenuation.

Many other mutations have been evaluated in experimental animals, not only for their immunogenic, attenuating, and stability characteristics but also for properties required for augmenting the safety, efficacy, and acceptance of potential vaccines, such as increasing the degree and breadth of antigenic expression and the compatibility with different viral antigens that would allow combination vaccines of RSV with parainfluenza and other respiratory viruses.[69,283]

Candidate subunit vaccines have used primarily the two major surface glycoproteins, F and G, which are the major targets for the production of neutralizing antibodies.[74,367] Clinical investigation has focused on vaccines of the F protein, which has greater cross-reactivity between RSV A and RSV B strains. Three generations of purified F protein vaccines, PFP-1, PFP-2, and PFP-3, that consist of immunoaffinity-purified, alum-absorbed F glycoprotein, have been evaluated in clinical trials. The initial PFP-1 vaccine contained small amounts of the G protein, which did induce an antibody response. PFP-1 and PFP-2 vaccines have been administered to normal adults, institutionalized adults, normal children, and those with chronic underlying conditions including chronic lung disease, cystic fibrosis, and asthma.[74,96,136,138,316] The PFP vaccines generally have been safe and immunogenic, producing good levels of neutralizing antibody, especially in seropositive individuals and in those receiving vaccine that also contained small amounts of the G protein.

The PFP-2 vaccine, administered during the third trimester in a study of maternal immunization, showed no adverse effects on the infants, but it was poorly immunogenic in the mothers.[287] At delivery, only low levels of maternal neutralizing antibody were present. However, increased levels of IgG, but not IgA, antibody to the F protein did occur in breast milk. The protective effect of this approach for breast-fed infants requires further study.

A meta-analysis of the PFP vaccine trials concluded that a significant relative risk of 0.55 (95% confidence interval, 0.35 to 0.88) in the overall number of RSV infections existed, but the heterogeneity of the studies cast doubt on the validity of this conclusion.[371] Vaccination with PFP did not show any effect on reducing the incidence of RSV lower respiratory tract disease.

Additional candidate vaccines that have been evaluated include a peptide vaccine, BBG2Na, containing a conserved region of the G protein fused to the albumin-binding domain of the streptococcal G protein, and chimeric vaccines of the F and G proteins.[327,368,400] More immunogenic vaccines are being investigated by using recombinant vectors and plasmids that contain complementary DNA of the F and G genes.

Novel adjuvants also are being developed, some of which can shift the immune response evoked by subunit vaccines from a T_H2- to a T_H1-type response in experimental animals. Enhanced immunogenicity appears possible with enterically active adjuvants and carriers, such as liposomes and biodegradable microspheres, and with adjuvants in vesicles of immunostimulating complexes.[74]

The novel development of individual vaccines and approaches is reducing the number of hurdles and detours on the road toward successful control of RSV. In view of the number of different populations from infants to elders who would benefit from protection against RSV infections, multiple approaches and vaccines may be required to achieve effective control of RSV infection and diminish its associated human and financial cost.

CHAPTER 195

Human Metapneumovirus

James D. Cherry

Human metapneumovirus (hMPV) is a respiratory tract pathogen first described in 2001 by van den Hoogen and associates.[88] It is the first known mammalian metapneumovirus associated with disease.[87,88] Avian pneumovirus (APV) is the only other known metapneumovirus.[91] hMPV is considered ubiquitous in humans on the basis of detection of the virus by polymerase chain reaction (PCR) in respiratory specimens of symptomatic children and adults* and the presence of a high rate of hMPV-specific antibodies in diverse populations throughout the world.[47,58,88] The features of hMPV infection in children and adults have been reasonably well characterized during the last 7 years. In children, the manifestations frequently are clinically indistinguishable from those of human respiratory syncytial virus (RSV).†

HISTORY

hMPV was isolated initially from specimens collected during a 20-year period from a group of 28 epidemiologically unrelated patients with respiratory tract disease in the Netherlands.[88] All viral isolates were from nasopharyngeal specimens collected in the winter months. The unidentified isolates replicated predominantly in tertiary monkey kidney (tMK) cells. The cytopathic effects of replicating virus were difficult to distinguish from those caused by RSV, except that the onset of features was delayed by several days. Electron microscopy revealed typical paramyxovirus-like pleomorphic particles and short envelope projections, with nucleocapsids rarely being observed. Reports of hMPV infection from Australia, Canada, England and Wales, Finland, and the United States soon followed.* The virus had been circulating within the Dutch population since at least 1958 based on the universal presence of antibodies to hMPV in sera collected from subjects who were aged 8 to 99 years old at that time.[88] Researchers have speculated that because APV is the closest relative of hMPV, a possible zoonotic event may have occurred before this time.[88] The late recognition of hMPV as a respiratory pathogen was the result of its unique growth requirements and kinetics in vitro.[88]

PROPERTIES

CLASSIFICATION

The complete sequence of the hMPV has been determined. The virus is a member of the *Metapneumovirus* genus in the subfamily

*See references 1-4, 6-12, 14, 16, 17, 19, 20, 22-31, 35, 38, 43, 45, 47-50, 53, 54, 57-68, 70-72, 74, 76-78, 80, 81, 83, 86, 91, 93-102.

Pneumovirinae and family *Paramyxoviridae*.[46,87] It is genetically similar to the avian pneumovirus.

STRUCTURAL AND ANTIGENIC PROPERTIES

The hMPV virion, like all paramyxoviruses, contains a nucleocapsid of single-stranded, negative-sense RNA within a lipid bilayer envelope derived from the plasma membrane of the host cell.[52] The virion, however, does not contain hemagglutinin or neuraminidase, which distinguishes it as a member of the *Pneumovirinae* subfamily.

Ultrastructural analysis of the hMPV virion by electron microscopy also is typical of paramyxoviruses and demonstrates spherical, pleomorphic, and filamentous particles with short envelope projections.[71,88] The spherical particles vary from 150 to 600 nm in diameter, with a mean of 209 nm,[71,88] whereas the envelope projections are 13 to 17 nm in size.[88] The nucleocapsid's diameter is 17 nm with lengths from less than 200 to more than 1000 nm.[71] Filamentous particles average 282 by 62 nm in size.[71]

The hMPV genome is approximately 13.4 kb in length and consists of eight identifiable open-reading frames that are transcribed into eight viral proteins.[87,88] All are distinct structural proteins and have been identified as transmembrane surface glycoproteins (fusion [F], attachment [G], and small nonglycosylated hydrophobic [SH]), matrix proteins (M and M2), and nucleocapsid-associated proteins (nucleocapsid [N], phosphoprotein [P], and polymerase [L]). Two structural features principally determine the distinction between the genera *Metapneumovirus* and *Pneumovirus* (Fig. 195–1). Metapneumoviruses lack the nonstructural (NS) proteins NS1 and NS2, and the gene order differs between the two genera. The genetic alignment of the M and L open-reading frames of metapneumoviruses (3′-N-P-M-F-M2-SH-G-L-5′) is different from that of pneumoviruses (3′-NS1-NS2-N-P-M-SH-G-F-M2-L-5′). However, the location of hMPV viral structural proteins within the virion is similar to that described for RSV.

Sequence analysis of the hMPV genome reveals the highest degree of identity with APV.[88] Of the four known serotypes of APV, hMPV most closely resembles APV serotype C, the type most commonly described in birds in the United States.[13,88] Sequence information on APV serotype D for comparison with hMPV is limited.[88]

Similar to RSV, significant variation also exists in genomic sequences or strains for hMPV isolates. Phylogenetic analysis of isolates has confirmed the existence of at least two distinct clusters or lineages and four sublineages of hMPV worldwide based on limited sequence analysis of the N, M, F, and L open-reading frames.[5,6,55,56,58,82,88,90] In separate studies, overall nucleotide comparison reveals 80 to 88 percent genetic similarity between the two clusters and 93 to 100 percent within each cluster. At the amino acid level, the differences are less distinct, with 94 to 97 percent similarity existing between groups and 97 to 100 percent shared identity found within each group. hMPV genetic strains from both clusters have been noted to co-circulate in the same year.[6] Strains from different years also have been identified in the same subcluster.[6,55,88] On the basis of differences in virus neutralization titers, the two distinct genomic lineages (genotypes A and B) also can be considered two serotypes.[90]

LABORATORY GROWTH

The use of tMK or LLC-MK2 (Rhesus monkey kidney) cells has shown the greatest success in culture of hMPV from clinical respiratory samples obtained by nasopharyngeal aspiration, nasopharyngeal swabs, endotracheal aspiration, or bronchoalveolar lavage.[6,71,75,88] The virus replicates poorly in Vero or A549 cells, with no growth detected in chick embryo fibroblast (CEF), Madin-Darby canine kidney (MDCK), or human lung mucoepidermoid carcinoma (NCI-H292) cells.[6,58,71,88] The characteristic cytopathic effect in cell culture is focal small round, granular, and refringent cells, without large syncytial formation in most cases.[6,71] The appearance of the cytopathic effect ranges from 3 to 23 days with a mean of 17.3 days.[6,88]

Other biologic properties of the *Paramyxoviridae* are detected with hMPV culture. Standard chloroform treatment results in a significant reduction in the median tissue culture infective dose ($TCID_{50}$) for tMK cells.[88] Virus-infected cell culture supernatants do not adsorb the erythrocytes (negative hemagglutinating activity) of chickens, guinea pigs, or turkeys.[71,88] Viral replication in vitro is dependent on the addition of trypsin to the cell culture medium.[88] This last feature of hMPV may have been what contributed to a delay in recognizing the virus as a respiratory pathogen because seminal research performed to identify respiratory agents failed to use trypsin as a culture supplement.[88] Other practices that also would have contributed to this delay include the poor replication of hMPV in the continuous cell culture lines routinely used in diagnostic virology laboratories for viral isolation, the slow viral replication in vitro leading to discarding of potential positive isolates before detection, an apparent lack of serologic cross-reactivity to other paramyxoviruses (e.g., RSV, influenza and parainfluenza viruses), and finally, the low nucleotide sequence homology to other known viral pathogens.[88]

ANIMAL SUSCEPTIBILITY

hMPV reproduces efficiently in the respiratory tract of cynomolgus macaques *(Macaca fascicularis)* and causes clinical infection.[88] Virus replication appears to peak between 2 and 8 days after inoculation into either the respiratory tract or conjunctivae.[88] The clinical features of primate infection are consistent with those of mild upper respiratory tract disease and suppurative rhinitis on histologic examination.[88] A similar attempt at experimental infection of turkeys and chickens has been unsuccessful, thus providing further supportive evidence that hMPV is a

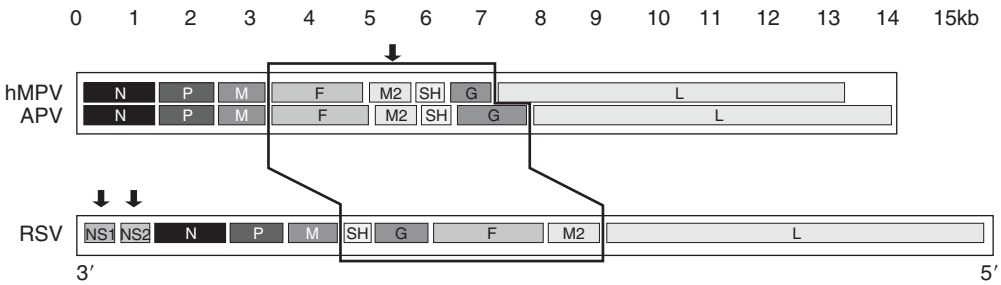

Figure 195–1 Genomic map of human metapneumovirus (hMPV) compared with avian metapneumovirus (APV) and human respiratory syncytial virus (RSV). The putative open-reading frames and the approximate nucleotide positions within the genome are indicated. The arrows signify areas of difference in gene constellation among hMPV, APV, and RSV.

primate pathogen associated with respiratory tract disease.[88] Intranasal inoculation of guinea pigs and ferrets does lead to the production of virus-specific antisera but no clinically obvious infection.[88] Mouse and cotton rat models have been developed for the study of hMPV infections.[78]

EPIDEMIOLOGY

GEOGRAPHIC DISTRIBUTION

hMPV has worldwide prevalence involving all continents but Antarctica and has universal seroprevalence in both the Northern and Southern Hemispheres.*

SEASONAL PATTERNS

hMPV has been recovered from children with respiratory illnesses throughout the year.[27,46,65,69,90,99] In temperate climates, hMPV infections peak in late winter and spring. This peak activity coincides with or occurs shortly after the peak of RSV respiratory infections.

STRAIN VARIATION

In contrast to influenza virus, of which a small number of strains spread around the world each year, outbreaks of hMPV appear to be local phenomena.[46] An outbreak in one community in one season might involve genotype A, whereas the major genotype in another community might be B. In a given year, viruses of both genotypes and their respective subgroups can circulate. Vicente and associates[93] looked for differences in clinical severity in 55 children infected with genotype A and 14 children with genotype B infections. Pneumonia occurred more frequently in genotype A infections (27.3%) than in genotype B illnesses (0%) ($p = .03$). Children with genotype A infections also were more likely to have oxygen saturation of less than 90 percent (21.8% vs. 0%), to be hospitalized (63.6% vs. 42.8%), and to be admitted to an intensive care unit (9.1% vs. 0%).

INCIDENCE AND PREVALENCE

Prospective observation for hMPV disease in the Netherlands and Finland during the winter of 2000 detected the virus in 9 and 10 percent, respectively, of respiratory samples from children with unexplained respiratory tract infection or acute wheezing.[45,88] In the United States, hMPV was detected retrospectively in 4 percent of hospitalized children younger than 5 years old with an acute respiratory illness in which a viral agent could not be identified.[65] In contrast, a community-based retrospective analysis of children in Tennessee during a 25-year period confirmed the presence of hMPV in 20 percent of nasal wash specimens collected from children with an undiagnosed lower respiratory tract illness.[99] In Australia, the annual detection rate of hMPV in respiratory specimens from children was 4.5 percent, although the incidence increased to 13 percent during the months of peak disease activity.[58]

hMPV infection in children, like RSV infection, inflicts its burden on children younger than 2 years old, particularly those younger than 12 months.[65,88] In children hospitalized for acute respiratory infection in the United States, hMPV affected predominantly children 0 to 12 months of age (50%), followed by those aged 1 to 2 years (42%).[65] Of these infants, infection occurred more commonly in the 7- to 12-month age group (31%) than in those aged 0 to 6 months (19%).[65] Children of white descent were overrepresented compared with children of all other races (65% versus 35%) in this series of patients.[65]

In numerous studies, the percentages of hMPV-caused respiratory illnesses in children has been compared with similar illnesses caused by RSV and other respiratory viruses as well.* In general, in any single year, RSV infections occur two to three times more frequently than do hMPV virus infections. Overall, rhinoviral and RSV infections occur most frequently, whereas adenoviral, parainfluenza virus 1, parainfluenza virus 3, and human bocavirus infections have a frequency similar to that of hMPV infections.

hMPV is assumed to be widely prevalent on the basis of the high level of hMPV-specific serum antibodies in the community. In the Netherlands, 70 percent of children demonstrated hMPV antibodies on immunofluorescent antigen assay by the time they reached 5 years of age; by the age of 10 years, 100 percent had these antibodies.[88] Similar work in Australia has confirmed the ubiquitous presence of seropositivity to hMPV, with 90 percent of the population positive at 5 years of age and 98 percent positive by 10 years.[58] Both groups have observed that total antibody titers are higher for those older than 2 years,[58,88] which may be due to serologic boosting and secondary infection in the second year of life after a primary infection when the child was an infant.

Ebihara and colleagues[25] compared the seroprevalence of antibodies to RSV and hMPV by age group. In the group younger than 4 months, the percentage positives were similar (hMPV 67% versus RSV 78%). In contrast, in the group aged 4 months to 1 year, only 11 percent of the infants had antibody to hMPV, whereas 48 percent had antibody to RSV. In the groups aged 1 to 2 years and 2 to 5 years, no significant differences in percentage positives were found between the two viruses.

Where stated, most reports of hMPV infection in children treated at hospitals have found a preponderance of affected males to females (1.2 to 2.3:1).† hMPV infections in older children have been noted, particularly in those who are immunocompromised or have a preexisting chronic lung condition.[6,26,29,70] hMPV has been touted as a potentially significant pathogen in immunocompromised transplant recipients, similar to RSV.[17,44,60] No information is available on the impact of differing socioeconomic environments on the age at initial infection with hMPV or severity of disease.

The spread of infection to nonimmune children also has yet to be determined, although it probably follows a pattern similar to that described for RSV, for which infection is introduced by an older family member.[34]

PATHOGENESIS AND PATHOLOGY

The method of transmission of hMPV is not known. However, because the virus is present in the nasopharynx in high concentrations, a reasonable conclusion is that its spread is similar to that of other respiratory viruses,[33,39] which could include contact transmission with large-particle respiratory secretions as well as hand-to-hand and hand-to-surface transmission, with self-inoculation. The virus in nasal secretions is mainly non–cell associated,[79] which suggests the possibility of small-particle aerosol transmission as well. In ill children, hMPV is shed in nasal

*See references 1, 3, 4, 6, 10-12, 16, 20, 22, 24, 27, 28, 30, 38, 42, 43, 46, 49, 50, 53, 58, 60, 62, 64, 65, 67, 68, 72, 74, 76, 81, 82, 88, 96-99, 101, 102.

*See references 1, 2, 4, 6, 11, 12, 16, 22, 25, 28, 30, 43, 49, 53, 61, 62, 67, 68, 74, 102.

†See references 1, 4, 11, 16, 30, 49, 62, 65, 88, 102.

secretions for a median of 5 days, a duration shorter than with RSV infections.[95] The case-to-case interval within households has not been well studied. In one small study, 82 percent of family members of children with hMPV infections had symptoms of upper respiratory tract infection.[95] These symptomatic illnesses occurred from 1 week before to 3 weeks after the onset of the child's illness. An older sibling was the apparent source of the illness in four of the seven young children. In addition to the presence of hMPV RNA in nasopharyngeal secretions, the viral RNA also was detected in perspiration of two of seven children and in the saliva of one of the seven children.[95]

In experimental hMPV infections in cynomolgus macaques, virus replication occurred in ciliated epithelial cells and pneumocytes, with associated lesions found throughout the respiratory tract.[46] Minimal to mild, multifocal erosive and inflammatory changes throughout the airways and an increased number of macrophages in the alveoli were noted. Vargas and associates[92] studied bronchoalveolar lavage specimens from six children with acute hMPV infections; all of these children had underlying or intercurrent diseases or both. They found epithelial degenerative changes and eosinophilic cytoplasmic inclusions within epithelial cells, multinucleate giant cells, and histiocytes.

Primary infection with hMPV results in a humoral antibody response that has been detected by neutralization in tissue culture and indirect immunofluorescence and enzyme-linked immunosorbent assay.[25,35,89]

van den Hoogen and colleagues[89] studied primary infections in cynomolgus macaques. They found that infection induced neutralizing antibody responses. The infected primates had higher antibody titer responses to homologous compared with heterologous viral strains. Postinfection antibody protected completely from homologous re-infection for 6 weeks. Eleven months after primary infection, protection had waned so that robust re-infection occurred.

With RSV and other respiratory viruses, a common hypothesis suggests that innate inflammatory responses contribute to pathogenesis.[51] Laham and coworkers[51] compared the levels of interleukin (IL)–12, tumor necrosis factor–α, IL-6, IL-1β, and IL-8 in the nasal washes of infants infected with hMPV with similar cytokine levels in infants with RSV and influenza infections. The IL-12, tumor necrosis factor–α, IL-6, IL-1β, and IL-8 levels in hMPV-infected infants were significantly lower than in those in infants with RSV infections. The IL-10 levels were low in both hMPV and RSV viral infections compared with the response in children with influenza viral infections. The authors concluded that their findings suggested that hMPV and RSV either cause disease by different mechanisms or share a common mechanism, which, however, is not the result of immune activation. Because the clinical manifestations are so similar, the latter suggestion seems more likely.

In a study using peripheral blood mononuclear cells from adults, Douville and associates[21] found that exposure to hMPV resulted in a stronger IL-6 and lower frequency, weaker intensity interferon-γ, IL-10, and CCL5 cytokine production than occurred with exposure to RSV.

Children who have a positive family history of asthma may be at increased risk for the development of postinfectious bronchial hyperreactivity or asthma.[72] Finnish children with acute wheezing episodes associated with hMPV infection had high levels of IL-8 and low levels of RANTES (regulated by activation, normal T cell expressed and secreted).[45] This finding is in contrast to that noted for RSV infections in vitro, in which RANTES concentrations (chemotactic factor for eosinophils) are high and IL-8 concentrations (chemotactic factor for neutrophils) are variable.[77] Whether the agent or the resultant disease leads to asthma or chronic lung disease is debatable, with conflicting reports in two small series of patients infected with hMPV.[45,72]

CLINICAL MANIFESTATIONS

hMPV has been found in nasopharyngeal specimens from children with both upper and lower respiratory illnesses. In numerous investigations, the clinical characteristics of hMPV infections have been compared with the clinical characteristics of RSV infections and less commonly with those occurring in other respiratory viral infections. In these comparative studies, the overall findings in hMPV infections clearly are similar to those in RSV infections. Overlapping findings also occur with human bocavirus, adenovirus, influenza virus, parainfluenza virus, and rhinovirus infections.

hMPV does not appear to be associated with asymptomatic carriage in the nasopharynx. van den Hoogen and colleagues[88] noted that no hMPV was found in respiratory samples taken from 400 asymptomatic children younger than 2 years.

UPPER RESPIRATORY TRACT MANIFESTATIONS

In a study of 41 children with hMPV infections, six were found to have upper respiratory illnesses and three had laryngotracheobronchitis.[76] Of the six with upper respiratory illness, only two were evaluated initially for respiratory symptoms. In a 20-year experience in Nashville, Tennessee, 118 children with upper respiratory illnesses were reported.[101] In this group, the following findings were noted: fever, 64 percent; coryza, 82 percent; cough, 66 percent; hoarseness, 8 percent; otalgia, 31 percent; rhinitis, 79 percent; conjunctivitis, 3 percent; pharyngitis, 44 percent; and abnormal tympanic membrane, 63 percent.

In a relatively large study in Switzerland of hMPV infections in outpatients, 5 percent had conjunctivitis, 73 percent had rhinitis, 40 percent had pharyngitis, 18 percent had otitis media, and 5 percent had croup.[4] Croup has been noted in 5 to 10 percent of cases in three other large studies.[1,11,12] In other studies, upper respiratory illness and common cold have been noted in association with hMPV infections.[1,12,78]

Acute otitis media is a common complication of hMPV infection.[38,78,100,101] In a study in Finland, 41 percent of 39 children with hMPV infections had acute otitis media.[38] The frequency of this complication was 61 percent in children aged 1 to 2 years old, 27 percent in those aged 2 to 4 years old, and 17 percent in those aged 5 to 9 years old. In a 25-year cohort of children with hMPV lower respiratory infection, one third of the children had acute otitis media.[100] In eight children with acute otitis media and hMPV infection, six had bacterial pathogens identified in middle ear fluid.[100] In one of these cases, hMPV was also identified in the middle ear fluid.

In another study of acute otitis media, 13 percent of the cases occurred in hMPV-infected children.[78] In a study in Japan in which eight children had acute otitis media in association with hMPV infection, three had hMPV identified in middle ear fluid.[83] Two of these children also had *Streptococcus pneumoniae* identified in the middle ear fluid. In other large studies, acute otitis media has been noted in 8 to 26 percent of hMPV infections.[1,4,81,98,102]

LOWER RESPIRATORY TRACT MANIFESTATIONS

The clinical manifestations of hMPV infections have been itemized in numerous studies, many of which have compared the findings with those occurring in RSV infections.* Because the frequency of clinical manifestations varies in different studies, defining meaningful differences between the clinical manifesta-

*See references 1, 3, 4, 6, 11, 12, 16, 24, 27, 29, 30, 43, 49, 64, 65, 67, 71, 72, 74, 81, 82, 86, 88, 97-99, 102.

TABLE 195–1 Symptoms and Signs in Young Children with Human Metapneumovirus Lower Respiratory Tract Infections*

Clinical Feature	Frequency Ranges (%)
Fever	50-90
Cough	50-90
Coryza	50-90
Respiratory distress	40-80
Crackles, rales	8-60
Wheezing	30-50
Tachypnea	60-90
Anorexia	40-60
Vomiting	10-20
Diarrhea	20-40
Pharyngitis	40-60
Irritability	40-60
Conjunctivitis	7-10
Rash	5-10
Otitis media	10-26

tions of hMPV infections and those of RSV infections is difficult. Bronchiolitis appears to occur more frequently in RSV infections and pneumonia more frequently in hMPV infections.[11,20] In a study in Norway, 48 percent of the hMPV infections were diagnosed as bronchiolitis, whereas 83 percent of the RSV infections had the same diagnosis ($p = .005$).[20] In the same study, pneumonia was diagnosed in 34 percent of the hMPV infections but in only 11 percent of the RSV infections. In this same study, children with hMPV lower respiratory tract infections appeared to be generally older than RSV-infected children with similar illnesses. Seventy-five percent of the RSV illnesses occurred in children who were younger than 2 years old, whereas only 50 percent of the hMPV illnesses occurred in the same time period.

Frequency ranges of symptoms and signs in hMPV infections in young children are presented in Table 195–1. As can be seen, the ranges vary considerably by feature in the studies reviewed. Presented in Figure 195–2 is the chest radiograph of a child with hMPV pneumonia.

In a study in Australia conducted between 2001 and 2004, 273 infections with hMPV were analyzed.[81] Of this total, 76 percent had an illness requiring hospitalization for 3 days or longer. Severe disease occurred in 10.6 percent of the children. Robinson and associates[76] noted 41 children with hMPV infections. Of this group, the majority were hospitalized, and 68 percent had an underlying medical condition. One child with multiple congenital anomalies including heart defects died. This child had pneumonia with a plural effusion. In another study, 35.2 percent of children with hMPV infections had associated underlying medical problems, such as a history of premature birth, chronic lung disease, complex congenital heart disease, and compromised immunity.[27] In a study in South Africa, 31 percent of the hMPV-infected children had underlying problems, including congenital heart disease in six, human immunodeficiency virus (HIV) infection in five, premature birth in two, chronic lung disease in two, acute lymphoblastic leukemia in one, gastroenteritis in four, renal failure in one, and gastroesophageal reflux in four.[64]

hMPV infection commonly is associated with recurrent wheezing and infectious asthma.[24,30,46,99] As might be expected, febrile convulsions are not uncommon occurrences in hMPV lower respiratory tract illnesses.[3,24,98]

Co-infections with hMPV and RSV were found to be more severe in several studies.[47,63,80] In a study in England, children with dual infections (hMPV and RSV) were more likely to be admitted to an intensive care unit for mechanical ventilation than were children with single-agent infections.[80] Madhi and coworkers[59] found that children hospitalized with hMPV infections frequently had pneumococcal co-infections.

INFECTIONS IN IMMUNOCOMPROMISED PERSONS

In a recent review, Kahn[46] noted that hMPV illnesses in immunocompromised patients often were prolonged and serious and occasionally were associated with death. However, most studies have involved adults and not children.[17,19,26] The most experience with hMPV infections and the immunocompromised state has occurred in children with HIV infections.[59,60,64] In one study, hMPV infections in 45 HIV-infected children were compared with hMPV infections in 154 children without HIV infections.[60] In this study, the HIV-infected children had a lower mean oxygen saturation, were less likely to have bronchiolitis, were more likely to have pneumonia, were more likely to have a longer hospitalization, and were more likely to have a positive bacterial blood culture than were the children who did not have HIV infections. In addition, two of the HIV-infected children died, whereas none of the non–HIV-infected children died. In another study, an HIV-infected child died with a nosocomially acquired hMPV infection.[64]

In cystic fibrosis, hospitalization for pulmonary exacerbations was associated with hMPV infection.[29]

ENCEPHALITIS AND ENCEPHALOPATHY

Glaser and associates[32] analyzed 1570 patients with encephalitis; in this study, there were four hMPV infections temporally related to the encephalitis. Before that study, Schildgen and coworkers[78] noted a similar association in a single patient, and, most recently, Hata and colleagues[37] described a fatal encephalopathy in a 6-month-old girl with hMPV infection. Computed tomographic scan of the brain showed low-density areas in the white matter.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

The findings in hMPV respiratory infections are similar to those found in RSV infections as well as in human bocavirus, adenoviral, influenza viral, parainfluenza viral, and rhinoviral infections. With pneumonia, primary and secondary bacterial infections should be considered.

SPECIFIC DIAGNOSIS

Presently, reverse transcriptase (RT)-PCR is the most common method used to detect hMPV.[63,66,84] Specimens for PCR may be obtained by nasopharyngeal aspiration, nasopharyngeal swab, nasal wash, or bronchoalveolar lavage. Primer pairs for RT-PCR have used conserved genomic regions of the M, N, F, and L open-reading frames of the hMPV genome.[6,45,46,66,71,72,82,84,99] Real-time RT-PCR also has been developed, and with selected primers, both subgroups of both genotypes as well as other respiratory viruses can be detected.

hMPV grows poorly in cell culture, and growth requires supplementation of the medium with trypsin.[46] In general, cell culture is not clinically useful for diagnosis. However, the use of LLC-MK2 cells in shell vials offers promise.[75]

hMPV can also be detected in respiratory secretions by immunofluorescence.[46,66] Antibody to hMPV can be detected by virus neutralization by plaque reduction in tissue culture.[18] At present, no commercial tests are available to detect IgG or IgM antibodies to hMPV.

TREATMENT

Treatment that has been supportive in hospitalized cases has included regular nasal suctioning, intravenous fluids, oxygen therapy, and mechanical ventilation when necessary.[62,88]

Ribavirin has been shown to have antiviral activity against hMPV in vitro and in mouse models.[36,63,66,84] An adult patient with severe hMPV pneumonia after lung transplantation recovered after receiving treatment with intravenous ribavirin for 15 days.[73] This patient initially did not improve with inhaled ribavirin for 4 days. The sulfated sialyl lipid (NMSO3), heparin, and a low-molecular-weight benzimidazole derivative all have been shown to have in vitro activity against hMPV.[46,84,103] In a cotton rat system, a recombinant human monoclonal antibody to hMPV fusion protein (FabDS7) had a treatment effect when administered intranasally 3 days after infection occurred.[104]

PROGNOSIS

The full spectrum of hMPV infections and possible sequelae are presently not known. Most infections are self-limited. However, severe infections requiring mechanical ventilation occasionally occur in previously normal children, and fatal illnesses have occurred in immunocompromised patients.

PREVENTION

Good infection control practices in health care environments are the only preventive measures for hMPV infection. At present, no vaccine or immune globulin or monoclonal antibody is available for the active or passive immunization against hMPV. However, in animal model systems, both active and passive biologic agents have shown promise.[15,40,41,46,85] Similar to the past experience with formalin-inactivated RSV vaccines, enhanced pulmonary disease has occurred after challenge in cotton rats immunized with a formalin-inactivated hMPV vaccine.[98]

Ulbrandt and associates[85] have shown that two different monoclonal antibodies that bind to the hMPV F protein were protective in hamsters. Their studies suggest that this approach could be useful in preventing respiratory illness caused by hMPV in high-risk young children.

SUBSECTION 8

Rhabdoviridae

CHAPTER 196

Rabies Virus

Stanley A. Plotkin ❂ H. Fred Clark ❂ Charles E. Rupprecht

Rabies is an acute, progressive viral infection of the central nervous system (CNS) transmitted from animals to people. Introduction of the agent by bite, scratch, or aerosol enables it to attach to and travel up the nerves to the brain. The encephalitis so caused is characterized by hydrophobia and almost always is fatal.

HISTORY[114,205]

Rabies has a long and colorful history. The Greeks called the disease *lyssa*. Democritus is thought to have made the first description of rabies in the dog in 500 BCE. The ultimate derivation of the English word *rabies* is from the Sanskrit word *rabhas*, which means "to do violence." Early writers believed that rabies followed the rising of the star Sirius, and the disease became associated with the dog days of summer.

Celsus, the Roman physician, writing in 100 CE, displayed an accurate understanding of the disease by attributing infection to a "virus" (i.e., a poison) in the saliva. He advocated cauterization of the wounds produced by rabid animals. Galen, writing a century later, advised surgical resection as the method for preventing rabies.

Rabies was well known in Europe during medieval times. The great Mohammedan physicians also mention it in their writings. Epizootics, however, were not recorded until 1271, when rabid wolves attacked people in Franconia. Epizootics associated with wolves then occurred frequently in various areas of Europe until early in the 18th century, when outbreaks of rabies in domestic dogs began in cities. Canine rabies probably was transmitted from Europe to the New World, where it became a common occurrence in North America and the West Indies by the 18th century and spread to South America early in the 19th century. However, the existence of rabies in New World bats probably predates that importation. The history of the disease in Asia is not as well known, but rabies clearly has been present since ancient times in China and India, although the current variants may be from a relatively recent crossover.[102]

The scientific study of rabies began with the demonstration by Zinke in 1803 that saliva transmitted the disease. The modern prevention of rabies was made possible by the work of Louis Pasteur in the 1880s. He showed that rabies could be transmitted by intracerebral inoculation of a preparation made from the brain of a rabid dog into uninfected rabbits or dogs and then serially transmitted by the same route. He thus demonstrated that rabies is a disease of the CNS. Among Pasteur's other discoveries were

the differentiation of furious and dumb rabies, the production of rabies by the intravenous route, and the attenuation of rabies virus in the dried spinal cords of infected rabbits. The famous episode of Joseph Meister, the French boy who received rabies vaccine in 1885, demonstrated that serial inoculations of dried infected rabbit spinal cord, proceeding from those containing most attenuated virus to least attenuated, in principle could protect against rabies.

Vaccination with nerve tissue vaccines quickly became standard, with important modifications being introduced by Roux, Fermi, and Semple. Semple vaccines, composed of infected sheep or goat brain tissue suspensions in which virus is completely inactivated by phenol, became the standard vaccine in the 1920s. Fuenzalida and Palacios introduced the use of suckling mouse brain vaccines in the mid-1900s to reduce the adverse events associated with myelin in brain-derived vaccines. In the latter 20th century, nerve tissue vaccines were replaced gradually by production of cell culture in most developed nations.[92]

THE VIRUS

The rabies virus apparently can infect all species of mammals, although wide variations in the sensitivity of different species have been observed. Laboratory propagation may be accomplished readily in mice or other standard laboratory animals; in vitro in neuroblastoma or certain hamster cell cultures; or, after adaptation, in certain cell lines of human or other mammalian origin.[167]

Electron-microscopic studies reveal that rabies is a bullet-shaped virus typically maturing at cytoplasmic plasma membranes and intracellular membranes of the endoplasmic reticulum in infected cultured cells (Fig. 196–1).[104] Standard virions are approximately 75 nm in diameter and 160 to 180 nm in length. Regular arrays of standard-sized virions maturing from plasma membranes are observed in infected salivary glands. Budding of virus from plasma membrane is much less pronounced in neurons of the CNS than in cell culture or salivary gland cells. However, meticulous electron-microscopic examination of experimentally and naturally infected brains has revealed that budding from membranes of perikarya and dendrites, as well as presence of virus in intracellular spaces of brain (especially at synaptic junctions), occurs regularly.[105] In addition, CNS neurons often exhibit both typical and bizarre morphologic forms of virus maturing in the cytoplasm. Cytoplasmic forms often develop in proximity to nucleocapsid matrix inclusions (Negri bodies).[144]

The gross morphologic characteristics and biochemical composition of rabies virus place it within the family *Rhabdoviridae*, genus *Lyssavirus*. Lyssaviruses of Old World or Australian origin isolated more recently exhibit antigenic and genetic relationships to rabies, predominantly on the basis of similarities of the nucleoprotein detected by fluorescent antibody and complement-fixation tests, reactions with monoclonal antibodies, and sequencing studies of the N protein gene. Thus, seven species (often designated genotypes) are now recognized, and more may exist.[87,132,199,242]

Rabies virus is lyssavirus type 1 and continues to account for the vast preponderance of isolates. Type 2 (Lagos bat virus), type 3 (Mokola virus), and type 4 (Duvenhage) were isolated exclusively in Africa, where they have predominantly bat reservoirs, but only Mokola and Duvenhage viruses have been associated with rare human infections. Lyssaviruses associated with European bat reservoirs have been separated into lyssavirus type 5 (European bat lyssavirus 1) and type 6 (European bat lyssavirus 2, rarely associated with human disease). Lyssavirus type 7 has been identified in Australia (Australian bat lyssavirus) and has a primary reservoir in fruit-eating bats but has caused fatal human infection, thereby ending Australia's previous rabies-free status.[192] Cats in South Africa have been infected frequently with Mokola virus and have died of the infection despite having received prior vaccination.[229] Indeed, types 2 and 3 are genetically more distant from canonical rabies virus, and vaccination may not protect against them.[163] The rabies virion now is recognized to be of a molecular composition similar to that of the rhabdovirus prototype virus, vesicular stomatitis virus. It is composed of a helical nucleocapsid core, which contains the RNA genome coupled to

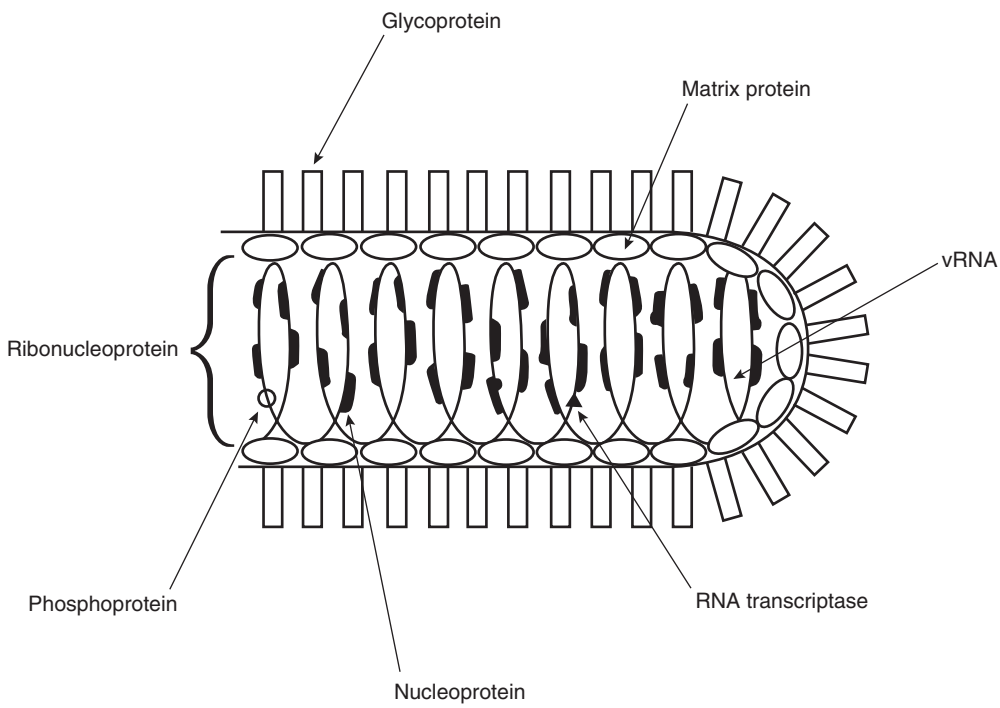

Figure 196–1 Drawing of the rabies virus. *(Courtesy of Dr. William Wunner, Wistar Institute, Philadelphia.)*

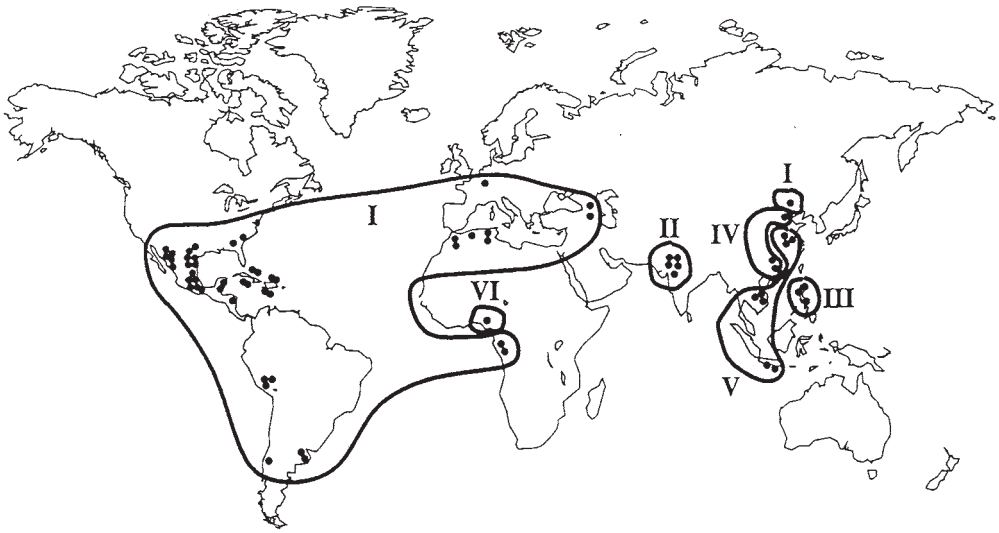

Figure 196–2 Distribution of genotypes of rabies virus. *(From Smith, J. S., Orciari, L. A., Yager, P. A., et al.: Epidemiologic and historical relationships among 87 rabies virus isolates are determined by limited sequence analysis. J. Infect. Dis. 166:296-307, 1992. Courtesy of Dr. J. S. Smith, Centers for Disease Control and Prevention, Atlanta.)*

nucleoprotein, the phosphoprotein, and a large protein presumably representing the RNA transcriptase replicase.[51] The core is surrounded by a lipoprotein envelope, which contains a matrix protein, a single glycoprotein, and lipids (primarily phospholipids and cholesterol).[29,203] The genome is a single-stranded RNA molecule containing approximately 11,932 nucleotides with a molecular mass of approximately 4.0×10^6 daltons.[28] It is a negative-stranded genome, that is, it must be transcribed to produce messenger RNA necessary for replication. Defective virions containing characteristic (for a given strain) sizes of incomplete RNA molecules have been demonstrated in cell culture-propagated virus populations, but their occurrence or role in natural infections has not been determined.

Important surface antigenic properties are associated primarily with the single glycoprotein,[203] a polypeptide containing three major oligosaccharide side chains.[60] The glycoprotein is the sole antigen responsible for induction of and reaction with virus-neutralizing antibody. Antibody to nucleoprotein administered passively has no virus-neutralizing or protective capacity but is the essential antibody for the diagnostic detection of intracellular rabies virus antigens (including Negri bodies) by immunofluorescent staining.[242] Active immunization with rabies nucleocapsid may contribute to immune protection, especially to heterotropic lyssaviruses, apparently by induction of a lyssavirus-specific T-cell immune response.[40,67]

Historically, only a single antigenic type of the rabies type 1 lyssavirus had been identified. However, strain specificity can be recognized on the basis of genomic sequence analysis[219] and strain differentiation by monoclonal antibodies. By these means, animal-specific strains and geographic distribution of strains can be discerned, and strains from human cases can be traced to the animal and place of origin.[201]

Researchers have demonstrated that rabies virus, like some other RNA virus populations, occurs as a quasi-species. The presence of viral subpopulations permits rapid adaptation to new hosts.[124,156]

Antigenic differences between both strains of fixed virus and different field isolates of diverse origin have been detected with the use of monoclonal antibodies[244] directed against glycoprotein or nucleoprotein antigens of the virus.[65] The use of monoclonal antibodies also allows easy distinction of rabies from rabies-related lyssaviruses.[187] Studies with monoclonal antibodies have revealed that worldwide, clustering of certain rabies virus antigenic subtypes is geographic and species specific.[210] As shown in Figure 196–2, at least six genetic groups of rabies viruses with relatively specific geographic localizations exist.[201] Within those areas, the virus may be transmitted by different species, such as dogs and foxes. Strains recovered from urban dogs fall into at least six variants according to the location of the city. In the United States, readily distinguishable subtypes of rabies virus have been determined to circulate in each of the major terrestrial wild mammal vector species (primarily skunks and raccoons) and in bats. Bat viruses rarely occur in terrestrial animals in North America, whereas in South America, viruses isolated from cows frequently originate from vampire bats.[65] In all well-studied rabies enzootic areas, researchers have determined that rabies circulates predominantly in a limited number of mammalian species characteristic of that area, and a single antigenic phenotype is characteristic of that transmission cycle.[65] However, distinct bat-adapted rabies virus strains may circulate independently in these areas or in areas where terrestrial animals are free of rabies. Different geographic subtypes of street rabies virus share varying proportions of the immunologically critically important glycoprotein epitopes with the vaccine strain (Pasteur) virus. Rabies viruses isolated from human cases of rabies in the United States have been shown to differ quantitatively in their glycoprotein antigenic composition from vaccine strain virus.[245] Despite intense investigation, however, no evidence supports the contention that cross-protection between the Pasteur strain rabies virus vaccine and antigenically distinguishable street strains is reduced to a degree justifying inclusion of new virus strains in human vaccines. Physicians have every reason to believe that present vaccine strains protect against all feral strains of lyssavirus type 1, provided the vaccine is sufficiently potent. The same cross-reactivity does not exist for all other lyssaviruses.

TRANSMISSION AND EPIDEMIOLOGY[41,42,221]

Infection with rabies may be induced readily in experimental animals through the oral, the respiratory, or a variety of parenteral routes. Epidemiologic evidence suggests that the vast preponderance of natural infections of humans and animals is caused by physical inoculation into subcutaneous and muscle tissue by a bite wound and rarely by exposure of mucosal surfaces; saliva is the usual body fluid that serves as the vehicle for virus to infect other animals or humans. Exceptional infections through the respiratory route have been noted in animals exposed to certain

caves heavily infested with bats and in persons exposed to virus aerosols experimentally produced in the laboratory.[115]

Domestic animals constitute the largest source of human exposure to rabies in most parts of the world. Dogs and cats are the principal transmitters of rabies to people in Asian countries, such as India, Indonesia, China, and the Philippines. The magnitude of the problem is illustrated by the fact that approximately 12,000 to 20,000 deaths are attributed to rabies annually in India alone,[240] and as many as 50,000 to 100,000 may occur throughout the world.[147] The incidence in India of two to four rabies deaths per 100,000 population may be exceeded only by that of Ethiopia, where the rate is 18 per 100,000.[92] The total number of people given postexposure vaccination probably is 4 million or more annually. On the other hand, many areas, including Japan, Italy, Switzerland, France, Spain, Scandinavia, and others, are considered to be rabies free.[30]

In a single year of an urban epizootic of dog rabies in one city in Mexico, an estimated 2.5 percent of the population received dog bites and 2.7 percent were given postexposure prophylaxis for rabies.[72] In Africa, the dog still is the most important vector, although in the south, jackals and mongooses also are common sources of rabies exposures.[27,53] In much of Africa, the incidence of rabies in people and dogs has increased in recent years because of social and political disruptions.[240]

Rabies in wildlife, predominantly foxes, now is enzootic in much of eastern continental Europe, having spread from Poland during the last 60 years.[30] This outbreak gradually has moved to involve most of Europe, excluding Great Britain and Scandinavia. However, vaccination of wildlife has reduced sharply the prevalence in the West.[113,169] The raccoon, dog, and arctic fox are important vectors in eastern Europe and Siberia.[31,123] Bat rabies exists throughout continental Europe, especially in Denmark, the Netherlands, and coastal areas.[159]

Rabies in Central and South America is related predominantly to dogs, but vampire bats also have considerable importance. Although humans sometimes are bitten, often they also are exposed to cattle infected by bat bites. However, despite common exposure, transmission of rabies from cattle to humans is an extremely rare event.[58]

In the United States and Canada, the skunk once was the rabid wild animal that most commonly attacked humans. In recent years, the raccoon has replaced the skunk as the most important potential source of infection among terrestrial mammals because of a rapid extension of raccoon rabies northward and southward from Virginia, in a range now continuous from Canada to Florida and west to Ohio.[39,68] This outbreak stems from introduction of raccoons into Virginia from a long-standing nidus of raccoon infection previously restricted to Florida and southeastern Georgia. Despite massive spread of raccoon rabies engendering great costs in terms of postexposure treatment and efforts at wildlife control, actual human cases of rabies attributable to raccoons have been rare.[5] The significance of the bat to rabies epidemiology varies. In the United States, a redoubtable reservoir of rabies in insectivorous bats is present in every state except Hawaii. This bat reservoir probably is responsible for a high proportion of all U.S. cases, including those that have no antecedent history of animal bite.[152,200] Between 1981 and 1998, an average of two human rabies cases occurred per year; 12 imported cases resulted from dog bites. However, between 1990 and 2005, 31 of 34 domestic cases (excluding four transplant-transmitted infections)[204] were caused by bat strains of rabies, predominantly strains from the silver-haired and Eastern pipistrelle bats.[3,37,81,123,167] The same trend has been observed in Canada.[11]

Strains isolated from the silver-haired bats are better able to grow in non-neuronal cells, and although prophylactic vaccination is effective, the infectiousness of these strains apparently is high.[158] In Colorado, 15 percent of tested bats were positive for rabies,[167] which may be a relatively silent infection in that mammal.[182]

Bats may bite sleeping humans but leave little trace behind.[2,129,235] Therefore, vaccination always is indicated if a confirmed rabid bat is found in the chamber of a sleeping person, and it may be indicated if a bat entered the chamber but escaped if there is a reasonable probability of bite exposure. In Europe, bats have been responsible for transmission of rabies-related lyssaviruses. Despite the rarity of this event, bats and vampirism are linked inextricably in legend with Dracula, the 15th-century despot who lived in current-day Romania.[94] In contrast, true vampire bats in Central and South America are responsible for considerable losses of domestic animals as well as human cases.[15]

On the average, only one or two cases of human rabies are reported in the United States each year, but thousands of animals still are infected. The distribution of infection among animals is shown in Table 196–1.[128] The cat now is a more important host of domestic rabies than is the dog.

True canine rabies has been eliminated in the United States. Moreover, vaccination has curtailed the prevalence of rabies in cats in the United States so greatly that many cities and other areas may be considered free of rabies in terrestrial animals, although the new spread of raccoon rabies has reversed this trend in the Middle Atlantic states. The importance of these facts is discussed under Postexposure Prevention.

As a result of the rarity of human rabies in the United States, many cases have not been diagnosed until autopsy. Transmission of rabies by corneal transplant to a new host from fatal cases of undiagnosed encephalitis has been reported.[104,204]

TABLE 196–1 Cases of Animal Rabies in the United States, 2004

PATHOGENESIS[66,106]

The initial stages of the infectious process are the least understood. Disease certainly depends on the entry of the virus into peripheral nerves, after which centripetal spread occurs rapidly. Replication of virus in muscle cells at a peripheral inoculation site has been demonstrated experimentally, and the virus has been shown to persist in myocytes at least 60 days after inoculation[45] but has not been proved to occur in nonexperimental situa-

tions.[46,160] Nonetheless, replication at a low level in myocytes, followed by subsequent infection of nerve cells, would explain the occasionally extended incubation periods of disease. Entry of virus into the peripheral nerve endings is mediated by attachment to the nicotinic acetylcholine receptor and other ganglioside receptors such as neural cell adhesion molecule (NCAM).[133] Once the virus is in the nervous tissue, spread can occur by cell-to-cell contact.[44,220] In any case, virus is thought to enter peripheral nerves at an extremely variable time after exposure, presumably at the site of neuromuscular or neurotendinal spindles, at motor end-plates, or (in the case of aerosol exposure) at olfactory end-organs.[161] Viremia apparently is an inconstant occurrence and of no import in the dissemination of infection.

The fact that virus transits along nervous pathways has been demonstrated by repeated experimental observations that the progress of disease may be interrupted by surgical excision or chemical destruction of nerves at sites central to the inoculation site.[19] Central progression of virus along neuronal pathways also has been demonstrated by electron-microscopic, immunofluorescent, and serial infectivity studies. Virus appears to be sequestered within neuronal cells during transmission (by axoplasmic flow) through peripheral nerves, and the virus can, therefore, be used experimentally to trace synaptic circuits.[119] Intra-axonal retrograde transport appears to be aided by interaction of the rabies virus P protein with the cytoplasmic protein dynein light chains.[109,181] Minimal numbers of virions are observed within neurons, and connective tissue elements of nerve sheaths never are infected. Because little maturation and release of virus from nerve plasmalemmal membranes occur during transit, little or no virus is presented to the immune system, which explains the absence of detectable humoral antibody until late in the disease that is characteristic of even prolonged incubation periods with rabies. Nonetheless, neutralizing antibody can enter the neuronal cytosol by endocytosis and block viral transcription.[64]

Virus enters the CNS at the spinal cord and thereafter travels rapidly to the brain. Early selective infection of the limbic system in the brain may cause disease characterized by extreme excitability and agitation (furious rabies), whereas the encephalitic depression symptoms are associated with early, widespread infection in the brain.[151] In either case, infection rapidly spreads to infect nearly all brain neurons within a few days of the onset of brain infection and CNS symptoms. Brain infection leads rapidly to death by mechanisms that are poorly understood. Fatal cases of encephalitis reveal little damage of neuronal cells, despite the ubiquitous neuronal infection.[82] On the other hand, persons kept alive by vigorous supportive therapy for lengthy periods of time after onset of disease may develop severe histopathologic encephalitic lesions. Studies in mice have shown that apoptotic mechanisms may be induced by rabies virus[107,224] and that more virulent rabies virus strains induce less apoptosis by expressing less G protein in neurons[157] or, alternatively, that the rabies G protein expression contribute to pathogenesis by down-regulating apoptosis.[157] Although ascending infection is specific to neurons, once the brain is infected, rabies virus spreads centrifugally to peripheral nerve plexuses, salivary glands, muscle fibers, and hair follicles.[108]

The entire manner of progression of the infecting virus, particularly those points in its transit vulnerable to immune intervention, remains to be determined fully. Clearly, preexisting humoral antibody protects, apparently by inactivating virus before it gains entry into the nervous system. After an immunized person is exposed to rabies, disease can be delayed or prevented in some cases by passive antibody, interferon treatment, or both,[112] but protection becomes efficient only when active immunization with potent vaccine accompanies such treatment.

That neutralizing antibodies are key to protection against rabies has been obvious for many years. However, studies have demonstrated the complexity of the immune response.[162] Although some experimental evidence argues for the importance of cytotoxic T lymphocytes in protection against rabies, Hooper and colleagues[103] infected mice that were unable to mount a cellular response and found no difference in disease with respect to normal mice. Nonetheless, early inflammatory responses, as well as rapid production of antibody, correlated with recovery from rabies. Thus, interferon and other mediators may supplement antibody in the prevention of rabies. Interestingly, rabies-specific cytotoxic T lymphocytes do not develop during the disease, and wild rabies virus may act as an immunosuppressor. Moreover, chemical immunosuppression enhances the development of experimental rabies. Interferon[20] and interleukin-2,[166] both important immunomodulators produced by cells, enhance protection against rabies. More sophisticated understanding of rabies pathogenesis is required before ideal combinations of immunotherapeutic procedures, possibly including interferon, finally can be formulated.

The reverse side of the coin is shown by the "early death" phenomenon, in which exposed animals or humans developed earlier onset of rabies if previously they had been immunized only partly. Sugamata and associates[207] have shown that early death depends on the presence of T cells, indicating that it is mediated by an immunopathologic cellular response. In addition, some authors have argued that cytotoxic T lymphocytes actually may contribute to rabies neuritic paralysis.[207,239]

CLINICAL MANIFESTATIONS

IN ANIMALS

Rabies encephalitis in animals is expressed in either a paralytic (dumb) or furious syndrome. Typical infections are characterized by behavioral changes and a rapid clinical course leading to coma and death, but rarely encephalitis can be nonfatal.[17] Because literally millions of animal bites of humans occur annually in the United States, the identification of aberrant behavior is a critical factor in many decisions to administer prophylaxis for rabies.

The prodromal stage of disease is marked by nonspecific signs, such as restlessness and malaise. Subsequently, placid dogs, cats, cattle, or horses may become vicious. Fear of humans and of areas frequented by them may be lost by wild animals. Thus, rabid foxes, normally nocturnal, may be seen wandering abroad in daylight, even in populous areas. Similarly, rabid bats often have been encountered flying in daytime hours. Early behavioral changes are not accompanied by paralysis.

The clinical course progresses rapidly to either dumb or furious disease. Dumb rabies typically is a depressed encephalitic disease. In addition to lethargy, selectively severe paralysis of throat muscles may be observed, which causes drooling of saliva because of difficulty in swallowing. Hydrophobia is not noted in animals. Furious rabies is characterized by an unusual state of alertness in which any visual or sound stimulation may incite an attack. Animals may roam indiscriminately, frequently feeding on stones, twigs, and other inanimate objects. Pets alternatively may exhibit unusually affectionate and playful behavior and then viciously bite those playing with them. Biting behavior may be noted by herbivores such as horses, mules, and cattle as well as by normally carnivorous pets and wild animals.

Both dumb and furious rabies have a rapid clinical course in domestic and wild animals. The period between onset of prodromal signs and death caused by respiratory paralysis rarely exceeds 7 to 10 days.[214] Although 10 days usually is given as the limit of virus excretion in the saliva of dogs before death supervenes, rare exceptions involving longer excretion have been reported experimentally and in animals observed in both Africa and Asia.[74,226]

The diagnosis of rabies in an animal depends on the demonstration of rabies antigens in the brain by fluorescent antibody

stains or of rabies RNA by reverse transcriptase–polymerase chain reaction (RT-PCR).

Control of Animal Rabies

Aside from large-scale removal of potentially rabid animal species, such as stray dogs, the most potent control method is vaccination. In domestic animals, immunization is accomplished readily by a variety of veterinary vaccines, although boosters must be given annually or after other stated intervals, depending on the vaccine.[4]

In wild animals, primarily raccoons in the United States and foxes in Europe, oral vaccination with use of baits containing vaccinia-vectored rabies glycoprotein or attenuated live virus has been successful.[68,169]

IN HUMANS[150,232,234,253]

The incubation period of rabies in some cases may be so long as to qualify it as a slow virus disease. Well-documented cases have occurred as long as 6 years after the bite.[232] However, most cases occur within 20 to 90 days after exposure. The shortest incubation period appears to be 7 to 10 days.

That incubation periods are longer after bites on the legs than after bites on the face is well known. The reason for this duration appears to be related not to the length of the nerve that the virus must traverse, because it travels rapidly even from the farthest site, but to the extent of innervation of different parts of the body. Bites on the tips of the fingers or on the genitalia have relatively short incubation periods for this reason. Children in general tend to have shorter incubation periods. Curiously, cases of vaccination failure tend to have shorter incubation periods, a fact that also is observed in experimental trials in animals. This early death effect is discussed under "Pathogenesis."

Hemachudha[96] has published a comprehensive review of human rabies. The first symptoms of rabies usually are vague and insidious. The patient simply may feel unwell or have anxiety or depression. Some fever or nausea may be present. The most striking prodromal symptom is itching, pain, or tingling at the site of the bite. This paresthesia is not present always and may take various forms, but its localization is a definite harbinger of rabies. The prodrome lasts 2 to 10 days, when the acute neurologic phase begins. The symptoms of this second phase are divided into furious versus paralytic rabies, most cases being in the furious category.

In furious rabies, the emphasis is on agitation, hyperactivity, fluctuating consciousness, bizarre behavior, and perhaps nuchal rigidity. Sore throat and hypersalivation are prominent complaints, and laryngospasm may cause hoarseness.

The legendary but all too real pathognomonic sign of furious rabies is hydrophobia. Initial attempts to swallow liquid result in painful spasms of the pharyngeal and laryngeal muscles, with aspiration of the liquid into the trachea. A conditioned response appears to be created, in which fear exacerbates the actual spasms. Warrell and associates[233] have hypothesized that brain stem encephalitis leads to destruction of inhibitors of inspiratory motor neurons. Respiratory tract instant reflexes are exaggerated, leading to inspiratory spasms. The hydrophobia has an important psychological element. In an extreme case, spasms occur if the patient merely is approached with water. Also frequently present is aerophobia, in which spasms occur when a current of air is fanned across the face. Priapism and increased libido also have been reported.

The neurologic examination findings in rabies are not uniform. Meningismus is a commonly occurring abnormality. Even more common occurrences are cranial nerve signs, particularly paralysis of the palate and vocal cords. The voice may develop a hoarse, barking quality. The reflexes may vary from hyperactive to absent, and involuntary movements are prominent. Magnetic resonance imaging shows involvement of gray matter in the hippocampus, hypothalamus, and brain stem.[143]

A distinct pattern of neurologic involvement is shown by approximately 20 to 30 percent of patients with rabies, particularly those bitten by vampire bats. Flaccid paralysis may start in the limb that was bitten originally and spread to other limbs. The cranial nerves become involved, and the face, rather than showing agitation, becomes expressionless. Hydrophobia is not a feature. Paralytic rabies is confused easily with Guillain-Barré syndrome. Hemachudha and colleagues[97,98] emphasized the importance of fever, intact sensation, urinary incontinence, and percussion myoedema in paralytic rabies.

The cerebrospinal fluid (CSF) is abnormal in a minority of patients, particularly those in whom meningismus is present clinically. When abnormal, the CSF shows a mild pleocytosis, mainly mononuclear. The peripheral white blood cell count shows increased polymorphonuclear cells.

The acute neurologic phase lasts 2 to 10 days, with eventual deterioration of the patient's mental status into coma. The patient may survive in this state for 2 weeks, particularly in dumb rabies. Before the final deterioration, the patient may have alternating periods of wild agitation and alert cooperation. During the alert state, patients may be able to discuss their illnesses and express fear of impending death. However, most often, death rapidly follows onset of coma unless intubation and ventilatory assistance are offered, in which case survival may be prolonged for months. During the comatose state, a variety of problems may be present, including cerebral edema, inappropriate antidiuretic hormone secretion, diabetes insipidus, and other manifestations of hypothalamic dysfunction; hypotension or arrhythmia; and pneumonia. Death caused by rabies in the acute stage occurs because of cardiac or respiratory problems. Cardiac arrhythmias with circulatory collapse commonly occur, and virus may be recovered at autopsy from the heart, which shows pathologic evidence of myocarditis. Respiration becomes increasingly labored, and death may occur during a laryngeal spasm or aspiration.

However, survival has been documented in a small number of individuals who had been vaccinated[7,38,91,178] and in a 15-year-old girl who was treated with coma induction, midazolam, ribavirin, ketamine, and amantadine.[252] The last two drugs may have rabies receptor blocking ability.

DIAGNOSIS

The diagnosis of rabies in humans begins with its diagnosis in the animal. The technique now most commonly used is to stain the brain of the previously apprehended animal with a fluorescein-labeled antibody to rabies. More recently, enzyme-coupled antibodies have been introduced, allowing the colored product to be seen under the light microscope. Rabies RNA also can be detected by dot hybridization or by RT-PCR amplification.[117] Virus isolation is used for confirmation, either by the classic procedure of intracerebral inoculation in mice or by inoculation of neuroblastoma cells followed by fluorescent antibody staining for rabies virus antigen.

Although the clinical expression of the disease in humans often is characteristic and establishment of the diagnosis is simplified by having a history of known exposure to an animal bite, encephalitic illness may occur, in which rabies virus involvement cannot be diagnosed with certainty without laboratory assistance.

When a patient has a history of being bitten by an animal, paresthesia at the wound site, and hydrophobia, determination of a clinical diagnosis of rabies is not difficult. Other diseases in which encephalitis occurs, such as those caused by arboviruses,

TABLE 196–2 Antemortem Diagnostic Test Results for 20 Human Patients with Rabies in the United States, 1980-1996

Test	No. of Patients Positive for Rabies Virus/Total No. Tested (%)	Earliest Positive (Day of Test Illness)
RT-PCR of saliva for rabies virus RNA	10/10 (100)	5
Brain biopsy for rabies virus antigen	3/3 (100)	8
Nuchal skin biopsy for rabies virus antigen	10/15* (67)	5
Virus isolation from saliva	9/15† (60)	5
Antibody to rabies virus in serum	10/18 (56)	5‡
Rabies virus antigen in touch impression from cornea	2/8 (25)	14
Antibody to rabies virus in cerebrospinal fluid	2/13 (15)	15§

**Two patients had earlier skin biopsy findings that were negative but became positive on subsequent biopsy.*
†One patient had an earlier test result that was negative.

Data from Noah, D. L., Drenzek, C. L., Smith, J. S., et al.: Epidemiology of human rabies in the United States, 1980 to 1996. Ann. Intern. Med. 128:922-930, *1998.*

enteroviruses, and herpes simplex virus, occasionally may cause confusion. However, if one finds signs of brain stem involvement in a patient whose sensorium basically is clear and who has no signs of a space-occupying lesion, the other diagnoses usually can be set aside.

Paralytic rabies may be misdiagnosed as Guillain-Barré syndrome, poliomyelitis, or post–rabies vaccine encephalomyelitis. Careful neurologic examination and analysis of the CSF often help rule out these diagnoses.

The spasms of tetanus can cause momentary confusion, but trismus is not part of rabies, and hydrophobia is not part of tetanus. Botulism (wound or ingestion) will cause paralysis, but the absence of sensory changes should exclude rabies.

Postvaccination encephalitis after nerve tissue vaccine poses a diagnostic problem in countries in which it still is used. It may require the performance of laboratory tests.

Perhaps the most confusing differential problem is hysteria in a person who thinks he or she has rabies. Normal blood gas analyses and the absence of variation in bizarre behavior suggest pseudorabies. Psychiatric and drug-induced reactions also may cause transient diagnostic problems.

Laboratory diagnosis now is possible before death. The virus may be demonstrated by fluorescent antibody stain of smears of corneal epithelial cells[126,195] or sections of skin from the neck at the hairline.[34,202] These test results are positive because virus migrates down the nerves from the brain, and both the cornea and hair follicles are richly innervated.

Serologic diagnosis also can be obtained if the patient survives beyond the acute period. In persons not given postexposure prophylaxis, only low levels of antibodies appear.[97] In contrast, patients who have received vaccine show a rapid rise in titer of virus-neutralizing antibodies between 6 and 10 days after the onset of symptoms.[89] Such antibodies are detected most rapidly by an in vitro rapid fluorescent focus inhibition test or by mouse neutralization tests. Rabies may be diagnosed in immunized persons by a rise in titer after the onset of clinical symptoms and is suggested by any antibody titer equal to or greater than 1:5000, a level not usually achieved by vaccines. High antibody levels in CSF are characteristic late in the course of rabies encephalitis; CSF antibody is not induced efficiently by vaccination.[89,234]

Rabies virus has been isolated from human saliva between days 4 and 24 after onset of disease.[89] Virus also may be isolated in some cases from CSF, brain tissue, or concentrated urine sediment during the first 2 weeks of illness. In persons surviving longer than 2 weeks, isolation of virus from body tissues or fluids (or from postmortem brain) may be impossible, presumably because of virus neutralization by humoral antibody.

Postmortem diagnosis can be confirmed by the presence of pathognomonic cytoplasmic inclusions (Negri bodies) in brain tissue, but they are present in less than 80 percent of cases. Rabies virus antigen may be detected by fluorescent antibody examination, with higher frequency in brain tissues of persons dying after a brief, acute course of disease. In postmortem tissues, histochemical staining with monoclonal antibody to rabies virus ribonucleoprotein especially may be useful because ribonucleoprotein possesses epitopes resistant to the formalin fixation and the paraffin-embedding process.[148] In studies of paraffin-embedded brain tissues (samples up to 40 years old), digestion of sections with proteinase K followed by immunofluorescence or RT-PCR assay gave 100 percent (300 of 300) positive results.[231] However, as in the case of virus isolation attempts, identification of virus antigen in brains of persons kept alive for prolonged periods after onset of disease may be extremely difficult.

Noah and coworkers[165] have summarized the results of attempts to diagnose rabies in humans pre mortem. Their data are summarized in Table 196–2,[165,172] which shows that RT-PCR analysis of saliva and brain biopsy are the most accurate methods of diagnosis, although even they may not be positive until the fifth day of illness.

Crepin and associates[56] had 100 percent success (9 of 9) in diagnosing rabies by use of RT-PCR assay of saliva accompanied by immunofluorescent examination of skin biopsy specimens. Most of these patients were diagnosed with specimens collected less than 5 days after onset of symptoms.

Rabies now has been recognized post mortem in patients whose history included transplantation of corneas from donors dying of encephalitis. All cases of undiagnosed fatal encephalitis, therefore, should be studied for rabies, and tissue from such patients should not be used for transplantation.[174]

POSTEXPOSURE PREVENTION[173]

LOCAL TREATMENT

Removal of saliva containing rabies virus is a crucial part of treatment and should be undertaken urgently. The wound should be flushed copiously with soap and water. Some authors, including us, would follow flushing with a local application of povidone-iodine or ethyl alcohol in whatever form is available immediately. The concentration of ethanol is important; 43 percent (86 proof) or higher gives the best results.[243]

Experimental data suggest that regardless of the solution used, adequate flushing is important, particularly in puncture wounds. Catheters should be inserted into puncture wounds and fluid

instilled by means of an attached syringe.[57,197] If this procedure proves to be too painful, the area can be anesthetized safely with local procaine-type anesthetics.[118,243] Suturing should be done only in line with good surgical practice and avoided when unnecessary.

EQUINE RABIES IMMUNE GLOBULIN

An experimental basis for the desirability of combining antiserum with vaccine was established in 1954.[127] A field test of combined vaccine-serum protection was made possible by a natural disaster, the attack of a rabid wolf on 29 Iranian villagers, 18 of whom were bitten on the head and neck.[23] Rabies developed in three of five persons who were treated with nerve tissue vaccine only but in only one of 13 persons who were given antiserum with nerve tissue vaccine.

Animal rabies serum is no longer available in the United States. However, an immune globulin from the serum of rabies-immunized horses (equine rabies immune globulin) is used extensively outside of the United States because of its lower price and greater availability (compared with human rabies immune globulin).[249] To reduce allergic reactions, pepsin digestion is used to convert the intact equine globulin to a $F(ab')_2$ preparation. The product is dispensed at a concentration of 200 IU/mL, and the dose that should be administered is 40 IU/kg, as much as possible infiltrated into the wound. Administration of higher doses may dampen the active immune response. The manufacturers recommend an intradermal skin test with equine products, but the sensitivity and specificity of the test for prediction of subsequent allergic reactions are poor, and abandonment of the skin test has been proposed.[250] At least one preparation of equine rabies immune globulin was purified sufficiently so that the allergic reaction rate was less than 1 percent,[248] whereas another yielded a 6 percent reaction rate.[247] Anaphylaxis with current equine rabies immune globulin rarely occurs.[193] A new equine rabies immune globulin is now available, heat treated to reduce the risk of viral contamination.[135] Because of shorter half-lives of fractional $F(ab')_2$ preparations, the World Health Organization (WHO) recommends human rabies immune globulin for severe bite exposure.

HUMAN RABIES IMMUNE GLOBULIN

To avoid possible reactions to animal proteins, gamma globulin was prepared from the plasma of volunteers hyperimmunized with rabies vaccine. Although expensive, human rabies immune globulin is preferable to equine rabies immune globulin for use in postexposure prophylaxis in the United States. Because the gamma globulin is homologous in humans, human rabies immune globulin persists longer in the circulation of inoculated persons but, for this reason, may have an even greater dampening effect on active immunization. Thus, Hattwick and associates[90] found that 23 doses of the old duck embryo vaccine were needed to overcome the suppressive effect on antibody production of 15 to 40 units of human rabies immune globulin per kilogram.

Pharmacokinetic measurements[95,142,146,186] resulted in a recommendation to give 20 IU of human rabies immune globulin per kilogram immediately, with as much as possible being injected locally. Local injection is important because serum levels of antibody after intramuscular injection are not high.[47] Although intravenous administration of human rabies immune globulin produces higher serum titers,[12] local injection still is preferred. No further dose is necessary or desirable because excessive antibody diminishes the active response to vaccine. Two equivalent preparations are available in the United States, one produced by Sanofi Pasteur and the other by Talecris.

If neither equine nor human rabies immune globulin is available, vaccination should be started immediately, followed by administration of human rabies immune globulin if it arrives within a week.[121] Because of the expense and occasional difficulty in obtaining adequate supplies of human rabies immune globulin as well as substantial variability of immunoglobin products tested in an animal model,[88] the WHO now is exploring the possibility of using instead "cocktail" mixtures of neutralizing monoclonal antibodies to rabies virus prepared in either murine[196] or human[62] hybridoma cell cultures. Such cocktails have shown effectiveness in animal studies.[22,86,179]

NERVE TISSUE VACCINE

Although used for 100 years following the introduction of the original Pasteur vaccine, nerve tissue vaccines are being replaced increasingly by cell culture vaccines in developing countries. Vaccines made in sheep brain or goat brain were widely used throughout Asia and Africa but were associated with a definite incidence of postvaccinal encephalitis.[14] The susceptibility to rabies vaccine–induced encephalomyelitis has been suggested to vary according to the genetic pattern of major histocompatibility class II alleles in the vaccinated host.[171] Suckling mouse brain vaccines are still used to some degree in Latin America to decrease sensitization to myelinated nerve tissue, which is thought to be the cause of autoimmune allergic encephalitis.[83]

However, a study from Tunisia found no evidence for humoral response to myelin in patients with encephalitis after receiving nerve tissue vaccine. Instead, antibodies to GM_1 and GD_{1a} gangliosides present on human cells were demonstrated.[138] Thus, the mechanism of encephalitis remains uncertain, beyond the conclusion that it results from non-rabies (virus) antigens in the nervous systems of animals, including sheep, lambs, and mice.

The efficacy of nerve tissue vaccine in humans never was evaluated by controlled studies. The Pasteur Institute of Southern India analyzed the incidence of disease in vaccinated and unvaccinated people bitten by animals that were proved rabid by the transmission of rabies to other animals or humans. Fifty-six percent of untreated persons developed rabies, compared with only 7 percent of vaccinated persons, for an effectiveness of approximately 88 percent.[225]

On the other hand, vaccination with nerve tissue vaccine of persons bitten on the head or neck by rabid wolves in Iran still was followed by a 40 percent overall mortality rate. In comparison, 15 of 32 villagers (47%) who failed to seek treatment after being attacked by a rabid wolf developed rabies.[101]

DUCK EMBRYO VACCINE

Duck embryo vaccine was developed to overcome the problem of encephalitic reactions to nerve tissue vaccine. In this respect, it was successful; the incidence of neuroparalytic reactions fell from 1 in 1000 with nerve tissue vaccine to 1 in 25,000 with duck embryo vaccine.[173,185,194] Unfortunately, a high price was paid in immunogenicity. In postexposure treatment of Americans, Corey and associates[54] found that 8 percent of those given courses of duck embryo vaccine failed to respond with the production of measurable antibody. Even more disturbing was the fact that 23 percent of recipients of duck embryo vaccine plus rabies antiserum did not develop antibody. Duck embryo vaccine contained enough duck protein to produce a significant number of allergic reactions.[185] Several human rabies cases were reported despite the use of duck embryo vaccine combined with serum.

CELL CULTURE VACCINES[175]

The ideal solution to the problems of immunogenicity and the safety of rabies vaccine clearly lay in the development of vaccines prepared from rabies virus grown in cell culture free of neural tissue. To avoid inclusion of foreign host proteins in the vaccine, the optimal cell cultures would be derived from humans.

The basic ingredients for the production of human diploid-cell vaccine (HDCV), the first cell culture vaccine widely used, were the development of the WI-38 normal human fibroblast cell line by Hayflick and Moorhead[93] and the adaptation of the Pitman-Moore strain of rabies virus to growth in WI-38 by Wiktor and associates.[241] Virus grown in human fibroblasts was concentrated by ultrafiltration to increase antigen content and then inactivated by beta-propiolactone.

After various schedules of HDCV were tried, researchers found that three properly spaced intramuscular doses invariably produced an immune response. A similar schedule of duck embryo vaccine resulted in titers 10 to 20 times lower. The excellent immunogenicity of HDCV has been confirmed amply,[3,13,35,55,85,177,222,246] and it became the "gold standard" against which other vaccines were measured.

Table 196–3 shows the serologic data of three persons who received postexposure prophylaxis.[176]

The crucial test of a rabies vaccine is protection of those actually exposed to the virus. In Europe, the HDCV has been used to treat thousands of people exposed to possible rabies. However, those situations in which rabies was confirmed in the biting animal are particularly important to consider. Kuwert and associates,[130,131] in Essen, vaccinated 68 persons after exposure to dogs, cats, cows, or wild animals with laboratory-confirmed rabies virus infection or exposed as a result of a laboratory accident. The schedule used was 1 mL intramuscularly on days 0, 3, 7, 14, 30, and 90. They had no failures of protection, no significant reactions, and excellent neutralizing and complement-fixing antibody responses.

Bahmanyar and associates[21] in Iran conducted another test of HDCV. Forty-five persons who were bitten by rabid wolves or dogs were given rabies antiserum, followed by the same schedule of vaccine as that used in Germany. Once again, no rabies was seen in vaccinees, despite a 40 percent risk (estimated from previous experience) if they had remained unvaccinated. Antibody measurements showed mean titers as follows: 7 days, 1.1 IU; 14 days, 10.7 IU; 30 days, 49 IU; and 100 days, 312 IU.

The Centers for Disease Control and Prevention (CDC) distributed HDCV of American manufacture after exposure to persons whose exposure to rabies was established.[8] No vaccine failure occurred, and all who received the full schedule of five 1-mL doses intramuscularly responded with antibodies to date.

Although a small number of vaccine failures have been reported in other countries after administration of the HDCV, ancillary prophylaxis recommendations were not followed scrupulously in each case.[10] The failure rate is estimated to be at most 1 in 12,000 courses of vaccination given in countries with high risk for rabies, such as Thailand.[164] General anesthetics given while the wound is repaired may increase the risk of vaccine failure.[76]

An effort has been made to produce vaccines with the desirable properties of HDCV at a lower cost that would make them broadly available in the developing nations, where the risk of human rabies is most severe.

Purified Vero cell rabies vaccine (PVRV) is the Pasteur strain of rabies (as used in HDCV) grown in the Vero cell line in industrial fermenters. The virus is concentrated, inactivated, and purified. PVRV has an immunogenic potency similar to that of HDCV. Successful postexposure experience has been reported in Tunisia,[43] China,[230] and Thailand, even after severe exposure.[110,209,234] The Vero cell vaccine has been purified further by chromatography.[136]

Purified chick embryo-cell (PCEC) rabies vaccine is produced in primary chick embryo-cell culture with use of the Flury low egg passage (LEP) strain of rabies virus. It is inactivated, concentrated, and purified, yielding a vaccine preparation of antigenic potency similar to that of PVRV and HDCV.[24] PCEC rabies vaccine was uniformly successful in preventing rabies in postexposure trials in the former Yugoslavia, including subjects who were exposed by wolf bite.[52,227] PCEC rabies vaccine also was shown to be equivalent to HDCV for postexposure immunization,[180] for boosting previously immunized subjects,[32] and for protection of mice against bat strains of rabies.[63]

Purified duck embryo-cell rabies vaccine is produced in embryonated duck eggs. The Pitman-Moore virus harvested from the eggs is purified, concentrated, and inactivated.[120]

Primary hamster cell kidney vaccine has been produced in China and was demonstrated to be immunogenic and to provide postexposure protection.[73] It now has completely replaced Semple vaccine in China.[73]

An argument has been made that a potent rabies virus might be made at low cost in continuous BHK-21 cells, and if it were inactivated with beta-propiolactone, the beta-propiolactone would so damage the cell DNA that the theoretical danger posed by cell DNA in vaccine would be eliminated totally.[155]

TABLE 196–3 Antibody Response in Three Children to Postexposure Rabies Vaccination with Human Diploid-Cell Vaccine

†Number of days after bite on which human diploid-cell vaccine first was administered.

Three types of rabies vaccine are licensed in the United States: HDCV; PCEC rabies vaccine; and a tissue culture vaccine made in fetal rhesus diploid cells by the Michigan State Department of Health, called *rabies vaccine adsorbed* (RVA), but which is not now distributed.[25] HDCV or PCEC rabies vaccine is recommended for postexposure prophylaxis when it is given by the intramuscular route according to the regimens listed in Table 196–4. The dose should not be reduced for children.[12] Decreased immune responses have been noted in vaccinees given injections in the gluteal area,[79] and therefore all intramuscular injections of rabies vaccine should be given in the deltoids. In the event of re-exposure of persons with a prior history of vaccination, two intramuscular booster doses should be given, as also stated in Table 196–4. Virtually 100 percent of these patients will have an anamnestic response.[211]

Numerous regimens have been developed for rapid immunization of exposed patients in poor countries who may seek medical help late or who may not return for subsequent doses.[208,228,234] To reduce costs, advantage is taken of the smaller volume needed for intradermal administration. However, no intradermal vaccine is licensed in the United States (see later). These regimens are listed in Table 196–4 and have the advantage of being less expensive. Note that if the 2-1-1 regimen is chosen, immune globulins will interfere with the response to the vaccine.[6]

The effectiveness of current rabies vaccines to protect against most rabies-related lyssaviruses appears to be good.[87,159]

DECISIONS TO VACCINATE (Table 196–5)

The physician must take into account numerous human and zoologic factors in deciding when to vaccinate, although reluctance to use vaccine now is based more on cost than on the pain of injections. A study performed in the United States[154] revealed that administration of rabies prophylaxis was inappropriate in 40 percent of cases in which it was given. However, the study also showed that 6 percent of those not receiving prophylaxis should have received it. Thus, the judgment of physicians needs improvement, not only for medical reasons but also because some incidents of exposure to rabies result in vaccination of many persons, with high cost.[184] Among the factors to be considered are the following:

Pregnancy

Pregnant women tolerate rabies vaccination without problem.[49,206]

Geography

Terrestrial animal bites in most large urban areas in the developed world are unlikely to be from rabid animals, although Philadelphia, Baltimore, New York, and Washington, DC, have become part of the raccoon epizootic, with transfer of disease to urban cats.

TABLE 196–4 Regimens for Pre-exposure and Postexposure Vaccination with Rabies Vaccines

Vaccination	Route	Days on Which Doses Are Given	Remarks
Pre-exposure	IM†	0, 7, 21, or 28	Standard U.S. 3-dose regimen
	ID‡	0, 7, 21, or 28	Economical, but not to be used in those taking antimalarial medications; unlicensed route in U.S.
Postexposure*	IM†	0, 3, 7, 14, 28	U.S. and WHO 3-dose recommendation
	IM†	0 (2 doses), 7, 21	Used in some countries when RIG is not indicated; so-called 2-1-1 schedule
	ID‡	0, 3, 7 (2 doses each), 28	Used in Thailand with PVRV, PCECV; so-called 2-2-2-0-1 schedule
	ID‡§	0 (8 doses), 7 (4 doses), 28, 90	Used in developing countries with HDCV, PCECV, or PVRV cell culture vaccines; so-called 8-0-4-0-1-1
Booster (for re-exposure)	IM†	0, 3	Only after documented vaccination with cell culture vaccine‖
	ID‡	0, 3	Only after documented vaccination with cell culture vaccine‖

**Together with rabies immune globulin.*
†Give 0.5 mL (PVRV) or 1.0 mL, depending on the vaccine, into the deltoid.
‡Give 0.1 mL, over the deltoids.
§Give 0.1 mL at multiple sites (see text).
‖Or demonstrated presence of virus-neutralizing antibodies after other vaccines.
ID, intradermal; IM, intramuscular; HDCV, human diploid-cell vaccine; PCECV, purified chick embryo-cell vaccine; PVRV, purified Vero cell rabies vaccine; RIG, rabies immune globulin.

TABLE 196–5 Rabies Postexposure Prophylaxis Guide—United States[34]

Animal Type	Evaluation and Disposition of Animal	Postexposure Prophylaxis Recommendations
Dogs, cats, and ferrets	Healthy and available for 10 days of observation	Persons should not begin prophylaxis unless animal develops clinical signs of rabies*
	Rabid or suspected rabid	Immediately vaccinate
	Unknown (e.g., escaped)	Consult public health officials
Skunks, raccoons, foxes, and most other carnivores; bats	Regarded as rabid unless animal proven negative by laboratory tests†	Consider immediate vaccination
Livestock, small rodents, lagomorphs (rabbits and hares), large rodents (woodchucks and beavers), and other mammals	Consider individually	Consult public health officials Bites of squirrels, hamsters, guinea pigs, gerbils, chipmunks, rats, mice, other small rodents, rabbits, and hares almost never require antirabies postexposure prophylaxis.

**During the 10-day observation period, begin postexposure prophylaxis at the first sign of rabies in a dog, cat, or ferret that has bitten someone. If the animal exhibits clinical signs of rabies, it should be euthanized immediately and tested.*
†The animal should be euthanized and tested as soon as possible. Holding for observation is not recommended. Discontinue vaccine if immunofluorescence test results of the animal are negative.

Type of Animal

Cats always are suspect if they go out of their way to bite. Dogs on the Mexican border are more suspect than are those farther north. Skunks, foxes, and raccoons involved in biting incidents must be considered rabid until proven otherwise. With the exception of woodchucks, rodents such as squirrels are unlikely to be rabid.

Bat Exposures

As stated before, rabies transmission from bats has become a threat to humans in the United States owing to an apparent increase in exposures to silver-haired and Eastern pipistrelle bats. The in vitro characteristics of the bat rabies strains, which may allow them to replicate better in non-neural tissues, plus the small and sometimes imperceptible bites these species inflict, led to the recommendation that vaccination may be appropriate when bats are handled without gloves and when sleeping individuals awake to find a bat in the room.[3]

Circumstances of Bite

The attempt to feed an undomesticated animal always must be considered provocative behavior. Invasion of an animal's territory may result in an attack, which is less suggestive of rabies than is an attack by an animal that invades human environments. However, judgment as to whether a bite was provoked is poorly predictive of rabies in enzootic areas.[127] If an animal appears clinically rabid, it should be euthanized immediately for confirmation of rabies by examination of the brain. If a dog, cat, or ferret appears normal, it may be kept for 10 days to see if it develops rabies.[150] Meanwhile, exposed humans should or should not be started on prophylaxis, depending on the known prevalence of rabies in the particular region.

Animal Vaccination

Rabies is an extremely rare occurrence in properly vaccinated animals.

Table 196–5 summarizes recommendations by the Advisory Committee on Immunization Practices on vaccination against rabies.[3] Advice can be sought from state and local health departments (particularly with regard to the occurrence of rabies in animals) and from the CDC directly.

FAILURE OF RABIES PROPHYLAXIS

The most common cause of vaccine failure is that immune globulin was not used simultaneously.[59,84,251] Active immunization will not regularly produce antibodies until 7 to 14 days after the first dose is given. Lack of local infiltration of immune globulins and the immunosuppressive effect of chloroquine may account for other failures. The presence of B-cell immunodeficiency in a patient requires measurement of antibodies after vaccination. Patients infected with human immunodeficiency virus (HIV) are likely to respond if their $CD4^+$ lymphocytes are higher than 300/μL. If not, their postvaccination antibodies also should be measured.[110] In HIV-infected children, a standard postexposure course of HDCV had no effect on the level of $CD4^+$ lymphocytes or the HIV viral load.[215] However, even with correct prophylaxis, failures may occur, perhaps because in severe exposures, virus is deposited directly onto nerve endings[100] or because of inadequate monitoring of vaccine and rabies immune globulin potency in developing countries.[18]

PRE-EXPOSURE IMMUNIZATION (Table 196–6)

The development of modern vaccines has made effective immunization of persons at risk of coming into contact with rabies virus

TABLE 196–6 Rabies Pre-exposure Prophylaxis Guide—United States[34]

Risk Category	Nature of Risk	Typical Populations	Pre-exposure Recommendations
Continuous	Virus present continuously, often in high concentrations	Rabies research laboratory workers*	Primary course
	Specific exposure likely to go unrecognized Bite, nonbite, or aerosol exposure	Rabies biologics production workers	Serologic testing every 6 months; booster vaccination if antibody titer is below acceptable level†
Frequent	Exposure usually episodic with source recognized, but exposure also might be unrecognized	Rabies diagnostic laboratory workers*	Primary course
	Bite, nonbite, or aerosol exposure Veterinarians and staff Animal-control and wildlife workers in rabies-enzootic areas	Spelunkers	Serologic testing every 2 years; booster vaccination if antibody titer is below acceptable level†
Infrequent (greater than in population at large)	Exposure nearly always episodic with source recognized	Veterinarians and animal-control and wildlife workers in areas with low rabies rates	Primary course
	Bite or nonbite exposure	Veterinary students Travelers visiting areas where rabies is enzootic and immediate access to appropriate medical care including biologics is limited	No serologic testing or booster vaccination
Rare (population at large)	Exposure always episodic with source recognized Bite or nonbite exposure	U.S. population at large, including persons in rabies-epizootic areas	No vaccination necessary

**Judgment of relative risk and extra monitoring of vaccination status of laboratory workers are responsibilities of the laboratory supervisor.*

†Minimum acceptable antibody level is complete virus neutralization at a 1:5 serum dilution by the rapid fluorescent focus inhibition test. A booster dose should be administered if the titer falls below this level.

possible before the actual exposure occurrs. Veterinarians, animal handlers, laboratory workers, and spelunkers need pre-exposure immunization. Large numbers of veterinary students have been vaccinated under a three-dose schedule at 0, 7, and 21 or 28 days. Rabies virus antibody titers were determined on the serum of each veterinary student. Nearly 100 percent developed antibodies, with geometric mean titers of 10 IU or greater, which is equivalent to a neutralizing antibody titer of at least 1:200.[183] The three-dose regimen listed in Table 196–4 induces antibodies in 100 percent of recipients. Pre-exposure immunization may be given with use of HDCV, PCEC rabies vaccine, or RVA by intramuscular administration. Outside the United States, any one of the alternative cell culture vaccines can be used on the same schedule.[191] Alternatively, and more economically, immunization may be performed intradermally according to the same schedule.

Because rabies in developing countries is primarily a disease of children, exploratory studies have been performed to determine if pre-exposure vaccination could be incorporated into routine pediatric schedules. Preliminary results from Vietnam show that routine rabies vaccination in infancy is feasible[137] and could even be performed by low-dose intradermal administration.[71] In areas enzootic for canine rabies, universal vaccination of children can be cost-effective if the incidence of dog bite is high.[48] Children infected with HIV can be immunized successfully if their $CD4^+$ cells exceed 15 percent of lymphocytes. Those with fewer $CD4^+$ cells will need at least double doses of rabies vaccine.[215]

Missionaries and Peace Corps personnel operating in rabies-endemic countries should receive pre-exposure vaccination.[16]

INTRADERMAL VACCINATION

For pre-exposure use, the intradermal route is considered an acceptable alternative to intramuscular injection, with the important proviso that persons receiving antimalarial or other immunosuppressive agents and perhaps older persons should have their titers checked after vaccination or receive the injections by the intramuscular route.

The success of intradermal vaccination depends on a technique that ensures intradermal rather than subcutaneous injection, but a margin of error exists.[26,78]

Today, essentially all intradermal vaccinations are done with PVRV and PCDC rabies vaccine. To reduce the costs of vaccination, intradermal vaccination for postexposure use has become popular in developing countries, but it no longer is approved in the United States. Although single-dose preparations are not available for the intradermal administration of the 0.1-mL dose, extensive experience in Thailand and elsewhere has validated the successful prevention of rabies with vaccine extracted from vials intended for intramuscular use.[71,223,236,237] However, attention must be paid to the correct administration of the dose into the skin, the sterility of unused portions of the vial, the volume of vaccine in the ampule, and the antigenic content of the vaccine used. The antigenic content should be at least 0.25 IU per 0.1 mL. The most popular intradermal schedule is the one developed by the Thai Red Cross, consisting of inoculations on days 0, 3, 7, and 28 days, with double doses given in the first three administrations. A former recommendation for a 90-day dose has been abandoned.[122] Poor responses to intradermal vaccine have been noted in those concurrently receiving chloroquine or immunosuppressives, such as corticosteroids.[3,168] Therefore, persons who must be vaccinated while they are taking chloroquine or related antimalarials should be given injections into the deltoid muscle, and postvaccination rabies serologic studies should be obtained on those patients and others who are immunosuppressed.

ALTERNATIVE SCHEDULES

Although the WHO schedules are firmly established for the induction of optimal immune responses, other schedules have been tested extensively to reduce the number of vaccination visits, particularly in the developing world. The most popular of these are the 2-1-1 schedule, in which a double dose is given intramuscularly at day 0, followed by single doses on days 7 and 21,[50,149] and the regimen developed by Warrell and associates,[236] consisting of eight intradermal doses on day 0, four intradermal doses on day 7, and single doses on days 28 and 91.

The 2-1-1 schedule may not be reliable if immune globulins also are administered.[134,136]

BOOSTER DOSES

Even with administration of cell culture vaccine, antibodies fall off rapidly after initial immunization, although most cell culture vaccine recipients have some detectable antibody at 2 years after initial vaccination. Nonetheless, once an immune response to rabies vaccine has developed, revaccination is almost certain to evoke a rapid response.[211] One booster of cell culture vaccine given to previously vaccinated persons results in a dramatic anamnestic response, with titers in one study rising from 2.8 IU to 94 IU at 14 days and more than 100 IU in 35 days.[175] As mentioned, with exposure to rabies in a previously vaccinated person, two intramuscular booster doses are recommended to provide a margin of safety. Single intramuscular or intradermal boosters are given to maintain immunity in individuals chronically exposed to rabies, according to the recommendations made by the CDC in Table 196–6 if serology suggests a waning titer.

In persons who have received pre-exposure immunization to rabies, the necessity of boosters is an important issue. Persons who definitely were exposed to a rabid animal should receive two booster doses of vaccine by the intramuscular route. Individuals who are likely to be exposed, such as rabies laboratory workers, are boosted to maintain their antibody titers above 0.5 IU (or complete neutralization at a dilution of 1/5). A follow-up study by Briggs and Schwenke[33] is interesting. They found maintenance of an adequate titer (>0.5 IU) at 1.5 to 2 years after vaccination in 99 percent of subjects who received vaccine by the intramuscular route and in 93 percent who received vaccine by the intradermal route. In Thailand, researchers demonstrated that persons who received pre-exposure rabies vaccination by the intradermal route mounted a slow response to boosters, and the authors suggested that in severe exposures, rabies immune globulin should be given despite the prior immunization.[110] However, the intradermal route can be used successfully to boost prior immunity.[213] Thraenhart and associates[217] observed 100 percent positive antibodies in 18 subjects studied between 2 and 14 years after they received vaccination. Thus, if a person is properly vaccinated with modern cell culture vaccines, subsequent boosting with rabies immune globulin is not indicated in postexposure prophylaxis.

ADVERSE REACTIONS

The available tissue culture vaccines are well tolerated. In more than 1770 human volunteers receiving pre-exposure immunization with HDCV administered intramuscularly, sore arm was noted in approximately 20 percent, headache in about 8 percent, malaise in 5 percent, and allergic edema in 0.1 percent.[175] During incidents involving mass postexposure prophylaxis, pain, swelling, and other local symptoms occurred in 30 to 74 percent of individuals.[3] Pregnancy is not a contraindication to receiving modern rabies vaccines.[49] Guillain-Barré syndrome and other

TABLE 196–7 Some Rabies Vaccines Developed for Humans

Vaccine Types	Remarks
Pasteur: dried rabbit spinal cord	Residual live virus
Fermi: phenolized sheep or goat brain	Residual live virus
Semple: phenol-inactivated sheep or goat brain	Contains nerve tissue
Fuenzalida: phenol-inactivated suckling mouse brain	Contains less myelin
Duck embryo: BPL inactivated	Allergy to duck proteins
Human diploid cell (HDCV): BPL-inactivated fetal human cell culture vaccine	Current standard; booster allergic reactions
Rhesus diploid cell (RVA): fetal rhesus cell culture, BPL inactivated	Fewer allergic reactions
Vero cell (PVRV): BPL-inactivated virus	Purified by density gradient centrifugation; grown in Vero monkey kidney cell line
Chick embryo cell (PCEC rabies vaccine): inactivated virus grown in chick embryo cells	Purified like PVRV
Vaccine recombinant glycoprotein (VRG): genetic construct expressing rabies	Probably will be used only in animals (see text)

BPL, beta-propiolactone.

neurologic problems have been rare occurrences, and their relationship to HDCV is uncertain.[125] Guillain-Barré syndrome that occurs after administration of nerve tissue vaccine is associated with antibodies to myelin basic protein.[99]

In contrast, booster vaccinations with HDCV have been associated with allergic reactions in approximately 6 percent of subjects.[1] These reactions are caused by the presence in the vaccine of human albumin that has been altered by the beta-propiolactone used to inactivate the virus.[9,212,238] The reactions are of the immune complex type (type III), with urticaria, edema, joint manifestations, fever, and malaise. CDC data suggest that when primary vaccination is given intramuscularly and booster intradermally or vice versa, reactions are more common than if all vaccination is by the same route.[80] Because the reaction is associated with the particular formulation of HDCV rather than with the rabies virus antigen itself, additional boosters may be given if necessary with PCEC rabies vaccine, PVRV, or HDCV manufactured in Canada (Sanofi Pasteur).[77] Reactions to PVRV and PCEC cell culture vaccines generally have been mild.[69] A comparative study of PVRV with HDCV showed lower or equivalent rates of local and systemic reactions, with no serious adverse events.[116] Because PCEC rabies vaccine is manufactured in chicken cells, egg allergy is a possible problem, and anaphylactic events as well as some rare and perhaps unrelated neurologic complications have been reported.

FUTURE DEVELOPMENTS

The world of rabies is far from static. Table 196–7 shows the progress of rabies vaccine development for humans. Perhaps the most dramatic future prospect is the development of vaccines in which the gene for rabies glycoprotein has been inserted into a viral vector, such as vaccinia, or the use of rabies virus itself as a cloning and expression vector system by reverse genetics.[36,190] These vaccines already have been used extensively in a large variety of animal species, in which they have been found to be safe and highly immunogenic.[188] In field studies, raccoons and other wild animals have been immunized successfully by the oral route with baits containing rabies recombinant vaccine. Such vaccination has eliminated fox rabies from large areas of western Europe[30] and reduced raccoon rabies in the eastern United States.[189,198] Other avenues being pursued include the use of potent adjuvants to enhance the immunogenicity of subunit vaccine,[75] the addition of the internal ribonucleoprotein to enhance protection through induction of cellular immune responses and higher antibody responses,[218] synthetic peptides constructed from epitopes of the single glycoprotein and nucleoprotein,[61] and plasmid vectors containing cDNA of the glycoprotein gene.[255]

Particular effort has been directed toward the development of DNA vaccines. They are alleged to be potentially inexpensive and particularly thermostable, but to date most have required an unsatisfactory interval to produce virus-neutralizing antibodies or to have induced virus-neutralizing antibodies of inadequate titer.[139-141] Dogs given two doses of Pasteur strain G protein DNA, administered intramuscularly, were shown to develop virus-neutralizing antibodies to rabies and to European bat lyssaviruses 1 and 2 and to have protection against virus challenge.[170] Jallet and colleagues[111] produced chimeric G DNAs of rabies and EBL1, or rabies and Mokola virus, to generate vaccines designed to induce virus-neutralizing antibodies in dogs to either all European lyssaviruses or all African lyssaviruses, respectively. In primates, rabies G DNA induced virus-neutralizing antibodies only if it was administered by gene gun.[141]

Other approaches have included efforts to express rabies G protein in yeast cells, which failed,[216] and in baculovirus in insect cells, which was successful. Although it is less glycosylated than is the virion G protein, the baculovirus-expressed G protein induced virus-neutralizing antibodies efficiently in mice; its immunogenicity was not improved by adding baculovirus-expressed rabies N protein.[70] In approaches using the rabies G protein cloned into adenovirus, researchers have shown that a replication-defective recombinant elicited enzyme-linked immunosorbent assay antibodies in mice inoculated onto mucosal surfaces[254] and that an adenovirus incorporating a special promoted-intron expression cassette efficiently induced rabies G protein in cell culture that induced virus-neutralizing antibodies in intraperitoneally inoculated mice.[145] The rabies G protein gene was cloned into canine herpesvirus; this recombinant induced virus-neutralizing antibodies efficiently in dogs inoculated by the intranasal route, suggesting that it might be useful as an oral product to control canine rabies.[256] Similar hopes are offered by a new recombinant canine adenovirus vaccine.

Molecular biologic approaches have not yet produced an ideal vaccine, especially for human use. In the near future, the most cost-effective and protective vaccines may be virion products propagated to high titer in an easily managed cell culture system, for example, the BHK-21 continuous cell line or transgenic plants.[153] Also, monoclonal antibodies may offer an effective alternative to human rabies immune globulin. Regardless of developments in human medicine, the key to future progress is a focus on elimination of canine rabies.

SUBSECTION 9

Arenaviridae and *Filoviridae*

CHAPTER 197

Lymphocytic Choriomeningitis Virus Infection

Rémi N. Charrel ❂ Xavier de Lamballerie

Lymphocytic choriomeningitis virus (LCMV) belongs to the genus *Arenavirus*, family *Arenaviridae*. *Mus musculus* (the common house mouse) constitutes the reservoir of LCMV in nature, but hamsters can also carry the virus. Humans usually become infected through direct contact with infected rodents or by inhaling infectious rodent excreta or secreta during occupational exposure (laboratory workers, rodent sellers) or when caring for rodents as pets. Although infection with LCMV usually is asymptomatic or mild and self-limiting, it can be severe and manifest as meningitis and encephalitis. Infection during pregnancy may cause abortion or congenital malformations.

HISTORY

In the 1930s, LCMV was discovered, at about the same time and independently, in three different localities in the United States. Armstrong and Lillie encountered the agent in a monkey when they passaged a recent isolate of St. Louis encephalitis virus.[3,6] In 1935, Rivers and Scott[47] described the first two cases of human infection with LCMV. Both these patients developed febrile illnesses characterized by headache, vomiting, and stiff neck; lumbar puncture revealed 720 and 1700 cells/mm^3, nearly all of which were lymphocytes. These investigators subsequently isolated five strains from patients with meningitis.[47] Traub[52] revealed the virus in a colony of albino mice. Mice were incriminated in these first isolations, and later observations proved beyond a doubt that *M. musculus* is the principal reservoir of LCMV in nature. However, not until 2007 was definitive evidence presented that LCMV-infected rodents caused disease in humans, as established by genetic comparative analysis.[24] For some time after its discovery, LCMV was regarded as the sole etiologic agent of Wallgren acute aseptic meningitis. However, it became clear that Wallgren syndrome had a multitude of viral causes, among which LCMV was of little relevance. In the years after other etiologic agents of acute aseptic meningitis, such as enteroviruses, mumps, or herpesviruses, were identified, LCMV progressively disappeared from the sight of virologists and general practitioners. This situation is exemplified by the low numbers of human cases or outbreaks of LCMV infection reported in the medical literature (<50 articles). Meanwhile, LCMV was used as an excellent model for the study of a variety of phenomena of biologic and medical relevance, such as immunologic tolerance, viral immunopathology, slow viral diseases, and latent viral infections, the last demonstrated by the large number of scientific articles on that topic (>2500 references in the PubMed bibliographic database found using "lymphocytic choriomeningitis" as the search criterion).

EPIDEMIOLOGY

LCMV belongs to the genus *Arenavirus*, family *Arenaviridae*. *M. musculus* (the common house mouse) constitutes the reservoir of LCMV in nature, but hamsters also can carry the virus. Humans usually become infected through direct contact with infected rodents or by inhaling infectious rodent excreta or secreta during occupational exposure (laboratory workers, rodent sellers) or household exposure (pet owners). The epidemiologic features vary when animals other than *M. musculus* are involved. Thus, LCMV transmitted from Syrian hamsters has occurred in areas where infected mice are not found. Altogether, 47 human cases have been traced to these pets and may have caused family outbreaks but no epidemics.

Human infection with LCMV is a rare occurrence. Specific tests conducted with diagnostic materials from several large hospitals revealed an incidence seldom exceeding one case per year.[48] Because *M. musculus* is the reservoir from which most human infections can be traced, efforts were made to clarify the geographic distribution of LCMV-carrying mice. Of 1795 house mice trapped in Germany, 65 carried the virus.[1] In 44 of 376 trapping areas, infected mice were found; these 44 positive sites were unevenly distributed, with a majority located in northern and northwestern Germany. In a later serologic survey, the proportion of people with LCMV-specific antibodies was significantly higher in rural areas where infected mice were known to live as compared with zoonosis-free districts. In areas where LCMV-carrier mice are frequently found, 9.1 percent of the rural population had neutralizing antibodies. In contrast, only 1.2 percent of the people residing in southern Germany, which is essentially free of LCMV-carrying mice, had neutralizing antibodies. Extrapolating from these statistics, approximately 1000 persons are newly infected each year in Germany. Thus, researchers estimate that in western Germany, at least 72,000 persons must have had an infection, based on an average life expectancy of 70 years and an approximate rate of new cases of 1000 per year. If this estimation is correct, most infections are not diagnosed, and many remain inapparent.

The occurrence of LCMV infection in persons from homes where mice have been proved to be carriers of the virus is well known.[6] Researchers have suggested that small, persistent zoonotic foci of infection exist, on the basis of the known natural history of the disease in mice and the circumscribed range of activity of mice. The percentage of infected house mice apparently varies in different communities, and it has been recorded at 21.5 percent in Washington, D.C.[5] and at 4 percent in Boston and New York.[33,56] However, because infected mouse colonies are dispersed unevenly, the proportion of infected animals in a given infected colony can be high, up to 95 percent.[24,27]

Many human cases have been reported in the context of occupational exposure to rodent colonies.[7,12,14,15,21,23,29-31,36,40,53] Outbreaks and isolated cases of LCMV infections were reported in laboratory personnel having contact with hamsters, not mice.[12,37,38]

Until 2005, no case of person-to-person transmission had been documented, and the general consensus was that LCMV could infect humans only after direct or indirect contact with an infected rodent. The more recent evidence that LCMV can be transmitted through organ donation should lead physicians to evoke LCMV as a possible cause of infection in the absence of established close contact with mice or hamsters.[16,26] In a report of LCMV infection developing after organ transplantation, the fatality rate was much higher (seven deaths of eight cases) than previously noted, perhaps a reflection of the immunosuppressive regimens required by these transplant recipients.[26] Another, similar episode occurred in Australia, where three patients died after receiving an organ transplant from the same donor. Metagenomic approaches provided clues about possible involvement of an arenavirus related to LCMV.[35,45]

Serologic studies conducted in healthy populations of large cities either by immunofluorescence assay (IFA) or enzyme-linked immunosorbent assay (ELISA) found immunoglobulin G (IgG) antibody prevalence varying between 0.3 and 4.7 percent: 0.3 percent in Marseille, France[20]; 1.7 percent in Spain by IFA[39]; 3.3 percent in Argentina[46]; 4.7 percent in Baltimore.[19] A study conducted in a region where murine typhus is endemic in Croatia reported an unexpectedly high prevalence, 36 percent, through IFA assay.[22]

CLINICAL FORMS

Several possible clinical forms of LCMV infection have been identified. In most cases, LCMV infection is minimally symptomatic or asymptomatic and consists of an influenza-like illness with fever, headache, myalgia, fatigue, general malaise. These symptoms are self-limited and resolve after a few days. These mild illnesses, which usually do not motivate patients to see a physician, most likely represent most LCMV infections, but the exact proportion is unknown. Historical articles reported that respiratory symptoms occur in LCMV infections. In a certain (but unknown) proportion of cases, a second phase is observed during which neurologic manifestations, such as meningitis, encephalitis, or even acquired hydrocephalus, can be recorded.

In 1942, Farmer and Janeway[25] proposed the following classification of LCM into four clinical categories:

1. Inapparent and subclinical infections: Immunologic studies suggested that these forms are quite common: 11 percent of 2000 sera tested contained neutralizing antibodies against LCMV.[4]

2. Nonmeningeal form, non–central nervous system (CNS) infection, systemic infection, influenza-like infection: This form consists of two stages: systemic illness, then convalescence. The incidence probably is underestimated because of the lack of laboratory documentation and the absence of specific or suggestive signs. Only vague assumptions can be made concerning the number of underdiagnosed cases. The diagnosis of LCMV usually is not suspected unless attention is directed to signs and symptoms suggestive of meningoencephalitis, although researchers have shown that generalized systemic infection may occur without any evidence of involvement of the CNS.[50] How often the disease manifests in this form or how often apparently asymptomatic infection occurs is not known. The demonstration of neutralizing antibodies in the blood of as many as 10 percent of the adult population suggests that infection with LCMV may occur more frequently than is suspected.[54]

3. Lymphocytic choriomeningitis, meningeal form: This form usually consists of three stages: systemic illness, meningitis (possibly delayed up to 2 to 3 weeks), and convalescence.[8]

4. Lymphocytic choriomeningitis, encephalomyelitic form: This form has three stages: systemic illness, encephalitis (possibly delayed), and convalescence.

Other CNS manifestations such as transverse myelitis, Guillain-Barré–type syndrome, and transient or permanent acquired hydrocephalus can be associated with LCMV infection.[10] LCMV-associated acquired hydrocephalus has been described only five times since the virus was discovered.[9,17,34,51] In all cases, the clinical picture was severe, and patients required ventriculostomy.

A fifth category (congenital LCM) should be added to the previous classification, corresponding to fetal consequences of LCMV infection during pregnancy. LCMV is a fetal teratogen. It can cause hydrocephalus, microcephaly or macrocephaly, intracranial calcifications, chorioretinitis, and nonimmune hydrops. More than 50 cases of congenital LCMV infection have been documented since 1955, with more than two thirds of these cases diagnosed since 1993. Chorioretinitis and hydrocephalus are the predominant characteristics among children diagnosed with congenital LCMV infection.[32] LCMV was isolated for the first time in the cerebrospinal fluid (CSF) of a congenitally infected infant, who had congenital hydrocephalus caused by LCMV infection with severe neurologic sequelae, including, in addition to hydrocephalus, chorioretinitis, blindness, and developmental delay.[49] The differential diagnosis of congenital LCMV infection includes toxoplasmosis, rubella, cytomegalovirus infection, herpes simplex, enteroviral infection, human parvovirus B19 infection, and syphilis.[11,43,55]

DIAGNOSIS

As in other viral diseases, direct diagnosis can be established by virus isolation using cell culture; Vero and L929 cells have proved effective for LCMV isolation, but other mammalian cells also can be used. Usually, either no effect or a mild cytopathic effect is noted. Several molecular techniques using polymerase chain reaction (PCR) technology have been described.[13,18,24,42,44] The main problem with all these techniques is that the genetic diversity of LCMV is poorly understood. Sequence data acquired from newer LCMV strains indicate that the genetic heterogeneity could be greater than 20 percent between two strains.[24] Therefore, one must keep in mind that a diagnostic assay able to amplify recognized LCMV strains may provide false-negative results with a new, uncharacterized strain. Further genetic analysis of newly discovered strains therefore will be key to developing better diagnostic tools in the future.

Several techniques have been described for establishing the diagnosis of LCMV infection in patients. Among these techniques, the one that was used commonly in the past, complement fixation assay, has been demonstrated to be poorly sensitive.[37] IFA and ELISA techniques are equivalent in terms of specificity and sensitivity. However, because of broad cross-reactivity among members of the genus *Arenavirus*, confirmation should rely on

neutralization assays to discriminate between LCMV and other arenaviruses.

Serologic study can be performed with serum or CSF samples. As in other viral diseases, a fourfold difference in titers indicates a recent infection. In a single sample, detection of specific IgM suggests a recent infection. Molecular detection of LCMV genomic RNA, as well as virus isolation, can be performed from CSF during CNS manifestations and possibly from serum or plasma.

TREATMENT

No treatment exists for LCMV infection. Ribavirin has been shown to be efficient for Lassa fever,[41] a viral hemorrhagic fever caused by another arenavirus related to LCMV. Ribavirin has never been used for treating a patient with LCMV infection.

CONCLUSIONS

Since 2000, several reports have shown that LCMV has not disappeared and that it still can cause severe or fatal cases. Renewed attention was drawn to LCMV after seven recipients of solid organ transplants died of LCMV infection.[26] Historically, this virus was a major cause of aseptic meningitis in the United States; LCMV ranked first during the World War II era and second during 1947 to 1952 period.[2] At that time, other major causes were mumps, herpes simplex, and leptospirosis. The focus on LCMV declined over the intervening decades, even though the rate of unrecognized causes of CNS infections still remains high, at more than 50 percent.[28] The reason for the diminishing interest in LCMV is not clear, but it may be related to the historical prevalence of the disease in rural rather than urban populations of developed countries. However, the growing proportion of urban people living below the poverty level may lead to conditions compatible with contact with mice and, therefore, may boost the incidence of rodent-associated diseases.

In addition, the capacity to diagnose LCMV has declined dramatically since the 1980s. Hence, the decreasing number of reported cases may reflect the decrease in clinical interest and the lack of diagnostic tests, rather than a genuine modification of the epidemiology of the disease. Standard techniques, such as IFA or virus isolation, have been virtually abandoned in clinical microbiology laboratories. In Europe, the situation has been critical since 2000; barely a handful of laboratories are capable of performing recognized serologic or molecular diagnostic tests. LCMV infection still exists, and cases are reported when physicians include LCMV in the differential diagnosis and when appropriate diagnostic tests are conducted. Efforts are essential to determine the epidemiologic landscape of the disease and to implement etiologic investigations of newborns with congenital malformations who present with CNS infections. The combination of poor diagnostic testing capacity and a lack of awareness of the virus among physicians may contribute directly to an underestimation of the current role of LCMV in medicine.

CHAPTER 198

Arenaviral Hemorrhagic Fevers

Rémi N. Charrel ✪ Xavier de Lamballerie

HISTORY

In the 1950s, a new disease emerged in the Buenos Aires Province of Argentina, a rich farming region. The causative agent of the Argentine hemorrhagic fever (AHF), named Junín virus, was isolated in 1958.[85] Junín virus is hosted by rodents widely distributed in the region, and human infection occurs through contact with infected excreta, usually by a respiratory pathway. AHF is a severe disease that is fatal in approximately 20 percent of cases in the absence of specific treatment. Intensive deforestation and extensive agricultural practices in this region have increased considerably the number of contacts between humans and rodents and thereby fueled the emergence of severe annual outbreaks. The cases were expanding progressively into north-central Argentina until they finally were controlled by the availability of a live-attenuated vaccine developed in early 1980s. Junín virus is estimated to have caused approximately 30,000 cases of symptomatic disease since its discovery.

Bolivian hemorrhagic fever (BHF) was described first in 1959 in the El Beni Department of eastern Bolivia. The causative agent, named *Machupo virus*, was isolated in 1963 and was found to be antigenically and genetically distinct from but related to Junín virus.[56] Machupo virus was responsible for large outbreaks with high incidence (up to 21% of the population) and a case-fatality rate approximately 20 percent during the 1960s. Effective rodent-control efforts interrupted these epidemics, and, after the mid-1970s, no cases of BHF were reported. After 20 years of silence, however, a total of 19 additional cases were reported in the same region from 1993 to 1999.[5]

An outbreak of severe hemorrhagic fever began in the state of Portuguesa, located in the central plains of Venezuela, in 1989. Initially thought to be dengue hemorrhagic fever, the causative agent was isolated in 1990, identified as a new arenavirus species, and named *Guanarito* after the municipality where the first epidemic occurred.[92] Venezuelan hemorrhagic fever (VHF) presents a seasonal occurrence clearly related to intense agricultural activity and to human contact with the soil and the rodents hosting Guanarito virus.

Little is known about Sabiá virus, which was responsible for one fatal case of hemorrhagic fever near São Paulo (Brazil) in 1994.[22] Subsequently, two other cases were reported in laboratory workers. The epidemiology and the natural reservoir of Sabiá virus remain unknown.

In 1999 and 2000, three fatal cases of illness were reported in female patients aged 14, 30, and 52 years; two resided in northern California and one in southern California.[17] These cases were associated with Whitewater Arroyo virus infections, a recently described arenavirus indigenous to southwestern United States and hosted by *Neotoma* rodents.[37]

In the Old World, Lassa fever was described initially in Nigeria in 1969, and the causative virus was identified during that same year.[10] The disease occurs also in Sierra Leone, Guinea, Liberia, and more sparsely in other countries of West Africa.

ETIOLOGIC AGENTS

Arenaviruses are enveloped single-stranded RNA viruses, with a genome consisting of two RNA segments, designated large (L)

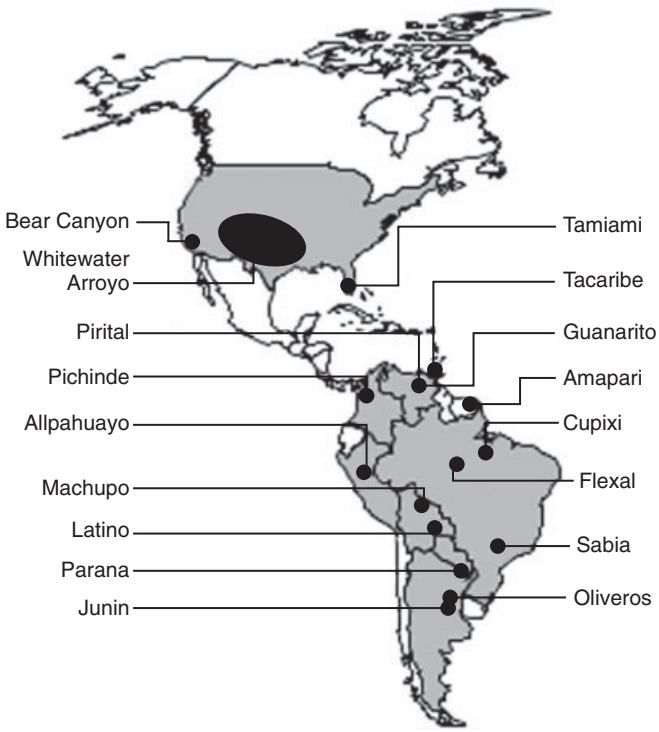

Figure 198–1 Geographic distribution of New World arenaviruses. Lymphocytic choriomeningitis virus is distributed worldwide and is not presented specifically on the map.

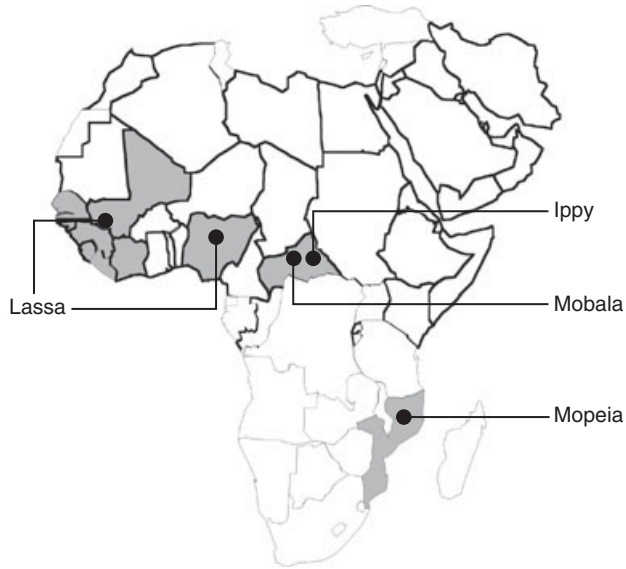

Figure 198–2 Geographic distribution of Old World arenaviruses. Lymphocytic choriomeningitis virus is distributed worldwide and is not presented specifically on the map.

and small (S). The L genomic segment (~7.2 kb) encodes the viral RNA-dependent RNA polymerase and a zinc-binding protein. The S genomic segment (~3.5 kb) encodes the nucleocapsid protein (N) and glycoprotein precursor (GPC; secondarily cleaved into the G1 and G2 envelope glycoproteins) in non-overlapping open-reading frames of opposite polarities.[96] Nucleocapsid antigens are shared by most arenaviruses, and quantitative relationships show a basic split between viruses of Africa and viruses of the Western Hemisphere. Individual viruses immunologically are distinct by neutralization test, which depends on the specificity of epitopes contained in the envelope glycoproteins.[88]

At the time this chapter was written, 22 arenaviruses were recognized. They have been classified according to their immunologic characteristics. Two groups are recognized: the Tacaribe serocomplex, including the New World viruses (Fig. 198–1), and the Lassa lymphocytic choriomeningitis (LCM) serocomplex, including the ubiquitous LCM virus and all recognized Old World viruses (Fig. 198–2). Genetic studies are congruent with serologic analyses. They also indicate that the 22 arenaviruses represent four phylogenetic lineages. The Old World (Lassa-LCM serocomplex) lineage comprises five viruses (LCM, Lassa, Mopeia, Mobala, and Ippy) and is deeply rooted in the three New World (Tacaribe serocomplex) lineages, designated A, B, and C (Fig. 198–3). The lineage A includes three North American viruses (Whitewater Arroyo, Tamiami, and Bear Canyon) and five South American viruses (Pirital, Pichindé, Flexal, Paraná, and Allpahuayo). The lineage B includes seven South American viruses (Sabiá, Junín, Machupo, Guanarito, Amapari, Tacaribe, and Cupixi). The lineage C comprises three South American viruses (Oliveros, Latino, and Pampa). Phylogenies reconstructed from each of the four genes independently demonstrated that the three North American arenaviruses (Whitewater Arroyo, Tamiami, and Bear Canyon) possessed a chimeric genome with the glycoprotein gene inherited from a clade B ancestor and the nucleoprotein gene inherited from a clade A ancestor; this mechanism could not be identified within the large genomic segment with both polymerase and matrix genes more closely related to those of clade A viruses.[18-20]

Lassa virus is the only Old World arenavirus that causes human hemorrhagic fever, whereas four New World members of the lineage B (Junín, Machupo, Guanarito, and Sabiá) have been associated with hemorrhagic fever in South America. Whitewater Arroyo virus has been associated recently with fatal human cases in North America.

EPIDEMIOLOGY

Specific rodents (usually one or two closely related species) are the principal hosts of the arenaviruses for which natural host relationships have been characterized (Table 198–1); the only exception is Tacaribe virus, associated with bats. The consensus is that the diversity of arenaviruses is the result of a long-term, shared evolutionary relationship (termed *co-evolution* or *co-speciation*) between the virus members of the family *Arenaviridae* and the rodents of the family *Muridae*.[7] Chronic infections of the host appear to be crucial to the long-term persistence of arenaviruses in nature. The infection in rodents is accompanied by a chronic viremia or viruria. Because of this specific association, the geographic area where each arenaviral disease is diagnosed is limited by the geographic distribution of the corresponding rodent host.

The rodent host of Junín virus is *Calomys musculinus*, a small field rodent. Since it was first isolated in 1959, the endemic area has expanded from a region of 16,000 km^2 in the north of Buenos Aires Province to a region that is now 150,000 km^2 (reaching north of Buenos Aires, south of Santa Fé, southeast of Córdoba, and northeast of La Pampa provinces). The human population at risk now is estimated to be almost 5 million.[32] AHF typically is a seasonal disease, with a peak frequency in the corn harvesting season from March to June; during this period, 75 percent of the infected people are male agricultural workers who are contaminated by inhalation of infected aerosols produced from rodent

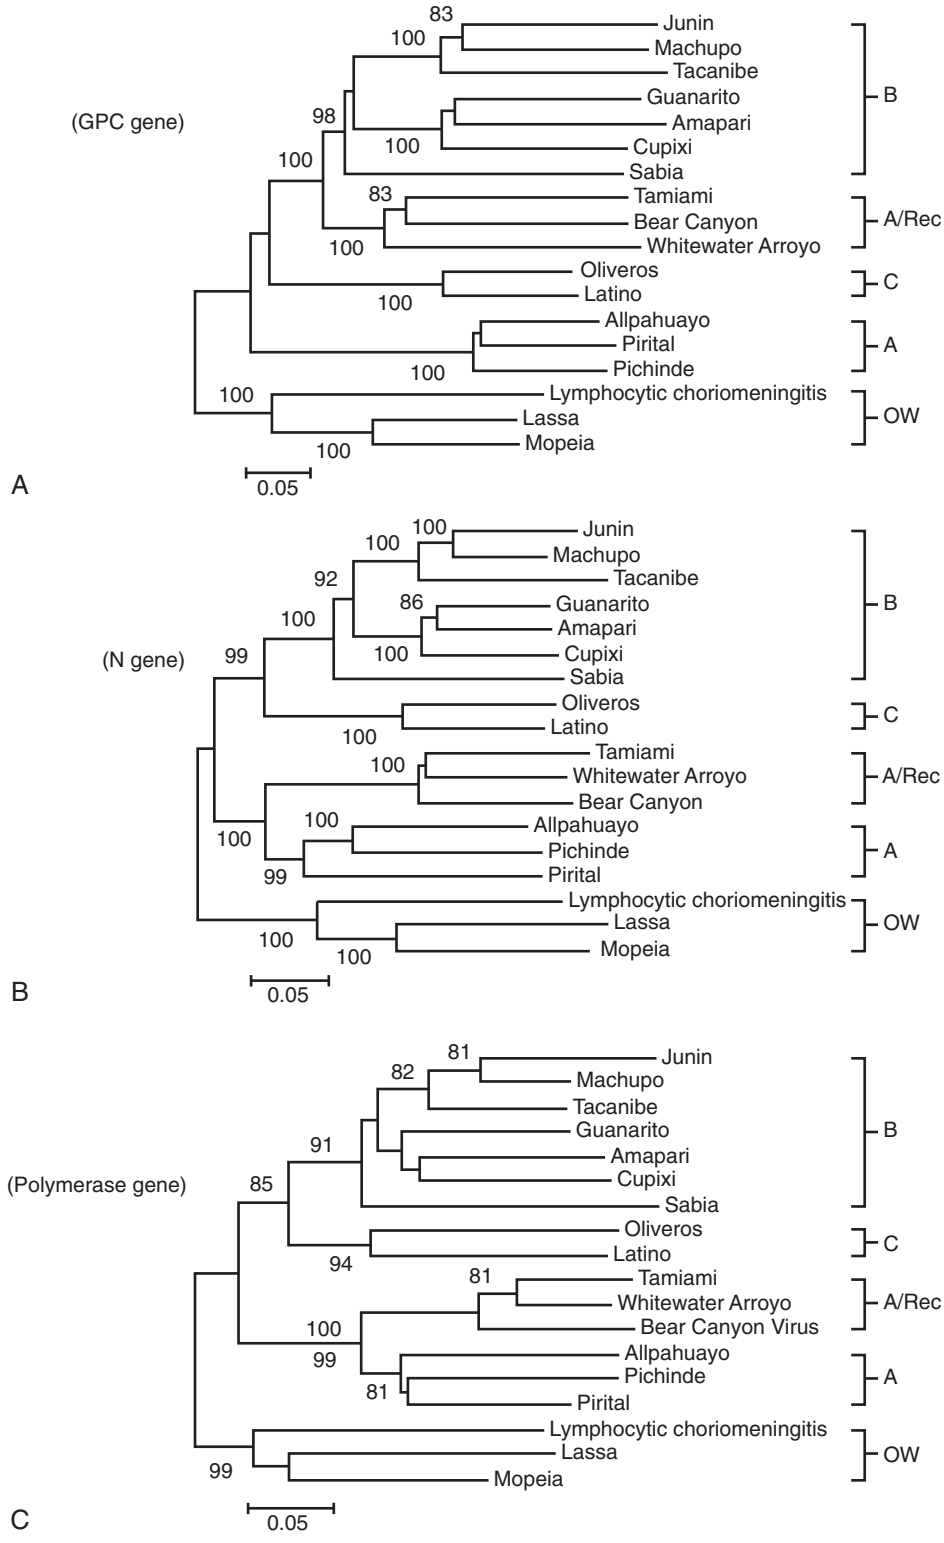

Figure 198–3 Phylogeny of arenaviruses based on the analysis of complete sequences of the GPC gene (**A**) and the N gene (**B**) and partial sequences of the polymerase gene (**C**). NW, New World arenaviruses; OW, Old World arenaviruses; A, B, and C show the three evolutionary lineages of New World arenaviruses. A/Rec denotes the recombinant lineage including the three North American viruses. Bootstrap values above 75% are indicated and correspond to 500 replications.

excreta or from rodents caught in mechanical harvesters.[70] Since 1958, cases have been recorded annually, with a variation ranging from several hundreds to 3500. The mortality rate for patients with confirmed AHF was 14 to 17 percent before immune plasma was used routinely.[71] Evidence indicates that the number of human cases reflects the proportion of infected *C. musculinus* in a particular area.[81]

Machupo virus, the causative agent of BHF, is hosted by *Calomys laucha* rodents. As for Junín virus, the dynamics of the rodent population determine the epidemiologic features in humans.[79] By contrast to *Calomys callosus*, *C. laucha* invades houses during inundation at the rainy season; this invasion results in human cases occurring with an attack rate identical in men, women, and children. The disease has been recorded only from

TABLE 198–1 Some Epidemiologic Features of Arenaviral Hemorrhagic Fevers

Fever	Virus	Case, Season, Place, Pattern	Annual Incidence	Geographic Distribution	Ecology	Rodent Reservoir	Comment
Argentine hemorrhagic fever	Junín	Males; corn harvest; March-June	20-200	North-central Argentina	Temperate pampa	*Calomys musculinus*	3- to 4-year rodent-disease cycle
Bolivian hemorrhagic fever	Machupo	All ages, both sexes; villages; February-July	<10	Northeast Bolivia	Tropical savanna	*Calomys callosus*	Rodent control successful
Venezuelan hemorrhagic fever	Guanarito	All ages, both sexes equally; house, gardens; no seasonality	0-100	Central Venezuela	Tropical mixed savanna	*Zygodontomys brevicauda* *Sigmodon alstoni*	Recently described
Lassa fever	Lassa	All ages, both sexes; villages; no seasonality	10,000	West Africa	Tropical forest savanna	*Mastomys natalensis*	No long-term cycle; nosocomial infections

a sparsely populated region in northeast Bolivia, the El Beni Province. From 1962 to 1964, a series of outbreaks involved more than 1000 patients, 180 of whom died. Nosocomial transmission of Machupo virus was clearly demonstrated,[87] although most of the recorded infections were acquired by direct contact with *C. laucha* or by aerosol contact through infected excreta.

In 1990, new cases of hemorrhagic fever were investigated in Venezuela; the culprit was found to be a new arenavirus, designated Guanarito virus after the region where the outbreak occurred.[92] Natural and experimental data suggest that two different rodent species are involved in the transmission cycle of Guanarito virus in nature: the cane rat *Zygodontomys brevicauda* and the cotton rat *Sigmodon alstoni*.[38,39,100] Since its discovery, Guanarito virus has been responsible for at least 200 cases of VHF. For unknown reasons, the number of reported human cases has dropped spontaneously since 1992, although rodent infection can still be demonstrated easily inside and even outside the original endemic zone.[106]

In California, three fatal cases recently were associated with Whitewater Arroyo virus, initially isolated from a wood rat (*Neotoma* spp.).[17,37] The present-day geographic range of rodents of the genus *Neotoma* extends from western Canada southward to Guatemala, Honduras, and Nicaragua. Of the 20 recognized *Neotoma* spp., nine occur in the United States, and evidence of arenavirus infection has been reported for five of them. Recent field studies have provided strong evidence that Whitewater Arroyo virus circulates in the states of New Mexico, Utah, Texas, Oklahoma, Arizona, and Colorado.[11,40] The abundance and habits of wood rats suggest that potential contact between *Neotoma* rodents and humans is limited.

Lassa virus is associated with rodents belonging to the *Mastomys* genus, widely distributed in sub-Saharan Africa. Documented cases of Lassa fever have been reported in different countries of West Africa, such as Nigeria, Liberia, Sierra Leone, Burkina Faso, Guinea, Ivory Coast, Ghana, Senegal, Gambia, and Mali.[12,42,43,52,77,93,101] Between 1985 and 1987, three of 5000 (0.06%) randomly selected persons living in six central African countries (Cameroon, Central African Republic, Chad, Congo, Equatorial Guinea, and Gabon) tested for serologic evidence of Lassa virus infection were found to have antibody.[46] In contrast, a second study conducted with individuals living in different parts of Nigeria found that 21.3 percent of the 1677 tested antibody positive.[101] Lassa fever is a disease of major public health importance in West Africa because it causes an estimated 5000 deaths and as many as 300,000 infections annually. The first epidemic was described in 1969 in Nigeria,[10] and soon was followed by several other epidemics in nearby countries. Among hospitalized patients, the mortality rate is estimated at 15 to 20 percent.[107] In hospitals located within the endemic area, 10 to 16 percent of the admissions are caused by Lassa fever. However, serologic surveys suggest that subclinical cases occur and result in a lower overall mortality (<1%).[77] The overall incidence of Lassa fever in West Africa may be tens of thousands to hundreds of thousands annually. The main characteristic of Lassa fever is that it is highly transmissible from human to human through direct contact with blood or secretions from infected patients and by aerosol exposure.[60] Many nosocomial outbreaks have been described. Another characteristic of Lassa fever is that a number of cases are acquired by local residents who seek out rodents for consumption.[98] Because of the prevalence of virus transmission, Lassa fever is a prominent threat of imported hemorrhagic fever cases; such cases have been reported in England,[23] Germany,[48] Japan,[53] the Netherlands,[104] Israel,[95] and the United States.[54] A recent comprehensive report of imported Lassa fever recorded 24 cases occurring from 1969 to 2004, with a fatality rate at 29 percent.[68]

PERSON-TO-PERSON TRANSMISSION

Although human-to-human transmission of BHF has been seen only rarely and then only after intimate contact, Machupo virus clearly was responsible for severe nosocomial outbreaks in which all cases were associated with a single index case who had returned from the endemic region. The only recognized hospital-based outbreak resulted in four secondary cases followed by a tertiary case acquired from a necropsy incident; all but one died. An epidemic recently was reported in which seven members of the same family were infected, with a fatal outcome for six.[15]

Nosocomial transmission is a common feature of Lassa fever, and many nosocomial outbreaks have been described.[33,60] However, it is apparent that this aspect of Lassa fever has been overestimated in reports based on infections in hospitals. The additional risk to hospital workers within the endemic zone is not great as judged by serosurveys, provided basic hygiene measures are respected in hospitals in dealing with suspected cases.[51] Good barrier nursing and protection of personnel by use of gloves, gowns, and eye shields have reduced the incidence of such infection in recent years. Broader surveys of community infections have revealed Lassa fever to be an important community-acquired disease, with a wide spectrum of clinical manifestations. Because Lassa virus has been isolated from milk, clearly a risk to nursing children exists.

In conclusion, the data demonstrating nosocomial and human-to-human transmission of several arenaviral diseases highlight the necessity for implementing biocontainment precautions in dealing with arenavirus-infected patients and materials.

TABLE 198–2 Some Laboratory Findings in Arenaviral Hemorrhagic Fevers

Disease	Viremia	RBC Increase	WBC	Urine Protein	AST/ALT
Argentine hemorrhagic fever	+	++	↓↓	+	N-200
Bolivian hemorrhagic fever	+/–	++	↓↓	+	N-200
Venezuelan hemorrhagic fever	++	++	↓↓	+	??
Lassa fever	++++	++	N-↑	++	100-1500

ALT, alanine aminotransferase; AST, aspartate aminotransferase; RBC, red blood cell; WBC, white blood cell count.

CLINICAL MANIFESTATIONS

The clinical picture of the South American arenaviral hemorrhagic fevers is almost identical, regardless of the virus responsible for the disease. The incubation period usually is 7 to 14 days, with an extreme extending from 5 to 21 days. Infection secondary to high-load inoculum may result in the reduction of the incubation period to 2 days. The onset is gradual with fever and malaise, secondarily joined by myalgia, back pain, headache, and dizziness. Hyperesthesia of the skin is a common manifestation. Petechiae of the skin and hemorrhages from the gums, vagina, and gastrointestinal tract beginning about the fourth day of illness herald the advent of hypovolemic clinical shock. Blood loss usually is minor, so the hematocrit generally increases as the capillary leak syndrome, the hallmark of the disease, becomes more severe (Table 198–2). Bleeding and prothrombin time may be prolonged, and reductions of factors II and VII of the coagulation cascade have been noted. Renal function generally is preserved until shock occurs, but urinary protein concentration may be high. Neurologic manifestations are prominent; intention tremor of the hands and inability to swallow or to speak clearly may develop, and these symptoms can progress to grand mal convulsions, coma, and death in the absence of significant capillary leak or hemorrhagic signs. Death usually occurs 7 to 12 days after onset of disease. Those who survive generally recover completely without permanent sequelae, although transient loss of scalp hair and Beau lines in digital nails are a common consequence of the high and sustained fever.

Symptoms that appear to be more specifically associated with one or another of the viruses have been reported.[103] Although the frequency of clinical and laboratory findings is identical for Junín and Machupo virus infections, clear differences exist with Guanarito virus infections. Pharyngitis, vomiting, and diarrhea are observed more frequently with Guanarito virus; in contrast, petechiae, erythema, facial edema, hyperesthesia of the skin, and shock are observed more frequently in the case of Junín or Machupo infection.

Fatal outcome of Junín virus infection is observed more frequently in pregnant women in the last trimester, and a high fetal mortality is associated with Junín and Machupo virus infection.[8,27,57]

The patients infected with Whitewater Arroyo virus were healthy before acquiring the virus infection. In one case, the virus probably was acquired by aerosol pathway while cleaning rodent droppings at home. In all cases, no history of travel outside California was found during the 4 weeks preceding the illness. The onset was characterized by nonspecific febrile symptoms including fever, headache, and myalgia. All patients presented with acute respiratory distress syndrome, and two developed liver failure and hemorrhagic manifestations. Death occurred within 8 weeks after the onset.[17]

Concerning Lassa fever, the clinical description is based on signs observed in hospitalized patients.[41,59,88] After having an incubation period that ranges from 7 to 14 days, patients suffer an insidious onset characterized by progressive fever, malaise, and generalized myalgia. Retrosternal pain frequently is associated with this phase. These symptoms increase in severity during the following week and are accompanied by nausea, vomiting, diarrhea, chest pain, abdominal pain, headache, sore throat, cough, and dizziness. Patients complain of sore throat, pharyngeal inflammation, and chest pain. As the disease progresses, vomiting, diarrhea, hemorrhagic manifestations, encephalopathy, and evidence of vascular permeability may be noted. During the second week, recovery may begin or the disease progressively worsens until harbingers of a fatal outcome are evident: severe edema, mucosal hemorrhages, pulmonary involvement, encephalopathy (with seizures and coma), or shock; at this stage, pleural and pericardial effusions and ascites are not rare findings. There frequently is liver involvement, but icterus is not usual. Death occurs in 15 to 20 percent of the hospitalized patients, usually in the second or third week of the course, and is associated with sudden cardiovascular collapse caused by hepatic, pulmonary, and myocardial damage. Few patients develop severe central nervous system (CNS) signs, and disturbances in consciousness and convulsions are markers of a poor prognosis. Deafness is an important sequela of Lassa fever; it may be unilateral or bilateral and is a consequence of the eighth cranial nerve dysfunction; it can be observed in as many as 30 percent of the patients.

Clinical disease among children generally is similar to that in adults. Systematic data are available for only Lassa fever patients.[83,107] Fever, vomiting, diarrhea, and cough are common presenting symptoms. Pulmonary signs, including rales and pleural effusion, are seen more commonly in children than in adults. Among very young children, especially those infected ante partum, an unusual condition called *swollen baby syndrome* has been described. It is marked by abdominal distention, widespread edema, and spontaneous bleeding.

Lassa virus replicates at a very high level in the placenta of pregnant women, which might account for the high mortality rate observed in these patients. The risk of death in pregnant women is estimated to vary from 7 percent in the first two trimesters to 30 percent in the third trimester, compared with the 13 percent mortality in nonpregnant women. A high fetal mortality rate varying from 92 percent in early pregnancy to 75 percent in the last trimester has been observed.[80,82,89]

Very little is known about the health consequences of infection with the other arenaviruses. Aerosol infections are common in workers of laboratories where arenaviruses are manipulated. Pichindé virus has resulted in several seroconversions without any notable clinical significance.[11] Flexal virus has resulted in two severe laboratory infections and should be regarded as potentially dangerous (F. Pinheiro, personal data). Tacaribe virus has resulted in a single case of febrile disease with mild CNS symptoms (J. Casals, personal data).

PATHOGENESIS AND PATHOLOGY

Human and nonhuman primate infection initially involves virus replication at the site of infection, usually in the lung after infected aerosol deposition. Replication occurs in the hilar lymph nodes, and despite interstitial infiltration, pneumonic foci usually

are not observed. Regardless of the route of infection, the macrophage is a site of important viral replication. With the exception of the hepatitis peculiar to Lassa fever, the pathologic process of arenaviral hemorrhagic fever is notable for the general lack of parenchymal histologic damage. Edema of tissues and focal hemorrhages in mucosal surfaces and fascia of many organs are common events. Rarely are blood clots found that are large enough to be of clinical significance. Thus, the crucial and life-threatening lesion in these diseases appears to be the capillary leak. How this lesion, in which plasma protein and fluid escape the circulation at a much higher rate than erythrocytes do, is produced still is not clear.[88]

Hemorrhages are common findings in New World arenaviruses causing hemorrhagic fever. The prominent thrombocytopenia has a central origin possibly linked to high levels of interferon observed in these patients.[62] Minor foci of necrosis with acidophilic inclusions (Councilman bodies) have been reported in patients with BHF,[21] and erythroid hypoplasia of bone marrow as well as lymphoid depletion of nodes and spleen may be present. Histologic evidence of disseminated intravascular coagulation generally is absent. Inflammatory lesions of the CNS are lacking. Mild inflammation of the myocardium has been noted in patients with BHF. The Argentine and Bolivian fevers may be marked by encephalopathy. Virus is not recovered from cerebrospinal fluid of patients presenting such CNS symptoms with the South American agents. Macrophages and lymphocytes or their precursors are targets for infection, and an activation of the complex cytokine cascade occurs, which can cause endothelial cells of small capillaries to lose the tight continuity that keeps protein and red cells inside the circulation. As part of this cascade, levels of interferon are elevated. Analysis of the serum levels of hematopoietic growth factors suggested a link between granulocyte colony-stimulating factor serum levels and the severity of the illness in humans.[74] Similarly, interleukin-8 is thought to play an essential role in neutrophil activation.[73] Specific antibodies may not appear until 3 to 4 weeks after the onset of the disease. However, New World arenaviruses causing hemorrhagic fever are neutralized more readily, and immune serum–based therapy has been successful for humans. Preliminary studies of VHF suggest that this disease resembles that caused by other South American relatives.[25,92] Genetic analysis of Junín and Guanarito virus sequences amplified from human cases in Argentina and Venezuela, respectively, failed to identify any genetic marker correlating with the human pathogenicity or with the severity of clinical forms.[44,106]

Although only three cases have been reported to date, Whitewater Arroyo virus infection seems to be associated with profound lymphopenia and thrombocytopenia.[17] To date, no studies have been performed to investigate the pathogenesis of Whitewater Arroyo virus infection. An interesting note is that Whitewater Arroyo virus belongs to the lineage A (based on genetic analysis performed in the nucleocapsid gene), in which no other members have been recognized so far as human pathogens. However, the small genomic segment of Whitewater Arroyo virus has been shown recently to have a dual origin: the gene encoding the nucleocapsid is inherited from an ancestor belonging to the lineage A, whereas the glycoprotein precursor gene is inherited from an ancestor belonging to the lineage B.[18] Further investigations are needed to clarify whether the lineage B–inherited GPC gene is responsible for the putative human pathogenicity of Whitewater Arroyo virus.

The hepatitis of Lassa fever is represented by different stages successively characterized by hepatocellular injury, necrosis, and regeneration, any of which may be present at death. In no instance is the degree of hepatic damage sufficient to be responsible for hepatic failure; consequently, the hepatitis of Lassa fever is not the primary cause of death.[58,76] For the cases characterized by encephalopathy, correlation could not be established with the presence of Lassa virus in the cerebrospinal fluid or with virus antibodies in cerebrospinal fluid or serum; no evidence shows that the encephalopathy observed in Lassa fever is the consequence of either direct cytopathic or immune-mediated mechanisms.[24] Direct damage to circulating leukocytes is not demonstrated, and profound thrombocytopenia does not occur.

In human cases of Lassa fever, no correlation exists between antibody levels and outcome of the disease.[35] More than one third of patients have antibodies to the nucleocapsid of the virus on admission to the hospital. These antibodies do not neutralize the virus, which is found in blood in concentrations much higher in severe infection than in any of the other arenaviral diseases. During convalescence, viral neutralizing antibodies evolve for months and rarely reach levels even one tenth of those that develop after infection with the other viruses in this group. Recovery from Lassa virus infection usually precedes the appearance of neutralizing antibodies, indicating that cellular immunity plays a primary role in viral clearance. Thus, it seems reasonable to speculate that compromise of cell-mediated immunity is responsible for uncontrolled virus replication and functional capillary collapse. Primates challenged with Lassa virus or naturally infected patients who recovered from acute Lassa fever usually do not exhibit a measurable neutralizing antibody response. Individuals who are seropositive exhibit a strong memory $CD4^+$ T-cell response against the nucleocapsid protein of Lassa virus.[99] Experiments based on inactivated vaccines have shown that in spite of the resulting synthesis of high titers of antibodies, vaccination did not prevent virus replication and death in nonhuman primates.[35] It, therefore, seems obvious that control of human Lassa fever involves mostly T cells through a T_H1-type immune response. In addition, immune response requires epitopes located on both GP1 and GP2 glycoproteins to protect efficiently primates challenged with Lassa virus.[35]

Several animals have provided reasonable models for the clinical disease seen in humans. Junín virus causes fatal hemorrhagic disease in guinea pigs; rhesus monkeys are good models for Lassa[55] and Machupo virus infections; and marmosets *(Callithrix jacchus)* reproduce the pathogenesis of Junín virus. Indeed, rhesus monkeys were used to predict the effectiveness of the antiviral drug ribavirin to treat Lassa fever, and guinea pigs were instrumental in the development of an attenuated vaccine for AHF. Recently, the paired Syrian golden hamster and Pirital virus (a nonpathogenic clade A arenavirus) has been shown to be a model to mimic clinical virologic and pathologic changes observed with Lassa fever in humans.[94]

Alpha-dystroglycan has been identified as a major receptor for LCM and Lassa viruses. In New World arenaviruses, only clade C viruses (Oliveros and Latino) use alpha-dystroglycan as a major receptor, whereas clade A and clade B arenaviruses use distinct and widely expressed receptors.[90,97] Functional receptors for South American hemorrhagic fever arenaviruses (Guanarito, Junín, and Machupo) were found on most human cell types and cells derived from nonhuman primates and rodents.[91]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

DIRECT DIAGNOSIS

Serum or heparinized plasma should be collected during the acute febrile stages of the disease; the samples need to be frozen on dry ice or in liquid nitrogen. Storage at temperatures higher than –40° C will result in the progressive loss of infectivity. Classically achieved by virus isolation, direct diagnosis now may be performed by reverse transcription–polymerase chain reaction (RT-PCR) assay. Isolation of the virus is achieved readily in cell culture, and Vero cells are a sensitive substrate for such direct

diagnosis. Because cytopathic effect is not always observed, arenavirus-infected cells are detected by immunofluorescence test.

For South American arenaviruses causing hemorrhagic fevers, the delay for isolation on Vero cells is 1 to 5 days, much faster than animal inoculation that requires 7 to 20 days before illness develops. Serum and throat washings collected 3 to 10 days after onset usually yield virus. Virus is isolated less frequently from urine. Specifically, Machupo virus is recovered from only 20 percent of acute-phase sera and even less frequently from throat washings or urine. When serum or throat samples are collected within 2 weeks of clinical onset, the success of isolating Lassa virus is very high. Virus is isolated less frequently from urine.

Viral RNA can be purified from serum, plasma, urine, throat washings, and tissues and can be used as a target for cDNA synthesis, with use of a reverse transcriptase. This cDNA can be amplified by a PCR assay with consensus primers or specific primers. The amplified region finally is sequenced for diagnostic confirmation. RT-PCR–based diagnosis offers the advantage of reducing the delay of response and of possessing a greater sensitivity compared with cell culture. This technique has been applied successfully to Lassa fever diagnosis. Specific primers designed to amplify certain arenaviruses have been proposed but still are not used for diagnostic purposes in epidemic conditions. Molecular tests based on the RT-PCR methodology are being developed increasingly for the diagnosis of arenaviral infections.[67] For Junín and Machupo virus infection specifically, this technique is the only one to be early and sensitive enough to detect low viremia encountered during the period in which immune plasma therapy can be used effectively.[64] At the time of admission to the hospital, RT-PCR detected Lassa virus RNA in 79 percent of the patients; for comparison, in these patients, immunofluorescence assay detected antibodies in only 21 percent. By the third day of admission, 100 percent of the patients tested positive by RT-PCR analysis, whereas only 52 percent tested positive by the immunofluorescence assay.[26] The drawbacks of molecular methods consist mostly of the need for sophisticated equipment to be fully applicable in the field conditions when an outbreak occurs.

Additional techniques for direct detection of viral presence in tissues are being actively developed; they include in situ nucleic acid hybridization techniques. Antigen-detection enzyme-linked immunosorbent assay (ELISA) has been a sensitive tool in a number of patients.

More recently, molecular assays taking advantage of the real-time PCR technology have been reported for the detection of the four South American arenaviruses causing VHF. Apart from assays specific for one virus, a universal clade B PCR assay proved able to detect 5 to 500 $TCID_{50}$ per reaction for Junín, Machupo, Guanarito, and Sabiá viruses and also for Tacaribe, Cupixi, and Amapari viruses.[105] These tests have application to laboratory diagnosis on human specimens but also can be used to detect arenaviruses in rodent tissues.

The first quality assurance study on the rapid detection of Lassa virus RNA included 24 participant laboratories from 17 countries; tenfold dilutions of Lassa virus–inactivated genetic material were detected with success varying from 21 to 85 percent, depending on the concentration in the sample.[84] Of interest is that specimens containing high concentration of viral RNA may lead to false-negative results by the inhibition of enzymatic reaction, suggesting that clinical specimens should be either spiked with internal control to monitor enzymatic reaction efficacy or tested after dilution.[28,84]

INDIRECT DIAGNOSIS

Serologic diagnosis is made by demonstration of a fourfold rise in the titer of specific antibody. A high immunoglobulin G (IgG) antibody titer or the presence of specific IgM is indicative of a probable case. Nucleocapsid antigens are shared by most of these viruses, and quantitative relationships show the basic split between the viruses of Africa and the Western Hemisphere. Individual viruses immunologically are distinct by neutralization test, which depends on the specificity of epitopes contained in the envelope glycoproteins G1 and G2. Samples collected in view of serologic diagnosis can be kept at –20° C. Blood obtained in the early convalescence may be infectious despite the presence of antibodies and therefore should be handled accordingly. Antibodies often are detected by indirect immunofluorescence because it is an inexpensive, rapid, and sensitive test. An alternative is the ELISA, the specificity of which is greater than, and the sensitivity of which is on the level of, the neutralization test. ELISA is therefore the test of choice for differentiating viral strains of arenaviruses, for confirmation of unexpected results, and for detection of infection from the distant past. All these tests have been tested in the conditions of an outbreak and revealed effective.

Antibodies specific to South American arenaviruses appear 12 to 30 days after the onset, which often correlates with clinical improvement.[86]

In the case of Lassa fever, antibodies detectable by immunofluorescence appear early and often are present during the acute illness with no apparent relation to viremia or clinical status; 50 percent of patients with Lassa fever develop IgM or IgG antibody during the first week, and more than 66 percent do so during the next week. Antigen-detection ELISA in conjunction with IgM-capture ELISA has shown promise for rapid and sensitive diagnosis of Lassa fever. Neutralizing antibodies usually develop only after 4 to 6 months of convalescence.

PREDICTIVE VALUE

In West Africa, the association of fever, pharyngitis, retrosternal pain, and proteinuria presented a predictive value of 81 percent. In the endemic area of Argentina, the constellation of asthenia and dizziness accompanied by petechiae and conjunctival congestion has been shown to be indicative for the diagnosis of AHF; the presence of leukopenia, thrombocytopenia, and proteinuria further reinforces the diagnostic suspicion based on clinical findings. The association of a platelet count of less than 100,000/mm^3 and a white blood cell count of less than 2500/mm^3 or less than 4000/mm^3 was reported to have a sensitivity at 87 percent and 100 percent, respectively, and a specificity at 88 percent and 71 percent, respectively.[49]

DIFFERENTIAL DIAGNOSIS

Differential diagnosis of Lassa fever should include malaria, typhoid, shigellosis, dengue, and yellow fever. For South American viruses causing hemorrhagic fever, the differential diagnosis includes yellow fever, dengue hemorrhagic fever, hepatitis, leptospirosis, hemorrhagic fever with renal syndrome caused by hantaviruses, rickettsial diseases, typhoid, sepsis with disseminated intravascular coagulation, and, in the case of CNS involvement, viral encephalitis.

Because of biosafety reasons, suspected cases must be reported to the national laboratories having the expertise and capacity for molecular diagnostics of viral hemorrhagic fevers together with a procedure adapted to handling and transportation of specimens. Isolation of virus must be attempted in biosafety level 4 (BSL-4) laboratory facilities.

PROGNOSIS AND TREATMENT

PROGNOSIS

The case-fatality ratio of AHF, which is greater than 15 percent without specific treatment, drops spectacularly to less than 1 percent when specific treatment is available.[49] Granulocyte colony-stimulating factor serum level seems to be a marker of severity of the illness.[74]

For Lassa fever, no correlation exists between antibody levels and outcome. Viremia levels in Lassa fever are important in terms of prognostic value; basically, the higher the viremia, the higher the mortality rate. The serum aspartate aminotransferase level also is an accurate prognostic marker; values above 150 U/mL are associated with a 55 percent mortality rate, whereas the overall mortality rate is approximately 15 percent.[58]

TREATMENT

Arenaviral hemorrhagic fever should be managed by monitoring and correction of fluid, electrolyte, and osmotic imbalances and of metabolic acidosis. Hydration should be done cautiously because of the generalized capillary leak and the possibility of precipitating pulmonary edema. If possible, bleeding should be treated with clotting factor and platelet replacement as guided by laboratory test results.

For Junín virus infection, immune serum therapy is effective in reducing the incidence of mortality when it is given within the first 8 days of illness.[30,71] Experimental evidence suggests that the plasma may work through attacking infected cells as well as viral neutralization. An important note is that 10 percent of the patients who received this treatment secondarily developed cerebellar signs, such as headaches and tremors. These clinical signs are transient; they are thought to be related to immunopathologic mechanisms induced by the treatment with convalescent plasma.

Despite the recognized efficacy of convalescent plasma for treatment of Machupo virus infection, the paucity of survivors and the lack of programs for collection and storage of BHF immune plasma anticipate the problem of shortage in case of a new outbreak. In recent cases, ribavirin was offered to two patients presenting with life-threatening infection; both recovered without sequelae. These promising results suggest the need for performing more extensive clinical studies to assess the usefulness of ribavirin for treatment of BHF.[61]

Junín and Guanarito viruses showed very high in vitro sensitivity to ribavirin and also showed antiviral effect in patients.[31] One of the laboratory-acquired Sabiá virus infections was treated successfully with ribavirin; the treatment was started early after the onset, and there was no production of neutralizing antibodies.

The late evolution and low titers of Lassa virus neutralizing antibodies render immune serum–based therapy less efficient than in treatment of South American arenaviral fevers.[75] In contrast, clinical studies have shown ribavirin to be of benefit in severe cases and that it therefore should be used as early as possible in the course of the disease. The intravenous regimen that is recommended is as follows:

- a loading dose of 30 mg/kg, then
- 15 mg/kg every 6 hours for 4 days, then
- 7.5 mg/kg every 8 hours for 6 days.

A recognized side-effect of ribavirin is hemolytic anemia, reversible when drug administration is interrupted.

THE FUTURE OF ANTIVIRALS IN THE DOMAIN OF ARENAVIRUSES

In the past 5 years, basic research has used reverse genetics to develop replicons and infectious clones that are used to investigate virus replication mechanisms, to test antivirals in vitro, and to better understand arenavirus cycles. The development of reverse genetic systems allows conduction of a detailed molecular characterization of the viral *cis*-acting signals and *trans*-acting factors that control each of the steps of the virus cycle, including RNA synthesis, packaging, and budding. Likewise, the ability to generate predetermined specific mutations in the genome and to analyze their phenotypic expression will contribute to elucidation of the arenavirus-host interactions as well as the mechanisms leading to severe hemorrhagic disease in humans. The development of a mini-replicon system for Lassa virus will help the investigation of replication and transcription and may facilitate the testing of antivirals outside BSL-4 laboratories.[50]

Infectious LCM virus has been recovered entirely from cDNA. Intracellular transcription from polymerase I–driven vectors and co-expression of the minimal viral transacting factors NP and L from polymerase II–driven plasmids resulted in the efficient formation of infectious virus with genetic tags in both genome segments; this cDNA-derived virus behaves identically to wild-type virus in both cell culture and infected mice.[36]

High throughput screening of molecules for their antiviral effects is being performed increasingly by both public laboratories and private companies. From 2003 to 2006, six articles reporting testing of molecules with antiviral efficacy on arenaviruses were published.[1,3,5,12,47,102]

PREVENTION AND CONTROL

Prevention of arenavirus disease consists of preventing transmission from rodents to humans, from humans to humans, and from infected specimens to laboratory personnel. Strategies for avoiding contact between rodents and humans have been effective in BHF.[69] Simple trapping of *C. callosus* in towns was successful in reducing human contact and thus reducing the disease to essentially zero. This is more difficult in AHF because conditions under which human exposure occurs are different from those in BHF. *C. musculinus* (reservoir of Junín virus) distribution is much wider than that of *C. callosus* (reservoir of Machupo virus), and Argentine agricultural practices continue to place workers at risk of exposure to reservoir hosts.

A collaborative effort conducted by the United States and Argentine governments led to the production of a live attenuated Junín virus vaccine named Candid 1, which has passed safety and immunogenicity tests in U.S. volunteers. Its efficacy was established in a double-blind trial in 15,000 agricultural workers at risk for natural infection in Argentina. Subsequently, more than 100,000 persons were immunized with Junín virus vaccine in Argentina. Recent animal protection studies suggest that the Junín vaccine could be protective against Machupo virus infections as well. A prospective study conducted during two epidemic seasons among 6500 male agricultural workers in Argentina showed that Candid 1 vaccine efficacy was 84 percent or higher and that no serious adverse effects could be expected.[72]

Neutralizing antibody titers to Candid 1 vaccine against AHF were studied for 2 years after vaccination in 330 volunteers. Of a total of 160 volunteers who received Candid 1, 54 had no detectable preinfection with arenaviruses, 55 had preexisting antibodies to Junín virus, and 51 had preexisting antibodies to LCM virus; the remaining 170 individuals received placebo. Levels of anti–Junín virus antibodies displayed a trend in which

titers increased with the virulence of the infecting strain, from Candid 1 through subclinical Junín virus infection, vaccination after subclinical infection, and Junín virus symptomatic infection. The study also demonstrated that the mean titer and neutralizing antibodies to Candid 1 did not vary significantly during the 2 years, was significantly lower than that elicited by wild strains of Junín virus, significantly increased the titers of preexisting anti-Junín antibodies, and was not modified by preexisting anti-LCM virus antibodies.[2]

Comparative sequence analysis of the L RNA segment of Candid 1 strain and the more virulent ancestors (XJ 44 and XJ 13) revealed 12 point mutations in the L polypeptide that are unique to the vaccine strain[45]; whether these changes are associated with the attenuated phenotype remains to be investigated by the use of the reverse genetic systems.

For VHF, no preventive measures have been developed. Attenuated Junín virus strains do not protect experimental animals against challenge with Guanarito virus. In VHF, the evidence suggests that transmission occurs around houses and in fields as in BHF, so measures to avoid contact between rodents and humans should be effective, as shown for BHF.

For Lassa fever, reducing the contact with *Mastomys natalensis* is a formidable task in West Africa, and this option does not seem to have a promising future. Because person-to-person transmission has been reported in Lassa fever, precautions should be taken to place patients in single rooms. The health care team should be small and adequately trained; they should wear gloves, gowns, and filter masks.[14,16] All secretions should be decontaminated.[63] Laboratory procedures should be done with care by use of inactivating methods of heat, chemicals, or irradiation.

In rhesus monkeys *(Cercopithecus aethiops)*, the humoral antibody response measured after they were challenged with purified inactivated Lassa virus, although as high as in humans who recovered from Lassa fever, was insufficient to protect the animals from a fatal outcome.[78] A naturally attenuated strain (Mopeia virus, from Mozambique) protects rhesus monkeys against challenge with Lassa virus, but field studies are required to establish the extent and nature of natural human infection with this virus before it can be considered seriously as a candidate for human vaccine development. Alternative approaches, including the use of vaccinia virus vectors bearing the Lassa virus GPC or N gene, are being investigated actively and show promising preliminary results.[34,35] Recently, two peptides encoded by the glycoprotein precursor were shown to display high-affinity binding to human leukocyte antigen (HLA)-A*0201 transgenic mice; mice immunized with these peptides were protected against challenge with a recombinant vaccinia virus that expressed Lassa virus glycoproteins. These two epitopes represent candidates for inclusion in epitope-based vaccine constructs.[6]

THE FUTURE OF VACCINE RESEARCH

Tremendous advances have been made during the past 5 years for vaccine development. Many different approaches were used. Reverse genetic exchange of the viral glycoprotein for foreign glycoproteins created attenuated vaccine strains that remained viable although unable to cause disease in infected mice; this phenotype remained stable even after extensive propagation in immunodeficient hosts. The engineered viruses induced T cell–mediated immunity, protecting against systemic infection and severe liver disease on wild-type virus challenge.[4] The yellow fever vaccine 17D has been used as a vector for the Lassa virus glycoprotein precursor, resulting in construction of recombinant virus, which was replication competent and processed Lassa virus glycoprotein in cell culture. The recombinant virus replicated poorly in guinea pigs but still elicited specific antibodies against Lassa and yellow fever antigens, and single subcutaneous injection protected guinea pigs against fatal Lassa fever.[66] Clone ML29 is a reassortant virus that encodes the nucleocapsid protein and glycoproteins from Lassa virus and the RNA polymerase and matrix protein of Mopeia virus; replication of ML29 was attenuated in guinea pigs and nonhuman primates. Guinea pigs vaccinated with ML29 survived after challenge with Lassa virus without developing either signs of disease or histologic lesions. Rhesus macaques inoculated with clone ML29 developed primary virus-specific T cells capable of secreting interferon in response to homologous and heterologous challenge (the latter with Mopeia virus and LCM virus). Vaccinated monkeys did not present any histologic lesions or signs of disease.[65]

CHAPTER 199

Filoviral Hemorrhagic Fever: Marburg and Ebola Virus Fevers

Eric Leroy

Ebolavirus and *Marburgvirus* are the only genera of the family *Filoviridae*, which belongs to the order Mononegavirales.[13] Ebola and Marburg viruses are among the most virulent pathogens for humans and great apes. Human outbreaks of acute hemorrhagic fever are associated with case-fatality rates of up to 88 percent, and Ebola virus also causes concomitant devastating outbreaks in Central African great apes. No specific treatment or vaccine is available.

Ebola and Marburg viruses are biohazard level 4 and biothreat category A agents and obviously must be manipulated in maximum security facilities.

ETIOLOGIC AGENTS

Members of the *Filoviridae* all have similar morphologic features. The viral particles are filamentary and often form bizarre configurations, such as 6-shaped forms and hairpins (Fig. 199–1), and may be up to 14,000 nm in length.[13,62] In contrast, the filaments are always 80 nm wide. The capsid contains a single negatively stranded RNA genome that encodes seven structural proteins and one nonstructural protein, the soluble glycoprotein.[63,76,77] Filoviruses replicate readily in Vero, MA-104, and SW-13 cells, although specific species seem to prefer particular primate cell lines. These viruses also are highly pathogenic for macaques, producing a hemorrhagic disease and killing more than 75 percent of infected animals.[15,17] The *Filoviridae* comprise two genera. The only member species of the "Marburg-like viruses" genus is Marburg virus itself. The "Ebola-like viruses" genus comprises four antigenically and genetically related species, named *Zaire ebolavirus*, *Sudan ebolavirus*, *Ivory Coast ebolavirus*, and *Reston ebolavirus*. With the possible exception of *Reston ebolavirus*, filoviruses are highly pathogenic organisms that must be handled in special laboratories (biosafety level 4) with maximal biologic containment. Guidelines on the management of patients and specimens suspected of harboring these viruses are available from the Centers for Disease Control and Prevention in Atlanta *(http://www.cdc.gov/ncidod/dvrd/spb)*. There are virtually no antigenic relationships between Marburg virus and Ebola virus. The four Ebola virus species exhibit extensive cross-reactivity in immunofluorescence methods and enzyme-linked immunosorbent assays (ELISAs). Virus neutralization, in contrast, has been virtually impossible to measure for any of the filoviruses, which has hindered epidemiologic and ecologic studies of these agents. Unlike the other three Ebola species, which are confined to Africa, *Reston ebolavirus* is found only in the Philippines among nonhuman primates.[30] Only the three African Ebola virus species appear to be pathogenic for humans.

HISTORY AND EPIDEMIOLOGY

MARBURG VIRUS

In 1967, simultaneous outbreaks of a previously unknown hemorrhagic fever occurred in Marburg and Frankfurt (Germany) and

in Belgrade (Serbia, former Yugoslavia) (Table 199–1).[50,51,65] The source was traced to African green monkeys *(Cercopithecus aethiops)* from a primate export facility in Entebbe, Uganda. Thirty-one cases occurred, including six by secondary transmission, and seven deaths occurred among primary cases. An unknown infectious agent was recovered from the blood and organs of these persons and was named Marburg virus, after the German city where the first cases occurred. Sporadic cases since then have been diagnosed in the south part of Africa in 1975[21] and in Kenya in 1982.[67] A lengthy outbreak occurred between 1998 and 2000 in Durba (eastern Democratic Republic of the Congo), affecting 154 people and killing 83 percent of victims (Fig. 199–2).[7] Most patients (94%) worked in underground gold mines. Because of the civil war raging in 1997, the cause of the outbreak was not identified until 1999, a year after the first cases occurred. The Durba outbreak was characterized by the circulation of multiple viral strains, pointing to multiple independent introductions from the unknown natural reservoir.[6,7] The largest recorded Marburg outbreak occurred recently, in Uige Province of northern Angola. It was the first recorded outbreak in the west side of Africa and lasted from October 2004 to July 2005, causing 252 cases and 227 deaths (fatality rate, 90%).[10] Complete genomic characterization showed that the culprit strain, named *Angola marburgvirus*, was closely related to previous East African isolates.[73-82]

EBOLA VIRUS

1976-1979: The First Recorded Ebola Outbreaks

Ebola first emerged in the form of two nearly simultaneous outbreaks in 1976, one due to *Sudan ebolavirus* and the other due to *Zaire ebolavirus*.

The first outbreak was due to *Sudan ebolavirus* and occurred in Sudan, near the border with the Democratic Republic of the Congo, mainly affecting the towns of Nzara and Maridi.[68] There were 284 cases and the mortality rate was 53 percent, a proportion characteristic of *Sudan ebolavirus* infection. The outbreak due to *Zaire ebolavirus* occurred in the Democratic Republic of the Congo, near the border with Sudan, 2 months later.[36] The epicenter was Yambuku, about 800 km from Nzara. This previously unknown disease was named for the river Ebola, which flows past Yambuku. There were 318 cases and the mortality rate was 89 percent, characteristic of *Zaire ebolavirus* infection. Later, an unconfirmed lethal case involving a 9-year-old girl living in Tandala, Democratic Republic of Congo, was reported,[31] followed by another *Sudan ebolavirus* outbreak in 1979, again in Nzara, with 34 cases and 22 deaths.[5]

1994-1997: Ebola Resurgence

After a 15-year period in which no further cases were recorded, Ebola re-emerged in 1994 for a 3-year period. This new phase

TABLE 199–1 Year and Location of Filoviral Hemorrhagic Fever Cases and Outbreaks

Year	Virus Species	Country	No. of Human Cases	Fatality Rate (%)
1967	*Marburg*	Germany and Serbia	37	19
1975	*Marburg*	South Africa	3	33
1976	*Zaire Ebola*	Zaire	318	88
1976	*Sudan Ebola*	Sudan	284	53
1976	*Sudan Ebola*	England	1	0
1979	*Sudan Ebola*	Sudan	34	65
1980	*Marburg*	Kenya	2	50
1987	*Marburg*	Kenya	1	100
1989	*Reston Ebola**	United States	0	0
1990	*Reston Ebola**	United States	0	0
1992	*Reston Ebola**	Italy	0	0
1994	*Marburg*	Zaire	11	Unknown
1994	*Zaire Ebola*	Gabon	44	63
1994	*Côte d'Ivoire Ebola*	Ivory Coast	1	0
1995	*Zaire Ebola*	Zaire	315	81
1996	*Zaire Ebola*	Gabon	37	57
1996	*Zaire Ebola*	Gabon	60	75

2000	*Sudan Ebola*	Uganda	425	53

**Symptomatic infections and fatal cases were observed in nonhuman primates only.*
†*Democratic Republic of Congo (DRC), formerly was known as Zaire.*

Figure 199–2 Geographic distribution of human outbreaks of Marburg virus fever in Africa.

was marked by the identification of a new species, *Ivory Coast*, and by four *Zaire ebolavirus* outbreaks. The only case caused by *Ivory Coast ebolavirus* occurred in 1994, when an ethnologist sickened a few days after performing an autopsy on a chimpanzee found dead in Tai National Park in Ivory Coast.[18,42,43] A large outbreak then occurred in 1995, in and around the town of Kikwit, south of the Democratic Republic of Congo,[56] with 315 cases and a mortality rate of 81 percent. Despite the deployment of more sophisticated scientific and medical resources than were available in 1976, this outbreak was as large as the 1976 one, probably because it affected a town of several hundred thousand inhabitants and where person-to-person transmission occurred mainly in two hospitals. Three other outbreaks, all due to *Zaire ebolavirus*, struck northeast Gabon between 1996 and 1997.[28] The first occurred in northeastern Gabon, close to the border with Cameroon,[2] in three gold-digger camps located in the heart of the forest. Some of the victims left the camps for the nearest hospital, located in Makokou, where they infected other patients and caused a second wave of virus dissemination. In total, 49 clinical cases and 29 deaths were recorded. The second outbreak hit the village of Mayibout, located south of Mekouka.[28] The first victims were 18 children who had helped to carry and butcher a chimpanzee carcass found in the forest. These 18 children infected their families and friends, who in turn transmitted the disease to neighboring villages. In total, this outbreak involved 31 people and caused 21 deaths. The third outbreak in this region occurred between October 1996 and March 1997.[28] It started among hunters, who infected a traditional healer, his assistant, and some of his patients, who in turn transmitted the disease to several towns and villages in Gabon. Fifteen cases and 11 deaths were recorded in Libreville, and a South African nurse was infected by a Gabonese physician who had traveled to Johannesburg. This outbreak, with 60 cases and 45 deaths occurring in a 6-month period, was noteworthy for its wide geographic range.

2000-2004: A Geographic Pattern of *Zaire Ebolavirus* and *Sudan Ebolavirus* Resurgence

ZAIRE EBOLAVIRUS OUTBREAKS

The first outbreak during this period occurred in northeast Gabon and northwest Democratic Republic of Congo between October 2001 and May 2002.[47] It spread along the main road between Mekambo (Gabon) and Mbomo (Democratic Republic of Congo) and, in fact, involved several independent epidemic chains of human-human transmission with different source animals.[46] All these epidemic chains started when local hunters found and manipulated the carcasses of an antelope, chimpanzees, and gorillas. Simultaneously, a second outbreak occurred in the Democratic Republic of Congo, in villages close to the Gabonese border, 200 km south of Mbomo. It then spread to the town of Kelle, about 65 km away. The origin of this outbreak is unknown. The third outbreak also affected the region of Mbomo, between 2002 and 2003.[20] It had two independent sources resulting in two independent chains, one in Mbomo and the other in Kelle. This outbreak involved 143 cases and caused 128 deaths. The fourth outbreak again affected the region of Mbomo, in late 2003; the first cases occurred in Mbanza, a village located about 30 km north of Mbomo. Thirty-five cases and 29 deaths were recorded.[80] The last outbreak occurred in 2005 in Etoumbi, 60 km south of Mbomo, where 12 cases and 9 deaths were reported. Simultaneously with the human outbreaks, *Zaire ebolavirus* also infected animals belonging to several species, including gorillas, chimpanzees, and duikers, probably accounting for the sharp declines in animal populations observed in these regions between 2001 and 2005.[32,46,79]

SUDAN EBOLAVIRUS OUTBREAKS

Two outbreaks of *Sudan ebolavirus* also occurred during this period (Fig. 199–3). One hit Uganda in 2000, causing 173 deaths

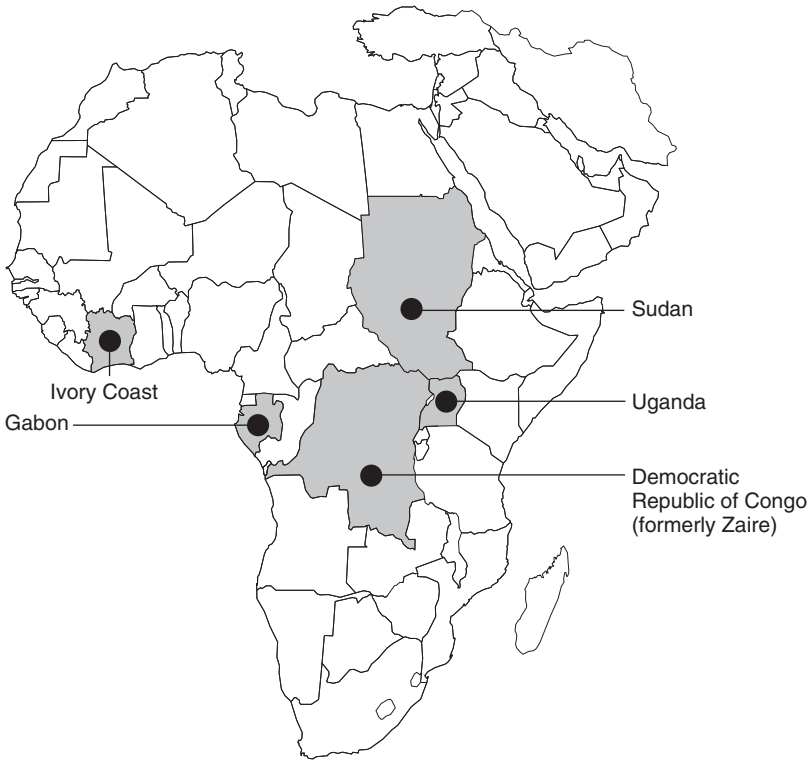

Figure 199–3 Geographic distribution of human outbreaks of Ebola virus fever in Africa.

among its 425 victims (mortality rate, 40.7%).[83] It was the largest of all recorded outbreaks and comprised three foci, one in the immediate area of Gulu, one in the town of Masindi, and one in Mbarara; the last outbreak was small, and the index patient was a soldier. A second *Sudan ebolavirus* outbreak occurred in Sudan in 2004 in the town of Yambio, located only a few dozen kilometers from Nzara and Maridi, which had been struck in 1976 and 1979. There were 17 cases and 7 deaths.[81]

THE PARTICULAR CASE OF *RESTON EBOLAVIRUS*

In 1989, it became apparent that Ebola virus is not restricted to Africa. A group of cynomolgus monkeys *(Macaca fascicularis)* from the Philippines, quarantined in a laboratory in Reston, Virginia, developed a lethal hemorrhagic disease.[34] Virions antigenically similar to Ebola virions were detected in tissues, and Ebola virus infection was confirmed by culture in Vero cells. In the following weeks, the introduction of new monkeys and the spread of the infection to several animal rooms meant that the entire cohort of more than 400 animals had to be destroyed. The building was fumigated and abandoned. The virus was recovered from another macaque in Philadelphia and later in a laboratory in Italy.[57] Although no humans fell ill during these episodes, several monkey handlers in the United States were shown to have seroconverted. In 1996, a cynomolgus monkey imported from the Philippines died in an animal facility in Texas, where two additional cases subsequently occurred, all caused by *Reston ebolavirus*.[61]

EBOLA VIRUS ECOLOGY AND BREAKTHROUGH TO HUMANS

The sources of most human outbreaks of viral hemorrhagic fever, including most Marburg outbreaks, the *Zaire ebolavirus* outbreaks that occurred between 1976 and 1997, and all outbreaks of *Sudan ebolavirus*, have not been identified.

In contrast, several outbreaks have been firmly linked to infected animal carcasses. As mentioned before, an ethnologist became infected by *Ivory Coast ebolavirus* in 1994 while performing an autopsy on a chimpanzee.[43] Similarly, the 1996 Mayibout outbreak in Gabon started among children who found and butchered a chimpanzee carcass in the forest.[28] The 1967 outbreak of Marburg virus infection in Marburg and Belgrade was linked to the handling of organs and tissues from vervet monkeys imported from Uganda.[50,65] Likewise, the sources of the *Zaire ebolavirus* outbreaks that occurred in the border region of Gabon and Democratic Republic of Congo between 2001 and 2003 are well documented; they all occurred after people handled animal carcasses they had found in the forest (mainly gorillas, chimpanzees, and duikers).[46]

Since 1976, 13 outbreaks and two isolated cases of Ebola, totaling about 1850 human cases and 1300 deaths, have struck countries spanning the equatorial forest regions of Africa.[80]

Ebola hemorrhagic fever is thus a zoonotic disease that often is transmitted to humans by direct contact with infected animal carcasses, which are themselves probably infected from the reservoir animal species that harbor the virus, symptomatically or asymptomatically. Since the first recorded human outbreak occurred, many field and laboratory studies have been conducted in attempts to identify Ebola virus reservoir species. Wild animals (vertebrates and invertebrates) were captured in the field, and blood and tissues were used to inoculate Ebola virus–permissive Vero cells. Six field studies, conducted from 1976 to 1995, examined a total of 7000 vertebrates and 30,000 invertebrates, but none was found to harbor Ebola virus.[36-54] Although small Ebola virus nucleotide sequences and Ebola virus–like nucleocapsids were detected in organs of six mice (*Mus musculus* and *Praomys* sp.) and a shrew *(Sylvisorex ollula)* caught in Central African Republic in 1999,[54] no conclusions could be drawn as to their reservoir status.

All attempts at experimental inoculation of rodents, bats, birds, reptiles, mollusks, arthropods, and plants have failed, although some bat species belonging to the genera *Epomophorus* and *Tadarida* developed transient viremia lasting nearly 4 weeks.[72,75] These results did not provide conclusive evidence that bats serve as an Ebola virus reservoir.

Other field collections were conducted during 2002 and 2003 in Gabon and Republic of Congo, in areas hit by the different outbreaks. A total of 1030 animals were captured, autopsied, and analyzed. The captures and laboratory analyses spanned a period of 4 years. The results showed that three species of fruit bat (*Hypsignathus monstrosus*, *Epomops franqueti*, and *Myonycteris torquata*) were asymptomatically infected by Ebola virus.[45] Indeed, anti–Ebola virus IgG was detected in the serum of 16 bats (four *Hypsignathus*, eight *Epomops*, and four *Myonycteris*), but no other animal species, including other bat species, were positive. Likewise, Ebola virus nucleotide sequences were detected in the organs of 13 bats (three *Hypsignathus*, five *Epomops*, and five *Myonycteris*). Sequencing of the amplified fragments confirmed they were specific to Ebola virus. Phylogenetic analysis of the sequences by the Bayesian and maximum parsimony methods showed they belonged to the species *zaire*. Although the virus itself was not isolated, this work provided the first biologic evidence that some fruit bat species harbor Ebola virus. In addition, these findings were in keeping with certain epidemiologic clues from previous outbreaks and with the transient viremia observed in some bat species after experimental challenge. The distribution of the bat species also matched that of the outbreaks.

CLINICAL MANIFESTATIONS

Marburg virus and the four Ebola virus species all cause severe hemorrhagic fever, but they differ in terms of the incubation period, clinical severity, and case-fatality rate.[49] After an incubation period ranging from 2 to 21 days (mostly 4 to 9 days), symptoms of Ebola virus fever occur abruptly. Most patients develop high fever, headache, muscle pain, stomach pain, fatigue, and diarrhea; some patients also have sore throat, hiccup, rash, and red and itchy eyes.[9,49] Bloody diarrhea and hematemesis also can occur. After about a week, probable fatal outcome is signaled by the onset of chest pain and shock, together with blindness and bleeding in some cases. The incubation period of Marburg virus fever is almost identical to that of Ebola virus fever; clinical onset also is abrupt, starting with fever, chills, headache, and muscle pain. A week later, some patients develop a maculopapular rash, nausea, vomiting, chest pain, abdominal pain, diarrhea, and sore throat. Clinical status deteriorates gradually, with jaundice, delirium, shock, liver failure, massive hemorrhaging, and multiorgan dysfunction.[9,33,58,66] Although the virus disappears quickly from the bloodstream of survivors, it can persist in the eyes and testicles.[11,51] Indeed, Marburg virus was recovered from the semen of one patient some weeks after clinical recovery.

Studies of nonhuman primates show that filovirus infection triggers clotting disorders, but their clinical repercussions are variable. In survivors, they are limited to conjunctival hemorrhage, easy bruising, failure of venipuncture sites to clot, and bloody vomiting and diarrhea. Most fatalities are associated with disseminated intravascular coagulation and systemic bleeding.[14,16,23,26,27]

Mild leukopenia is a common development early in filovirus diseases, but leukocytosis may appear later in response to secondary bacterial infection (usually of the lungs). Thrombocytopenia (<100,000 platelets/mm^3) always is present, and coagulation studies are abnormal at the time of onset of bleeding. Fibrin split products indicative of disseminated intravascular coagulation have been detected in humans and experimentally infected primates. Serum transaminase activity is markedly elevated, whereas the bilirubin level is normal and clinical jaundice is a rare development. Serum protein levels are depressed, the hematocrit is increased, and proteinuria is a common finding.

PATHOLOGY

Limited information is available on human filovirus infections, whereas a large body of data has been obtained with experimentally infected rodents and nonhuman primates. Why some people recover from filovirus fevers and others die remains unclear.

No major difference exists in the pathogenesis of the different filovirus diseases. Studies of *Zaire ebolavirus* show that dendritic cells and macrophages are the initial host targets at the entry site.[12,23,27] These infected cells then disseminate through the bloodstream and lymphatics to all organs, where they release virions that infect monocytic cells in lymph nodes, spleen, liver, and other organs and tissues.[1] In the later stages of the disease, the virus also infects other cell types, such as hepatocytes, adrenal cortical cells, and endothelial cells, causing lysis and necrosis.[26] Lymphocytes do not seem to be infected, but they nonetheless undergo bystander apoptotic lysis.[24]

The pathogenetic mechanisms of filovirus infection involve both direct damage to infected cells[70,78] and indirect insults through interactions between the virus and the adaptive immune system.[53] By contrast with other viruses, filoviruses can infect and kill a wide variety of cells throughout the body. This apparent lack of target cell specificity may be due to the binding of the viral surface glycoprotein to widely distributed cell surface lectins.[64] Infection of macrophages and dendritic cells can suppress various cellular functions, including the production of proinflammatory mediators such as interferon-α, interleukin-1β, and tumor necrosis factor-α (TNF-α),[4,8,29] contributing to the suppression of innate antiviral responses and weakening adaptive immune responses. Studies of serial samples from infected nonhuman primates have shown that lymphocytes undergo apoptosis in vivo, probably through the TRAIL and FAS pathways.[23,24] These findings are compatible with the massive intravascular apoptosis of peripheral monocytic cells observed in patients who died (but not in those who survived) during the 1996 outbreaks in Gabon.[3] This bystander lymphocyte destruction has been suggested to play a major role both in immunosuppression and in the onset of septic shock observed in nonsurvivors. Various studies have shown that filovirus infection of endothelial cells causes their lysis and a loss of vascular integrity, leading to disseminated intravascular coagulation, vascular dysfunction, and finally shock.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

In the clinical setting, Marburg and Ebola virus fevers must be distinguished from other viral hemorrhagic diseases occurring in Africa as well as from the many bacterial, rickettsial, and protozoal diseases that can cause similar initial signs and symptoms. The absence of jaundice helps eliminate yellow fever and Rift Valley fever. For patients seen outside Africa, the travel history is the most important diagnostic sign available to physicians. Early laboratory diagnoses of Ebola virus and Marburg virus infection are based on antigen-capture ELISA, reverse transcriptase–polymerase chain reaction (RT-PCR), real-time PCR, and virus isolation.[38-40,44,74] These tests are the most accurate tools for diagnosis of acute Ebola virus fever. Later in the course of the disease, or after recovery, diagnosis relies on immunoglobulin M (IgM)-capture ELISA or IgG antibody detection. Interestingly, however, specific antibodies do not develop in a significant proportion of patients in whom the disease is fatal. Recently, a study

showed that these diagnostic tools also could be used for oral fluid specimens obtained from clinical patients.[19] Because large quantities of Ebola virus are present in dermal tissue, skin necropsy with immunohistochemical analysis has been proposed for postmortem diagnostic confirmation.[85] These specimens are easy to collect, and formalin fixation renders them safe for transport. Skin biopsy testing is not sufficiently sensitive for early diagnosis, however, and thus should be reserved for dead or dying patients.

Cases have been classified into three categories, depending on the patient's clinical manifestations and epidemiologic data:

- Suspect: a person with fever and a history of contact with a potential case (i.e., a person with unexplained bleeding, or with fever plus three or more of the following symptoms: headache, vomiting, loss of appetite, diarrhea, weakness or severe fatigue, abdominal pain, body aches or joint pains, difficulty swallowing, difficulty breathing, and hiccups; and any person having died of unknown causes).
- Probable: a case that meets the preceding criteria and is assessed and reported by a physician.
- Confirmed (laboratory-confirmed case): a case that meets the surveillance case definitions, and the patient is positive for Ebola virus antigens, Ebola virus IgG antibodies, or Ebola virus genomic sequences (RT-PCR).

TREATMENT AND PREVENTION

No specific treatment of filoviral hemorrhagic fevers is available. Ribavirin and interferon have no effect on filoviruses, and no other antiviral compounds have been found to be effective.[35] Treatment relies on symptomatic measures aimed at maintaining hydration and nutritional status and at preventing or curing bacterial and parasitic infections. Convalescent plasma has been used, but its efficacy has not been proved. In a study conducted during the 1995 Kikwit Ebola epidemic, seven of eight patients who received blood collected from convalescent donors recovered, warranting a thorough evaluation of passive immune therapy.[55] One person infected by *Sudan ebolavirus* after a laboratory accident survived after receiving plasma from *Zaire ebolavirus* survivors. Likewise, several patients who received early treatment with Marburg virus immune plasma appeared to have milder disease. Hyperimmune globulin raised in horses protected baboons in recent experimental studies.[52] Goat immune globulin has been tested in laboratory animals and also was given to laboratory researchers suspected of being infected by Ebola virus[41]; one researcher with highly probable infection made a full recovery. Recently, administration of recombinant nematode anticoagulant protein c2 (rNAPc2), a potent inhibitor of tissue factor–initiated blood coagulation, attenuated proinflammatory and coagulopathic responses and prolonged the survival of macaques that had received a lethal inoculum of Ebola virus.[22] This opens up interesting new possibilities for postexposure protection.

Attempts also are being made to develop a vaccine against Ebola virus. Several candidate vaccines were effective in guinea pigs but less so in macaques.[25] Experimental vaccines have so far been based on viral particles inactivated by heat, formalin, or gamma irradiation[48]; plasmids coding for the Ebola virus glycoprotein (GP) or nucleoprotein (NP)[84]; recombinant GP-expressing Venezuelan equine encephalitis virus[59] or variola virus; and Ebola virus particles encapsulated in liposomes.[60] In contrast, a vaccine candidate based on three injections of GP-encoding DNA given 4 weeks apart, followed by a booster with recombinant inactivated GP-expressing adenovirus, protected macaques from infectious challenge 1 week later.[71] However, the small inoculum used to challenge the macaques (6 plaque-forming units [pfu]), together with the lengthy immunization protocol, renders this candidate vaccine impractical.

A new advance was made recently with the development of two candidate vaccines that appear to be effective in both guinea pigs and macaques. The first consists of a single injection of 2×10^{12} particles of recombinant inactivated adenovirus 5 expressing both the GP and the NP (ADV-GP/NP). A variant consisting of two injections 9 weeks apart also has been tested. The two variants gave total protection and induced interferon-γ production by $CD8^+$ T cells, as well as a humoral response, after both low-dose challenge (13 pfu) and high-dose challenge (1500 pfu) 1 or 4 weeks later. No change in $CD4^+$ T lymphocyte status was observed. The single injection offers faster but shorter protection than does the dual injection.[69] The second candidate vaccine consists of a single dose of 10^7 pfu of live attenuated, recombinant, vesicular stomatitis virus expressing the Ebola GP (VSVΔG/*Zaire ebolavirus*). This immunization fully protected macaques from a high-dose challenge (1000 pfu) 28 days later. It induced a moderate increase in anti-GP IgG (mainly neutralizing antibodies) and a strong increase in interferon-γ^+ and TNF-α^+ CD8 T cells and interferon-γ^+ and TNF-α^+ CD4 T cells. Nearly 30 macaques so far have received this immunization, and none of them has developed any clinical signs after infectious challenge.[37]

SUBSECTION 10

Coronaviridae and *Toroviridae*

CHAPTER 200

Coronaviruses and Toroviruses, Including Severe Acute Respiratory Syndrome

Kenneth McIntosh ✪ Chi Wai Leung ✪ Ellis K. L. Hon

The family *Coronaviridae* is composed of two genera, *Coronavirus* and *Torovirus*. The two genera are related in that they appear similar on electron microscopy and share similar strategies of replication (along with other members of the order Nidovirales). They differ, however, in the size of their RNA genome and structural proteins as well as in the morphologic features of their nucleocapsids. Until recently, coronaviruses were considered to cause upper respiratory tract illness and probably also some undetermined fraction of viral diarrhea. In the final months of 2002 and extending into 2003, a new coronavirus, the severe acute respiratory syndrome (SARS) coronavirus (SARS-CoV), was found to be the cause of an acute, severe, frequently fatal respiratory disease with prominent systemic symptoms (severe acute respiratory syndrome, or SARS). The outbreak spread worldwide from its origin in southern China and probably represented the transmission from animal (possibly the palm civet) to human. In retrospect, the emergence of SARS and the subsequent explosion of new information about coronaviruses are consistent with what was already known about coronaviruses: they are widespread pathogens in the animal kingdom, they evolve rapidly through mutation and recombination, and they jump species barriers.[104] Coronaviruses cause a wide variety of important diseases in animals, including infectious bronchitis and nephrosis in chickens; gastroenteritis and encephalitis in young piglets; enteritis in turkeys, dogs, and calves; hepatitis and encephalitis in mice; pneumonitis and sialodacryoadenitis in rats; and infectious peritonitis in cats. Recently, multiple strains of unknown pathogenicity have been recovered from multiple species of bats.[223] Toroviruses are, at least as presently known, exclusively enteric pathogens, both in animals and in humans.

Since the first report of human coronavirus (HCoV) isolation in 1965,[203] the HCoV group of RNA viruses has been confirmed as a frequent cause of the common cold in children and adults. They also have been implicated as contributors to lower respiratory infections in children and adults, and more recently, they have been shown to be important causes of respiratory disease in the elderly.[56,214] Their role in acute or chronic gastroenteritis is less clear.

The first HCoV was cultivated by Tyrrell and Bynoe[203] at the Common Cold Unit in Salisbury, England, with the use of human embryonic tracheal and nasal epithelial mucosal organ cultures. The authors were able to produce colds regularly in volunteers inoculated with organ culture fluid from the first and later passages of an agent, B814, obtained from a boy with a cold.[15]

Working independently, Hamre and Procknow[73] in 1966 described the isolation of five viruses, including the prototype strain HCoV-229E, in primary human embryonic kidney cell cultures. Four of these agents were obtained from medical students with upper respiratory illnesses and one from a healthy student. The growth of six additional HCoVs, including the second human prototype HCoV-OC43, was reported in 1967 by McIntosh and associates,[139,141] who used human embryonic tracheal organ cultures inoculated with secretions from adults with upper respiratory infections.

That the HCoVs were related to similar agents known to infect animals soon became evident. By electron microscopy, 229E and B814 were demonstrated to be morphologically identical to each other and to avian infectious bronchitis virus.[2] Subsequently, mouse hepatitis virus was demonstrated to be very similar morphologically and to be antigenically related to HCoV-OC43.[139,143] Shortly thereafter, these and similar agents were placed in the genus *Coronavirus* of the family *Coronaviridae*, named for the crownlike appearance of their surface projections on electron microscopy.[202]

Poor growth and a lack of cytopathic effect in cell culture were, until recently, major deterrents to research on HCoV. With the development of the polymerase chain reaction (PCR), and after the dramatic emergence of SARS in 2002 and 2003[25,111,175,201,238] and the discovery of the SARS-CoV,[50,101,168] the

field of coronavirology has developed widely and rapidly. Besides the SARS-CoV and its related animal strains,[70,106,123] two more human coronaviruses have now been described, NL-63[54,60,207] and HKU-1,[107,222] both of which clinically resemble traditional respiratory coronaviruses 229E and OC43 more than the SARS-CoV. The full spectrum of viruses in the human host likely is still to be delineated because several HCoVs, including the very first isolate, HCoV-B814, remain antigenically and genetically uncharacterized.[14,16,143,203]

Toroviruses were, like coronaviruses, first described in animals. They were detected in the 1970s and 1980s in the feces of cattle (Breda virus) and horses (Berne virus).[218,225] Shortly thereafter, Beards and colleagues[10] reported finding particles with a similar appearance in feces of adults and children with gastroenteritis. These particles aggregated in the presence of antiserum to the bovine and equine viruses. Neither the human nor the bovine viruses have been grown in tissue culture.

ETIOLOGIC AGENTS

CORONAVIRUSES

Coronaviruses are medium to large (80 to 220 nm) pleomorphic, spherical or elliptical, enveloped RNA viruses with widely spaced, petal-shaped, 20-nm-long surface projections giving the virus the appearance of a solar corona.[138] They are labile to heat, lipid solvents, and acid pH. The RNA genome is 27 to 32 kb (large for an RNA virus), single stranded, positive sense, and infectious.[104] The genomes of multiple coronaviruses have been sequenced completely, including those of HCoV-229E, HCoV-OC43, NL-63, HKU-1, and multiple strains of the SARS-CoV.[60,70,76,207,212,213,222] The genome and its surrounding capsid are arranged in helical symmetry and enclosed within a lipoprotein envelope.

Within the coronavirus particle, a nucleoprotein (N) surrounds the RNA genome, and together they appear as a coiled tubular helix within the bilayer lipid-containing envelope. The envelope contains two or three glycoproteins: a matrix protein M, which is embedded in the envelope; a surface component S, which is the structural protein of the petal-shaped spikes; and a hemagglutinin esterase HE, which is found in several of the group II viruses, including HCoV-OC43, and contains sequences closely related to influenza C hemagglutinin. Before the discovery of the SARS-CoV, the antigenic interrelationships of these four proteins permitted both the animal coronaviruses and HCoVs to be arranged into three groups, and recent genetic analyses confirm this classification scheme. The SARS-CoV and the related animal coronaviruses may form a fourth group, although they appear also to be related most closely to group II, and the final taxonomy has not yet been established.[65] The four respiratory HCoV serotypes, each along with several other mammalian coronaviruses, have been placed in group I (229E and NL-63) or group II (OC43 and HKU-1), and avian infectious bronchitis virus and several other avian coronaviruses belong to group III.

Coronaviruses contain a positive-sense, single-stranded RNA genome of 26 to 31 kb, the largest of any RNA virus group. In coronavirus replication, all processes take place in the cytoplasm. In the first step, the virus attaches to the cell membrane by using its HE or S protein in the petal-shaped spike. HCoV-229E uses aminopeptidase N (CD-13) as a cellular receptor,[231] and both the SARS-CoV and NL-63 use angiotensin-converting enzyme 2,[79,122] whereas the receptor for HCoV-OC43 still has not been identified definitively. Penetration occurs as a result of S protein–mediated fusion of the viral envelope with the plasma membrane. The genome then codes for the formation of an RNA-dependent RNA polymerase, which initiates the transcription of subgenomic mRNA through a negative-stranded intermediary. The mRNA molecules, as in other members of the virus order Nidovirales, form a nested set; the sequences of the first open-reading frame at the 5′ end (after a leader sequence) contain the coding region, and subsequent sequences through to the polyadenylated 3′ end are untranslated.[164] Virions then are assembled by budding into cytoplasmic vesicles in the rough endoplasmic reticulum and Golgi region.[72] Virus particles are released by cell lysis or fusion of post-Golgi, virion-containing vesicles with the plasma membrane.

TOROVIRUSES

Toroviruses are morphologically similar to coronaviruses in that they are pleomorphic, membrane-coated viruses, 100 to 120 nm in largest diameter, and bear club-shaped surface projections.[217] A photomicrograph of a torovirus particle is shown in Figure 200–1, juxtaposed to an intestinal coronavirus at the same magnification. The nucleic acid–containing core of the virus has a unique appearance on electron microscopy: it assumes a doughnut shape (i.e., a torus) if it is viewed from the right angle.[9,51,218] Berne virus, first isolated in the 1970s from horses with diarrhea, grows in equine cell tissue culture and has been characterized most thoroughly. The human toroviruses, like the bovine toroviruses, do not grow in tissue culture. Toroviruses differ from enteric coronaviruses in being somewhat smaller and more pleomorphic and in having somewhat less distinct surface projections.[51]

The complete bovine torovirus genome has been sequenced recently.[49] Toroviruses contain S glycoproteins on their surface, but no significant sequence homology exists between them and the S proteins of coronaviruses.[67,196] A second surface protein with HE activity and sequence homology to the HE proteins of both influenza C virus and mouse hepatitis virus has been found on Breda virus, the bovine torovirus.[45] Whether this molecule exists on human toroviruses is not known, although human toroviruses do hemagglutinate rabbit erythrocytes.[51] Toroviruses contain membrane and nucleoproteins similar to those of coronaviruses but with no sequence homology. Although the replicase contains sequence similarity to that of coronaviruses, because their mRNAs do not have 5′ leader sequences, their replication strategy must have important differences.[164,196]

EPIDEMIOLOGY

Early epidemiologic surveys of HCoV infections were carried out by serology with 229E or OC43 viruses used as antigens.[20,99,131] Recently, PCR-based surveys of 229E, OC43, NL-63, and HKU-1 have been performed in various collections of respiratory samples. These collections usually have represented frozen samples from patients of various ages with respiratory illness but sometimes include samples from asymptomatic subjects. As expected, the results of such surveys depend heavily on the selection of subjects (hospitalized or not; age; symptomatic or not) as well as the method of sample collection (nasopharyngeal aspirate, throat or nasopharyngeal swabs, bronchoalveolar lavage), season, and number of years represented. Because of selection in such surveys, the information obtained almost always is biased or limited in one way or another.

SARS-CoV epidemiology is quite separate and has been described both by PCR testing of respiratory and stool samples and by serology, which is reviewed in the section devoted to the outbreak below.

Because enteric HCoVs rarely have been propagated in culture, epidemiologic study of these agents has been hindered by lack of antigens for serology. Likewise, the epidemiology of

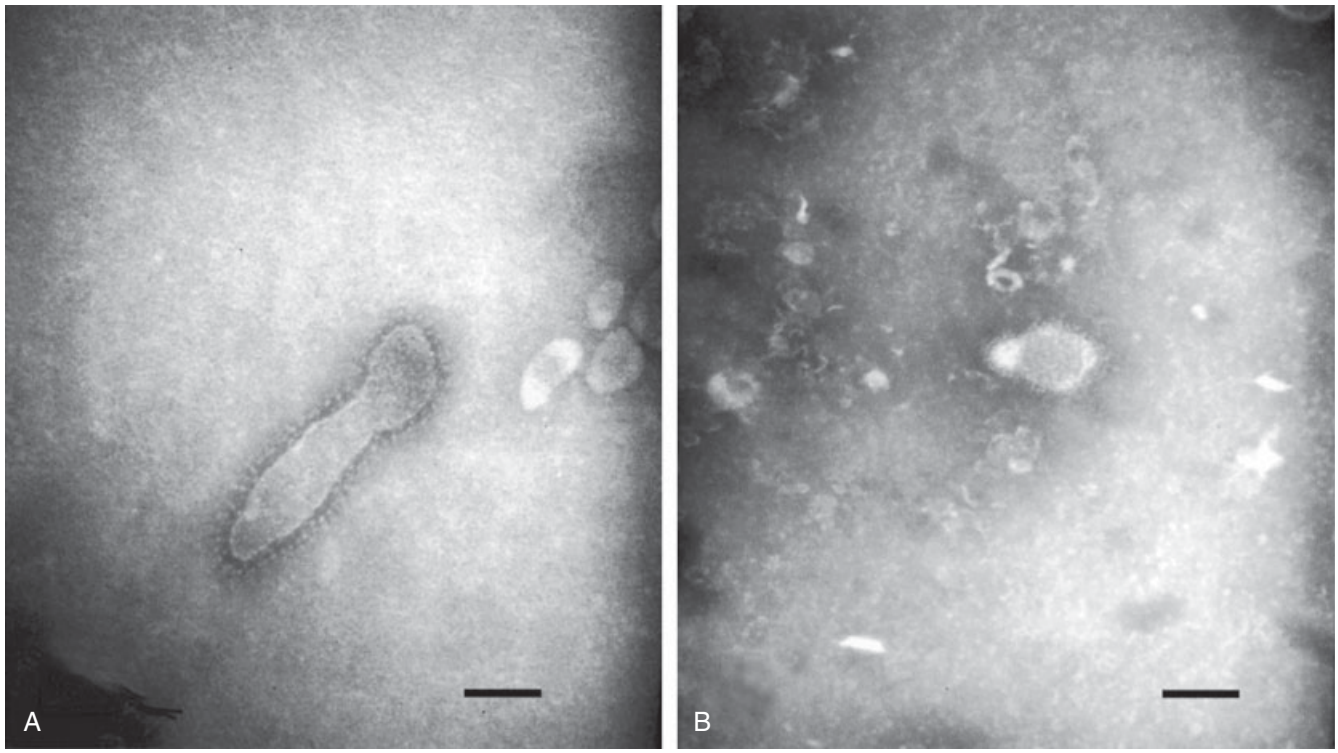

Figure 200–1 Negatively stained virus particles in stool samples representing a typical intestinal coronavirus (**A**) and torovirus (**B**). The bar represents 100 nm. The particles both show the typical petal-shaped projections, but those of the coronaviruses are more finely formed and distinct than those of the toroviruses. *(Photomicrograph kindly provided by Dr. Martin Petric, Department of Laboratory Medicine, Hospital for Sick Children, Toronto, Canada.)*

human toroviruses has not been well delineated. What information is available about the epidemiology of both enteric coronaviruses and toroviruses is outlined in the later section on clinical manifestations.

GEOGRAPHIC PREVALENCE

Respiratory coronavirus infections occur worldwide. Seroprevalence studies using 229E and OC43 antigens have been conducted in the United States, Europe, Brazil, and Iraq.[16,24,74,75,94,95,144] With enzyme-linked immunosorbent assay (ELISA), prevalence of antibody in adults from all areas where they have been examined approaches 90 to 100 percent. Coronavirus NL-63 has been found in PCR studies in Europe, the United States, Canada, Australia, Japan, Korea, Taiwan, and Hong Kong.* Coronavirus HKU-1 has been found in Hong Kong, the United States, Europe, and Australia.[55,195,205,224]

SEASONAL INCIDENCE AND ANNUAL RECYCLING PATTERN

Although HCoV infections may occur at any time of the year, most are seen in midwinter to early spring. The irregular year-to-year pattern that has been described for OC43 and 229E, namely, that individual serotypes predominated during a given year, followed by one or more years of low activity,[147,148] may apply also to NL-63 and HKU-1. An alternative pattern was seen in healthy children in Georgia, prospectively examined for 229E and OC43 infection from 1960 through 1968, where a considerable HCoV-229E outbreak occurred in 1961 to 1962, followed by 2 years with a low incidence and 4 subsequent years in which the incidence was moderate and similar from year to year.[94,95]

During outbreaks, individual coronavirus types may be responsible for a large fraction of respiratory infections. HCoV-229E was associated with a significant outbreak in medical students at the University of Chicago in 1966 and 1967, where 66 (35%) of 191 sampled students were infected.[71] In Tecumseh, Michigan, a large 229E outbreak that occurred between January and April 1967 affected 68 percent of 38 families and 34 percent of 159 individuals tested. Sharp outbreaks also can occur in hospitalized infants; at National Jewish Hospital in Denver, 16 of 20 hospitalized asthmatic infants were infected with HCoV-OC43 in December 1968,[142] and smaller outbreaks with OC43,[194] 229E,[62] and NL-63 have been seen in neonatal intensive care units.[54]

RATIO OF CLINICAL TO SUBCLINICAL ILLNESS

In healthy children and adults, HCoVs probably cause frequent asymptomatic infections. In the surveillance of healthy older children in Atlanta, Georgia, only 38 and 47 percent of 229E and OC43 seroconversions, respectively, were associated with respiratory illness.[94,95] In a group of infants and young children in metropolitan Washington, DC, tested for OC43 seroconversion, at least 50 percent of the infections were subclinical.[144] In contrast, in Denver, Colorado, of children hospitalized with atopic asthma, 19 were infected with either 229E or OC43 and 17 were symptomatic.[142]

It is not yet clear how frequent asymptomatic infections are with NL-63 and HKU-1. Only a single study using PCR for

*See references 5, 7, 13, 31, 40, 41, 52, 54, 60, 91, 207.

NL-63 has examined samples from asymptomatic control patients, and in this study, overall, 3 percent of symptomatic children and 1.7 percent of asymptomatic controls yielded NL-63.[13] The difference was not significant. No studies of HKU-1 in asymptomatic subjects have been published.

AGE SPECIFICITY OF INFECTION

Antibody to both 229E and OC43 appears in early childhood, and the prevalence increases rapidly with age. Asymptomatic and symptomatic infection occurs in individuals of all ages, including the elderly. In the Tecumseh families studied during a community-wide 229E epidemic in 1967, only 3 of 54 infections occurred in children younger than 4 years. The attack rate then rose to a peak of 14 percent in individuals 15 to 29 years of age and subsequently fell with increasing age.[24] The results were different in an outbreak of HCoV-OC43 infection. With this virus, the highest rate, 29 percent, occurred in children 4 years of age or younger, and rates decreased very little even into adult years, when the incidence was 22 percent.[148]

Prospective studies during the first year of life of viruses found by PCR in nasopharyngeal samples obtained during acute respiratory symptoms have found coronaviruses, including OC43, 229E, and NL-63, in 6 to 16 percent of episodes.[91,102,114] When samples from asymptomatic infants have been included, the percent positive was significant (4.4% versus 5.5% in symptomatics).[102]

Several studies have emphasized the importance of coronavirus infection in the elderly and the burden of infection, particularly in individuals in chronic care facilities and those with underlying cardiopulmonary disease.[160]

TRANSMISSION

Human volunteers can be infected readily through nosedrops, and a typical cold can develop 2 to 3 days later; therefore, natural infections are assumed to occur through the respiratory route. Nosocomial transmission of coronavirus respiratory infection has been reported. One study took place in a neonatal intensive care unit, where prospective surveillance by immunofluorescence testing of nasal aspirates performed for 15 months detected 10 infections with coronavirus OC43, all of them nosocomially acquired.[194] All infants had apnea, bradycardia, or abdominal distention, or a combination of these pathologic effects, at the time of infection. Another, conducted similarly, found that HCoV was the most frequent nosocomial viral infection in neonates and coincided with positive samples in members of the nursing staff.[62] The mode of transmission was not demonstrated in either study.

INFECTION AND IMMUNITY

PATHOGENESIS, INCUBATION PERIOD, AND SEROLOGIC RESPONSE

In healthy adults, HCoVs seem to replicate only in the upper respiratory tract and to produce little direct cytopathologic effect. In human embryonic tracheal organ culture, a decline in ciliary activity after serial passage was the only cytopathic effect observed.[141,203] Very similar events appear to take place in vivo. Electron microscopy of nasal epithelial biopsy specimens from a young girl with chronic rhinitis and bronchitis showed preservation of cellular structures and cilia despite replication of coronavirus particles.[1]

OC43 and 229E have been detected in nasopharyngeal cells,[145] and 229E virus titers from 10 to more than 1000 $TCID_{50}$ (median tissue culture infective dose) were found for a week or more in nasopharyngeal washings.[152] Bende and associates[11] studied the course of 229E colds in 24 volunteers and delineated the typical signs, symptoms, and virus shedding patterns; 8 volunteers were asymptomatic. The incubation period of HCoV colds is, on average, 2 days and usually lasts approximately 1 week.[15] In small infants, virus may be detectable in respiratory secretions for 3 weeks and longer.[91] Recovery is likely to be dependent on cell-mediated immunity. Infections in immunocompromised subjects may be severe and prolonged.[5,58,169]

Little is known about the pathogenesis or immunity of HCoV or torovirus infection of the gastrointestinal tract. In contrast, numerous studies have been devoted to the pathogenesis of SARS,[170] and this subject is discussed briefly later.

RE-INFECTION

Evidence from human volunteer experiments demonstrates that strain-specific antibody can be protective. Reed[178] infected volunteers with one of several 229E-like viruses. She found that immunity to homotypic challenge endured for at least 1 year but that immunity to heterotypic HCoV-229E strains in these same volunteers was much lower. IgA antibody may play an important protective role.

CLINICAL MANIFESTATIONS OF RESPIRATORY TRACT INFECTIONS

THE COMMON COLD AND OTHER UPPER RESPIRATORY TRACT ILLNESSES

A significant association of HCoVs 229E and OC43 with respiratory illnesses—most of them cold-like—has been demonstrated in prospective studies of adults and families with children. In the Chicago medical students described earlier, HCoV-229E attack rates were 31 percent during "illness periods" and only 9 percent in "wellness periods" ($p < .001$); the illnesses did not differ significantly from undifferentiated acute respiratory tract infections caused by respiratory syncytial virus, parainfluenza viruses, or rhinoviruses.[71] These findings have been confirmed in several other epidemiologic studies.[24,94,95]

Symptoms in the adults in the two investigations cited earlier were much like those in human volunteers inoculated with HCoV.[11,15,19,20,178] Infected volunteers contracted typical common colds, with perhaps more rhinorrhea than occurs in rhinovirus colds; sore throat, cough, malaise, and headache were noted in approximately 50 percent of volunteers. Twenty percent had fever.

The proportion of total respiratory disease or colds attributable to HCoV varies by season, from year to year, and also by the methodology used. Most serologic surveys have concluded that approximately 8 to 10 percent of all colds are associated with coronavirus infection.[134] A well-controlled study used PCR for 229E and OC43 to estimate the contribution of coronaviruses to illness at all ages leading to a visit to general practitioners in the Netherlands. Coronaviruses were found in 8 percent of subjects with acute respiratory tract infection, in comparison to 5.5 percent of nonrespiratory controls. Rhinoviruses were found most commonly in this group (24.7% versus 16.6% of controls).[210] One survey of first respiratory illnesses in the first year of life that used PCR with primers for 229E, OC43, and NL-63 found coronaviruses in 13 of 82 (16%) infants.[91] As more studies

are performed that span longer periods of time, that sample properly matched asymptomatic controls, and that include all known respiratory HCoV strains, the true incidence is likely to become clearer.

The possible role of coronaviruses in the etiology of otitis media with effusion has been the subject of several studies using PCR for 229E and OC43 in both nasal secretions and middle ear fluid. In one study, 92 children with acute otitis media were investigated. Coronavirus sequences were found in 16 children (17%), in the nasopharynx in 14 and in middle ear fluid in 7. This prevalence was less than that of both respiratory syncytial viruses (26%) and rhinoviruses (32%).[171] Another large study showed a much lower incidence of 2.4 percent.[161]

LOWER RESPIRATORY TRACT DISEASE

Asthma and Recurrent Wheezing

Substantial evidence indicates that HCoVs can precipitate asthma attacks,[85,90,142,146,165] although their role in this regard is clearly secondary to those of rhinoviruses and respiratory syncytial virus.[87] In a 2-year surveillance (1967 to 1969) of 32 mostly atopic children aged 1 to 5 years and hospitalized in Denver, Colorado, for severe, recurrent bouts of wheezing, 19 HCoV infections were diagnosed.[142] Six children were infected simultaneously with either parainfluenza virus or respiratory syncytial virus. Of the remaining 13 patients, all were symptomatic; three had mild wheezing, and seven had acute asthma attacks, two of which required intravenous therapy.

Pneumonia and Other Severe Lower Respiratory Tract Infections

The first evidence of a possible causative role of coronaviruses in lower respiratory tract disease was found in a study of hospitalized infants during 1967 to 1970.[140] Infections with both HCoV-229E and HCoV-OC43 were noted, and HCoV was the third most frequently occurring virus (behind respiratory syncytial virus and parainfluenza virus type 3), both in incidence and in specific association with pneumonia and bronchiolitis. Many of these infants required oxygen. HCoV-229E was grown in tissue culture from oropharyngeal swabs obtained from two of the infants with pneumonia.

With the advent of PCR for detection of coronaviruses and the addition of two new HCoV strains, NL-63 and HKU-1, that can be detected by PCR, the information about the presence of these viruses in children with serious respiratory disease has expanded greatly. Nonetheless, it is very difficult, from a perusal of published studies, to judge just how important coronaviruses are as serious pathogens in this setting. For example, despite the veritable explosion of publications on NL-63 with, at this writing, more than a dozen papers describing the presence of this virus in hospitalized children, only a single properly controlled study has been reported in which children of the same ages without respiratory symptoms were sampled during the same period and in the same hospital.[13] In this study, spanning two respiratory seasons, 3.0 percent of children with respiratory disease and 1.7 percent of controls carried NL-63. Similar ratios have been found when 229E and OC43 have been sought in children with and without respiratory symptoms (8.0% versus 5.5% in one study with all age groups, and 5.5% and 4.4% in a study during the first year of life).[102,210] In addition, coronaviruses frequently co-infect with other respiratory viruses, so the contribution of the coronavirus infection to the resultant illness is difficult to gauge. This difficulty is not different from that encountered with multiple other viruses, including human metapneumovirus, human bocaviruses, adenoviruses, parainfluenza viruses, and rhinoviruses.

With these many caveats in mind, Table 200–1 shows six studies of hospitalized patients in which coronaviruses, along with other recognized respiratory viruses, were sought. None of the six studies sought infections with all four presently recognized respiratory HCoV strains. Two studies, one of which included

adults as well as children, used PCR for three of the four strains. From these studies, it seems likely that coronaviruses are found in the respiratory tracts of 5 to 8 percent of hospitalized pediatric patients with respiratory infections and that they probably play some role as pathogens (using inferences from their pathogenicity in adult volunteer inoculations and studies showing temporal coincidence of shedding with respiratory symptoms at all ages),[91,209] but because of high rates of co-infection and asymptomatic infection, their exact role is not clear.

In newborns, apnea, bradycardia, and increased demand for oxygen have been described during coronavirus infection.[62,193,194]

Whether differences exist in the clinical or epidemiologic features of infection between HCoVs 229E and OC43, on the one hand, and the more newly described NL-63 and HKU-1, on the other, remains unclear. HKU-1 has been studied mostly in adults, and those surveys that have included adequate numbers of children present an unclear picture of the clinical associations.[55,107,205] It does seem likely that NL-63 infections are common in infants and children hospitalized with respiratory disease.*

A suggestion has been made that NL-63 is seen particularly in croup.[41,208] Several children with either NL-63 or HKU-1 have had prominent gastrointestinal symptoms.[205,206] Information about the clinical spectrum of infections in children is thus far, however, scant. No volunteer inoculations with either virus have occurred.

Severe Acute Respiratory Syndrome

SARS is a new infectious disease that had its origin in Foshan, a city 24 kilometers from Guangzhou in Guangdong Province, China, in November 2002. After a few sporadic cases, probably independently contracted from contact with palm civets or other animals kept in markets for slaughter, the virus began spreading between humans.[36] A professor of nephrology who probably was infected in his teaching hospital in Guangzhou traveled to Hong Kong, became ill, and spread the virus during a stay in a hotel to individuals who then traveled to Vietnam, Singapore, Europe, Canada, and the United States. Meantime, the virus had spread within mainland China, where 2521 cases occurred in Beijing alone.[125] By the time the epidemic ended in the summer of 2003, 8096 probable cases had been reported in 29 countries and areas, with 774 deaths (9.6% mortality).[228] The total number of health care workers affected was 1706 (21.1% of all probable cases). Globally, children younger than 18 years accounted for only an estimated 5 percent of cases. Interestingly, the severity of the syndrome appears to have been greater in adults and adolescents than in young children, and no mortality was reported in children.[227]

ETIOLOGY

Although several putative viruses, and even *Chlamydia*, were associated with SARS when it first appeared, the cause, a novel coronavirus, the SARS-CoV, has been identified independently or collaboratively by numerous investigators.[50,101,168,175] SARS-CoV produces a cytopathic effect in Vero and FRhK-4 cells and can be identified by a reverse transcription–PCR in blood, plasma, respiratory specimens, and stool. Antibody to this coronavirus is detected in convalescent sera from patients by indirect fluorescent antibody testing and ELISA. IgG class neutralizing antibodies recognize amino acid sequence 441-700 of the spike protein (S protein) as the major epitope.[108]

This newly discovered coronavirus is the causative agent of SARS. Little doubt exists that it originated in animals, possibly bats, and then spread to exotic animals kept in cages in parts of southeastern China before they were slaughtered for human consumption.[36,70,92,106,123] The genome of the SARS-CoV has been sequenced by multiple investigators.[36,70,135,184,185] It is approximately 29,700 nucleotides in length, and the most widespread human strains had a 29–base pair deletion in the eighth open-reading frame, in comparison to strains isolated from palm civets. Its genetic organization is similar to that of other coronaviruses, and it appears to be an off-shoot of group II coronaviruses, although its final taxonomic position has not been determined.

As mentioned before, the SARS-CoV uses angiotensin-converting enzyme 2 as the key functional cellular receptor. The virus also binds to the C-type lectin CD209L (also known as L-SIGN) and DC-SIGN.[79,108,122] It has also been shown to require further protease cleavage by cathepsin L after attachment.[83,190]

EPIDEMIOLOGY

It is an enormous tribute to the collaborative efforts of many clinicians, public health departments, the World Health Organization, and numerous laboratories that the SARS epidemic was quenched after only approximately 8 months of activity. It is also a reflection of several important aspects of the infection in human hosts. The estimates for the incubation period of SARS converge at 2 to 10 days (range, 1 to 14 days). Most countries reported a median incubation period of 4 to 5 days and a mean of 4 to 6 days after exposure.[227] The disease begins with systemic symptoms such as fever, malaise, chills or rigor, headache, and myalgia, with respiratory symptoms, particularly cough and coryza. Dyspnea and, in some patients, diarrhea appear later. Most transmissions have been person to person through respiratory droplets, contact, or fomites. Because infected individuals become most infectious approximately 10 days after symptoms begin and only after severe respiratory symptoms become prominent, most presumed cases can be identified before they become highly infectious. This allowed isolation and institution of proper barrier precautions to inhibit spread within the community or hospital.[163,167,181] This protection was achieved despite the fact that the virus could, under the right circumstances, spread widely through aerosols, as demonstrated in one well-described cluster of cases that developed during a 3-hour airplane ride, as well as a community outbreak that probably resulted from infected air currents both inside and outside a densely populated high-rise housing complex in Hong Kong.[162,234]

Children with SARS are apparently less infectious than are their adult counterparts. Transmission from children has been documented but seems to be rare.[30] The extent of asymptomatic SARS-CoV infection in at-risk adult close contacts appears low.[29,34,43,78,84,105,109,118,216] Data on asymptomatic children, although fewer, were similar.[118,121,126]

PATHOPHYSIOLOGY

The SARS-CoV produces a disease in the human host quite different from that produced by respiratory or gastrointestinal coronaviruses. Although the primary site of disease is the respiratory tract, with radiologic evidence of patchy airspace disease, either ground-glass opacity or focal consolidation in the lungs,[6,12,111,115-117,175] early, essentially universal viremia with widespread involvement of multiple organs occurs. The tissue tropism of SARS-CoV includes not only the lungs but also the gastrointestinal tract, liver, spleen, pancreas, adrenals, heart, kidneys, skeletal muscles, sweat glands, parathyroid glands, pituitary, cerebrum, and lymph nodes.[47,57,159] SARS is thus a systemic disease with extrapulmonary dissemination, resulting in viral shedding in respiratory secretions, stool, urine, and possibly even sweat. There is prominent lymphopenia, with depression of both $CD4^+$ and $CD8^+$ T lymphocytes, leukopenia, thrombocytopenia, ele-

*See references 5, 7, 8, 40, 41, 52, 54, 63, 91, 199, 206, 207.

vated lactate dehydrogenase level, and mildly prolonged activated partial thromboplastin time. In comparison with adults, elevated serum values of alanine aminotransferase, aspartate aminotransferase, creatine kinase, and D-dimer are less commonly seen in children.[12,38,80,115-117,119,156,157] A prominent innate immune response to SARS-CoV infection includes acute-phase proteins, proinflammatory cytokines, chemokines, and C-type lectins such as mannose-binding lectin, which may play a protective role. In contrast, apparently no type 1 interferon response occurs.[108] Limited investigations have demonstrated the presence of very high circulating levels of interleukin-1β, interferon-γ–inducible protein 10, and monokine induced by interferon-γ, with normal or near-normal levels of interleukin-6, tumor necrosis factor–α, and RANTES (regulated on activation, normal T cell expressed and secreted).[154,155] These preliminary results suggest that SARS-CoV induces a selective activation of the caspase-1–dependent pathway in infected macrophages and predominantly induces a type 1 T-helper lymphocyte [T_H1]–mediated immune response, which promotes effective viral clearance but has relatively little effect on immune-mediated allergic reactions such as hyperreactive bronchoconstriction.[156] The immunologic profile and severity of lymphopenia during the course of illness correlated well with the clinical outcome in affected children.[120]

The tissue and organ damage produced by SARS-CoV likely is caused by both local viral replication and the immunopathologic consequences of the host response. Postmortem findings showed gross consolidation of the lungs and diffuse alveolar damage with pulmonary edema and hyaline membrane formation.[111,159,201] Other areas had cellular fibromyxoid organizing exudates in the airspaces. Interstitial spaces had only mild lymphocytic infiltrates. Vacuolated and multinucleated pneumocytes also were noted, along with changes of bronchiolitis obliterans.[158] Splenic and lymph node atrophy as well as depletion of all lymphocyte types, including dendritic cells, also was found.[69]

CLINICAL PRESENTATION

The largest series of proven, pediatric cases of SARS is that of Leung and coworkers in Hong Kong.[115,117] Forty-four children had infection confirmed by seroconversion to the SARS-CoV, and all also satisfied a modified clinical case definition: fever (rectal temperature ≥38.5° C or oral temperature ≥38° C); chest radiograph with pulmonary infiltrates or signs of acute respiratory distress syndrome (ARDS); likely or proven contact with another case within 10 days of onset; and at least one of a large number of general symptoms, such as chills, malaise, myalgia, cough, hypoxia, lymphopenia, or failure to respond to antibiotics for community-acquired pneumonia after 2 days of therapy.[115,117] The median age was 12 years, with more than 90 percent of patients being older than 5 years. The disease had many features similar to that in adults: onset with fever and, particularly in adolescents, systemic, influenza-like symptoms. Coryza was seen significantly more frequently in children younger than 13 years (61%) and much more frequently than in adults. The prodromal period was followed by cough in 64 percent and diarrhea in 20 percent, but the signs and symptoms of progressive pneumonia, occurring frequently in adults, were seen in a small minority and mostly in adolescents. Cough was not invariably present during the illness, even in severely affected children.[117] The combined relative frequency of presenting clinical features reported in the two largest series of serologically confirmed children with SARS is summarized in Table 200–2.

Chest radiographs and high-resolution computed tomography findings were similar to those in adults, showing peripheral consolidations and ground-glass opacities, with pleural effusions being rare (Figs. 200–2 to 200–4).[6] Radiographic features are nonspecific, but high-resolution computed tomography of the thorax in clinically suspected cases may be an early diagnostic aid when initial chest radiographs appear normal.[116] The most prominent laboratory findings were leukopenia and, particularly, lymphopenia, with reduction in all lymphocyte types. Children with more severe disease often had thrombocytopenia, laboratory evidence of disseminated intravascular coagulation, and elevated levels of lactate dehydrogenase, alanine aminotransferase, and creatine kinase.

TABLE 200–2 Frequency of Presenting Clinical Features of SARS in Children Younger than 18 Years*

Presenting Features	No. of Children (*N* = 64)	%
Fever	62	97
Malaise	36	56
Cough	36	56
Coryza	26	41
Chills or rigor	21	33
Sputum production	19	30
Headache	18	28
Myalgia	18	28
Anorexia	15	23
Nausea and vomiting	13	20
Dizziness	12	19
Diarrhea	11	17
Sore throat	7	11
Dyspnea	6	9
Abdominal pain	4	6
Lethargy	3	5
Chest pain	1	2
Cyanotic attack	1	2

**Pooled data based on references 38 and 117.*

Mortality in children has not been reported worldwide, although the disease can be severe in young infants or even life-threatening in adolescents.[35,59,191] Several independent observations have confirmed that SARS was less severe in children than in adults.* Nonetheless, follow-up imaging studies demonstrated persistent abnormalities in some children 6 months and even 1 year after the acute pneumonia.[44,120]

The performance characteristics of the modified clinical case definition used by Leung and colleagues[117] during the epidemic in Hong Kong, before the advent of serologic diagnosis, were respectable, with sensitivity of 97.8 percent, specificity of 92.7 percent, positive predictive value of 88 percent, and negative predictive value of 98.7 percent. The excellent negative predictive value was extremely useful in the outbreak situation to facilitate decision making on the need for isolation and cohorting of hospitalized children, where inadvertent mixing of infected and non-infected children could be disastrous.

In spite of the apparent universality of viremia, no evidence of perinatal transmission to infants born to infected pregnant women was found.[156,157,183,189,221,236] However, SARS-CoV infection has been associated with both maternal and fetal morbidity and mortality.[156,157,189,220,221]

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of SARS in children includes the many viral, bacterial, mycoplasmal, and chlamydial agents that cause acute febrile respiratory illnesses in children (see Chapters 23, 25, 26, 27, 96, 149, 165, 168, 190, 191, 194, 195, 201, and 208). Particularly important to consider are agents that cause acute febrile respiratory illnesses in both adults and children. These agents include influenza viruses A (in particular, avian influenza

Figure 200–2 Chest radiographs and high-resolution computed tomography scan of the thorax in two children with SARS. **A,** Admission chest radiograph of a 15-year-old girl showing left lower lobe consolidation 3 days from onset of fever. **B,** Progressive radiographic deterioration resulting in bilateral widespread consolidation at the time of intubation and mechanical ventilation of the same patient 12 days from onset of fever. **C,** Normal chest radiograph of a 16-year-old girl taken on admission 2 days from onset of fever. **D,** High-resolution computed tomography scan of the thorax of the same patient showing peripheral subpleural focal consolidation of the right lower lobe not evident on chest radiograph. *(From Leung, C. W., Kwan, Y. W., Ko, P. W., et al.: Severe acute respiratory syndrome among children. Pediatrics* 113:*e535-543, 2004.)*

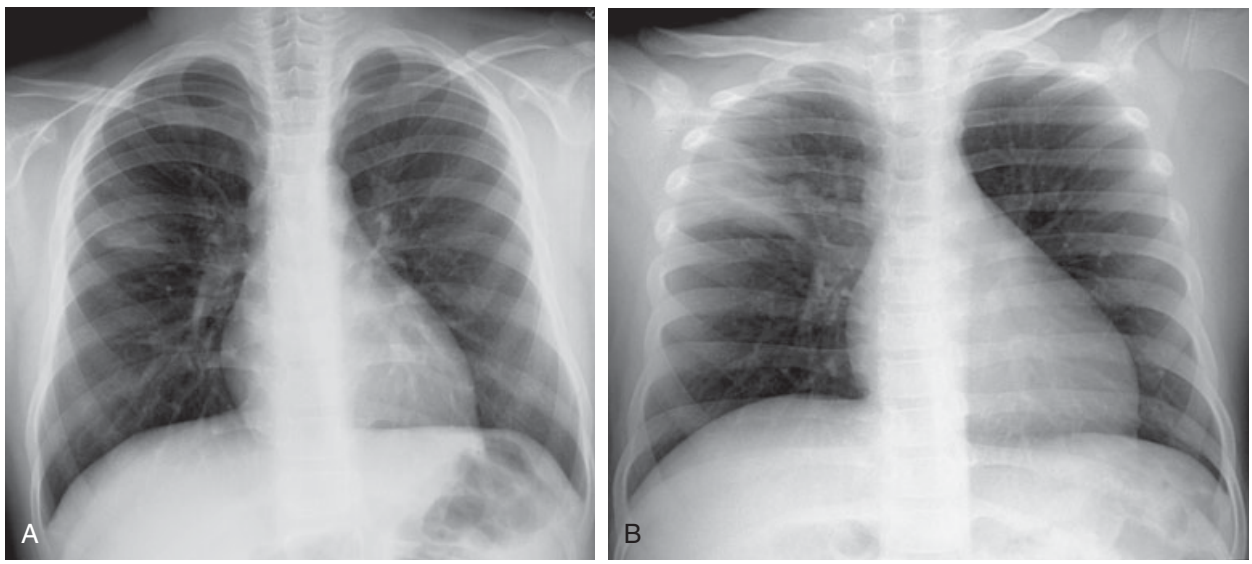

Figure 200–3 Serial chest radiographs in a 2-year-old boy who presented with fever and cough. **A,** Radiograph at presentation shows an ill-defined airspace consolidation in the periphery of the right upper lobe that abuts the horizontal fissure. **B,** This finding was followed by an increased consolidation in the right upper lung field on day 5. Complete resolution of the airspace consolidation occurred by day 14 (not shown). *(From Hon, K. L. E., Leung, C. W., Cheng, W. T. F., et al.: Clinical presentations and outcome of severe acute respiratory syndrome in children. Lancet* 361:*1701-1703, 2003.)*

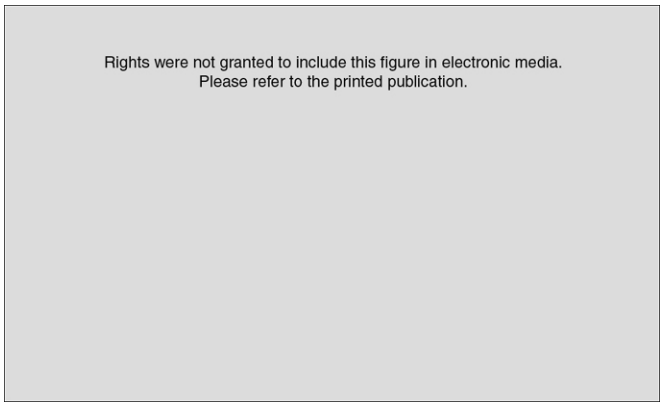

Figure 200–4 High-resolution computed tomography scan of a 13-year-old girl who presented with persistent fever for 1 week with chills, rigors, rhinorrhea, and myalgia. Mixed airspace consolidation and ground-glass opacity are seen in the left lower lobe. *(From Babyn, P. S., Chu, W. C., Tsou, I. Y., et al.: Severe acute respiratory syndrome [SARS]: Chest radiographic features in children. Pediatr. Radiol.* 34*:47-58, 2004.)*

H5N1) and B; parainfluenza viruses 1, 2, 3, and 4; respiratory syncytial virus; human metapneumovirus; several adenoviral types; *Chlamydia pneumoniae*, *Chlamydia psittaci*, *Mycoplasma pneumoniae*, and *Legionella pneumophila*; and the many causes of acute bacterial pneumonia.

SPECIFIC DIAGNOSIS

For surveillance purposes, both the World Health Organization and the Centers for Disease Control and Prevention (CDC) developed and revised case definitions as the SARS epidemic evolved.[26,226] The current CDC definition of a case has two levels, probable and confirmed, as well as two parts, clinical and epidemiologic.

A probable case is a person who meets the clinical criteria for severe respiratory illness and the epidemiologic criteria for likely exposure to SARS-CoV. Severe respiratory illness is defined as temperature above 38° C and one or more clinical findings of lower respiratory illness (e.g., cough, shortness of breath, difficulty breathing), plus one or more of the following findings: radiographic evidence of pneumonia, or ARDS, or autopsy findings consistent with pneumonia or ARDS without an identifiable cause. The epidemiologic criteria for likely exposure to SARS-CoV are close contact with a confirmed case of SARS-CoV disease or close contact with a person with mild-moderate or severe respiratory illness for whom a chain of transmission can be linked to a confirmed case of SARS-CoV disease in the 10 days before onset of symptoms.

A confirmed case of SARS is a person who has a clinically compatible illness (i.e., temperature above 38° C with constitutional symptoms or lower respiratory symptoms) that is laboratory confirmed.

In the absence of known cases anywhere in the world, the laboratory takes a particularly important place in establishing the specific diagnosis. The "gold standard" for laboratory diagnosis is a rise in antibody titer during illness. Rapid diagnosis can be accomplished by finding the virus, viral antigens, or viral nucleic acid in appropriate specimens obtained during illness. The most sensitive rapid diagnostic test appears to be conventional or, more recently, real-time quantitative, reverse transcription-polymerase chain reaction (RT-PCR) assays of either plasma or respiratory secretions (e.g., nasopharyngeal aspirate) obtained during the first two weeks of illness.[153,173] The improved RT-PCR assays are critical in establishing an early diagnosis of SARS, with sensitivity approaching 80 percent and specificity 100 percent in the first 3 days of illness when it is performed on nasopharyngeal aspirates, the preferred specimens.[174] A detection rate of 87.5 to 100 percent obtained in the plasma of eight pediatric patients within the first week of illness similarly suggests that plasma SARS-CoV RNA quantification is a very sensitive and potentially useful early diagnostic tool.[153] The overall diagnostic yield in the second week of illness is greater than 80 percent when stool specimens also are examined, with stool yielding better results than those of respiratory specimens.[28] A recently described real-time nested PCR assay performed on throat swabs is capable of detecting fewer than 10 copies of viral genome per reaction and achieves a much shorter turn-around time than conventional nested RT-PCR.[89]

Although antibody to the SARS-CoV, detected by indirect fluorescent antibody testing or ELISA, is seen specifically only after infection with this virus has occurred, a one-way cross-reactivity with OC43 and 229E (i.e., rises in reactivity are seen against these antigens during SARS) has occurred, with the OC43 cross-reactivity being the stronger of the two.[33] Absence of seroconversion to SARS-CoV beyond 28 days from disease onset generally excludes the diagnosis.[116]

Establishing the diagnosis of SARS by isolating SARS-CoV from specimens inoculated in appropriate cell cultures is limited by low sensitivity and slow growth in culture. The virus was isolated successfully from NPA cultures in only 16 percent of children in the largest pediatric series.[117] Cell culture is also technically demanding, and amplification of the viable virus is associated with potential biohazards necessitating biosafety level 3 containment. Currently, however, with the exception of animal inoculation, it is the only means to demonstrate the existence of viable SARS-CoV.

TREATMENT

When SARS first emerged, most cases were treated empirically with systemic ribavirin under the dire situation of an explosive epidemic of life-threatening infection in multiple countries and without a definitively identified etiologic agent. More recently, doubts have been expressed about the virologic efficacy of ribavirin in the treatment of SARS,[35] and some evidence indicates that the treated adult patients did more poorly than did the untreated ones.[37,215] The level of ribavirin required for inhibition of virus growth in vitro is such that adequate levels probably cannot be achieved without causing significant toxicity.[186]

High-dose corticosteroids (≥10 mg/kg intravenous methylprednisolone daily for up to 3 days plus a tapering regimen of oral prednisolone lasting several weeks) also were used widely during the epidemic and were, in several nonrandomized analyses, considered helpful.[77,238] Immunomodulation by corticosteroid therapy initially was considered beneficial in complementing empiric antiviral treatment with ribavirin. The rationale for use of corticosteroid in severe disease is the blunting of host damage caused by excessive proinflammatory cytokine responses, although use of such treatment in the early phase of illness has been shown to increase the plasma viral load in SARS.[110] In retrospect, ribavirin alone probably had no significant effect in arresting the progression of the disease, and corticosteroids are likely to be unnecessary for patients who do not develop moderate to severe hypoxemia. However, many clinicians who have treated patients with SARS successfully contend that corticosteroids may be life-saving in the later phase of illness in those threatened by impending acute respiratory failure. The place of corticosteroids in the rescue therapy of patients who clearly have experienced failure of supportive care remains to be determined. Interferon-α also has been considered to be possibly helpful in an uncontrolled study.[128] The role of other compounds with antiviral potentials against SARS-CoV remains to be elucidated.[116]

No evidence-based therapeutic approach for SARS currently exists. With more understanding of the pathogenesis as well as

the clinical course of the disease, treatment will evolve. Further studies are required to define the role of supportive care, antiviral therapy, and immunotherapy.

OUTCOME

The short-term outcome of SARS among children generally is good in comparison with that of adults.[117] Mild radiologic abnormalities detectable by high-resolution computed tomography and mild abnormalities in pulmonary function testing were observed 6 months after onset in 34 percent and 10.5 percent of a series of 47 children, respectively.[120] However, all children were asymptomatic and had normal clinical examination findings. In contrast, some adult patients have developed residual pulmonary fibrosis, persistent respiratory symptoms, and deranged lung function, despite recovery from the primary illness.[3,82] Follow-up study in a series of 27 children 15 months after the diagnosis of SARS was established suggested that aerobic capacity may be reduced in some despite normalization of lung function in all patients, likely a consequence of impairment in lung perfusion at peak exercise and post-SARS deconditioning.[233]

An important delayed complication in survivors of SARS, probably related to treatment with high-dose corticosteroids, is avascular necrosis (AVN) of the femoral head and, less commonly, the femoral condyle, humeral head, or talus. The incidence in Hong Kong, based on a territory-wide magnetic resonance imaging screening study of 1203 patients performed 6 to 9 months after onset of disease occurred, was 13.3 percent in adults and 9.3 percent in children between the ages of 10 and 18 years, many of whom were asymptomatic. Of the seven affected children in Hong Kong, five had AVN of the femoral head and four had knee involvement.[39] The incidences of AVN as reported in two series of symptomatic patients from Beijing, China, were 23 percent and 43 percent.[81,229] Cumulative steroid dosage appears to be the most important risk factor for predicting AVN. The risk of onset of post-SARS osteonecrosis was 0.6 percent for patients receiving less than 3 g and 13 percent for those receiving 3 g or more of prednisolone-equivalent dose.[68] Why none of the 44 children was affected by AVN in the largest pediatric series (C. W. Leung, unpublished data) whereas five of 21 (23.8%) children in another series were affected, although they all shared a similar treatment protocol, remains unexplained. The cumulative steroid dosage for the affected children ranged from 1.2 to 6.8 g prednisolone-equivalent administered for a total duration of 17 to 42 days.[27] Whether symptomatic AVN is more likely to progress than is asymptomatic AVN is not clear. However, it is reassuring, on the basis of past experience with steroid-related AVN, that not all lesions will progress necessarily to collapse of the articular surface without surgical intervention, and early AVN of the femoral head can resolve spontaneously. Preliminary follow-up data obtained at 12 to 18 months after detection of AVN suggest that the condition can remain static, progress, or regress.[39] The natural history of post-SARS AVN, especially in growing children, remains to be elucidated by longer term follow-up.

The long-term mental health impact of SARS on adult patients and infected health care workers has been the subject of recent research.[219] Data on the psychological outcomes of children recovering from SARS are limited.[117]

PREVENTION

The mainstay of prevention of SARS is implementation of effective infection-control practices in hospitals and quarantine procedures outside hospitals. In retrospect, many secondary cases of SARS in health care personnel were preventable. Patients with respiratory illnesses consistent with SARS should be isolated at triage and placed in a negative air pressure room for treatment. Because SARS is spread by contact, droplets, and aerosols, and because the nose, mouth, and eyes are sites for primary inoculation, health care workers should wear appropriate masks and goggles or face shields while tending patients, especially in performing procedures in which splashing and aerosolization are likely to occur. Because fomites appear to be important factors in the transmission, medical equipment should be restricted to patient rooms or adequately disinfected after contact with patients. Finally, adequate handwashing before and after contact with patients is critical.[42]

ENTERIC HUMAN CORONAVIRUS AND TOROVIRUS INFECTIONS

CORONAVIRUSES

From the earliest descriptions of HCoVs, because of the prominence of coronaviruses as a cause of diarrhea in young calves and pigs, attempts have been made to find coronaviruses in the stool and to associate them with enteric disease. The particles that have been seen, often called *coronavirus-like particles* (CVLPs), have appeared as frequently in stools from well subjects as in those with diarrhea in many studies, and at times they have been difficult to distinguish from cellular membrane fragments. Indeed, their authenticity as viruses has been called into doubt on occasion.[48,132,149,166]

This situation has been confused further by the more recent separation of toroviruses from enteric coronaviruses, although this separation probably will lead ultimately to clarification of this murky field. Many of the specimens that were considered to contain CVLPs in earlier papers very well may have contained toroviruses. At present, electron microscopists think that these virus genera can be distinguished in most instances on the basis of morphologic appearance alone,[51] and in many cases the presence of human toroviruses can be confirmed by serologic testing for stool antigens with bovine antisera containing bovine torovirus (Breda virus) antibody.[10,97,100]

The first reports of HCoV as a possible cause of human gastroenteritis appeared in 1975; CVLPs were found by electron microscopy in the stools of English adults in three sharp outbreaks of nonbacterial gastroenteritis.[21,23] In the same year, CVLPs were reported in the stools of healthy adults in India.[137] These rather contrasting publications from England and India heralded the beginning of a continuing controversy on the etiologic importance of these agents as enteric pathogens.[132,149]

The firmest link of CVLPs to human enteric disease is with gastroenteritis in the very young, especially neonatal necrotizing enterocolitis (NEC). A controlled epidemiologic investigation of NEC was conducted in two hospitals in France, one with and one without an NEC outbreak.[32] Within each hospital, newborns with "no pathologic occurrence" were used as controls. In the NEC-free hospital, no CVLPs were found in the stools of 21 controls, but two patients with mild diarrhea had CVLPs. In the NEC hospital, 23 of the 32 (72%) NEC patients had fecal CVLPs, whereas only 3 of 26 (11.5%) controls were positive ($p < .02$). Similarly, CVLPs were observed in infants who were part of an NEC outbreak in a special care nursery in Texas.[179] This outbreak yielded a virus that subsequently has been adapted to growth in tissue culture and to some extent characterized.[130]

In September 1979, an episode of acute, severe (bloody stools, bilious gastric aspirates, abdominal distention) gastroenteritis occurred in a neonatal intensive care unit in Arizona, and several clinical signs were associated significantly with CVLPs in patients' stools.[211] Two children died in this outbreak, and another infant death, with careful electron-microscopic description of coronavirus infection in the distal end of the small bowel,

occurred in Oklahoma.[180] In Italy, a case-control study of infants and young children with enteritis found a significant difference in the presence of fecal CVLP between the ill and control groups: 16.3 percent in ill children and 1.6 percent in controls ($p < .01$).[64]

Despite the foregoing evidence for a causal relationship between CVLPs and gastrointestinal disease, reservation about the role of CVLPs in children's enteric disease still remains, chiefly because CVLPs are found so often in the feces of healthy children, particularly, although not exclusively, in the developing world.[96,136,137,176,188,192] Many of these studies need to be repeated with use of PCR of stool for detection of the various coronaviruses.

Attempts have been made to cultivate CVLPs in cell and organ culture and to compare the resultant virus suspensions antigenically with other HCoVs or animal coronaviruses. As mentioned earlier, a possible enteric HCoV was cultured from a child with NEC, and this virus has been adapted further to growth in a mouse macrophage cell line and mosquito cells.[130] This virus is antigenically unrelated to HCoV-229E and HCoV-OC43. A hemagglutinating coronavirus antigenically and genetically related to a bovine coronavirus, BCV-LY138, has been isolated from a 6-year-old child with severe diarrhea.[237]

TOROVIRUSES

Studies of the clinical manifestations of human torovirus infection are still in their infancy, and certainty of the details is difficult to ascertain. Their pathogenicity still should be considered a matter of some doubt, although the few controlled studies that have been performed have been more consistent than have those of enteric coronaviruses; even though torovirus particles are found in the feces of both symptomatic and asymptomatic individuals, an excess in the symptomatic individuals clearly occurs.[86,98] These studies have included children from Canada and Brazil.

In the study from Brazil, 20 of 91 fecal samples from children in the community with diarrhea contained torovirus antigen detectable by ELISA, and toroviruses were associated significantly with both acute and chronic diarrhea ($p = .02$ in both instances).[98] In the study from Canada, symptomatic and asymptomatic hospitalized children were sampled for fecal viruses; toroviruses were found in 35.0 percent of the symptomatic children and 14.5 percent of the asymptomatic children. In comparison to those with stools containing either rotaviruses or astroviruses, torovirus-infected children were older (mean age of 4.0 versus 2.0 years) and their infections more often were acquired nosocomially (57.6% versus 31.3%). Vomiting occurred less commonly with torovirus infection, but occult blood was noted more frequently. A large proportion of symptomatic torovirus infections occurred in immunocompromised children.[86] One case of torovirus found in the feces of a child with acute abdomen has been described.[204]

A recent report described toroviruses in nonepidemic NEC of neonates.[127] During a 5-year period from 1996 through 2001, toroviruses were found by electron microscopy in 48 percent of infants with NEC, in contrast to 17 percent of controls during the same interval ($p < .001$). The mortality rate was 14 percent.

NEUROLOGIC DISEASES

Coronaviruses are the cause of some animal neurologic disorders, including a murine demyelinating disease with some features resembling multiple sclerosis. In humans, a serosurvey of HCoV infection in southern Finland discovered evidence of HCoV-OC43 infection in six patients with acute neurologic episodes, including one with polyradiculitis.[182] A recent case of acute demyelinating encephalitis accompanying OC43 respiratory infection was described in which OC43 RNA was detected by PCR in the spinal fluid.[232] Several observations have suggested a possible role of coronavirus infection in multiple sclerosis: (1) isolation of coronaviruses (SK and SD) from the central nervous system tissue of two patients with multiple sclerosis,[18] (2) demonstration that coronavirus SD can cause demyelination in a primate model,[151] (3) direct visualization of CVLPs in the brain of a patient with multiple sclerosis,[200] and (4) identification by in situ hybridization or PCR of coronavirus RNA in the brains of patients with multiple sclerosis.[4,150,198] However, coronaviruses SK and SD are antigenically and genetically very similar to mouse hepatitis virus and were isolated with the use of mouse tissues; the possibility that these isolates were of mouse origin has not been excluded. In addition, other studies have failed to demonstrate coronavirus RNA in the central nervous system tissue of patients with multiple sclerosis[197] or have found such RNA in the same proportion of patients with demyelinating diseases as in controls.[46] Further investigation will be needed to establish whether HCoVs are related causally to any neurologic disease in humans.

VIRUS ISOLATION

Respiratory Coronaviruses

Human embryo tracheal or nasal mucosal organ cultures were used first for primary isolation of multiple HCoV strains, including B814, OC43, and several less well characterized strains.[141,203] OC43 subsequently was adapted to growth in monkey kidney, BSC-1, and rhabdomyoma cells.[17,187] The 229E-type strains were shown to replicate and to produce a cytopathic effect in secondary human embryo kidney[73] or certain diploid cell lines: WI-38, MRC-5, and MA-177.[71,93] A recent report has described the growth and cytopathic effect of OC43-like strains in the HUH7 hepatocarcinoma cell line.[61] This line also has been used for primary isolation of HKU-1 strains.[205] NL-63 strains grow directly from clinical samples in tertiary monkey kidney cells, with subsequent growth in LLC or Vero cells.[60,207] The SARS-CoV was isolated in and grows well in Vero-E6 cells.[50,101]

Enteric Coronavirus-like Particles

Growth of these agents in cell or organ culture has been reported,[22,179,237] and one isolate has been adapted to growth in tissue culture.[130]

Toroviruses

Human toroviruses have not been grown in any culture system.

VIRUS DETECTION TECHNIQUES

Respiratory Coronaviruses

Respiratory coronaviruses can be sought successfully in clinical samples by direct antigen-detection techniques or by nucleic acid detection. Both immunofluorescence[88,145,194] and ELISA have been used successfully for establishing the diagnosis of HCoV infection.[85,133,146]

During the past decade, PCR has opened up the field of coronavirus diagnosis. Not only is the method the most sensitive for all the known strains of HCoV, but it also can be designed

to pick up new strains.[54] Attempts to design a set of "pan-coronavirus" primers have, however, always led to suboptimal sensitivity.[54,63] The exact design of the tests also influences greatly their sensitivity and specificity.

Enteric Coronaviruses

Enteric coronaviruses have been detected primarily by electron microscopy of negatively stained preparations from clarified stool specimens. The possible confusion of coronaviruses and toroviruses in such preparations has been discussed earlier. Immune electron microscopy has been helpful in identifying such viruses in purified preparations but not directly in stool samples.

An antigen-detection ELISA for enteric coronavirus has been described and applied to fecal specimens from healthy and diarrheal subjects in Thailand.[112,113] PCR has not been used widely to detect coronaviruses in diarrhea, although HKU-1 was found both in the respiratory tract and in the stool in two patients as part of a larger study of respiratory disease.[205]

Toroviruses

As with enteric coronaviruses, the primary detection method for toroviruses is electron microscopy of clarified fecal specimens. Torovirus identity can be specified further by either immune electron microscopy or antigen-detection ELISA with the use of antisera prepared against the Breda virus of calves.[9,97,98] With increasing experience, electron microscopists can differentiate toroviruses from enteric coronaviruses on the basis of morphologic features alone.[51,86] There are no reports of PCR detection of toroviruses in humans.

SERODIAGNOSIS

A rise in antibody titer after day 28 of onset of symptoms is the gold standard for diagnosis of SARS-CoV infection, most commonly with use of ELISA or indirect fluorescent antibody testing in Vero-E6 cells. The finding of antibody in convalescent serum is highly specific for SARS-CoV infection, although one-way cross-reactivities exist with both 229E and, especially, OC43.[53] For respiratory coronaviruses, complement fixation,[24,140,144,148,182] hemagglutination inhibition (for HCoV-OC43 only),[95] neutralization,[53] ELISA,[20,66,99,133] indirect hemagglutination,[94] and Western blot[172] have been used.

Serodiagnostic techniques specific for enteric coronaviruses have not been described. Serodiagnosis of torovirus infections has been performed by both immune electron microscopy and hemagglutination inhibition.[51]

PREVENTION AND TREATMENT

Barrier methods were extraordinarily successful in the limitation and final elimination of the SARS epidemic, and contact precautions likely would serve to reduce the spread of respiratory and gastrointestinal coronaviruses as well.

The high re-infection rate with the respiratory HCoVs as well as the number of related strains suggests that a vaccine may be ineffective in preventing HCoV-caused respiratory illness.

The value of antivirals in SARS is reviewed earlier. There are no known effective antivirals for the respiratory coronaviruses.

SUBSECTION 11

Bunyaviridae

CHAPTER 201

HANTAVIRUSES

Louisa E. Chapman ❂ C. J. Peters ❂ James N. Mills ❂ Kelly T. McKee, Jr.

HISTORICAL PERSPECTIVE

Hantaviruses are the etiologic agents of a diverse group of rodent-borne hemorrhagic fevers that are responsible for considerable morbidity and mortality worldwide. Although recognized by so-called modern medicine only relatively recently, clinical syndromes now known to be associated with these viruses have been described by traditional practitioners across the globe from antiquity.[16,85,102] In the 20th century, Soviet scientists reported sporadic outbreaks of febrile renal failure with hemorrhage in the eastern Soviet Union between 1913 and 1930,[11] and Japanese and Soviet scientists recognized annual outbreaks of a similar syndrome in Manchuria and Siberia between 1932 and 1935.[31,101,145,154]

In 1934, Swedish scientists described a novel disorder, characterized by fever, abdominal and back pain, and renal abnormalities.[110,176] Epidemic disease with these features occurred among German and Finnish troops stationed in Lapland during World War II.[60,150] Physicians called this syndrome *nephropathia epidemica*.

North American medical practitioners initially became acquainted with a similar syndrome in the early 1950s, when a previously unrecognized febrile illness characterized by shock, hemorrhage, and renal failure developed in thousands of soldiers serving with United Nation forces during the Korean War. Physicians called this syndrome, which had a mortality rate of 5 to 15 percent, *epidemic hemorrhagic fever*.[33,103]

In 1953, Gajdusek[40] noted similarities among epidemic hemorrhagic fever, the severe and frequently fatal Far Eastern diseases described by Soviet and Japanese scientists, and the Scandinavian disorder and proposed a common origin. Subsequent validation of this hypothesis (see "The Organism") ultimately prompted adoption of the collective term *hemorrhagic fever with renal syndrome* (HFRS) to describe this clinical entity characterized by varying degrees of renal dysfunction and hemorrhage with fever.

In June 1993, investigation of a cluster of unexplained respiratory deaths in previously healthy young adult residents of rural areas in the southwestern United States led to recognition of a "new" febrile disorder in North America. Application of sophisticated serologic and virologic tools to diagnostic specimens from patients with this disease quickly pointed to a hantavirus related to, but distinct from, those causing HFRS.[79,112] This disorder, now called *hantavirus pulmonary syndrome* (HPS) or *hantavirus cardiopulmonary syndrome* (HCPS), proved to be different clinically from classic HFRS, but as virologic and epidemiologic studies of the etiologic agent and its reservoirs were completed, similarities to other hantaviruses became apparent.

THE ORGANISM

CLASSIFICATION AND ANTIGENIC COMPOSITION

The genus *Hantavirus* of the family *Bunyaviridae* was defined in 1985.[135,138] The members of the genus *Hantavirus* are classified

among the bunyaviruses because of their shared morphologic, physicochemical, and molecular properties. Like other members of the family *Bunyaviridae*, hantaviruses are negative-stranded, lipid-enveloped RNA viruses with tripartite genomes; genomic segments are designated as large (L), medium (M), and small (S). Also like other bunyaviruses, they display Golgi-associated morphogenesis and usually acquire their envelopes by budding into intracytoplasmic vacuoles.[136] However, they are serologically distinct from other family members and possess unique terminal genomic sequences.[135,137] The genus *Hantavirus* contains the only members of *Bunyaviridae* that lack arthropod vectors. As a general rule, each hantavirus is highly adapted to a specific rodent species and depends on persistent asymptomatic infection in wild rodents for maintenance in nature.

PHYSICAL PROPERTIES

Morphologically, hantaviruses are spherical, 80 to 120 nm in diameter, and have surface glycoprotein projections embedded in a lipid bilayer envelope. Elongated particles (110 to 120 nm long) often are observed, and they display a characteristic grid-like pattern on their surfaces.[48,136]

SUSCEPTIBILITY

Hantaviruses are inactivated readily by lipid solvents and most disinfectants, including dilute hypochlorite solutions, detergents, ethyl alcohol (70%), most general-purpose household disinfectants, and beta-propiolactone (0.1% at 4° C for 3 days).[49,76,127] Limited studies with Hantaan virus have shown sensitivity to a pH of 5 or less and to temperatures of 56° C or higher.[49,88] Knowledge about the survival time in the environment in the absence of disinfection is somewhat limited. Studies have shown persistent infectivity in dried cell culture medium for as long as 2 days and in neutral solutions for several hours at 37° C or several days at lower temperatures.[13] Hantaan virus was detected after 96 days under "wet" conditions at 4° C, and it remained viable for 2 minutes in 30 percent ethanol.[51] Cell culture supernatants of Puumala and Tula hantaviruses remained infectious for 5 to 11 days at room temperature and for as long as 18 days at 4° C but were inactivated after 24 hours at 37° C.[139] That hantavirus transmission is possible through indirect contact with contaminated environmental surfaces was demonstrated through a study in which Puumala virus excreted by experimentally infected bank voles into bedding maintained infectivity to recipient voles at room temperature for 12 to 15 days.[66]

LABORATORY PROPAGATION AND TISSUE CULTURE GROWTH

Hantaviruses are fastidious but can be grown in culture through serial blind passage. They routinely establish persistent, noncytolytic infections and generally do not replicate to high titer.[49,136] The prototype member of the group, Hantaan virus, was isolated in 1978[92] and propagated successfully in cell culture in the A-549 cell line in 1981.[38] However, Vero E-6 cells subsequently were found to be a better cell culture system for this and other hantaviruses.[49] Hantaviruses have been isolated and propagated successfully through direct inoculation of homogenates of infected tissue from wild-caught rodent hosts onto cell lines or after amplification through serially infected, colonized rodent hosts.[34,38,47,49,92,113,134,170] Recovery of hantaviruses from human specimens has been difficult and infrequent. More than 25 hantaviruses currently are recognized as causing human disease, although many of them have not been fully characterized, and the reservoirs of a few have not been determined. The major viruses are listed in Table 201–1. Some hantaviruses have been isolated in cell culture, but many are known only from genetic material amplified from human or rodent tissue. This list will be expanded and modified as our knowledge of classification and new viruses increases. Laboratory infection of persons working with cell culture–adapted Hantaan virus has occurred occasionally, but laboratory transmission of hantaviruses from infected rodents to humans is a particularly common occurrence.[27,30,68,87,89,97,156,157] Consequently, attempts to propagate the virus should be performed only when using biosafety level 3 or 4 facilities and practices.[13,15]

TRANSMISSION

Hantaviruses are zoonotic; each hantavirus generally is associated with a distinct rodent species or subspecies in which it establishes a chronic, inapparent infection. Hantavirus infection of rodents produces brief viremia that results in dissemination of virus to the lungs, salivary glands, and kidneys. Once infected, the rodent sheds virus in urine, saliva, and (to a lesser extent) feces throughout its life, despite the development of neutralizing antibodies.[90] In general, infection does not diminish the longevity or the reproductive potential of the infected rodent, although juvenile mice infected with Sin Nombre virus may survive for a shorter time in nature than do uninfected juveniles.[29] Vertical transmission has not been demonstrated, and pups born to infected dams appear to be protected by maternal antibody.[28,67,107] Enzootic infection appears to be maintained by exposure to nesting materials contaminated with infectious secretions, by grooming behavior, and by intraspecies biting.[29,89,90]

Humans typically become infected with hantaviruses after contact with contaminated secreta or excreta from infected rodents by inhalation of small-particle aerosols, by direct contact of infectious materials with broken skin or mucous membranes, or, rarely, by percutaneous inoculation of infectious materials (e.g., rodent bite). The primacy of respiratory droplets or airborne particles as the mode of transmission to humans is supported by evidence from outbreaks of disease among laboratory workers and sporadic cases resulting from brief exposure to rodent-infected habitats.

The risk of human hantavirus infection is a function of the density of the local rodent reservoir population, the prevalence of infection among rodents, and the frequency of activities that result in contact between humans and rodents or rodent excreta. Individual hantavirus infections usually occur when humans disturb rodent habitats or rodents enter human housing.[175] The risk for contracting disease after rodent exposure remains unquantified; however, one serosurvey suggested that persons in North America whose occupation entails close physical contact with rodents have a low risk for acquiring hantavirus infection.[39] Epidemics generally are associated with changes in the behavior of human populations that result in large-scale exposure of persons to rodent-infested areas (e.g., military maneuvers, agricultural or forestry activities) or environmental changes that result in rapid increases in the density of rodent populations (e.g., increased abundance of food items). Person-to-person transmission of hantaviruses associated with HFRS has not been demonstrated. The experience to date with HPS has been similar in North and Central America.[163] However, interpersonal spread clearly occurred during a 1996 outbreak in southern Argentina.[36,165] Subsequent independent investigations support this observation by having identified clusters in Argentina and Chile that suggest person-to-person transmission associated with Andes virus.[82,100,161] Interpersonal transmission thus appears to be a feature peculiar to Andes virus.

TABLE 201–1 Some Currently Recognized Hantaviruses

Virus Strain	Principal Reservoir	Distribution	Disease Association
Hantaan	*Apodemus agrarius mantchuricus*	Far East Northern Asia	HFRS (severe)
Seoul	*Rattus norvegicus*	Worldwide	HFRS (mild/moderate)
Dobrava	*Apodemus flavicollis*	Balkans	HFRS (severe)
Puumala	*Myodes (Clethrionomys) glareolus*	Scandinavia Northern Europe Balkans	HFRS (mild) (nephropathia epidemica)
Tula	*Microtus arvalis/Microtus levis*	Western Russia, eastern Europe	HFRS
Saaremaa	*Apodemus agrarius agrarius*	Europe	HFRS (mild)
Amur	*Apodemus peninsulae*	Far Eastern Russia	HFRS
Sin Nombre	*Peromyscus maniculatus*	North America	HPS
New York	*Peromyscus leucopus*	United States	HPS
Monongahela	*Peromyscus maniculatus nubiterrae*	Eastern United States	HPS
Black Creek Canal	*Sigmodon hispidus spadicipygus*	Florida	HPS
Muleshoe	*Sigmodon hispidus texianus*	Texas, Louisiana	HPS
Bayou	*Oryzomys palustris*	Southeastern United States	HPS
Andes	*Oligoryzomys longicaudatus**	Southern Chile, Argentina	HPS
Oran	*Oligoryzomys longicaudatus**	Northern Argentina	HPS
Laguna Negra	*Calomys laucha*	Central South America	HPS
Choclo	*Oligoryzomys fulvescens*	Panama	HPS
Juquitiba	*Oligoryzomys nigripes*	Southeastern Brazil	HPS
Araraquara	*Necromys lasiurus*	Southeastern Brazil	HPS
Castelo dos Sonhos	Unknown	Central Brazil	HPS
Lechiguanas	*Oligoryzomys flavescens*	Central Argentina	HPS
Bermejo	*Oligoryzomys chacoensis*	Northwestern Argentina Central Brazil	HPS
Prospect Hill	*Microtus pennsylvanicus*	United States	None recognized
Thottapalayam	*Suncus murinus* (insectivore)	India	None recognized
Sangassou	*Hylomyscus simus*	West Africa	None recognized
Tanganya	*Crocidura theresae* (insectivore)	Guinea	None recognized

**The reservoirs of the Andes and Oran viruses are genetically distinct, but of uncertain taxonomic status. Nevertheless, both are currently referred to as* O. longicaudatus*. (D. Enria, personal communication). Additional hantaviruses have been associated with occasional human disease in Europe, Asia, and the Americas.*
HFRS, hemorrhagic fever with renal syndrome; HPS, hantavirus pulmonary syndrome.

EPIDEMIOLOGY

GEOGRAPHIC DISTRIBUTION

Hantaviruses have been found on every continent except Antarctica. With the exception of HFRS caused by Seoul virus, hantavirus diseases occur almost exclusively in rural areas. Hantaan virus, the cause of classic HFRS, is carried by the striped field mouse *Apodemus agrarius mantchuricus*. This rodent is distributed across eastern Russia, China, and the Korean peninsula.[168] The principal reservoir for Puumala virus, the etiologic agent of a milder HFRS variant found in Scandinavia, northern Europe, and Russia west of the Ural Mountains, is the bank vole, *Clethrionomys glareolus*.[91,141]

In Europe, at least four viruses have been linked etiologically with HFRS: Puumala, Tula, Saaremaa, and Dobrava; Tula virus is associated with voles (*Microtus* spp.); Saaremaa virus is hosted by a subspecies of the striped field mouse (*Apodemus agrarius agrarius)*; Dobrava virus is associated with *Apodemus flavicollis*, the yellow-necked field mouse.[2,4,5,47,124,125] *Rattus* spp. (primarily *Rattus norvegicus*) serve as reservoirs for the Seoul-like viruses identified worldwide; human infections have been seen most frequently in eastern Asia. Outbreaks of severe and occasionally fatal HFRS among animal handlers and laboratory scientists have been caused by inapparent infection of laboratory rats with Seoul-like viruses.[86]

Genome sequences of a novel hantavirus species were detected in an African wood mouse (*Hylomyscus simus*) in Guinea.[74] This agent, provisionally named "Sangassou" virus, was more similar to Eurasian hantaviruses than to those causing HPS in the Western Hemisphere. It was sufficiently distinct to represent a separate clade, but it has not been linked to clinical illness.

Numerous hantaviruses associated with native murid rodents are known to exist in the Americas. Several, all associated with rodents of the family Muridae, subfamily Sigmodontinae, are of medical importance in the United States.[121] The deer mouse, *Peromyscus maniculatus*, is the reservoir rodent for Sin Nombre virus, the agent associated most frequently with human disease in North America.[20,34] This rodent is distributed widely over the United States, Canada, and parts of Mexico. In addition, HPS cases in the eastern United States have been associated with viruses called *New York* and *Monongahela*, which are closely related to Sin Nombre virus and are found in *Peromyscus leucopus* (white-footed mouse) and *P. maniculatus nubiterrae*, respectively.[56,148] Clinical HPS has been recognized in areas outside the known ranges of *P. maniculatus* and *P. leucopus*, however, and a search for other virus-rodent pairings has yielded at least three additional U.S. hantaviruses. Black Creek Canal virus and Muleshoe virus are associated with two species of cotton rats, *Sigmodon hispidus spadicipygus* and *Sigmodon hispidus texianus*, respectively, and Bayou virus is hosted by the rice rat, *Oryzomys palustris*.[55,70,73,111,130,153] Several hantaviruses associated with sigmodontine rodents have not been implicated in human disease. El Moro Canyon virus is hosted by the harvest mouse (*Reithrodontomys megalotis*), and Limestone Canyon virus is hosted by the brush mouse (*Peromyscus boylii*). No human infections have been documented with these viruses, and the potential for causing disease, if any, is unknown.[54,132] Seoul virus introduced by *Rattus* has been associated with human infections in several large cities, but acute (HFRS-like) disease has been confirmed only in Recife, Brazil.[23,45,46,83] Several hantaviruses associated with voles (family

Muridae, subfamily Arvicolinae) in North America are not associated with human disease: Prospect Hill virus has been recovered from meadow voles (*Microtus pennsylvanicus*) in Maryland, and related but distinct hantaviruses are inferred to be present in other voles by detection of genetic sequences by reverse transcriptase-polymerase chain reaction (RT-PCR).[168,169]

In recent years, South America clearly has surpassed North America in terms of numbers of human HPS cases and numbers of hantaviruses and host species identified.[6,58,162,164] All the HPS-causing hantaviruses in South and Central America are associated with sigmodontine rodents. Some of the most important viruses are as follows: Andes virus, hosted by *Oligoryzomys longicaudatus* in southern Argentina and Chile; Lechiguanas virus, associated with *Oligoryzomys flavescens* in central Argentina; Laguna Negra virus, hosted by *Calomys laucha* in Northern Argentina, Paraguay, and Bolivia; Juquitiba virus, associated with *Oligoryzomys nigripes* in Brazil; and Choclo virus, associated with *Oligoryzomys fulvescens* in Panama. Several other hantaviruses responsible for significant disease in South America are listed in Table 201–1. The recognition of clinical HPS in Canada[149] and Central and South America clearly has established HPS as a panhemispheric rather than a geographically circumscribed disease. However, all HPS agents identified or suspected to date belong to a single genetic group of hantaviruses and are associated with rodents of the family Muridae, subfamily Sigmodontinae. These rodent species are restricted to the Americas, in accordance with the findings that HPS has been an exclusively Western Hemisphere disease.[110]

SEASONAL PATTERNS

The natural population cycles of rodents and the seasonal nature of certain human behavior result in a pattern of human hantavirus disease that varies both seasonally and annually.[11,15,16,41,85,102,154] Although the incidence of disease varies by season, cases of hantavirus-associated human disease are recognized year-round in all disease-endemic areas.[12,71,86,141]

In eastern Asia and Russia east of the Ural Mountains, HFRS occurs primarily during the late fall and early winter, with smaller peaks during the spring and summer. Most Scandinavian HFRS occurs between the late summer and early spring, whereas European HFRS in warmer regions (e.g., France, Belgium) tends to peak in the spring.[160] In the Balkans, the presence of multiple viral strains results in a more diffuse seasonal distribution of human disease. Persons whose occupations or avocations bring them to rural settings, such as agricultural workers, foresters, biologists, hunters, campers, and soldiers stationed in the field, are at greatest risk for contracting HFRS.

HFRS caused by Seoul virus tends to occur throughout the year, and descriptions of a seasonal occurrence of Seoul virus infection have been conflicted.[19,93] Cases of Seoul virus disease also have a more even age and sex distribution than do rural hantavirus infections, presumably because of the peridomestic nature of the agent's reservoir.

The temporal distribution of HPS cases suggests a mild spring-summer seasonality of human disease. However, environmental and geographic factors influence this pattern; HPS cases have been identified throughout the winter and early spring.[12,14,35,44,171]

PREVALENCE

Worldwide, human hantavirus infections may number in the hundreds of thousands of cases annually.[168] Because of the predominantly rural nature of the disease and its prevalence in developing regions of the Eurasian land mass (e.g., rural China), accurate case reporting (and statistical data) for HFRS is limited. Researchers have estimated that more than 100,000 cases of HFRS occur each year in China.[146,168] One report suggested an incidence of 1.6 to 29.6 per 100,000 population during 1980.[65] In the former Soviet Union, more than 4000 cases per year were recorded between 1978 and 1989, 96 percent of which occurred in "European" republics. Rates in western regions near the Ural Mountains were higher (20 to 40 per 100,000 population) than were those in eastern districts (2 to 5 per 100,000 population).[152] In Korea, approximately 500 persons with HFRS, approximately half of whom are soldiers, are hospitalized annually.[152] In central and northern Sweden, a mean annual incidence of 4.3 per 100,000 population has been reported, although northern locales have rates of more than 20 per 100,000 population.[141]

As of March 2007, 467 cases of HPS had been confirmed in the United States. Although a few cases were identified retrospectively, most have occurred since 1993. More than 2500 cases were documented in South America during approximately the same time-frame (including 864 cases in Brazil alone).

DEMOGRAPHIC FEATURES

Hantavirus infections are recognized infrequently in the pediatric age group.[3,42,71,72,141,152,172] The disease occurs principally in adults, with fewer than 10 percent of cases diagnosed in children. A slight male preponderance has been noted in reported cases.

The peak incidence of HFRS in Europe, the Balkans, and the Far East occurs in individuals who are 20 to 50 years of age.[80,86,119,154] Few cases have been reported in children younger than 10 years. Both HFRS and HPS cases in young children often are recognized in association with cases in other family members.[3,42,80,109,117] A male preponderance of cases has been observed for both the severe (Korean) and milder (European) forms of HFRS in children.[1,75,109,172] Although this pattern, also seen in adults with HFRS, suggests differential susceptibility or risk of exposure by gender, the number of recorded cases, particularly in the youngest age groups, is too small to draw firm conclusions.

The underrepresentation of children recognized to have HFRS and HPS may not be explained by age-related avoidance of activities resulting in exposure. The limited data available (see "Clinical Manifestations") suggest that hantavirus infections in children may induce milder disease than that seen in adults, although typical (even fatal) HPS has been described. Comprehensive population-based serosurveys are sparse and have been inadequate to define age-associated infection rates. The apparently immune-mediated pathologic process of this disease (see "Pathogenesis and Pathology") is possibly more evident in persons experiencing infection in adulthood.

CLINICAL MANIFESTATIONS

HEMORRHAGIC FEVER WITH RENAL SYNDROME

Two major clinical variants of HFRS have been recognized traditionally. Severe disease associated with high morbidity and mortality rates occurs primarily in areas of the world where Hantaan and Dobrava viruses are endemic: across the northern half of Asia, China, the Korean Peninsula, and the Balkan nations. Milder illness with little mortality occurs in areas where Puumala and related viruses have been recovered; this latter disease, known also as *nephropathia epidemica*, is found throughout northern Europe, Scandinavia, and western areas of the former Soviet Union. In the Balkans, the coexistence of Puumala virus–like strains with viruses causing more serious disease has resulted in a mixture of clinical findings in the former Yugoslavia and neigh-

boring countries. Benign manifestations of HFRS are well recognized in many regions where Hantaan virus is found, however, and clinically severe disease occasionally results from Puumala virus infection.[122] Hence, it is important to appreciate the protean nature of this disorder and to recognize the potential for disease of any severity whenever and wherever human infection with hantavirus occurs.

Severe HFRS, such as that associated with Hantaan or Dobrava virus, is a complex, multiphasic disorder that presents a substantial challenge in patient management. The clinical course of HFRS caused by Hantaan virus in adults spans a wide spectrum from mildly symptomatic disease to severe hemorrhagic fever and death. Subclinical infections probably occur infrequently.[126,172] In most cases, the clinical course is relatively benign, with severe disease developing in approximately 20 to 30 percent of patients. Modern-day case-fatality rates range from 2 to 7 percent. In Korea, approximately a third of recognized Hantaan virus infections follow a clinical course consisting of progression through five clinically and pathophysiologically defined stages: febrile, hypotensive, oliguric, diuretic, and convalescent.[93,142] Phases often blur, however, and in milder cases, one or more phases may not be discernible. After an incubation period of 2 to 3 weeks (range, 4 to 42 days), most patients report the abrupt onset of high fever, headache, chills, dizziness, myalgia, anorexia, and backache. Approximately one third of patients experience prodromal mild respiratory or gastrointestinal symptoms. Nausea, vomiting, abdominal pain, and intense thirst may be evident at initial evaluation but increase in severity in succeeding days. Photophobia, blurred vision, and eyeball pain are reported frequently. Physical examination reveals a restless, acutely ill patient with flushing of the face, neck, and upper thoracic region. Relative bradycardia is present. Conjunctival and pharyngeal injection, together with facial puffiness, is characteristic. In more than 90 percent of patients, petechiae develop on the soft palate, axillae, lateral aspect of the thorax, conjunctivae, or face, generally between the third and sixth days of illness. Tenderness occurs commonly over the costovertebral angles and diffusely throughout the abdomen. Hematologic studies in the first 3 to 4 days of illness reveal leukocytosis with a left shift in more than 90 percent of patients, as well as almost universal thrombocytopenia; the hematocrit at this stage generally is normal or slightly increased. Proteinuria develops by the third to fourth day, and microscopic hematuria, hyposthenuria, and mild pyuria are reported in most patients; fibrin clots in urine are a characteristic finding.

This febrile phase generally lasts approximately 1 week, followed by abrupt defervescence. Approximately 40 percent of patients then become hypotensive; in most cases, the drop in blood pressure is mild and brief, but in severely ill persons (30% to 50% of hypotensive patients), clinical shock develops. Tachycardia replaces bradycardia, the pulse pressure narrows, and cyanosis and mental confusion may be seen. The hypotensive phase may last from a few hours to 3 days, and 30 to 40 percent of deaths occur during this period.

As patients recover from hypotension, they enter a period of oliguria. This phase occurs in approximately 60 percent of patients and generally lasts for several days. Anuria develops in approximately 10 percent of patients. Blood pressure normalizes, and hypertension often develops. Clinical manifestations of uremia, including protracted vomiting and hiccups, may be seen. More extensive hemorrhagic manifestations such as ecchymoses, hemoptysis, hematemesis, melena, gross hematuria, and, rarely, bleeding in the central nervous system (CNS) become evident during the oliguric phase. Striking elevations in blood urea nitrogen and creatinine levels are common findings. Biochemical disturbances (electrolyte derangements, metabolic acidosis, uremia) may be severe, and in such cases, dialysis may be lifesaving. Approximately half of fatalities occur during the oliguric phase.

Between 10 and 14 days into the illness, renal function is restored spontaneously in most patients, and a period of diuresis follows. Polyuria may be substantial, and urine output frequently exceeds 3 to 6 L/day. With the onset of diuresis, clinical recovery is initiated; however, the rapid change in fluid status may precipitate further electrolyte disturbances, so close monitoring remains necessary.

Convalescence typically lasts from 3 to 6 weeks, but in many cases, a longer period passes before health is restored completely. Weight gain and strength are recovered slowly. Proteinuria resolves, but hyposthenuria persists for months. Most patients recover completely, although permanent sequelae may result from such complications as anterior pituitary or other CNS hemorrhage.

The disease has been reported infrequently in children.[42,75,172] However, the data available indicate that clinical manifestations are similar to and perhaps somewhat less severe than those observed in adults. In a series of 63 children identified retrospectively over a 15-year period in Korea, fever was universal, whereas abdominal pain, headache, and vomiting were present in 73 percent or more of patients (Table 201–2).[172] Proteinuria (100%), leukocytosis (71%), thrombocytopenia (80%), hypocholesterolemia (87%), and elevations in creatinine (94%), blood urea nitrogen (94%), and alanine transaminase (80%) were the laboratory abnormalities found most commonly. Petechiae and hypotension occurred infrequently (38% and 11%, respectively), and frank hemorrhage did so rarely. Eleven patients (18%) required dialysis. The mortality rate was 5 percent, and the remaining patients recovered without sequelae.

HFRS occurring in adults after they are infected with Seoul virus resembles that described for Hantaan virus infection, but the clinical manifestations generally are much milder.[93] Fever and constitutional symptoms are similar in the two types of infection, but hypotension occurs infrequently in persons infected with Seoul virus (10% of cases), and clinical shock is a rare event. The

TABLE 201–2 Prominent Clinical and Laboratory Features of Hemorrhagic Fever with Renal Syndrome in Children

Features	Korea[172] (%)	Sweden[1] (%)	Finland[109] (%)

NR, not recorded.

frequency and severity of thrombocytopenia are less with Seoul virus infection, whereas elevations of transaminases occur commonly (>60% of cases). The mortality rate for HFRS caused by Seoul virus is 1 percent or less.

The Scandinavian or European form of HFRS (nephropathia epidemica) generally is a much more benign disease than that attributed to Hantaan virus; fatal outcomes are observed, but the case-fatality rate is less than 1 percent. In contrast to the findings with Hantaan virus, subclinical infection apparently occurs commonly with Puumala virus; one report suggested a case-to-infection ratio of 1:10.[115]

In adults, nephropathia epidemica typically is a biphasic disease of 1 to 3 weeks' duration.[24,119,159] The onset usually is abrupt, with no apparent prodrome. High fever is the initial symptom in 95 percent of patients. On examination, a facial flush is a usual finding. This febrile phase lasts from 3 to 6 days. The development of nausea, vomiting, abdominal pain, back pain, somnolence, and, occasionally, joint pain heralds the onset of the second, or renal, phase. The abdominal pain may be of such severity and character that an acute abdomen is suspected, and many patients have undergone surgery for suspected appendicitis before nephropathia epidemica was diagnosed. Visual disturbances are common manifestations, and hypotension, if it develops, usually is mild. Petechiae are seen relatively infrequently. The renal stage generally lasts 1 to 2 weeks and is characterized by the development of oliguria, proteinuria, hematuria, and hyposthenuria. Modest elevations in blood urea nitrogen and creatinine accompany the oliguria, which typically lasts for no more than a few days before diuresis begins. Mild leukocytosis and thrombocytopenia occur during the renal phase, whereas electrolyte disturbances sufficient to require dialysis are infrequent events. As with other forms of HFRS, convalescence may be prolonged, and hyposthenuria may persist for many months. Recovery typically is complete, although minor abnormalities in renal function and blood pressure have been described.[81,114]

As with Hantaan virus–associated HFRS, nephropathia epidemica in children is recognized infrequently. Clinically, the disease also appears to be similar to and, in most cases, milder than that seen in adults. Among 32 Swedish cases reported (18 identified retrospectively and 14 prospectively), fever (100%), headache (100%), anorexia (100%), abdominal pain (93%), vomiting (91%), nausea (86%), and back pain (76%) were the most prevalent symptoms (see Table 201–2).[1] Proteinuria (100%), microscopic hematuria (80%), elevated serum creatinine (76%), and thrombocytopenia (68%) were the laboratory abnormalities most frequently found. Leukocytosis was a relatively uncommon finding (22%) in this series. Six children (19%) had hemorrhagic manifestations, and one complained of blurred vision. In a separate 32-patient series from Finland, fever (100%), nausea (81%), vomiting (72%), and back pain (63%) again were prevalent, but headache and abdominal pain (59%) were reported less frequently (see Table 201–2).[109] Proteinuria (97%), hematuria (73%), and elevated serum creatinine (84%) were common findings. Thrombocytopenia (87%) was reported more prominently among Finnish than Swedish children. Approximately one fourth of Finnish children displayed hemorrhagic manifestations. The proportion of transient visual blurring was identical to that seen in adults (25%). Some disease manifestations (e.g., thrombocytopenia, renal function abnormalities) may be absent, however, and the disease should be considered in the differential diagnosis of "fever of unknown origin" in endemic areas.[158] Three children with Puumala virus nephropathy in the Czech Republic were admitted with interstitial nephritis following a flulike prodrome. All were mildly febrile, with anemia and elevated C-reactive protein, erythrocyte sedimentation rate, serum creatinine and proteinuria. Biopsy-confirmed renal abnormalities returned to normal within 4 weeks after steroid treatment.[32] No children in these series required dialysis.

HANTAVIRUS PULMONARY SYNDROME

Classic HPS in adults is a biphasic illness that challenges the diagnostic acumen and clinical management skills of physicians. The incubation period was 7 to 39 days (median, 18 days) for 20 people with defined exposure to Andes virus in a high-risk area,[161] an observation consistent with the incubation period of 9 to 33 days (median, 14 to 17 days) for 11 cases of patients with HPS and well-defined exposure in the United States[173] and the 3-week incubation period observed in two boys with HPS bitten by the same mouse.[144] The clinical features of the prodrome phase are not pathognomonic, and the diagnosis rarely is suspected before the abrupt clinical deterioration occurs that heralds onset of the cardiopulmonary phase. HPS characteristically begins with a prodrome that lasts on average 3 to 4 days but may extend as long as a week or more.[17,31,95,121,160] This phase is typified by fever and myalgia, particularly of the back or lower extremities. Although a cough may develop as the prodrome progresses, illnesses initially characterized predominantly by upper respiratory symptoms, such as cough and coryza, are unlikely to be HPS.[17,31,95,108] More than half of patients with HPS also have gastrointestinal symptoms (e.g., nausea, vomiting, diarrhea) that usually are mild.[17,31] Occasionally, HPS-associated gastrointestinal symptoms have been mistaken for an acute surgical abdomen or another intra-abdominal process. The presence of thrombocytopenia in the context of a compatible prodrome is highly suggestive of HPS.[17,31,77,108,143]

The onset of the cardiopulmonary phase is abrupt and often life-threatening. Patients usually are hospitalized within 12 to 24 hours of initial medical evaluation, and most deaths occur during the first 24 to 48 hours in the hospital.[17,18,31,95] Clear chest radiographs have progressed to diffuse bilateral pulmonary involvement during the course of several hours. Interstitial edema, present in only 5 percent of patients with adult respiratory distress syndrome, is present in most patients with HPS on initial radiography, and alveolar flooding that is usually indistinguishable from the peripheral pattern seen in the acute phase of adult respiratory distress syndrome develops in most patients.[69] This noncardiogenic pulmonary edema, resulting from a diffuse pulmonary capillary leak, can be differentiated from cardiac (hydrostatic) pulmonary edema by the presence of low pulmonary artery occlusion pressure and an increased protein content in edema fluid.[50] Secretions recovered when patients with HPS are intubated generally are acellular, resemble plasma or pulmonary edema fluid, and have been observed to clot in severe cases.[31,50] The presence of significant numbers of polymorphonuclear leukocytes in pulmonary secretions suggests an alternative cause.

The pulmonary decline usually is accompanied by the onset of shock caused by myocardial dysfunction and relative hypovolemia.[17,50,95] In severe cases, hemodynamic measurements show high systemic vascular resistance combined with low cardiac and stroke volume indices. Progression to death is associated with worsening cardiac dysfunction unresponsive to treatment, despite provision of adequate oxygenation.[50] At autopsy, the myocardium of patients who died of Araraquara virus–associated HPS contained endothelial cells and interstitial macrophage-type cells harboring hantavirus antigen and viral particles accompanied by a mononuclear cell inflammatory interstitial infiltrate that met the international consensus criteria for infectious inflammatory myocarditis and was absent from the autopsy myocardium of persons who died after having either necrotizing pancreatitis associated with acute lung injury or nonthoracic trauma.[129,131] This infectious inflammatory cardiomyopathy may be responsible for HPS-associated myocardial depression and shock. In one South American study, the absence of clinical and laboratory signs of circulatory shock on admission was associated with a favorable outcome.[133]

Thrombocytopenia may be present in the late prodrome and almost always is found during the cardiopulmonary phase. Addi-

tional laboratory abnormalities in hospitalized patients include hemoconcentration, prolonged prothrombin and partial thromboplastin times, elevated serum lactate dehydrogenase concentration, decreased serum protein concentration, mild leukocytosis with a marked left shift, and the frequent presence of myeloid precursors on the peripheral smear.[17,31,77,95,121] Proteinuria is a common occurrence. Serum creatinine often is elevated modestly in severe cases, although renal failure is not characteristic of infection with Sin Nombre virus, despite episodes of hypotension and other predisposing conditions that are present in many patients. Among patients who survive, recovery may be as dramatic as the decline; survivors may be extubated within 3 to 7 days after admission to the intensive care unit and may be discharged from the hospital within 2 weeks.[121]

Renal failure was more prominent in two reported cases of HPS caused by infection with Black Creek Canal virus and Bayou virus.[29,73] The hantavirus disease associated with Andes virus[98] in Argentina and Chile and that from other related virus infections in Brazil[111] and Paraguay[166] closely resemble Sin Nombre virus disease. Renal failure accompanied some cases in a focus in northern Argentina.[117]

Subclinical or mild disease rarely follows Sin Nombre virus infection.[143] However, although initial case-fatality rates of 70 to 80 percent were reported in 1993, a wider clinical spectrum became recognized once clinicians developed heightened suspicion and diagnostic assays became more readily available. As of March 2007, the overall case-fatality rate for HPS cases in the United States was 35 percent. This apparent decline in the incidence of mortality may reflect improvements in survival attributed to improved clinical management. However, it undoubtedly also reflects a decrease in the tendency to suspect this diagnosis only with the fatal and near-fatal disease that existed early in the clinical understanding of this syndrome.

HPS has been recognized infrequently in children younger than 17 years. Several case reports and reviews of pediatric patients with HPS (identified through the Centers for Disease Control and Prevention [CDC] surveillance and a university database) indicated that the geographic distribution, clinical course, and mortality rates in children and adolescents are similar to those described for adults.[3,10,72,84,116,128] Fever, headache, dyspnea or cough, gastrointestinal disturbances, and myalgia are common manifestations in the prodromal phase. Tachypnea and fever are frequent on hospital admission; in one case series, however, hypotension at presentation was an uncommon finding (33%).[128] In one patient, dizziness with an apparent vestibular component was described.[72] Thrombocytopenia, a left shift in the leukocyte differential count, elevated levels of hepatic transaminases and lactate dehydrogenase, and hypoalbuminemia typically are seen on admission. Although leukocytosis and hemoconcentration are not found early reliably, they may appear later in the course of illness. Investigators suggested that the mortality rate among prepubertal children may be somewhat lower than that seen in older individuals,[10] but as patient numbers have accumulated over time, overall case-fatality rates in pediatric and adolescent patients seem to be similar to those seen in adults (30% to 40%). In one series, hypotension and absence of fever at admission were found to be predictive of respiratory failure, whereas elevated prothrombin time (≥14 seconds) at admission was predictive of mortality.[128] In one small case series from Argentina, the case-fatality rate for HPS in 5- to 11-year-old children was somewhat higher (60%).[123] In the same report, the authors noted evidence of passive hantavirus antibody transfer from a pregnant mother to her fetus, without subsequent illness in the infant. Additionally, a woman who nursed a 7-month-old infant contracted HPS and subsequently died. Hantavirus antibodies were detected to high titer (>1:6,400) 8 and 15 months later in the baby (who remained healthy), a finding suggesting possible asymptomatic mother-to-child transmission of the infection through breast-feeding.[123]

COMPLICATIONS

In general, human infection with HFRS-associated hantaviruses results in an acute illness with prolonged incapacitation followed by complete recovery. Unless complicated by organ hemorrhage (e.g., CNS bleeding), residua have not been observed. However, epidemiologic associations between hypertensive renal disease and evidence of previous U.S. hantavirus infection have been reported.[45,46] In one study, 5 years after recovery, 50 percent of patients who had HFRS were hypertensive, with a higher glomerular filtration rate and urinary protein excretion compared with 21 percent of controls. These differences resolved by 10 years.[105] These data require further study to determine their significance.

Although prolonged prothrombin and partial thromboplastin times occur commonly in hospitalized patients with HPS, overt disseminated intravascular coagulation and overt hemorrhage occur infrequently.[17,174] Patients in whom disseminated intravascular coagulation is established rarely survive longer than 48 hours. One patient who did survive a cardiopulmonary phase accompanied by overt disseminated intravascular coagulation died 3 weeks later of gangrenous complications.

The South American viruses have been associated with more extrapulmonary manifestations than have the Sin Nombre infections in the United States. Evidence of bleeding is found more commonly, and other complications are reported with greater frequency.

PATHOGENESIS AND PATHOLOGY

Serum antibodies develop within 3 to 7 days of the onset of illness in patients infected with hantaviruses. Early clinical events are presumed to be accompanied by viremia; however, significant signs and symptoms develop in temporal association with the onset of a measurable antibody response. In HPS, a statistically significant association has been demonstrated between plasma viral RNA levels at hospital admission and the severity of disease.[167] Pathologic studies of fatal HFRS cases indicated that multiple organ systems are involved, but a triad of lesions consisting of hemorrhagic necrosis of the renal medulla, anterior pituitary, and cardiac right atrium is described as characteristic.[63] In HPS, multiple organ involvement with variable degrees of vascular congestion is noted in all fatal cases. However, the predominant findings at autopsy have involved the lungs, with pulmonary edema and serous effusions seen grossly and interstitial pneumonitis with a mononuclear cell infiltrate, intra-alveolar edema, and focal hyaline membrane formation described microscopically. Immunohistochemical studies demonstrated the widespread presence of hantavirus antigens in endothelial cells of the microvasculature, particularly in the lungs but also in the kidneys, heart, spleen, pancreas, lymph nodes, skeletal muscle, intestine, adrenal gland, adipose tissue, urinary bladder, and brain. However, few histologic changes have been noted in the kidney, brain, and heart of autopsied patients with HPS.[174]

Hantaviruses replicate primarily in human endothelial cells, but without apparent cytopathic effect.[174] However, endothelial cell mRNA responses to infection by pathogenic and nonpathogenic hantaviruses, observed by DNA array analyses, showed differential patterns of gene activation.[43] Pathogenic Hantaan and New York-1 viruses appeared to suppress early interferon responses that were activated by nonpathogenic Prospect Hill virus. Hantaan virus uniquely induced multiple chemokines (interleukin-8 [IL-8], IL-6, growth-regulated oncogene-beta [GRO-β]), cell adhesion molecules (intercellular cell adhesion

molecule [ICAM]), and complement cascade–associated factors that could play a role in HFRS immunopathogenesis. Although New York-1 virus failed to induce most of the cellular chemokines activated by Hantaan, it uniquely induced β_3 integrin–linked potassium channels, an action that could be important to HPS-induced vascular permeability. Whereas the mechanisms underlying the observed pathologic lesions are incompletely understood, both cellular and humoral immune-mediated mechanisms have been implicated.[7,25,33,63,155] Virus-specific cytotoxic T lymphocytes have been observed during acute phases of HFRS,[61] and elevated levels of inflammatory cytokines (interferon-γ [IFN-γ], tumor necrosis factor-α [TNF-α], TNF-β, IL-6, and IL-10) have been found in sera and renal biopsies of patients.[61,78,96,151] Animal studies suggested a role for T-helper cells and antibodies as well.[26] The abrupt onset of noncardiogenic pulmonary edema in HPS occurs after the development of an immune response directed against viral antigen present throughout the endothelial cells lining the pulmonary capillaries, and such edema leads to a pulmonary capillary leak syndrome.[120]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

A high index of suspicion is essential for recognition of hantavirus infection in persons living or traveling in disease-endemic areas. The protean nature of the disease in children is such that almost any ill-defined febrile disease (or fever of unknown origin) associated with abdominal or back pain in an appropriate geographic setting should stimulate consideration of the diagnosis, particularly if the clinical syndrome is accompanied by myalgia, if thrombocytopenia or proteinuria is present, or if a history of exposure to rodents or rural environments in disease-endemic areas is elicited.[143]

The differential diagnosis of HFRS includes rickettsial disease, leptospirosis, meningococcemia, other viral diseases, post-streptococcal syndromes, pyelonephritis, leukemia, and hemolytic-uremic syndrome. Differentiating from an acute intra-abdominal or pelvic process, such as appendicitis, may be extremely difficult on clinical grounds.

The differential diagnosis of HPS includes rickettsial diseases, leptospirosis, influenza, streptococcal pneumonia, legionellosis, *Yersinia pestis* infection (plague), meningococcemia, brucellosis, mycoplasmal and fungal pneumonias (including *Coccidioides immitis* and *Histoplasma pneumonias*), tularemia, psittacosis, pancreatitis accompanied by adult respiratory distress syndrome, and autoimmune disorders (including thrombotic thrombocytopenia purpura). A prominent cough or sore throat or a localized infiltrate on a chest radiograph that does not generalize within hours argues for a non-hantaviral cause.[17,53,108] A constellation of the absence of a cough in the presence of dizziness, nausea or vomiting, a low platelet count, a low serum bicarbonate level, and an elevated hematocrit discriminated HPS from similar patients with unexplained adult respiratory distress syndrome in two studies.[17,108] Thrombocytopenia or a falling platelet count provides a valuable clue late in the prodrome. After the onset of pulmonary edema, the presence of four of five findings (thrombocytopenia, myelocytosis, hemoconcentration, lack of significant toxic granulations in neutrophils, and more than 10% of lymphocytes with immunoblastic morphologic findings) has sensitivity for HPS of 96 percent and specificity of 99 percent.[77] Frequent use of pulse oximetry also is of assistance.

Laboratory diagnosis of HFRS or HPS is made by demonstrating specific anti-hantavirus immunoglobulin M (IgM) antibodies in acute-phase serum by enzyme immunoassay in the IgM capture format. A fourfold or greater rise in specific IgG antibodies by enzyme immunoassay or immunofluorescence[79,94] in sequential sera (ideally obtained ≥2 weeks apart) also is useful. The availability of purified recombinant hantavirus antigens has enhanced diagnostic specificity in both the enzyme immunoassay and Western blot assay systems.[37,64,177] Enzyme-linked immunosorbent assay and indirect fluorescent antibody tests are broadly cross-reactive, particularly among viruses from rodents of the same subfamily.[21,22] For example, a recombinant Sin Nombre virus antigen detects antibodies against Bayou, Black Creek Canal, Andes, and several other viruses from sigmodontine rodents, and it maintains reactivity with antibodies directed against arvicolid rodent–associated viruses (e.g., Puumala and Prospect Hill). Neutralizing antibody assays are more specific, but technical requirements preclude their routine use. Immunohistochemical techniques have been applied to tissue samples from patients infected with hantaviruses.[174] Nucleic acid primers from several hantavirus strains have been generated, and they have enabled nucleotide sequences from fresh or frozen tissues to be amplified by RT-PCR. RT-PCR usually is successful on whole blood or blood clots obtained within the first 7 to 10 days of illness. However, the expense and effort of performing the method are not justified unless the resulting genetic sequence information is needed for definition of the viral strain or for epidemiologic studies.[2,112] Attempts to isolate hantaviruses from human specimens are generally unrewarding.

TREATMENT

Cautious fluid management and hemodynamic and intensive care unit support are the most important aspects of the clinical management of any hantavirus disease.[50,95] Early hospitalization and avoidance of even minor trauma are essential to maintain the integrity of damaged vascular beds in these patients. Transport of patients should be minimized; the barotrauma associated with transport in underpressurized aircraft may be particularly hazardous.[9] Attention to fluid management and metabolic status is especially critical. In patients with HFRS, restriction of fluids may be necessary early in the course of disease as renal function diminishes, but large input may be required later during diuresis to cover massive losses. Electrolyte abnormalities and metabolic acidosis occur commonly. Peritoneal dialysis or hemodialysis may be lifesaving in severe cases.[9] In patients with HPS, the nature of the pulmonary disease predisposes to iatrogenic pulmonary edema; careful attention must be paid to maintaining appropriate central venous and pulmonary arterial pressure to avoid such complications. Tissue perfusion and adequate oxygenation are the goals of supportive therapy with this syndrome. Oxygen supplementation and mechanical ventilation are required nearly always. Inotropic agents may be necessary to maintain tissue perfusion.[50,95] Studies have suggested that cytotoxic T-lymphocyte activity and other aspects of inflammatory response contribute to the capillary leakage observed in patients with HFRS or HPS, and case reports have attributed clinical improvement to treatment with corticosteroids and veno-venous hemodiafiltration.[52,140] The safety and efficacy of steroid treatment have not been confirmed through controlled clinical trials.

Hantaan and Sin Nombre viruses exhibit similar in vitro sensitivity to ribavirin. One prospective, placebo-controlled trial suggested that intravenous ribavirin was effective in reducing the mortality and morbidity rates associated with HFRS in China.[62] In contrast, although 30 patients with HPS who received investigational, open-label intravenous ribavirin generally tolerated it well, treatment was accompanied by a low frequency of early drug-associated adverse events, most significantly anemia and resulting transfusion, and no clear evidence of benefit was obtained.[17,18] A subsequent randomized placebo-controlled trial was stopped short of a definitive end-point because of

small enrollment without trends supporting either efficacy or adverse events.[104] However, the study sample size was insufficient to exclude adverse events that occurred at a rate of less than 27 percent.[99] Similar doses of intravenous ribavirin resulted in hemolysis in 76 percent, a 2 g/dL hemoglobin level decrease in 49 percent, and discontinuation because of toxicity in 18 percent of 126 patients treated for sudden acute respiratory syndrome (SARS), findings consistent with observations during the open-label trial.[8,17,18,99] This contrast in clinical experience is not explained by differences in dosing schedules; patients in all three protocols received identical doses.[8,18,62] All hantaviruses have been sensitive to the antiviral effects of ribavirin in vitro. The lack of any dramatic effect by intravenous ribavirin in HPS is probably the result of the rapid progression of the disease; HPS-associated deaths usually occur within the first 48 hours after admission and therapeutic intervention.[16-18,31,50,62,95]

Ribavirin is not licensed for intravenous use in the United States. Teratogenic concerns mandate careful informed consent if the use of this drug is considered in children, pregnant women, or nursing mothers.

PREVENTION

PRIMARY PREVENTION

The most effective preventive measure available for hantavirus infection is the avoidance of rodents and their habitats. However, eradication of rodent reservoir hosts in disease-endemic areas is not feasible. Prevention efforts are directed more appropriately toward reducing the frequency of rodent-human interactions through environmental hygiene practices that minimize rodent density in home and work environments and avoidance of known rodent-infested areas and activities that increase the risk of human exposure to aerosolized infectious rodent excreta. Such avoidance may be particularly important during times of high rodent populations in specific localities. In fact, in the southwestern United States, remote sensing patterns from the year before can predict local areas of increased risk for acquiring the disease, thus allowing precisely targeted public health messages and interventions.[44]

Detailed guidelines on measures appropriate to eliminate rodents from homes in disease-endemic areas, to clean rodent-contaminated areas safely, and to minimize the risk for workers occupationally exposed to rodents and participants in outdoor recreational activities have been published.[106] Although rodent ectoparasites do not transmit hantaviruses, in the southwestern United States, several rodent species are also hosts to fleas that transmit *Y. pestis*. In such areas, insecticides should be used in conjunction with rodent extermination measures because eradication of rodents without concurrent control of the associated fleas may increase the risk of human plague.[106]

VACCINE PROSPECTS

Inactivated vaccines to Hantaan and Seoul viruses have been developed in South Korea and China. Some of these vaccines induce neutralizing antibody responses in humans and are being tested in field studies.[118,146,147] A recombinant vaccinia strain expressing Hantaan antigens has been tested in human volunteers in the United States and has been shown to induce a serum neutralizing antibody response.[138] Various other approaches to vaccine development use Puumala, Dobrava, or Andes viral elements (as well as Seoul or Hantaan), but none has progressed to clinical trials. An immediate need exists for a vaccine to Hantaan and perhaps other hantaviruses, but lack of a realistic animal model of human disease has hampered efforts to perform full preclinical evaluation of candidates. This is particularly important because the diseases are immunopathologic, and some monoclonal antibodies can enhance macrophage infection in vitro. The discovery that hamsters infected with Andes virus provide a reproducible model for HPS that mimics the human disease very closely[59] provides an avenue to explore mechanisms of disease and also vastly improves preclinical evaluation of hantavirus vaccines. Nonetheless, even more than with other viral vaccines, double-blinded, placebo-controlled trials are needed urgently to provide definitive evidence of protection and to exclude adverse effects.

HOSPITAL INFECTION CONTROL

The use of universal precautions in handling the blood and body fluids of all patients is prudent practice. In addition, a certified biologic safety cabinet should be used for all handling of human body fluids in situations in which splatter or aerosolization is possible.[13] Viral antigens can be detected in necropsy specimens, and RT-PCR readily detects viral genetic material in necropsy tissue and in blood and plasma obtained from hantavirus-infected persons early in the course of the disease.[57,174] However, secondary transmission of hantaviruses associated with HFRS has not been documented after contact with acutely ill persons or exposure to their clinical laboratory specimens. The experience with North American hantaviruses linked to HPS has been similar.[13,163] However, a single well-documented episode of person-to-person spread during an Andes virus outbreak in South America and subsequent cluster analyses, in addition to anecdotal experience with this agent, suggest that it may be an exception.[36,82,100,165] This latter incident notwithstanding, the many years of experience with HFRS and HPS indicate that once the diagnosis has been confirmed, isolation of hospitalized patients to prevent nosocomial transmission generally is not required. Sera and other specimens from hantavirus-infected persons can be handled safely by using biosafety level 2 facilities and practices. Higher biosafety levels are recommended for attempts to propagate hantaviruses.[13,16]

CHAPTER 202

La Crosse Encephalitis and Other California Serogroup Viruses

James E. McJunkin ✪ Linda L. Minnich

The term *California serogroup* does not describe the widespread geographic distribution of viruses in the serogroup but simply reflects the name of the prototype virus initially discovered in California in 1943.[58] In fact, La Crosse virus (LACV), the most prevalent and pathogenic member of the serogroup, produces disease in the Midwest and eastern United States but not in the West Coast region.[2,18,48,51,85,121,122] LACV is estimated to cause 8 to 30 percent of all cases of encephalitis in the United States annually and is the most common arboviral infection of children in North America,[107] occurring mostly East of the Mississippi River (Fig. 202–1). Although mortality from La Crosse encephalitis (LACE) is relatively low (0.3%)[107] compared with certain

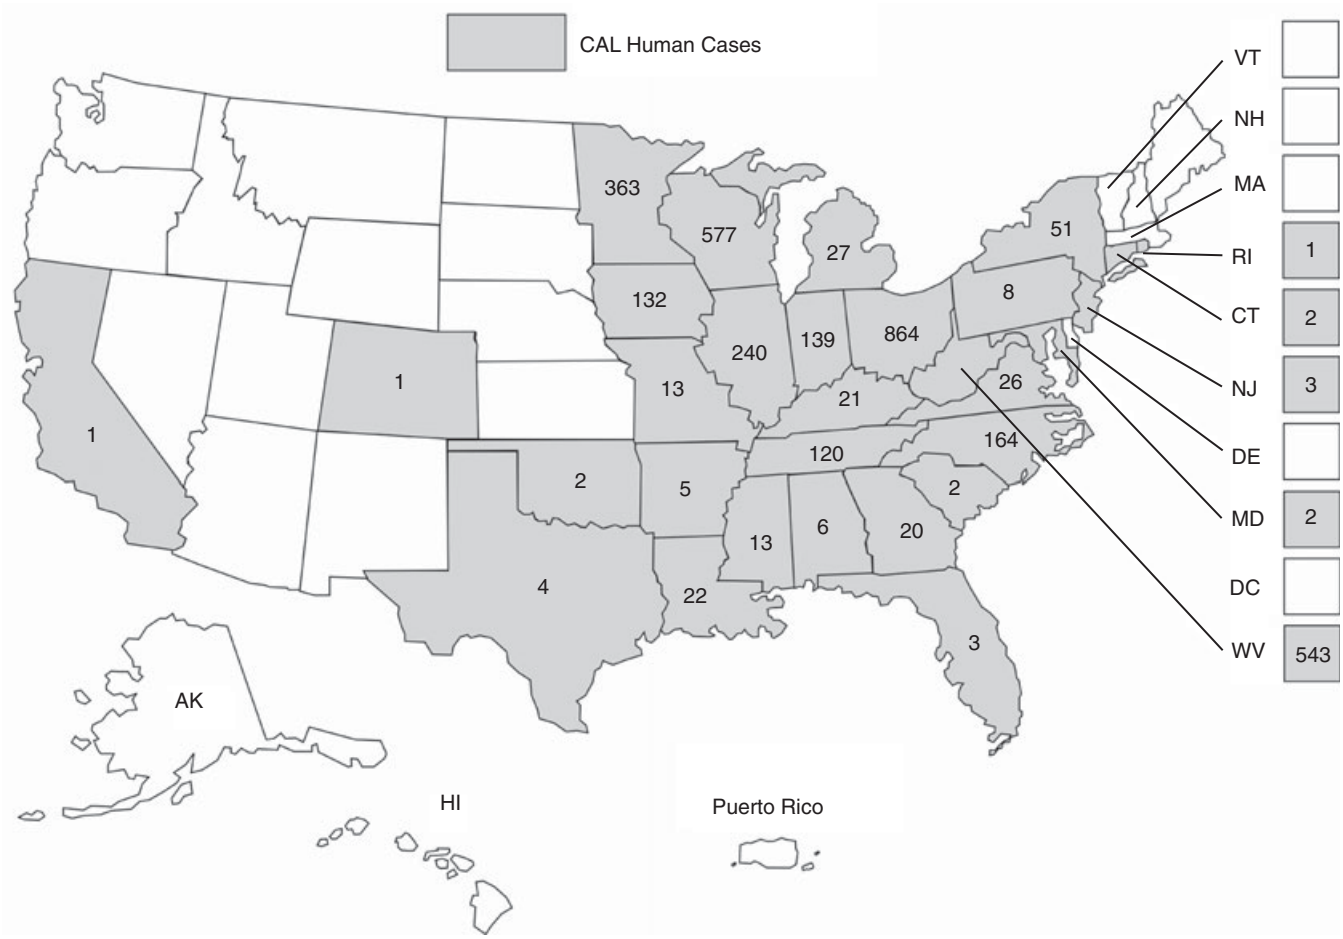

Figure 202–1 Reported cases of encephalitis attributable to California serogroup virus by state, 1964 to 1995.

other arboviral illnesses such as with West Nile virus (WNV) or Eastern equine encephalitis, the medical, psychosocial, and economic costs to affected individuals in endemic areas are significant. Acute morbidity includes seizures in roughly half of hospitalized cases, mental status changes in one third, cerebral edema in 16 percent, and cerebral herniation in 2 to 3 percent. One fourth of all hospitalized patients require mechanical ventilation.[87] Long-term morbidity following severe disease may include cognitive delays in up to one third and attention-deficit hyperactivity disorder (ADHD) in up to two thirds.[87] In a study of the economic and social impact of LACE in an endemic region of western North Carolina, the average direct and indirect medical costs per patient (from a group of 24 patients) were roughly $33,000 (≤$35,000), with the projected cost for five patients with neurologic sequelae ranging from approximately $50,000 to $3 million per patient.[124] Although the number of confirmed cases of LACE cases is in the range of 40 to 200 per year in the United States, underrecognition and underreporting are common problems. Because LACV is the most clinically significant member of the California serogroup, it is the main focus of this chapter, but other members of the serogroup are addressed briefly as well. Clinical information of greatest relevance to practitioners is contained in the sections on clinical manifestations, diagnosis, differential diagnosis, and treatment.

ETIOLOGIC AGENT

In 1960, a 4-year-old girl died of "rural encephalitis" in a hospital in La Crosse County, Wisconsin. Four years later, Dr. Wayne Thompson and colleagues isolated a novel virus from frozen homogenates of the child's brain by intracerebral inoculation of suckling mice.[118,120] Soon after its discovery, LACV was identified as a member of the California serogroup and is one of five (prototype California encephalitis [CE] virus, LACV, snowshoe hare virus, Jamestown Canyon [JC] virus, and trivittatus) such viruses causing human disease in North America. The California serogroup is 1 of 16 in the *Bunyavirus* genus. Inkoo and Tahyna viruses are members of the California serogroup distributed in Europe.

The LACV virion is described as pleomorphic and roughly 90 to 100 nm in diameter, having a host-derived viral envelope in which virus encoded glycoproteins G1 and G2 are located on spikes 5 to 10 nm long. The virus replicates in the cytoplasm and buds from the Golgi apparatus. Of the three segments of the RNA genome, the large (L) RNA segment encodes for the polymerase, the medium (M) RNA encodes for the G1 and G2 glycoproteins and a nonstructural protein (NSm), and the small RNA segment encodes for the nucleocapsid (N) protein and nonstructural protein NSs.[15]

The M segment that encodes the G1 and G2 glycoproteins is a major determinant of viral *neuroinvasiveness* in mice and susceptibility of *Ochlerotatus triseriatus* mosquitoes to oral and intrathoracic infection.[45,48,109] Neuroinvasiveness may be linked to the cell receptor and fusion functions associated with glycoproteins.[45,47] The G1 protein of LACV is involved in viral attachment to mammalian cell receptors, functioning as a type II fusion protein,[103] and is involved in hemagglutination and viral neutralization.[45,48,76,77,109] Group- and LACV-specific epitopes are present on G1. The G2 glycoprotein mediates viral attachment to insect cells,[84] but more recent work emphasizes that G1 also is required for infection of mosquito cells (in vitro and in vivo) to occur.[56] Although the M segment genome largely determines neuroinvasiveness (i.e., the ability to invade the central nervous system [CNS] from an extraneural site) through its glycoprotein products (especially G1), more recent evidence using viral reassortants of different virulence implicated the L segment as a major factor in determining neurovirulence (i.e., the ability to infect CNS tissue after direct cerebral injection).[35] Finally, a viral component encoded by the S segment seems to serve an emerging role in pathogenesis. This NSs was shown in insect and mammalian cells to inhibit the RNA interference (RNAi) pathway, thus inhibiting a mechanism (RNAi) of innate immune response to viral infection. NSs also plays a role in promoting apoptosis, the main mechanism by which LACV kills cells.[14,112] Investigators have shown that a truncated G1 protein preparation induces a protective immune response in the suckling mouse model through neutralizing antibody (see "Prevention").[100] Apparently, neutralizing antibody can prevent neuroinvasion by interruption of the transient viremia, which occurs just after virus inoculation.

Oligonucleotide maps of LACV isolates from various areas of the United States have grouped the viruses into three types. Upper Midwest viral strains are of two types, A and B; type C varieties are found in scattered areas of the eastern part of the United States.[39,79] Variations in strains indicate that changes in the viral genome occur by genetic drift. Genetic reassortment through exchange of RNA segments also has been demonstrated in nature, with one proposed mechanism involving dually infected mosquitoes, particularly those initially with transovarial infection before superinfection with a second closely related virus.[15] Study of the genome of viral isolates from three fatal cases indicated a high degree of conservation of nucleotide sequences among these isolates.[24,63]

ECOLOGY

LA CROSSE VIRUS

Borucki and coworkers provided an in-depth review of LACV replication in vertebrate and invertebrate hosts.[16] *Ochlerotatus triseriatus* (formerly known as *A. triseriatus*), the eastern tree hole mosquito, is the reservoir of LACV in nature and the vector for transmission of infection to humans.[51,126,127] Humans do not maintain prolonged viremia and therefore are dead-end hosts. The mosquito is distributed principally in eastern hardwood deciduous forests, where it breeds in tree holes; however, it also is adapted to breeding in small artificial containers that hold rainwater, such as discarded cans, bottles, and tires. The mosquito is diurnal and feeds actively during the day. Although these insects disperse over a wide area, fairly permanent foci of infected mosquitoes are observed in sharply delimited areas, and isolation of virus and human cases recur each summer in established foci.[8,51,78,116]

The most important mechanism for maintenance of LACV in nature is vertical (transovarial) transmission in *O. triseriatus*. The virus overwinters in infected eggs, which give rise to infected mosquito progeny the following year, thereby providing the mechanism of recurrent disease each summer in endemic areas.[91,115,127] Research indicated that transovarial transmission of LACV in *O. triseriatus* is controlled by a single gene locus.[50] The LACV also is maintained in nature through horizontal transmission by venereal propagation in *O. triseriatus* and through amplification of the virus in the vertebrate hosts on which vector mosquitoes feed.[91,126,127] Vector competence, related in part to the ability of the female mosquito to become infected in the first place, may be associated with malnutrition of the mosquito, which compromises her mesenteric barrier and may then allow infection to occur after taking an LACV-infected blood meal.[50,98] The principal amplifying hosts involved in horizontal transmission are chipmunks and squirrels.[132] Other wild vertebrates such as foxes and woodchucks also may contribute to amplification. Although domestic livestock and pets do not contribute to horizontal amplification of the virus, certain species do show seroconversion to California serogroup viruses, and these species may prove to be useful markers of viral presence in a given area.[44] For example, outbreaks of fatal encephalitis have occurred in puppies, and dogs have been used in an animal model of CNS infection.[13]

Concern that *Aedes albopictus*, the Asian tiger mosquito, has entered the transmission cycle for LACV [6,7,29,30,53,66] was heightened when LACV-infected *A. albopictus* mosquitoes were isolated in nature in areas proximate to human cases in 2001.[43] In addition, an elevated burden of *A. albopictus* near the residence of patients with LACE was associated significantly with LACV infection in cases versus controls.[41] This mosquito species, which is dispersed widely in the southeastern region of the United States, has significant potential to expand the geographic range and circumstances in which LACV (and possibly other California serogroup viruses) could be transmitted.

OTHER CALIFORNIA SEROGROUP VIRUSES

A brief discussion of the ecology of other California serogroup viruses follows. Although JC virus was isolated first in Colorado and is distributed widely in the West and Midwest, most cases of human illness have been reported in New York, New England, Ontario, and the upper Midwest. Seroconversion for JC virus also has been found frequently (18%) in native Alaskans.[125] Various *Aedes* mosquitoes (e.g., *A. communis* in the West, *Aedes stimulans* in the upper Midwest, *Aedes abserratus* in Connecticut) function as vectors.[32,51,52,54] As opposed to LACV, in which large mammals do not play a role in viral propagation in nature, JC virus horizontal amplification includes deer as the primary amplifying host, with up to 80 percent seroconversion found in adult deer populations in endemic areas.[96,97,133] The overwintering mechanism of JC virus has not been elucidated, although transovarial transmission in *Aedes provocans* has been demonstrated.[12]

Snowshoe hare virus is distributed throughout Canada, including the Yukon and Northwest Territories, in adjacent northern states, and in Russia and China. *Culiseta inorata* and various *Aedes* spp. transmit the virus to snowshoe hares (*Lepus americanus*), ground squirrels (*Citellus undulatus*), and other mammals. Transovarial transmission in vector mosquitoes has been demonstrated.[60]

Trivittatus virus is transmitted and maintained through vertical transmission by *Aedes trivittatus* in the Midwest and is vectored in the South by *Aedes infirmatus*. CE virus is distributed in the western part of the United States, where *Aedes melanimon* and *Aedes dorsalis* are the principal vectors.[50,57,104,119]

Inkoo and Tahyna viruses cause a febrile illness with CNS and respiratory tract infection, respectively, in Scandinavia, Central Europe, and western Russia. Viral recombinants

have been demonstrated.[35] Inkoo also has been found in native Alaskans.[125]

EPIDEMIOLOGY

LACE principally is a disease of children. Among reported cases in the United States from 1972 to 1981, 75 percent were in children younger than 10 years old, and only 3 percent occurred in persons 20 years or older.[74,130] Most cases are seen in boys, with a ratio of approximately 2:1 in most series.[93,118] Table 202–1 summarizes demographic data and clinical characteristics for a large series of hospitalized children.[87] The annual incidence of CNS LACV infection in individuals younger than 15 years in endemic regions is approximately 10 to 30 per 100,000.[75,129] LACV infections are endemic in the United States, with infections typically occurring from July through October, chiefly in rural areas of the east-central states.[74,121] As mentioned earlier, the medical and economic burden to affected individuals and society in endemic areas is significant.

The geographic distribution of LACV infection corresponds to natural divisions in which beech, oak, and maple woodlots are prevalent.[51] Although LACE has been considered a disease of the Midwestern and mid-Atlantic states (with highly endemic zones in Minnesota, Wisconsin, Illinois, Iowa, Ohio, and West Virginia), cases have been found in 30 states, mostly east of the Mississippi River (Fig. 202–2). One highly endemic focus has been recognized in western North Carolina for many years,[115] and sporadic cases have been found as far south as Louisiana and as far east as Connecticut (see Fig. 202–1). Although certain foci of infection appear to remain well localized,[92,115] investigations in eastern Tennessee that showed a low seroprevalence in the general population (only 0.5%) despite a recent marked increase in the number of pediatric cases in that region suggested that true increases in the prevalence of LACV infection (indicating a newly established endemic focus) are occurring in some areas as well.[71,72]

Active surveillance efforts can increase case findings markedly, as seen in West Virginia,[75] where after the death of a child from LACE in 1987, more than 150 cases were diagnosed during the next 8 years (versus only 15 cases ever previously reported in West Virginia).[89] The Centers for Disease Control and Prevention (CDC) records further showed that from 1987 to 1997, West Virginia became the most highly endemic state in the United States, often accounting for roughly half or more of the cases reported to the CDC annually.[22] Therefore, the public health importance of LACE nationally is not known fully because the virus is distributed discontinuously in the eastern part of the United States, where the disease could be endemic but underrecognized.[11,67,129] Improved recognition will require a high index of suspicion by clinicians because the virus typically is not recoverable on culture of cerebrospinal fluid (CSF) and therefore requires specific serologic testing (see "Diagnosis").

Further confounding efforts to understand the true prevalence of disease is the finding that inapparent infections are far more prevalent than is clinically evident disease (see "Clinical Manifestations").[74] Seroprevalence rises with age in endemic areas.[115,116] Serosurveys have shown that point-prevalence rates vary in endemic locations from 30 percent in rural areas to 15 percent in urban locations.[93] Although the risk appears to be highest in rural areas, many cases occur in suburban residential locations, and travel to forested recreational areas in endemic regions is reported by other patients.[33,67,119] A case-control study performed in a highly endemic county found several characteristics of the peridomestic environment to be associated with a risk of acquiring LACE: tree holes on the residential premise, proximity of the house to the forest edge, and the presence of artificial containers and large numbers of discarded tires.[129] A more recent case-control study in eastern Tennessee also showed an association of LACE with proximity (within 100 m) of tree holes to the residence, with increased time of patients spent outdoors, and with an increased burden of *A. albopictus* in the peridomestic environment.[41] These studies support other work pointing to the proximity and abundance of natural and artificial mosquito breeding sites as the principal risk factors from an environmental perspective.[92,95]

With regard to California serogroup viruses in the United States other than LACV, JC virus seroprevalence rates of 5 to 40 percent have been found in the upper Midwest. Most reported cases (21 of 29 in one series) have occurred in male patients.[113] Unlike LACE, cases are found in all age groups. As for snowshoe hare virus, human infections have been documented by serosurvey in Alaska and throughout Canada.[51] Antibody prevalence rates were more than 30 percent in some areas; seroprevalence in the male population was double the rate in the female population. Sporadic infection with CE viruses other than LACV probably occurs frequently in the western part of the United States.[104] However, symptomatic cases with California encephalitis prototype virus rarely occur.[38]

TABLE 202–1 Epidemiologic and Clinical Data on 127 Children with La Crosse Encephalitis*

Variable	Value
Sex: No. (%)	
Male	90 (71)
Female	37 (29)
Age in Years: No. (%)	
0.5-2	9 (7)
3-5	30 (24)
6-8	42 (33)
9-11	26 (20)
12-14	19 (15)
15	1 (1)
Month of presentation: No. (%)	
June	3 (2)
July	31 (24)
August	38 (30)
September	44 (35)
October	11 (9)
Symptoms on Presentation: No. with Findings/Total No. (%)†	
Headache	105/126 (83)
Fever	107/125 (86)
Vomiting	89/127 (70)
Disorientation	50/119 (42)
Seizures‡	58/127 (46)
Signs on Admission: No. with Finding/Notal No. (%)	
Nuchal rigidity	31/120 (26)
Glasgow Coma score ≤12	42/127 (33)
Focal neurologic signs	23/126 (18)

**For symptoms on presentation and signs on admission, data were missing for some patients. Because of rounding, not all percentages total 100.*

†Typically, the patients with headache or fever were admitted 3 or 4 days after presentation; those with vomiting were admitted 1 or 2 days after presentation; and those with disorientation or seizures were admitted on the day of presentation.

‡Seizures were generalized in 22 patients, partial in 24, and partial with secondary generalization in 22.

Data from McJunkin, J. E., de los Reyes, E. C., Irazuzta, J. E., et al.: La Crosse encephalitis in children. N. Engl. J. Med. 344:801-807, 2001.

PATHOGENESIS

LACV, which infects the salivary glands of the mosquito vector, is introduced into the host's skin and subcutaneous tissue during

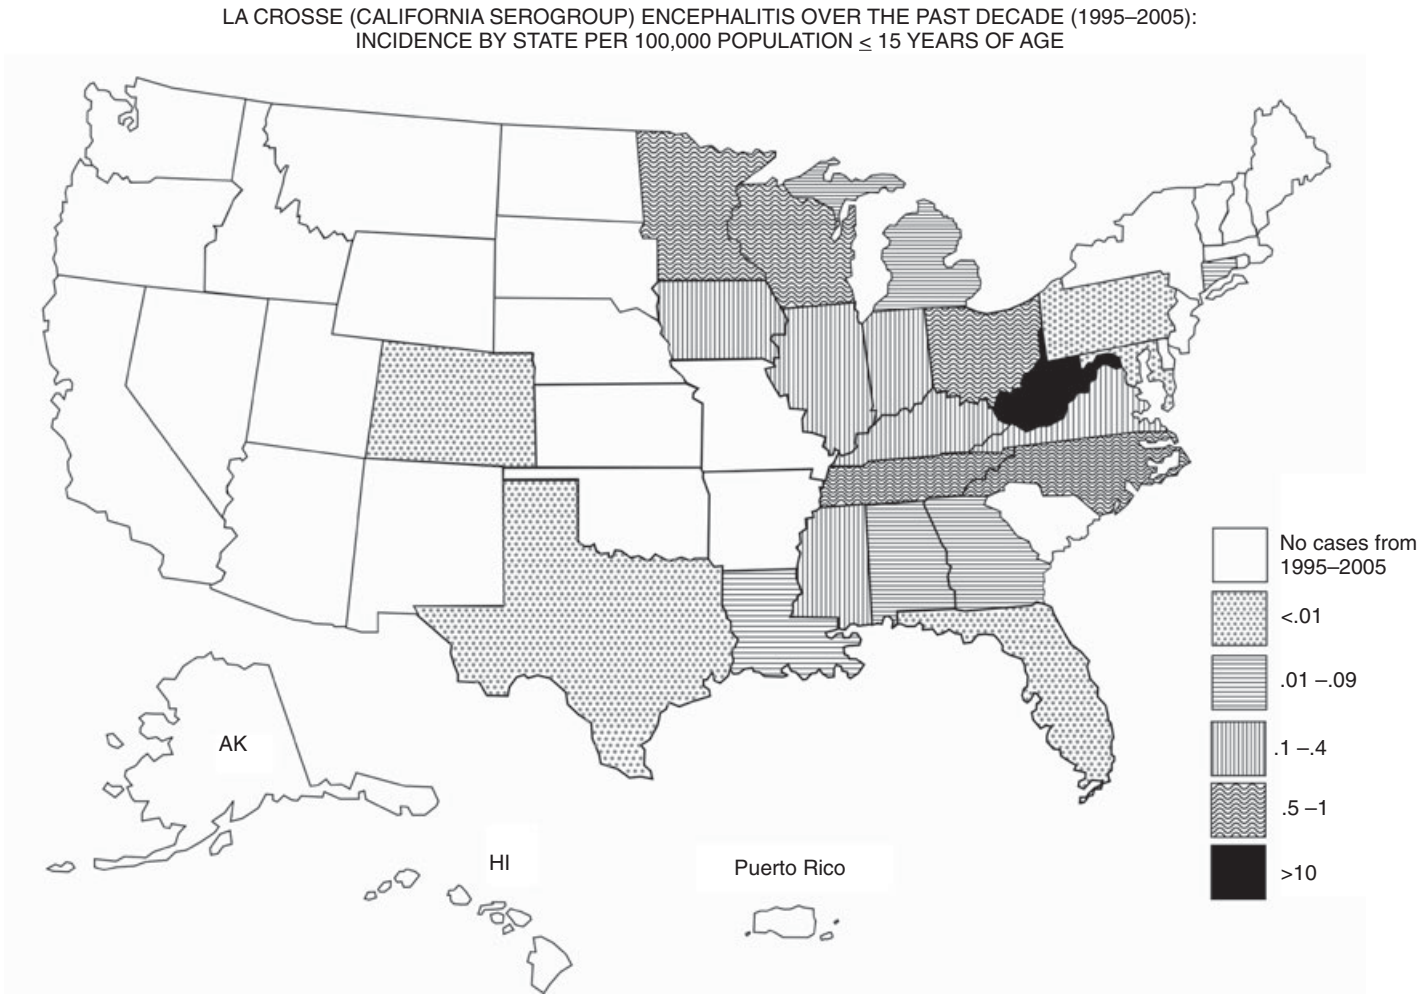

Figure 202–2 Incidence of La Crosse encephalitis over the past decade (1995-2005) per 100,000 population ≤15 years of age.[22,123]

feeding. Probing alone is infectious. Completion of a blood meal is not necessary for transmission to occur. Local viral replication in adjacent muscle tissue leads to systemic viremia that seeds the reticuloendothelial system, muscle, and chondrocytes; such seeding results in further amplification of the viremia and allows invasion of the CNS.[46,47,68,70] Entrance to the CNS probably is gained by infection of vascular endothelial cells initially, followed by infection of neurons and glial cells.[68,70] Case reports suggest that vascular involvement in human LACE may be important in the pathogenesis of focal deficits (from stroke) and more generalized cerebral edema (possibly from vasogenic edema).[83,90] Polymerase chain reaction (PCR) studies of the location of LACV within the CNS found evidence of viral RNA within the cortex but not in other tissues of the CNS.[24] The latter is consistent with the results of magnetic resonance imaging (MRI) in one study that showed findings predominantly consistent with lesions in cortical areas.[87]

Studies indicate that the extraneural phase of viral replication and neuroinvasiveness are mediated largely by the M segment of the genome primarily through G1 glycoprotein, which has cell receptor and fusion functions.[45,47,48,103,109] A more recent study in adult mice indicated that once the virus has gained access to the CNS, replication in CNS tissue (i.e., neurovirulence) is mediated largely by the L RNA segment, probably through viral polymerase.[40,48] Previous work had implicated the M segment in neurovirulence as well, but in that study neurovirulence was defined as time to death after intracutaneous inoculation.[109] The host immune response involves neutralizing antibody, which mediates viral aggregation, inhibition of viral attachment to cells, and inhibition of viral penetration and uncoating.[77] Other aspects of the immune response shown to play a role in protection against CNS LACV infection in animal models are $CD4^+$ T cells and MxA protein, the latter of which is induced by the interferon-α/β system.[61,80,105,108] Susceptibility and complications of LACE may have an immunogenic component, as indicated by an association of illness and seizures with certain human leukocyte antigens.[20] Neuronal cell death may be mediated largely by apoptosis (programmed cell death), as determined by studies in mice,[101] and the nonstructural protein NSs has been found to promote apoptosis, as well as interrupting the RNAi pathway.[14,112] It is interesting that bc1-2 expression can inhibit apoptosis in certain cell lines.

CLINICAL MANIFESTATIONS

The clinical spectrum of illness in LACV infections ranges from inapparent infection or a mild febrile illness to aseptic meningitis and fatal encephalitis.[4,5,25,26,28,55,62,117,131] The ratio of inapparent to clinical infection has ranged from 26:1 to 322:1.[74] Most clinically apparent infections are associated with signs and symptoms of meningoencephalitis. Severe cases tend to mimic herpes simplex encephalitis (HSE) at initial evaluation, whereas mild cases may manifest as aseptic meningitis. Although the case-fatality rate is less than 1 percent, a series of 127 hospitalized

patients included 3 with the near-lethal complication of cerebral herniation. In addition, nearly half of all patients required admission to intensive care, and one fourth required mechanical ventilation.[87]

Children typically have a 3- to 4-day prodrome of fever, headache, and vomiting; diarrhea usually is absent. The illness further evolves such that disorientation (42%) or seizures (46%), or both, may be seen frequently on the day of admission. Most seizures are partial or partial with secondary generalization (58%), and the remainder of seizures are generalized. Status epilepticus develops in approximately one fourth of children with seizures. Rarely, patients may have a sudden onset of seizures with little or no preceding fever or headache.[87]

On examination, signs of meningeal irritation and changes in mental status are found in approximately one quarter and one third of patients, respectively.[87] Focal neurologic signs, principally focal seizures, paresis, aphasia, and abnormal reflexes, are seen in 16 to 25 percent of patients with LACE. Focal and generalized seizures occur in 42 to 62 percent of cases, and status epilepticus develops in 10 to 15 percent. Focal neurologic signs, whether found on physical examination or on electroencephalographic (EEG) or imaging studies, should be taken as evidence of presumptive HSE, thus indicating the need to start empiric acyclovir until diagnostic studies for LACE and HSV are completed.[130] Table 202–1 summarizes clinical characteristics and demographic data, of a large series of hospitalized children with LACE.[87]

From the same study, which is the largest and most recent series studied (n = 127),[87] the hospital course was complicated by hyponatremia (21%) generally consistent with the syndrome of inappropriate antidiuretic hormone (SIADH) secretion, recurrent or de novo seizures (13%), signs of increased intracranial pressure (ICP) (13%), and, rarely, cerebral herniation (2.3%). Approximately 1 in 10 patients (including the 3 with herniation and 10 others with recurrent seizures, coma, or both) experienced neurologic deterioration after hospital admission, usually between 36 and 72 hours of admission. Risk factors associated with deterioration were the presence of disorientation or vomiting at admission and a trend toward seizures at admission. Such neurologic deterioration appeared to be related temporally to a decrease in serum sodium or an increase in body temperature in some cases, findings suggesting that these conditions may be risk factors for in-hospital deterioration as well. This tendency for 1 in 10 hospitalized children with LACE to deteriorate neurologically after admission represents a significant challenge for clinicians (see "Treatment").

Clinical findings in patients infected with other members of the California serogroup deserve brief mention. JC virus infections often are associated with prodromal respiratory symptoms in conjunction with aseptic meningitis or clinical encephalitis. Among 39 patients with proven or suspected CNS infection with JC virus, 10 had encephalitis, and 7 reported upper respiratory symptoms or pneumonia.[51,113]

The few reported patients with snowshoe hare virus infection have had manifestations ranging from an influenza-like illness to aseptic meningitis and fatal encephalitis. One fatality was reported in a 14-year-old girl who had symptoms and signs that suggested Reye syndrome.[36] In a 59-year-old man, radiologic and EEG findings showed a temporal lobe focus, which led to performance of a brain biopsy and a clinical and pathologic diagnosis of herpes encephalitis, although herpes virus was not isolated. Serologic examination later confirmed the diagnosis of snowshoe hare virus infection. Mild febrile illness attributed to infection with trivittatus virus has been described in some patients, and CNS infections have been identified in others.[93] Three cases of symptomatic infection caused by prototype CE virus have been reported. All three patients had signs and symptoms of encephalitis.[57]

Laboratory examinations for LACV infection were well outlined in one series (Table 202–2).[87] The total CSF leukocyte count typically was elevated only moderately (the median white blood cell [WBC] count in CSF was 75), and 25 percent of patients had red blood cells in CSF.[87] In numerous reports, elevated protein levels were observed in less than one third of cases.[4,26,28,62,87] Approximately 10 percent of children have negative or equivocal findings on initial CSF analysis, only to have numerous WBCs within 24 to 48 hours on repeat lumbar puncture. The findings that the peripheral WBC count is elevated in half the cases (>15,000 WBCs/mm^3) and that neutrophilia often is present frequently raise suspicion of bacterial meningitis or partially treated bacterial meningitis.

Brain imaging techniques usually are negative, but they have a higher yield in more advanced disease. In 127 children studied, 92 had computed tomography (CT) scans. Only 11 of these scans were positive; 8 showed generalized edema and 3 showed focal findings, all in supratentorial locations. In 3 children whose courses were complicated by cerebral herniation, CT scans became positive only after the herniation event (i.e., admission CT scans were negative [Fig. 202–3]). From this same series (n = 127), 10 children had MRI scans of the brain, 4 of which were abnormal and showed focal areas of gadolinium enhancement, predominantly in cortical areas (see Fig. 202–3).[86] Case reports suggest that MRI may reveal lesions not detected by CT in

TABLE 202–2 Laboratory Values at Admission in Patients with La Crosse Encephalitis

Variable	Mean Value ± SD	Range	Percentile					Remarks
			10th	25th	50th	75th	90th	
Cerebrospinal Fluid								
White blood cell count (per mm^3)	130 ± 151	2-867	10	26	75	184	316	<200/mm^3 in most cases
Differential count (% lymphocytes)	—	2-100	10	27	62	77	90	Predominance of lymphocytes
Red blood cell count (per mm^3)	71 ± 213	0-1,500	0	1	5	20	177	Elevated (≥20/mm^3) in 25%
Glucose (mg/dL)*	75 ± 20	37-149	56	62	71	83	105	Normal
Protein (mg/dL)	37 ± 15	10-85	20	27	34	45	56	Rarely elevated
Peripheral Blood								
White blood cell count (per mm^3)	15,700 ± 5900	6,800-49,700	8,900	11,500	14,800	19,000	22,600	Usually elevated (>15,000/mm^3)
Differential count (% polymorphonuclear leukocytes)	—	17-94	58	66	76	82	86	Predominance of polymorphonuclear leukocytes

**To convert values for glucose to millimoles per liter, multiply by 0.05551.*

Data from McJunkin, J. E., de los Reyes, E. C., Irazuzta, J. E., et al.: La Crosse encephalitis in children. N. Engl. J. Med. 344:801-807, 2001.

Figure 202–3 La Crosse encephalitis. A computed tomographic scan of an unusually severe case of La Crosse encephalitis shows small ventricles and multifocal hypodense lesions with loss of gray-white differentiation in the right frontotemporoparietal and left temporal regions. Computed tomographic scans are usually negative in La Crosse encephalitis (see text).

LACE. In a 20-month-old infant with right hemiparesis, CT on admission was negative, but MRI on day 1 showed evidence of acute infarction of the left basal ganglia.[83] In another 12-month-old child with clinical evidence of neurodegeneration, MRI showed areas of increased signal intensity in the periventricular white matter, even though the initial CT scan had been negative.[42] However, CT is still favored as the initial imaging study in children acutely ill with LACE because the need for anesthesia and intubation in performing MRI in children can confound examinations of mental status and supportive care.

EEG abnormalities have been found in 71 to 90 percent of patients tested. Focal EEG findings, usually slowing, may appear in as many as 44 percent of abnormal EEG tracings. Evidence indicates that periodic lateralizing epileptiform discharges (PLEDs), previously thought to be virtually pathognomonic of HSE, also are seen in LACE; 8 of 90 EEG tracings in one series were positive for PLEDs.[34,87] In 4 of these 8 cases, patients required continuous EEG surveillance to monitor treatment of nonconvulsive status epilepticus.[87] Patients with PLEDs represent a worrisome subgroup of all LACE patients because they have longer, more complicated, hospitalizations and probably worse long-term outcomes.[34a]

DIAGNOSIS

Clinicians must communicate with virology laboratory colleagues when choosing diagnostic tests for encephalitis so that the limitations of these tests are understood. To select appropriate laboratory tests, information about the clinical findings and travel history must be combined with knowledge of the local epidemiology and natural history of viral infections.

Although the preferred approach to the diagnosis of viral encephalitis is to identify the viral agent by isolation or detection of antigen or nucleic acid in CSF, limitations of these procedures for LACV require the diagnosis to be made by serologic methods at this time. For example, CSF culture is not a reliable means for establishing a diagnosis; in fact, no reports of successful isolation of LACV from CSF have been published. Isolation from brain tissue has occurred on three occasions.[73,92] Improvements of LACV RNA detection from previous methods[19,23,63,81] (including nucleic acid base amplification and reverse transcriptase PCR) have been used successfully in detection of viral RNA in vector mosquito samples and human brain tissue,[82] but the development of this method for making a clinical diagnosis using blood or CSF samples remains experimental. Therefore, serologic methods to detect LACV antibody continue to be the primary method of diagnosis. Immunoglobulin M (IgM)–specific antibody to LACV can be detected reliably in serum and CSF by two methods: (1) IgM capture enzyme immunoassay (EIA) or (2) indirect immunofluorescence (IF). With either method, detection of LACV IgM in CSF or a fourfold rise in LACV antibody titer on convalescent serum yields a *confirmatory diagnosis* of LACE, whereas an acute rise in LACV IgM in a single serum sample yields a *presumptive diagnosis*. IgM capture EIA is a sensitive serologic test that detects virus-specific IgM in 83 to 100 percent of cases.[9,10,13,17,35,37] An IgG capture EIA method has been developed to be used in tandem with IgM capture EIA.[69] The main advantage of IgM capture is that it is less operator-dependent than is the IF method, which requires careful observance of visual reading criteria by experienced personnel. For this reason, IgM capture EIA is the method used and is considered the gold standard by the CDC in their definition of LACE diagnosis. Conversely, possible limitations of the IgM capture method include longer turnaround time and the problem that standardized procedures and reagents are not available for commercial use, as opposed to the IF method.

In all diagnostic tests for LACE, false-positive results (compromised specificity) remain the key clinical issue. Unfortunately, neither currently available serologic method can guarantee 100 percent specificity, especially because in rare instances LACV IgM reportedly has remained elevated in serum for more than 1 year. A false-positive test could result in serious consequences if, for example, antiviral therapy for herpes simplex virus infection were discontinued erroneously or if antibiotic therapy for partially treated bacterial meningitis were discontinued. Therefore, clinicians should be in direct communication with laboratory colleagues concerning specificity data for their laboratory, particularly in cases in which treatable alternative diagnoses, such as HSE or partially treated meningitis, remain in the differential diagnosis on clinical grounds.

From a practical standpoint, the use of rapid diagnostic techniques for LACV (e.g., detection of IgM by indirect IF) may benefit patients by reducing unnecessary antibiotic or antiviral therapy, *provided the positive IgM test for LACV also is combined with reliably negative tests for treatable bacterial and viral agents (especially a negative PCR test for herpes simplex virus in patients with severe or focal encephalitis)*. No currently available Food and Drug Administration (FDA)–approved antiviral treatment for LACV exists.

DIFFERENTIAL DIAGNOSIS

The principal consideration in the differential diagnosis is HSE.[111,112] Clinical descriptions consistently disclose a high rate of focal neurologic findings or focal seizures, or both, in LACE (≈30%). The frontal and temporal lobe locations of abnormalities detected by EEG studies (including PLEDs in some cases) and

by brain imaging studies in some cases of LACE also may point to a presumptive diagnosis of HSE.[4,87] Hemorrhagic pleocytosis, which can be seen in both HSE and LACE, also may favor presumptive diagnosis and therapy of HSE, especially in the clinical setting described earlier. Because late institution of therapy in HSE is associated with a poor outcome, a reasonable approach is to make an early diagnosis of presumptive HSE in cases of encephalitis with focal findings or in severe encephalitis pending definitive diagnosis.[128]

In patients with less fulminant signs of CNS infection, enteroviral aseptic meningitis is a common consideration, especially because it often occurs in summer and early fall. The presence of rash, pharyngitis, myocarditis, or conjunctivitis is a clue to enterovirus and is not characteristic of LACV infection. In a study comparing enteroviral CNS infection with LACE, patients with LACE were significantly more likely to manifest aphasia, loss of consciousness, seizure, and admission to the pediatric intensive care unit than were patients with enteroviral CNS infection.[59] In areas where immunizations may be eschewed for religious reasons, poliomyelitis remains an important diagnostic consideration. Mumps encephalitis is another consideration, even in the absence of parotid swelling, and low CSF glucose levels may be a clue to this diagnosis.[94]

Patients with Rocky Mountain spotted fever (RMSF) may exhibit signs of CNS disturbance, and one should remember that rash may be absent in 20 percent of patients with RMSF. Catscratch or mycoplasma pneumonial encephalopathy may be valid considerations in the differential diagnosis. Certainly, other *Arboviridae* should be considered in the differential diagnosis, and many laboratories now test simultaneously for *Arboviridae* known to occur in the United States (St. Louis encephalitis virus, Eastern equine encephalitis, Western equine encephalitis virus, and WNV) in patients with severe seasonal (summer or fall) encephalitis. A rare and tragic consideration in a child presenting with encephalitis is rabies, which may occur in the absence of a known animal bite. Certainly, a wide array of viruses, bacteria, and even amebae and parasites can cause CNS infection, and they are reviewed in other chapters of this text.

TREATMENT

Because no FDA-approved specific antiviral therapy for LACE is available currently, careful supportive care is the mainstay of therapy. A reasonable general supportive strategy is to assess these patients as one would assess a child with closed head injury because, in both instances, (1) changes in the level of consciousness cannot be assumed to be caused by a normal need to sleep and therefore need to be monitored serially and (2) changes in the level of consciousness generally are the best and earliest indicator of evolving intracranial pathology, as opposed to brain stem signs (e.g., pupillary abnormalities, bradycardia with hypertension). Therefore, serial monitoring of the level of consciousness is the most important aspect of neurologic monitoring (using the Glasgow Coma Scale [GCS]), even if the child has minimal change in level of consciousness at the time of admission.

Three particularly important decision points in management depend on the presence or absence of (1) disorientation, (2) further deterioration in GCS scores, and (3) focal findings. Once the child becomes disoriented (GCS score typically <13), as shown by changes in mental status in an older child (or perhaps by lack of recognition of parents in an infant), the child is monitored best in an intensive care setting. Children presenting with seizures at admission also deserve consideration for admission to intensive care, as do those with unremitting vomiting and/or HA despite admission to the general pediatric floor.[87] Further deterioration in the GCS to a score of 8 or less generally indicates that the patient no longer is able to protect the airway adequately, and appropriate intervention is needed. Cases suggesting HSE because of focal findings or coma, or both, warrant presumptive treatment with acyclovir pending definitive diagnosis (see "Diagnosis").

Many of the same strategies that apply in treating children at risk for increased ICP are used in treating those with LACE. A reasonable approach is to perform funduscopy and consider CT of the brain before performing lumbar puncture and to note the opening pressure of the latter. General treatment strategies include the following: airway and (if necessary) ventilatory management designed to avoid hypercapnia; hemodynamic management to optimize mean arterial pressure (and presumably cerebral perfusion pressure); neurologic strategies to optimize seizure control and measures to avoid an excessive cerebral metabolic rate; and strategies designed to avoid hypo-osmolality, hyperthermia, and other factors that may exacerbate intracranial hypertension. Intubated patients should be sedated adequately and may need additional analgesia or sedation before noxious procedures such as endotracheal suctioning are performed.

In a large series of hospitalized patients with LACE, 1 in 10 patients with LACE deteriorated neurologically after admission. Risk factors identified to occur more often before in-hospital deterioration were the occurrence of GCS <13 disorientation (mainly seen as seizures and vomiting). In addition, the data suggested that hyponatremia and hyperthermia may be related temporally to clinical deterioration in patients with LACE.[87] Regarding therapeutic implications of the risk of developing hyponatremia, the recommendation is that isotonic fluids (normal saline or 5% dextrose in normal saline) be used at maintenance rates (in addition to deficit replacement) to minimize the tendency for the development of hyponatremia while maintaining intravascular volume.[87] Serum sodium should be monitored approximately every 8 hours during the acute phase of the illness. If evidence of SIADH is documented (and cerebral salt wasting is ruled out) by careful monitoring of fluid status and urine and serum sodium and osmolality, careful restriction of fluids may then be considered.

Because of data suggesting that hyperthermia may be associated with neurologic deterioration in some patients, having a low threshold for treatment of fever with antipyretics is recommended. In critically ill patients with evidence of increased ICP, cooling blankets may be considered in the presence of persistent hyperthermia, provided shivering and discomfort are controlled.

Patients suffering neurologic deterioration may need repeat EEG or brain imaging studies (or both) because nonconvulsive status epilepticus can occur and because the initial brain imaging results may be normal but later imaging may show evidence of cerebral edema. Some experience has been gained in the monitoring of ICP in LACE.[73] High ICP was documented in three of six patients in whom monitors were placed, and such monitoring was considered by clinicians to be a useful adjunct in those cases.[87] Establishing clinical and imaging criteria for which patients might benefit from insertion of an ICP monitoring device remains a dilemma, particularly because ictal/postictal events in LACE can confound the neurologic examination regarding possible signs of increased ICP.

Currently, no specific antiviral therapy is approved by the FDA for the treatment of LACE. Previous laboratory studies suggested ribavirin's potential as a therapeutic agent.[21,23,27,64,65,90,102,110,114] Intravenous ribavirin initially was administered on a compassionate-use basis in a human case of severe LACE in 1994,[88] and subsequently it was used similarly in six severe cases without serious adverse effects (McJunkin and associates, unpublished data). Despite this preliminary work, which was encouraging from a safety standpoint at modest doses, higher doses may be necessary for achievement of optimal CSF levels. Unfortunately, adult studies done at these higher doses and our anecdotal infor-

mation in two cases of pediatric LACE treated at this higher dosage range suggest a less favorable safety profile. In addition, the relatively low prevalence and mortality of LACE (as compared with WNV, for example) render studying ribavirin therapy to demonstrate efficacy a difficult task indeed.

OUTCOME

LACV infections are associated with a case-fatality rate of less than 1 percent. However, a series of hospitalized patients (n = 127) showed near-lethal disease from cerebral herniation in three cases and a sizable proportion of patients who required mechanical ventilation (25%) or intensive care (50%).[87]

Psychometric evaluation of recovered patients had failed to show significant differences in standard tests of cognitive ability when compared with controls or normative data in the general population.[86,106] However, a 2001 study of 28 recovered patients, most of whom had severe LACE (e.g., associated with seizures or coma, including 3 patients with cerebral herniation), showed a mean full-scale intelligence quotient (IQ) of 87.8 (95% confidence interval, 82.2 to 93.2); 35 percent of these patients had an IQ less than 80, and 46 percent demonstrated significant disparities between verbal and performance IQ scores. In addition, 60 percent of this group had positive tests for ADHD.[87] This study lacked a contemporaneous, matched control group, but certainly compared with normative data, these findings strongly suggest that neurocognitive and behavioral deficits do occur after LACE, particularly in severe cases of the disease. In addition, previous data indicating changes in performance on tests administered before and after illness suggested effects in children who were more seriously ill.[86] In another small series, abnormalities in visual-motor function and intellectual impairment were observed more often in patients who had focal abnormalities in the acute illness.[106]

Six to 15 percent of patients who have recovered from LACE have recurrent seizures.[26,31] The risk of having a recurrent convulsive disorder was approximately 25 percent in patients who experienced a seizure during the acute phase of illness.[31,49] The interval between the onset of recurrent seizures and recovery from acute infection ranged from a few days to years (mean, 4 years).[31] Persistent hemiparesis was a residual abnormality in 2 of 151 patients monitored for up to 6 years after recovery, but one patient had a brain biopsy performed on the opposite hemisphere.[26] Unilateral infarction of the basal ganglia and hemiparesis were described in the case of an infant.[83] Another infant with a presumed LACV infection initially had an apparent neurodegenerative disease secondary to acute disseminated encephalomyelitis.[42] See the description at the beginning of this chapter of the economic costs of LACE.

PATHOLOGY

Pathologic descriptions of two fatal cases were reported.[73] In gross appearance, the brain was swollen, and the meninges were congested. The principal brain lesions were neuronal degeneration, patchy inflammatory lesions, and vasculitis. The cerebrum and basal ganglia were the principal sites of involvement, but petechial hemorrhages and edema were noted in the spinal cord of one patient. In both cases, lesions in the cerebrum were confined to the frontal, parietal, and temporal lobes, and the cerebellum was not involved.

The focal inflammatory lesions and perivascular reactions are composed primarily of mononuclear cells. Neuronolysis and neuronophagia are observed in foci of inflammation and necrosis, along with reactive polymorphonuclear, mononuclear, and microglial responses. Small extravasations of erythrocytes may appear as well. Lymphocytic perivascular cuffs are seen, but inclusion bodies are not. In one case, a focal area of necrosis, hemorrhage, and formation of a hematoma was present in the temporal lobe, a finding corresponding to a mass lesion seen on CT.[18]

In one case, brain biopsy material examined by indirect IF demonstrated LACV antigen in neurons and perhaps in endothelial cells. The same biopsy material from this patient showed minimal necrosis and perivascular cuffing on light microscopy.[90] The finding of minimal necrosis despite abnormal CT findings and deep coma is interesting in view of the relatively benign outcome of LACE, even in patients who experience deep coma or exhibit CT abnormalities. This finding is in marked contradistinction to HSE, in which the presence of either deep coma or CT lesions is a poor prognostic factor consistent with the extensive necrosis seen pathologically.[128] Findings in a mouse model indicated that neuronal cell death in LACE may be mediated largely by apoptosis (as opposed to necrosis).[101]

PREVENTION

Large-scale spraying of insecticides is not an effective intervention for elimination of *O. triseriatus* because this tree-dwelling mosquito tends to be protected by the leaf canopy of its habitat. Public health prevention has focused on elimination of breeding sites of *O. triseriatus*. Such efforts in endemic areas have included removal of used tires and other containers that hold small pools of water and (less commonly) sealing tree holes with cement or gypsum wool insulation.[119] The sheer number of such potential breeding sites necessitates intervention on a community-wide basis.[91] Public health education on mosquito prevention is available through the "Fight the Bite Mosquito Prevention Program"[3] and through a CDC educational program called "Neato Mosquito" (the latter available at www.CDC.gov, as are fact sheets). Home visits to patients with new cases of LACE may identify risk factors around the home or in neighboring areas, with implications for uninfected siblings of the index case and possibly for children in the community. Counties identified with cases may be targeted during the subsequent spring for town meetings, television coverage, or tire removal campaigns. Such targeted interventions have been tracked in highly endemic areas of West Virginia in recent years. The proper use of insect repellents, playing in open fields, and avoidance of tree-shaded areas may confer a reduction in risk by minimizing exposure to the vector. Insect repellents acceptable for children may contain up to 30 percent DEET, but DEET-containing products should not be used on infants younger than 2 months of age. In 2005, the American Academy of Pediatrics and the CDC revised recommendations such that repellants containing picaridin are considered an acceptable alternative to DEET.[1] Less effective but perhaps acceptable alternatives include oil of lemon eucalyptus and 2 percent soybean oil. None of the alternatives to DEET have been proven to also repel ticks, a possible advantage of DEET-containing products, which do have efficacy against ticks. All products must be used as directed by the manufacturer.

The potential for development of a vaccine comes from work with a truncated G1 protein preparation that induces a protective immune response in suckling mice through neutralizing antibody.[100] Protection against neuroinvasion was achieved by interruption of the transient viremia, which occurs just after inoculation of the virus. More recently, a DNA-based vaccine that encodes for viral glycoproteins (G1 and G2) also induced a protective neutralizing antibody response in mice.[99,108] Should ecologic preventive measures fail to lower disease rates in endemic areas, development of a vaccine for use in persons living in these areas may prove worthwhile.

Acknowledgment

We extend many thanks to Christine A. Welch, M.S., Charleston (West Virginia) Area Medical Center, Health Education and Research Institute, for her invaluable assistance in research of the literature and manuscript preparation.

CHAPTER 203

Other Bunyaviridae

CHAPTER 203a

Rift Valley Fever

C. J. Peters

Rift Valley fever (RVF) is primarily a disease of sheep and cattle. It is transmitted by mosquitoes and is caused by a virus with selective affinity for the parenchymal cells of the liver, which undergo characteristic eosinophilic degeneration. Infection with RVF virus causes a short but severe disease in sheep and cattle. Most pregnant ewes and cows abort, and more than 90 percent of newborn lambs die. Case-fatality rates in older sheep and cattle are lower but nonetheless significant. People usually acquire the infection from aerosols generated from the body fluids and tissues of animals dying of the disease and, less commonly, from bites of infected mosquitoes, especially during epidemics. See Swanepoel and Coetzer[10] for a comprehensive review.

HISTORY

RVF probably has occurred for many years in Africa and was recognized first at the beginning of the 20th century with the introduction of intensive livestock husbandry. In 1912, large numbers of newborn lambs died of an unknown disease in the Rift Valley of Kenya, and in the following year the clinical features were described. Daubney and associates[3] proved that the causal agent was a filterable virus, which they suspected was transmitted by mosquitoes because animals protected by screens did not contract the disease. In 1944, the virus was isolated from mosquitoes caught in the Semliki Forest in western Uganda, and it was proved later that *Erethmapodites chrysogaster* was able to transmit the infection under experimental conditions. Between 1950 and 1974, at least 15 major epizootics of RVF occurred in livestock in various areas of sub-Saharan Africa. During 1975, an extensive epizootic of RVF took place in South Africa, with many human cases and several deaths documented.[4]

An extensive epizootic of RVF also occurred in Lower Egypt in 1977. Hundreds of thousands of domestic animals, including cattle, buffaloes, goats, and sheep, were lost. Associated with this epizootic was the largest human epidemic of the disease ever known, in which 200,000 humans were infected and 600 died.[5] This outbreak emphasized the increasing threat of RVF to humans and domestic animals and showed that RVF virus was an important cause of hemorrhagic fever in Africa. In 1987, an epidemic of RVF occurred in Mauritania after flooding of the Senegal River basin following completion of the Diama Dam; at least 1200 human cases and 200 deaths occurred in one affected area alone. Epidemics and epizootics were reported in Madagascar in 1990,[7] in Egypt in 1993,[2] in eastern Africa in 1997 to 1998,[1] and in Yemen and Saudi Arabia in 2000.[8] The cases in the Arabian peninsula are the first outside Africa and demonstrate the potential of RVF to spread. Based on isolation of the virus, RVF probably occurs sporadically throughout most of sub-Saharan Africa. Zinga virus, previously described as a cause of sporadic human disease in central Africa, has been shown to be a strain of RVF virus.

ETIOLOGIC AGENT

RVF virus is destroyed by solvents such as ether and is inactivated readily by formalin; it is destroyed by heating at 56° C for 40 minutes. When stored at 4° C or –10° C, the virus loses its infectivity in about 3 months. The virus can be preserved indefinitely on dry ice at –70° C or in lyophilized form.

Fully formed virions are spherical and approximately 94 nm in diameter. They mature in the cytoplasm, although intranuclear inclusions occur in vivo and in cell culture. The virus multiplies readily in a variety of cell lines of animal and human origin. RVF virus has been assigned to the *Phlebovirus* genus of the family *Bunyaviridae*. The virus is highly pathogenic for mice, young rats, and hamsters, and death occurs in 95 to 100 percent of these animals 36 to 96 hours after inoculation.

VECTORS

In studies in South Africa, the virus has been transmitted experimentally by *Culex theileri*, *Culex zombaensis*, *Culex neavei*, *Aedes juppi*, and *Erethmapodites quinquevittatus*. Epizootics of RVF have occurred in years of unusually heavy rains that filled natural depressions in the land (pans or dambos), thereby favoring the proliferation of flood-water mosquitoes. Studies in Kenya have shown that transovarial transmission of the virus in pan-breeding *Aedes* of the subgenus *Neomelanoconion* is the probable mechanism of virus maintenance and periodic recrudescence. *Culex pipiens* was implicated as a vector in Egypt during the 1977 to 1978 epidemic. During epizootics, domestic livestock serve as viremic, amplifying hosts in the transmission cycle.

CLINICAL MANIFESTATIONS

Humans are very susceptible to RVF virus. During the epizootics in South Africa, most veterinarians and many farmers engaged in work with sick sheep and cattle became infected. In most cases, infection was linked to direct contact with the carcasses, tissues, and organs of animals that died of RVF. Transmission probably occurred by the aerosolized body fluids of the animals. Some patients gave no history of such contact; in these cases, the infection is presumed to have been transmitted by mosquitoes or possibly acquired by drinking infected milk. The virus can be transmitted readily to laboratory personnel by direct contact with infected animals or by the respiratory route from aerosol droplet infection.

The incubation period of RVF is 3 to 7 days; its onset is sudden, with chills, myalgia, joint pain, headache, and a biphasic fever that lasts approximately 1 week. Patients often feel nauseated and may vomit or complain of abdominal fullness and pain. The face is flushed, the conjunctivae are injected, and the tongue is furred. Bradycardia is present, and slight tenderness over the liver, which may be enlarged, can be present. Many patients become delirious, and some have hallucinations. In a small proportion (<1%) of patients, the infection is complicated by retinitis. Late in the course of the illness or early in convalescence, unclear vision may be noted, and the patient may have a central blind spot. This visual defect is associated with a cotton-wool exudate on the macula. Both eyes are involved occasionally, and the loss of vision is a severe handicap. These lesions gradually resolve, and the patient's vision returns to normal in most cases. Meningoencephalitis manifested as intense headache, confusion, and stupor may occur as a complication in fewer than 1 percent of patients during or after the second wave of fever. Lumbar puncture relieves the headache. Cerebrospinal fluid (CSF) shows slight pleocytosis, mostly of lymphocytes, a normal glucose level, and a slightly increased protein content. Antibody to RVF virus may be demonstrated in the fluid. Few patients with encephalitis die. Recovery usually is complete but may be prolonged. Occasionally, the patient is left with permanent sequelae.

Hemorrhagic fever, a complication with a case-fatality rate of 15 percent, develops in approximately 1 percent of patients with RVF. The mortality rate was disproportionately lower in children than in adults during the 1977 Egyptian epidemic. In cases of severe illness, a hemorrhagic diathesis may develop that includes epistaxis, hematemesis, melena, and, sometimes, cerebral hemorrhage. Profuse gastrointestinal hemorrhage may be fatal. Jaundice may be evident.

LABORATORY FINDINGS

The patient has initial leukocytosis that is followed by leukopenia. Profound thrombocytopenia and other defects in coagulation may be observed. Disturbance in liver and kidney function also may be documented. The diagnosis of RVF is suggested when human beings suffer from an acute, severe, but short febrile illness at the same time that an epizootic with high mortality is occurring in sheep.

The diagnosis usually can be confirmed by isolation of the virus in mice or cell culture from blood and, in fatal cases, from the liver. The development of antibodies can be demonstrated by immunofluorescence, immunoglobulin M (IgM) enzyme-linked immunosorbent assay, hemagglutination inhibition, complement fixation, and neutralization. In patients with encephalitis, IgM antibodies are detectable in CSF.

TREATMENT

Treatment is symptomatic. When a hemorrhagic diathesis develops, treatment should be directed toward controlling bleeding. Transfusions of fresh-frozen plasma and platelets may be beneficial. Disseminated intravascular coagulation has been documented in a monkey model, but its role in human disease is uncertain.

PREVENTION

RVF is mainly a disease of adults and usually is acquired occupationally. It is a serious hazard faced by veterinarians, ranchers, and laboratory personnel in the course of their work. Because RVF usually is acquired by direct contact with the tissues of infected sheep and cattle, the risk of acquiring infection can be reduced by wearing gloves, protective masks, and goggles when postmortem examinations are carried out on animals that have died of unknown causes. Because of the value of domestic animals in many economically depressed areas of Africa, sheep and cattle often are housed within family compounds. Sick or dying animals usually are killed to salvage their meat. In this peridomestic environment, children also can be exposed to virus aerosols and readily become infected. Infection from a mosquito bite is possible as well, and for this reason, the use of repellents and bed nets is recommended.

The primary strategy for preventing RVF in both humans and animals relies on vaccination of sheep and cattle, which are the amplifying hosts. Attenuated strains of the virus have been developed and used successfully on a mass scale to immunize livestock. These attenuated vaccines are associated with some abortions in pregnant ewes and cows. An inactivated vaccine is safe and is in widespread use in Africa.

A live attenuated vaccine designated MP-12 was developed by passage of RVF virus in the presence of the mutagen 5-fluorouracil.[6] The vaccine has proved safe for use in domestic

livestock, does not produce abortions, and offers considerable promise as a veterinary and human vaccine. Formalin-inactivated vaccines produced in cell culture[9] have been used on an investigational basis in more than 3000 persons with a seroconversion rate greater than 95 percent. A single case of Guillain-Barré syndrome was reported, but its relation to vaccination was uncertain. Human vaccination is recommended for high-risk occupational groups. Various genetically engineered vaccine candidates are under development.

CHAPTER **203b**

Crimean-Congo Hemorrhagic Fever

Robert B. Tesh

Crimean-Congo hemorrhagic fever (CCHF) is a serious and potentially fatal viral illness, often having hemorrhagic manifestations. The clinical entity and its viral origin were described first in Russia by Chumakov in 1945, but the agent was not propagated or available for study until 1967.[8] Since then, CCHF virus has been reported from many countries in eastern Europe, central Asia, and Africa.[2,6,8] Exposure to ticks or contact with the blood of infected livestock or people are the usual sources of human infection.

ETIOLOGIC AGENT

CCHF virus, the etiologic agent, is a member of the genus *Nairovirus*, family *Bunyaviridae*. It is lethal to newborn mice after intracerebral inoculation. CCHF virus replicates in some vertebrate cell lines, but isolation in mice is more sensitive because the virus usually does not cause any discernible cytopathic effect under fluid overlay. Thus, indirect methods such as immunofluorescence or reverse transcriptase polymerase chain reaction (RT-PCR) must be used to detect CCHF viral antigen or nucleic acid in the cells.

A relatively high level of viremia develops in persons with CCHF and persists for 6 to 8 days after onset of the illness.[6] Blood from acutely ill CCHF patients is quite infectious, and numerous nosocomial infections have occurred in hospital personnel caring for patients with this disease.[1,2,5] CCHF virus is relatively stable in blood and serum and has been recovered from specimens stored as long as 2 or 3 weeks at 4° C.

EPIDEMIOLOGY

CCHF virus is known to occur over a wide geographic area, including eastern Europe, central Asia, and much of Africa (Fig. 203–1).[2] Most cases of the disease probably are unrecognized because of its sporadic occurrence and largely rural distribution.

The epidemiology of CCHF is complex and not fully understood because of the variety of tick and mammalian species that have been found to be naturally infected with the virus.[8] The basic transmission cycle of CCHF virus varies from region to region, depending on the developmental stage and species of ticks involved and their preferred mammalian hosts.[8] In addition, transovarial and trans-stadial transmissions of CCHF virus also have been demonstrated in some tick vectors. In general, human cases of CCHF usually are associated with periods of abundant prevalence of ticks and feeding activity.[2] For example, in eastern Europe, cases of CCHF typically occur between May and August, when the tick population is active. Humans usually acquire CCHF from a tick bite or from contact with blood or other tissues of infected livestock.[2,6,8] Most patients have a history of contact with large domestic animals (farmers, abattoir workers, and veterinarians). Health care workers are another high-risk group.

Numerous CCHF nosocomial outbreaks have occurred in hospital workers and laboratory technicians.[1,2,5] These persons usually have had direct contact with the blood of patients with CCHF. The mortality rate reported in secondary cases has been high, particularly in persons with needle-stick injury or those involved in management of patients with gastrointestinal bleeding.[2]

CLINICAL MANIFESTATIONS

The course of CCHF infection typically has four distinct phases: incubation, pre-hemorrhagic, hemorrhagic, and convalescent (Fig. 203–2).[2,7] The incubation period generally is 3 to 7 days. The pre-hemorrhagic phase begins suddenly with fever (39° C to 41° C), nausea, diarrhea, vomiting, myalgia, and general toxemia. Patients usually are flushed, with conjunctival and scleral injection. Hepatosplenomegaly occurs in as many as 30 percent of cases. This second phase lasts approximately 3 days (range, 1 to 7 days). The hemorrhagic phase usually begins between the third and fifth day of the disease and lasts only 2 to 3 days. The appearance is sudden and can vary from petechiae to large hematomas on the skin and mucous membranes. Profuse bleeding from the nose, gums, gastrointestinal and genitourinary tracts, and lungs can occur at this stage, resulting in tachycardia, shock, and, sometimes, death. Not infrequently, intra-abdominal bleeding occurs during this third phase and causes acute pain; some of these patients are subjected to surgery because of suspected appendicitis or intestinal perforation. If the patient survives the hemorrhagic phase, convalescence begins about the 10th day, with a slow convalescent period lasting 2 to 6 weeks.[2] Viremia is intense and prolonged in CCHF, especially in fatal cases, so blood from these patients should be treated with extreme care.

Leukopenia and thrombocytopenia are consistent features of CCHF and occur early in the disease.[2,3,7] Other abnormal laboratory findings usually include elevated levels of serum aspartate

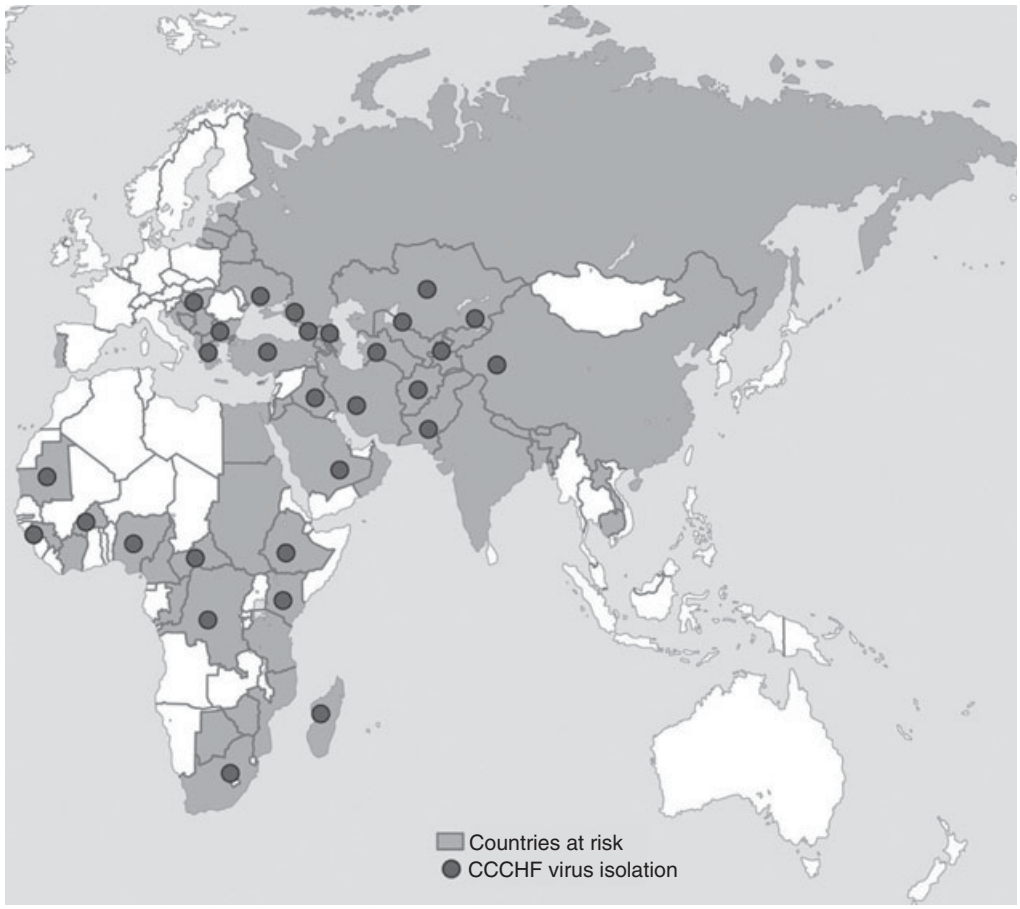

Figure 203–1 Known distribution of Crimean-Congo hemorrhagic fever (CCHF) virus in the world. (See companion Expert Consult web site for color version.) *(From Ergonul, O.: Crimean-Congo hemorrhagic fever. Lancet Infect. Dis. 6:203-214, 2006.)*

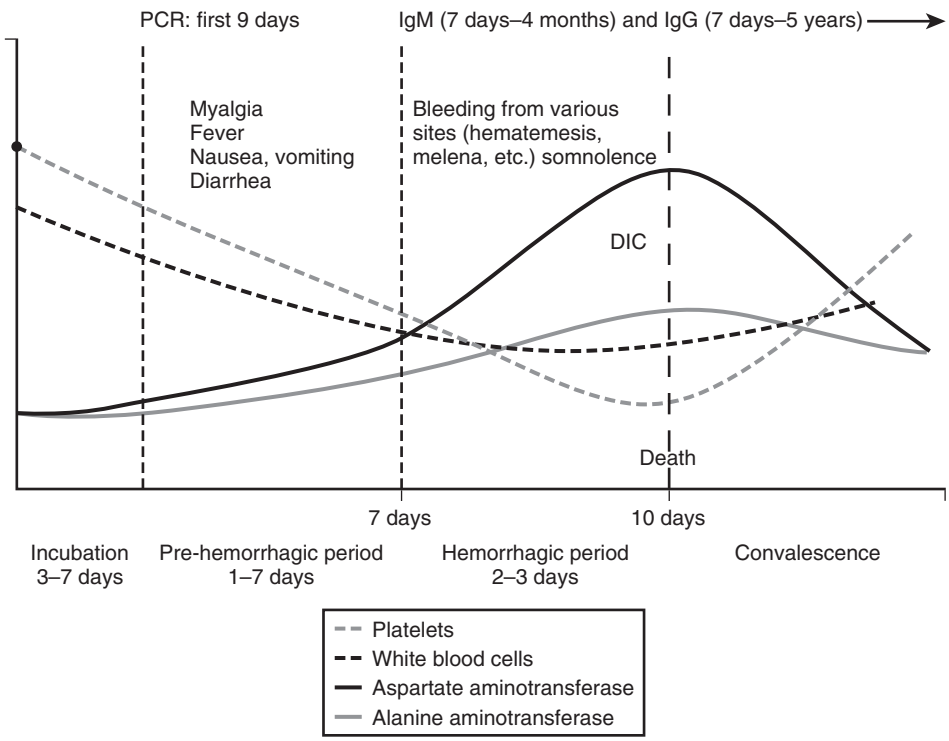

Figure 203–2 Clinical and laboratory course of Crimean-Congo hemorrhagic fever. DIC, disseminated intravascular coagulation; IgM, immunoglobulin M; PCR, polymerase chain reaction. *(From Ergonul, O.: Crimean-Congo hemorrhagic fever. Lancet Infect. Dis. 6:203-214, 2006.)*

and alanine aminotransferase, lactate dehydrogenase, bilirubin, creatinine, and urea. Coagulation tests such as prothrombin time and activated prothrombin time are prolonged. Fibrinogen may be decreased, and fibrin degradation products may be increased. These laboratory tests generally return to normal levels with the onset of convalescence.

PATHOGENESIS

The pathogenesis of CCHF is not well understood, but the available evidence suggests that endothelial damage and dysfunction play an important role in the hemostatic failure.[2,5,7] Fluorescent antibody studies on organs in fatal cases of CCHF show a concentration of viral antigen in the reticuloendothelial cells of the liver and spleen, a finding suggesting that these cells are major sites of virus replication.[7] Other pathologic changes observed at autopsy include generalized vascular lesions with endothelial damage that give rise to scattered focal hemorrhage and edema in most organs.[2] In severe cases, dysfunction of the coagulation system and disseminated intravascular coagulation appear to be prominent features of the disease.

DIAGNOSIS

A clinical diagnosis of CCHF is difficult to establish before the onset of hemorrhagic manifestations because the initial symptoms are nonspecific, and cases usually occur sporadically. As a result of the frequency and severity of the abdominal pain associated with the pre-hemorrhagic and hemorrhagic phases of CCHF, the disease sometimes is misdiagnosed as appendicitis or gastric ulcer. Such patients may be subjected to unnecessary surgery, which can be fatal to both the patient and the attending medical personnel.[1,2,6] Once hemorrhagic manifestations appear, the differential diagnosis should include erythema multiforme (Stevens-Johnson syndrome), leptospirosis, hemorrhagic fever with renal syndrome, Ebola virus infection, Lassa fever, Rift Valley fever, Q fever, and yellow fever, depending on the region of the world where the patient was exposed.

A definitive diagnosis of CCHF can be made by isolating the virus from the patient's serum or detecting viral nucleic acids by PCR, during the first week of illness. Immunoglobulin G (IgG) and IgM antibodies do not appear until 7 to 10 days after the onset of symptoms in nonfatal cases.[6,7] Establishing the diagnosis early is critical for proper management of the patient and prevention of potential nosocomial infections.

TREATMENT

Treatment of CCHF is largely supportive and should include immediate hospitalization and strict bed rest.[2,6] Because death usually results from acute blood loss and shock, patients may require transfusions of fresh blood, platelets, or plasma (or all three). Administration of immune plasma obtained from convalescent donors can be used early in the course of the illness or for persons, such as hospital personnel, who are exposed to the virus inadvertently. Reports have suggested that ribavirin may be beneficial for treatment of CCHF.[2-4] The mechanism of action is unknown. A World Health Organization report recommended ribavirin treatment for 10 days, with 30 mg/kg as an initial loading dose, then 15 mg/kg every 6 hours for 4 days, and then 7.5 mg/kg every 8 hours for 6 days.[2] Milder cases of CCHF probably do not require treatment with ribavirin.

PROGNOSIS

The mortality rates reported for CCHF have varied from approximately 15 to 70 percent,[2,6,8] although these figures are probably high, because milder cases of the disease may not be recognized or reported. If the patient survives the hemorrhagic phase of the disease, recovery is complete, and permanent immunity results.

PREVENTION

No vaccine of proven safety or efficacy for prevention of CCHF exists. Personal protection measures are recommended for people living or working in heavily tick-infested areas. People exposed occupationally to potentially infected animal blood should wear protective clothing and gloves to prevent skin contact with infected tissue or blood. Hospital personnel caring for patients with CCHF should follow barrier nursing and isolation protocols, which include use of gloves, gowns, face shields, and goggles.

CHAPTER 203c

PHLEBOTOMUS FEVER (SANDFLY FEVER)

Robert B. Tesh

Phlebotomus fever is an acute, self-limited febrile illness of 2 to 4 days' duration that usually is acquired from the bite of infected phlebotomine sandflies. Phlebotomus fever also is known as *sandfly fever*, *pappataci fever*, and *3-day fever*. The disease is endemic in many areas of central Asia, northern Africa, and southern Europe. Historically, phlebotomus fever has been largely of military interest because the introduction of large numbers of susceptible troops into endemic areas often has resulted in epidemics of the disease.[8] More recently, the disease has been reported with increasing frequency in civilian populations and in tourists visiting endemic areas.[3,4,7]

In 1909, Doerr and associates first demonstrated that the causative agent of the illness was a virus transmitted by *Phlebotomus papatasi*. In 1954, Sabin successfully adapted the agent to

mice and described two distinct serologic types, designated the Naples and Sicilian strains.[8] Subsequently, 44 additional serotypes were isolated from various regions of the world; all these agents are included in the genus *Phlebovirus*, family *Bunyaviridae*. Although most of the phleboviruses probably are capable of producing human illness, the discussion here is limited to the three (Naples, Sicilian, and Toscana) that are associated most commonly with human illness. Rift Valley fever virus also is a member of this genus and frequently causes a phlebotomus fever–like illness in infected persons.[6] However, humans generally acquire Rift Valley fever from the bite of infected mosquitoes or from aerosol, and the sequelae of Rift Valley fever are more severe and occasionally fatal.

ETIOLOGIC AGENT

The phleboviruses are RNA-containing viruses, spherical, and 90 to 100 nm in diameter.[3,8] The Naples, Sicilian, and Toscana viruses produce a cytopathic effect, as well as plaques in Vero cells. Most laboratory animals are not susceptible to infection with these viruses, although the viruses usually can be adapted to newborn mice by serial passage intracerebrally. For this reason, tissue culture is recommended for primary isolation of these agents.

EPIDEMIOLOGY

The geographic distribution of the Naples and Sicilian virus types in the Old World closely parallels that of their presumed vector, *P. papatasi* (Fig. 203–3).[8] Toscana virus has been isolated in Portugal, Spain, France, Italy, and Cyprus and has been associated with two other peridomestic sandfly species, *Phlebotomus perniciosus* and *Phlebotomus perfiliewi*.[3,8]

These phlebotomine species are tiny, sand-colored, biting flies about 2 to 3 mm long. Because of their small size, they have little difficulty squeezing through ordinary screens and mosquito netting. They usually are nocturnal, and only the female bites. Sandflies move in short hops and usually do not travel more than a few hundred meters from their resting and breeding sites. During the day, peridomestic species such as *P. papatasi* and *P. perniciosus* rest in dark corners and crevices, often within houses. The larvae develop in loose soil and organic debris in stone walls, animal sheds, privies, open wells, and gardens. Because of their indoor habits, these peridomestic species are quite vulnerable to residual insecticides.

In central Asia and the Mediterranean region, sandflies are active during the late spring and summer. The incidence of phlebotomus fever follows the same seasonal pattern.

Many phlebotomus fever viruses appear to be maintained in the sandfly population by transovarial (vertical) transmission.[8] Thus, sandflies appear to serve as both vectors and reservoirs of these viruses. Unlike most other arboviruses, whose activity depends on the presence of susceptible and viremic vertebrate hosts, phlebotomus fever viruses are probably active continuously during each sandfly season, regardless of the immune status of the local human population. Serologic studies of persons living in endemic areas of the disease indicate that most of the residents are infected early in life.[8,9] In these communities, sporadic cases of phlebotomus fever occur in children because most of the adult population is already immune. However, because of the benign nature of the disease, its sporadic occurrence, and its similarity to many other viral diseases of childhood, most cases are unrecognized. When large numbers of susceptible persons (soldiers, tourists, refugees, and so on) enter an endemic area of phlebotomus fever, however, bite transmission occurs, and an epidemic of the disease quickly appears.[8]

CLINICAL MANIFESTATIONS

The incubation period for phlebotomus fever averages 3 to 5 days.[1,8] The illness begins suddenly with fever, severe frontal headache, retro-orbital pain, conjunctival injection, photophobia, malaise, anorexia, nausea, vomiting, myalgia, and lower back pain. The face may be flushed, but a true rash is absent. The disease is self-limited, and symptoms usually disappear within 1 to 3 days; however, a general feeling of weakness and depression often occurs for a week or more after the illness.

Meningitis and meningoencephalitis with Toscana virus infection have been described with increasing frequency in southern Europe.[2-4,7] In addition to the classic symptoms of phlebotomus fever, these patients exhibit nuchal rigidity, a positive Kernig sign, a clouded sensorium, and, occasionally, nystagmus and tremor. To date, no deaths have been recorded. Childhood cases of the meningoencephalitic form of Toscana virus infection have been reported,[2] but this form of the infection occurs more commonly in adults.

One attack of phlebotomus fever usually confers lifelong immunity against the infecting virus type but not against heterologous serotypes.[8] For this reason, second cases of the disease have been reported in the same individual in areas where two or more virus serotypes are active.

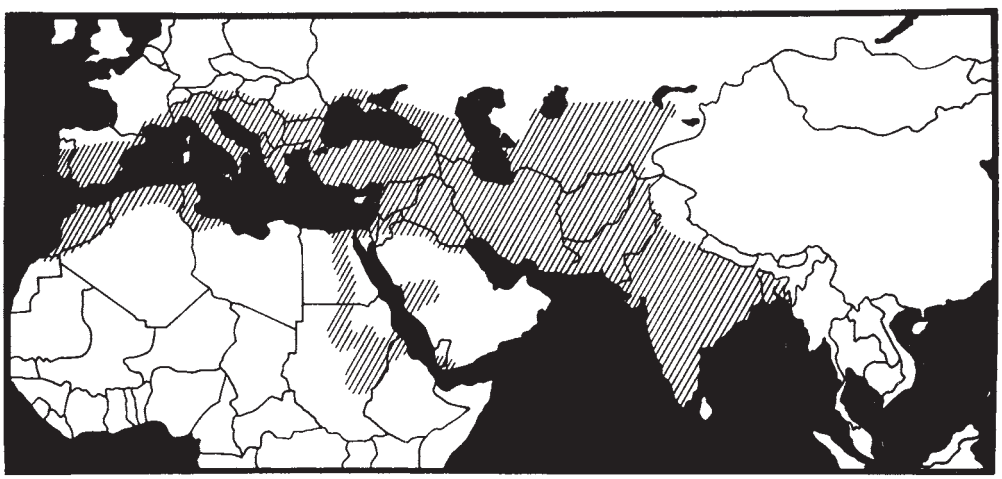

Figure 203–3 The known geographic distribution of *Phlebotomus papatasi*, the presumed vector of sandfly fever (Naples and Sicilian types), in central Asia, the Mediterranean region, and adjacent areas of Africa. *(Modified from Tesh, R. B., Saidi, S., Gajdamovic, S. J., et al.: Serological studies on the epidemiology of sandfly fever in the Old World. Bull. World Health Organ. 54:663-674, 1976.)*

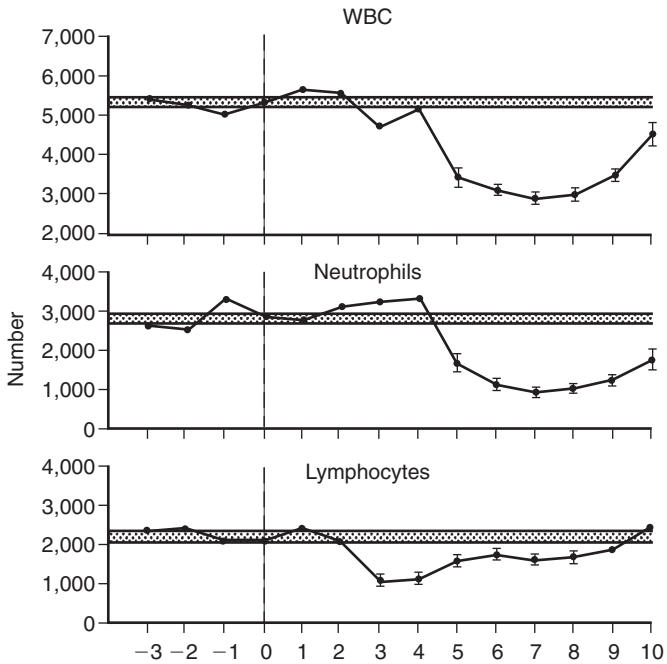

Figure 203–4 Mean total white blood cell (WBC) count as well as absolute neutrophil and lymphocyte counts in 11 adult volunteers inoculated (day 0) with the Sicilian strain of sandfly fever virus. The average incubation period in the subjects was approximately 70 hours. *(Modified from Bartelloni, P. J., and Tesh, R. B.: Clinical and serologic responses of volunteers infected with phlebotomus fever virus [Sicilian type]. Am. J. Trop. Med. Hyg. 25:456-462, 1976.)*

Marked leukopenia usually is observed in patients with phlebotomus fever.[1] It is characterized by initial lymphopenia, followed by protracted neutropenia (Fig. 203–4). In patients with central nervous system involvement, pleocytosis and an elevated protein content are observed in the cerebrospinal fluid (CSF).

PATHOLOGY

Fatalities caused by phlebotomus fever have not been reported, and little is known of the pathologic changes produced by these viruses.

DIAGNOSIS

The diagnosis of phlebotomus fever often can be made on the basis of clinical and epidemiologic evidence. A sudden outbreak during the summer months of a short febrile illness with severe headache and marked leukopenia in visitors or other newcomers to an endemic area where sandflies are abundant should suggest the disease. Depending on the region, the differential diagnosis may include dengue, West Nile fever, malaria, influenza, and numerous other respiratory and enteroviral infections.

Transient (24 to 36 hours), low-level viremia occurs during this illness; therefore, isolation of the virus from blood is unusual. In a few instances, Toscana virus has been isolated directly from the CSF of persons with central nervous system symptoms.[2] Molecular techniques (reverse transcriptase polymerase chain reaction [RT-PCR]) have been described for direct detection of Toscana virus in clinical samples[3]; however, one of the problems with using molecular methods to detect phleboviruses directly in clinical material is the wide genetic diversity among members of each serotype. In addition, limited sequence data are available for many of the phleboviruses. At present, serologic tests offer the simplest method for establishing a specific diagnosis of phlebotomus fever. Antibodies are present in serum 7 to 14 days after infection and can be demonstrated by immunofluorescence,[4] enzyme immunoassay,[5] or neutralization testing.[1] A fourfold rise in antibody titer from acute to convalescent sera or the presence of specific immunoglobulin M antibodies provides presumptive evidence of a recent phlebotomus fever virus infection. At present, these serologic tests are not generally available and usually are performed in only a few arbovirus laboratories.

TREATMENT

Treatment is symptomatic, and hospitalization usually is not necessary, except in more severe cases of Toscana virus infection. Occasionally, narcotics are required to relieve the severe headache associated with the disease.

PROGNOSIS

Phlebotomus fever is a self-limited, nonfatal illness. Recovery is complete.

PREVENTION

Control measures are directed primarily against the vector. Household spraying with residual insecticides is quite effective in reducing peridomestic sandfly vectors and controlling the disease. The use of personal insect repellents (e.g., diethyltoluamide) and fine-mesh bed nets is also effective in avoiding sandfly bites.

CHAPTER 203d

OROPOUCHE FEVER

Francisco P. Pinheiro ● Amelia P. A. Travassos da Rosa ● Pedro Fernando da C. Vasconcelos

Oropouche (ORO) fever is an arbovirus infection that causes an acute febrile episode accompanied by headache, myalgia, arthral-

gia, and other systemic symptoms. The symptoms usually recur a few days after the end of the first febrile episode, at which time they generally are less severe. Aseptic meningitis may develop in some patients. Patients make a full recovery, without any apparent aftereffects, even in the most serious cases. No fatalities have been confirmed as being attributable to ORO fever. One of the most striking characteristics of ORO virus (OROV) is its ability to produce epidemics in urban population centers, most of which reportedly have occurred in the Brazilian Amazon region. Many of these outbreaks have had a major impact on the stricken cities.

The first case of the disease was described in 1955 in a resident of Vega de Oropouche, Trinidad, from whose blood the agent was isolated.[1] The disease was detected again in 1961, this time in the city of Belém, Pará State, northern Brazil, where it caused an epidemic that affected at least 11,000 people.[17] This epidemic was followed by many other epidemics, several of an explosive nature, in urban population centers throughout the Brazilian states of Pará, Amapá, Amazonas, Tocantins, Maranhão, Rondônia, and Acre.[7,12,17,21,22,24,27,28] Outside Brazil, epidemics of ORO fever were reported in Panama in 1989 (Quiroz, E., and associates, Panama, unpublished data, 1989) and in the Amazon region of Peru in 1992[5] and in 1994 (Ministry of Health, Peru, and U.S. Naval Medical Research Institute Detachment [NAMRID], Lima, unpublished data, 1994).

ETIOLOGIC AGENT

ORO fever is caused by OROV, which belongs to the genus *Orthobunyavirus* of the family *Bunyaviridae*.[23] The virus has enveloped spherical particles 90 to 100 nm in diameter; the capsid has helical symmetry; and the single-stranded, negative-sense RNA contains three segments, designated large (L), medium (M), and small (S) RNA.[11,23] Complete nucleotide sequences have been determined for all three RNA segments.[2,26,29] Phylogenetic analysis has revealed that all OROV strains form a monophylogenetic group consisting of three distinct lineages. Lineage I contains the prototype strain from Trinidad and most of the Brazilian strains, lineage II contains six Peruvian strains isolated between 1992 and 1998 and two strains from western Brazil isolated in 1991, and lineage III comprises four strains isolated from Panama during 1989.[26] Antigenically, OROV belongs to the Simbu group, which, in turn, is part of the Bunyamwera supergroup of arboviruses. The virus has a hemagglutinin that is active against geese erythrocytes, and it can be recovered from infected hamster serum treated with acetone (Travassos da Rosa, Belém, unpublished data, 1969). Intracerebral and intraperitoneal inoculation of OROV into baby mice and intracerebral, intraperitoneal, and subcutaneous inoculation of the virus into adult hamsters produce lethal infections. The virus replicates in numerous cell cultures, including Vero, BHK-21, and primary chicken embryo fibroblast, and it causes a cytopathic effect.[23] The agent is sensitive to the action of sodium deoxycholate.[10]

EPIDEMIOLOGY

GEOGRAPHIC DISTRIBUTION

Thus far, the only reported cases of ORO fever have occurred in Argentina, Brazil, Panama, Peru, and Trinidad (Fig. 203–5). However, most cases have been limited to the Brazilian Amazon region, with none reported in other areas of Brazil.

With a few exceptions, all episodes of ORO fever have been in the form of urban epidemics, including those in Belém and Manaus, the largest cities in the Brazilian Amazon region. The city of Belém, capital of Pará State, was struck by three major epidemics during a 20-year period. The city of Santarém and surrounding villages also were affected by a major epidemic in 1974 and 1975.[21] The first epidemics that occurred outside Pará State, those striking the cities of Manaus and Barcelos in Amazonas State[4] and the city of Mazagão in what was then the Amapá Territory, were reported early in the 1980s.[15] After a period of quiescence lasting until 1988, new outbreaks of the disease struck the cities of Porto Franco and Tocantinópolis in the states of Maranhão and Tocantins, respectively.[28] The next reported epidemics occurred in 1991, this time in more distant locations, namely, in the cities of Ariquemes and Ouro Preto D'Oeste in Rondônia State; the epidemic's impact on these cities was so great that it was reported in the national press. In 1994, another outbreak involving at least 6000 people was recorded in Serra Pelada, Pará State.[27] Other outbreaks were recorded in 1996 and affected at least five urban centers in the states of Pará, Amazonas, and Acre.[22] Thus, during 1961 to 1996, more than 30 epidemics of ORO fever were recorded in Brazil. Several small outbreaks also were recognized in Canãa dos Carajás in 2003 and in Tapará Village at Porto de Moz in 2004, both municipalities in Pará State (Vasconcelos, P. F. C., unpublished data, 2004). In April of 2006, a large epidemic of ORO fever occurred in northeastern Pará that affected several municipalities. Autochthonous cases of ORO fever also were diagnosed in the municipalities of Magalhães Barata, Maracanã, Marapanim, Igarapé-Açu, São Francisco do Pará, and Viseu. A retrospective serologic study conducted among inhabitants of urban and rural communities of the municipality of Magalhães Barata showed that 320 of 631 persons had immunoglobulin M (IgM) OROV antibodies detected by enzyme-linked immunosorbent assay (ELISA), thus suggesting that approximately half of the 8000 inhabitants had been infected. In this episode, a single isolate was obtained and sequenced, and the OROV genotype II was recognized (Vasconcelos, P. F. C., and Nunes, M. R. T., personal communication, 2006). The last recorded epidemic in those municipalities occurred in 1980.[7]

Serologic surveys[7,15,19,22] estimated that more than 360,000 people were infected during this period (Vasconcelos, P. F. C., and Nunes, M. R. T., unpublished data, 2006). However, this estimate actually is quite conservative because the incidence of this viral disease was not computed in many major outbreaks (Belém, 1968; Porto Franco and Tocantinópolis, 1988). Possibly more than a half million people in the Brazilian Amazon region may have been infected with the OROV since the beginning of the 1960s.

In addition to the aforementioned epidemic areas, countless small villages scattered throughout virtually the entire Amazon region have residents who show hemagglutination-inhibition antibodies against OROV. In general, the prevalence of these antibodies is less than 3 percent, with the exception of Ilha de Gurupá, where it is 10.7 percent.[22] An OROV strain was isolated from a novel primate host (*Callithrix* spp.) in Arinos, Minas Gerais State, southeastern Brazil,[14] thus extending the enzootic area further to southern Brazil.

Outside Brazil, outbreaks were reported in Panama and Peru. The outbreak in Panama occurred in 1989 in the village of Bejuco, which is located approximately 50 km west of the capital (Quiroz, E., and associates, Panama, unpublished data, 1989). The first epidemic in Peru was reported in 1992 in the city of Iquitos in the Peruvian Amazon region.[5] Subsequently, an outbreak occurred in Puerto Maldonado, Madre de Dios, also in the Peruvian Amazon region (Ministry of Health, Peru, and NAMRID, Lima, unpublished data, 1994). Studies performed in Peru suggested that transmission of OROV occurs continuously in the population of the city of Iquitos and surrounding villages.[30] Evidence of immunity to OROV was detected in nonhuman primates in Colombia, a finding thus suggesting the presence of OROV in that country as well.[10] OROV has been isolated from febrile persons in Jujuy, northern Argentina (Fabbri, C., Nunes,

Figure 203–5 Sites of outbreaks of Oropouche fever reported in the Americas from 1961 to 2006.

M. R. T., Vasconcelos, P. F. C., and Enria, D., unpublished data, 2006). The nucleotide sequencing of S RNA showed that the Argentinean strains constituted a separate phylogenetic group that was classified as a new genotype (genotype IV).

INCIDENCE

A significant characteristic of ORO fever is the exceptionally high attack rates seen during several outbreaks. Although incidence rates varied in different outbreaks, a rate of 30 percent was quite common. The proportion of those infected who suffered overt disease is not known with certainty, but in one epidemic, clinical disease developed in 63 percent of those infected.[7]

Gender-specific attack rates vary. Rates in female patients were slightly higher than those in male patients in villages in the Bragantina area, eastern Pará State, which was struck by the virus in 1979,[7] and the opposite was true in the outbreak in Belém that same year. However, in the reported epidemics in Santarém, the infection struck female patients twice as often as male patients.[6] ORO fever affects all age groups, although in certain outbreaks, the incidence was higher in children and young adults.

DIFFUSION OF EPIDEMICS

As indicated earlier, ORO fever epidemics have struck different locations at varying intervals. However, many outbreaks have been marked by bona fide epidemic sweeps, with countless numbers of villages within a particular geographic area affected by the virus. This diffusion phenomenon was observed in Bragança in 1967, in Santarém in 1974 and 1975, and even more dramatically in Belém and in the Bragantina area from 1978 to 1980 (where at least 10 towns were stricken), as well as in Rondônia in 1991. Spread of the virus most likely is attributable to the movement of viremic individuals throughout areas in which the virus vector is present.

SEASONAL FLUCTUATION

Most epidemics of ORO fever typically occur during the rainy season, which, in the case of the Pará State, corresponds to the period between January and June. However, many epidemics have extended into the dry season, although with less intensity. The seasonal nature of ORO fever most likely is linked to the higher density of populations of *Culicoides paraensis*, commonly known as the biting midge, the urban virus vector, in months with higher levels of rainfall, combined with a higher concentration of exposed individuals. Downward trends in epidemics of ORO fever generally are associated with the arrival of the dry season and the resulting lower density of biting midge populations and smaller numbers of exposed individuals.[11,24]

ENDEMIC TRANSMISSION

During interepidemic periods, isolated cases of ORO fever undoubtedly occur in Brazil but remain undiagnosed. Although no systematic studies have been conducted to investigate endemic transmission of OROV in Brazil, seroepidemiologic investigations have indicated that the prevalence of anti-OROV antibodies in humans is 0 to 2 percent in areas where endemic transmission has not been reported,[22] but it increases to 17 to 44 percent after outbreaks.[6,11,23] These data suggest that endemic transmission of OROV is quite low in Brazil.

TRANSMISSION MECHANISM

Laboratory studies and broad-based surveys conducted by the Evandro Chagas Institute of Belém during the course of epidemics point to the importance of the insect *C. paraensis* in the *Ceratopogonidae* family as the urban vector for OROV.[16,20] These tiny insects, commonly known as maruins (biting midges) in the Amazon region, are active during the day, particularly in the late afternoon hours. They crave human blood and bite people inside as well as outside their homes.[9,21,25] The disease is transmitted by inoculation of the virus into exposed individuals by bites of infected midges.

TRANSMISSION CYCLES

Studies conducted by the Evandro Chagas Institute[22] suggest that OROV is perpetuated in nature through two different cycles, namely, an urban cycle and a wild cycle. In the urban or epidemic cycle, the virus is transmitted from person to person by the bite of *C. paraensis*. One of the most conclusive pieces of evidence attesting to this assertion lies in demonstration of the ability of *C. paraensis*, after feeding on the blood of viremic patients, to transmit the virus to hamsters bitten by the midges 5 or more days later.[20] Moreover, these midges typically are found in high densities during periods of epidemics. They breed mostly in the decomposing trunks of felled banana trees, in rotting husks of cocoa beans,[8] and in piles of detritus formed in tree hollows.[13] They are scattered throughout tropical and subtropical areas of the Americas.[13]

Attempts to transmit the virus from one hamster to another through the bite of the *Culex quinquefasciatus* mosquito (a species commonly found in urban areas throughout the Amazon region) demonstrated that the virus was transmitted only in the presence of extremely high levels of viremia, which rarely occurs in infected humans.[16] Thus, this finding virtually rules out all likelihood that the epidemic vector is *C. quinquefasciatus*. Curiously, the virus isolation rate from *C. paraensis* during periods of epidemics is only 1:12,500,[11] a finding suggesting that we are dealing with a low-efficiency vector. Apparently, humans are the only vertebrates involved in the urban cycle of OROV because studies of domestic animals conducted during the course of numerous outbreaks ruled out the possibility that these animals play an amplifying role.

As far as the wild, silent cycle of the virus is concerned, evidence suggests that among vertebrates, the *Edentata* (sloth), nonhuman primates, and possibly certain species of wild birds serve as hosts. Although to date OROV has been isolated from a single pool of *Aedes serratus* in Brazil and once from *Coquillettidia venezuelensis* in Trinidad,[1,22] the possible involvement of biting midges in the virus' wild cycle nonetheless should be investigated.

The link between the two cycles most likely is humans themselves, who, after contracting the infection in enzootic forested areas and then returning to an urban setting during the viremic phase, become a source of infection for biting midges. The virus replicates in the tissues of biting midges, which, after the extrinsic incubation period, bite and infect exposed individuals. These individuals, in turn, serve as a source of infection for other midges, thereby forming a chain of transmission resulting in the unleashing of an epidemic.

INCUBATION PERIOD

Observations conducted during numerous epidemics suggest that the incubation period ranges from 4 to 8 days. A laboratory worker who accidentally was infected orally exhibited symptoms of the viral disease 3 days later, and another technician fell ill 4

days after being infected, probably through the respiratory route.[22]

TRANSMISSIBILITY PERIOD

The blood of infected patients is infectious to *C. paraensis* for the first 3 or 4 days after the onset of symptoms, when the level of viremia is high enough to infect the midges. Experimental studies have shown the length of the extrinsic incubation period to be 5 days or more.[20] The virus is not transmitted directly from one person to another.

RATIO OF SYMPTOMATIC CASES

A prospective study conducted in the city of Santa Izabel in Pará State during the course of the epidemic of 1979 showed the ratio of symptomatic to asymptomatic cases to be roughly 2:1.[7] The study was performed during the period from March through June of that year. It involved 274 individuals exposed to the virus who were monitored by clinical examination and laboratory testing on a weekly basis throughout the study. By the end of the study period, 78 (28.5%) of these individuals had serologic evidence of OROV infection, with clinical manifestations of the disease developing in 49 (63%) of the 78.

CLINICAL MANIFESTATIONS

In most cases of ORO fever, the infection takes the form of an acute febrile episode, which runs its course. However, certain patients may show typical signs and symptoms of aseptic meningitis, which also runs its course without complications.

CLASSIC FEBRILE FORM

This form of the disease is characterized by the sudden onset of symptoms after an incubation period ranging from 4 to 8 days. The first symptoms to appear are fever, headache, chills, dizziness, muscular pain, arthralgia, and photophobia. Retro-ocular pain and conjunctival congestion also may be present. In addition, some patients suffer from nausea, which may be accompanied by episodes of vomiting. Not uncommonly, patients have severe anorexia and insomnia. At times, cough and coryza are present as well, although these manifestations may be attributable to intercurrent infections. Certain patients complain of fleeting burning or stinging sensations in different parts of their body. The presence of an exanthem is a rare finding. Two laboratory workers who were infected accidentally reported a longer and heavier menstrual flow than usual.[21,22] The fever can be quite high, 39° C or 40° C, and in some cases it may be higher than 40° C. The headache usually is localized in the front or back part of the head, although it also may be diffuse. It generally is severe and, in some cases, may not respond readily to common analgesics. Generalized myalgia is present and sharpest in the neck, along the vertebral column, and in the area of the sacrum. The pain may be extremely severe. Patients generally describe feeling as though their body had been crushed or they had been beaten. Usually, generalized arthralgia also is present. Certain patients have dizzy spells so severe that in some cases they collapse. Any epigastric pain generally is mild. Patients have no sign of jaundice, hepatomegaly, or splenomegaly. Occasionally, swollen lymph nodes are detected in the submaxillary and occipital regions, and these findings could be totally unrelated to the viral infection.

The intensity of the clinical symptoms varies. In some cases, the symptoms are quite severe and even may cause prostration, whereas in others, they can be rather mild. Many patients are bedridden and, during epidemics, flood area hospitals, thus causing serious overcrowding.

The acute phase of the disease generally lasts 2 to 5 days but can be as long as a week. The myalgia, conversely, may persist for 3 to 5 days after the fever has disappeared. Some patients report having prolonged asthenia for as long as a month. Certain patients complain of a persistent headache lasting up to several weeks. No human deaths have been attributed to OROV infection.[11]

Nearly 60 percent of all patients have one or more recurrences in the first or second week after disappearance of the manifestations of the acute phase of the disease.[7,15,22] Relapses may take the form of reappearance of all the acute-phase symptoms of the disease, or they may be limited strictly to fever, asthenia, and dizziness. In some reported patients, relapses were accompanied by a urinary tract infection of bacterial origin. An abscess, most likely bacterial, developed in the oropharynx of one particular patient approximately 10 days after recovery from the original febrile condition. In some cases, patients may suffer a series of relapses during a period of 2 to 3 weeks.[22] All attempts to isolate OROV during relapses have failed.

Observations made during the course of the 1980 outbreak in Belém revealed that an exanthem developed in approximately 5 percent of all laboratory-confirmed cases.[15] The exanthem appeared between the third and sixth day after onset of the fever, disappeared 2 or 3 days later, and mainly involved the thorax, back, arms, and legs.[15,19] During the outbreak in Manaus, many patients exhibited a maculopapular exanthem beginning on the torso and spreading to the upper and lower extremities.[4] In another rare case, a 4-year-old child whose infection was confirmed by serodiagnosis experienced nystagmus, generalized tremors, and somnolence.[7] These symptoms lasted approximately 8 days, and the child apparently made a full recovery.

The effects of ORO fever on pregnancy are unknown. The only available data in this regard come from studies conducted in Manaus of nine pregnant patients, two of whom, both in the second month of pregnancy at the time, suffered miscarriages.[4]

ASEPTIC MENINGITIS

At first, patients exhibit manifestations typical of the initial acute phase of the infection. As the illness progresses, a few days later, the headache and dizziness become increasingly severe, and some patients begin to experience other neurologic symptoms, generally during the second week of the illness, that lead them to seek medical care. The main complaints cited by patients are fever, extremely severe headache in the back of the head, and dizziness. Approximately one third of all patients complain of nausea and vomiting. Some patients suffer from moderate lethargy. They also may have trouble holding themselves upright. Some patients complain of double vision or diplopia. They generally try to keep from moving their heads to avoid aggravating their pain. In most cases, physical examination of these patients reveals varying degrees of stiffness of the neck but no signs of paresis or paralysis. Some patients experience nystagmus. Despite the seriousness of these neurologic symptoms, patients make a full recovery. Electroencephalograms taken of four patients showed no abnormalities. The incidence of meningitis in patients who seek medical care is less than 5 percent.[18]

PATHOGENESIS

Little is known about the pathogenesis of ORO fever. Apparently, the agent produces a systemic infection in humans that

induces a viremic phase, but the organs in which the virus replicates have not been identified. Virtually all infected patients exhibit viremia during the first 2 days of their illness. By the third day, the rate of viremia drops to 72 percent, and it falls to 44 and 23 percent by the fourth and fifth days, respectively. Viremia titers generally are higher than 3.0 $\log_{10}$ median lethal dose per 0.02 mL in mice, with approximately 10 percent of patients exhibiting virus titers as high as 5.0 to 5.3 during the course of the first 2 days of their illness. By the third day, virus titers are 1 log lower than in the first 2 days, and titers plummet by the fourth day.[22]

Similarly, little is known about the pathogenesis of relapses, which occur commonly. That no sign of viremia could be detected in any of the countless patients examined while suffering relapses is noteworthy.

The finding that OROV is capable of causing aseptic meningitis, combined with isolation of the virus from the cerebrospinal fluid (CSF) in one patient with meningitis,[18] suggests that the virus has the ability to penetrate the blood-brain barrier. With no known confirmed fatalities attributable to OROV, no data are available on the possible organic lesions caused by this agent in humans.

Laboratory tests on young hamsters inoculated with OROV showed that the virus has essentially hepatoviscerotropic properties, with isolated necrosis of hepatocytes or focal necrosis and the involvement of Kupffer cells exhibiting reactive hyperplasia; animals invariably succumb to the infection. In newborn mice, the virus exhibits marked neurotropism, and animals show signs of focal encephalitis within 24 to 48 hours after being inoculated.[3]

LABORATORY FINDINGS

Leukopenia associated with neutropenia is found commonly, although in certain cases moderate leukocytosis may be present. The leukopenia can be severe, with reports of leukocyte counts as low as 2000/mm^3. No signs of cell abnormalities are present. Aspartate and alanine aminotransferase levels are normal or may show a moderate increase, but in no case do they exceed 135 U/mL of serum. Platelet counts usually are normal but occasionally may be slightly low. The erythrocyte sedimentation rate and levels of urea, creatinine, and glucose in blood are normal, as are urine tests.[22]

The CSF of patients with aseptic meningitis shows pleocytosis and an increased concentration of protein.[18] The cell count varies from 7 to 310 cells/mm^3 of CSF; both segmented and mononuclear cells are present, with a predominance of segmented cells. In one case, the cell count in CSF fell from 130 to 30 in a 1-week period, and another patient's cell count fell from 70 to 10 cells over a 3-week interval. In general, a moderate increase in protein levels occurs in the CSF, although one patient's protein level was more than 100 mg/mL. Glucose levels remain normal.

LABORATORY DIAGNOSIS

Specific confirmation of the infection is made by isolating the virus from patients' blood or by performing OROV-specific serologic assays.[23] To isolate the virus, blood samples need to be taken during the first 5 days of the illness, preferably in the first 2 days, when viremia is present in virtually all cases. The virus can be isolated by intracerebral or intraperitoneal inoculation of serum from infected patients into baby mice or young hamsters (in this case, subcutaneous inoculation can be used as well). Viral isolates also can be recovered in different cell cultures, such as Vero and BHK-21. The virus is identified by complement fixation or neutralization using OROV-specific ascitic fluid or antisera. Serodiagnosis is accomplished by the demonstration of an increase in antibody in paired serum samples taken during the acute and convalescent phases of the disease by hemagglutination inhibition, complement fixation, or neutralization. A positive IgM antibody capture ELISA (MAC-ELISA) on a single serum sample provides a presumptive diagnosis of recent infection, particularly in the presence of a clinical picture consistent with the disease; the test usually is positive after the fifth day of illness. A rapid and highly sensitive one-step TaqMan reverse transcriptase polymerase chain reaction (RT-PCR) assay has been described for detection of OROV and certain other orthobunyaviruses; it was found to be more sensitive than is the established nested PCR system.[31]

DIFFERENTIAL DIAGNOSIS

Because of the nonspecific nature of the symptoms, a clinical diagnosis of ORO fever is difficult to make, and often the disease is mistaken for other febrile illnesses such as dengue fever and malaria. In fact, malaria and dengue fever initially were suspected as the cause of numerous epidemics of ORO fever. Detailed clinical records combined with epidemiologic data can help establish a differential diagnosis, the certainty of which hinges on the absence of plasmodia in blood samples and the lack of laboratory evidence of dengue infection. Other viral and bacterial febrile diseases must be considered in the differential diagnosis. Accordingly, clinical and epidemiologic data and nonspecific tests will need to be taken into account, although establishing an accurate diagnosis requires specific tests.

Febrile forms of the disease accompanied by an exanthem need to be distinguished from other exanthematous febrile symptoms caused by dengue, measles, parvovirus B19 infection, infection with human herpesvirus type 6 or 5, enteroviral infections, and allergies to medication. Finally, differentiating cases of aseptic meningitis associated with OROV infection from cases of aseptic meningitis associated with other causative agents requires a specific etiologic diagnosis.

TREATMENT

Because ORO fever has no specific treatment, management is symptomatic. Rest is important and should be continued for several days after disappearance of the initial acute manifestations because relapses are thought to occur more often in patients who prematurely resume regular activities, particularly strenuous ones. Aspirin or another antipyretic should be taken to lower the fever, and the use of ordinary analgesics is recommended for headache, myalgia, and arthralgia. However, certain reported patients whose headaches failed to respond to this treatment were treated with morphine derivatives. Also recommended are fruit juices or glucose solutions. Severely dehydrated patients may be treated with intravenous fluids.

PREVENTION AND CONTROL

The most effective way to prevent, avert, or curb the impact of epidemics of ORO fever is to combat its vector, *C. paraensis*. To be effective, vector control effort needs to focus on the midge's adult and larval forms. Given that *C. paraensis* is habitually active during the day, application of insecticides to its habitats by thermonebulization or ultra-low-volume aerosolization may help to reduce populations of adult biting midges. Because this *Culicoides* species is most active during the late afternoon hours,[25] ultra-low-volume spraying may be more effective during this period. However, carefully planned studies are needed to assess how to

maximize the effectiveness of spraying by determining the type and concentration of insecticide to be used, the necessary volume of insecticide per treatment area, the size of the droplets, the frequency and timing of applications, and other factors. At the same time, making an effort to control the larvae by applying larvicides to corresponding habitats or, better yet, by conducting drives to eliminate or burn breeding sites such as rotting cocoa bean husks and the decomposing trunks of felled banana trees is essential.[8] Obviously, the success of these measures will depend largely on community involvement. Providing proper community education is important. Individuals can protect themselves by applying insect repellent directly to the skin. However, these types of products provide only temporary action, and they may be unaffordable to the poor.

No vaccine against ORO fever exists at this time. In light of the relatively benign nature of this viral disease, developing a general-purpose vaccine for at-risk populations living in areas where they are exposed to the disease is difficult to justify.

CHAPTER 203e

TOSCANA VIRUS

Rémi N. Charrel ● Xavier de Lamballerie

HISTORY

Toscana virus (TOSV) was isolated first in 1971 from the sandfly *Phlebotomus perniciosus* collected in Monte Argentario (Grosseto Province, central Italy).[52-54] Three strains were isolated from female sandflies. So far, most clinical and epidemiologic studies have been conducted in Italy, although studies from other Mediterranean countries have been published more recently. Results of these studies indicate that TOSV is a major viral pathogen involved in aseptic meningitis during summer months in these countries. A bibliographic search using "Toscana virus" as keywords in the PubMed database retrieved 65 research and review articles. Fewer than 50 percent of them reported imported or autochthonous human cases acquired in Italy, Spain, Portugal, France, or Cyprus; the diagnosis was established through viral isolation, polymerase chain reaction (PCR) and sequencing, serology, or a combination of these methods. Despite increasing evidence of its major role in human disease, TOSV remains poorly studied, and most physicians have little awareness concerning its potential to cause central nervous system (CNS) infections. Moreover, TOSV cases were reported from few countries where sandflies are prevalent; whether this factor is an accurate reflection of the reality or whether it relates to a lack of investigation is unknown. Thus, one of the major aims of this review is to disseminate knowledge of the role played by TOSV in human disease and to stimulate interest in conducting new studies to increase our understanding of the prevalence of TOSV in the countries surrounding the Mediterranean.

ETIOLOGIC AGENT: VIRUS PROPERTIES AND CLASSIFICATION

According the eighth report of the International Committee on Taxonomy of Viruses (ICTV), TOSV is a serotype of Sandfly fever Naples virus within the genus *Phlebovirus* in the *Bunyaviridae* family. TOSV is an arthropod-borne virus. The lack of biochemical and genetic data for most phleboviruses dictates that the species be defined by serologic relationships; these viruses are distinguishable by a fourfold difference in two-way neutralization tests. TOSV and Sandfly fever Naples virus cross-react serologically, except in the plaque reduction neutralization test (PRNT), in which a one-way specificity is observed (i.e., TOSV mouse immune ascitic fluid [MIAF] neutralizes Sandfly fever Naples virus and TOSV, whereas Sandfly fever Naples virus MIAF neutralizes only Sandfly fever Naples virus, not TOSV). By using other serologic tests (indirect immunofluorescence assay [IFA], hemagglutination inhibition, complement fixation, enzyme-linked immunosorbent assay [ELISA]), in most cases serologic cross-reactions are observed among TOSV, Sandfly fever Naples virus, and Sandfly fever Sicilian virus. Phleboviruses are arthropod-borne viruses that contain a negative-sense, single-stranded RNA genome that consists of three segments, designated large, medium, and small, that encode the RNA-dependent RNA polymerase,[22] the envelope glycoproteins, and the nucleoprotein, respectively. Phylogenetic analyses performed using the medium segment identified three major lineages separate from Rift Valley fever virus and Uukuniemi virus: lineage 1 includes Sandfly fever Sicilian virus and Sicilian-like viruses isolated from Italy, Cyprus, India, Iran, and Greece; lineage 2 includes Sandfly fever Naples, Naples-like viruses, and genotypes (Tehran and TOSV) isolated from Italy, Portugal, Iran, the former Yugoslavia, Egypt, Cyprus, and India; lineage 3 includes phleboviruses from the New World such as Punta Toro, Buenaventura, and related viruses.[27]

EPIDEMIOLOGY

Phlebotomus fever viruses have been isolated from sandflies in southern Europe, Africa, central Asia, and the Americas, and evidence exists for the presence of different viruses in the same sandfly population. The simultaneous occurrence of Sandfly fever Sicilian virus, Karimabad virus, and Isfahan virus (a *Vesiculovirus*) was documented in Iran,[45] and Verani and colleagues[52] isolated TOSV (associated with human disease) and Arbia (not yet shown to cause infection in man) viruses in Italy in the same sandfly population. Sandfly fever Naples (but not the TOSV serotype) and Sicilian viruses have the widest geographic distribution, parallel to their vector's *(Phlebotomus papatasi)* distribution. Isolation reports and serologic studies indicate that sandfly fever Naples and Sicilian viruses are present in the coastal Mediterranean regions of Europe and North Africa, the Nile valley, most of Southwest Asia, areas adjacent to the Black and Caspian Seas, and central Asia including Bangladesh.[46] Until recent years, the known distribution of TOSV was limited to Italy and Portugal.[18,31] In Italy, the virus was isolated both from the vectors (*P. perniciosus* and *Phlebotomus perfiliewi*) and from humans, whereas the presence of the virus in Portugal was suspected on the basis of a strain isolated from the cerebrospinal fluid (CSF) of a Swedish patient returning to his home country from Portugal. More recently, the geographic distribution of the virus has been extended to France, Spain, Slovenia, Greece, Cyprus, and Turkey, according to results from viral isolation and serologic surveys.[17,21,25,28,33] The geographic distribution of Toscana virus is shown in Figure 203–6.

Figure 203–6 Geographic distribution of Toscana virus in Europe. (See companion Expert Consult web site for color version.)

ITALY

Preliminary clues pointing to the role of TOSV in CNS infections in Italy were provided by case reports of imported cases diagnosed in the United States,[8] and Germany.[42] Italy was the first country where TOSV activity was demonstrated, and subsequently most studies concerning the epidemiology of TOSV were conducted there. A large study carried out between 1977 and 1988 showed that the virus was the cause of meningitis in two different regions of Italy, Tuscany and Marche, with a seasonal peak occurring in August, corresponding to the peak of sandfly activity.[31] Since then, the virus has been isolated in other regions of central and southern Italy. More recently, thanks to reverse transcriptase PCR (RT-PCR) and specific recombinant immunoenzymatic assays, research into TOSV as an etiologic agent of neurologic diseases has been performed in other regions of northern Italy (Emilia Romagna and Piedmont).[23]

Striking evidence that TOSV was the most prominent viral cause of summertime meningitis was reported in the late 1990s.[49] In one of the most comprehensive studies dedicated to CNS infections and viruses, the authors of the study reported that TOSV represented 81 percent of the viruses detected in CSF from patients presenting with meningitis and other CNS infections; TOSV sequences were detected in 85 of a total of 104 samples of CSF that provided positive results for viral sequences (enteroviruses [n = 12], mumps virus [n = 3], herpes simplex virus [HSV] type 1 [n = 3], measles virus [n = 1]). These results were obtained using a PCR system based on a nested protocol previously described by the same authors.[48] It would be interesting to perform a similar study using recently developed, more sensitive diagnostic tools for detecting DNA and RNA viruses that cause CNS infections, namely, real-time PCR assays.

A study of children living in rural or suburban areas of Siena (central Italy) showed that 40 percent of meningitis or encephalitis cases could be linked to infection with TOSV.[7] A 7-year study (1990 to 1996) performed in Siena showed that 52 percent of aseptic meningitis cases in adults were associated with TOSV (seroconversion, presence of immunoglobulin M [IgM], PCR detection).[5] All studies are in agreement regarding the monthly distribution of human cases of TOSV infections: the highest risk of acquiring TOSV is in August (++++), then July and September (++), and finally June and October (+). Populations living in rural areas and with high levels of outdoor activity are at the greatest risk of acquiring TOSV infection. An occupational risk study conducted on forestry workers in Siena, Florence, and Arezzo showed that 77.2% (278/360) of these workers had positive IgG for TOSV (ELISA test) by comparison with an urban population that exhibited a 22 percent prevalence for IgG (64/290). In con-

trast, only 6 percent of forestry workers of the Piedmont area showed TOSV IgG.[50]

The first evidence of TOSV infection in Umbria was published in 2003 in the form of a retrospective study of 93 aseptic meningitis and meningoencephalitis cases recorded from 1989 to 2001. A total of 36 percent and 6 percent of meningitis and meningoencephalitis cases, respectively, could be associated with TOSV through serology-based diagnosis. Of particular interest is the observed 16 percent of IgG-positive individuals in the healthy control population.[23]

TOSV infections in Emilia Romagna were documented for the first time in 2002. A total of nine cases were recorded over a 3-year period (1999 to 2201) with six meningitis cases, two meningoencephalitis cases, and one case of erythema with fever. Of these nine patients, six could be considered imported cases because these patients spent time in Tuscany before the onset of the disease; the three other cases are classified as autochthonous because no traveling out of the province of Emilia Romagna could be documented.[34] Most recently, TOSV was detected in the CSF of patients with meningitis and encephalitis in Naples, southern Italy.[14]

SPAIN

The first case of TOSV infection reported from Spain occurred in the late 1980s in a Swedish tourist after visiting Catalonia and was documented by PRNT.[19] Subsequently, Spanish researchers and physicians reported many cases of TOSV infection and conducted several comprehensive epidemiologic studies demonstrating that TOSV was one the three main causes of meningitis in Spain.[29] A total of 15 strains of TOSV were isolated between 1988 and 1996 from the CSF of patients with acute aseptic meningitis in Granada, Spain.[28] A total of 724 CSF samples from patients with suspected aseptic meningitis were tested through viral isolation in cell culture. TOSV was isolated from the CSF of 17 patients (7% of all viral isolates), 15 of whom were previously reported in the foregoing reference. The first case was diagnosed in June of 1988 and the last in August of 2002.[29] TOSV was ranked as the third most common cause of aseptic meningitis after enteroviruses ($n = 199$, 82% of virus isolation) and mumps virus ($n = 21$), a finding suggesting that its etiologic role in CNS infections in Spain is not as high as observed in central Italy. Investigation of 23 cases of meningitis in patients living in the Mediterranean coast of Spain and of 168 cases of meningitis in patients from all regions of Spain permitted the diagnosis of TOSV infection to be established in 4 (17%) and 5 cases (3%), respectively. These data suggest that the situation in Spain is similar to that observed in France, with lower prevalence of CNS infections compared with that observed in central Italy.

Sequence data obtained from Spanish isolates of TOSV and other phleboviruses confirmed that natural genome variability may hamper establishing the diagnosis of these agents by molecular methods, so this issue must be kept in mind when developing assays. Generic nested RT-PCR, followed by sequencing of the amplified products, was developed for the detection and specific identification of every member of the *Phlebovirus* genus, including TOSV (Table 203–1). A modification of this method, using newly designed primers, also allowed the researchers to make specific direct detection and identification of TOSV isolates originating from different geographic areas. The testing of clinical samples with these assays confirmed the role of TOSV as a causative agent of acute aseptic meningitis in the central region of Spain.[37] All clinical cases of sandfly fever among Swedish tourists that were serologically confirmed during 1986 to 1989 were investigated. Aside from the case of TOSV from Spain, 37 cases of Sandfly fever Sicilian virus infection and one case of Sandfly fever Naples virus infection were documented among tourists returning from Cyprus.[19] A collection of 88 serum and 53 CSF samples taken from 81 selected patients with acute aseptic meningitis of unknown origin, who were living in Madrid or on the southern Mediterranean coast of Spain, was studied retrospectively for the presence of TOSV-specific IgG and IgM antibodies. Specific IgM in serum or intrathecally produced anti-TOSV IgG was detected in 7 patients, 3 residents from the Mediterranean region and the remaining 4 from the Madrid region.[17] A large study conducted in different regions of Spain showed the presence of IgG antibodies to TOSV (26.2%), Sandfly fever Naples virus (2.2%) and Sandfly fever Sicilian virus (11.9%) in 1181 adults and 87 children.[28] A total of 457 serum samples taken from healthy individuals, 2 to 60 years old, from the south of the Madrid region was investigated for anti-TOSV IgG. The overall prevalence of anti-TOSV was 5 percent.[17]

In June of 2003, a collaborative, multidisciplinary network was created in Spain for the study of arthropod- and rodent-borne

viral diseases (the EVITAR network). Within this context, a study on seroprevalence to TOSV infection in Granada (southern Spain) was conducted, for which an exhaustive population study was done. In this work, the overall seroprevalence rate was 24.9 percent. A statistically significant increase in the seroprevalence rate was observed with age (9.4% in individuals <15 years compared with 60.4% in individuals >65 years). In addition, several cases of TOSV were documented in numerous geographic areas of Spain (Badajoz, Málaga, Granada, Almería, Murcia, Alicante, Valencia, Madrid, and Barcelona), mostly in the southern, central, and Mediterranean areas of the country (EVITAR network, Tenorio, A., personal communication).

FRANCE

The first reported case of TOSV infection acquired in France was in a German traveler returning from southern France.[16] The story of TOSV in Italy led virologists in Marseille to develop the tools necessary for establishing the diagnosis based on serology, molecular biology, and traditional virology. A collection of 205 RNA samples comprising human clinical specimens sent to the virology laboratory from April to December of 2001 for suspected enterovirus infections was tested for the presence of TOSV RNA by a previously described nested RT-PCR protocol[48]; 5 of 205 samples were positive, and sequence analysis revealed a 100 percent identity with the homologous region of strain ISS.Phl.3. A total of 72 sera collected from April to September of 2003 in patients admitted for meningitis was tested for the presence of TOSV IgM and IgG using ELISA; 3 of 72 (4.2%) samples were IgM-positive, and 13 of 72 (18%) were IgG-positive (Charrel, R. N., and de Lamballerie, X., unpublished data). A total of 134 sera collected from patients who were admitted for febrile neurologic manifestations (encephalitis, meningoencephalitis, peripheral manifestations, but not meningitis) was tested for the presence of TOSV IgM and IgG; none of 134 samples was positive for IgM, whereas 26 of 134 (19.6%) samples were positive for IgG (Charrel, R. N., and de Lamballerie, X., unpublished data). A similar study was performed with 92 healthy blood donors from Marseille; 11 of 92 (12%) samples were positive for IgG, and 1 of 92 was positive for IgM. Values observed from the latter group were not significantly different from the values obtained across the two groups of patients.

During surveillance for West Nile virus in southern France, sera from suspected cases (meningitis) were tested for TOSV, and several contained specific IgM. Two cases of meningitis caused by TOSV were diagnosed by seroconversion and by viral isolation, the first instance of TOSV isolation reported in the literature from a clinical case.[33] Two other cases (one meningitis and one febrile illness) also have been published.[25] Other sporadic cases have been diagnosed through indirect IFA (presence of IgM, seroconversion) and PCR detection with sequencing, or a combination of both techniques. Sequence analysis of TOSV demonstrates that both the Italian and Spanish genotypes circulate in southern France in sandflies but also cause human infections.[10]

Together, data confirm that TOSV circulates in southeastern France and is responsible for cases of meningitis. Further investigation will be necessary to determine the importance of the role played by TOSV, in comparison with other viruses, in CNS infections in the summertime.

CYPRUS

Several studies were conducted in Swedish United Nations soldiers based in Cyprus in 1985. Blood samples were obtained from the 362-soldier battalion just before and immediately after their 6-month tour of duty. Of 298 serum pairs available, seroconversion for TOSV was observed in a single case without any clinical manifestations.[21] Seroprevalence studies showed that 20 percent (96/479) of the healthy population had TOSV IgG.[20] Every summer, numerous unexplained febrile cases are observed among the Greek Army Forces in Cyprus. For this reason, blood samples were collected from febrile patients in 2001 and 2002. Serology and molecular methods revealed that the causative agent was a phlebovirus. A virus strain was isolated from the blood sample of a patient taken on the first day of the disease. Sequence analysis of a partial L RNA segment revealed that the Sandfly fever virus strain from Cyprus differs from Sandfly fever Sicilian virus by 6.7 percent at the nucleotide level (Papa, A., unpublished data). For six patients from whom a convalescent serum sample was available, all had antibodies to phleboviruses (Sandfly fever Sicilian virus, Sandfly fever Naples virus, and TOSV), detected by indirect immunofluorescent assays. Cross-reactivity in serology was observed among the three serotypes of phleboviruses; a greater number of patients had antibodies to Sandfly fever Sicilian virus and higher antibody titers were present against Sandfly fever Sicilian virus than against Sandfly fever Naples virus and TOSV.

GREECE

Phleboviruses are present in Greece.[45] Results of a study showed that the prevalence of Sandfly fever Naples virus and Sandfly fever Sicilian virus neutralizing antibodies among Athens residents older than 30 years was 36 percent and 13 percent, respectively, whereas 4 percent of younger persons had Sandfly fever Naples virus antibodies, and all were negative to Sandfly fever Sicilian virus.[44] These differences were the result of the insecticide-spraying malaria eradication campaigns.[45] A phlebovirus, strain Corfu (Pa Ar 814), was isolated in 1981, on Corfu island from *Phlebotomus major*.[35] Using spot slides with Vero E-6 cells infected with this strain, researchers found a seroprevalence of 4 percent among healthy farmers, woodcutters, and shepherds.[2] Studies of populations living on the Ionian Islands and western mainland of Greece showed a seroprevalence of 60 percent and 35 percent, respectively, by electroimmunoassay (EIA) (Enzywell TOSV IgG/IgM Diesse) (unpublished data). To date, no studies have been performed of meningitis or encephalitis cases caused by TOSV in Greece.

PORTUGAL

One imported case of TOSV was reported in Portugal, in a man who presented with severe headache and fever without neck stiffness. A CSF sample showed 134 monocytes. Viral isolation was successful, and identification was performed by plaque neutralization.[18] In addition, one German patient returning from vacation in Portugal presented with meningitis; the diagnosis was established by ELISA and confirmed by immunoblot assay.[41]

GERMANY

In a seroepidemiologic survey of 859 health care workers and medical students, anti-TOSV IgG was detected in 1.0 percent of samples by IFA, and in 0.7 percent by EIA. In 2034 German patients hospitalized for various diseases, 1.6 percent tested positive for anti-TOS IgG by IFA and 0.8 percent by EIA. Anti-TOSV IgG was detected in 43 samples of commercial immunoglobulins at titers of 10 to 1000 by EIA. Although the seroprevalence of antibodies to TOSV is low in Germany, TOSV infection should be considered in patients returning from endemic areas who

complain of fever and headaches and who have symptoms of meningitis.[40]

CYCLE IN NATURE

THE VECTORS OF TOSCANA VIRUS

TOSV was isolated first from *P. perniciosus*. Other strains have been isolated from *P. perfiliewi* but never from *P. papatasi*. TOSV also has been isolated from the brains of the bat *Pipistrellus kuhli* trapped in areas where *P. perniciosus* and *P. perfiliewi* were present.[52-54] Isolation from bats has been reported for a large number of mosquito-borne arboviruses, including flaviviruses such as yellow fever virus, dengue virus, West Nile virus, and St. Louis encephalitis virus, with no clear information regarding implications for the ecologic cycle of these viruses. Transovarial transmission of TOSV in sandflies has been demonstrated in the laboratory and by viral isolation from male *Phlebotomus* species. Venereal transmission from infected males to uninfected females also has been demonstrated. *P. perniciosus* is distributed throughout the Mediterranean region as two races. The typical *P. perniciosus* race occurs in Italy as well as in Malta, Tunisia, and Morocco. It is replaced in southern Spain by the Iberian race (with the pni mtDNA sublineage).[32] TOSV was detected both in male and in female pools of phlebotomine sandflies captured during the summer seasons of 2003 and 2004 in Granada. The most probable transmission vector for TOSV in Spain is *P. perniciosus* because approximately 70 percent of captured individuals comprised this species. Detection in pools of males suggests vertical or sexual transmission of TOSV among phlebotomine sandflies. TOSV RNA was detected in *Sergentomyia minuta*, a sandfly known to feed on reptiles and assumed not to feed on humans; this property may prevent *S. minuta* from being a vector of human infection.[9] However, *Sergentomyia* flies have been reported to be infected with a variety of arboviruses.[9]

THE RESERVOIR OF TOSCANA VIRUS

The reservoir of TOSV is most likely the vector. Neither mammals nor birds have been recognized as a potential reservoir, although few studies have been carried out on mammals and almost none on birds. Whether humans can play a role in the virus cycle by infecting naïve sandflies is not known.

Although numerous phleboviruses have been isolated from the blood of sick persons and from wild animals, the importance of vertebrates in the maintenance of the transmission cycle of these viruses remains unclear. Transient and low-level viremia is present after phlebovirus infection in humans and in susceptible laboratory animals.[4,12,43] Moreover, a large quantity of virus must be ingested to infect sandflies.[11] It seems unlikely that a biting sandfly would often come into contact with an animal with viremia high enough to infect the insect orally. Verani and colleagues[52] examined different species of wild vertebrates (wild mouse, bank vole, stone marten, coypus, porcupine, bat, fox, and hedgehog) by serology and viral isolation; one virus strain was isolated from the brain of a bat *Pipistrellus khuli*, whereas no hemagglutination-inhibition antibodies were found in sera.[52]

CLINICAL MANIFESTATIONS

ASYMPTOMATIC OR MINIMALLY SYMPTOMATIC INFECTION

Seroprevalence studies suggest that some infections caused by TOSV are asymptomatic or minimally symptomatic. Additional studies will be necessary to evaluate the ratio of symptomatic to asymptomatic or minimally symptomatic infections.

FEBRILE ILLNESS

In some cases, TOSV infection causes a self-limiting febrile illness without CNS manifestations. These patients usually are neither hospitalized nor investigated further and may account for the probable underestimation of TOSV infection rates.

MENINGITIS

After an incubation period ranging from a few days to a maximum of 2 weeks, the onset of disease is brutal (70%), with headache (100%, 1 to 5 days), fever (76% to 97%), nausea and vomiting (67% to 88%), and myalgias (18%). On physical examination, neck rigidity (53% to 95%), Kernig signs (87%), poor levels of consciousness (12%), tremors (2.6%), paresis (1.7%), and nystagmus (5.2%) are apparent (Loredana Nicoletti, personal communication). In most cases reported so far, CSF samples contained more than 5 to 10 cells with normal levels of glucose and protein. Leukocytosis (29%) or leukopenia (6%) may be observed in the blood. The mean duration of the disease is 7 days, and the outcome usually is favorable.

OTHER CENTRAL NERVOUS SYSTEM MANIFESTATIONS

Although TOSV infection in most cases is a mild disease with a favorable outcome, a few severe cases have been reported in the literature. Two young brothers and a sister living in Umbria experienced TOSV infection in the form of severe meningoencephalitis with stiff neck, deep coma, maculopapular rash, diffuse lymphadenopathy, hepatosplenomegaly, renal involvement, skin rash with lamellar desquamation, tendency for bleeding, and diffuse intravascular coagulopathy. CNS manifestations occurred after 3 weeks of fever. Convalescence was marked by hydrocephalus that required a ventriculoatrial shunt. The diagnosis was established by serologic means and PCR sequencing. The occurrence of such severe manifestations in relatives suggests the existence of an immune defect, although this possibility was not tested.[3] Two cases of encephalitis without meningitis were diagnosed by serology and the detection of TOSV sequences in the CSF; for both patients, the outcome was favorable, without late manifestations.[15] One case of meningitis complicated by abducens nerve palsy was reported in a German tourist returning from Italy.[38] One patient developed chronic meningoencephalitis, with persistence of TOSV (detected by viral culture and RT-PCR) in CSF samples for more than 30 days (Navarro-Mari, J. M., personal communication).

OTHER DISEASE MANIFESTATIONS NOT INVOLVING THE CENTRAL NERVOUS SYSTEM

To date, no published data exist to suggest that TOSV could cause manifestations other than those previously mentioned. However, to our knowledge no study has been designed to investigate the potential of TOSV to cause other manifestations in humans.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

SEROLOGY

Immunofluorescence Assay

Seroconversion and the detection of IgG or IgM can be achieved in cells infected with TOSV. However, cross-reactivity exists

among members of the genus *Phlebovirus* and specifically between TOSV and other serotypes of Sandfly fever Naples virus.

Enzyme-Linked Immunosorbent Assay

ELISA tests have been developed with either crude antigens or purified virus obtained from infected cells. The advantage of ELISA resides in its capacity to test a large number of specimens rapidly; however, cross-reactions most likely also are observed. An ELISA test based on a recombinant nucleoprotein gene has been developed and is now available commercially from an Italian company. More recent seroprevalence studies were based on this test.[17,28]

Plaque Reduction Neutralization Test

PRNT is the test of choice when confirmation of the virus species is necessary. Therefore, careful interpretation of seroprevalence data is necessary because, in most cases, these data were obtained with ELISA or IFA tests that cannot discriminate among Sandfly fever Naples virus, Sandfly fever Sicilian virus, and TOSV.

Although seroconversion remains the serology gold standard for establishing the diagnosis of viral diseases, the presence of specific IgM in a single serum sample is considered to indicate a recent infection. This finding must be interpreted very carefully because, as demonstrated with West Nile virus and certain alphaviruses, TOSV infection may elicit specific IgM lasting for a very long time; Calisher and colleagues reported 418-day persistence in a 66-year-old immunocompetent patient.[8] This finding requires further investigation. TOSV serologic and molecular markers could be investigated concurrently with the screening of blood donors in the regions where the vector circulates and where human cases are reported. Long-term surveillance of TOSV-infected patients could indicate whether persistence of IgM is a common feature of TOSV infection or is rare. With this in mind, the presence of IgM in asymptomatic patients could result from an old infection instead of indicating an asymptomatic recent infection.[6] The major immune response elicited by TOSV infection is against the nucleoprotein. However, all sera that tested positive for IgG against TOSV also exhibited neutralizing properties.

VIRAL ISOLATION

Isolation from clinical samples can be achieved by using CSF but not serum. CSF samples yielding virus recovery by cell culture are collected in the first 2 to 4 days of the disease.

TOSV replicates in a variety of animals; intracerebral, intraperitoneal, and subcutaneous routes lead to death in the newborn mouse; intracerebral and intraperitoneal routes lead to death in the weanling mouse; in the guinea pig and rabbit, intracerebral inoculation results in paralysis and irregular death, whereas intraperitoneal inoculation is not fatal and results in antibody synthesis. *Macaca fascicularis* succumbs after intracerebral inoculation, but recovers with antibody production after intraperitoneal inoculation.[26]

TOSV replicates in Vero, BHK-21, CV-1, and SW13 cells with cytopathic effect but not in C6/36 cells.[26,54] However, cell culture appears to have a low sensitivity for detecting TOSV because only 14 percent of PCR-positive CSF specimens inoculated onto Vero cells led to viral isolation.

GENOME AMPLIFICATION BY REVERSE TRANSCIPTASE POLYMERASE CHAIN REACTION ASSAYS

In some cases, the relatively low level of virus in blood and CSF samples hampers attempts to isolate the virus. In such cases, molecular techniques based on PCR have been shown to be more sensitive than is IgM detection or viral isolation. Three different methods for establishing molecular diagnosis of TOSV have been developed. To date, all studies aimed at the molecular detection of TOSV sequences in the CSF of patients presenting with meningitis or other CNS manifestations have used classic PCR detection through single-round or nested protocols. Tests of an RT-PCR assay alone, without a further nested PCR step, showed that this method did not appear to be valid for the detection of TOSV, because no sample was positive after the first reaction. This result could stem from a very low amount of virus in CSF samples.[48] Two of the three molecular detection systems[39,48] use specific primers for amplification of regions of the S segment, and one is based on degenerate oligonucleotides designed in the L segment.[37] The most widely used system was designed by Valassina and coworkers.[48] It has been used successfully in Italy[49] and France (Charrel, R. N., et al., unpublished data) for establishing TOSV diagnoses. Their primers also have been used in combination with others able to detect enteroviruses in a fast duplex one-step RT-PCR for differential diagnosis of these major neurotropic viruses.[51] In 2003, another method for detecting TOSV was developed.[37] A nested RT-PCR for detecting TOSV of Italian or Spanish origin was produced using degenerate primers. The method is a modification of the generic method used for detecting phleboviruses and is able to detect all the members of the genus, including TOSV. The replacement of one of the generic primers used in the nested reaction by one able to detect only TOSV strains renders the diagnosis of this virus more specific. This method has been used in establishing the diagnosis of Spanish cases of TOSV infection. The description of two genotypes of TOSV according to geographic origin demonstrates a need for caution when designing molecular methods for diagnosis, to avoid obtaining false-negative results.[36] However, all these techniques are time-consuming and require sequence determination to confirm the diagnosis. One of the major drawbacks of molecular techniques, principally those requiring the manipulation of PCR tubes for gel loading and nested PCR reactions, is the risk of contamination. Real-time PCR systems, including a fluorescent dye–labeled probe, have reduced dramatically the risk of contamination because these systems rely on one-round RT-PCR assays without the need for gel loading or sequencing. The sensitivity of clinical tests for human viruses using real-time RT-PCR is close to that obtained by nested PCR protocols, and the results are obtained within 3 hours. Therefore, such technology must now be applied to TOSV diagnosis. However, to develop real-time PCR assays that detect all variants of TOSV circulating in Mediterranean countries and causing diseases in humans, a considerable amount of work on the sequence determination of strains reflecting viral heterogeneity observed in different countries will be necessary. The report of a Spanish genotype, genetically divergent from the strains circulating in Italy, which is not detected by PCR systems previously reported in Italy, underlines the requirement for a large program of strain isolation and full-length genome sequencing to achieve this goal.

GENETIC DIVERSITY OF TOSCANA VIRUS

STRAINS ISOLATED

TOSV has been isolated from sandflies of two different species, *P. perniciosus* and *P. perfiliewi*, as well as from a bat (*P. khuli*) and from humans. Whereas isolation from sandflies is quite common, at least in Italy, isolation from wild vertebrates is a rare event, and to date only one such strain has been isolated. The prototype TOSV strain, ISS Phl.3, was isolated from sandflies *P. perniciosus* in 1971. This strain has been sequenced completely and is used as reference for further genetic studies.[1,13,24] A total of 84 virus

strains was obtained from 16,374 male and female sandflies (*P. perniciosus* and *P. perfiliewi*) collected in two localities of the Tuscany region of Italy between 1980 and 1985. Thirty-seven (44%) strains were identified as TOSV and 47 (56%) were identified as a new member of the *Phlebotomus* fever serogroup, Arbia virus. The overall virus isolation rate from sandflies was 0.5 percent. Viral isolation rates for both viruses were similar in different years and in the two localities, a finding suggesting that the two virus types were active in the sandfly population simultaneously (maximum activity in July).[52] Seventeen strains of TOSV have been isolated in Spain from clinical cases.[29] Several strains have been isolated in southeastern France from clinical cases and remain to be characterized. Sequence analysis of the PCR products from Spanish TOSV isolates from phlebotomine sandflies and patients showed that homology within the nucleotide and amino acid sequences among them was 97 to 100 percent (EVITAR network). Overall, genetic characterization of the strains isolated since 1971 must be achieved through a collaborative network to address numerous unresolved questions rapidly.

GENETIC DIVERSITY

Numerous strains from Italy have been partially sequenced, and only minor differences in nucleoprotein (NP) sequences were found among strains isolated in the early 1980s from both species of sandflies, from the bat, and from humans, with no more than one amino acid substitution.[30] Similar results were described in a study on some variants in the NP gene of strains isolated from humans in the years 1995 to 1998; only one variant showed a single amino acid substitution out of an 80–amino acid region.[47] Changes in the amino acid sequence may render this protein less efficient in its interaction with the viral nucleic acid and possibly may be lethal for the virus and subject to negative selection.

A different situation has been described in Spain for partial sequences in the large segment encoding the polymerase activity. A phylogenetic analysis performed from L segment sequences obtained from 11 clinical isolates from Granada and compared with the homologous sequence of an Italian reference strain showed that Spanish sequences were closely related to one another and distantly related to the Italian strain.[37] This finding suggests the presence of at least two geographically distinct populations of TOSV. Both genetic populations of TOSV circulate in France, geographically located between Italy and Spain.

PHYLOGENY AND EVOLUTION

To date, sequence data are too scarce to perform significant phylogenetic analyses. Therefore, it will be necessary to set up an extensive program of complete genome sequencing of the strains collected in different regions and simultaneously encourage the development of viral isolation programs in all countries surrounding the Mediterranean, where vectors are circulating, to understand more clearly the genetic diversity, phylogenetic relationships, and mechanisms driving the evolution of TOSV.

Retroviridae

CHAPTER 204

HUMAN RETROVIRUSES

CHAPTER 204a

ONCOVIRUSES (HUMAN T-CELL LYMPHOTROPIC VIRUSES) AND LENTIVIRUSES (HUMAN IMMUNODEFICIENCY VIRUS TYPE 2)

Susan L. Gillespie ● Gordon E. Schutze

The discovery of human T-cell lymphotropic virus type I (HTLV-I) in 1980 demonstrated for the first time that humans could be infected by retroviruses, which previously were known as animal pathogens that could cause malignant disease.[7,89,265] HTLV-I subsequently was found to cause adult T-cell leukemia/lymphoma (ATLL) and now is recognized to be associated with the following spectrum of disease manifestations: a chronic degenerative neurologic disease (HTLV-I–associated myelopathy [HAM]/tropical spastic paraparesis [TSP]); relapsing, severe generalized dermatitis in children (infective dermatitis); and numerous inflammatory or autoimmune conditions, or both, such as uveitis, arthropathy, polymyositis, bronchoalveolitis, and Sjögren syndrome.[43,193,208,306] In 1982, a second antigenically related retrovirus of the oncovirus subfamily, HTLV-II, was identified from a patient with a T-cell variant of hairy-cell leukemia.[148] The pathogenicity of this virus remains unclear, although the virus has been found in some individuals with $CD8^+$ lymphoproliferative diseases and neuromyopathies.[93] The more recent discovery of HTLV-III and HTLV-IV demonstrated that diversity among these viruses is greater than previously understood.[373]

This chapter retains selected contributions previously made by Lynne Mofensen.

CLASSIFICATION

Retroviruses form a family of single-stranded RNA viruses that are unusual because they contain a diploid RNA genome that replicates by flow of genetic information through a DNA intermediate, a process known as reverse transcription. The name *retrovirus* is derived from this characteristic. This unique capability results from the presence of a virally encoded, RNA-dependent DNA polymerase, reverse transcriptase, that catalyzes transcription of viral RNA into a double-stranded DNA copy. This viral DNA intermediary becomes integrated into host-cell DNA, where it then resides as a provirus; this process occurs by a specialized recombination mechanism requiring another viral protein, integrase. This capacity for genomic integration

correlates with the capability of retroviruses to cause lifelong infection, evade the usual mechanisms of immune clearance, and produce chronic diseases in the host that manifest only after a long asymptomatic period that may last years to decades. Retroviruses infect both animals and humans.

Retroviruses that infect humans have a more complicated genome that encodes for numerous regulatory genes involved in modulating viral replication. These retroviruses were divided historically into three subfamilies on the basis of nucleotide sequences and genetic organization. The subfamilies were the *Oncovirinae* (oncogenic or transforming viruses, which include HTLV), the *Lentivirinae* (slow viruses with cytopathic effects, which include human immunodeficiency virus types 1 [HIV-1] and 2 [HIV-2]), and the *Spumavirinae* (foamy viruses).

Although they share some similarities in genomic structure and life cycle, the different subfamilies of retroviruses have distinct in vitro and in vivo effects and different strategies for evading host immunity. Oncoviruses generally transform cells in culture, stimulate target-cell proliferation, and cause tumors in their hosts. Lentiviruses cause cell fusion and multinucleated giant-cell formation, are cytopathic in cell culture, and cause slow infections characterized by immunodeficiency in their hosts. The spumaviruses behave like other retroviruses because their viral RNA is transcribed into DNA and then integrated into the host genome. The reverse transcriptase step, however, occurs during budding and assembly, so the genome that is produced is actually DNA, as in the hepadnaviruses. These data suggest that spumaviruses may represent a link between hepadnaviruses and retroviruses.[229] Although no case of spumaviral disease in any natural or human host has been reported, concern exists about the potential threat of human disease because primate workers known to be infected with these viruses have donated blood in the United States.[115] Further data will need to be obtained to understand the potential threat these viruses may represent in the future.

MORPHOLOGY AND GENOMIC STRUCTURE

Retroviruses have a distinct morphology. They are enveloped RNA viruses that have diameters of 80 to 120 nm, a thin, electron-dense outer envelope, and an electron-dense core that is either spherical (HTLV) or cylindric (HIV). The envelope of all retroviruses is composed of a lipid bilayer derived from the host-cell plasma membrane during budding of the virus from the cell surface, with surface projections consisting of the viral envelope proteins (Fig. 204–1). The retroviral core protein encloses a ribonucleoprotein of genomic RNA complexed with viral reverse transcriptase and integrase.[49] The genome is a messenger-sense, linear, single-stranded RNA composed of two identical subunits held together by hydrogen bonds at their 5′ ends. The 5′ and 3′ ends of the RNA contain repeated sequences that give rise to elements in viral DNA called long terminal repeats (LTRs).

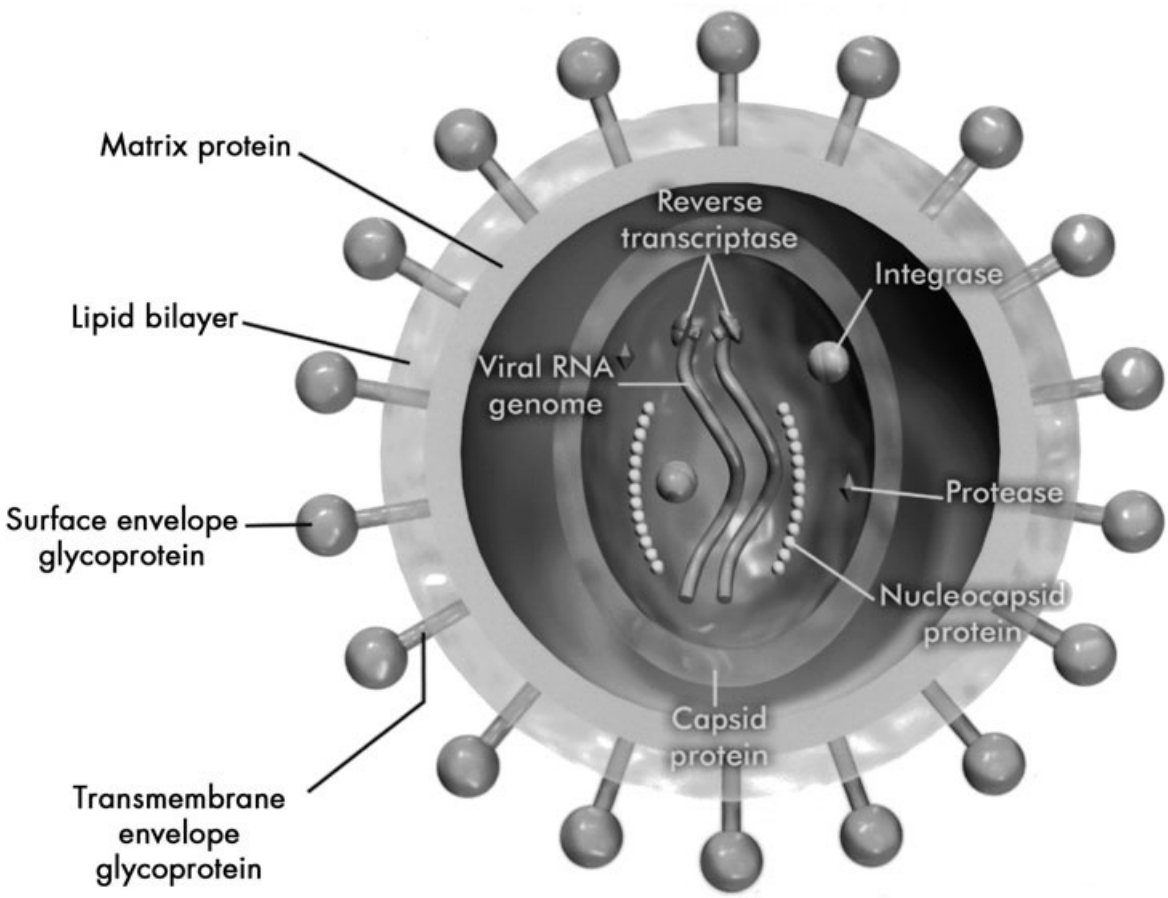

Figure 204–1 Retroviral structure. The mature retroviral virion is spherical; the central viral core is spherical in HTLV oncoviruses and cylindric in HIV lentiviruses. The core is surrounded by a lipid bilayer envelope derived from the host-cell membrane during bussing, the surface projections consisting of the viral surface and transmembrane envelope proteins. The viral matrix protein surrounds the virion core and is associated with the viral transmembrane envelope glycoproteins. The virion core is a structural shell composed of the viral capsid proteins. Within the shell are two copies of single-stranded viral RNA and multiple copies of the virally encoded reverse transcriptase, protease, and integrase enzymes. The viral nucleocapsid protein is bound to the RNA copies and may serve to condense the viral RNA into the capsid shell during virion assembly.

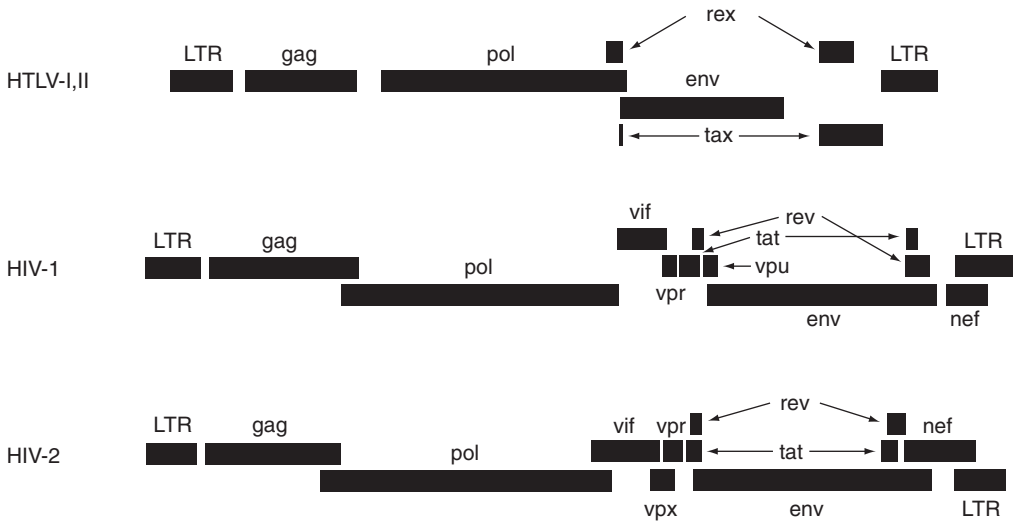

Figure 204–2 Retroviral genome. This schematic depiction of the human T-cell lymphotrophic virus (HTLV) and human immunodeficiency virus (HIV) genomes shows that HTLV has a more complex genome than most animal retroviruses do and that HIV, in turn, has additional regulatory genes. Details of the functions of these genes are summarized in the text. LTR, long terminal repeat. *(Reprinted by permission from Gallo, R. C., Wong-Staal, F., Montagnier, L., et al.: HIV/HTLV gene nomenclature. Nature 333:504, 1988. Copyright Macmillan Magazines, Ltd.)*

The LTRs are composed of nucleic acid sequences that provide signals critical for structural transformation of the viral genome, including initiation and progression of reverse transcription of viral RNA into DNA, integration of viral DNA into the host genome by viral integrase, and initiation of viral mRNA transcription from the integrated provirus and binding sites for viral and cellular proteins and that positively and negatively influence mRNA transcription.[273,328,340,374] Between the LTRs are the genes that encode the major structural proteins of the virus, the enzymes found in the viral particles, and additional proteins with specialized intracellular functions.

As noted earlier, all retroviruses contain a minimum of three genes, *gag* (group-specific antigen), *pol* (polymerase), and *env* (envelope). They are arranged in a 5′ to 3′ order, with LTRs at each end (Fig. 204–2).[105] The *gag* gene encodes the structural protein products that form the core particle of the virus, including nucleocapsid, capsid, and matrix proteins. The *pol* gene products include the enzymes required for genome replication (viral RNA-dependent DNA polymerase and ribonuclease H), proviral integration (integrase), and polyprotein processing (protease). The *env* gene encodes the major components of the viral coat, the surface and transmembrane glycoproteins. Retroviral genes generally are expressed first as large overlapping polyproteins that undergo processing into functional peptide products by viral or cellular proteases.

ONCOVIRAL REGULATORY AND ACCESSORY GENES

In addition to the standard retroviral genes, the oncoviruses HTLV-I and HTLV-II contain several regulatory and accessory genes important for viral replication and activation of host genes that are encoded in open-reading frames (ORFs) in a unique region at the 3′ end of the genome called the pX region.[6,134] The HTLV-I pX region contains four ORFs, whereas HTLV-II contains five ORFs. Two of these ORFs common to both viruses (ORF III and ORF IV) encode the regulatory proteins Rex and Tax.

The *rex* (regulator of expression of virion proteins) gene encodes a nucleolus-localizing phosphoprotein that affects mRNA splicing and export from the nucleus to the cytoplasm. For cellular genes, mRNA splicing and export are tightly coupled. After cellular genes are transcribed into mRNA, splicing occurs in the cell nucleus before mRNA can be exported into the cytoplasm for translation into proteins. Incompletely spliced mRNA molecules are retained in the nucleus.[206,328] However, for retroviral reproduction, the export of full-length, unspliced viral RNA into the cytoplasm is required to serve as genomic RNA for integration into progeny virions and to serve as mRNA for the production of viral structural proteins. Thus, retroviruses had to develop a mechanism to bypass the cellular regulatory process; for HTLV, the Rex protein serves this function. This protein is expressed predominantly at an early stage of viral gene expression and enhances the transport of single-spliced and unspliced viral mRNA coding for structural proteins, as well as transport of the viral genome from the nucleus to the cytoplasm. The Rex protein also exerts a negative effect on the transport of multiply spliced viral mRNA to the cytoplasm. These multiply spliced mRNA molecules code for regulatory proteins, including Rex and Tax.[340]

The *tax* (transactivator) gene encodes a nuclear protein that plays a critical role in the regulation of viral replication and also stimulates a large number of cellular genes involved in activation and proliferation of T cells, including lymphokines, lymphokine receptors, and nuclear proto-oncogenes.[381,382] The Tax protein does not bind directly to DNA but rather interacts with host-cell transcriptional factors to produce a multifaceted array of molecular effects.[22] The Tax protein activates mRNA transcription by binding to several different host-cell transcription-enhancing factors, including those of the nuclear factor NF-κB family. In addition to activating transcription of the HTLV genome, the Tax transcription factor complex acts to stimulate transcription of many cellular genes, including those encoding interleukin-2 (IL-2), IL-2 receptor-α, tumor necrosis factor, cyclooxygenase 2 (a prostaglandin synthetase), and some nuclear oncogenes.[215,381,382] Tax also represses transcription of tumor suppression genes and the expression of cellular DNA polymerase-β, a key enzyme for repair of damaged DNA. Additionally, Tax can bind directly to and inhibit some cell cycle regulation and tumor suppressor proteins, thereby interfering with cell cycle regulation and resulting in abnormal promotion of the cell cycle and enhancement of cellular proliferation.[382] Finally, Tax increases the genetic instability of the cell by impairing cellular DNA repair mechanisms, a process that leads to an accumulation of mutations and an increase in chromosomal anomalies. In vitro, Tax protein can immortalize human T cells and induce tumors in transgenic mice. However, in vivo, malignant disease develops in fewer than 5 percent of HTLV-1–infected individuals. Thus, although the *tax*

gene probably is involved in malignant transformation of infected T cells, it is not sufficient by itself to explain the final development of malignancy.[8,343,381,382]

Less is known about the function of the HTLV accessory proteins that are encoded by the remaining ORFs in the pX region (e.g., p12, p13, and p30 in HTLV-I and p10, p11, p22/20, and p28 in HTLV-II). The best characterized accessory protein is HTLV-I p12 from ORF I, which is a conserved, hydrophobic protein localized to the internal cell plasma membrane and perinuclear regions of the cell.[44] The p12 protein contains amino acid motifs commonly found in proteins involved in intracellular signaling pathways and probably interacts with cellular proteins, perhaps cellular kinases, to modulate intracellular signaling in infected cells. The protein also interacts with the β and γ chains of the IL-2 receptor. This protein may be required for activation of host cells during the early stages of infection, for cellular transformation, and for efficient viral infectivity, similar to the function of the *nef* gene of the lentivirus HIV-1.[4] The corresponding ORF I protein in HTLV-II, p10, does not bind the IL-2 receptor and is not associated with the constitutive activation of the IL-2 signaling pathway that is seen with HTLV-I–transformed cells.[44] These differences may be associated with differences in pathogenicity between the two oncoviruses.

LENTIVIRAL REGULATORY AND ACCESSORY GENES

More detailed data are available about the function of lentiviral genes.[73] The lentiviruses HIV-1 and HIV-2 have more complex genomes containing at least six regulatory genes in addition to *env*, *gag*, and *pol*. The lentiviral genes corresponding to the oncoviral *tax* and *rex* are called *tat* and *rev*; these genes are found in all known human and animal lentiviruses and appear to be essential for replication.[206]

Like the oncoviral *rex* gene, *rev* is expressed early in the viral replication cycle and undergoes splicing in the nucleus; multiply spliced *rev* mRNA transcripts then are exported to produce Rev protein in the cytoplasm. This protein contains a nuclear localization signal that facilitates entry of the protein back into the nucleus. Rev then binds to unspliced viral mRNA at a *cis*-acting Rev response element (RRE) located on the mRNA. A nuclear export signal sequence on the carboxy-terminal domain of Rev next targets the unspliced viral mRNA for export to the cytoplasm by binding to the cellular protein CRM1 (exportin 1) and exiting the nucleus through the host-cell export pathway.[53] The full-length unspliced viral mRNA then serves as a translational template for expression of the Gag and Pol proteins and also serves as genomic RNA for incorporation into new virions.

In contrast to the oncoviral Tax protein, which binds to host-cell proteins and has multiple effects in addition to promoting initiation of HTLV gene transcription, the lentiviral Tat protein binds to an RNA target, the Tat activation region (TAR), located immediately 3′ to the LTR transcription start site, and plays a primary role in the expression of HIV viral transcripts by enhancing mRNA elongation. At least two host-cell cofactors are involved in this process.[328] Cellular cyclin T binds to the activation domain of Tat, which increases both the affinity and specificity of the resulting complex for TAR. A host-cell encoded kinase then is recruited to the Tat-cyclin T-TAR complex and phosphorylates the carboxyl-terminal domain of the host-cell RNA polymerase II, which in turn enhances mRNA transcript elongation.

The remaining lentiviral accessory regulatory genes *nef*, *vpr*, and *vif* provide fine-tuning by enhancing or, less commonly, by diminishing viral replication. Another accessory gene, *vpu*, is found only in HIV-1, whereas HIV-2 and simian immunodeficiency virus (SIV) lack the *vpu* gene but contain a gene called *vpx*. The *nef* gene, like *tat* and *rev*, is expressed early in the replication cycle. Similar to the HTLV-I p12 protein, *nef* encodes a hydrophobic, membrane-associated protein that probably interacts with and modulates cellular signaling pathways and is required for optimal infectivity in vivo and for activation of infected host cells. Nef protein significantly enhances the cytoplasmic delivery of viral particles entering the cell through fusion at the plasma membrane, possibly by enhancing phosphorylation of the viral matrix protein and thereby allowing dissociation of the matrix and associated pre-integration nucleoprotein complex from the virion capsid proteins.[292,328] Nef also down-regulates cell surface expression of $CD4^+$ by accelerating $CD4^+$ receptor endocytosis through interaction with the cytoplasmic tail of $CD4^+$ and a protein complex (AP-2 adaptor complex) responsible for recruiting membrane-associated proteins to clathrin-coated pits for endocytosis.[73] This process reduces the potential interference of membrane-associated $CD4^+$ with the release of budding virions. Major histocompatibility complex (MHC) class I receptor expression also is down-regulated by Nef.

The Vpr protein is present in the virion itself, may act to regulate cellular events after penetration and uncoating of the virus to facilitate viral replication, and is involved in efficient localization of the nucleoprotein pre-integration complex into the nucleus.[49,114] Vpr appears to interact with a specific site on nucleoporins in the nuclear pore complex to facilitate nuclear entry.[328] Similar to the Vpr protein, the HIV-2 Vpx protein is found in the virion and appears to affect the efficiency of early replication events, but the precise mechanism is unknown.[49,179]

The *vif* (virion infectivity factor) accessory gene is expressed late, along with structural and enzymatic proteins. The Vif protein is predominantly cytoplasmic but also exists in a membrane-associated form.[206] Vif protein is phosphorylated by a host-cell protein kinase, which seems to be important for viral growth in primary cells.[104] Vif appears to stabilize the pre-integration provirus; viral particles that are produced in the absence of Vif are incapable of incorporating the provirus into host-cell chromosomes.[206] Vif also may function to prevent premature processing of Gag precursor proteins by viral protease in the cytoplasm, thereby ensuring that the Gag-derived peptides that form the viral nucleoprotein core are available at the plasma membrane for assembly with other viral components.

The HIV-1 *vpu* gene also is expressed late. The Vpu protein is associated with the endoplasmic reticulum in infected cells, where it binds the $CD4^+$ molecule and prevents it from translocating to the plasma membrane; instead, the $CD4^+$ molecule is targeted for proteolysis through the cytoplasmic ubiquitin-proteasome pathway.[73,328] This process prevents trapping and subsequent degradation of HIV envelope proteins by $CD4^+$ in the cytoplasm, thus increasing the ability of the viral envelope proteins to reach the cell membrane. Vpu, like Nef, also down-regulates MHC class I receptor expression. In addition, Vpu may be important in virion assembly and release of particles.[45,92,354]

VIRAL REPLICATION

The lentiviruses can infect and replicate in nondividing, terminally differentiated cells, and transmission can occur by cell-free or cell-associated virus. HIV-1 has high replication rates in vivo, with an average of 10^9 to 10^{10} viral particles produced each day. Free viral particles are estimated to have a half-life of less than 6 hours, and productively infected cells have a half-life of approximately 1 day.[132,243,363] The relentless rounds of reverse transcription rapidly generate extensive viral genetic variation within a single individual that results in a genetically related "swarm," or quasi-species, of viruses and provides the ability to escape the host immune response rapidly.

In contrast, the oncoviruses require that the host cell undergo division for productive infection to be established, and they replicate in vivo largely by mitosis rather than by reverse transcription.[195] In addition, transmission is predominantly, if not solely, accomplished by means of cell-cell contact.[60] The events that occur during primary HTLV infection are reverse transcription of the viral genome, integration of the provirus into DNA, transcription of mRNA, synthesis of viral proteins, and a burst of viral expression. However, after a period of active replication, viral persistence is facilitated by a prolonged phase of clonal proviral expansion produced by transactivation of host-cell genes by Tax, which results in cellular DNA replication and the production of new cells containing the HTLV proviral genome.[218] Unlike viral nucleic acid replication by the error-prone viral reverse transcriptase, cellular mitosis is much less prone to mutation and generates little viral genetic variation. Moreover, the provirus remains hidden from immune surveillance. Thus, oncoviruses have extraordinary genetic stability in comparison with lentiviruses. The genetic variability of the HIV-1 envelope protein that exists within the viral quasi-species in a single individual 5 years after infection is greater than the genetic variability found in all HTLV-I proteins identified worldwide to date.[360]

These differences are related to divergence among the retroviral subfamilies in genetic organization, transcription, and function of the major regulatory genes (*tax* and *rex* for the HTLVs and *tat* and *rev* for HIVs). The Tax and Tat proteins both are transactivating enhancer proteins. However, the HTLV Tax protein interacts with cellular proteins and activates cellular genes, thereby resulting in disruption of the cell cycle and induction of cell proliferation. In contrast, the HIV Tat protein has more focal effects; it recognizes a small RNA domain in the HIV LTR and serves primarily to transactivate HIV replication. The Rex and Rev proteins have similar functions; both interact with genomic mRNA structures (the Rex responsive element and Rev responsive element) to enhance transport of the unspliced and partly spliced viral mRNA molecules from the nucleus to the cytoplasm, and both also down-regulate the transport of multiply spliced mRNA transcripts that encode for early regulatory proteins, including the mRNA molecules coding for themselves. In the oncoviruses, Tax and Rex are derived from the same mRNA, and, therefore, down-regulation of Rex mRNA transport results in decreased Tax mRNA transport and protein production. This process leads to diminished transactivation of HTLV genome transcription and prevents massive viral production. In contrast, the HIV Tat protein comes in two functionally equivalent forms, a 72- and an 86-residue protein. The 72-residue Tat protein is derived from a joint Rev/Tat mRNA, but the 86-residue Tat protein comes from a small Rev-independent mRNA. Although Rev, like Rex, has a negative effect on its own expression, as well as that of Tat, this effect is mitigated by the expression of a Tat mRNA that is not dependent on expression of Rev mRNA, thereby resulting in continued production of the Tat transactivating protein and constant and massive transcription of the HIV genome.

RETROVIRAL LIFE CYCLE

All retroviruses have two phases in their life cycle: an infection phase (including viral attachment, entry, reverse transcription, and proviral integration) and an expression phase (including transcription, translation, assembly, and budding of the virion) (Fig. 204–3).[49] In general, more detail is known about replication in lentiviruses than in oncoviruses.

Infection Phase of Retroviral Replication

Retroviruses attach to cells through recognition and binding of viral outer surface envelope proteins to specific proteins on the surface of the host cell; such cell surface receptor specificity probably accounts for the species and cellular tropism of retroviruses.[145,239] The surface glycoprotein of the retroviral envelope has three structural and functional domains separated by conserved hinges and is noncovalently linked to the transmembrane protein by disulfide bonds. The envelope transmembrane protein anchors the entire envelope glycoprotein complex on the virion surface and is responsible for the fusogenic capacity of the viral envelope. The transmembrane protein of all retroviruses has several conserved motifs, including a "leucine zipper" coiled motif followed by the N-terminal hydrophobic "fusion peptide" responsible for fusion with the host-cell membrane. After binding of the viral surface protein to the host-cell receptor occurs, conformational changes permit correct exposure of the transmembrane fusion peptide to the host-cell membrane. The interaction of several fusion peptides may serve to destabilize the lipid bilayer of the target-cell membrane by forming a "fusion pore" between the two bilayers[82] to facilitate fusion of the viral and cellular membranes and release of the viral RNA-protein complex into the cytoplasm.[103,317,343]

The cell surface receptor for HTLV-I and HTLV-II has not been characterized completely. Oncoviruses transmit infection primarily by fusion of infected cells with uninfected cells and the subsequent formation of syncytia. In HTLV-I, fusion is thought to be mediated by the HTLV envelope proteins expressed on the surface of infected cells and by cell adhesion molecules, such as vascular cell adhesion molecule type 1 (VCAM-1), intracellular adhesion molecule type 1 (ICAM-1), ICAM-3, and the membrane permease CD98, on target-cell surfaces.[22] Although HTLV-I envelope–expressing infected cells can form syncytia with cells from most cell lines, in vivo, HTLV-1 is found only in $CD4^+$ lymphocytes.[60] In contrast, HTLV-II displays a preferential tropism for cells of the $CD8^+$ T-lymphocyte phenotype.[139,172]

The lentiviruses HIV-1 and HIV-2 infect cells that express $CD4^+$, the human leukocyte antigen (HLA) class II receptor, on their cell surface.[239] These cells include $CD4^+$ T lymphocytes, cells of the monocyte/macrophage lineage, and microglia in the brain. A high-affinity interaction between the surface glycoprotein and the $CD4^+$ receptor produces a conformational change that results in exposure of another site with high affinity for a secondary co-receptor required for the entry of HIV-1 and some HIV-2 isolates into the cell. The chemokine receptor CCR5 is the co-receptor used by monocyte/macrophage-tropic HIV-1, whereas the CXCR4 chemokine receptor is used by T-lymphocyte-tropic HIV-1; although most HIV-1 strains use only one receptor, some strains of HIV-1 are dually tropic and can use both receptors.[30,63,70,246] Additional co-receptors may support the entry of more restricted types of HIV isolates. For example, the chemokine receptor CCR3 is used by some macrophage-tropic HIV-1 strains and mediates entry of the virus into microglia; CCR2b, CR8, STLR/STRL-22, GPR15, GPR1, and the cytomegalovirus protein US28 also support entry by various HIV-1 and HIV-2 strains.[110,328] Whereas nearly all strains of HIV-2 can use $CD4^+$ together with the chemokine receptor CCR5 or CXCR4 (or both), most HIV-2 isolates also can interact with multiple other co-receptors.[216,296] Additionally, some HIV-2 isolates can use CXCR4 or other receptors, such as CCR3, as a primary receptor and infect cells lacking the $CD4^+$ molecule.[74]

Early post-entry events include uncoating of the virus, which appears to require interaction of viral structural proteins with host-cell components that may have been incorporated into the virion during viral assembly. In HIV-1, interaction of the viral capsid protein with the host-cell cyclophilin A that is associated with the virion core during viral assembly may destabilize the multimeric capsid complex.[180,328] Additionally, a virion-associated host-cell protein kinase phosphorylates the viral matrix protein and thereby allows dissociation of the capsid and nucleocapsid proteins from the rest of the virus at the cell membrane. The

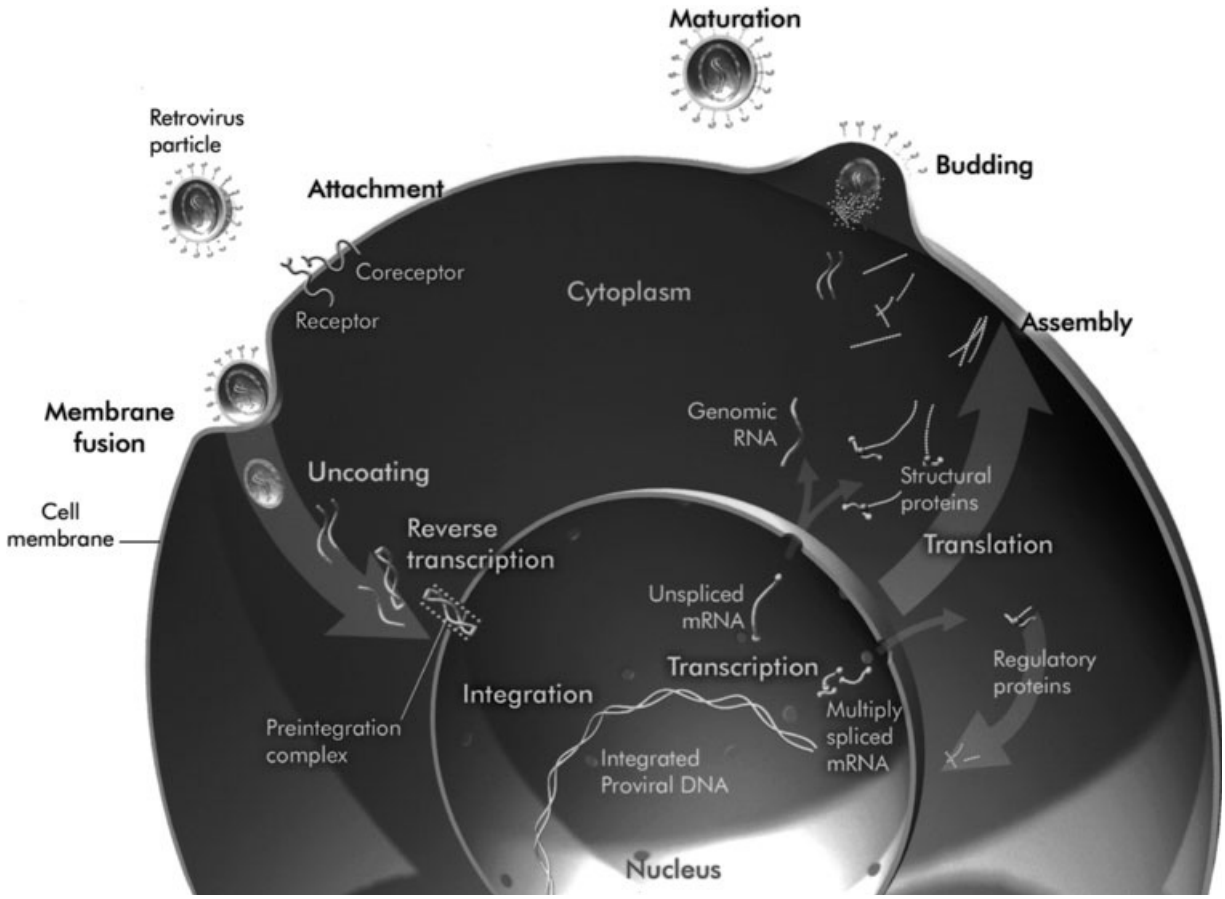

Figure 204–3 Life cycle of retroviruses. Details of viral replication are discussed in the text. *(Adapted from Furtado, M. R., Callaway, D. S., Phair, J. P., et al.: Persistence of HIV-1 transcription in peripheral blood mononuclear cells in patients receiving potent antiretroviral therapy. N. Engl. J. Med.* 340:*1620, 1999.)*

HIV-1 Vif protein, which co-localizes with the Gag-derived proteins, is thought to confer enhanced stability to the remaining cytoplasmic viral nucleoprotein complex.

Retroviral RNA-to-DNA transcriptional events are initiated in the cytoplasm through the action of the viral enzymes reverse transcriptase (RNA-directed DNA polymerase) and ribonuclease. Viral single-stranded RNA is transcribed into a viral RNA/DNA hybrid complex by the DNA polymerase; the ribonuclease then destroys the original RNA and permits the DNA polymerase to complete transcription of a second DNA strand to form a linear double-stranded DNA copy of the original viral RNA.[103] Retroviral integration is mediated by a large nucleoprotein complex that forms in the cytoplasm and is called the *pre-integration complex*. This complex includes the viral nucleic acids and a subset of viral proteins, including the matrix protein, reverse transcriptase, integrase, and, in the lentiviruses, Vpr.[328] The viral integrase enzyme component of this complex recognizes specific sequences within the viral LTR and cleaves two nucleotides from the 3′ ends as an initial processing step for integration; this process occurs while the pre-integration complex is still in the cytoplasm.[14] Integrase appears to be the principal viral determinant of integration specificity.[174] In the lentiviruses, which can infect nondividing cells, the pre-integration complex is imported actively into the nucleus during interphase. Nuclear transport is mediated by nuclear localization sequences on the matrix protein and on integrase and by interactions of Vpr with nucleoporins in the nuclear pore complex.

Once nuclear entry has been gained, the integrase joins the recessed 3′ ends to phosphates in the host DNA for insertion of the DNA duplex into the host genome.[14,50] A final step in integration is thought to involve cellular factors involved in DNA repair, in particular, a DNA-dependent protein kinase. This kinase is hypothesized to repair gaps left by the integrase around the sequence inserted into the host DNA; the result is a fully integrated provirus.[50,56]

Expression Phase of Retroviral Replication

Once viral DNA is integrated into the host cell, the proviral genome resembles other cellular genes and becomes highly dependent on the host cell for further replication, with the host-cell machinery used for replication, expression, and production of protein. Regulation of transcription is a complex process requiring interaction among the integrated proviral LTRs, host-cell DNA transcription factors, and the lentiviral Tat protein or oncoviral Tax protein.

The early phase of viral gene expression is characterized by the presence of spliced and unspliced viral mRNA in the nucleus, but only multiply spliced mRNA in the cytoplasm. In HTLVs, these mRNA molecules serve to direct production of the Tax and Rex regulatory proteins; in HIVs, they direct production of the Tat, Rev, and Nef proteins. The transition from early regulatory to late structural gene expression is characterized by the selective transport of unspliced and partially spliced mRNA into the cytoplasm; as discussed previously, in lentiviruses, this process depends on sufficient amounts of the Rev protein and, in oncoviruses, the Rex protein.[49,343] The unspliced or partially spiced mRNA transcripts that enter the cytoplasm encode for structural proteins

and are first expressed as large overlapping polyproteins. These polyproteins undergo processing into functional peptide viral structural components by the action of virally encoded and host-cell protease enzymes.

The retroviral Env protein is synthesized as a large precursor protein; it undergoes initial glycosylation in the endoplasmic reticulum, with subsequent disulfide bonding, folding, and oligomerization, and then is transported to the Golgi complex, where it is cleaved by a host-cell protease into surface and transmembrane proteins, which undergo further glycosylation.[60] The two mature glycoproteins are noncovalently associated through disulfide bonds. After cleavage occurs, the complexed proteins are transported and inserted into the plasma cell membrane by the cellular secretory pathway.[81]

The retroviral *gag* and *pol* genes are transcribed into a single mRNA transcript, which subsequently is translated into two separate polyprotein precursors, the Gag and Gag-Pol precursor proteins; the Gag-Pol polyprotein is translated by a ribosomal frame shift between the Gag and Pol mRNA reading frames. The Pol component of the Gag-Pol precursor protein is cleaved to form the viral enzymes reverse transcriptase, ribonuclease, and protease. The Gag precursor encodes the major structural proteins of the virion core, which do not undergo proteolytic processing into mature proteins until after assembly of the immature virion at the plasma membrane occurs.

Virion assembly and budding occur through targeting, accumulation, and association of different domains of the Gag and Gag-Pol precursor proteins at the inner face of the plasma membrane where the envelope proteins are being expressed.[81,83,275,353] The M domain, an amino acid sequence contained in the N-terminal area of the matrix portion of the Gag protein, has a membrane-targeting sequence that directs the Gag and Gag-Pol polyproteins to the cytoplasmic face of the plasma membrane. Myristylation of the N-terminal portion of some (lentiviruses) or all (oncoviruses) of the Gag precursor protein matrix domain is required for membrane targeting to occur and to allow Gag protein assembly at the membrane. In lentiviruses, the matrix domain interacts with the long cytoplasmic tail of the viral envelope transmembrane protein inserted into the membrane of the cell.[83] The I domain, an amino acid sequence contained in the nucleocapsid portion of the Gag polyprotein, participates in the Gag-Gag interactions to promote protein polymerization and also appears to be required for incorporation of the Gag-Pol precursor into virions.[81] The nucleocapsid domain of the Gag polyprotein interacts with viral genomic RNA through specific (sequence-specific nucleic acid binding) and nonspecific (interaction of basic residues with RNA) mechanisms and plays an important role in RNA binding, dimerization, and encapsidation and in facilitating Gag protein interactions and packaging into tight complexes.[48,81]

The interactions of these three domains in the precursor protein thus lead to assembly and emergence (but not release) of the viral "bud" from the cell surface.[260] On electron microscopy, large, electron-dense patches of Gag multimers are visualized under the plasma membrane that deform the membrane outward as they grow. More advanced intermediates appear as spheres connected to the cell by a thin stalk. During the process of budding, substantial amounts of cellular surface antigens, such as β_2-microglobulin and HLA-DR, are incorporated into the viral envelope. Additionally, during the process of virion assembly, host-cell proteins may be incorporated into the virion. For example, in HIV-1, a host-cell protein, cyclophilin A, interacts with the Gag polyprotein to form a complex in the virion core.[80,332] This host factor appears to be required for the formation of infectious virions, and it may play a role in early events after viral entry, as discussed earlier.[328]

In addition to the capsid, nucleocapsid, and matrix protein domains, other polypeptide segments that are required during the late stages of viral assembly are contained in the Gag polyprotein. They are referred to collectively as "late assembly" or "L" domains, and they are found in both lentiviruses and oncoviruses. In lentiviruses, the C-terminal portion of Gag (p6) includes a highly conserved amino acid motif that is needed to recruit the cellular machinery required for efficient release of budding virus from the cell membrane.[260,298,313,353] The Gag protein of oncoviruses also contains a late domain, although it is located in the N-terminal region of the protein.[313] Some investigators have suggested that these domains engage in interactions with host proteins that are located at the plasma membrane and that facilitate final release of the budding virus from the cell.

In HIV-1, the late domain is thought to interact with the cellular protein ubiquitin. Ubiquitin is a small protein present in cells that, together with cellular proteasomes, is involved in collecting or destroying cellular proteins that are damaged or no longer needed; it exists in cells as a free molecule or is covalently attached to lysines in a variety of proteins. When a protein is linked to multiple ubiquitin molecules (polyubiquitination), the protein becomes targeted for degradation by cellular proteasomes. However, when a protein is linked to a single ubiquitin molecule (mono-ubiquitination), instead of degradation, protein function is modulated; for example, mono-ubiquitination of plasma membrane receptor proteins promotes internalization and down-regulation of the receptor through endocytosis in a nonproteolytic process that has some similarities to virus budding. After protein degradation occurs, the ubiquitin molecule is recycled as a free molecule. HIV-1 particles have been shown to contain ubiquitin, predominantly as a free molecule, but 2 to 5 percent of the Gag-derived, late assembly domain protein p6 is mono-ubiquitinated.[313] One hypothesis is that the late domain of Gag contains an amino acid sequence that binds to residues on the ubiquitin ligase enzyme and thereby results in mono-ubiquitination of the Gag protein. The Gag-ubiquitin conjugate then may attract undefined cellular factors, perhaps those normally involved in endocytosis, that trigger release of the retrovirus from the cell membrane.[260] In the absence of the late domain, an infected cell becomes covered with virus that remains tethered to the plasma membrane by narrow stalks.

Maturation of the virion requires cleavage of the Gag precursor by the virally encoded protease and triggers structural changes that produce mature virions with the characteristic spherical oncoviral or cylindric lentiviral capsid. The Gag polyprotein gives rise to the following: the matrix protein, which lines the inner face of the viral membrane; the capsid protein, which forms a core shell surrounding the viral RNA genome and its associated proteins; and the nucleocapsid protein, which coats and condenses the RNA genome. This step occurs concomitantly with or immediately after the external budding process.

GENERAL METHODS OF DIAGNOSIS OF RETROVIRAL INFECTION

Detection of retroviral antibody has been the test most widely used to diagnose infection in older children and adults. However, because of transplacental passage of maternal antibody, antibody testing during infancy is not diagnostic of infection, and direct viral detection methods are necessary for establishing the diagnosis. In addition, during primary infection, a window period exists during which ongoing viral replication is detectable by virologic tests, but antibody tests will be negative or indeterminant because a detectable antibody response has not developed.

Antibody testing for retroviruses most frequently involves the use of an initial screening test followed by performance of a more specific confirmatory test. Initial screening generally involves the detection of viral antigens from disrupted whole virus or synthetic or recombinant viral antigens in an enzyme-linked

immunosorbent assay (ELISA). A positive ELISA is confirmed by the more specific immunoblot (or Western blot), which measures the presence of antibodies to a number of virus-associated proteins, both structural and nonstructural. Viral antigens (from disrupted whole virus or synthetic or recombinant antigens) undergo electrophoresis through polyacrylamide gel to separate the antigens by size. The separated antigens then are transferred to nitrocellulose paper, incubated with the patient's serum, and subsequently incubated with enzyme-linked antihuman antibody and chromogenic substrate, which results in visible bands where patient antibodies are bound by antigens. Analysis of band patterns permits more specific identification of the virus. Other techniques used to measure antibodies to retroviruses include indirect immunofluorescence assay (IFA), radioimmunoprecipitation assay (RIPA), and biologic assays for antibody to envelope glycoproteins (neutralization or syncytium inhibition assays).

Because antigenic differences exist between HIV-1 and HIV-2, HIV-1 screening tests are not reliable for the detection of HIV-2. A commercial HIV-1/HIV-2 combination assay is available that has high sensitivity for detection of both viruses; a supplemental immunoblot assay is used to confirm the viral subtype.[41,196] Serologic diagnosis of HTLV infection is similar to that of HIV and involves the use of a screening enzyme immunoassay (EIA) and confirmatory immunoblot or RIPA. However, these tests do not distinguish between antibodies directed at HTLV-I or HTLV-II.[43] In patients with positive serology, virologic detection tests, such as proviral amplification by polymerase chain reaction (PCR) or viral isolation, have been used.[57] Assays containing several synthetic peptides and recombinant proteins have been developed and appear to be capable of differentiating between HTLV-I and HTLV-II.[31,280]

Direct detection of virus by culture is intensive, expensive, and time-consuming; several weeks often are required for results. The ability to isolate HTLV and HIV depends on the patient's disease state, immune status, and viral load. The ability to culture retroviruses has been improved by co-cultivation of patient cells with human peripheral blood mononuclear cells that have been stimulated in vitro with mitogens (e.g., phytohemagglutinin) and growth factors (e.g., IL-2), as well as by removal of patient $CD8^+$ (suppressor) cells from the co-culture. In infants and children, the small volume of blood available for culture and the low virus load in some cases may render virus isolation challenging.

Other methods used for detecting virus include (1) antigen capture assays to detect free circulating viral antigens (e.g., p24 HIV-1 core antigen), (2) IFA and immunohistochemistry to detect viral antigens in tissue, (3) detection of viral nucleic acids by Southern blot analysis, (4) in situ hybridization or dot blots, (5) PCR to detect proviral DNA in leukocytes or tissue, and (6) assays to detect viral RNA in plasma or other fluids. DNA PCR can be used to quantitate virus and is highly sensitive because it is capable of amplifying tiny quantities of viral nucleic acids enzymatically to detectable levels with a system of specific nucleotide primers and probes. This technique can be modified to detect viral RNA by using reverse transcription to convert viral RNA to DNA and by performing PCR on the DNA product or by using other techniques such as branched-chain amplification or nucleic acid sequence-based amplification.[35,257,310]

ONCOVIRUSES: HUMAN T-CELL LYMPHOTROPHIC VIRUS TYPES

HUMAN T-CELL LYMPHOTROPHIC VIRUS TYPE I

HTLV-I was the first human retrovirus identified and was isolated initially from a patient with cutaneous T-cell lymphoma.[265] HTLV-I now is known to be the causative agent of adult ATLL, neurologic disorders (HAM/TSP), infective dermatitis in children, and numerous other disorders that are possibly autoimmune (Table 204–1).

EPIDEMIOLOGY

Evaluation of the global distribution of HTLV-I initially was complicated by the considerable antigenic similarity between HTLV-I and HTLV-II (≈60% homology in nucleotide sequences). The first ELISA and Western blot assays designed to detect HTLV were not able to discriminate between the presence of antibodies to HTLV-I and those to HTLV-II; DNA PCR was required to distinguish type-specific proviral sequences. Thus, early epidemiologic studies often were unable to distinguish between HTLV-I and HTLV-II infection. Second-generation assays use synthetic type-specific peptides that enable researchers to differentiate between HTLV-I and HTLV-II antibodies.[31,280] More recent studies have been able to discriminate the epidemiologic distribution of the two viruses more accurately.

On a global basis, an estimated 15 to 25 million individuals are infected with HTLV-I. Based on genetic analysis, HTLV-I is classified into three major types.[207,379] The Melanesian type, which was isolated from Melanesians in Papua New Guinea and

TABLE 204–1 Diseases Associated with Human T-Cell Lymphotrophic Virus Types I and II

Strength of Association	Human T-Cell Lymphotrophic Virus Type I	Human T-Cell Lymphotrophic Virus Type II
Strong	Adult T-cell leukemia/lymphoma	Neurologic disorders (spastic paraparesis/ myelopathy to more widespread central nervous system involvement)
	Myelopathy (HTLV-1–associated myelopathy tropical spastic paraparesis)	
	Infective dermatitis	
	Uveitis	
	Arthropathy	
	Interstitial pneumonitis

Weak	Renal failure	
	B-cell leukemias	
	Small cell lung cancer	

HTLV-I, human T-cell lymphotrophic virus type I.

the Solomon Islands in the South Pacific and from Australian aborigines, is the most divergent in that it exhibits only 93 percent sequence similarity in the envelope gene with other HTLV-I strains.[17,380] The other two HTLV-I types exhibit 97 percent sequence similarity. The second distinct genetic type is found in central Africa. The third, the Cosmopolitan type, includes isolates from various areas, and it represents the majority of HTLV-I isolates. The Cosmopolitan group has been divided further into four subtypes based on LTR sequencing: Transcontinental (A), Japanese (B), West African (C), and North African (D). Subtype A, the most widespread, has been isolated from Japan, the Caribbean basin, South America, India, Iran, far-eastern Russia, and South Africa (hence the name "Transcontinental"). Subtypes B and C are more restricted geographically, with subtype B found primarily in Japan and rarely in India and subtype C found in West Africa and the Caribbean basin. Subtype D was identified more recently in Morocco, Algeria, and North Africa.

Because the genetic variability and intra-subtype genetic drift of HTLV-I are limited, the geographic distribution of viral types has been hypothesized to represent the anthropologic movement of virus-carrying populations over the course of time.[379] Most HTLV-I isolates from the same ethnic group in different locations and from different groups inhabiting the same area have phylogenetic similarities. For example, in North and South America and the Caribbean, most HTLV-I isolates belong to subtype A and are thought to have originated from ancestral Mongoloid peoples who migrated from Asia to the American continents. In addition to subtype A, subtype C has been identified in the Caribbean and may reflect forced migration of black slaves from West Africa to the New World. Two HTLV-I subtypes have been found in Japan, with subtype A predominant in the northern and southern territories and subtype B more predominant in southwestern Japan; this dispersion has led to speculation that these differences reflect immigration of different populations to different areas of the Japanese archipelago.

HTLV-I is highly endemic in southwestern Japan, particularly on the islands of Kyushu, Shikoku, and Okinawa, where roughly 30 percent of the adult population is seropositive.[134,376] Geographic clustering of HTLV-I infection in southwestern Japan is observed, and marked variation may be observed within small geographic areas; such microclustering has been speculated to be attributable to the limited interchange, particularly intermarriage, between neighboring communities in Japan.[376]

Regions of moderate HTLV-I endemicity include areas of the Caribbean, such as Jamaica, Trinidad, Barbados, and the West Indies, where seroprevalence rates range between 2 to 5 percent in black adults.[18,189,223,361] Parts of Africa also appear to have large reservoirs of HTLV-I infection; possible endemic areas have been identified within Gabon, Chad, Nigeria, Cameroon, Guinea, Democratic Republic of Congo (formerly Zaire), and the Ivory Coast.[43,65,349] The seroprevalence rate in the African adult population is approximately 0.5 to 1 percent; however, the distribution of HTLV-I is not uniform and is characterized by clusters of high endemicity. Foci of HTLV-I infection also have been identified in Central and South America, including Panama, Brazil, Colombia, Venezuela, Surinam, Guyana, Ecuador, and Peru.[52,223] HTLV-I seroprevalence rates in Brazilian blood donors range from 0.08 percent in the south to 1.8 percent in the northeast, although seroprevalence in specific populations such as Brazilian Indians has been as high as 38 percent.[52,87,201] The HTLV-I seroprevalence rate in pregnant women in northeastern Brazil was 0.84 percent.[24]

HTLV-I seroprevalence in low-risk populations in the United States and Europe is less than 1 percent. Seroprevalence rates in blood donors in the United States in the year after initiation of blood screening were 0.016 to 0.021 percent. Female donors and blacks, Hispanics, and Asians were more likely to be seropositive than were male donors and whites.[40] During the same period, seropositivity in applicants for the U.S. Armed Forces was similarly relatively low but twice that observed in blood donors, 0.41 per 1000.[281] Similar to the demographics observed for seropositive blood donors, the prevalence in black applicants was more than 30 times that in white applicants, and a disproportionate rate of seropositivity in female applicants was observed. Clusters of HTLV-I infection also have been reported in blacks in the southern and southeastern United States and in immigrants from HTLV-I–endemic areas.[64,68,133,364] HTLV-I seroprevalence rates in blood donors in Europe have ranged between 0 and 0.02 percent.[333] In inner-city London, HTLV seroprevalence in pregnant women was 1.1 per 1000 women, with the highest prevalence noted in women from the Caribbean (17.0 per 1000) and western and central Africa (3.2 per 1000); in women born in nonendemic areas and who were not black Caribbean, seroprevalence was 0.06 to 0.12 per 1000.[3]

Factors that influence HTLV-I seropositivity are age, race, sex, and geography. In endemic areas, the prevalence in children is low but starts to increase during the teenage years; this age-related increase is more marked for girls and women than for boys and men. By 40 to 50 years of age, women are significantly more likely to be infected than are men. This sex- and age-related pattern may be the result of more efficient male-to-female sexual transmission of HTLV-I among sexually active adults.[29,324]

With the development of advanced immunoassays, differentiating the epidemiology of HTLV-II and HTLV-I infection has been possible. In a study of 1.7 million blood donors in the United States, the prevalence of HTLV-I and HTLV-II infection was 9.1 and 22.3 per 100,000 donors, respectively.[228] Thus, approximately 30 percent of volunteer blood donors found to be HTLV-seropositive are infected with HTLV-I, and 70 percent are infected with HTLV-II.[152] HTLV-I seroprevalence was associated with the following: older age; female sex; hepatitis C seropositivity; black, Hispanic, or Asian race/ethnicity; and birth outside the United States.[228] These data are consistent with HTLV-I infection in the United States in that it is concentrated primarily in persons born in or having sexual contact with persons from HTLV-I–endemic areas of Africa, the Caribbean, and Japan. In contrast, HTLV-II has been found primarily in injecting drug users and their sexual contacts.[152]

MODES OF TRANSMISSION

HTLV-I does not replicate efficiently in vivo and is transmitted through infected T cells in breast milk, semen, and blood. Modes of transmission of HTLV-I are similar to those of HIV-1: sexual contact, parenteral transmission through blood transfusion of a cellular blood product or through intravenous drug use, and perinatally, most often through breast milk. The efficiency of transmission of HTLV appears to be significantly lower than that of HIV because HTLV is highly cell-associated, whereas HIV can be transmitted in a cell-free and cell-associated manner.

Sexual Transmission

Sexual transmission is a significant source for acquisition of HTLV-I in adults. Male-to-female sexual transmission appears to be more efficient than is female-to-male transmission.[376] In one study from Japan, the risk of transmission of HTLV-I from an infected husband to his wife over a 10-year period was 61 percent, whereas the risk of transmission from an infected wife to her husband was less than 1 percent.[147] Sexual transmission of HTLV-I from infected men to their wives in Japan increased with older age of the male partner and elevated HTLV-I antibody titer, thus suggesting that a longer duration of infection and an elevated viral load may be associated with increased transmissibility.[314]

Data from studies in the United States are consistent with the findings in Japan. Risk factors for male-to-female sexual transmission of HTLV-I were examined in the Retrovirus Epidemiology Donation Study, which, since 1988, has enrolled from five participating blood centers volunteer blood donors who have been found to be seropositive for HTLV. The proportion of female sexual partners of infected men who were infected themselves (38%) was nearly twice that of male partners of infected female donors (20%).[152] In addition, ratios of transmitter-to-nontransmitter couples were similar for HTLV-I and HTLV-II, thus suggesting similar transmission efficacy of the two viruses. HTLV-transmitting men had been in their sexual relationships longer (mean, 225 versus 122 months) and had proviral loads higher than those of nontransmitters. Transmitting men also tended to have higher antibody titers against various viral proteins than did nontransmitters; in general, antibody titers correlated highly with viral load.

In Japan, rates of seropositivity also were found to be higher in persons with a history of sexually transmitted diseases, a finding suggesting that disruption of the genital mucosa or an increase in leukocytes in genital secretions and semen, or both, may increase the risk of transmission.[236] In studies from several different countries, prevalence of HTLV-I was found to be elevated in female sex workers.[61,99,236,371] The lack of consistent use of condoms, the duration of prostitution, older age, infection with *Chlamydia trachomatis* or syphilis, antibody to herpes simplex virus type 1, and concomitant HIV-1 infection were associated with elevated HTLV-I prevalence.[99,236] An increased risk for HTLV-I seropositivity also was observed in persons attending clinics that treat sexually transmitted diseases.[78,157,236,367] In such clinics in the United States, HTLV seropositivity ranged from 0.18 to 2.0 percent.[157] Risk factors for the acquisition of HTLV-I infection by women included multiple sexual partners, bruising during sex, syphilis, and concomitant HIV infection, whereas for men, hepatitis B antigenemia, bruising during sex, older age at onset of sexual activity, married status, and an agricultural occupation were associated with an increased risk.[78]

Homosexual men in endemic areas have an increased risk of acquiring HTLV-I, presumably through anal intercourse. In Trinidad, HTLV-I seropositivity was sixfold higher in homosexual men than in the general population, and in Baltimore, Maryland, male-to-male sexual activity was associated with an elevated risk of seropositivity in men seen in clinics for sexually transmitted diseases.[16,367] The higher rate of HIV than HTLV infection in homosexual men in Trinidad is an indication of the higher efficiency of HIV transmission.

Mother-to-Child Transmission

HTLV-I infection does not appear to interfere with the course of pregnancy and is not associated with congenital abnormalities.[24] However, mother-to-child transmission of HTLV-I is the major source of infection in children. Studies in Japan showed that more than 90 percent of HTLV-I–seropositive children have mothers who are seropositive themselves; overall, 15 to 25 percent of children born to infected women become infected.[86,123,147,341,369] Transmission to the infant appears to occur predominantly post partum, as reflected by infant seroconversion to seropositivity after the loss of passively transferred maternal antibodies. Depending on the study, 11 to 40 percent of breast-fed children of HTLV-1–infected women become infected versus 0 to 13 percent of bottle-fed children.[122,124,245,325,337,369,370,383] Numerous variables, including longer duration of breast-feeding, elevated maternal HTLV-I antibody titer, high maternal HTLV-I proviral load, presence of HTLV-I–bearing cells in breast milk, female gender of the child, older maternal age, long duration of membrane rupture (>4 hours), and lower maternal income, are associated with a risk of transmission of HTLV-I.[121,122,124,154,191,325,341,369,370]

Substantial evidence supports the conclusion that most incidents of transmission of HTLV-I occur through breast-feeding.[123] HTLV-I antigen has been detected in the breast milk of seropositive mothers, and HTLV-I proviral DNA has been identified by PCR in mononuclear cells from the breast milk of HTLV-I–carrier women.[158,233] HTLV-I infection of milk cells may not be restricted to T lymphocytes. Breast-derived luminal epithelial cells, which are present in human milk during early and long-term lactation, can be infected persistently with HTLV-I and undergo transformation in vitro. These cells can transmit HTLV-I infection to epithelial cells in breast milk or the intestines or to T cells derived from milk or blood.[312] In a marmoset animal model, transmission of HTLV-I was shown to occur by oral feeding of lymphocytes from the breast milk of HTLV-1–infected mothers.[159,378] Lymphocyte-facilitated infection of gastrointestinal epithelial cells has been hypothesized to be the mechanism for transmission.[385]

The risk of transmission through breast milk most likely is multifactorial and involves the duration of exposure, the amount and activation level of the virus, and the presence of protective or enhancing specific and nonspecific immunity. The median time to infection in a Jamaican cohort was estimated to be 11.9 months.[86] A duration of breast-feeding longer than 6 months appears to be associated with at least a threefold increased risk of transmission.[325,369,370] In one study in Japan, no child who was breast-fed for less than 6 months became infected, and in a study in Jamaica, children born to mothers with higher titers of HTLV-I antibody had a delayed time to seroconversion, a finding thus suggesting that passive transfer of maternal HTLV-I antibody may affect transmission timing and risk.[191,323,325] In an experimental rabbit model, passive immunization with HTLV-I hyperimmunoglobulin prevented milk-borne transmission of HTLV-I.[291] However, in some studies, higher levels of maternal antibody were associated with a higher risk of transmission, presumably because higher antibody levels may reflect a higher viral load.[369] Current recommendations are to provide formula feeding for infants born to HTLV-I–seropositive women.[43,122] However, in situations in which formula feeding is not possible, cessation of breast-feeding when the child reaches the age of 6 months, or earlier, may reduce the risk of transmission.[326]

Transmission may be possible, albeit infrequently, during the in utero or intrapartum period. Approximately 3 to 4 percent of infants born to carrier mothers are infected despite being bottle fed, a finding suggesting that intrauterine or intrapartum transmission may occur, but with much lower efficiency than with transmission through breast milk.[122,156,323] The finding that the duration of rupture of the membrane is associated with transmission of HTLV-I suggests that some percentage of transmission may occur intrapartum. HTLV-I has been shown to infect intestinal and cervical epithelial cell lines in vitro.[384,385] A study in 2002 used PCR to evaluate 41 children born to HTLV-1–infected mothers but who had not been breast-fed. No infected children were identified, but 81 percent of the babies were delivered by elective caesarian section.[26] This type of delivery has been demonstrated to be an effective measure against transmission of HIV, so it may affect the transmission of HTLV as well.

Parenteral Transmission

Parenteral transmission by transfusion and intravenous drug use is well documented and appears to be the most efficient mode of transmission, with a 15 to 60 percent chance of infection occurring in those receiving HTLV-1–infected cellular products.[250,279] Comparative rates of transmission of HTLV-I, HTLV-II, and HIV-1 were evaluated retrospectively in a large repository of U.S. blood donor serum from the Transfusion Safety Study.[67]

Consistent with a requirement for cell-cell contact for transmission of HTLV and in contrast to HIV-1, transmission of HTLV-I and HTLV-II was observed only with the transfusion of cellular blood components. Infectivity appeared to decrease with an increasing period of blood storage; no apparent transmission occurred after the transfusion of components stored more than 10 days, a finding suggesting that the known decrease in the ability of donor lymphocytes to be activated or to proliferate with storage renders the cells non-infectious. In this study, rates of transfusion-related transmission of HTLV-I and HTLV-II were similar; approximately 27 percent of recipients of blood components from seropositive donors became infected. In contrast, 89 percent of the recipients of HIV-1–positive blood became infected, regardless of the blood product component type, and no effect of storage on transmission risk was seen. The median time to seroconversion after the transfusion of HTLV-I–contaminated blood products is 51 days.[46]

In a study of HTLV-infected blood donors, both HTLV-I and HTLV-II infection was associated with low educational attainment, accidental needle-sticks or cuts, previous blood transfusion, seven or more sexual partners, and a sexual partner from an HTLV-I–endemic area.[297] However, injection drug use or having sex with injecting drug users was associated with HTLV-II only and not with HTLV-I infection.

Screening of blood donors in the United States since 1988, as well as in other countries such as Japan, reduced transfusion-related transmission markedly. However, in countries in which screening of blood for HTLV-I and HTLV-II is not performed, transfusions provide an important source of infection. In a study of hospitalized children in Gabon in Africa, multiple blood transfusions secondary to complications of sickle-cell disease were as predominant a mode of transmission of HTLV-I as was perinatal transmission.[62] Similarly, in Martinique, HTLV-I seroprevalence in patients with sickle-cell anemia was 10 percent versus 1 to 3 percent in normal blood donors, and HTLV-I–seropositive patients had received more transfusions than had seronegative persons.[290]

Descriptive studies have suggested that ecologic factors may influence the rate of seropositivity in a population; for example, residence in a lower-altitude, tropical environment was associated with higher rates of seropositivity in some reports.[189,204] A role for insect vectors, such as mosquitoes, was postulated. However, no evidence has shown that retroviruses can replicate in arthropods, and any hypothesized insect-borne transmission would need to occur mechanically by the mouth parts of biting insects that were contaminated with a significant amount of infected and infectious lymphocytes; such transmission, if it occurred, would be expected to be very unusual.[79] Additionally, the prevalence of antibodies to arboviruses was not significantly greater in HTLV-seropositive than in HTLV-seronegative persons.[221]

DISEASE ASSOCIATIONS

After being infected with HTLV-I, most infected individuals remain clinically asymptomatic for life. However, persistent viral infection and antigen production elicit a strong humoral and cellular immune response in infected individuals that results in high antibody titers to HTLV-I structural and regulatory proteins and increased circulating activated HTLV-I Tax protein–specific cytotoxic T lymphocytes.[54,138] In addition, even in asymptomatic patients, spontaneous in vitro proliferation of lymphocytes is observed.[164]

Early in the course of primary infection, the HTLV-I proviral load is high but becomes controlled rapidly. Within 90 days of primary infection, a narrow range of proviral load is observed in an individual that generally stays relatively constant over the course of time.[194,249,330] Antibody titer is highly correlated with proviral load after the initial set-point is reached. The HTLV-I proviral load in asymptomatic HTLV-I carriers can be as high as 5 percent of all peripheral blood mononuclear cells, and it is particularly high in individuals with HAM/TSP, in whom as many as 20 percent of peripheral blood mononuclear cells can be infected.[194,217] A high peripheral blood proviral load appears to predate the development of neurologic and ophthalmologic HTLV-I–associated disease entities.

In adults, the diseases associated with HTLV-I infection are malignancies and chronic degenerative neurologic syndromes. Pediatric manifestations of HTLV-I infection have been identified, and researchers now recognize that these diseases may occur more commonly in children and adolescents than previously recognized.[26] HTLV-I may be a prototype for other retroviruses yet to be discovered that predispose to the development of active diseases with long latency after exposure at birth or early in life.

ADULT T-CELL LEUKEMIA AND OTHER MALIGNANCIES

ATLL was the first clinical disease to be linked with HTLV-I infection. This aggressive form of leukemia/lymphoma first was described in Japan in 1977, before the discovery of HTLV-I. Although an infectious origin was postulated because of geographic clustering of ATLL in southern Japan, only after the discovery of HTLV-I in 1980 was a causal link established between HTLV-I seropositivity and ATLL.[265] ATLL is the most common form of leukemia in Japan, with approximately 700 new cases diagnosed yearly.[321,322]

ATLL is found primarily in HTLV-I–endemic areas or in migrants from such areas. The incidence of ATLL in the United States is low; cases are seen primarily in immigrants from HTLV-I–endemic areas or in blacks in the southeastern United States, in whom endemic HTLV-I infection has been documented.[274] In a study in central Brooklyn, which has a large Caribbean migrant population, the annual incidence of ATLL in African Americans was approximately 3.1 per 100,000 person-years.[176]

ATLL occurs more commonly in women in Africa and the Caribbean but more commonly in men in Japan (male- to-female ratio of 1.4:1).[126,261] The mean age at onset is between 40 and 60 years; however, the average age at onset of ATLL is somewhat lower in patients from the Caribbean and Africa (43 years) than in those from Japan (58 years).[376] The disease very rarely occurs in children. The incubation period for ATLL appears to be 20 to 30 years or longer after infection with HTLV-I, and researchers have postulated that ATLL results from HTLV-I infection acquired during the first few years of life.[227] The lifetime risk for development of ATLL is estimated to be 2 to 5 percent in individuals infected before reaching the age of 20 years.[43,193,220]

During the long latent period of HTLV-I infection, most infected individuals show polyclonal proliferation of cells harboring integrated HTLV-I provirus. Asymptomatic HTLV-I carriers may experience a pre-ATLL state associated with mild leukocytosis or the presence of abnormal lymphocytes with characteristic lobulated nuclei ("flower cells") that are found to have monoclonal or oligoclonal HTLV-I provirus integrated into the cell genome. More than 50 percent of such persons will experience resolution of the leukocytosis spontaneously. Why ATLL develops in only a small percentage of HTLV-1–infected individuals is not clear. Because malignant transformation probably is a multistep process, intermediate factors such as the host immune response or oncogenic environmental stimuli, or both, may be involved.[134] Diagnostic criteria for ATLL[307] are shown in Table 204–2.

Clinical manifestations of ATLL include lymphadenopathy in 50 to 80 percent of patients and hepatosplenomegaly in 25 to 67 percent (Table 204–3). Skin lesions, which occur in 40 to 60

percent of patients, include the following: large nodules; plaques; ulcers; a generalized papular rash appearing on the limbs, trunk, or face; or any combination of these lesions. An elevated white blood cell count ranging from 10,000 to 300,000/mm^3 occurs in approximately two thirds of patients, and abnormal T lymphocytes (flower cells) containing lobulated nuclei may be seen. Hypercalcemia occurs in 32 to 63 percent of patients. In patients with hypercalcemia, ATLL cells have been found to secrete excessive amounts of parathyroid hormone–related peptide, probably because of Tax-mediated transactivation of the gene for this protein.[72] Osteolytic bone lesions occur in 2.5 to 10 percent. The central nervous system (CNS), which is affected in 2.5 to 10 percent of patients, can act as a sanctuary and has been found to be an important site for relapse when chemotherapy is given to treat ATLL.[261] Opportunistic infections occur commonly because of the defective T-cell–mediated immunity observed in ATLL and are a primary cause of mortality. In patients with preexisting infestation with the roundworm *Strongyloides stercoralis*, a hyperinfection syndrome accompanied by gram-negative sepsis may occur and has a mortality rate of greater than 70 percent. Other common opportunistic infections include bacterial infections, *Pneumocystis* pneumonia, and serious fungal infections. Findings indicative of poor survival include age older than 40 years, increased tumor bulk, poor performance status, high lactate dehydrogenase level, hypercalcemia, and the presence of clones of cells containing multiple or defective copies of the HTLV-I provirus.[183,277]

TABLE 204–2 Requirements for Diagnosis of Adult T-Cell Leukemia/Lymphoma

1. HTLV-I seropositivity
2. Histologic or cytologic proven lymphoid malignancy with T-cell surface antigens present
3. Abnormal T lymphocytes ("flower cells") consistently present in peripheral blood (except for lymphoma subtype of ATLL)
4. Demonstration of clonality of proviral DNA as well as clonal integration of proviral DNA

ATLL, adult T-cell leukemia/lymphoma; HTLV-I, human T-cell lymphotrophic virus type I.

TABLE 204–3 Clinical Findings in Adult T-Cell Leukemia/Lymphoma

Median Age of Onset	40-60 yr
Gender	Caribbean, Africa: females > males Japan: males slightly > females (1.4:1)
Clinical/Laboratory Findings	
Generalized lymphadenopathy	50%-80%
Hepatosplenomegaly	25%-67%
Skin involvement	40%-60%
Elevated white blood cell count	60%-66%
Hypercalcemia	32%-63%
Pulmonary involvement	14%
Lytic bone lesions	2%-10%
Central nervous system involvement	2%-10%

Clinical and laboratory criteria have been used to differentiate ATLL into four subtypes: acute, chronic, lymphoma, and smoldering (Table 204–4).[42,261,307,376] The distribution of clinical ATLL subtypes varies geographically. In Japan, most cases are acute ATLL with leukemic manifestations; however, in the Caribbean, most cases are initially of the lymphoma subtype.[176,177]

Acute ATLL is the rapidly aggressive form of leukemia/lymphoma that was recognized first in Japan. It is the most common subtype and has the shortest survival time. Clinical findings include the following: characteristic cutaneous involvement in 40 percent of patients that ranges from a maculopapular rash to tumorous lesions; leukemia with circulating abnormal lymphocytes; generalized lymphadenopathy, hepatomegaly, splenomegaly, or any combination of these conditions; lytic bone lesions; hypercalcemia; and immunodeficiency leading to opportunistic infections. Either chronic or lymphoma-type ATLL is seen in approximately one fifth of patients with ATLL. Chronic ATLL has a more indolent clinical course than does acute ATLL, with a median survival of approximately 24 months. Chronic ATLL

TABLE 204–4 Clinical Subtypes of Adult T-Cell Leukemia/Lymphoma: Clinical and Laboratory Findings

	Adult T-Cell Leukemia/Lymphoma Clinical Subtype			
	Acute	**Chronic**	**Lymphoma**	**Smoldering**
Percentage with Subtype	57%	19%	19%	5%
Survival				
Median	6 mo	24 mo	10 mo	>24 mo
Four-year rate	5%	27%	6%	63%
Clinical Findings				
Lymphadenopathy	±	±	Yes	No
Hepatomegaly/splenomegaly	±	±	±	No
Skin involvement	±	±	±	±
Bone lesions	±	No	±	No
Bone marrow involvement	±	No	±	No
Laboratory Findings				
Absolute lymphocyte count ($\times 10^9$)	≥4	≥4	<4	<4
Abnormal circulating lymphocytes	≥5%	≥5%	≤1%	≥5%
Polylobulated lymphocytes ("flower cells")	Yes	Occasional	No	Occasional
Calcium	Normal or elevated	Normal	Normal or elevated	Normal
Lactate dehydrogenase	Normal or elevated	<2 times normal	Normal or elevated	<1.5 times normal

**If less than 5% of circulating abnormal lymphocytes are present in the smoldering adult T-cell leukemia/lymphoma subtype, at least one histologically proven lesion from the lungs or skin should be present.*

overlaps with cases of T-cell chronic lymphocytic leukemia and is associated with moderate leukocytosis in which 0.5 to 3 percent of circulating cells are malignant. Cutaneous manifestations may be observed, but nodal or extranodal involvement occurs rarely, and hypercalcemia is absent. Lymphoma-type ATLL has a median survival of approximately 10 months and overlaps with T-cell non-Hodgkin lymphoma, with prominent lymphadenopathy and the presence of monoclonally integrated HTLV-I in the malignant cells and little to no peripheral blood involvement. Smoldering ATLL occurs least commonly, in approximately 5 percent of patients, and is relatively indolent. It is characterized by abnormal cells in the absence of leukocytosis and resembles mycosis fungoides with slow progression, cutaneous involvement manifested as erythema or infiltrative plaques or tumors, and mild lymphadenopathy or splenomegaly, or both.

The pathogenesis of ATLL is not known. The typical phenotype of ATLL cells is $CD3^+$, $CD4^+$, $CD8^-$, and $CD25^+$ (IL-2 receptor-positive). Monoclonal HTLV-I provirus is found integrated into the DNA of ATLL malignant cells. HTLV-I is known to transform normal $CD4^+$ lymphocytes in vitro and results in immortalization, high levels of IL-2 expression, and increased expression of the IL-2 alpha-chain receptor on the cell surface. The presence of excessive receptors for IL-2, a known growth factor for T cells, may be linked to development of the proliferative leukemic process of ATLL.[376] Additionally, the HTLV-I Tax protein activates the promoters of many genes involved in cell growth and differentiation and interferes with DNA repair functions.[218] One hypothesis is that the continuous proliferation observed in HTLV-1–infected cells may render them more susceptible to spontaneous mutagenesis, as well as to the effect of external carcinogens.[1] Although tax does not directly transform cells and has no homology to known proto-oncogenes, the finding that persistent clonal expansion of HTLV-1–infected cells precedes the development of ATLL suggests that tumor cells may originate in clonally expanding nonmalignant cells through a multistep process that may include the acquisition of mutations in genes such as *p53* or *p16*.

The host immune response also may be involved in malignant transformation. An association between progression to ATLL and HTLV-I antibody titer has been reported. In a study of 5 cases of ATLL and 38 matched HTLV-1–infected controls without ATLL, researchers found a 1.6-fold increase in the risk of ATLL with every 2-fold increase in HTLV-I antibody titer.[125] However, despite having higher HTLV-I antibody levels, all patients with ATLL had low or undetectable levels of HTLV-I anti-Tax antibody for as long as 10 years preceding the diagnosis of ATLL when compared with HTLV-I carriers without ATLL. Malignant ATLL cells also are less likely to express detectable levels of Tax mRNA and are more likely to have partial deletion of the HTLV-I genome. The Tax protein is the major target of cytotoxic T cells in HTLV-I infection, and suppression or defective expression of the Tax protein on the surface of infected cells may permit escape from immune-mediated cell lysis.[125] Indeed, HTLV-1–infected patients with ATLL have poorly detectable Tax-specific cytotoxic T-cell activity,[150,248] which could permit more unrestrained proliferation of infected cells and lead to increased HTLV-I viral load, higher HTLV-I antibody levels to non-Tax viral proteins, and, eventually, malignant transformation.

Treatment regimens for ATLL remain unsatisfactory, with high rates of relapse. Combination chemotherapy with cytotoxic agents results in a complete response in 20 to 45 percent of individuals, but the duration of the response is short, generally lasting only a few months.[261,320] The combination of zidovudine and interferon-α has been shown to be active in the treatment of ATLL, even in patients in whom conventional multiagent chemotherapy has failed.[96,119] Because viral replication is not required for malignant transformation to ATLL and the level of viral replication during the leukemic phase of ATLL is barely detectable, clinical response is not likely to result directly from an antiretroviral effect of these drugs. Zidovudine produces cytostatic effects through termination of DNA replication and may exert direct antitumor effects; this agent has been shown to block HTLV-I–induced cell transformation in vitro. Interferon-α has multiple biologic effects, including an antiproliferative effect through inhibition of protein synthesis and cell growth, and it also may enhance immune recognition of tumor cells by inducing the expression of MHC molecules on the tumor cell surface. However, although survival is prolonged, this therapy is not curative, and relapse occurs. Novel treatments are being investigated. ATLL cells are known to overexpress IL-2 receptor on their surface. Therefore, immunotherapy with toxin-conjugated monoclonal antibodies to the alpha chain of the IL-2 receptor has been studied in clinical trials, with remissions lasting from 9 weeks to 3 years.[356-358] Topoisomerase inhibitors and retinoids also have been evaluated.[261] In vitro, ATLL cells are susceptible to lysis by Tax-specific cytotoxic T cells, a finding that led to the hypothesis that stimulation of cellular immunity to Tax may inhibit tumor growth.[150,248] In a rat model, the use of an HTLV-I Tax-directed DNA vaccine induced cytotoxic T-cell activity against Tax-expressing cells, and adoptive transfer of these cells effectively suppressed in vivo growth of HTLV-I–transformed tumor cells.[248]

Other malignant diseases have been associated with HTLV-I infection, although the supporting evidence for these associations is less clear than that for ATLL. Cutaneous T-cell lymphomata, such as mycosis fungoides and Sézary syndrome, have been described in adults and a child with HTLV-I infection.[18,107,355,388] In one small study of eight patients with Sézary syndrome, HTLV-I mRNA expression was found in four patients.[95] Multiple myeloma and B-cell chronic lymphocytic leukemia also have been described in patients infected with HTLV-I. These malignancies may arise as a result of chronic antigenic stimulation of B cells by HTLV-1–infected T cells, with such stimulation leading to uncontrolled B-cell expansion. In the Caribbean, HTLV-I has been associated with the development of T-cell non-Hodgkin lymphoma.[192] A single case of small cell cancer of the lung with monoclonally integrated HTLV-I in the tumor was reported. A pulmonary infiltrative syndrome resembling lymphoid pulmonary hyperplasia seen in HIV-1–infected children has been reported in patients with HTLV-I–associated myelopathy.[316]

HUMAN T-CELL LYMPHOTROPHIC VIRUS TYPE I–ASSOCIATED MYELOPATHY

In the 1880s, a "multiple neuritis" syndrome consisting of a predominantly ataxic motor neuropathy was reported in Jamaica. In subsequent years, similar syndromes of unknown origin were described in other geographic locales and given different names, including *Strachan disease*, *central neuritis*, *Jamaican neuropathy*, *tropical spastic paraplegia*, and *tropical spastic paraparesis*.[389] The identification of HTLV-I in 1980, the development of antibody tests to diagnose HTLV-I infection, and the recognition that HTLV-I and TSP were endemic in the same geographic locations led to the hypothesis that these entities could be associated. In 1985, Gessain and colleagues[94] performed a case-control study in Martinique in which patients with TSP of unknown cause were compared with a control group of nurses and blood donors without neurologic disease. Sixty percent of the patients with TSP versus only 4 percent of controls had HTLV-I serum antibodies detected.[84,94] In the same year, a report was published on the detection of HTLV-I antibodies in the cerebrospinal fluid (CSF) and serum of individuals afflicted with TSP.[284] In 1986, a series of Japanese patients with a similar clinical syndrome who

also had HTLV-I antibodies in their CSF were described, and these investigators proposed that the syndrome be called *HTLV-I–associated myelopathy*.[253] At a 1988 meeting of the World Health Organization's (WHO's) Scientific Group on HTLV-I Infections and Its Associated Disease, researchers proposed that HAM and HTLV-I–associated TSP were clinically and pathologically identical and recommended that the disorder be known by the acronym *HAM/TSP*.[375]

The disease usually occurs in HTLV-I–endemic areas, including the Caribbean, southern Japan, equatorial Africa, Central and South America, Melanesia, and southern Africa. Sporadic cases have been described in nonendemic areas, usually in immigrants from endemic areas or their sexual contacts or in recipients of blood transfusions (before the advent of HTLV blood screening). Incidence and prevalence estimates are unreliable because of the insidious nature of the disease and the lack of recognition of early symptoms by clinicians. In HTLV-I–seropositive persons in Japan, the incidence of HAM/TSP is 3.1 per 100,000 HTLV-1–infected persons per year. In contrast, the annual incidence of HAM/TSP in HTLV-1–infected persons in Jamaica and Trinidad was 22.1 per 100,000 persons.[187] This difference in incidence is hypothesized to reflect an association between the time that HTLV-I infection is acquired and the type of disease manifestation that occurs. In the Caribbean, most HTLV-I infection is acquired sexually during adult life, and HAM/TSP is the most common clinical manifestation of the disease; in contrast, in Japan, most infection is acquired by maternal-to-child transmission during infancy, and ATLL is the most common disease manifestation. Case reports of HAM/TSP occurring after receipt of blood transfusions and the finding in Japan and Martinique that 13 to 20 percent of patients with HAM/TSP had a history of receiving blood transfusions accelerated the decision of blood banks in the United States to screen for HTLV-I antibodies. In Japan, a 16 percent decrease in the number of HAM/TSP cases occurred in the 2 years after initiation of blood screening.[88,252]

Although the mean onset of disease is in the fourth decade of life, incubation of this disease appears to be shorter than that of ATLL. In patients with HTLV-I infection acquired by transfusion in whom HAM/TSP subsequently developed, the median time to development of symptoms after receiving a transfusion was 3.3 years, and in one report, HAM/TSP occurred 18 weeks after blood transfusion.[100,252] Onset of symptoms is uncommon in persons younger than 20 or older than 70 years. However, HAM/TSP was reported in a child as young as 6 years old after the development of transfusion-acquired HTLV-I infection.[252] The rate of HAM/TSP increases with age from 20 through 50 years and then declines.[184] The lifetime risk of HAM/TSP in an HTLV-1–infected person is estimated to be 1.9 percent overall, with a slightly higher incidence in women (1.8%) than in men (1.3%).[187]

The clinical features of HAM/TSP include chronic progressive spastic paraparesis and weakness of the limbs, particularly the legs, that results in an insidious onset of gait disturbance (Table 204–5). Mild sensory loss and painful paresthesias may develop and result in complaints of extremity numbness or dysesthesia and low back pain. Bowel and bladder sphincter impairment may occur and cause constipation, urinary frequency or incontinence, and impotence. Neurologic examination shows hyperactive deep tendon reflexes, clonus, extensor plantar reflexes, proximal muscle wasting, and a spastic paraparesis with a slow, scissoring gait; mild sensory changes may be observed. Cognitive function and the cranial nerves usually are spared. Systemic nonneurologic symptoms suggestive of an autoimmune process, such as pulmonary alveolitis, uveitis, arthropathy, Sjögren syndrome, and vasculitis, also may be noted.[134,135,316] Progression is variable; 10 years after onset, 30 percent of patients are bedridden, and 45 percent require crutches to walk.[97]

Nonspecific lesions of the brain are observed with magnetic resonance imaging (MRI) in as many as 75 percent of patients, but no clear correlation has been established between the lesions and symptoms. Atrophy of the spinal cord may occur, usually in the thoracic region. Multiple foci of increased T2 signal intensity are found in the periventricular white matter, similar to the findings observed in patients with multiple sclerosis. However, cognitive impairment may be noted in multiple sclerosis but is not found in HAM/TSP, and HTLV-I sequences have not been detected in the peripheral blood or CNS of patients with multiple sclerosis.[251]

High HTLV-I antibody levels are found in both peripheral blood and CSF. In CSF, mild to moderate pleocytosis, increased

TABLE 204–5 Clinical Findings in Human T-Cell Lymphotrophic Virus Type I–Associated Myelopathy/Tropical Spastic Paraparesis

Incidence	Primarily sporadic and occurring in adults, rare in childhood; female preponderance (2:1)
Onset	Usually insidious, rarely abrupt
Main neurologic findings	Chronic spastic paraparesis, slowly progressive
	Leg weakness, more marked proximally
	Bladder disturbance with urinary incontinence usually early, constipation later; impotence or decreased libido
	Paresthesias (tingling, pins/needles, burning) more prominent than objective physical signs
	Low lumbar pain with radiation to legs
	Impaired vibration sense, proprioception less often
	Hyperreflexia of lower limbs, often with clonus and Babinski signs
	Hyperreflexia of upper limbs; weakness may be absent
	Exaggerated jaw jerk in some patients
	Normal cognitive function
Less frequent neurologic findings	Cerebellar signs, optic atrophy, deafness, nystagmus, other cranial nerve deficits, hand tremor, absent or depressed ankle jerk
	Rarely, convulsions, cognitive impairment, dementia, impaired consciousness
Other possible neurologic findings	Muscular atrophy, fasciculation (rare), polymyositis, peripheral neuropathy, polyradiculopathy, cranial neuropathy, meningitis, encephalopathy
Possible systemic non-neurologic findings	Pulmonary alveolitis, uveitis, Sjögren syndrome, arthropathy, vasculitis, ichthyoses, cryoglobulinemia, monoclonal gammopathy, adult T-cell leukemia or lymphoma
Laboratory diagnosis	Detection of HTLV-I antibodies or antigens or viral isolation in blood and CSF
	Mild lymphocytic pleocytosis in CSF
	Lobulated lymphocytes in blood or CSF
	Mild to moderate increase in protein in CSF

CSF, cerebrospinal fluid; HTLV-I, human T-cell lymphotrophic virus type I.

protein, or oligoclonal immunoglobulin bands (or any combination of these findings) may be observed. Elevated CSF neopterin, an indicator of cellular immune activation, may be present. In approximately 50 percent of patients, atypical flower lymphocytes are observed and account for approximately 1 to 15 percent of peripheral blood lymphocytes; these cells also may be seen in CSF.[135] Unlike the monoclonal integration observed in ATLL, polyclonal integration of HTLV-I is noted in cells from patients with HAM/TSP.

Pathologically, HAM/TSP is characterized by perivascular demyelination and neuronal lesions. Macroscopic atrophy of the spinal cord occurs, with changes consistent with a chronic inflammatory process characterized by perivascular cuffing of mononuclear cells and lymphocytic infiltration of the brain and spinal cord. Early in the disease, these lymphocytes consist of both $CD8^+$ and $CD4^+$ T cells, along with B lymphocytes and macrophages in areas of parenchymal damage.[140] HTLV-I proviral DNA can be demonstrated in $CD4^+$ cells in the infiltrates by in situ PCR. Evidence suggests that these HTLV-1–infected cells migrate from the peripheral blood and cross the blood-brain barrier to enter the nervous system.[39] Later in the disease, the inflammatory cells are fewer in number and consist primarily of $CD8^+$ cytotoxic T cells. Marked myelin and axonal destruction and astrocytic gliosis are prominent. The lower thoracic spinal cord is particularly affected, and parenchymal damage of both white and gray matter of the cord may be present. In the brain, although perivascular mononuclear cell infiltration may be seen, parenchymal damage is an unusual finding. However, rare patients may have white matter lesions, cerebellar symptoms, amyotrophic lateral sclerosis–like symptoms, or neuropathy.[135]

The pathogenesis of HAM/TSP is not known. An increased HTLV-I viral load and an augmented humoral and cellular immune response to HTLV-I are reported in patients with HAM/TSP. When compared with asymptomatic HTLV-I–seropositive individuals or those with ATLL, patients with HAM/TSP have higher HTLV-I antibody titers, a higher proviral load, and elevated levels of spontaneous lymphocyte proliferation and proinflammatory cytokines, including IL-1, interferon-α, and tumor necrosis factor-α.[194,231,232] HTLV-I–specific $CD8^+$ cytotoxic T cells can be found in the CSF as well as the peripheral blood of patients with HAM/TSP, and a significant reduction in the naïve T-cell population occurs with a concomitant increase in the memory/effector $CD8^+$ cell population.[141,142,231] Examination of the T-cell receptor repertoire shows significant expansion of the $CD8^+$ T-cell population in patients with HAM/TSP as opposed to asymptomatic carriers. Many of these $CD8^+$ cells correspond to cytotoxic T lymphocytes directed against epitopes of the immunodominant Tax protein of HTLV-I.[342]

One postulated mechanism for nervous system damage is direct infection of CNS glial cells by HTLV-I; a direct cytotoxic immune response to the glial cell is generated and results in demyelination.[134] However, HTLV-I expression appears to be localized to infiltrating $CD4^+$ lymphocytes within the spinal cord lesions rather than nervous system parenchymal cells, and no clear evidence has established that HTLV-I infects CNS cells.[234] Alternatively, the heightened HTLV-I–specific immune response in patients with HAM/TSP and neuropathologic findings suggests that immune-mediated mechanisms may have a role in the pathogenesis of disease.[175] The activated HTLV-I–specific cytotoxic $CD8^+$ T cells observed in patients with HAM/TSP could secrete cytokines that may induce demyelination as well as increase the transmigration of additional HTLV-1–infected lymphocytes to the inflammatory lesion.[134,231,234]

Specific characteristics of the virus also may influence disease manifestations. In one study, a specific tax gene phylogenetic subgroup, *tax A*, was found to occur more commonly in patients with HAM/TSP than in healthy HTLV-I carriers, thus suggesting that functional or immunogenic differences in the transactivating Tax protein among HTLV-I viral types may play a role in causing disease.[85] Another hypothesized mechanism is more indirect and involves an HTLV-I–associated activation of autoreactive cells that could lead to an autoimmune process inducing myelin destruction. The finding that numerous autoimmune-like diseases may occur in HTLV-1–infected patients and may coexist with HAM/TSP is consistent with the latter hypothesis.[135] A genetic susceptibility to the development of HAM/TSP also may exist. HTLV-1–infected patients with the class I allele HLA-A*02 had a proviral load one third less than that of HTLV-I carriers who lack this allele, and they had half the odds for development of HAM/TSP.[144] Because the risk for HAM/TSP is related to proviral load, this relationship may be the result of a more efficient antiviral cellular immune response in individuals with a particular class I HLA allele.

Similar to ATLL, no curative treatment has been developed for HAM/TSP. However, prolonged survival may be seen. Mean survival after the onset of symptoms is 10 years, and the major causes of death are infection and cancer.[340] Symptomatic treatment includes measures to maintain muscle function and reduce spasticity. Treatment with systemic or intrathecal corticosteroids may induce a transient benefit in approximately 50 percent of patients, particularly those with early-stage disease, and zidovudine alone or combined with interferon-α therapy has shown some promise.[101,112,134]

HUMAN T-CELL LYMPHOTROPHIC VIRUS TYPE I–ASSOCIATED UVEITIS

Idiopathic, non-infectious uveitis has been reported to occur in HTLV-I–seropositive individuals, usually those who otherwise are asymptomatic.[208,209,235,306] In endemic areas in Japan, 38 percent of patients with idiopathic uveitis were infected with HTLV-I as compared with 19 percent of patients with nonuveitic ocular disease and 10 percent with uveitis of known origin.[210] In the younger age group (20 to 49 years) with idiopathic uveitis, HTLV-I seroprevalence was 49 percent. Similarly, in Brazil, an area of lower HTLV-I endemicity, HTLV-I seroprevalence also was elevated in patients with idiopathic uveitis; 1.8 percent of patients with idiopathic uveitis were HTLV-I–seropositive versus none of those with uveitis of known origin.[377] In a survey of 105 asymptomatic Brazilian HTLV-I carriers, uveitis was found in 2.8 percent of infected persons. In epidemiologic surveys in Japan, the prevalence rate of HTLV-I–associated uveitis in HTLV-1 carriers was lower, estimated to be approximately 0.1 percent.[377] The mean age at onset in a series of Japanese patients was 43 years in men and 48 years in women.[210] As noted for HAM/TSP, genetic factors also may be associated with a susceptibility to or the severity of HTLV-I–associated uveitis.[301]

The syndrome is characterized by the abrupt onset of blurred vision, foggy vision, floaters, or any combination of these findings. The predominant finding on ocular examination is intermediate uveitis with infiltrating cells and lacework-like membranous vitreous opacities. Approximately 14 percent of patients have panuveitis with uveoretinal lesions and mild retinal vasculitis, and 5 percent have iritis alone.[210] The uveitis is generally mild to moderate, and visual acuity is affected only slightly in most patients. Uveitis is unilateral in 57 percent and bilateral in 43 percent. The disease usually responds to topical or systemic steroids within a few weeks, although recurrence may be seen in 25 to 50 percent of cases within 2 months to 2 years after therapy is discontinued.[210,235] Many patients (≈20%) have hyperthyroidism (Graves disease) that precedes or follows the onset of uveitis. A study of 105 asymptomatic Brazilian HTLV-I–seropositive adults found abnormal results in at least one lacrimal film evaluation test in 40 percent versus 23 percent of uninfected controls,[377] a finding thus suggesting that abnormal early

ocular abnormalities may be present in asymptomatic HTLV-1 carriers.

HTLV-I antibody has been detected in the aqueous humor of patients with HTLV-I uveitis.[210] Additionally, proviral HTLV-I DNA has been demonstrated in T cells found in the intraocular fluid of 59 percent or more Japanese patients with HTLV-I uveitis. Production of cytokine by HTLV-1–infected T cells is hypothesized to be the cause of the intraocular inflammation.[210,289,340] Significant amounts of cytokines, including tumor necrosis factor-α, are produced by HTLV-1–infected T-cell clones that have been established from the ocular fluid of patients with HTLV-I–associated uveitis and by the retinal glial cells of rats experimentally infected with HTLV-I.[289,301]

PEDIATRIC MANIFESTATIONS

Infective Dermatitis

A severe, generalized, chronic relapsing dermatitis of childhood called *infective dermatitis* was described first in Jamaican children in 1966.[318] In 1967, researchers observed that cultures of the nares or skin lesions in children with infective dermatitis often were positive for *Staphylococcus aureus* or beta-hemolytic streptococci.[359] Patients with these infections responded well to antibiotic therapy but relapsed once therapy was withdrawn. The refractory nature of the disorder with frequent exacerbations, infections with bacteria that usually were nonvirulent, and resistance to treatment suggested an association with immune dysfunction. After HTLV-I was identified in 1980, epidemiologic studies demonstrated that HTLV-I was endemic in Jamaica; because HTLV-I infection was known to be associated with immune dysfunction and enhanced susceptibility to infections,[199] an association between infective dermatitis and HTLV-I infection was hypothesized.

In 1990, La Grenade and colleagues first described an association of infective dermatitis and HTLV-I infection in Jamaican children.[167] In a study of 14 children with typical infective dermatitis and 11 with atopic dermatitis, all children with infective dermatitis were found to be HTLV-I–seropositive versus none of those with atopic dermatitis. In a later, expanded report, all of 50 children with infective dermatitis were found to be HTLV-I–seropositive, as opposed to only 14 percent of 35 with atopic dermatitis.[164] Subsequently, cases of infective dermatitis were reported in HTLV-1–infected children in Trinidad, Colombia, Brazil, and Japan.[28,338]

The clinical features of infective dermatitis include the acute onset in early childhood of severe exudative eczema, typically without preceding infantile eczema. It is characterized by exudation and crusting involving the perinasal skin and nostrils, external ear and retroauricular areas, eyelid margins, scalp, neck, axillae, and groin. The eczema may be accompanied by a generalized, fine, papular rash on the trunk and back. A dermatopathic lymphadenitis with palpable lymph nodes also may be observed.[168] A chronic, watery nasal discharge in the absence of other causes of rhinitis is a common finding, and *S. aureus* or beta-hemolytic streptococci often are cultured from nose and skin lesions. Long-term antibiotic therapy is required to control the disease. Diagnostic criteria for HTLV-I–associated infective dermatitis are shown in Table 204–6.

In Jamaican children with infective dermatitis, HTLV-I antibody titers were significantly higher than those in asymptomatic HTLV-1–infected children. Children with infective dermatitis were more likely than those with atopic dermatitis to be anemic and to have lower serum albumin, higher white blood cell counts and erythrocyte sedimentation rates, lymphocytosis with atypical lymphocytes, and elevated serum immunoglobulins.[168] These findings are consistent with chronic inflammation and antigenic stimulation caused by the relapsing bacterial infections characteristic of infective dermatitis. However, elevated levels of T-cell activation also were seen in children with infective dermatitis, along with a higher $CD4^+$ and $CD8^+$ T-lymphocyte number, $CD4^+/CD8^+$ ratio, and percentage of HLA-DR antigen-positive T cells. These findings may be related primarily to HTLV-I infection rather than being secondary to infective dermatitis. In a cross-sectional study of asymptomatic HTLV-I–seropositive and HTLV-I–seronegative Jamaican children 11 to 31 months of age, HTLV-I infection was associated with an increase in $CD4^+$ cells expressing HLA-DR on their surface that was progressive and related to the duration of infection.[190] This finding may be an early marker for HTLV-I infection in children and indicative of an early perturbation in the immune system.

Complications of infective dermatitis occur in 30 to 35 percent of patients. The most common complications are crusted (Norwegian) scabies, corneal opacities, chronic bronchiectasis, and infection with parasitic worms such as *S. stercoralis*.[166] Other reported complications include lymphocytic interstitial pneumonitis and glomerulonephritis, which reflect the systemic complications of HTLV-I infection. Early death caused by severe bacterial infections with sepsis or the development of other later manifestations of HTLV-I infection may occur. Although ATLL and HAM/TSP in children are reported only rarely, a few cases of ATLL or HAM/TSP developing in patients with infective dermatitis after 12 to 25 years were reported.[25,108,169,338] The class II HLA haplotype DRB1*DQB1* was found in HTLV-1–infected children with infective dermatitis and also in infected Japanese

TABLE 204–6 Diagnosis of Human T-Cell Lymphotrophic Virus Type I–Associated Infective Dermatitis

Type of Criteria	Clinical/Laboratory Findings
Major criteria (diagnosis requires the presence of items 1, 2, and 5, with at least 2 items present from 1)	1. Crusting eczema involving the scalp, eyelid margins, perinasal skin, external ear and retroauricular areas, axillae, groin, and/or neck (must include 2 sites or more) 2. Chronic watery nasal discharge and/or crusting of the anterior nares without other signs of rhinitis 3. HTLV-I seropositivity 4. Chronic relapsing dermatitis with prompt response to appropriate antibiotic therapy but prompt recurrence as soon as therapy is stopped 5. Onset in early childhood
Minor or less specific criteria	1. Positive skin or anterior nares cultures for *Staphylococcus aureus* and/or beta-hemolytic streptococci 2. Fine, generalized papular rash 3. Generalized lymphadenopathy (with histologic dermatopathic lymphadenitis on biopsy, if performed) 4. Anemia 5. Elevated erythrocyte sedimentation rate 6. Hyperimmunoglobulinemia (IgD and IgE) 7. Elevated $CD4^+$ and $CD8^+$ T-cell count and elevated $CD4^+/CD8^+$ ratio

HTLV-I, human T-cell lymphotrophic virus type I; IgD and IgE, immunoglobulins D and E.

adults with HAM/TSP.[170] These findings suggest a possible genetically increased susceptibility to some HTLV-I disease manifestations, perhaps secondary to an exaggerated host immune response to HTLV-I infection in individuals with this haplotype.[170,188] Children with HTLV-I–associated infective dermatitis, therefore, may be at risk for development of more serious HTLV-I–associated disorders later in life.

Histologically, an inflammatory lymphocytic infiltrate is seen within the skin lesions. The HTLV-I genome was detected by PCR in lymphocytes cultured from biopsy specimens of skin lesions in patients with infectious dermatitis, although cultured fibroblasts were negative, thus suggesting that HTLV-1–infected lymphocytes had infiltrated the skin.[166] Cultured keratinocytes from children with infectious dermatitis were shown to exhibit overexpression of proinflammatory and anti-inflammatory cytokines that could be induced directly or indirectly by HTLV-I infection.[348] Secretion of cytokines by HTLV-1–infected cells may amplify or maintain a persistent inflammatory reaction in the skin and, when combined with the enhanced susceptibility to infection induced by HTLV-I–associated immunodysfunction, could result in the clinical manifestations of infective dermatitis. In a rabbit model, infection with HTLV-I by intravenous inoculation was associated with the development of generalized exfoliative papillary dermatitis characterized by T-cell infiltrates in the epidermis and epithelium of the hair follicle, similar to that seen in cutaneous T-cell lymphoma.[309] HTLV-I envelope sequences were detected by DNA PCR in rabbit skin biopsy samples, and HTLV-I was isolated from cultures of affected skin. Researchers postulated that infective dermatitis represents an HTLV-I–associated immunodeficiency syndrome resulting from exposure to HTLV-I in early life, primarily through mother-to-child transmission.

Treatment of infective dermatitis is symptomatic and targeted at controlling bacterial superinfection with the use of antibiotic therapy. However, long-term therapy is needed because of the relapsing nature of the illness. Occasionally, mild topical steroids are used for severe dermatitis.

Other Pediatric Manifestations

Renal manifestations rarely have been reported in association with infective dermatitis in children. Miller and colleagues reported a syndrome of infective dermatitis, glomerulonephritis, renal failure, severe hypertension with hypertensive encephalopathy, microangiopathic hemolytic anemia, and significant glomerulosclerosis with fibrosis on renal biopsy specimens in two Jamaican children infected with HTLV-I.[205] Pulse methylprednisolone was effective in reversing the renal failure in a child who was in the early stage of illness, but steroids were ineffective in a child treated later in the course of illness. In HTLV-1–infected adults, a syndrome of hemolytic-uremic syndrome or thrombotic thrombocytopenic purpura with severe hypertension, or both, has been reported.[66,339] Chronic renal failure has been reported rarely in adults with ATLL. In one patient with ATLL, HTLV-I antigen with bound immunoglobulin was demonstrated by immunofluorescence in the glomerulus, a finding suggesting that glomerular deposition of HTLV-I–associated immune complexes may be the cause of the renal damage.[230] Alternatively, concomitant infection with group A beta-hemolytic *Streptococcus* during the immunodeficiency associated with HTLV-I could result in streptococcal-associated glomerulonephritis.

OTHER DISORDERS

Numerous autoimmune disorders have been associated with HTLV-I. In a study of 113 HTLV-1–infected patients in southern Florida, rheumatologic or autoimmune diseases were not uncommon manifestations.[112] HTLV-I–associated large joint chronic arthropathy has been described. Clinically, the disorder is manifested as oligoarthritis of the shoulder, wrists, or knees, with a chronic course. Some patients may have accompanying myalgia or bronchitis.[238] Proliferative changes are observed in nonlymphocytic mesenchymal and synovial cells, along with synovial overgrowth. HTLV-I antibodies are detected in the synovial fluid of affected joints, and HTLV-I proviral DNA has been found in synovial cells and synovial fluid lymphocytes.[160,340] Chronic inflammatory arthropathy can develop in HTLV-I transgenic mice.[139] HTLV-I Tax protein may be associated with proliferation of synovial cells that leads to erosion of cartilage and bone.

HTLV-I–associated polymyositis has been described in patients with HAM/TSP, as well as in those without neurologic impairment.[213,256,376] Muscle biopsy is consistent with myositis with mononuclear interstitial infiltrates, necrosis, and regeneration. HTLV-I provirus has been identified by in situ hybridization in $CD4^+$ cells in the inflammatory cell infiltrate.[120] The mechanism by which HTLV-I produces disease is unknown. It is probably not a direct viral effect because HTLV-I does not appear to infect muscle cells.[256] As hypothesized for HAM/TSP, the pathologic process could be the result of an autoimmune response, or it could be caused by the production of cytokines in focal inflammatory infiltrates in muscle by activated HTLV-1–infected $CD4^+$ cells and subsequent bystander damage to the myofibers.

Asymptomatic, subclinical lymphocytic pneumonitis has been described in patients with HAM/TSP. Bronchoalveolar lavage has shown the presence of a T-lymphocyte alveolitis, with highly soluble IL-2 receptor levels also found in lavage fluid from these patients.[315,316] On lung biopsy, marked lymphocytic infiltration of the lung is seen. The presence of HTLV-I provirus in alveolar lymphocytes obtained by lavage was described in 7.5 to 30 percent of patients with HAM/TSP and in fewer than 5 percent of HTLV-1–infected patients without myelopathy.[135]

HTLV-I also has been associated with Sjögren syndrome, a chronic exocrinopathy causing keratoconjunctivitis sicca, xerostomia, and sialadenitis and characterized by a lymphocytic infiltration of the lacrimal and salivary glands; the origin has been hypothesized to be autoimmune. In a study in Japan, HTLV-I seroprevalence in patients with Sjögren syndrome was 23 percent, significantly higher than the 3 percent HTLV-I seroprevalence in blood donors.[331] HTLV-I antibody titers in HTLV-I–seropositive patients with Sjögren syndrome were significantly higher than those in asymptomatic HTLV-I carriers and similar to those seen in patients with HAM/TSP. However, in contrast to that in patients with HAM/TSP, the HTLV-I proviral load in peripheral blood was not always high. HTLV-I salivary immunoglobulin A (IgA) antibodies occurred commonly in HTLV-I–seropositive patients with Sjögren syndrome but very rarely in asymptomatic HTLV-I patients or those with HAM/TSP, a finding thus suggesting potential increased viral activity within the salivary glands.[331] In a study of HTLV-1–infected patients from Guadeloupe, French West Indies, a sicca-like syndrome was found in almost 80 percent of patients, approximately half of whom also had neurologic findings.[19] HTLV-I provirus has been identified by PCR in acini cells and inflammatory infiltrates in the labial salivary glands of patients with HAM/TSP, as well as in healthy HTLV-I carriers with the sicca syndrome.[329] In addition, one of the symptoms of Sjögren syndrome is impaired sweating, and HTLV-I pX sequences have been identified in samples of eccrine sweat gland epithelia from HTLV-1–infected individuals.[303] Transgenic animal models have indicated that HTLV-I is tropic for ductal epithelium of the salivary and lacrimal glands.[102]

HTLV-I infection, even in the absence of other disease manifestations, is associated with immune dysfunction. Perturbations in lymphokine and cytokine production have been observed with

HTLV-I in vitro, most likely caused by Tax-mediated transactivation of various host-cell pathways. Spontaneous lymphocyte proliferation is seen in asymptomatic seropositive patients, as well as in patients with HAM/TSP,[362] and changes in T-cell subsets reflecting an increase in activation markers, such as the IL-2 receptor, also may be observed. Opportunistic infections such as *Pneumocystis* pneumonia and Norwegian scabies can develop in HTLV-1–infected patients without other disease manifestations, and these patients are more likely to experience numerous other infections, including tuberculosis, leprosy, and strongyloidiasis.[224,225,282,350] HTLV-1–infected patients have lower eosinophil counts than those of uninfected patients, perhaps related to the increased susceptibility of HTLV-1–infected persons to parasitic diseases.[226]

DUAL INFECTION WITH HUMAN IMMUNODEFICIENCY VIRUS TYPE 1

Because some of the geographic areas endemic for HTLV-I also are endemic for HIV-1, dual infection with both viruses may occur.[15,16] In a study in the coastal port of Santos, Brazil, concurrent infection with HTLV-I and HTLV-II was seen in 6.0 and 7.4 percent of HIV-1–infected individuals, respectively.[75] Intravenous drug use and seropositivity to hepatitis C virus were correlated with co-infection with either HTLV-I or HTLV-II.

Based on in vitro studies indicating that the HTLV-I tax gene product can interact with the Tat response element of the HIV-1 LTR and enhance HIV-1 replication, researchers proposed that dual infection may increase the progression of HIV-1 disease or increase the frequency of HTLV-I–associated diseases.[308] However, whether enhanced replication of HIV-1 occurs in dually infected patients in vivo is unclear. In one study in Brazil, no significant difference in HIV-1 plasma RNA levels was observed in 23 patients with HIV-1/HTLV-I co-infection and in 92 patients with HIV-1 infection alone.[113]

The findings of several small clinical studies were consistent with the hypothesis of potential enhanced disease progression with co-infection. HTLV-I/HIV-1 co-infection in intravenous drug users was found to be associated with a threefold increase in mortality when compared with drug users who had only HIV-1 infection.[258] In a study in Trinidad, co-infected individuals had faster progression to acquired immunodeficiency syndrome (AIDS) than did those with HIV-1 infection alone, and in a study from Rio de Janeiro, patients dually infected with HIV-1 and HTLV-I had a more advanced WHO HIV disease stage.[13,293] Those patients with advanced disease and dual infection had higher $CD4^+$ lymphocyte counts than did those with a similar disease stage but who were infected with HIV-1 alone; similar findings also were reported in another study.[76,293] The $CD4^+$ number, therefore, may be an unreliable predictor of immunodeficiency in dually infected patients; HTLV-I may induce an elevated $CD4^+$ number through enhancement of lymphocyte proliferation, but the function of these cells may be abnormal.[36]

In addition, HIV-1 infection possibly increases the likelihood for development of some HTLV-I–associated diseases. Expression of HTLV-I and HTLV-II appears to be up-regulated in patients co-infected with HIV-1.[20] Several reports have been published of patients with dual infection in whom a typical HAM/TSP syndrome developed, and antibodies to HIV-1 and HTLV-I were present in the blood and CSF of one dually infected patient with neurologic disease.[2,21,202]

HUMAN T-CELL LYMPHOTROPHIC VIRUS TYPE II

HTLV-II was identified first in patients with hairy-cell leukemia.[148,285,286] HTLV-II is closely related to HTLV-I, with approximately 60 percent homology in nucleotide sequences.[165] HTLV-II infection is endemic in Native American populations and probably is an ancient infection that has been maintained in the population by sexual transmission and mother-to-child transmission through breast-feeding.[106,171,173] More recently, HTLV-II has been introduced into urban settings in the United States, Europe, and Asia, where transmission occurs primarily through intravenous drug use or transfusion of contaminated blood. The role of this virus in causation of disease has not been as definitively established as that for HTLV-I, but a possible association with lymphoproliferative and neurologic disorders has been suggested (see Table 204–1).

VIRAL PATHOGENESIS/MOLECULAR BIOLOGY

Like HTLV-I, HTLV-II can transform cells in vitro. However, HTLV-II displays a preferential tropism for and induces clonal expansion of cells of the $CD8^+$ T-lymphocyte phenotype.[47,136,182] In an evaluation of HTLV-I1–infected patients, HTLV-II was detected exclusively within $CD8^+$ lymphocytes in most individuals and less frequently in both $CD4^+$ and $CD8^+$ T cells in some individuals.[136,168] Whether the difference in cell tropism between HTLV-I and HTLV-II may lead to variations in pathogenicity between the two viruses is unknown.

Based on nucleotide sequencing of the viral envelope and phylogenetic analysis, two major molecular subtypes of HTLV-II have been identified and designated HTLV-IIA and HTLV-IIB; these subtypes have a 4 to 7 percent divergence in the gene encoding the envelope transmembrane protein.[107] Studies focusing on the LTR and pX regions of the provirus have shown additional differences. The Tax protein appears to differ in length between the two subtypes, with the HTLV-IIB Tax protein being 25 amino acids longer than the HTLV-IIA Tax protein.[259] Functionally, the HTLV-IIA Tax protein is a weaker inactivator of the *p53* tumor suppressor gene and a less potent transactivator of the viral LTR in vitro than is the Tax protein from HTLV-I or HTLV-IIB, and limited data suggest that the proviral load may be lower in HTLV-IIA–infected than HTLV-IIB–infected individuals.[71,184] Based on phylogenetic analysis of nucleotide sequences in the LTR region of the virus, two additional subtypes have been identified in restricted geographic locations, HTLV-IIC and HTLV-IID.[71,184] The Tax protein of HTLV-IIC is the same length as that of HTLV-IIB, and the length of Tax in HTLV-IID is intermediate between the A and B-C subtypes.

EPIDEMIOLOGY

HTLV-II is endemic in a large number of Native American populations in the United States (Navajo and Pueblo Indians in New Mexico and the Seminole Indians in Florida) and numerous indigenous Amerindian populations in Latin America, including Panama, Colombia, Argentina, Brazil, and Chile.[107,117,129,130,178,186,365] HTLV-II seroprevalence in these Amerindian tribes varies between 2 and 30 percent.[128,186,220,351] Although HTLV-I is endemic in Africa, HTLV-II seroprevalence appears to be relatively low; in one study, the prevalence of HTLV-II was 0.8 percent in the Ivory Coast, 0.05 percent in Guinea, and 0.02 percent in Senegal.[32] However, in a study in Eritrea, 2.1 percent of female sex workers were found to be HTLV-II–seropositive.[10]

In the United States, Europe, and Southeast Asia, HTLV-II infection is found primarily in intravenous drug users, with seroprevalence rates ranging from 3 to 18 percent.[33,34,157] In the United States, HTLV-II accounts for most of the HTLV infections in intravenous drug users.[43] In a study of HTLV-II and HIV seroprevalence in drug users from eight metropolitan areas in the

United States, the overall prevalence of HTLV-II alone was 15.1 percent, the prevalence of HIV-1 alone was 9.9 percent, and that of dual HIV-1/HTLV-II infection was 3.3 percent; HTLV-II prevalence was higher in the Southwest and Midwest than the Northeast, whereas HIV-1 prevalence was highest in the Northeast.[33] HTLV-II seroprevalence in drug users was highest in black and Hispanic persons, increased with age, and it was higher in women than in men in all age groups. The female preponderance of HTLV-II infection may indicate more efficient sexual transmission of HTLV-II from men to women than vice versa; similar findings have been noted with HTLV-I. In persons attending clinics for sexually transmitted diseases in the United States, nearly two thirds of HTLV infections are caused by HTLV-II.[157] In a study involving blood donors in the United States, HTLV-II prevalence was 22.3 per 100,000 donors and was highest in West Coast blood centers.[228] HTLV-II infection was associated with an age of 40 to 49 years, first-time blood donation, female sex, high school or lower education level, and hepatitis C seropositivity.

The geographic distribution of HTLV-II subtypes varies.[106] HTLV-IIA is the predominant infection in intravenous drug users in North America and Europe and is widespread worldwide. HTLV-IIB predominates in Paleoindian groups, such as the Native North American population, although a mixture of HTLV-IIA and HTLV-IIB also has been reported in some tribes.[131] In South America, HTLV-IIB infection is seen in native populations in Panama, Colombia, and Argentina, but an indigenous Brazilian Indian population in the Amazon appears to be infected with HTLV-IIC, also seen in intravenous drug users in urban areas of Brazil.[71] In Europe, a mixture of infections is noted; for example, HTLV-IIA is found primarily in Sweden, whereas HTLV-IIB is more prevalent in Spain and Italy. HTLV-IID has been detected in central African Pygmies.

MODES OF TRANSMISSION

HTLV-II, like HTLV-I, is transmitted by transfusion of contaminated cellular blood products, by injection with contaminated needles, sexually, and from mother to child. Whether differences in efficiency of transmission exist between the two viruses is unclear.

Sexual transmission is an important mode of HTLV-II acquisition, although data are more limited for HTLV-II than for HTLV-I. Studies in non–drug-using native populations have shown a strong association of HTLV-II infection between spouses.[185,351] Among Guaymi Indians in Panama, HTLV-II seroprevalence approaches 10 percent. Seropositivity in women is associated with an early age at first sexual intercourse, the number of lifetime sexual partners, and the number of long-term sexual relationships; in men, sexual intercourse with prostitutes is associated with seropositivity.[185] In HTLV-II–seropositive injecting drug users, higher rates of seropositivity are found in individuals with a history of sexually transmitted diseases.[33,299,352] Preferential male-to-female transmission has been reported, as with HTLV-I. In HTLV-II–seropositive blood donors, a history of sexual contact with an intravenous drug user or an HTLV-I1–infected sexual partner was associated with increased risk of HTLV-II seropositivity.[297] In addition, a high prevalence of HTLV-II seropositivity in patients who are not intravenous drug users but who have sexually transmitted diseases also supports the role of sexual contact in HTLV-II transmission.[297]

Injecting drug use is the primary mode of HTLV-II acquisition in the United States. In a study of HTLV-infected blood donors (the Retrovirus Epidemiology Donor Study), HTLV-II infection was associated significantly with injection drug use or sexual contact with an injecting drug user, whereas HTLV-I infection was not.[297] Having had an abortion also was an independent risk factor for the acquisition of HTLV-II infection by female blood donors, probably because abortion is a marker of increased unprotected sexual activity. Other risk factors, such as seven or more sexual partners, were common to both HTLV-I and HTLV-II. Sex with an injecting drug user was a particular risk factor for women; 65 percent of HTLV-I1–infected women reported that they had a sexual partner who used injection drugs, and 20 percent of women reported that they also injected drugs themselves. HTLV-II infection in drug users has been associated with nonwhite race, older age, markers of previous hepatitis B virus infection, the use of a specific needle-sharing practice called backloading, a history of herpes simplex virus type 2 infection, and a history of receiving money for sex.[33,299,352] In an Italian study of risk factors for development of HTLV in patients seen in a clinic for sexually transmitted diseases, injecting drug use was associated with HTLV-II infection, whereas HTLV-I infection was associated more strongly with sexual behavior.[97] Among injecting drug users, seroprevalence for HTLV-II was 8.2 percent versus 2.1 percent for HTLV-I. HTLV-I infection was associated with exposure to syphilis and non-European nationality.

HTLV-II also has been detected in the breast milk of carrier mothers, and mother-to-child transmission has been described in those who breast-feed.[118,167,169,343] The rate of transmission of HTLV-II through breast milk described in the few small studies available (≈14%) is slightly lower than that found for HTLV-I. Like HTLV-I, HTLV-II appears to be transmitted infrequently in the absence of breast-feeding.[88,106,151,347] Passive immunization with HTLV-II hyperimmunoglobulin in rabbits prevented blood-borne transmission of HTLV-I1–infected cells.[214] Only HTLV-II and not HTLV-I immunoglobulin was effective in preventing HTLV-II transmission, a finding thus suggesting that despite some cross-reactivity on conventional ELISAs, cross-neutralization between the viruses is minimal or nonexistent.[214]

CLINICAL DISEASE

When compared with HTLV-I, HTLV-II infection appears to be associated with a much lower prevalence of virus-associated neoplasia. Although HTLV-II was isolated initially from the cells of patients with hairy-cell leukemia,[30,148] subsequent studies did not confirm this association. In an HTLV-II–endemic population of Native Americans in New Mexico, no apparent increase in the incidence of hairy-cell leukemia, mycosis fungoides, and chronic lymphocytic leukemia was observed over that in other ethnic groups.[129]

When cancers do develop, they are of the $CD8^+$ cell phenotype. Unusual skin disorders resembling cutaneous lymphoma have been reported in a small number of patients co-infected with HIV-1 and HTLV-II. Severe erythroderma with subsequent exfoliation of the skin accompanied by eosinophilia and dermatopathic lymphadenopathy was reported in two intravenous drug users with dual infection.[153] In contrast to most cutaneous lymphomata in the United States, which are of the $CD4^+$ cell phenotype, the infiltrating T cells were of the $CD8^+$ phenotype. In a third HIV-1/HTLV-II co-infected patient with a cutaneous $CD8^+$ T-cell lymphoma, the skin infiltrate was found to contain $CD8^+$ cells with HTLV-II DNA.[264] HTLV-II infection of $CD8^+$ cells was described in one patient with large granular cell lymphocytosis and in another patient with large granular lymphocytic leukemia.[181,200] However, HTLV-II was found in only 2 percent of patients with large granular lymphocytic leukemia in a subsequent study of 51 patients.[116] HTLV-II infection also was described in one patient with mycosis fungoides.[387]

Evidence suggests that HTLV-II may be associated with neurologic disorders ranging from a spastic paraparesis-myelopathy

similar to HAM/TSP to more widespread involvement of the CNS.[222] Myeloneuropathies indistinguishable from HAM/TSP have been reported in patients infected with HTLV-II alone or co-infected with HIV-1.[21,127,220,222,228] In addition, a chronic neurodegenerative disorder with ataxia as a prominent feature has been reported in patients with HTLV-II infection.[111,305] In patients in whom HTLV-II was subtyped, type A was identified. Most cases occurred in women, similar to the observed female preponderance in patients with HAM/TSP. Patients with HIV-1 infection who have sensory peripheral polyneuropathy have been found to have a higher prevalence of HTLV-II co-infection, as diagnosed by serology and DNA PCR, than have HIV-1–infected patients without neuropathy, thus suggesting that HTLV-II may be involved in the pathogenesis of the neuropathy.[386]

Although immune deficiency and an increased risk of infections have been reported in HTLV-1–infected individuals, the data are less clear for HTLV-II. An initial report from San Francisco described an association of HTLV-II seropositivity and bacterial infections, particularly skin and soft tissue infections and bacterial pneumonia, but the results were confounded by intravenous drug use, which in itself could increase the risk for infections, in nearly all HTLV-II–seropositive patients.[211] In a case-control study of intravenous drug users from Baltimore with an overall HTLV-II seroprevalence of 7 percent, no significant association between HTLV-II seropositivity and the development of bacterial pneumonia, infective endocarditis, and skin abscess was found.[288] However, in a study of blood donors infected with HTLV-I or HTLV-II who were also HIV-1–seronegative, HTLV-II infection was associated with an increased incidence of bronchitis, bladder or kidney infection, and oral herpes simplex virus infection and with a borderline increase in the incidence of pneumonia.[225] Clearly, the natural history and clinical manifestations of HTLV-II need further delineation in the context of ongoing prospective natural history studies.

OTHER FORMS OF HUMAN T-CELL LYMPHOTROPHIC VIRUS

Additional forms of HTLV that are distinctly different from HTLV-I and HTLV-II have emerged.[37,373] The identification of HTLV-III and HTLV-IV among central African bushmeat hunters demonstrates greater HTLV diversity than was recognized previously. Preliminary data would suggest that HTLV-III comes from a simian origin, whereas HTLV-IV does not appear to have a known simian counterpart. Both these newer forms of HTLV are serologically indistinguishable from HTLV-I and HTLV-II by current assays and highlight the need for accurate testing. Although no clinical maladies have been attributed to HTLV-III or HTLV-IV to date, concern exists over the spread of infection by blood donations from infected persons or by those who participate in primate hunting. Further research will be required to understand more clearly what implications these newer forms of HTLV have on human disease.

LENTIVIRUSES: HUMAN IMMUNODEFICIENCY VIRUS TYPE 2

HIV-2 has a morphology and life cycle similar to those of HIV-1 but with significant antigenic, biologic, epidemiologic, and clinical differences (Table 204–7). Both viruses have similar modes of transmission and can result in immune depletion and AIDS. However, whereas HIV-1 has a global distribution, HIV-2 is confined primarily to West Africa and is found only sporadically in Europe, the United States, and other countries. The clinical latency period and rates of perinatal and sexual transmission also are lower than those for HIV-1. The basis of such

TABLE 204–7 Comparison of Human Immunodeficiency Virus Types 1 and 2

Characteristic	HIV-2	HIV-1
Viral Genome	*vpx* gene, no *vpu* gene *nef* gene longer in HIV-2, defective *nef* gene in 10% Difference in number and identity of transcription enhancers for LTR (less responsive to stimulation?)	*vpu* gene, no *vpx* gene Defective *nef* gene in <1% Greater responsiveness of LTR to transcription enhancers?
Geographic Distribution	West Africa Restricted distribution outside Africa, primarily in countries with ties to West Africa Europe: Portugal, France, Germany, Spain South America: Brazil India	Global
Modes of Transmission	Sexual, blood-borne, mother-to-child	Sexual, blood-borne, mother-to-child
Risk of Sexual Transmission	3-fold lower than HIV-1	
Seroconversion in commercial sex workers in Senegal[149,197]	Incidence of seroconversion in commercial sex workers in Senegal: 1% per year	Incidence of seroconversion in commercial sex workers in Senegal: 2%-3% per year
Risk of Mother-to-Child Transmission (without Antiretroviral Prophylaxis)	0%-4%	25%-35%
Viral Load (without Therapy)	28- to 30-fold lower than HIV-1	
Viral set-point:		
Seroconversion in Guinea-Bissau[9]	Median RNA, 2,500 copies/mL	Median RNA, 70,000 copies/mL
Commercial sex workers in Senegal[266,267]	Median RNA, 263 copies/mL	Median RNA, 7,182 copies/mL
Pregnant women in the Gambia[247]	Geometric mean RNA, 410 copies/mL	Geometric mean RNA, 15,100 copies/mL
Rate of $CD4^+$ T-Cell Decline	1% per year	10% per year
Time to Development of AIDS	<0.5% per year	3%-5% per year
Increase in Mortality Above that of HIV-Seronegative Individuals	2- to 4-fold increase	10-fold increase

HIV, human immunodeficiency virus; LTR, long terminal repeat.

differences in natural history between these two lentiviruses is unknown and may result from characteristics of the virus, the host, or both.

VIRAL GENOME/PATHOGENESIS

Seven genetic groups of HIV-2 (A to G) have been identified. However, current data suggest that only HIV-2 subtypes A and B are established in significant amounts in human populations.[23] No differences in replication potential between the two subtypes appear to exist.[55] HIV-1 and HIV-2 differ in the number and size of their accessory genes. HIV-2 lacks the genetic equivalent of the HIV-1 *vpu* gene. The HIV-1 vpu protein plays an important role in intracellular processing of $CD4^+$, specifically the down-regulation of $CD4^+$ receptor expression on HIV-1–infected cells. This characteristic could enhance the ability of cytoplasmic HIV-1 envelope proteins to reach the cell membrane and also enhance release of budding virions; no equivalent functional protein exists in HIV-2. HIV-2 contains the *vpx* gene, which is not found in HIV-1 but shares homology with the HIV-1 *vpr* gene and may affect early events in the replication cycle. Additionally, the *nef* ORF in HIV-1 is shorter than that in HIV-2, and the prevalence of defective *nef* genes in patients with HIV-2 infection (≈10%) is significantly higher than previously seen in HIV-1–infected individuals (<1%).[319] In HIV-1, deletions in the *nef* gene have been described in patients with long-term nonprogression.

The seven-transmembrane G-protein–coupled chemokine receptors CCR5 and CXCR4 are the major co-receptors used for HIV-1 and HIV-2 infection in vivo. Cell tropism of HIV is determined by the expression of $CD4^+$ and these co-receptors. Cell tropism is thought to play a role in both virus transmission and disease progression. Most transmitted HIV-1 viruses are R5 tropic, highlighted by the substantial protection from infection observed in individuals homozygous for a 32-bp deletion in CCR5. CXCR4 binding viruses emerge late in disease in as many as 50 percent of patients with AIDS. This change in co-receptor use correlates with progression of disease in infected individuals, although it is not a prerequisite as not all infected individuals demonstrate this co-receptor switch.

X4 strains target primarily new populations of T cells that express CXCR4 but not CCR5. Multiple other members of the chemokine receptor family and other receptor molecules can support infection of indicator cell lines in vitro. They include CCR3, CCR8, GPR1, GPR15, CXCR6, RDC1, and apj. In general, HIV-2 and SIV strains use a wider range of these alternative co-receptors than HIV-1.

Chemokine receptors together with $CD4^+$ molecules allow binding of HIV and ultimately entry into host cells. Binding of HIV to these host-cell surface molecules permits close interaction between or fusion of the virus and cell membranes to occur. Whereas both HIV-1 and HIV-2 infect $CD4^+$ T lymphocytes and use the CXCR4 or CCR5 co-receptors for cell entry, HIV-2 can use multiple additional co-receptors.[216] The cytopathicity of HIV-2 appears similar to that of HIV-1 and is determined by the type of co-receptor used for cell entry. In an in vitro study comparing HIV-1 and HIV-2 co-receptor use and cytopathicity in human lymphoid cells, HIV-2 specificity for the CCR5 co-receptor alone or in combination with other co-receptors was associated with restricted cytopathicity, whereas specificity for CXCR4 was linked to a more virulent phenotype, as observed for HIV-1.[296]

More recently, co-receptor use of HIV variants isolated from individuals who had undetectable viral loads, preserved $CD4^+$ cell counts, and a nonprogressive clinical course was compared with those from individuals with more progressive disease. In this comparison, HIV-2 variants were found to use CCR5, GPR15, and CXCR6 with high efficiency regardless of the clinical course. Consistent with prior studies, only HIV-2 variants isolated from individuals with viremia or overt progressive disease could use CXCR4. X4 variants were not observed in all individuals with progressive infection, a finding indicating that, although the capacity to use CXCR4 is likely a determinant of HIV-2 virulence, it is not the only one.

Studies have shown that the use of CCR1, CCR2b, and CCR3 co-receptors is rare.[27] Thus, the lesser virulence of HIV-2 compared with that of HIV-1 does not appear to be the result of a restriction in co-receptor use or lower intrinsic cytopathic potential. The linkage between syncytium-inducing phenotype and CXCR4 co-receptor usage was not observed in HIV-2 as it was in HIV-1. In addition, the broadening of the co-receptor usage did not necessarily increase the pathogenic potential of HIV 2 strains.[345]

In a study of sero-incident cases of HIV-1 and HIV-2 infection in Guinea-Bissau, the viral set-point after seroconversion was 28-fold lower in HIV-2 than in HIV-1 recent seroconverters.[9,242] Other studies have shown a broader-based neutralizing antibody response and higher antibody levels in HIV-2- than HIV-1–infected individuals.[197,327] These findings suggest that HIV-2 may have low rates of viral replication or a reduced ability to mutate and escape the host immune response, or both.

Productive lentiviral infection depends on continued activation of target cells. The lower rate of viral production in HIV-2–infected cells also could reflect a lesser ability of infected cells to respond to activation or could indicate that the cells themselves have lower activation states. The transcriptional enhancer/promoter region of the HIV-2 LTR differs from that of the HIV-1 LTR in the number and identity of enhancer elements, and transcriptional up-regulation of viral production may be disrupted more easily than for HIV-1.[196,266] This factor could result in lower responsiveness of the HIV-2 LTR to transcription factors in activated T cells. For example, the HIV-2 LTR has been shown to be less responsive to stimulation of viral gene expression by tumor necrosis factor-α than is the HIV-1 LTR.[109]

Lentiviral envelope glycoproteins can induce production of cytokines and other immunologic disturbances; differences in the effect of the HIV-1 and HIV-2 envelope glycoprotein also could contribute to differences in the pathogenicity of the viruses. Recombinant HIV-2 envelope glycoprotein is superior to the HIV-1 envelope in stimulating the production of interferon-γ and IL-16, both of which inhibit viral replication, and less effective in producing expression of IL-4, which stimulates viral replication.[237,302] The HIV-2 envelope glycoprotein inhibits T-cell proliferation more than does the glycoprotein of HIV-1 in vitro, and it also was found to inhibit expression of cell surface activation markers.[38] The presence of an HIV-2 protein that reduces immune system stimulation may decrease replication, result in lower levels of HIV-2 viremia, and also decrease $CD4^+$ cell apoptosis. The rate of total lymphocyte apoptosis has been found to be lower in HIV-2 than in HIV-1 infection.[203] In one study, 50 percent of peripheral blood mononuclear cells from HIV-2–infected commercial sex workers resisted in vitro challenge with CCR5-dependent HIV-1 but not CXCR4-dependent HIV-1.[163] Additionally, high levels of beta-chemokines RANTES (regulated on activation, normal T-cell expressed and secreted), macrophage inflammatory protein 1α (MIP-1α), and MIP-1 β, the natural ligands of the CCR5 receptor, were secreted when these resistant peripheral blood mononuclear cells from HIV-2–infected individuals underwent stimulation. These investigators hypothesized that beta-chemokine–mediated resistance could play a role in the potential protection of some HIV-2–infected individuals from secondary HIV-1 infection.

EPIDEMIOLOGY

HIV-2 is endemic in the former Portuguese and French colonies in West and South Central Africa, including Guinea-Bissau, Burkina Faso, the Gambia, Cape Verde, Senegal, and the Ivory Coast, as well as in Angola and Mozambique.[196] Transmission occurs principally through heterosexual contact. The overall prevalence of HIV-2 in these areas is approximately 1 to 2 percent, but seroprevalence rates of 8 percent in pregnant women in Guinea-Bissau have been observed.[334] In high-risk groups such as urban commercial sex workers, HIV-2 prevalence rates of 15 to 64 percent have been reported.[196]

HIV-2 group A infections have been identified predominantly in the western part of West Africa, mainly Guinea-Bissau, Senegal, the Gambia, and Mali.[22] HIV-2 group B infections have been found in central and eastern West African countries such as the Ivory Coast, Ghana, and Nigeria. HIV-2 has only limited distribution outside West Africa and has been described primarily in regions in Europe, South America, and India with historical socioeconomic ties to West Africa. In Europe, the greatest numbers of HIV-2 cases have been reported in Portugal, France, and Germany.[272] The cultural and economic ties of Portugal to its former colonies in West Africa probably facilitated the spread of HIV-2 to Europe and possibly Brazil, also a former Portuguese colony. As many as 4.5 percent of cases of AIDS in Portugal are caused by HIV-2, and in northern Portugal, HIV-2 accounts for 12 percent of HIV infections.[311] In France, 1 to 2 percent of all pediatric HIV infections are caused by HIV-2.[77] HIV-2–infected individuals have been identified in England, Wales, and Northern Ireland in increasing numbers. The prevalence of HIV-2 infection among clinic attendees with sexually transmitted diseases was 0.006 percent (6/104,006) in 2002. Most of these patients likely were infected through heterosexual intercourse in West Africa, including Nigeria (40%), Ghana (24%), Ivory Coast (17%), Sierra Leone (5%), and the Gambia (5%). Of 1324 HIV-infected adults, 917 (69%) were HIV-1 infected and 52 (6%) were HIV-2 or HIV-1/HIV-2 co-infected; the HIV type was not reported in the remaining 355 (27%). The ratio of HIV-2 and HIV-1/HIV-2 dual infections to HIV-1 infections varied greatly by country of infection, with the Gambia (11.7% to 15.2%) and Ivory Coast (7.2% to 9.8%) having a high proportion of HIV-2 infections and Nigeria (0.7% to 1.0%) a low proportion.[69] However, indigenous HIV-2 transmission also may occur, inasmuch as HIV-2 infections not directly linked to West Africa have been reported in Portugal, France, and Spain.

HIV-2 infection has been reported in India; as many as 7 to 8 percent of all HIV infections in certain regions are caused by HIV-2. In the United States, fewer than 100 cases of HIV-2 infection have been reported to the Centers for Disease Control and Prevention (CDC), and since the implementation of combination HIV-1/HIV-2 screening of the blood supply in June of 1992, no transfusion-acquired HIV-2 cases have been reported to the CDC.[40,41]

DUAL INFECTIONS WITH HUMAN IMMUNODEFICIENCY VIRUS TYPES 1 AND 2

Although some reports suggested that infection with HIV-2 may be protective against HIV-1 infection, that suggestion was not confirmed in other studies.[13,240,335,336,368] In two studies, HIV-2–positive subjects actually had a tendency toward a higher risk of acquiring HIV-1 infection than did seronegative individuals.[240,368] Dual infection with HIV-1 and HIV-2, confirmed by PCR and culture, has been observed in areas that are endemic for both viruses.[91,262] Susceptibility to dual HIV-1 and HIV-2 infection was studied in a macaque model of HIV infection.[255] The timing of secondary virus exposure was found to be a critical factor in the risk of acquiring infection. Productive mixed infections were established with simultaneous exposure or when viral challenge occurred within 4 weeks after primary infection developed. However, animals exposed at 8 weeks or more after primary inoculation were resistant to secondary infection. The mechanism of protection is not known.

Although HIV-1 infection predominated among a sampling of women living in Dakar, Senegal, HIV-2 and HIV-1/HIV-2 dual infections occurred more commonly among female sex workers compared with other women.[300] In studies conducted in England, Wales, Northern Ireland, Guinea-Bissau, and Dakar, when compared with HIV-1, the seroprevalence of HIV-2 was higher in older age groups. For example, in Guinea-Bissau, among individuals older than 50 years, HIV-2 prevalence was 12 percent in men and 16 percent in women.[69,300] The older age of those infected with HIV-2 probably reflects the longer asymptomatic period of HIV-2 infection, older age at the time of infection or at diagnosis, or possible differences in patterns of migration between HIV-1 and HIV-2 infected women.

MODE OF TRANSMISSION

The modes of acquisition of HIV-2 appear to be identical to those of HIV-1: heterosexual and homosexual intercourse, intravenous drug use, receipt of contaminated blood products, and vertical transmission. However, the infectivity of HIV-2 is lower than that of HIV-1, and transmission of HIV-2 by sexual intercourse appears to be less frequent than that observed with HIV-1.[149]

Like other sexually transmitted infections, the likelihood of transmission of HIV depends in part on the quantity of HIV in genital tract secretions. HIV-1 is detected more commonly in semen than is HIV-2. The viral loads in semen correlate with the plasma viral loads. In one report, HIV-2–infected subjects had 0.7 $\log_{10}$ lower HIV semen viral load than those with HIV-1, even after adjusting for plasma load.[98] Female genital shedding of HIV is important in both heterosexual and mother-to-child transmission of the virus. In a cross-sectional sampling of women living in Dakar, Senegal, HIV-1 shedding occurred more commonly than did HIV-2 shedding. HIV-2 shedding was associated with older age, severe vitamin A deficiency, advanced HIV disease, and $CD4^+$ cell counts lower than 200. Viral shedding was not detected in any women with dual HIV-1/HIV-2 infection.[300] Researchers estimated that the likelihood of sexual transmission of HIV-2 per sexual exposure is threefold less than with HIV-1.[147,194] The pandemic spread of HIV-1 compared with the more limited geographic spread of HIV-2 is likely the result of different rates of transmission of these two viruses. This difference in transmission of the two HIV viruses is reflected in the declining prevalence rates of HIV-2 in endemic areas over time.

In a study in Guinea-Bissau, the overall prevalence of HIV-2 infection in 1996 was 9.7 percent in police officers and 5.5 percent in pregnant women, as opposed to 0.9 percent in each group for HIV-1.[240] However, during the 7-year period from 1990 to 1996, the incidence of HIV-1 infection increased significantly in both groups, whereas the incidence of HIV-2 decreased, thus implying more efficient transmission of HIV-1. In a similar study of commercial sex workers in Senegal, the incidence of HIV-1 infection increased 12-fold despite a prevalence of HIV-2 at baseline that was approximately 2-fold higher than that for HIV-1.[149,197]

PERINATAL TRANSMISSION

Data from most studies of mother-infant pairs indicate that perinatal transmission of HIV-2 appears to be a rare occurrence, with mother-to-child transmission rates ranging from 0 to 4

percent.[5,93,247,269,334] In a large prospective study from the Ivory Coast, the risk of perinatal transmission from HIV-1–infected mothers was 21-fold greater than from HIV-2–infected mothers; transmission rates were 1.2 percent from HIV-2–infected mothers versus 24.7 percent from HIV-1–infected mothers.[5] In another large study in the Gambia, the estimated rate of mother-to-child transmission of HIV-2 was 4.0 percent versus 24.4 percent for HIV-1.[243] In this study, three of eight HIV-2–infected infants were infected after reaching 2 months of age, a finding suggesting that HIV-2, like HIV-1, can be transmitted postnatally through breast milk. The maternal plasma viral load is a significant risk factor for perinatal transmission of both HIV-1 and HIV-2 infection. In the study in the Gambia, for every 1 $\log_{10}$ increase in plasma RNA, the odds of transmission were 2.7 for HIV-1 and 2.8 for HIV-2.[247] Maternal RNA levels were significantly lower in HIV-2–infected than in HIV-1–infected mothers. After adjusting for viral load, the odds of transmitting HIV-1 were similar to those for HIV-2; this finding suggests that the level of viremia, as opposed to the type of virus, was the major determinant of the difference in mother-to-child transmission rates between HIV-1 and HIV-2. Transmission from women who are dually seropositive for HIV-1 and HIV-2 has been described; HIV-1 appeared to be transmitted more efficiently than does HIV-2, and HIV-1 transmission rates from dually infected women were similar to those from women infected with HIV-1 alone. Transmission of dual infection to the infant, though a rare occurrence, has been described. In the Ivory Coast cohort, 19.0 percent of women with dual HIV-1 and HIV-2 infection transmitted HIV to their infants; of 11 infected infants, 10 were infected with HIV-1 alone, and 1 was dually infected.[5]

DIAGNOSIS OF HUMAN IMMUNODEFICIENCY VIRUS TYPE 2

The diagnosis of HIV-2 can be accomplished by culture of HIV-2 from peripheral blood mononuclear cells (PBMCs), measurement of HIV-2 proviral DNA, detection of HIV-2 RNA in peripheral blood, or detection of antibodies to HIV-2. Although HIV-1 and HIV-2 share a similar genetic organization, significant divergence in genetic sequence exists, with differences of 58 percent for the *gag* gene, 59 percent for the *pol* gene, and 39 percent for the *env* gene. More similarity is seen between HIV-2 and primate simian immunodeficiency virus (SIV), in which the nucleic acid sequence homology between HIV-2 and SIV_{SM} and SIV_{MAC} strains is approximately 75 percent.[196] Because of this antigenic variation, screening EIAs for HIV-1 antibody may not detect antibody to HIV-2, and thus combination screening tests containing antigens from both viruses have been developed.[42] Confirmatory Western blot testing to detect HIV-2 requires the use of HIV-2–specific assays because not all samples from persons infected with HIV-2 will be positive on HIV-1 Western blot.

Rapid HIV detection tests have proven to be valuable tools for establishing the diagnosis of HIV. In several patient populations, when compared with ELISAs, rapid tests have been shown to have specificities and sensitivities close to 100 percent for the detection of either HIV-1 or HIV-2. The accurate detection of dually infected individuals has been less reliable; most individuals who were identified as dually infected by rapid test ultimately were diagnosed with HIV-2 only. When dual infections were identified by sequential rapid tests, performance of a supplementary test was necessary to allow the accurate discrimination between HIV-1 and HIV-2.[162,287]

The significance of this phenomenon is uncertain, but it may reflect the poor replication level of the HIV-2 virus and the resultant low end of antibody production. Host-related factors may include altered humoral or cellular responses to the HIV-2 virus. Another report showed HIV-2–specific cytotoxic T-lymphocyte activity in individuals in West Africa who may have been exposed to HIV-2 but who remained seronegative.[146]

VIRAL LOADS

Assays for the detection of HIV-2 RNA are not currently available commercially. However, in multiple studies examining HIV-2 viral load, an inverse relationship was found between $CD4^+$ lymphocyte counts and plasma HIV-1 and HIV-2 viral loads in singly infected individuals. Plasma HIV-1 levels were approximately 10 times higher than plasma HIV-2 levels throughout the comparable span of $CD4^+$ lymphocyte counts, and HIV-1 and HIV-2 regression lines had very similar slopes. Plasma HIV RNA levels were influenced independently by the type of HIV and $CD4^+$ lymphocyte counts, but not by sex or age. Among dually infected individuals, no correlation was found between $CD4^+$ counts and either plasma HIV-1 or HIV-2 levels.

The viral set-point is significantly lower in HIV-2 infection than it is for HIV-1 infection. Recent HIV-2 seroconverters have plasma HIV RNA levels 28 times lower than those of recent HIV-1 seroconverters. For HIV-1, the viral set-point has been demonstrated to be a very good predictor of outcome of disease. Differences between HIV-1 and HIV-2 in natural course, transmissibility, and epidemiologic features result, in large part, from lower viral levels in plasma. HIV-2 infection may resemble a slowly progressive or nonprogressive HIV-1 infection. The finding that HIV-2 is contained to a higher degree than is HIV-1 may reflect differences in the interaction between the immune system and the two HIV types or inherent differences in the biologic characteristics of the two viruses. Autologous neutralizing antibodies more frequently are found in HIV-2–infected individuals than in HIV-1–infected individuals and also may contribute to the slower disease progression in HIV-2.

In a study in Guinea-Bissau of individuals dually infected with HIV-1 and HIV-2, the interaction between the two viruses and the host defense mechanisms was less predictable. Although an inverse relationship existed between levels of $CD4^+$ lymphocytes and proviral HIV-2 DNA as compared with singly infected individuals, no correlation was found between levels of $CD4^+$ lymphocytes and plasma RNA or between HIV-1 and HIV-2 RNA load.[9]

A different study compared the $CD4^+$ cell counts and viral loads of individuals infected with HIV-1, HIV-2, and both HIV-1 and HIV-2. $CD4^+$ cell counts were significantly higher in those patients infected with HIV-2 compared with dually infected and HIV-1–infected individuals (582×10^6 cells/L, 165×10^6 cells/L, and 107×10^6 cells/L, respectively). HIV-1 viral loads were similar between HIV-1–infected and dually infected subjects, as were HIV-2 viral loads in HIV-2–infected and dually infected subjects. The HIV-1 viral loads were two times higher than HIV-2 viral loads.[161]

Studies indicate that levels of integrated proviral HIV-2 DNA in peripheral blood mononuclear cells are similar to those in comparable groups of HIV-1–infected individuals.[11,139,266] Despite similar proviral levels in HIV-1 and HIV-2, patients infected with HIV-2 have a significantly lower plasma viral load, a finding thus suggesting a lower rate of expression of the HIV-2 proviral DNA template.[58,266,267,304,334]

CLINICAL MANIFESTATIONS

HIV-2 is fully pathogenic in humans, and the clinical spectrum of disease caused by HIV-2 is similar to that of HIV-1. However, the rate of $CD4^+$ T-cell depletion and clinical progression to AIDS is slower, and more favorable survival is observed, although the mortality rate is increased in comparison with seronegative

persons.[143,155,196,198,358,366] As for HIV-1, the HIV-2 viral load significantly correlates with progression of disease as measured by $CD4^+$ T-cell decline or mortality, and differences in viral load throughout most of the natural history of HIV-1 and HIV-2 infection probably account for the differences in progression of disease and transmissibility reported between the two viruses.[9,12,266,267,311]

In a cohort study of HIV-2–infected and HIV-1–infected women in Senegal, the rate of decline in $CD4^+$ T-lymphocyte count was approximately 1 percent per year for women infected with HIV-2 versus 10 percent per year for HIV-1.[198] The median time to development of AIDS in HIV-1–infected women was 10 years; in contrast, HIV-2–related AIDS-free survival was so high that a median estimate of the time to a diagnosis of AIDS could not be determined.[197] Once the immune status deteriorates, however, the mortality rate does not differ greatly from that of HIV-1 infection. In community-based studies comparing the risk of death in infected versus uninfected adults, the relative risk of dying with HIV-2 infection was increased by 2- to 4-fold, in contrast to a 10-fold increase with HIV-1 infection.[219,268,278] Immunologic findings are similar to those in HIV-1 infection, with polyclonal hypergammaglobulinemia, increased T-cell activation, decreased lymphocyte proliferation, reduced antigen recall, and mildly elevated $CD8^+$ and reduced $CD4^+$ T-lymphocyte counts. However, in most cases, these changes are not as severe as those observed with HIV-1 infection. In a comparison of HIV-1–infected and HIV-2–infected persons with similar $CD4^+$ T-cell counts, the quantitative viral load was significantly lower in those infected with HIV-2.[304] In patients with a $CD4^+$ cell count greater than 500/mm^3, none of the HIV-2–infected individuals had a detectable plasma viral load, as compared with 52 percent of HIV-1–infected persons. In a study of sero-incident cases of single or dual infection with HIV-1 and HIV-2 in Guinea-Bissau, dually infected individuals had lower plasma RNA levels than did singly infected individuals.[9]

Similar to the clinical outcome of HIV-2 infection in adults, slower rates of progression of disease and better survival rates have been observed in HIV-2–infected versus HIV-1–infected or dually infected children.[5,59,241,254,271] In a prospective study in the Gambia, the 18-month mortality rate of children born to HIV-2–infected mothers did not differ significantly from that of children born to HIV-seronegative women (7% versus 6%, respectively).[254] In contrast, the relative risk of death in children born to HIV-1–infected versus HIV-2–infected or seronegative mothers was increased by 2.3- and 2.6-fold, respectively. The excess number of deaths in children of HIV-1–infected mothers was caused primarily by HIV-1 infection in the child; the mortality rate was 35 percent in HIV-1–infected children, as opposed to 9 percent in uninfected children born to HIV-1–infected mothers. In contrast, no deaths occurred in HIV-2–infected children.

In Guinea-Bissau, the overall child mortality rates were similar in children born to HIV-2–seropositive and HIV-seronegative women (16.3% versus 14.6%, respectively).[241] However, despite generally slower progression in HIV-2–infected children, severe immunodeficiency and AIDS occurring early in life rarely have been reported with HIV-2 infection.[90,212] In a cohort study in the Gambia, among HIV-infected patients with $CD4^+$ counts 500 cells/μL or greater, HIV-2–infected patients had a significantly lower mortality rate than that of HIV-1–infected or HIV-1/HIV-2–dually infected patients. Among HIV-infected patients with advanced disease ($CD4^+$ counts <200 cells/μL), all had a poor prognosis, and no difference in mortality rates occurred among HIV-1, HIV-2, or dually infected patients. Mortality was associated with increasing age and male sex and was inversely related to $CD4^+$ count. The mortality hazards ratio for men was 1.63 times higher than that for women even after adjusting for $CD4^+$ count, HIV type, and age.[295] Mortality in infants born to HIV-1–infected or dually infected mothers was 2.6 to 4.2 times higher than that in infants born to HIV-2–infected mothers (mortality rates of 133, 82, and 32 per 1000, respectively).[58]

This finding is similar to that observed in the Gambia, where the childhood mortality rate was 15 percent for children born to HIV-1–infected mothers, compared with 7 percent for those born to HIV-2–positive mothers and 6 percent for those born to HIV-seronegative mothers.[254] In a small cohort study investigating the survival of children born to HIV-1–positive and HIV-2–positive mothers, the mortality rates for HIV-1–infected and HIV-2–infected children were significantly higher than those of uninfected children.[294] The mortality hazards ratio of HIV-1–infected children was 3.1 times that of HIV-2–infected children but was not statistically significant. The overall mortality of HIV-uninfected children of HIV-1–seropositive and HIV-2–seropositive mothers was not significantly different from that in children of HIV-uninfected children.[295]

TREATMENT OF HUMAN IMMUNODEFICIENCY VIRUS TYPE 2 INFECTION

HIV-1 and HIV-2 reverse transcriptase (RT) enzyme regulates the formation of double-stranded viral DNA that is to be integrated into the host-cell genome. RT catalyzes the incorporation of deoxynucleoside triphosphates (dNTPs) forming a negative-sense DNA strand by using HIV-positive sense RNA as a template. The RT RNase activity catalyzes the degradation of the positive-sense RNA from the negative-sense DNA. The RT DNA polymerase then uses the negative-sense DNA as a template to form double-stranded proviral DNA. Nucleoside reverse transcriptase inhibitors (NRTIs) resemble endogenous dNTPs. These agents inhibit the formation of viral DNA by competitively inhibiting dNTPs for the RT enzyme and, then once incorporated into the HIV DNA strand, terminating the chain by preventing formation of 3′,5′-phosphodiester bonds. In vitro studies of antiretroviral activity against HIV-2 show NRTIs to have inhibitory effects against wild type and mutant HIV-2 clones.[263] The effective concentrations of lamivudine (3TC), didanosine (ddI), zalcitabine (ddC), and stavudine (d4T) needed to inhibit wild-type HIV-2 are very similar to what is effective against wild-type HIV-2. Researchers initially thought that HIV-2 was inhibited by zidovudine (ZDV, formerly AZT), but more recent studies suggested that wild-type HIV-2 harbors polymorphisms that confer resistance to zidovudine and significantly reduces its susceptibility to this agent.[276]

HIV-1 NRTI resistance results from base changes within the RT genome, provoking amino acid substitutions in the transcribed enzyme that, in turn, confer structural changes at the enzyme active site or at associated functional areas. In HIV-1, each NRTI induces a predictable set of genetic alterations in a step-wise fashion. Primary mutations generally arise first, with secondary mutations developing during continued therapy. HIV-2 RT resistance can be conferred by mutations at sites homologous to those from HIV-1 RT NRTI resistance. In a cell-free system, side-directed mutagenesis of HIV-2 RT amino acid residues homologous to residues in HIV-1 RT reduces the sensitivity of mutated HIV-2 to NRTIs. HIV-1 RT mutation T215Y confers resistance to AZT. Clinical studies of HIV-2 clones taken from patients receiving NRTI-containing antiretroviral therapy (ART) confirmed that phenotypic resistance is associated with genotypic changes. Amino acid changes associated with HIV-1 NRTI resistance at M184 and Q151M also seem to occur in HIV-2 and have been associated with NRTI treatment failure.[344] The significance of other mutations in the HIV-2 RT gene after exposure to NRTI is unknown; also not known is whether mutations in the NRTI gene accumulate in a step-wise fashion conferring increasing resistance to NRTI therapy. Non-nucleoside

reverse transcriptase inhibitors (NNRTIs) bind to a hydrophobic pocket near the polymerase site of HIV-1 RT. In vitro studies that measure HIV-2 susceptibility to inhibition by NNRTs supported the conclusion that these types of drugs have no effect against HIV-2.[372] Natural resistance of HIV-2 to this class of agents is thought to be conferred by a single amino acid, Leu-188. A change in amino acid at this site renders HIV-2 RT sensitive to efavirenz and delavirdine but not to nevirapine.[137] Newer NNRTIs inhibit HIV-2 at effective concentrations at least 50 times higher than those that inhibit HIV-1. These concentrations limit the clinical utility of these agents against HIV-2. NNRTIs generally show little to no inhibition of HIV-2 in vitro at nontoxic levels.[365]

Studies indicated that some HIV-1 protease inhibitors (PIs) also may inhibit HIV-2.[197] HIV-1, HIV-2, and SIV proteases belong to the aspartyl protease family. They are responsible for the post-translational processing and cleavage of the polyprotein products Pr GAG and PrGAG-POL into functional core proteins and essential enzymes including RT, integrase, and protease. Proteases are necessary to produce a mature retrovirus. PIs competitively bind to the protease substrate site, with resulting production of immature non-infectious particles. PIs are effective against HIV-2 protease, but they bind with a 10 to 100 times weaker affinity to HIV-2 protease, depending on the inhibitor. Studies of individual PIs showed nelfinavir and saquinavir to exert the same inhibitory activity against HIV-2 as against HIV-1, whereas ritonavir and indinavir were one to two orders of magnitude less inhibitory against HIV-2. ART against HIV-2 with dual PI or triple NRTI/PI-based therapy results in decreased HIV-2 viral load, increased $CD4^+$ T-cell count, and an improvement in AIDS related symptoms. Clinical studies examining PI susceptibility of HIV-2 clones from individuals both before and after receiving ART showed that indinavir, saquinavir, lopinavir, and tipranavir had full activity against wild-type HIV-2. Nelfinavir and amprenavir were less active against these clones. During ART with PIs, HIV-2 mutations were present, including in a patient who had been treated with lopinavir and who developed the proV47A, which translated into high-level resistance to indinavir, lopinavir, and amprenavir and hypersusceptibility to saquinavir. In isolates from the second patient, several different mutations resulted in decreased susceptibility to all PIs tested except saquinavir.[283] Naturally occurring polymorphisms or secondary mutations may decrease the activity of nelfinavir and amprenavir. On selection of primary resistance, mutations and preexisting secondary changes may play a role in the acquisition of a multi-PI resistance phenotype in HIV-2. Although PI resistance to HIV-1 is not completely understood, the HIV-2 protease active sites appear to differ, and this may confer natural HIV-2 resistance to ritonavir and indinavir. The D30N mutation as a natural polymorphism in HIV-2 reduces the efficacy of nelfinavir against HIV-2. A genotypic analysis of four HIV-2–infected individuals demonstrated the M46I mutation in all four individuals. V82F in one patient was associated with progressive decline in $CD4^+$ lymphocytes, despite treatment with indinavir. In a case report of two patients infected with both HIV-1 and HIV2, ART successfully suppressed HIV-1 but failed to suppress HIV-2. Treatment-experienced HIV-2–infected patients achieved HIV-2 viral suppression on a ritonavir-boosted indinavir or lopinavir highly active ART (HAART) regimen.[346]

In a cohort study on patients in Abidjan, Cote d'Ivoire, HIV-2–infected patients treated with dual ART or nelfinavir-containing regimens had incomplete HIV-2 viral suppression, whereas those treated with indinavir-containing regimens had complete and sustained viral suppression.[4] HIV-2 protease is 50 percent homologous to that of HIV-1. Researchers showed that mutations that confer resistance to PIs in HIV-1 were found in homologous positions in the HIV-2 protease. Natural polymorphism patterns were different in HIV-1 and HIV-2 proteases. In particular, highly polymorphic positions of HIV-2 (positions 14, 40, 43, 46, 65, and 70) from ART-naïve patients were highly conserved in HIV-1 strains. The highest levels of natural polymorphism in HIV-1 were observed at positions 35, 37, 41, 62, 63, 64, 77, and 93. Three regions of both HIV-1 and HIV-2 protease were highly conserved: positions 25 through 32, which includes the protease active site; the flap region; and positions 78 through 87. In protease sequences from ARV-naïve HIV-2 infected individuals, HIV-1 drug resistance-associated codons were identified in most cases (amino acids 36I, 46I, and 71V) or in all cases (amino acids 10V, 32I, 47V, and 73A). Fifty-nine percent of sequences from untreated HIV-2 patients harbored 46I. This finding corresponds in HIV-1 to a major drug resistance mutation to indinavir and to a minor drug resistance mutation to ritonavir, nelfinavir, and amprenavir, lopinavir/ritonavir, and atazanavir. These findings suggest a naturally reduced susceptibility of HIV-2 to these agents, even in an untreated individual.[51] In vitro studies using serial cultured cells passaged in the presence of serially diluted PIs documented the emergence of drug resistance over time. At baseline, HIV-2 was found to express natural protease polymorphisms at several positions that could be implicated in emergent drug resistance. Certain mutations were selected with different PIs. Whereas treatment-associated mutations all were associated with homologous mutations in the HIV-1 protease, mutations in the HIV-2 sequence were identified that had not been associated previously with drug resistance in either HIV-1 or HIV-2.[244] Genetic diversity of the HIV-2 genome renders it unlikely to be susceptible to the currently available HIV-1 fusion inhibitors.[270]

CHAPTER 204b

Impact of Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome

Filiz O. Seeborg ● William T. Shearer ● I. Celine Hanson

Human immunodeficiency virus (HIV) infection continues to have a significant clinical impact on our world. The World Health Organization (WHO) and Joint United Nations Programme on HIV/AIDS (acquired immunodeficiency syndrome) estimates that across the globe, 4.3 million people were newly infected with HIV-1 in 2006 (Table 204–8).[216] Of these newly infected individuals, 530,000 (10%) were children younger than 15 years of age. In 2004, half of the 40,000 new cases of HIV infection in the United States were in patients aged 13 to 25 years, a reflection of the change in the route of HIV infection for youth from perinatal to heterosexual transmission.[35] Racial and ethnic disparities among newly HIV-infected individuals continue to be observed worldwide, including in developed nations such as the United States. Between 2001 and 2004, black male and female patients accounted for more than 50 percent of newly diagnosed U.S. infections.[40] In 2005, the annual U.S. rate for HIV infection in Hispanics was three times greater than that for non-Hispanics. Despite the advances that have been made in care during the decades since the HIV infection first was described, HIV/AIDS continues its worldwide spread.[37] Eradicating racial disparities and preventing HIV infections in the changing face of the U.S. and global epidemic will be the medical and public health challenges for this century.[34,204]

DEFINITION AND STAGING

Pediatric AIDS was reported to the Centers for Disease Control and Prevention (CDC) first in 1982; AIDS was first reported in adults in 1981.[34] The first definitions of pediatric AIDS were published in 1985. In 1994, the classification system again was revised to include more advanced viral diagnostic technology and a system for staging pediatric HIV disease that involved both clinical and immunologic axes.[30] Table 204–9 outlines the clinical

TABLE 204–8 Estimated Number of Adults and Children Newly Infected with Human Immunodeficiency Virus during 2006

Country	Number of Infected Adults/Children 2006
African Continent	2.81 million (2.41-3.21 million)
East/South Asia	960,000 (610,000-2.6 million)
Eastern Europe/Central Asia	270,000 (170,000-820,000)
Latin America	140,000 (100,000-410,000)
North America	43,000 (34,000-65,000)
Caribbean	27,000 (20,000-41,000)
Western/Central Europe	22,000 (18,000-33,000)
Oceania	7,100 (3,400-54,000)
TOTAL	4.3 (3.6-6.6 million)

axis of the staging system, which is composed of four clinical categories (N, A, B, C).[30] The clinical axis is intended for unidirectional use in any individual child; that is, severity of disease proceeds from N (asymptomatic), to A (mildly symptomatic), to B (moderately symptomatic), to C (severely symptomatic), and then to HIV-associated death. Clinical category C describes children with AIDS-defining characteristics, namely, wasting, encephalopathy, opportunistic infections, and malignancies, but it excludes lymphoid interstitial pneumonitis/pulmonary lymphoid hyperplasia (LIP/PLH). Clinical category B describes children with other specific HIV-associated illnesses (e.g., single episodes of bacteremia, leiomyosarcomas, lymphoproliferative lung disorders, anemia, thrombocytopenia) and excludes children with a clinical category C event. Clinical category A describes children with two or more specific HIV-associated illnesses, namely, lymphadenopathy, hepatomegaly, splenomegaly, upper respiratory tract infections/sinusitis/otitis media, parotitis, and dermatitis, and excludes children with a clinical category C or B event. Clinical category N describes children without clinical category C, B, or A events; these children may or may not be completely asymptomatic (single category A events, such as lymphadenopathy, may exist).

Table 204–10 provides an expanded description of the immunologic axis of the staging system, which includes categories 1 (no evidence of immune suppression), 2 (moderate immunosuppression), and 3 (severe immunosuppression).[30] The immune axis is limited to quantitative assessment (absolute count, percentage, or both) of the peripheral blood helper T-cell ($CD4^+$) population. Each category is linked to age-matched $CD4^+$ cell counts and percentages; age groups include 0 to 11 months, 12 to 71 months, and 72 months and older. Age-matched $CD4^+$ percentages and count standards for moderate to severe immunosuppression are identical to those provided in the 1995 revised guidelines for pediatric *Pneumocystis jiroveci* prophylaxis interventions.[31]

EPIDEMIOLOGY AND TRANSMISSION AND PREVENTION

TRANSMISSION BY BLOOD PRODUCTS

Pediatric HIV transmission has been documented by blood and blood products, by perinatal transmission from mothers with identified risk factors, by breast milk,[66] and by sexual transmission to children and adolescents,[86] a development that may become epidemic. Since HIV screening techniques, including nucleic acid amplification testing to pooled blood products, were adapted and recombinant factor products were used increasingly, transmission of HIV by blood products rarely has been reported in the United States.[61]

PERINATAL TRANSMISSION

In the United States, the total annual number of AIDS cases resulting from perinatal transmission peaked in 1992, with just fewer than 1000 newly affected children reported.[16] Predominance of perinatal transmission is found worldwide, especially in countries where adult heterosexual transmission is uniquely prevalent (e.g., in Africa).[176,204] Before the use of perinatal antiretroviral interventions, the transmission rate for perinatally acquired HIV infection was reported to be between 12 and 25 percent in the United States and Europe and is probably higher in Africa.[54,174,213] The perinatal transmission rates reported here define transmission only in the context of live infant outcomes. The incidence of spontaneous fetal loss in HIV-infected pregnant women has been suggested to be increased and may represent increased HIV perinatal morbidity.[130]

Maternal risk factors associated with enhanced perinatal HIV transmission and identified through national surveillance in reported AIDS cases include drug abuse, heterosexual infection by sexual partners with risk factors for acquiring HIV disease, and maternal transfusion before 1985. Prospective and retrospective evaluations of maternal predictors for perinatal HIV transmission have been the focus of multiple studies. Maternal transmission predictors identified to date include maternal viremia (measured as quantitative HIV RNA polymerase chain reaction [PCR] or viral load),[71,81] maternal immunosuppression, or an inadequate immune response (measured by the $CD4^+$ cell count, neutralizing antibody production)[71,141] and viral characteristics (chemokine receptor tropism, resistance patterns of maternal virus at delivery or infant virus at birth).[17] Pregnancy and placental variables (delivery mode, duration of rupture of membranes, chorioamnionitis) also may influence the risk of perinatal transmission of HIV.[161,202,211] Infant variables evaluated as predictors of transmission of HIV include specific human leukocyte

antigen (HLA) markers and the infant cellular immune response (cytokine production, activated T-cell function).[70,73,140] In addition, immunogenetic factors (chemokine co-receptor expression) have been suggested to confer protection against progression of disease.[184]

Perinatal transmission of HIV has been proposed to take place in the antepartum, peripartum, and postpartum periods.[198] The distribution of transmission across these timing periods has not been defined precisely, but in non–breast-feeding populations, more than 50 percent of transmission is estimated to occur at the end of pregnancy.[123] The timing of the first positive culture in perinatally infected infants—that is, early (the first 7 days of life) versus late (second week of life or later)—has been used epidemiologically to differentiate children potentially infected in utero from those with intrapartum infection.[22] Such distinctions and a need for more precise definition of the timing of distribution of perinatal transmission are of paramount importance in defining interventions for interruption of transmission. Such interruption is especially important because investigators have suggested that early HIV-1 infection can have an impact on the rate of neurodevelopmental dysfunction within the first 2 years of life.[196]

In an African study, evaluation of gender-specific risks for mother-to-child transmission of HIV showed preference for intrapartum transmission to female infants.[208] In this cohort, the overall transmission rate at birth was 9.5 percent. HIV-exposed male infants (n = 966) had a 6.3 percent transmission rate as compared with 998 HIV-exposed female infants, who had a 12.6 percent transmission rate. Attempts to assess progression of disease have led to descriptions of subpopulations of HIV-infected children: rapid, usual, and slow progressors.[111,120] Standardized definitions for rapid or usual progressors are lacking. A stringent definition of slow progressors has been proposed (8 years of age without evidence of clinical or immunologic decline).[96] In a multicenter, longitudinal U.S. study of 360 HIV-infected children, maternal advanced disease (clinical class C symptoms, lowered $CD4^+$ cell count, and increased viral load) was associated with faster progression of disease in infected infants.[2]

Advances in perinatal primary antiretroviral therapy (ART; antepartum, peripartum, and postpartum delivery of zidovudine in non–breast-feeding HIV-infected women without severe immunosuppression) in the United States and developing nations led to a decrease in perinatal transmission rates. In 1994, Pediatric AIDS Clinical Trials Group (PACTG) protocol 076 documented the remarkable effectiveness of zidovudine in reducing the maternal-infant transmission of HIV-1 by 66 percent.[54] The three-part regimen consisted of the following: (1) zidovudine initiated during 14 to 34 weeks' gestation (100 mg orally five times daily) and continued throughout pregnancy, (2) intrapartum zidovudine (intravenous loading dose of 2 mg/kg followed by a continuous infusion of 1 mg/kg until delivery), and (3) oral zidovudine for the newborn infant (2 mg/kg per dose every 6 hours orally for 6 weeks) or intravenous dosing for infants unable to tolerate oral administration (1.5 mg/kg per dose every 6 hours). Recommendations for prophylaxis continue to promote use of zidovudine for prevention of mother-to-child transmission; a more thorough review is available at http://AIDSinfo.nih.gov. Inclusion of highly active ART (HAART) and zidovudine to suppress HIV viral load and restore or preserve immune function in pregnant HIV-infected women resulted in a further reduction in transmission rates in the United States, now reported as less than 2 percent.[56] Guidelines to prevent perinatal transmission include promotion of early maternal and infant testing, prevention counseling for women of child-bearing age, and treatment intervention in women of child-bearing age with newly identified HIV infection.[166] The selection of ART to reduce perinatal HIV transmission must include consideration of optimal treatment for the infected pregnant women and balance potential for fetal harm. Maternal factors that should be considered include the mother's viral load, degree of immunosuppression, medications for use in treatment of co-morbid conditions (e.g., tuberculosis, hepatitis C virus) and the potential for inducing viral resistance. Transmission of resistance HIV to infants has been described in the literature, but it is an infrequent event.

Other considerations to prevent perinatal transmission of HIV include scheduled delivery to minimize prolonged rupture of membranes, including a recommendation from the American College of Obstetrics for scheduled cesarean section for women with viral loads exceeding HIV RNA levels of 1000 copies/mL.[53] In a meta-analysis of 15 North American and European cohorts of HIV-infected pregnant women (n = 100 women), vertical transmission rates differed by 5 percent for those with scheduled delivery by cesarean section (transmission rate, 2%) as compared with those with other delivery modes (transmission rate, 7.3%).[211] Evaluation of the morbidity and mortality related to such scheduled cesarean sections suggests that HIV-infected pregnant women may have a higher incidence of postpartum hemorrhage with resultant transfusion, sepsis, pneumonia, and death than do their non-infected pregnant peers undergoing the same scheduled procedure (odds ratio, 1.6).[137] HIV-infected pregnant women without detectable viral loads should be informed preoperatively of their risk for having morbidity related to cesarean section performed to prevent perinatal HIV transmission.

If the maternal HIV status is unknown at the time of delivery, options for perinatal transmission prophylaxis may not be available for use in the antepartum or postpartum period. Early and rapid HIV testing is being promoted as a public health measure to prevent perinatal HIV transmission. In the multicenter Mother-Infant Rapid Intervention at Delivery (MIRIAD) study, voluntary rapid HIV testing and 24-hour counseling were conducted at 16 U.S. hospitals, with mean turn-around time of 66 minutes for test results.[23] The sensitivity and specificity of the rapid test performed on whole blood were 100 and 99 percent, respectively, and the positive predictive value of the testing compared favorably with the standard of enzyme immunoassay (EIA).

SEXUAL TRANSMISSION: SECOND WAVE OF PEDIATRIC ACQUIRED IMMUNODEFICIENCY SYNDROME

In the adult, young adult, and adolescent populations, sexual acquisition of HIV infection is the predominant transmission pattern. The intersection of pediatric sexual abuse and transmission of HIV has been reported. Sexual abuse in young children and infants may be associated with the transmission of sexual disease (e.g., syphilis, gonorrhea, human papillomavirus). HIV infection should be considered in the differential diagnosis of possible sexually transmitted diseases in children assessed for sexual assault. In contrast to the infrequent reports of sexual transmission in infants and children younger than 13 years of age, adolescents, who account for 1 percent of AIDS cases in the United States, are infected frequently by sexual transmission.[133] In an inner city urban U.S. community, 41 percent of sexually active female youth described having vaginal intercourse and receptive anal intercourse in casual relationships.[107] Use of condoms was reported in 64 percent of youth, but receptive anal intercourse was used by some as a form of contraception, and condom use in this setting was reported in only 41 percent of these encounters. The American Academy of Pediatrics (AAP) stressed the importance of preadolescent and adolescent care and encouraged performing examinations in patients who are 11 to 14 years of age. Health care providers can take advantage of these pre-teen/teen visits as an opportunity to explore sexual exposures

of youth in their care and to educate sexually active youth on options for contraception.

Because the symptom-free period for clinical expression of HIV infection in adolescents may approach adult standards (i.e., >10 years), many young adults (20 to 29 years of age) with AIDS probably became infected with HIV during adolescence.[133] Adolescents with AIDS, like affected infants and children, are more likely to be poor and black or Hispanic. Reported risks for transmission in adolescents vary by age, sex, and race or ethnicity. Behavioral transmission (men who have sex with men [MSM] and heterosexual contact) and transmission of unknown risk predominate as reported risk behavior in U.S. youth. The category of heterosexual contact accounts for the largest proportional increase in the reported risk of transmission in both female and male adolescent cases of AIDS. The nature of youth (experimentation, search for self and sexual identity, and inability to access health care easily) places adolescents at risk for heterosexual transmission of HIV infection.

Recommendations for post-exposure prophylaxis (PEP) for nonoccupational exposure to blood, genital, or other body fluids were updated by the CDC in 2005.[194] With exposure to these fluids from an HIV-infected individual and with determination of significant exposure risk, a 28-day regimen of HAART is recommended if administration can begin within 72 hours of exposure. For these exposures, risk is defined as 1 per 10,000 exposures to the infected source. Other risk assignments are blood transfusions (9000 per 10,000 exposures), percutaneous needle-stick injuries (30 per 10,000 exposures), and sexual exposure risk ranging from 50 (anal receptive intercourse) to 0.5 (oral intercourse). Merchant and colleagues[151] published a stratified regimen for PEP in children and youth that includes modification of the dosing regimen, evaluates adverse events commonly associated with PEP, and recommends institution of antiretrovirals within 1 hour of exposure when possible.

OTHER MODES OF TRANSMISSION

Less frequently reported transmission routes of HIV infection are important for pediatric health care providers to acknowledge and target. The risk of transmission of HIV through breast-feeding is reported infrequently in the United States. In a study of HIV-infected, breast-feeding mothers and their exposed infants, Dunn and associates[66] documented a 14 percent risk of HIV transmission through breast-feeding above and beyond the established perinatal transmission risk. These studies prompted the adoption of guidelines for preventing transmission by this route by avoiding breast-feeding in HIV-seropositive postpartum mothers in the United States. Transmission of HIV to infants by breast-feeding represents approximately half of all perinatal transmission worldwide, and the risk of transmission continues with prolonged breast-feeding after the first year of life.[122]

Children may be prone to needle-stick or sharps injuries that occur in a non-hospital, non-medical setting (e.g., needle-stick injury associated with inappropriately discarded needles in public places such as public parks, bathrooms). Recommendations for psychological support, discussion of adherence to prescribed medications, and toxicity monitoring are recommended by the AAP Committee on Pediatric AIDS.[101]

To date, no data suggest that HIV infection is transmitted casually from HIV-infected children to siblings, playmates, or caregivers.[190] Documentation of transmission routes and lack of casual transmission have prompted defining appropriate measures for "mainstreaming" of HIV-infected children and families.[63] This measure includes school, daycare, and foster care and adoption placement for HIV-infected children and promotes social incorporation of these children.

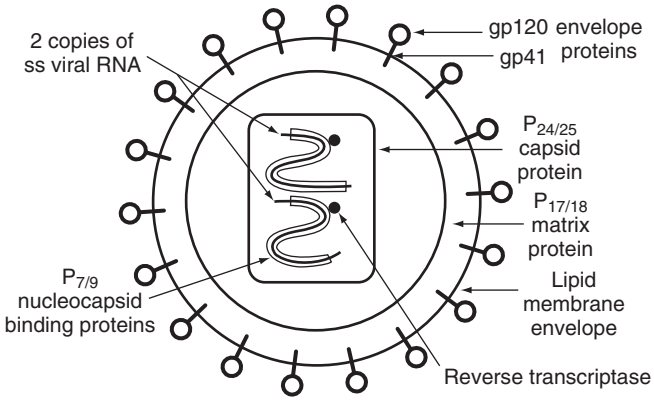

Figure 204–4 Diagram of the virion of human immunodeficiency virus type 1 (HIV-1). *(From Demmler, G. J., and Taber, L. H.: Virology of HIV-1. Semin. Pediatr. Infect. Dis. 1:17-20, 1990.)*

ETIOLOGY

Identification of the origin of AIDS followed closely behind the clinical description of this complex immunodeficiency. In 1983, investigators worldwide identified a viral cause for AIDS and described human lymphotropic virus III, lymphadenopathy-associated virus, and a virus associated with persistent generalized lymphadenopathy.[51,85] These viruses subsequently were identified as similar and now are called HIV-1, or simply HIV (Fig. 204–4).[58] Two species of HIV are recognized: HIV-1 and HIV-2. HIV-1 has been the more prevalent pathogenic species and, especially in the United States, almost uniformly has been associated with reported AIDS cases. Viral divergence is not uncommon, and HIV-1 can be divided into three groups: M, major; O, outliers; and N, non-M/non-O; the M group represents the major group with subtypes (clades) showing significant symmetry.[6] The major subtypes have been identified, and data from the WHO HIV Vaccine Initiative identified clade C in 50 percent of global infections in 2004.[102] Clade B is identified most frequently in industrialized countries, including the United States. In 2004, recombinant subtypes were responsible for 18 percent of worldwide infections; continued collection of such data will be important in the successful development of a vaccine that can be applied universally to stem transmission of HIV. A detailed description of these RNA viruses, their method of viral introduction into the affected host, and their impact on critical immune components is provided in Chapter 204a.

PATHOGENESIS

THE DEVELOPING IMMUNE SYSTEM

In perinatally infected infants, the disruption that HIV creates in the fetal/newborn immune system is envisioned best by considering the intricate normal differentiation pathways of the bone marrow stem cell.[222] Lymphocyte (T- and B-lymphocyte) differentiation pathways are presented in Figure 204–5 to illustrate points where genetic defects can occur and then cause congenital immunodeficiency. In many regards, the immunodeficiency of neonatal HIV infection parallels that of genetically inherited immune disorders.

HIV affects almost all immune cell types and alters their ability to produce important chemokines and interleukins that are integral to immunologic homeostasis. Independent of cell damage, host response also can vary according to individual

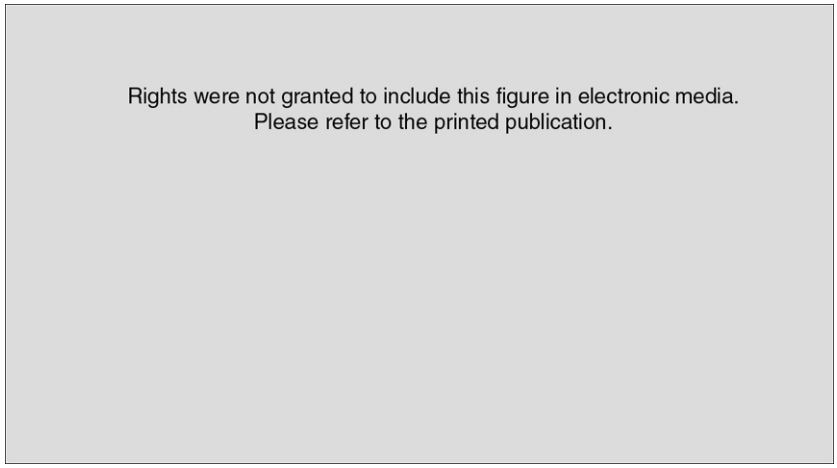

Figure 204–5 Model of the events of cellular maturation, cellular interaction, and cellular biosynthesis required for a normal immune response. The *arrows* indicate presumed defects in various immunodeficiency states. *Position 1*, Failure of B- and T-cell development (e.g., severe combined immunodeficiency disease). *Position 2*, Failure of development of the thymus (e.g., DiGeorge syndrome). *Position 3*, Failure of maturation of stem cells into pre-B cells (e.g., thymoma, hypogammaglobulinemia). *Position 4*, Failure of maturation of pre-B cells into B cells (e.g., X-linked hypogammaglobulinemia). *Position 5*, Failure of maturation of B cells into plasma cells (e.g., common variable hypogammaglobulinemia). *Position 6*, Hypercatabolism of immunoglobulin (e.g., myotonic dystrophy). *Position 7*, Reduced helper T cells (e.g., subset of common variable hypogammaglobulinemia). *Position 8*, Increase in suppressor T-cell activity (e.g., subset of common variable hypogammaglobulinemia). *Position 9*, Excessive loss of immunoglobulins and lymphocytes (e.g., intestinal lymphangiectasia). *(From Waldmann, T. A.: Immunodeficiency diseases: Primary and acquired.* In *Samter, M., Talmage, D. W., Frank, M. M., et al.: [eds.]: Immunological Diseases. 4th ed. Boston, Little, Brown, 1988, pp. 411-465.)*

genetic HLA representation and predict either probability of infection occurring following exposure or progression of disease.[76] $CD4^+$ cells bear a receptor (the $CD4^+$ molecule itself) for the gp120 component of the HIV virion coat, and through this mechanism viral entry into the host cell is allowed. This entry does not occur in isolation, and host expression of a chemokine receptor (CXCR4 for T-lymphotropic HIV strains; CCR5 for monocyte tropic HIV strains) interacts in promoting viral particle binding to the host-cell membrane and release of viral particles into the cytoplasm.[47] Data suggest that heterozygous allele expression of these co-receptors may affect expression and progression of HIV disease. Density expression of CCR5 molecules in infants has been correlated with progression of disease even in the presence of ART and with the slope of $CD4^+$ cell decline from birth.[42]

Once infected, the infant with perinatal transmission exhibits a quick rise in detectable HIV viral load that can exceed 750,000 copies/mL in the first weeks or months of life and persists unchecked without institution of antiviral therapy through the first years of life.[1] This persistent and lengthy viremia in early perinatal HIV infection differs from acute HIV-1 infection in adults, in which viremia initially may be equally elevated but abates with host immunologic response (albeit without complete elimination) over the course of a shorter time frame (weeks to months). These distinctions in host response reflect the more ineffective infant immunologic host response to HIV infection. Proposed mechanisms of immune dysfunction associated with continued viremia in infants include thymic damage with thymocyte depletion, disruption of thymic architecture, early $CD4^+$ cell depletion that affects $CD8^+$ cell response to HIV antigens, early lymphocyte activation as measured by $CD8^+DR^+CD38^+$ T cells that impede effective host T-cell response, and genetic predisposition to allow enhanced HIV entry into host cells.[180,227] Most clinicians opt for early treatment of HIV-infected infants younger than 1 year of age, independent of the clinical or immunologic ($CD4^+$ cell count) presentation. Studies have documented both viral control and improved response to HIV-specific antigens with such efforts.[226]

IMMUNE DYSFUNCTION

Abnormalities in adult HIV infection include leukopenia, lymphopenia, and decreased $CD4^+$ helper-inducer cells with an expanded $CD8^+$ cell population, which results in an inverted CD4/CD8 ratio, typically less than 1.0. Early in the course of infection, T-lymphocyte function has been noted to be diminished (<50%), with decreased in vitro responses to soluble antigens preceding $CD4^+$ cell depletion. Although in vitro responses to plant lectins, such as phytohemagglutinin, concanavalin A, and pokeweed, appear to be normal early in the course of HIV infection, these responses begin to decrease with clinical decline; characteristically, mitogen responses to pokeweed disappear first. Anergy is not unusual to commonly tested antigens (tetanus, *Candida*). Because of HIV-related paralysis of $CD4^+$ cells, production of interleukin-2 (IL-2) is reduced, thereby weakening the immune amplification system.[75] HIV-infected $CD4^+$ cells release soluble IL-2 receptors. These elevated serum IL-2 receptor levels produce a blockade of cell-bound IL-2 receptors by competition for IL-2. $CD8^+$ cell response to HIV-specific antigens is impaired.[165] Children with HIV infection seldom are lymphopenic in terms of values observed in adults. If lymphopenia is observed in children with HIV infection, it usually is seen in older children or in children who have progressed to end-stage HIV disease. In fact, $CD4^+$ cell counts in HIV-infected children commonly exceed 400 cells/mm^3. Moreover, Denny and associates[59] showed that in infants aged 12 to 24 months, a $CD4^+$ cell value of less than 1000 cells/mm^3 is significant for selective HIV-related $CD4^+$ depletion; in infants younger than 12 months, a value of less than 1500 cells/mm^3 similarly applies. Lymphoproliferative responses to recall antigens have been documented as relatively normal findings early in the course of infection; decline is correlated with the onset of clinical symptoms. As described earlier in discussions of pathogenesis, HIV-1–specific $CD8^+$ cytotoxic-suppressor cell function has been documented as being ineffective in infants with primary infection (early perinatal infection).

Following administration of HAART, T-cell function against specific HIV antigens continues to be imperfect. Despite lower-

ing of viral load, $CD4^+$ cell depletion may not be completely restored for many weeks. Differential restoration of subpopulations of $CD4^+$ cells (effector memory cells more commonly encountered than naïve cells) may occur. In 643 children with significant $CD4^+$ depletion ($CD4^+$ cells <250 cells/mm^3) and viremia, HAART resulted in a median rise of $CD4^+$ cell count of 100 cells/mm^3 over the course of 2 years, but anergy was reported in 80 percent, lack of proliferative response to the specific antigen of tetanus in 73 percent, and impaired serologic response to hepatitis A virus vaccination in 54 percent.[132] Hence, despite administration of ART, T-cell immune restoration may not be complete in all affected children.

B-cell dysfunction is identified similarly in HIV-infected adults and children and manifests as hypergammaglobulinemia. HIV-infected adults also demonstrate circulating immune complexes and production of autoantibodies secondary to polyclonal activation of B cells by HIV itself or concomitant viral infection with cytomegalovirus (CMV) or Epstein-Barr virus (EBV).[129] In particular, immunoglobulin G (IgG) levels may rise to 2 to 3 standard deviations (SDs) above the mean of normal values, and serum IgA, IgM, and IgE levels may be elevated as well. This extreme hypergammaglobulinemia in children may be caused by polyclonal stimulation of B cells by HIV or co-infection with CMV or EBV, or it may be caused by the absence of normal $CD4^+$ immunoregulatory cells. Specific antibody functions measured as childhood vaccine responses often are abnormal and are not always completely restored in the most severely immunocompromised individuals following administration of HAART therapy.[132]

Other host defense cells affected by HIV infection include natural killer (NK) cells. In adults with chronic HIV infection, reported NK abnormalities include differential representation of certain NK subpopulations, down-regulation of NK ligand expression that affects cytotoxicity of HIV-infected cells, and NK-dendritic cell interactions that switch from a T_H1 response (interferon-γ [IFN-γ]) to a T_H2 response.

Monocytes and macrophages play important roles in the pathogenesis of HIV infection by serving as reservoirs of HIV. Defective chemotaxis and bacterial killing have been observed in HIV-infected monocytes and macrophages, as has defective induction of IL-1, which possibly accounts for the decreased IL-2 response in $CD4^+$ cells.[195] The immune system also seems to contribute directly to HIV-induced encephalopathy (Fig. 204–6).[21,105] HIV-induced encephalopathy is particularly devastating in young infants, who fail to reach early motor milestones or, worse, regress from acquired early development. The incomplete state of myelination of central nervous system (CNS) tissue may account for susceptibility to the neurologic effects of HIV infection. In adults with progression of disease, depletion of $CD4^+$ cells has been linked to shifts in co-receptor use (from CXCR4 to CCR5), and these individuals with more severe disease appear to harbor predominantly CCR5-dependent (R5) viral strains.[88] HIV-containing monocytes are thought to transport HIV into the CNS and infect microglial cells including astrocytes.[50] Also implicated in HIV-associated neurologic complications are glial soluble factors that may have a direct neurotoxic effect.[127] Cytokines and reactive oxygen species released by HIV-infected lymphocytes and macrophages in the CNS may damage exposed nerve tissue.[221] The normal CNS immune defense system can attempt to enhance neuronal survival.

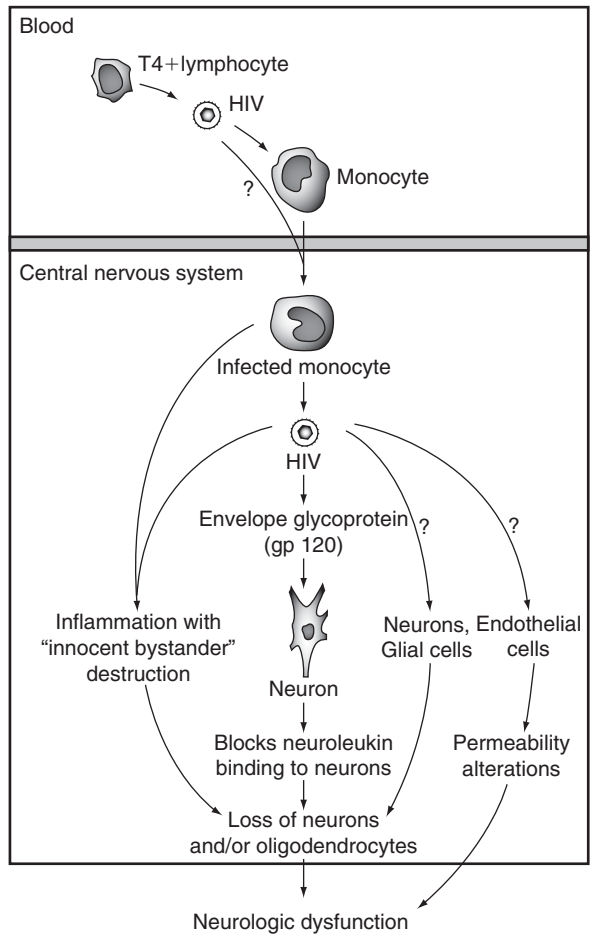

Figure 204–6 Role of the immune system in pediatric human immunodeficiency virus (HIV)–induced encephalopathy. HIV-infected $CD4^+$ lymphocytes and macrophages enter the central nervous system. HIV may escape from these transport cells and infect nerve cells directly or cause indirect damage to neurons by the release of cytokines such as tumor necrosis factor and interleukin-2. *(Reprinted by permission from Ho, D., Pomerantz, R. J., and Kaplan, J. C.: Pathogenesis of infection with human immunodeficiency virus. N. Engl. J. Med.* 317*:278-286, 1987.)*

ORIGIN OF IMMUNODEFICIENCY

The use of HAART has provided important opportunities to evaluate immune restoration in infected hosts. $CD4^+$ cell-depletion hypotheses of programmed cell death (apoptosis), depletion of tissue-associated $CD4^+CD45^+$ effector memory cells during acute infection, chronic ineffective immune activation (cellular and humoral), and switch from CXCR4-dependent virus (X4 virus) in acute infection to CCR5-dependent virus (R5 virus) in chronic infection all have been implicated as causes of HIV-induced immunodeficiency.

Ligands that induce apoptosis have been studied in HIV-infected individuals, and tumor necrosis factor–related apoptosis inducing ligand (TRAIL) has been documented to result in neuronal death.[152] TRAIL-associated apoptosis appears to require CXCR4 co-receptor expression but not CCR5 or CD4 receptor expression.[139]

Investigators hypothesize that HIV first depletes mucosal $CCR5^+CD4^+$ effector memory cells, thus leaving short-lived central memory or naïve $CD4^+$ cells and other immunoregulatory cells in a chronic state of activation that leads to an ineffective host response.[60,95] Infection of $CCR5^+CD4^+$ effector memory cells also is associated with higher expression of CTLA-4, a potent negative regulator for $CD4^+$ cells.[228] High expression of CTLA-4 may interrupt IL-2 production by $CD4^+$ cells, thereby impeding the ability of these cells to proliferate and hence depleting the population. The resultant chronic immune activation may lead to disorganization of the host immune response and further deplete $CD4^+$ cell regeneration. For patients with the most

profound CD4+ T-cell depletion, reduction of viral load with antiviral agents does not immediately result in correction of their immune defects.[88] The study of immune reconstitution with HAART may illuminate the immunopathogenesis of HIV infection. For example, after administration of HAART, CD4+ NK T cells that play an important part in regulatory immune response to viral infections are restored rapidly. Restoration of such CD4+ cell populations after administration of HAART and their important immune function may explain why, in the presence of persistently skewed CD4+ cell expression in peripheral blood, clinical disease appears to improve dramatically.[219]

In perinatal HIV infection, the role of the placenta in affording protection or permitting infection continues to be defined, and potential perinatal cofactors are beginning to be understood more clearly. Langston and associates[130] suggested that HIV may be fetotoxic, with an impact most notably reported in the thymus, where precocious involution, epithelial injury, and, occasionally, severe thymitis are described. Loss of lymphocytes at the corticomedullary junction of the thymus implies a defect induced by HIV in the immunologic selection process.

CLINICAL MANIFESTATIONS

In children and adults, HIV infection causes a spectrum of clinical abnormalities that affect multiple organ systems and include the symptom constellation of AIDS. Table 204–11 lists the pre-HAART frequency of AIDS-defining events per 100 child-years.[155]

Infection with HIV, independent of a diagnosis of AIDS, may be attended by nonspecific clinical findings, including mild failure to thrive, hepatosplenomegaly, acquired microcephaly, parotitis, generalized lymphadenopathy, nonspecific intermittent diarrhea, intermittent fever, and chronic skin disease. These clinical symptoms are shared by other pediatric disease processes and can, when manifested singly in an HIV-infected host, cause a delay in establishing the diagnosis. However, a careful and detailed history should provide helpful insight into potential HIV risk factors and should prompt inclusion of HIV infection in the differential diagnosis. With the use of HAART, HIV infection has become a chronic disease, and new clinical disease manifestations (e.g., lipodystrophy, hyperlipidemia), most closely related to chronic antiviral use, have been described. In general, the health of HIV-infected children has improved during the last decade. Data from the Pediatric Spectrum of HIV Disease Study shows lower hospitalization rates from 30.4 percent in 1990 to 12.9 percent in 2002.[13]

TABLE 204–11 Frequency of Opportunistic Infections in Human Immunodeficiency Virus–Infected Children before Widespread Use of Highly Active Antiretroviral Therapy

Pre-HAART Era (Event Rates >1/100 Child-Years)
Candidiasis

OPPORTUNISTIC INFECTIONS

Opportunistic infections plague HIV-infected individuals and are the most prominent cause of morbidity and mortality in this cohort. Before the use of HAART intervention, opportunistic infections in children more often were primary infections as compared with the case in adults, who had reactivation of infection.[155] The introduction of effective HAART with associated host immune restoration significantly modified the expression of certain opportunistic infections in adults and children.[207] In children, the overall incidence of these infections declined from 14.4 cases per 100 patient-years before 1997 to 1.1 cases per 100 patient-years.[163] Additionally, in pre-HAART years, the age at clinical presentation was much younger, and age younger than 3 years was associated with very rapid CD4+ cell decline. Although the number of these opportunistic diseases has diminished, their prevalence appears to be unaffected. The administration of combination HIV therapy, including protease inhibitors (PIs) in adults and children, has improved the survival of perinatally infected children.[89]

Pneumocystis Pneumonia

P. jiroveci (formerly *P. carinii*) pneumonia (PCP) is the opportunistic infection most commonly reported in HIV-infected children. Declines in the incidence of PCP have been documented, with rates of 5.8 cases per 100 patient-years reported before 1997 and 0.3 cases per 100 patient-years reported after 1997.[163] PCP has a fulminant course in the pediatric population, with the highest mortality rates occurring in affected children younger than 1 year old. In a study of 172 children with perinatal HIV infection without HIV-specific intervention, 9 percent had PCP when they were younger than 1 year, with a median survival of 1 month.[183] Clinical expression of pediatric PCP often can be distinguished from other pulmonary diseases by the severity of the hypoxemia (higher alveolar-arterial oxygen gradients), elevated serum lactate dehydrogenase levels, the rapidity of progression of disease with tachypnea and fever, characteristic diffuse interstitial infiltrates on radiography, and the usual lack of digital clubbing.[98] The more insidious manifestation of PCP characteristic of HIV-infected adults, namely, prolonged fever (>7 weeks), cough, and dyspnea (averaging 3 weeks), is appreciated less commonly in infants and children. Radiographically, pediatric PCP is associated with diffuse interstitial markings progressing to the "white-out" picture of adult respiratory distress syndrome (Fig. 204–7).[99] However, PCP can be seen initially as a unilateral streaky pneumonic infiltrate, as lobar consolidation, or with accompanying pleural effusions.

Aggressive diagnostic measures may be indicated to establish a diagnosis of PCP. Bronchoscopic alveolar lavage (BAL) is the preferred diagnostic tool in adults and children and should be considered a first choice for presumed PCP in children who cannot provide sputum specimens for evaluation. In older children and adults, evaluation of sputum for the presence of *Pneumocystis* with appropriate stains or monoclonal antibodies may preempt the need for using invasive diagnostic measures. Lung biopsy carries the highest sensitivity for identifying the organism but has attendant morbidity related to thoracotomy or video-assisted thoracoscopy (VATS) and placement of a chest tube.

Acute PCP is treated with parenteral trimethoprim-sulfamethoxazole (TMP-SMX) or pentamidine or atovaquone for patients with TMP-SMX or pentamidine hypersensitivity. TMP-SMX treatment consists of 15 to 20 mg/kg/day of the

TMP component delivered intravenously three to four times daily. Adjunctive corticosteroid therapy given early in moderate to severe PCP provides significant benefit with only limited evidence of concomitant immune suppression and attendant infectious complications.[83,193] Concomitant CMV and PCP has been documented in HIV-infected children. In this clinical situation of concomitant viral infection, no existing data recommend delay of corticosteroid use. Treatment of PCP should not be altered. Dosing regimens for corticosteroids are published and include options for use of oral prednisone or oral methylprednisolone or intravenous methylprednisolone.[32]

Following the occurrence of PCP infection, secondary PCP prophylaxis (therapy initiated after acute disease treatment and resolution) is recommended. Proposed pediatric regimens include TMP-SMX at 150 mg/m^2/day and 750 mg/m^2/day, respectively, in two divided doses on 3 consecutive days/week (acceptable alternate regimens include a single dose on 3 consecutive days/week, two divided doses on 3 alternate days a week, two divided doses daily), dapsone for children 1 month or older at 2 mg/kg daily (single dosing not to exceed 100 mg/day) or 4 mg/kg weekly (single dosing not to exceed 200 mg), for children 5 years or older, pentamidine (aerosolized [300 mg by Respirgard II inhaler monthly]), and atovoquone (30 mg/kg daily for children 1 to 3 months and >24 months and 45 mg/kg daily for children 4 to 24 months).[31] In adults and adolescents, recommendations to discontinue secondary PCP prophylaxis are proposed once there is documentation of immune restoration (CD4$^+$ cell counts that have increased to >200 cells/mm^3 for ≥3 months as a result of HAART).[32] Data from the European PCP-Withdrawal Study Group suggest that with immunorestoration of HAART, the risk of PCP development is low, and withdrawal of PCP prophylaxis as recommended in the adult host appears to be a reasonable risk.[218] U.S. guidelines continue to recommend lifelong primary PCP prophylaxis in individuals who acquired their PCP before reaching13 years of age.[155]

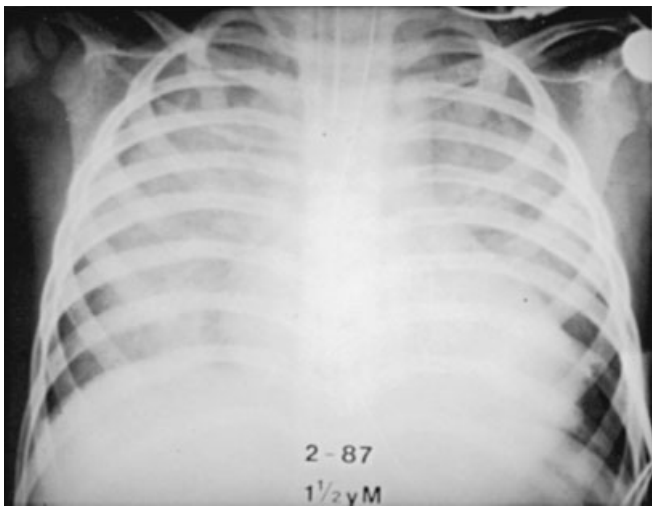

Figure 204–7 Classic diffuse interstitial infiltrates of acute and fatal *Pneumocystis carinii* pneumonia in a 15-month-old child with perinatal acquired immunodeficiency syndrome. *(From Hanson, I. C.: Respiratory infections in HIV-infected children. Immunol. Allergy Clin. North Am. 13:205-217, 1993.)*

Primary PCP prophylaxis (therapy initiated to prevent primary infection) for adults and children is accepted as standard care.[32] Pediatric regimens and dosing for secondary PCP prophylaxis do not differ from those outlined earlier. In 1993, the CDC published the first PCP prophylaxis guidelines for HIV-infected children; these guidelines linked the institution of therapy to the level of immunosuppression as measured by the CD4$^+$ cell count or percentage.[28] After implementation of these guidelines, Simonds and associates[191] reviewed the incidence of reported PCP cases to the CDC and noted no decline in case numbers. Of 300 children with PCP reported to the CDC between January of 1991 and June of 1993, 66 percent had never received prophylaxis. In addition, 18 percent of infants younger than 1 year old experienced PCP with CD4$^+$ counts that were higher than the guideline thresholds for immunosuppression. Based on these data, guidelines for PCP prophylaxis in children were modified in 1995, and Table 204–12 outlines the institution of therapy by age and CD4$^+$ cell monitoring.[31] The most significant changes in the revised guidelines included (1) an emphasis on early detection of HIV infection in infants for optimal implementation of the guidelines, (2) provision of PCP prophylaxis to all HIV-exposed infants in the first months of life, and (3) emphasis on quarterly immune monitoring. The low potential for associated morbidity from the administration of PCP prophylaxis allows for implementation of therapy to all infants, independent of HIV status, in the first months of life, when their risk has been documented to be highest and is least likely to correlate with immune monitoring. Data from Pediatric AIDS Clinical Trials Group protocol 1088 documented that primary PCP prophylaxis in HIV-infected children could be discontinued safely with immune restoration on stable ART.[162]

Mycobacterium avium–Intracellulare Complex

The *M. avium–intracellulare* complex (MAC), which caused disseminated infections in both adults and children with HIV infection in the early 1980s and 1990s, waned significantly in incidence with the increasing and successful use of HAART. In a 1990 review of opportunistic infections in pediatric patients with AIDS, 43 of 552 (7.8%) children from birth to 9 years of age

TABLE 204–12 Recommendations for *Pneumocystis* Pneumonia Prophylaxis and CD4$^+$ Monitoring for Infants Exposed to and Children Infected with Human Immunodeficiency Virus by Age and Human Immunodeficiency Virus Infection Status

Age/HIV Infection Status	PCP Prophylaxis	CD4$^+$ Monitoring
Birth to 4-6 wk, HIV exposed	No prophylaxis	1 mo
4-6 wk to 4 mo, HIV exposed	Prophylaxis	3 mo
4-12 mo HIV Infected or indeterminate	Prophylaxis	
6, 9, and 12 mo HIV infection reasonably excluded	No prophylaxis	None
1-5 yr, HIV infected	Prophylaxis *if* CD4$^+$ count is <500 cells/μL or CD4$^+$ percentage is <15%	Every 3-4 mo
6-12 yr, HIV infected	Prophylaxis *if* CD4$^+$ count is <200 cells/μL or CD4$^+$ percentage is <15%	Every 3-4 mo

HIV, human immunodeficiency virus; PCP, Pneumocystis *pneumonia prophylaxis.*

From Centers for Disease Control and Prevention: 1995 Revised guidelines for prophylaxis against Pneumocystis carinii *pneumonia for children infected with or perinatally exposed to human immunodeficiency virus. National Pediatric and Family HIV Resource Center and National Center for Infectious Diseases, Centers for Disease Control and Prevention: M. M. W. R. Recomm. Rep. 44:6, 1995.*

were found to have disseminated MAC infection.[99] The incidence of pediatric MAC infection in HIV-infected children dropped from 1.3 cases per 100 patient-years reported before 1997 to 0.2 cases per 100 patient-years after 1997.[163] Epidemiologically, MAC has been linked to significant immunosuppression ($CD4^+$ cell counts <50 cells/mm^3) in adults.[32,106,156] Researchers noted that the development of MAC infection in children may be associated with $CD4^+$ counts greater than 50 cells/mm^3, especially in children younger than 6 years old.[175] Symptoms of MAC infection include fever, malaise, weight loss, anorexia, and night sweats. Gastrointestinal manifestations are not uncommon and have included abdominal pain, diarrhea, malabsorption, and intestinal perforation. Rarely, MAC has been reported with extrabiliary obstructive jaundice (presumed to be secondary to lymphadenopathy) and endobronchial masses. The diagnosis of disseminated MAC infection relies on identification of these microorganisms from the blood, lymph tissue, bone marrow, liver, lungs, and gastrointestinal tract. Therapy for disseminated MAC infection in the pediatric population includes some combination of clarithromycin or azithromycin (maximal dosing of 500 mg and 250 mg, respectively) and/or rifabutin (maximal dosing of 300 mg). The epidemiologic link with severe immunosuppression and the advent of therapeutic prophylactic interventions (clarithromycin or azithromycin and/or rifabutin) prompted the implementation of MAC prophylaxis guidelines for adults, adolescents, and older children (6 years and older) with $CD4^+$ cell counts lower than 50 cells/mm^3.[29]

An unusual immune restoration inflammatory syndrome (IRIS) has been described as a paradoxical event after immune recovery has been achieved in adults and adolescents receiving HAART.[203] IRIS is associated with reactivation of opportunistic infections such as MAC. Activation of other latent complications, including carcinoma and neurologic symptoms, has been described.[215] Specific recommendations regarding prophylaxis in the context of IRIS are not yet defined. In IRIS, treatment of the reactivated opportunistic infection may include administration of anti-inflammatory agents including systemic steroids.

Mycobacterium tuberculosis

The increasing incidence of tuberculosis globally has affected the HIV-infected population because factors that increase the transmission of tuberculosis also affect the transmission of HIV. In a cohort of pregnant and nonpregnant HIV-infected women monitored in a multicenter longitudinal study, the prevalence of tuberculosis determined by medical history or positive skin tests was 14 percent.[155] In tuberculosis-positive individuals aged 25 to 44 years in the United States, the incidence of co-infection with HIV ranged from 9.9 to 24.2 percent in low- to higher-reporting states.[33] Factors associated with the acquisition of pediatric tuberculosis have included primarily family and caregiver risks.[9] In a study of 60 HIV-infected families, the incidence of tuberculosis was approximately 6 percent, with both HIV-infected and HIV-uninfected children affected. The vector for transmission was identified as an infected family member or caregiver. Tuberculosis should be considered in the differential diagnosis of pulmonary disease in HIV-exposed children. Treatment of active tuberculosis in an HIV-infected child includes at least a four-drug regimen, and the duration of treatment is 9 to 12 months, with the longest duration being in children with extrapulmonary disease. Careful monitoring of ART is necessary in HIV-infected children receiving concomitant antituberculosis therapy because drug-drug interactions can occur. For example, rifampin induces hepatic cytochrome P-450 and may have an impact on ART agents metabolized through that same pathway. Each HIV-infected child should be evaluated annually for exposure to tuberculosis.

Cytomegalovirus

In 1987 reports to the CDC, disseminated CMV infection occurred in 19 percent of pediatric patients with AIDS.[174] The adult spectrum of CMV disease, including retinitis, pneumonitis, esophagitis, gastritis, colitis, hepatitis, cholangitis, and encephalitis, is not reported uniformly in the pediatric AIDS literature. CMV clearly can cause primary pneumonitis in children or can be found in association with other pulmonary pathogens, especially *Pneumocystis*. Unusual gastrointestinal manifestations have included pyloric obstruction, enterocolitis, and oral and esophageal ulcers. CMV retinitis in children, in contrast to adults, is described infrequently and appears to be decreasing in incidence. Reported in 1.4 cases per 100 child-years before 1997, the incidence appears to be 0.1 cases per 100 child-years since 1997 and the wider use of HAART.[163]

Treatment of CMV disease associated with HIV infection focuses on progression of disease and not on a curative outcome. Therapeutic intervention includes the use of ganciclovir, valganciclovir, foscarnet, or cidofovir. These drugs have significant side effects, including bone marrow suppression and renal toxicity. Administration of these agents is divided into induction and maintenance dosing. The optimal interval for efficacy has not been determined and often is selected on an individual basis. Although many adults report experiencing subjective and objective improvement while receiving therapy, discontinuation of therapy is associated with high relapse rates, independent of the affected site. Careful monitoring of children receiving treatment for CMV and ART is imperative because the use of both classes of agents may depress bone marrow function. Guidelines to prevent CMV infection in HIV-infected persons have been published and include the use of oral ganciclovir.[80] Oral ganciclovir may provide primary prophylaxis in HIV- and CMV-infected children with severe immunosuppression ($CD4^+$ cell count <50 cells/mm^3). Prevention of complications of CMV in HIV-infected children with severe immunosuppression should include careful and regular (every 4 to 6 months) retinal monitoring for evidence of eye disease. Once secondary prophylaxis for disseminated CMV disease is initiated, its discontinuation should be considered on a case-by-case basis because current data to support discontinuation are limited. As reported with MAC, reactivation of CMV disease in the IRIS has been described.

Other Herpesvirus Infections

Infections with the herpesvirus family are not uncommon events in HIV-infected children. Chronic herpes simplex virus (HSV) infection was reported in 5 percent of children with AIDS before the use of HAART.[174] In general, HSV infection in pediatric AIDS has been limited to mild to severe localized infections without reports of dissemination. Varicella-zoster virus (VZV) and herpes-zoster virus (HZV) infections have contributed significant morbidity to HIV-infected persons. Disseminated and chronic HZV infections are reported in pediatric patients with AIDS. The judicious use of acyclovir for chronic infection is warranted to lessen the probability of emergence of resistant strains. Prevention of herpes infections in school-aged children is especially important because exposure to varicella may be considerable. Administering varicella-zoster immune globulin, if available, should be considered for susceptible HIV-infected children with exposure to VZV. Because the varicella vaccine is an attenuated live viral vaccine, its use in HIV-infected children is limited currently to children with asymptomatic or mildly symptomatic HIV disease and no evidence of immune suppression.[39]

Fungal Diseases

Chronic *Candida* infection plagues HIV-infected children. Affected mucous membranes or skin often does not respond well

to treatment with topical antifungal agents. Fluconazole has been documented in an open multicenter study to be as effective and safe as is ketoconazole for the treatment of oropharyngeal candidiasis.[104] In severe fungal infections, amphotericin B or other agents effective against the *Candida* spp. should be administered intravenously. Prophylaxis for candidal infections is not recommended because of concern for development of resistance to azoles such as fluconazole, which could limit the use of these agents in the care of disseminated or mucosal disease.[32]

Other disseminated fungal diseases, such as histoplasmosis and cryptococcosis, less commonly affect pediatric patients with AIDS. Histoplasmosis may be prevalent in HIV-infected children who reside in parts of the United States where *Histoplasma capsulatum* is endemic. Symptoms of histoplasmosis include fever, rash, cough, lymphadenopathy, splenomegaly, thrombocytopenia, low-grade disseminated intravascular coagulopathy, adult respiratory distress syndrome, meningoencephalitis, and neurologic abnormalities consistent with intracranial mass lesions. Symptoms of cryptococcosis include fever, headache, pulmonary involvement, and subacute meningitis or meningoencephalitis. Primary prophylaxis for adults and adolescents is suggested for those with compromised immune systems. Specifically, fluconazole is suggested as primary cryptococcosis prophylaxis for adults and adolescents with $CD4^+$ cell counts of less than 50 cells/mm^3 and itraconazole for histoplasmosis prophylaxis in adults and adolescents with $CD4^+$ cell counts of less than 100 cells/mm^3. Recommendations to discontinue prophylaxis as a result of HAART-related improved immune function have been developed for cryptococcosis and include sustained (≥6 months) $CD4^+$ cell counts higher than 100 to 200 cells/mm^3. In contrast, no such recommendations exist for discontinuation of histoplasmosis prophylaxis in HIV-infected adults or adolescents with evidence of HAART-related reconstitution of immunity.

Bacterial Diseases

Pediatric patients have an increased incidence of severe bacterial infections, including infections with *Streptococcus pneumoniae*, *Staphylococcus aureus*, and various gram-negative organisms. The risk of contracting community-acquired invasive bacterial infections has been estimated to be three times higher than the rate in non–HIV-infected children.[5] In a study of 372 HIV-infected children monitored for a median of 17 months, 14 percent experienced one or more laboratory-proven serious bacterial infections.[212] More recent findings suggested that the incidence of bacterial disease dropped from rates of 4.7 cases per 100 patient-years before 1997 to 0.2 cases per 100 patient-years after 1997.[163] Reported clinical infections included bacteremia, pneumonia, osteomyelitis, meningitis, and sinusitis. Therapy is directed against the specific isolated bacterial pathogen, and the dosing and duration of therapy depend on the affected site. Prophylaxis against bacterial infections initially should include vaccination with appropriate childhood vaccines, including *Haemophilus influenzae* type b, pneumococcal conjugate vaccines, and meningococcal conjugate vaccines.[41] Other medications available for bacterial prophylaxis include intravenous immunoglobulin (IVIG) and TMP-SMX. In a study that predated the widespread use of ART agents in children, the use of IVIG (400 mg/kg every 28 days) increased the time free from serious bacterial infections in those with $CD4^+$ cell counts exceeding 199 cells/mm^3 and decreased morbidity as measured by hospitalizations.[154] A subsequent analysis of concomitant IVIG and zidovudine use documented the efficacy of IVIG in children not also receiving TMP-SMX for PCP prophylaxis.[199] Given the expense and cumbersome route of administration, IVIG has been reserved as prophylaxis for HIV-infected children with evidence of hypogammaglobulinemia or those with more than two invasive bacterial infections in a 1-year period.

PULMONARY COMPLICATIONS

In addition to PCP and chronic sinopulmonary infection, noninfectious pulmonary complications of pediatric AIDS are associated with morbidity. In a series of more than 150 children with perinatal HIV infection early in the U.S. epidemic, the lymphoproliferative lung disorders lymphoid interstitial pneumonitis (LIP)/pulmonary lymphoid hyperplasia (PLH) were reported most frequently, and 17 percent of these children were affected.[183] Histopathologically, LIP and PLH appear to be distinct entities, although whether these disorders represent a continuum of reactive hyperplasia of lymphoid tissue is somewhat controversial. In LIP, small lymphoid infiltrates are dispersed throughout parenchymal lung tissue and often are accompanied by alveolar epithelial hyperplasia and interstitial widening. PLH describes larger, dense nodular aggregates of lymphoid tissue both in distal parenchymal tissue and in the walls of bronchi and bronchioles (Fig. 204–8A). Compression of blood and lymphatic vessels by these nodules may contribute to the accompanying clinical interstitial widening. The cause of LIP/PLH has not been defined. Associations with in situ EBV and the HIV genome have been noted, and an increase in local nonspecific and HIV-specific IgG and IgA production has been described.

Clinically, LIP/PLH is characterized by a nonproductive cough and the insidious onset of progressive hypoxia. The hypoxemia may be subtle and best appreciated during febrile, upper respiratory tract illnesses. Digital clubbing, generalized lymphadenopathy, chronic parotitis, or failure to thrive may accompany LIP/PLH. Radiographically, LIP/PLH often demonstrates characteristic interstitial infiltrates with a nodular pattern (see Fig. 204–8B). This radiographic picture frequently mimics that of miliary tuberculosis and warrants exclusion of this pulmonary infection. In an immunocompromised, anergic, HIV-positive child, simple delayed hypersensitivity skin testing for exclusion of tuberculosis may not suffice, and BAL or gastric aspiration for detection of acid-fast microorganisms may be necessary. Lung biopsy is the definitive diagnostic procedure for LIP/PLH. However, in HIV-infected children, a presumed diagnosis of LIP/PLH by the less invasive exclusion of infectious pathogens is preferred.

Therapy for LIP/PLH is not defined clearly because the clinical outcome is variable. HIV-infected children with LIP/PLH have been noted to have spontaneous remissions without therapeutic intervention, whereas other affected children progress to respiratory insufficiency and failure. Therapeutic interventions have included IVIG supplementation, ART, and corticosteroids (daily or alternate-day dosing ranging from 0.5 to 2.0 mg/kg/day), and observation. No significant associated infectious sequelae (bacteremia, fungemia) of corticosteroid use were reported in treated children. Supportive therapy consisting of oxygen supplementation, chest physical therapy, and attention given to adequate nutritional intake is helpful adjunctive treatment.

Other non-infectious pulmonary complications have been reported less frequently in the pediatric HIV-infected population and include bronchiectasis, vasculitis, and diffuse interstitial pneumonitis. An association of overrepresentation of asthma in HIV-infected children and youth treated with HAART has been reported that appears to correlate with the immune reconstitution of $CD4^+$ cell counts.[79]

CENTRAL NERVOUS SYSTEM COMPLICATIONS

Neurologic abnormalities have been documented in persons with HIV and can be attributed to opportunistic infections, adverse events of primary treatment, or primary infection with HIV, especially in light of HIV's described tropism for monocytes. Ten percent of adults with AIDS initially have neurologic symptoms,

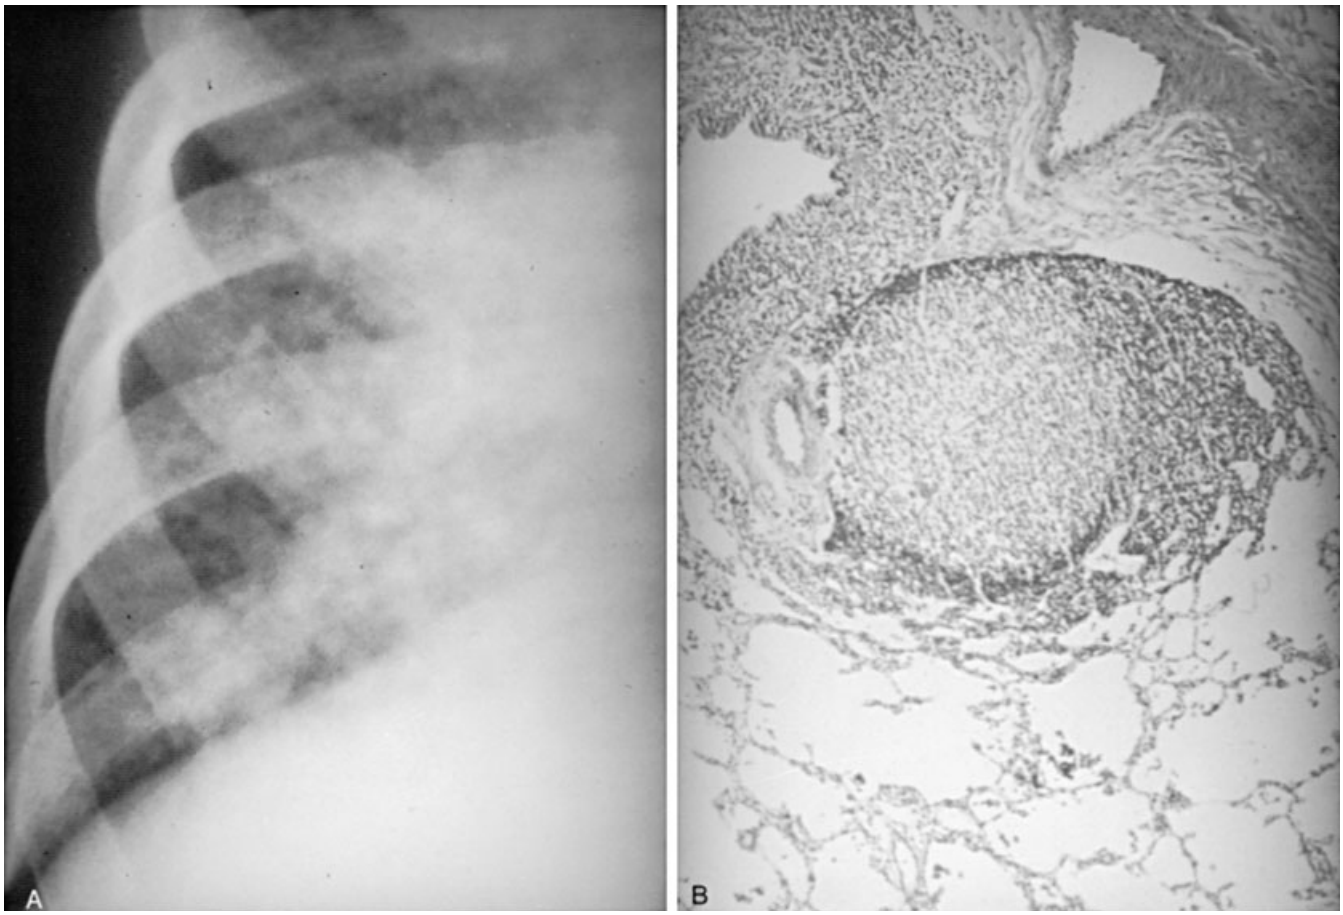

Figure 204–8 **A**, Chest radiograph documenting parenchymal nodularity in a 3-year-old child with perinatal acquired immunodeficiency syndrome (AIDS). **B,** Pulmonary lymphoid hyperplasia in the same infant with perinatal AIDS and histologic changes, including interstitial widening and prominent peribronchial lung nodes.

and 40 percent are affected during their clinical course.[146] Belman and associates[12] and Epstein and colleagues[69] described significant neurologic complications in children, including seizure disorders, attention-deficit disorders, developmental delay, and acquired microcephaly and encephalopathy. In 1987, expansion of the CDC surveillance criteria for the diagnosis of AIDS incorporated neurologic deficits by including AIDS dementia or encephalopathy.[27] In adults, dementia included "clinical findings of disabling cognitive and/or motor dysfunction interfering with occupation or activities of daily living." In 1994, the definition of HIV encephalopathy was adapted directly to children and consists of at least one of the following features present for at least 2 months: (1) failure to attain or loss of developmental milestones or loss of intellectual ability, verified by a standard developmental scale or neuropsychological tests; (2) impaired brain growth or acquired microcephaly demonstrated by head circumference measurements or brain atrophy identified by computed tomography (CT) or magnetic resonance imaging (MRI) (serial imaging is required for children younger than 2 years old); and (3) acquired symmetric motor deficit manifested by two or more of the following: paresis, pathologic reflexes, ataxia, or gait disturbance.[30] Before the use of potent antiviral treatment, the incidence of HIV encephalopathy in the pediatric AIDS population was 23 percent.[135]

The precise pathogenesis of the encephalopathic changes associated with HIV infection remains elusive, although cellular tropism of HIV has been implicated. Histopathologically, most children with involvement of the CNS show significant brain atrophy. Inflammatory lesions usually are sparse and alone cannot account for the significant amount of atrophy observed. Other purported factors potentially contributing to diminished brain size have included the following: (1) direct or indirect interference of HIV with brain growth (HIV toxic effect versus competition with brain growth factors such as neuroleukin), (2) severe malnutrition, (3) severe hypoxia from cardiac and pulmonary compromise, and (4) therapeutic regimens for infectious or noninfectious processes that mandate the prolonged use of medications that may inhibit brain growth. In a cohort of perinatally infected children followed with repeated developmental examinations over a 4-year period (3 to 7 years), cognitive development was depressed for those with an AIDS-defining event or severe immunosuppression as measured by low $CD4^+$ cells.[197] In this cohort of 422 infected children evaluated in The Women and Infants Transmission Study, early AIDS-defining illnesses increased the risk of developing chronic static encephalopathy during preschool and early school years. Infants with less severe disease had cognitive function equal to their uninfected controls. Attention-deficit hyperactivity disorder, learning disability, and graphomotor weakness have been described in higher proportion in HIV-infected children with transfusion-acquired infection.

Behavioral, neurodevelopmental, and, occasionally, imaging improvements have been documented with nucleoside analogue intervention. In a study of 146 perinatally HIV-infected children born between 1990 and 2003, the prevalence of encephalopathy (progressive or static) decreased from 40.7 percent before 1996 (limited combination antiviral therapy) to 18.2 percent after that

year.[185] In this cohort, neurocognitive scores remained stable over the course of a 6-month period in children receiving combined antiviral therapy, and only a weak association with lowered viral load could be found. Clearly, antiviral therapy not only must achieve effective serum and plasma concentrations but also must be able to cross the blood-brain barrier and affect HIV-infected CNS monocytes.

Children with neurologic or behavioral deficits and HIV infection should be evaluated by a pediatric neurologist, and developmental, audiologic, and ophthalmologic assessments are warranted. These children may need support systems including physical therapy, medications to assist with seizure control or contractures, specialized equipment (e.g., braces, splints, wheelchairs), and, as needed, medications or devices to assist with swallowing or food ingestion.

A clinical syndrome of aseptic meningitis, often recurring and presumed to be solely related to HIV infection, has been described in adults.[146] In pediatric AIDS, bacterial pathogens predominate as the most common cause of meningitis, and the aforementioned recurrent aseptic meningitis syndrome appears to be a rare occurrence.[8] Assessments of cerebrospinal fluid (CSF) in HIV-infected children without overt clinical CNS involvement usually are normal but occasionally reveal pleocytosis, elevated protein content, and elevated intrathecal antibody synthesis directed toward HIV itself or HIV antigen.[90] HIV rarely is isolated from CSF. Other pathogens reported in the pediatric HIV-infected population include *Candida* spp., CMV, *M. tuberculosis*, *Toxoplasma*, and *Cryptococcus*. In the reported adult cases of IRIS-associated progressive multifocal leukoencephalopathy, brain biopsy lesions reveal severe demyelination and perivascular inflammatory response of monocytes and T lymphocytes.[92]

GASTROINTESTINAL COMPLICATIONS

Gastrointestinal complications of HIV disease are encountered frequently in both children and adults. Among children with AIDS reported to the CDC in 1988 and 1989, wasting syndrome was described in 16 percent.[173] Wasting has been revised from the 1987 definition to its present definition (1994): (1) persistent weight loss greater than 10 percent of baseline, (2) downward crossing of at least two of the percentile lines on the weight-for-age chart in a child 1 year or older, or (3) less than the 5th percentile on a weight-for-height chart on two consecutive measurements at least 30 days apart, plus (a) chronic diarrhea (at least two loose stools per day for ≥30 days) or (b) documented fever (≥30 days, intermittent or constant).[30] Associated protein and micronutrient (zinc, selenium) deficiencies have been documented in HIV-infected adults and children.[45] Despite use of HAART, gastrointestinal conditions, nutritional deficiencies, and fluid and electrolyte disorders continue to be the most frequent described diagnoses for hospitalized HIV-infected children.[124]

More widespread use of maternal ART to prevent HIV transmission has resulted in a decline in the percentage of HIV-exposed infants with low birth weight.[182] A study of more than 11,000 HIV-exposed or infected infants observed between 1989 and 2004 showed a 14 percent decline in low birth weight, from 35 to 21 percent, and this decline occurred independent of race or ethnicity. In contrast, growth and metabolic abnormalities persist in HIV-infected children either as a direct consequence of HIV infection or as an adverse outcome of antiviral therapy. Wasting and weight loss in HIV-infected individuals appear to be independent predictors of mortality and are associated with lower $CD4^+$ cell counts.[142] These studies have prompted careful attention to the nutritional needs of HIV-infected children. In addition to provision of optimal caloric and nutritional supplementation, therapies that serve as appetite stimulants have been used increasingly and include cyproheptadine, megestrol acetate (Megace), and dronabinol (Marinol).[210] The efficacy of these agents is not permanent, especially when concomitant opportunistic infections are evident.

The use of more potent ART regimens, particularly those including PIs, has resulted in unwanted biochemical lipid abnormalities and changes in body composition for some HIV-infected adults and children. In a 2004 study of 94 infected children receiving long-term PI-containing antiviral regimens, 10 percent developed redistribution of fat, 52 percent developed dyslipidemia without associated somatic changes, and 38 percent had no associated findings.[209] In this cohort, changes in redistribution of fat and dyslipidemia were most likely to occur near ages consistent with the start of puberty (10 to 15 years). In a multicenter U.S. Perinatal AIDS Collaboration Transmission Study, 178 HIV-infected children were evaluated for hypercholesterolemia or hypertriglyceridemia, and 47 and 67 percent, respectively, met criteria for these diagnoses at least once during their follow-up.[25] In this cohort, hypercholesterolemia was associated with multiple PI-containing regimens and undetectable HIV viral load as measured by RNA PCR. Hypertriglyceridemia was predicted by elevated body mass index and use of the PI ritonavir (RTV). These clinical findings of lipodystrophy and dyslipidemia have been treated with some success with diet, exercise, or lipid-lowering medications, although the lipid-lowering medications may result in drug-drug interactions when they are combined with antivirals.

MALIGNANCY

B-cell non-Hodgkin lymphoma occurs in 3 to 4 percent of patients, and Kaposi sarcoma occurs in as many as 40 percent of HIV-infected MSM.[7] In a retrospective study of 4954 children with AIDS in the United States (1978 to 1996), approximately 2.5 percent had documented malignant diseases: non-Hodgkin lymphoma (n = 100), Kaposi sarcoma (n = 8), leiomyosarcoma (n = 4), and Hodgkin disease (n = 2); 10 others had unspecified cancers.[14] With increasing use of HAART in the mid-1990s, the incidence of primary CNS lymphoma in HIV-infected adults declined, but malignancy continues to be reported.[113] Associated in situ infection with HIV, EBV, or both, has been documented in pediatric malignancies, although the precise role in pathogenesis is not defined. Early chemotherapeutic intervention has enhanced the quality of life and longevity and often has been provided in conjunction with ART.

Kaposi sarcoma clearly occurs much less commonly in HIV-infected children. The pathogenesis of Kaposi sarcoma, both HIV and non-HIV related, has been elucidated, and human herpesvirus-8 has been documented in lesions.[103,157] Pathogenesis has been linked to oncogenesis and cytokine-induced growth. The clinical manifestations of Kaposi sarcoma associated with AIDS affect multiple organs. The skin, gastrointestinal tract, lungs, and heart have been affected by Kaposi sarcoma proliferations. Management of Kaposi sarcoma has improved with increasing use of HAART to restore immune function in HIV-infected individuals.[26]

Since 1987, more than 13 children with AIDS have been reported with smooth muscle malignancies, specifically, leiomyosarcomas of the gastrointestinal tract.[44,147] McClain and colleagues[147] documented (by PCR and in situ hybridization techniques) the association of EBV with leiomyosarcoma in children with AIDS. Since the advent of HAART, HIV-related malignant disease in the U.S. is reported less frequently. In a study of 2969 HIV-infected children followed in the Pediatric AIDS Clinical Trials Group 219/219C from 1993 to 2003, only 37 cases of malignant disease were reported, representing a prevalence of 0.6 percent malignancies and an incidence of 1.56 per 1000 person-years.[117] In this analysis, the standardized incidence

cancer rate for infected children was 10.08 as compared with uninfected exposed controls. The incidence of cancer was highest in children with severe immunocompromise and in those who had received HAART for less than 2 years. In contrast, developing nations continue to report high incidences of malignant disease.[192]

OTHER COMPLICATIONS

Cardiac Abnormalities

Cardiac manifestations of HIV infection in children have been described and include progressive left ventricular dysfunction, as measured by a diminished shortening fraction that may be associated with immune suppression.[134] Clinically, HIV-infected children have been described with congestive heart failure and cardiomegaly, cardiac tamponade, nonbacterial thrombotic endocarditis, conduction disturbances, and sudden death, presumably secondary to primary ventricular arrhythmia associated with severe cardiomyopathy. In a postmortem analysis of 30 HIV-infected children followed longitudinally in the prospective P2C2 HIV Multicenter Study, 50 percent had cardiomegaly with associated clinical findings of increased heart rate, increased left ventricular mass, and chronic heart disease.[115] A higher prevalence of postmortem pericardial effusions was also noted.

In a study of 81 HIV-infected children, unexpected cardiorespiratory arrest occurred in 9 percent, chronic congestive heart failure in 10 percent, and dysrhythmias in 35 percent of children.[138] Asymptomatic children with HIV infection additionally have been documented to exhibit cardiac abnormalities. No evidence suggests that HIV is directly cardiotoxic, although HIV has been documented within myocardial cells by in situ hybridization.[77] Other factors may have an impact on the development of cardiac abnormalities and include malnutrition and infectious agents such as CMV and EBV. In one study of HIV-infected children receiving nucleoside analogue ART (zidovudine or didanosine), the odds of developing cardiomyopathy were 8.4 times greater in children receiving zidovudine but not didanosine.[62]

The increasing use of HAART and, specifically, PIs in the pediatric HIV-infected population prompted careful management of associated hypercholesterolemia and hyperlipidemia.[104] In univariate analysis, hypercholesterolemia in children with HIV infection treated with a PI regimen was associated with elevated systolic blood pressure but not with body mass.[74] Careful follow-up of lipid profiles should be evaluated routinely in HIV-infected children receiving antiviral therapy.

Renal Dysfunction

Renal disease is yet another clinical manifestation of HIV infection. In a retrospective evaluation of 155 pediatric patients with AIDS, 12 were noted to have significant proteinuria.[205] The renal abnormalities described included nephritis (focal glomerulosclerosis and mesangial hyperplasia) and nephrosis. In fact, focal sclerosis and segmental sclerosis were described in more than half of reported children.[206] The immunopathologic characteristics of HIV-associated nephropathy include inflammatory infiltrations predominantly composed of activated T cells ($CD4^+$ cells usually exceeding $CD8^+$ cells).[172]

Persistent metabolic acidosis associated with renal tubular disease and high anion gap acidosis has been reported in pediatric HIV infection.[172] In a group of 202 HIV-infected children, 34 (17%) had evidence of persistent acidosis. Renal disease in HIV-infected children often appears in concert with profound immunodeficiency and end-stage HIV disease. Because most pediatric patients with AIDS and renal disease have perinatally acquired HIV infection, the importance of congenital or early concomitant infections (e.g., CMV) has been postulated to affect pathogenesis. The nephrosis of HIV disease can be particularly difficult to treat in an already malnourished, hypoproteinemic, HIV-infected child. Corticosteroid therapy may be attempted but often ameliorates symptoms with variable efficacy. Many of the reported children with renal disease have associated growth failure. Nutritional supplementation and dietary restriction may be supportive adjunctive therapy.

Bone Marrow Suppression

Hematologic abnormalities associated with HIV infection in children include leukopenia, anemia, and thrombocytopenia. Neutropenia often has been described in association with circulating antineutrophil antibodies and may respond to blockade therapy with IVIG. Granulocyte colony-stimulating factor has been used successfully in neutropenia, both drug-induced and HIV-associated.[94,160]

The anemia of HIV infection may be microcytic, hypochromic as seen in chronic infection, autoimmune with positive Coombs testing, or typical of nutritional deprivation (iron or vitamin B_{12} deficiency). The origin of anemia in AIDS is difficult to sort out and is confounded by multiple cofactors that affect red blood cell counts, that is, poor nutritional status and concomitant use of toxic therapeutic agents (zidovudine). In adults and children, recombinant erythropoietin has been beneficial in treating anemia associated with antiviral therapy.[18] In developing nations, infant anemia of HIV exposure or infection coupled with acute local parasitic infections (malaria) may significantly affect infant morbidity. The risk for developing severe and potentially fatal malarial anemia is increased for HIV-exposed or infected children with concomitant acute parasitemia, as compared with HIV-negative controls.[164]

Immune thrombocytopenia has been reported in 13 percent of children with symptomatic HIV infection with an onset as early as the first year of life.[67] This phenomenon appears to be immune-mediated, although its pathogenesis is not defined clearly. The presence of platelet-associated IgG in HIV-infected children has been reported to have a sensitivity of 93 percent; however, its specificity is only 13 percent, a finding thus suggesting that platelet-associated IgG is unlikely to be a cause of thrombocytopenia.[68] Therapy for thrombocytopenia in children and adults has included no intervention, platelet transfusions, systemic corticosteroids, IVIG, ART, and, most recently in adults, IFN-α. Immune thrombocytopenia has resolved spontaneously in some children with simple supportive measures.

DIAGNOSIS OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION IN INFANTS AND CHILDREN

EARLY TRANSMISSION TO FETUSES

Information is scant on the role of the human placenta in transmitting HIV infection from mother to fetus. Studies suggested that fetal infection can take place as early as 9 to 11 weeks of gestational age.[20,145] Preliminary examination of birth placental tissue from HIV-infected mothers in another study indicated that HIV core antigens could be detected in approximately 50 percent of the cases studied (23 of 51); furthermore, HIV antigens were localized in the Hofbauer cells.[217] Finally, investigators documented that placental trophoblasts can be infected by CD4-independent isolates of HIV-1 in vitro.[3]

An increase in the incidence of intrauterine fetal demise was demonstrated in the literature in HIV-infected pregnant women.[65,130] In HIV-negative fetuses, placental lesions known to be associated with fetal demise were identified: abruption, infarc-

TABLE 204–13 Guidelines for the Diagnosis of Human Immunodeficiency Virus Infection in Infants Born to Human Immunodeficiency Virus–Infected Mothers

Definitive HIV Diagnosis for Infants 18 mo or Older
Two positive enzyme-linked immunosorbent assays and a positive confirmatory serologic test, e.g., Western blot or immunofluorescence assay
OR
Any two positive viral detection assays on separate specimens:
HIV culture
HIV polymerase chain reaction
p24 antigen test
OR
Documentation of a pediatric AIDS-defining illness
Presumptive Diagnosis for Infants Younger Than 18 mo
A single positive viral detection assay (excluding cord blood):
HIV culture
HIV polymerase chain reaction
p24 antigen assay
Definitive Diagnosis for Infants Younger Than 18 mo
Any two positive viral detection assays on separate specimens:
HIV culture
HIV polymerase chain reaction
p24 antigen test
OR
Documentation of a pediatric AIDS-defining illness

tion, and other infections (CMV). In HIV-positive fetuses, similar placental lesions could not be identified, and death was attributed to HIV infection of fetal tissue as detected by in situ hybridization. Two hypotheses for transmission are proposed: (1) direct cell-to-cell spread of HIV from infected maternal mononuclear cells through the placental cells and eventually to fetal tissue itself and (2) infected maternal cells that gain access to the fetal circulation.

METHODS USED TO DIAGNOSE INFECTION IN CHILDREN OLDER THAN 18 MONTHS

In children older than 18 months in whom the presence of maternal anti-HIV antibody no longer is a confounding variable, the conventional tests used to diagnose HIV infection in adults are applicable (Table 204–13). Thus, enzyme-linked immunoassay (ELISA), Western blot analysis, indirect fluorescent antibody assay, p24 HIV antigen analysis (p24Ag), HIV culture, and HIV PCR may be used. Of these tests, ELISA and Western blot analysis are the most practical, and two positive ELISAs in addition to a positive Western blot confirm a diagnosis of HIV infection. Combination kits that test for both HIV-1 and HIV-2 are now used.

METHODS USED TO MAKE AN EARLY DIAGNOSIS OF INFECTION IN INFANTS AND CHILDREN YOUNGER THAN 18 MONTHS

The clinical manifestations of HIV infection in children are varied and nonspecific and include chronic pneumonitis, failure to thrive, hepatosplenomegaly, thrombocytopenia, and chronic diarrhea. In children younger than 18 months, a positive serologic determination of HIV is not accepted as indicative of the presence of HIV infection because of passive maternal antibody. Documentation of HIV infection in children younger than 18 months requires identification of viral components from blood. The most commonly used virologic assay in the United States is HIV PCR (DNA or RNA) or virologic culture.[166] In resource-poor countries where virologic laboratories are not available, the CD4/CD8 ratio may be used to diagnose infants with HIV infection.[188]

Table 204–13 outlines the current guidelines for determining positive HIV infection status in infants younger than 18 months who are born to HIV-infected mothers. HIV DNA PCR is the preferred pediatric testing tool because it can be used to identify integrated proviral HIV DNA in the mononuclear cells of infants. Cord blood determinations for HIV are problematic because of contamination by maternal cells. Experience with the use of PCR or culture technology in neonates born to HIV-infected women has documented HIV infection as early as the first days or month of life.[153] The estimated sensitivity of HIV DNA PCR is 38 percent from birth to 48 hours of life, 93 percent by 14 days of age, and 96 percent by 28 days of age. HIV-1 RNA PCR measures extracellular viral RNA and has sensitivity of 25 to 40 percent in the first weeks of life and 90 to 100 percent by the time the child reaches 2 to 3 months of age.[226]

Current pediatric PCP prophylaxis guidelines suggest that infants with two negative virologic assays (HIV culture or HIV PCR), both performed at 1 month or older and at 4 months or older, most likely are not infected with HIV, and interruption of the therapeutic intervention is warranted.[31] Hence, early diagnosis in HIV-exposed infants has been improved both for identification of HIV-infected children (as early as the first month of life) and for uninfected children labeled as seroreverters (as early as the fourth month of life). Schedules for testing of HIV-exposed infants vary nationally. However, advances in diagnostic technology allow for early testing of HIV-exposed infants, including shortly after birth through 14 days of life, at 1 to 2 months of age, and then again at 3 to 6 months. Confirmation of negative virologic assays (HIV PCR) should be performed with typical serologic testing (ELISA or Western blot) when the child is 12 to 18 months of age.

The assays outlined earlier easily detect HIV-1 subtype B HIV commonly found in developed nations. To detect non-B HIV infection in individuals from or in developing nations, HIV RNA PCR may be preferred, because it has a lower incidence of false-negative assays as compared with HIV DNA PCR. If non-subtype B HIV is suspected, then use of HIV RNA testing that is sensitive for these subtypes (e.g., more sensitive RNA PCR assays or branched DNA assays that are commercially available in the United States) should be considered.

IMMUNOLOGIC AND CLINICAL MONITORING OF HUMAN IMMUNODEFICIENCY VIRUS–INFECTED CHILDREN

Laboratory monitoring of HIV-infected children is linked to those variables that predict morbidity and mortality, namely, $CD4^+$ T-cell percentage and HIV RNA PCR. Clinical evaluations should occur at a minimum of every 3 months, or sooner if the patient has clinical signs or AIDS-defining events, and measures of $CD4^+$ T-cell and HIV RNA PCR should be performed. Because of variability across commercially available RNA PCR assays that may be as great as twofold, the individual HIV-infected patient should, when possible, be tested with a single assay type.[226] Recommendations for changes in treatment based on changes in $CD4^+$ T-cell percentages or HIV RNA PCR should be undertaken in consultation with a specialist who routinely provides care to HIV-infected individuals. Evaluation of the individual HIV-

infected child for viral resistance can be accomplished with use of commercially available phenotyping or genotyping assays. Such studies should be performed in consultation with an HIV specialist. Depending on treatment regimens, most children also should have laboratory studies performed to assess their potential for developing treatment-induced toxicities including bone marrow suppression, metabolic acidosis, dyslipidemia disorders, and pancreatitis. It is recommended that this cohort annually receive dental, ophthalmologic, cardiologic, and neurodevelopment assessments. Routine recommendations for childhood vaccine delivery are outlined later.

TREATMENT

PRIMARY ANTI–HUMAN IMMUNODEFICIENCY VIRUS TREATMENT

Implementation of HAART consisting of at least three antiviral drugs has enhanced survival rates, improved immune status, and reduced opportunistic infections, as previously outlined.[19,87,148,171] Increased survival of HIV-infected children brings challenges in selecting successive new ART regimens for now chronically ill children, and specific issues to address include short- and long-term toxicities related to therapy and development of drug resistance.

In general, the principles of therapy are similar in all affected age groups. Treatment should be aggressive and use multiple drugs as early in the course of the infection as possible to suppress viral replication fully, reduce development of resistant viral strains, minimize drug-related toxicity, and preserve immune function. Considerations specific to the pediatric host include the following: (1) early clinical severity of HIV disease, viral load, and level of immune suppression; (2) availability of appropriate drug formulations and dosing; (3) unique pharmacokinetics (body composition, renal excretion, liver metabolism, enzyme maturation); (4) regimen potency, complexity, short- and long-term toxicity potential; (5) impact of changing therapy; (6) co-morbidities that affect drug choice; (7) drug interactions; and (8) the ability of the parent or child to adhere to a prescribed regimen.

Guidelines for initiation of therapy differ somewhat for adults and children. Current pediatric recommendations include initiation of therapy for symptomatic and immunosuppressed HIV-infected children, and for children aged less than 12 months regardless of clinical, immunologic, or virologic status (Table 204–14). Current ART intervention is designed to target different steps in the replication cycle of HIV (Fig. 204–9).[118] The Working Group on Antiretroviral Therapy and Medical Management of HIV-Infected Children currently recommends aggressive combination of at least three medications from at least two drug classes for initial treatment of HIV-infected infants, children, and adolescents.[226] With improvements in treatment formulations, dosing recommendations for antiviral agents can alter over time. Hence, for updated specific dosing and drug-drug interactions of antiviral agents, the reader is referred to The Working Group on Antiretroviral Therapy and Medical Management of HIV-Infected Children guidelines available at http://AIDSinfo.nih.gov.

INHIBITORS OF HUMAN IMMUNODEFICIENCY VIRUS CELL ENTRY

Entry of HIV-1 into target cells begins with interactions of the viral envelope protein gp120 with CD4 and a chemokine co-receptor, usually CCR5 or CXCR4. Both cellular receptors and structures in envelope proteins associated with membrane attachment and fusion are targets for therapeutic intervention.

Blockade of Human Immunodeficiency Virus by CD4-Receptor Inhibitors

CD4-based molecules can neutralize HIV by several mechanisms. Initial studies demonstrated the efficacy of soluble preparations of CD4 (sCD4) against HIV in vitro.[108,181,214] A chimeric molecule consisting of recombinant CD4 and immunoglobulin G (rCD4-IgG) was developed with an extended half-life and enhanced efficacy. Shearer and colleagues[186] documented safety, evidence of placental transfer, and appropriate elimination after intravenous administration of rCD4-IgG2 in pregnant women. In a phase I/II study, 18 children infected with HIV-1 received single or multiple intravenous doses of rCD4-IgG2 and demonstrated evidence of antiviral activity and tolerance.[187] Certain small molecules may competitively inhibit viral entry by binding gp120, thus blocking the gp120-CD4 interaction. BMS-806, a prototype of these small molecules, demonstrates its antiviral activity by blocking conformational changes in the viral envelope glycoproteins.[229]

Blockade of Human Immunodeficiency Virus by Chemokine (Co-receptor) Inhibitors

Agents that target blockade of CXCR4 and CCR5 currently are being evaluated in clinical trials. Concerns about the use of co-receptor inhibitors include potential for unintended immune modulation and for viral escape to occur from tropism selection with resultant disease progression.[159] Maraviroc (Selzentry), a

TABLE 204–14 Indications for Use of Antiretroviral Therapy by Age in Human Immunodeficiency Virus–Infected Children*

Age	HIV-Related Symptoms	CD4/Viral Studies	Recommendation
All	Significant	—	Treat
	AIDS-defining event	—	Treat
<12 mo	Asymptomatic *and*	CD4 <25%	Treat
	Any	—	Treat
1-<4 yr	Asymptomatic	*and* CD4 <20%	Treat
	Mild symptoms *and*	CD4 <20%	Treat
≥4-12 yr	Asymptomatic	*and* CD4 <15%	Treat
	Mild symptoms *and*	CD4 <15%	Treat

first-in-its-class, selective CCR5-co-receptor antagonist, received approval by the FDA for use in adults in August 2007. It is recommended as adjunct therapy to combination antiviral regimens and targets treatment of CCR5-tropic HIV-1 (R5 virus). The most common adverse effects are cough, fever, upper respiratory infections, rash, musculoskeletal symptoms, abdominal pain, and dizziness.

Blockade of Human Immunodeficiency Virus by Interference with gp120-CD4 Interactions

Polyanionic compounds such as dextran sulfate and heparin inhibit binding of HIV to the cell membrane, targeting the V3 loop of gp120.[158] Because of their systemic toxicity, most of these compounds have been evaluated in clinical trials as topical microbicides to prevent sexual transmission of HIV in humans. PRO 2000, a naphthalene sulfonate polymer exhibiting its effect by binding to CD4, is a potent inhibitor of M-tropic strains of HIV (R5 viruses) in human cervical explants.[78] PRO 2000 gel (0.5%) is effective and well tolerated in clinical trials following vaginal application. An additional substance, the green tea flavonoid, epigallocatechin gallate (EGCG), binds to the CD4 molecule at the gp120 binding site, thus inhibiting gp120-CD4 interaction in a dose-dependent manner.[225] Such substances promise adjunctive mechanisms to restrict HIV infection.

Blockade of Human Immunodeficiency Virus by Fusion Inhibitors

As previously described, fusion of the HIV envelope (glycoprotein gp41) with the target-cell membrane is an important step in host-cell infection. During fusion, FP of gp41 inserts into the target-cell membrane, and gp41 heptad repeats (HR1 and HR2) alter their conformation to form a 6-helix bundle. This process results in the formation of a fusion pore through which the HIV capsid passes into the target cell. Fusion inhibitors represent the first class of entry inhibitors for which there is a licensed drug. Enfuvirtide (T-20) is a synthetic peptide that binds to the HR1 domain of gp41, prevents six-helix formation, and thus inhibits fusion.[43,170] Enfuvirtide is approved for use in HIV-infected adults and children aged 6 years or older whose HIV infection has not been controlled by other anti-HIV drugs. Addition of enfuvirtide to an optimized background regimen of ART agents has demonstrated modest decreases of HIV viral load for long periods.[49] The most common adverse effects include mild to moderate erythema, induration, pain, lymph node swelling, itching, and tenderness at the injection site. Other side effects reported are diarrhea, nausea, fatigue, headache, dizziness, peripheral neuropathy, and hypersensitivity reactions.[48,57] However, in the absence of a fully suppressive ART regimen, mutations associated with resistance to enfuvirtide are demonstrated to be rapid.

NUCLEOSIDE ANALOGUE REVERSE TRANSCRIPTASE INHIBITORS

Nucleoside analogues have no direct effect on HIV reverse transcriptase. Following phosphorylation by the host-cell kinases, they inhibit viral reverse transcriptase by competing with the natural substrate at the same binding site on the enzyme. With their incorporation into the newly forming proviral DNA, further viral transcription is prematurely terminated. Six nucleoside

analogue reverse transcriptase inhibitors (NRTIs) are licensed and currently available in the United States: zidovudine (ZDV), didanosine (ddI), stavudine (d4T), lamivudine (3TC), abacavir (ABC), and emtricitabine (FTC).

Zidovudine

Early pediatric studies demonstrated clinical, immunologic, and virologic improvements after intravenous and oral administrations of ZDV.[149] However, sustained CD4+ cell restoration with ZDV monotherapy could not be achieved.[150]

ZDV is available in capsules, oral solution, tablets, and intravenous infusion forms. ZDV has good oral bioavailability (65%) and CNS penetration, with a mean serum half-life of 0.5 to 3 hours. It is rapidly metabolized in the liver by glucuronidation and is eliminated primarily by glomerular filtration and active tubular secretion. The most frequent adverse effects of ZDV are granulocytopenia and macrocytic anemia, often requiring limitations on doses. Some clinicians administer growth factors to counteract these adverse effects.[93] Other toxic effects include symptomatic myopathy, lactic acidosis, and hepatosteatosis.

In 1994, PACTG protocol 076 documented the remarkable effectiveness of ZDV in reducing the rate of maternal-infant transmission of HIV-1 by 66 percent (Fig. 204–10).[54] The short-term toxicity most frequently described among infants was mild and reversible anemia. Most clinicians continue to use ZDV as part of their regimen to prevent maternal transmission, but maternal dosing often includes additional antiviral medications to suppress maternal viral load optimally, and the administration of ZDV follows current adult standards of twice-daily dosing and not those used in the original PACTG 076 formulation.

ZDV and other nucleoside analogues are suspected of inducing mitochondrial dysfunction secondary to their affinity for mitochondrial gamma DNA polymerase. This effect has been a source of particular concern for the ZDV- and HIV-exposed fetus and infant. Adding to this concern was a report from a large French study that 12 of 2644 NRTI- (predominantly ZDV) and HIV-exposed infants had evidence of mitochondrial dysfunction.[11] An additional 14 children in this cohort had unexplained symptoms that could be attributed to mitochondrial dysfunction.

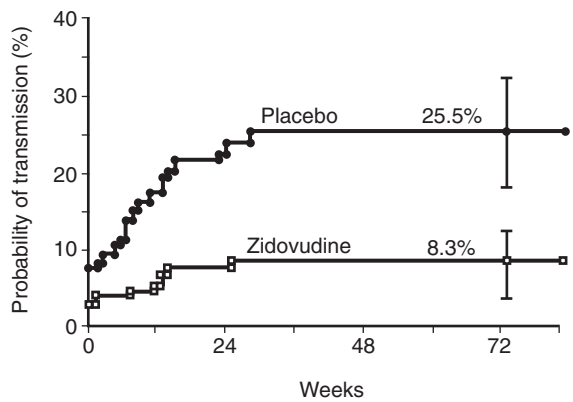

Figure 204–10 Analysis demonstrating a 66 percent reduction in perinatal transmission rates from 25 to 8 percent with antepartum, peripartum, and postpartum zidovudine therapy in human immunodeficiency virus–infected pregnant women and their infants. *(Reprinted by permission from Connor, E. M., Sperling, R. S., Gelber, R., et al.: Reduction of maternal-infant transmission of human immunodeficiency virus type 1 with zidovudine treatment: Pediatric AIDS Clinical Trials Group Protocol 076 Study Group. N. Engl. J. Med. 331:1173-1180, 1994.)*

In response to this and other smaller cohort publications, the Perinatal Safety Review Working Group reviewed deaths in 5 large HIV-exposed perinatal cohorts (total of >11,000 NRTI- and HIV-exposed infants and children) in the United States to determine whether similar cases of severe mitochondrial toxicity could be documented.[64] Prophylaxis with ZDV was not associated with findings consistent with mitochondrial dysfunction, including a careful review of the cohort's 85 deaths. In early treatment studies, low birth weight and premature delivery were ascribed to nucleoside analogue exposure in small study cohorts.[136] With further treatment including HAART and specifically ZDV, low birth weight appears to be reduced in incidence.[182] Concerns about NRTI therapy in HIV-exposed but uninfected infants led to other large-scale studies that documented safety of the maternal-infant ZDV regimen through age 18 to 38 months.[100,200]

Resistance to ZDV has been described, and the characteristic finding is a mutation at codon 215 of the reverse transcriptase.[110] In 1995, ACTG protocol 116B/117 performed a randomized comparison of didanosine with continued ZDV therapy in 187 patients with advanced HIV-1 disease who had received at least 4 months of ZDV treatment.

Didanosine

In early studies, ddI was well tolerated, and improvements in clinical and immunologic measures were documented in previously untreated HIV-infected children and those who had received prior ZDV treatment.[15,109,110] ddI is formulated as an enteric capsule with fewer gastrointestinal side effects and should be administered on an empty stomach. Common toxicities are diarrhea, abdominal pain, and nausea. The frequency of severe clinical toxicities, pancreatitis, and peripheral neuropathy is dose-related. Lactic acidosis, severe hepatomegaly with steatosis, and retinal and visual changes also have been reported in patients treated with ddI. This drug may interact with other ART agents and produce toxicity or unwanted clinical outcomes. For example, ddI should be used cautiously in combination with tenofovir, a nucleotide analogue, because of increasing plasma levels of ddI and decreasing CD4+ cell counts.[224]

Stavudine

Like ZDV and ddI, d4T is a potent inhibitor of in vitro HIV replication. In a phase I/II clinical trial of d4T in HIV-infected children, d4T was well tolerated without dose-related clinical or laboratory adverse events. The oral bioavailability ranges from 61 to 78 percent, and the CSF concentrations range from 16 to 97 percent 2 to 3 hours following oral administration.[119] Compared with ZDV, d4T is associated with better preservation of CD4+ lymphocyte counts.[121] d4T is available in capsule and oral solution forms. Reported severe toxicities include peripheral neuropathy, pancreatitis, lipodystrophy, and lactic acidosis. d4T and ddI should not be combined in the same regimen because of in vitro antagonism.

Lamivudine

3TC has good antiviral potency to both HIV-1 and hepatitis B virus (HBV), and the drug is well tolerated orally.[167] 3TC is available in both tablet and solution forms; its bioavailability is not affected by food. A combined product (Combivir) provides a preformed tablet formulation of ZDV (300 mg) and 3TC (150 mg). Toxicities are rare but include pancreatitis and lactic acidosis.

Abacavir

ABC is approved for use in combination with other ART agents in children and adults. It is well absorbed, is unaffected by food,

is well tolerated, and has good in vivo and in vitro potency in reducing HIV viral load when combined with other ART agents.[178] An important clinical side effect of this drug is ABC hypersensitivity reaction that occurs in approximately 5 percent of patients at a mean of 11 days after initiation of this agent.[57] Symptoms include fever, rash, malaise or fatigue, and gastrointestinal symptoms such as nausea and vomiting. HLA-B*5701 is documented to be a risk factor for development of hypersensitivity to ABC.[201] Suspected hypersensitivity to ABC requires permanent discontinuation of this agent because hypotension and death have occurred on repeat challenge. ABC is available in tablet and oral solution forms. A combined product, Trizivir, provides a preformed tablet formulation of ZDV (300 mg), 3TC (150 mg), and ABC (300 mg). Epzicom, another preformed tablet, contains 3TC (300 mg) and ABC (600 mg).

Emtricitabine

FTC was approved for use in combination with other anti-HIV medications. It is similar in many aspects to lamivudine and, like that drug, is active against both HIV-1 and HBV.[177] FTC has potent in vivo antiretroviral activity, 4 to 10 times more potency than 3TC in vitro, and is well tolerated.[223] Because of cross-resistance of FTC to the M184V resistance, mutations commonly observed in patients in whom a 3TC-containing regimen has failed, this agent has little utility in 3TC-experienced patients. It is available as a hard gelatin capsule and as an oral solution. Skin discoloration that manifests as hyperpigmentation on the palms and soles is a unique toxicity of FTC therapy and is usually mild.

NUCLEOTIDE REVERSE TRANSCRIPTASE INHIBITORS

Nucleotide reverse transcriptase inhibitors (NtRTIs) function like previously described NRTIs, but they do not require phosphorylation. Tenofovir disoproxil fumarate (tenofovir DF, TDF), is an orally bioavailable prodrug of tenofovir. It is the first NtRTI approved for use in the United States, but its use is limited to adolescents and adults. Tenofovir has good in vivo potency against both HIV-1 and HBV.[84] Tenofovir has long serum and intracellular half-lives that allow once-daily dosing. High-dose tenofovir treatment has been associated with skeletal abnormalities in young animals[220] and a significant decrease in absolute bone mineral density in HIV-infected children.[82] These changes in bone mineral density seemed to stabilize by 24 weeks of the treatment, and none of the patients experienced fractures during the study period. A combined product, Truvada, provides a preformed tablet formulation of FTC (200 mg) and TDF (300 mg) available for use once daily.

NON-NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS

Non-nucleoside reverse transcriptase inhibitors (NNRTIs) work by binding directly to the reverse-transcriptase enzyme, thus rendering it nonfunctional. Three available drugs in this class are approved for use in the United States: nevirapine (NVP), delavirdine, and efavirenz (EFV). Only NVP and EFV have been approved for use in pediatric HIV-infected populations and hence only these drugs are described. The major disadvantage of the current NNRTI agents is the rapid development of resistance with resultant cross-resistance across all class-related drugs.

Nevirapine

NVP has been shown to have antiretroviral efficacy in a number of different combination regimens in children. The most promising use of nevirapine has been documented in perinatal HIV transmission. The HIVNET 012 study in Uganda demonstrated that a single 200-mg dose of NVP taken by an HIV-infected breast-feeding mother at the onset of labor and a 2 mg/kg dose of NVP given to the infant within 72 hours of birth could reduce the mother-to-child transmission rate by 42 percent by 6 weeks of age when compared with short-course ZDV regimens.[97] The reduction in the relative risk of transmission persisted through 18 months of age.[112] NVP is available in both tablet and oral solution forms. Severe hepatotoxicity, hepatic necrosis, and hepatic failure have been reported in children as early as the first 12 weeks of life. NVP should be discontinued permanently in children or adults who develop severe rash or rash with constitutional symptoms and hepatotoxicity. Women with $CD4^+$ counts greater than 250 cells/mm^3 appear to have particularly increased susceptibility to nevirapine toxicity.

Efavirenz

EFV is approved as a single-daily dosing agent and for that reason has been attractive for use in adolescents and older children. It is available in capsule and tablet forms only. A combined product, Atripla, provides a preformed tablet formulation of FTC (200 mg), TDF (300 mg), and EFV (600 mg) available for use once daily in adults. In addition to toxicities of rash and elevated transaminase levels, CNS abnormalities including somnolence, insomnia, bad dreams, irritability and depression have been reported within the first 2 weeks of treatment. EFV has been reclassified as Food and Drug Administration pregnancy category D because in animal models EFV was associated with cleft palate and anencephaly.[24] Use in women of child-bearing age should include intermittent pregnancy testing and counseling for pregnancy prevention.

PROTEASE INHIBITORS

PIs are relatively small peptides that share structural features with the substrates for viral protease. These molecules bind to and inhibit viral protease, thereby preventing the virus from maturing into an infectious virion. These drugs are extremely potent in reducing plasma RNA viral loads. They exhibit a high barrier for development of drug resistance. As a class, they interact with the hepatic cytochrome P-450 enzyme system, and many induce their own metabolism. Thus, the potential for significant drug-drug interactions is considerable. Examples of such interactions include those with oral contraceptives, antituberculous drugs, antiepileptic drugs, some antihistamines, and methadone. Adverse events of use of PI include previously described metabolic complications (dyslipidemia, lipodystrophy, insulin resistance, gastrointestinal effects of nausea or diarrhea), higher pill burden than with NRTI- or NNRTI-based regimens, and poor palatability of liquid preparations. Currently, 10 PIs are approved for treatment of HIV infection: saquinavir, RTV, lopinavir (LPV)/RTV, indinavir, nelfinavir (NFV), atazanavir, amprenavir (APV), fosamprenavir, tipranavir, and darunavir. Only 4 of these PIs are approved for use in HIV-infected children: RTV, LPV/RTV, NFV, and APV.

Ritonavir

RTV is a potent inhibitor of the hepatic cytochrome P450 3A4 isoenzyme and therefore can improve the bioavailability and prolong the elimination half-life of most co-administered PIs.[55] This PI has been used as a pharmacokinetic booster in low doses combined with indinavir, LPV, saquinavir, APV, fosamprenavir, atazanavir, and tipranavir to enhance these PI serum levels. It is available in capsule and oral solution forms. When RTV is used

at lower doses as a pharmacokinetic booster of other PIs in adults, it is used as 100 mg twice daily or 200 mg once daily. Dose escalation at 2- to 3-day intervals is necessary to minimize the common side effect of nausea or vomiting. Other side effects include paresthesias, hyperlipidemia, and lipodystrophy.

Lopinavir/Ritonavir

LPV/RTV (LPV/r) is a co-formulation of LPV and RTV. RTV acts as a pharmacologic enhancer rather than as an ART agent by inhibiting the metabolism of LPV and increasing LPV plasma concentration. It is available in tablet (200 mg LPV/50 mg RTV) and oral solution (80 mg LPV/20 mg RTV per mL; contains 42.4% alcohol by volume) forms. Currently, it is not approved for use in neonates and infants. Clinical trials are under way for infants younger than 6 months. Major toxicities are diarrhea, nausea, vomiting, headache, asthenia, and lipid abnormalities. The 42.4 percent alcohol content in this oral formulation leads to almost uniform symptoms of nausea or vomiting and often can be overcome with concomitant delivery of foods with strong tastes. Dosing compliance may be affected by taste and caregiver discomfort in delivery.

Nelfinavir

NFV has been used widely in pediatric populations. It is available in tablet and oral powder forms. The most common side effects of NFV are diarrhea and lipodystrophy.

Amprenavir

APV is contraindicated in children younger than 4 years old, pregnant women, or patients with hepatic or renal failure because of the large amount of propylene glycol content of the oral solution. Patients should be switched from oral solution to liquid-filled capsules as soon as they are able to take the capsule formulation, to reduce exposure to the propylene glycol content of the oral solution. Because both the capsule and oral solution forms of APV contain vitamin E, patients receiving either form of APV formulation should not take vitamin E supplements. APV is a sulfonamide. The potential for cross-sensitivity between other sulfonamides and APV is unknown. APV should be used with caution in patients with a known sulfonamide allergy. Adverse events with this drug include gastrointestinal intolerance (nausea, vomiting, diarrhea), life-threatening rash (including Stevens-Johnson syndrome), and lipodystrophy.

INTEGRASE INHIBITORS
